anti-Akt/PKB, and anti-Glial Fibrillary Acidic Protein (GFAP) antibodies were obtained from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Anti-IL-1 β , anti-Fas ligand (FasL) and anti-caspase-3 antibodies were purchased from BOSTER Biological Engineering Co (Wuhan, China). Goat anti-rabbit and goat anti-mouse secondary antibodies were obtained from Santa Cruz Biotechnology. RNA polymerase chain reaction (PCR) kit (AMV) was purchased from TaKaRa Biotechnology (Dalian, China). O-Dianisidine tetrazotized and β -naphthyl acid phosphate were purchased from Sigma Chemical Co. The caspase-3 colorimetric assay kit was obtained from BD Bioscience Clontech (1020 East Meadow Circle Palo Alto, CA).

Animals and drug treatment Groups of Sprague Dawley rats (Grade II, certificate No 2003-0009; Experimental Animal Center of China Medical University, Shengyang, China), maintained at an ambient temperature of 22–24 °C under a 12 h:12 h L:D cycle, were used in this experiment. The rats initially weighing 180–200 g were administered with SF through an intragastric method (50 mg/kg, 100 mg/kg and 250 mg/kg, daily) for 3 weeks prior to A β ₂₅₋₃₅ injection and 1 week after the injection. The rats were anesthetized with chloral hydrate (300 mg/kg) and placed in a stereotaxic apparatus. The rats were injected intracerebroventricularly with A β ₂₅₋₃₅ (10 μ L) or saline solution by means of a Hamilton microsyringe. The injection lasted 5 min and the needle with the syringe was left in place for 2 min after the injection for the completion of drug infusion. Control rats were injected with saline solution. The following studies were carried out 7 d after the injections.

Immunohistochemical staining for glial fibrillary acidic protein Seven days after injection of A β , the rats were perfused transcardially with 4% paraformaldehyde in phosphate-buffered saline (PBS). The brains were removed and post-fixed for 24 h and were embedded in paraffin wax. Serial coronal sections (5 μ m thickness) were cut from various sections of the brain. After the coronal sections were rinsed in PBS 3 times, endogenous peroxidase activity was blocked by incubation with 3% H₂O₂ for 10 min. The sections were incubated with 10% normal goat serum. After the blocking serum was removed, sections were incubated with polyclonal antibody against GFAP (1:100 in Tris-buffered saline (TBS) containing 2.5% normal goat serum) overnight at 4 °C, then with biotinylated secondary antibody at 37 °C for 20 min. The GFAP-positive cells were detected using strept-avidin-biotin complex (SABC) and DAB kits.

Western blot analysis Western blotting was carried out for the analysis of IL-1 β , p38 MAPK, ERK1/2, Akt/PKB, FasL and caspase-3. Hippocampal CA1 areas were stereotaxically

dissected free. The tissue was homogenized in RIPA buffer [1% Triton, 0.1% sodium dodecylsulfate (SDS), 0.5% deoxycholate, ethylenediaminetetraacetic acid 1 mmol/L, Tris 20 mmol/L (pH 7.4), NaCl 150 mmol/L, NaF 10 mmol/L], and insoluble material was removed by centrifugation at 12 000×g for 20 min at 4 °C. Protein concentrations were quantified by the method of Lowry^[15]. Tissue samples were equalized for protein concentration. Proteins were resolved by 9%–15% SDS-polyacrylamide gel electrophoresis (PAGE), and transferred to nitrocellulose membranes. The membranes were blocked with 5% milk powder in TBS (pH 7.6) for 1 h and incubated overnight at 4 °C with suitably diluted primary antibodies. After extensive washing with TBS, the membranes were incubated with anti-IgG-alkaline phosphatase conjugate. Finally, the blots were developed with the alkaline phosphatase substrate O-dianisidine tetrazotized along with β -naphthyl acid phosphate. Quantification of protein bands was achieved by densitometric analysis using Chem Image 5500 software (UVP, USA).

Analysis of caspase-3 activity The activity of caspase-3 proteases was measured using a caspase-3 colorimetric activity assay kit. Briefly, hippocampal CA1 areas were washed, homogenized in lysis buffer, incubated on ice for 20 min, analyzed for protein concentration, and diluted to equalize for protein concentration. All samples (95 μ L) were added to 5 μ L of 1 mmol/L caspase-3 substrate (Ac-DEVD-pNA, 50 μ mol/L final concentration) and incubated for 1 h at 37 °C. Cleavage of Ac-DEVD-pNA by active caspase-3 resulted in the liberation of *p*-nitroanilide (pNA) into solution. The release of pNA was quantitated spectrophotometrically by measuring absorbance at 405 nm (Biocell 2010, Anthos Labtec Instruments, Austria), and enzyme activity was calculated with reference to a standard curve of pNA concentration versus absorbance. The data were represented as the nmol pNA·min⁻¹·mg of protein⁻¹.

Polymerase chain reaction analysis for interleukin-1 β gene expression A semiquantitative reverse transcription-PCR (RT-PCR) assay was used to determine the mRNA levels of IL-1 β in relation to β -actin message. Total RNA was extracted from hippocampal CA1 areas using TRIzol reagent (Invitrogen Life Technologies, Paisley, PA4 9RF, UK). cDNA synthesis was carried out on 1 mg total RNA using random 9mers by RT with 2.5 IU of Avian Myeloblastosis Virus (AMV) reverse transcriptase in RT buffer in the presence of 1 mmol/L each of dNTP and 10 IU of RNase inhibitor. The thermal cycler (Biometra, Germany) was programmed for 10 min at 30 °C, 30 min at 42 °C, 5 min at 99 °C, and 5 min at 5 °C. Equal amounts of cDNA were used for PCR amplification for 35 cycles, using a 3-step program (30 s at 94 °C, 30 s

at 56 °C, and 1 min at 72 °C). After amplification, the products were separated by 7.5% SDS-PAGE (cast in the presence of ethidium bromide) and visualized under UV light. The following sequences of the primers were used: rat IL-1 β (sense), 5'-TGA CTC GTG GGA TGA TGA CG-3'; rat IL-1 β (antisense), 5'-CTG GAG ACT GCC CAT TCT CG-3'; β -actin (sense), 5'-GTG GGC CGC TCA AGG CAC CAA-3'; β -actin (antisense), 5'-CTT TAG CAC GCA CTG TAG TTT CTC-3'.

Statistical analysis All data were presented as mean \pm SD. Statistical analysis was carried out with one-way ANOVA, followed by LSD's *post hoc* test, which was provided by SPSS 11.5 statistical software. The level of significance was accepted as $P < 0.05$.

Results

Sodium ferulate inhibited the amyloid- β_{25-35} -induced increase in interleukin-1 β protein synthesis and mRNA expression Intracerebroventricular injection of preaggregated A β_{25-35} increased protein expression of IL-1 β , and densitometric analysis revealed that the mean value in samples prepared from A β -treated rats was significantly higher than that of control rats. SF (50, 100, and 250 mg/kg) significantly inhibited a A β_{25-35} -induced increase in protein expression of IL-1 β in a dose-dependent manner (Figure 1). An A β -associated increase in IL-1 β protein was mirrored by an A β -induced increase in IL-1 β mRNA levels. SF induced a similar inhibition in IL-1 β mRNA (Figure 2). On the other hand, the control results showed that only SF (100 mg/kg, daily for 4 weeks) had not effect on basal levels of IL-1 β protein and mRNA expression in hippocampal CA1 areas (data not shown).

Sodium ferulate inhibited the amyloid- β_{25-35} -induced astrocyte activation The astrocyte reaction was visualized by means of the immunoreactivity for glial fibrillar acidic protein, a specific marker of astrocytes. A β_{25-35} resulted in infiltration of astrocytes in hippocampal CA1, as well as transformation of astrocytes from a resting to an activated state, highlighted by phenotypic changes characterized by long, thick branching. SF at 50 mg/kg, 100 mg/kg, and 250 mg/kg significantly inhibited the A β_{25-35} -induced astrocytic reaction in hippocampal CA1 (Figure 3).

Sodium ferulate inhibited the amyloid- β_{25-35} -induced increase in phospho-p38 MAPK expression The p38 MAPK pathway, a major proinflammatory signal transduction pathway, is hyperactivated in the AD brain^[16]. Therefore, p38 MAPK activation was examined by immunoblotting in rat hippocampal CA1 using anti-phospho-p38 MAPK, an antibody that specifically recognizes the activated, tyrosine-phosphorylated form of p38 MAPK. The results showed

Figure 1. Inhibitory effect of sodium ferulate (SF) on the amyloid- β ($A\beta$)₂₅₋₃₅-induced increase in interleukin (IL)-1 β protein expression in rat hippocampus. The immunoreactivities of IL-1 β in hippocampal CA1 areas of $A\beta$ ₂₅₋₃₅ and $A\beta$ ₂₅₋₃₅+SF, as well as control animals, were determined by Western blotting. β -Actin was analyzed as a sample loading control. Lane 1, control; lane 2, $A\beta$ -treated; lanes 3–5, $A\beta$ +SF at 50 mg/kg, 100 mg/kg and 250 mg/kg, respectively. The bar chart shows the semiquantitative analysis of the expression of IL-1 β . *n*=4. Mean \pm SD. ^c*P*<0.001 vs control group. ^e*P*<0.05, ^f*P*<0.01 vs $A\beta$ ₂₅₋₃₅ group.

Figure 2. Reverse transcription-polymerase chain reaction analysis of the amyloid- β ($A\beta$)₂₅₋₃₅-induced increase in interleukin IL-1 β mRNA expression, and the inhibitory effect of sodium ferulate (SF; 50 mg/kg, 100 mg/kg and 250 mg/kg). mRNA encoding IL-1 β was expressed in the hippocampus of $A\beta$ ₂₅₋₃₅ and $A\beta$ ₂₅₋₃₅+SF, as well as control animals. mRNA encoding β -actin was used as a sample loading control. Lane M, DNA marker; lane 1, control; lane 2, $A\beta$ -treated; lanes 3–5, $A\beta$ +SF at 50 mg/kg, 100 mg/kg and 250 mg/kg, respectively.

that $A\beta$ ₂₅₋₃₅ led to a significant increase in phospho-p38 MAPK

protein expression. The $A\beta$ -induced increase in activation of p38 MAPK was paralleled by an $A\beta$ -induced increase in IL-1 β protein expression. The $A\beta$ -induced increase in activation of p38 MAPK was prevented by SF (50, 100, and 250 mg/kg, daily for 4 weeks) in a dose-dependent manner (Figure 4). In addition, SF (100 mg/kg, daily) treatment alone for 4 weeks did not result in a significant reduction in the basal expression of phospho-p38 MAPK in rat hippocampus (data not shown).

Intracerebroventricular injection of amyloid- β ₂₅₋₃₅ downregulated ERK-1/2, Akt/protein kinase B and the effects of sodium ferulate Although IL-1 β -induced enhancement of p38 MAPK activation may lead to deterioration in cell function and even cell death, we considered that downregulation of cell survival signals may also contribute to $A\beta$ -induced damages and, therefore, we analyzed the activity of ERK1/2 and Akt/PKB in the hippocampal CA1 region. The results showed that 7 d after injection, $A\beta$ ₂₅₋₃₅ elicited a significant decrease in the activated, tyrosine-phosphorylated form of ERK1 and ERK2, especially phospho-ERK1, compared to control rats. $A\beta$ completely inhibited the expression of phospho-ERK1. SF (50 mg/kg, daily for 4 weeks) partly abolished the $A\beta$ ₂₅₋₃₅-induced decrease in ERK1 and ERK2 activation, but SF (100 mg/kg and 250 mg/kg, daily for 4 weeks) did not prevent the decrease in phosphorylated ERK1 and ERK2 induced by $A\beta$ ₂₅₋₃₅ (Figure 5A). SF treatment alone (100 mg/kg, daily for 4 weeks) exerted a decrease in phosphorylated ERK1 and ERK2 that did not reach statistical significance compared with control rats (data not shown). However, the underlying cause of this effect of SF (100 mg/kg and 250 mg/kg) on phosphorylated ERK1 and ERK2 remains to be identified. No significant difference in total ERK1/2 was apparent, as shown in the sample immunoblot (Figure 5B). Treatment with $A\beta$ ₂₅₋₃₅ also decreased the expression of phosphorylated Akt/PKB compared with control rats. SF (50 mg/kg, 100 mg/kg and 250 mg/kg, daily for 4 weeks) completely reversed the effect of $A\beta$ ₂₅₋₃₅ on phosphorylated Akt/PKB compared with control rats in a dose-dependent manner. The level of phospho-Akt/PKB expression in $A\beta$ ₂₅₋₃₅+ SF (100 mg/kg and 250 mg/kg) was significantly greater than in control rats (Figure 5C). However, no significant difference in the expression of total Akt/PKB was observed among treatment groups (Figure 5D). In addition, SF alone (100 mg/kg, daily for 4 weeks) had no obvious effect on the basal phosphorylation of Akt/PKB in the hippocampus (data not shown).

Sodium ferulate prevented the amyloid- β ₂₅₋₃₅-induced increase in caspase-3 activity and caspase-3 protein expression in rat hippocampus Caspase-3 activity was measured

Figure 3. Immunohistochemical demonstration of the inhibitory effect of sodium ferulate (SF) on astrocyte activation induced by intracerebroventricular injection of amyloid- β ($A\beta$)₂₅₋₃₅ in rat hippocampal CA1 regions. (A) Control group; (B) a coronal slice obtained from $A\beta$ ₂₅₋₃₅-injected rats; (C) $A\beta$ ₂₅₋₃₅+SF at 50 mg/kg; (D) $A\beta$ ₂₅₋₃₅+SF at 100 mg/kg; (E) $A\beta$ ₂₅₋₃₅+SF at 250 mg/kg. $\times 400$.

by cleavage of the caspase-3 substrate (Ac-DEVD-pNA). As shown in Figure 6A, caspase-3 activity was significantly enhanced in hippocampal CA1 prepared from $A\beta$ -treated rats compared with control rats. This $A\beta$ -induced increase in caspase-3 activity was inhibited by SF (50 mg/kg, 100 mg/kg and 250 mg/kg). Western blot analysis showed that $A\beta$ ₂₅₋₃₅ evoked a significant increase in caspase-3 protein expression. SF (50 mg/kg, 100 mg/kg and 250 mg/kg) prevented the increase in $A\beta$ -induced caspase-3 protein expression (Figure 6B).

Sodium ferulate decreased the amyloid- β ₂₅₋₃₅-induced expression level of Fas ligand protein Previous studies have shown that survival factor withdrawal leads to the induction of FasL protein and mRNA in cerebellar granule neurons

and PC 12 cells^[17]. The binding of FasL to the Fas receptor is a prototypic signal for apoptosis, and therefore it was of interest to determine whether SF inhibits the $A\beta$ -induced increase in FasL protein expression. As shown in Figure 7, $A\beta$ ₂₅₋₃₅ significantly enhanced the expression level of FasL protein in hippocampal CA1 regions. SF (50 mg/kg, 100 mg/kg and 250 mg/kg) demonstrated inhibition of the $A\beta$ -induced increase in FasL protein expression level in a dose-dependent manner (Figure 7).

Discussion

Injection of aggregated $A\beta$ into the brain of experimental animals may represent a valuable tool for studying the neu-

Figure 4. Inhibitory effects of sodium ferulate (SF) on the amyloid- β ($A\beta$)₂₅₋₃₅-induced increase in p38 mitogen-activated protein kinase (MAPK) activation in the rat hippocampus. The immunoreactivity of p38 MAPK in the hippocampus of $A\beta$ ₂₅₋₃₅ and $A\beta$ ₂₅₋₃₅+SF, as well as control animals, was determined by Western blotting. Lane 1, control; lane 2, $A\beta$ -treated; lanes 3–5, $A\beta$ +SF at 50 mg/kg, 100 mg/kg and 250 mg/kg, respectively. The bar chart shows the semiquantitative analysis of the expression of p38 MAPK. $n=4$. Mean \pm SD. ^c $P<0.01$ vs control group. ^f $P<0.01$ vs $A\beta$ ₂₅₋₃₅ group.

rotoxic effect of this peptide. We found that intracerebroventricular injection of $A\beta$ ₂₅₋₃₅ induced an increase in IL-1 β protein and mRNA expression in hippocampal tissue, and this increase, in combination with enhanced activation of p38 MAPK and reduced activation of ERK1/2 and Akt/PKB, mediates the $A\beta$ -induced activation of cell death events as assessed by activation of caspase-3. However, several of these changes, including $A\beta$ -induced increase in caspase-3 activation, were prevented by treatment with SF. Indeed in AD brain, the increased levels of phosphorylated (active) p38 MAPK and diminished expression of Akt/PKB were detected^[16,18]. Maher *et al* also found that increased IL-1 β in the cortex of aged rats was accompanied by downregulation of ERK and PI3 kinase (an upstream kinase of Akt/PKB)^[19]. These observations bear a marked similarity to our results. The $A\beta$ -induced diminished expression of phospho-ERK1/2 and phospho-Akt/PKB in hippocampal tissue indicates that the neuron survival signal transduction pathway is impaired. The $A\beta$ -induced increase in p38 MAPK phosphorylation and decrease in phosphorylated ERK1/2 and Akt/PKB parallel some changes that are hallmarks of cell death. For example, an increase in caspase-3 activity and FasL protein expression were observed in hippocampal tissue treated with $A\beta$, suggesting that sequential activation triggers apoptotic changes in the hippocampus.

Increased activation of p38 MAPK accompanied the $A\beta$ -induced increase in IL-1 β concentration, consistent with previous observations in hippocampal cells^[20]. The evidence presented here pinpoints IL-1 β -induced increased activation of p38 MAPK as a pivotal event in triggering changes that are characteristic of apoptotic cell death, for example, caspase-3 activation. Thus, inhibition of p38 MAPK by SB203580 has been shown to prevent the increase in IL-1 β -induced caspase-3 activity^[21]. A significant finding of this study is that SF treatment prevents the $A\beta$ -induced increase in activation of p38 MAPK, caspase-3 and FasL expression, indicating a potential neuroprotective effect of SF. These findings suggest that the effects of SF on the activity of p38 MAPK and caspase-3 may be secondary to its ability to suppress the $A\beta$ -induced increase in IL-1 β synthesis.

It has also been shown that cell death is accompanied by a decrease in survival signals^[22]. PI3K/Akt and ERK1/2 have been shown to be important for neuronal survival. Over-expressing active Akt/PKB rescues cells from apoptosis^[23]. We report in this study that, in addition to increased p38 MAPK activation, the increase in caspase-3 activation may be associated with attenuated activity of ERK and Akt/PKB. SF treatment significantly prevented these $A\beta$ -induced changes and, therefore, in $A\beta$ -treated rats that were treated with SF, we found that caspase-3 activity was significantly decreased and paralleled the changes in activities of both ERK and Akt/PKB. These results are consistent with those described by Daniels *et al*^[24] and Meng *et al*^[18]. Therefore, downregulation of Akt/PKB may be another mechanism by which $A\beta$ induces apoptosis. To our knowledge, this is the first indication that Akt/PKB activation in the hippocampus is decreased by $A\beta$ *in vivo*. Thus, $A\beta$ -induced increase in caspase-3 activity, which is considered to be a reliable indicator of apoptotic cell death, may arise from the coupled increase in p38 MAPK activation and decrease in ERK and Akt/PKB activation.

Several observations have contributed to the development of the idea that FasL expression and, consequently, Fas activation play a role in neurodegeneration^[2,25], and we report that increased hippocampal expression of FasL accompanied the $A\beta$ -induced increase in p38 MAPK phosphorylation and caspase-3 activation. The binding of Fas to FasL triggers activation of caspase-8 and, in turn, caspase-8 activates caspase-3^[26]. SF markedly prevented the $A\beta$ -induced increase in FasL protein expression.

In conclusion, our data suggest that $A\beta$ -induced increased IL-1 β , coupled with increased p38 MAPK activation, leads to cell death as assessed by activation of caspase-3. In addition, the data also show that downregulation of the

Figure 5. Sodium ferulate (SF) inhibited the amyloid- β ($A\beta$)₂₅₋₃₅-induced downregulation of phospho-extracellular signal-regulated kinase (ERK)1/2 and phospho-Akt/protein kinase B (PKB) expression. (A) Effect of SF on the $A\beta$ ₂₅₋₃₅-induced decrease in phosphorylated ERK1/2. (B) Total ERK1/2 showed no change. (C) Effect of SF on the $A\beta$ ₂₅₋₃₅-induced decrease in phosphorylated Akt/PKB. (D) Total Akt/PKB expression showed no change after stimulation with $A\beta$ ₂₅₋₃₅. The bar chart below each blot shows the semiquantitative analysis of the protein expression. Lane 1, control; lane 2, $A\beta$ -treated; lanes 3–5, $A\beta$ ₂₅₋₃₅+SF at 50 mg/kg, 100 mg/kg and 250 mg/kg, respectively. survival signals ERK and Akt/PKB may contribute to the demise of the cells. These are significantly abrogated by SF treatment, which also attenuates $A\beta$ -induced increase in caspase-3 activity and FasL expression.

Abstract

Aim: To establish an *in vitro* injured motor neuronal model and investigate the neuroprotective effects and possible mechanism of celecoxib, a selective cyclooxygenase-2 (COX-2) inhibitor, on this model. **Methods:** After macrophages were stimulated with lipopolysaccharide (LPS)+interferon- γ (IFN- γ) in the presence or absence of celecoxib for 24 h, the cell-free supernatant of LPS-stimulated macrophages was transferred to the culture of NSC34 cells. Viability of NSC34 cells was assessed by MTT assay after a further 24 h and 72 h incubation. After macrophages were stimulated by LPS+IFN- γ for 12 h or 24 h, the release of prostaglandin E₂ (PGE₂), nitric oxide (NO), reactive oxygen species (ROS), tumor necrosis factor α (TNF- α) and interleukin-1 β (IL-1 β) from macrophages was measured by radioimmunoassay, Griess assay, fluorescence assay and enzyme-linked immunosorbent assay, respectively. The mRNA levels of COX-2, inducible nitric oxide synthase (iNOS), TNF- α and IL-1 β in macrophages were determined by reverse transcription-polymerase chain reaction after macrophages were stimulated for 6 h and 12 h. **Results:** The supernatant of LPS-stimulated mouse macrophages induced the death of NSC34 cells and celecoxib protected the NSC34 cells against this toxicity. The LPS-induced increases in the release of PGE₂, NO, TNF- α and IL-1 β from macrophages were attenuated by pre-treatment with celecoxib. However, celecoxib showed no effect on the ROS levels upregulated by LPS+IFN- γ in the macrophage supernatant. The mRNA levels of COX-2, iNOS, TNF- α and IL-1 β were increased in LPS-activated macrophages and, except COX-2, reduced by pre-treatment with celecoxib. **Conclusion:** An *in vitro* injured motor neuronal model was established by using the toxicity of LPS-stimulated mouse macrophages toward motor neuronal NSC34 cells. In this model, celecoxib exerted neuroprotective effects on motor neurons via an inhibition of the neurotoxic secretions from activated macrophages.

Introduction

Amyotrophic lateral sclerosis (ALS) is a progressive fatal neurodegenerative disorder that primarily affects motor neurons in the cortex, brainstem and spinal cord. Evidence suggests that mutations in Cu/Zn superoxide dismutase (SOD-1), glutamate-mediated excitotoxicity, free radical-mediated damage, mitochondrial dysfunction and apoptosis may be involved in the pathogenesis of ALS^[1]. However,

the cause of ALS is not completely understood.

Accumulating evidence indicates that inflammatory processes, especially the activation of microglia, are involved in the pathogenesis of ALS^[2]. Activated microglia are present before the onset of clinical symptoms and prior to significant motor neuron loss in transgenic mice with mutations of the SOD-1 gene, an animal model of ALS^[3]. Furthermore, some critical markers of microglia activation have also been found post-mortem in the cerebral cortex and spinal cord of pa-

tients with ALS^[4,5]. Inflammatory processes would produce harmful effects on neuron survival in ALS tissues, include a prominent upregulation of inducible nitric oxide synthase (iNOS) activity with the subsequent generation of nitric oxide (NO)^[6], the increased generation of reactive oxygen species (ROS) and glutamate^[7], the enhanced secretions of inflammatory cytokines, such as tumor necrosis factor α (TNF- α), interleukin-1 β (IL-1 β), and interleukin-6 (IL-6)^[8], as well as the enhanced expression of cyclooxygenase-2 (COX-2) with the subsequent production of prostaglandin E₂ (PGE₂)^[9].

COX-2 was demonstrated to be crucial for prostaglandin synthesis in inflammation. COX-2 expression was shown to be dramatically increased in the spinal cord of both of ALS transgenic mice and ALS patients^[10,11]. PGE₂ levels were also markedly increased in ALS cases compared to non-ALS specimens^[12]. In addition, a selective COX-2 inhibitor, SC236, protected motor neurons in an organotypic cell culture model of ALS^[13]. Furthermore, celecoxib, a highly selective COX-2 inhibitor clinically available for the treatment of rheumatoid arthritis^[14], was proved to prolong survival in a transgenic mouse model of ALS^[15]. These results support a potential role for COX-2 in the neurodegenerative processes of ALS and suggest that a selective COX-2 inhibitor may be effective in the treatment of ALS. However, research on the neuroprotective mechanism of COX-2 inhibition on a cellular level, and drug screens using an injured motor neuronal model are still lacking.

In order to investigate the possible neuroprotective mechanism of the COX-2 inhibitor on ALS and to screen candidate anti-inflammatory drugs for ALS, an injured motor neuronal model, which simulates *in vivo* human microglia activation and the neuronal damage observed during neurodegenerative disease processes, was developed in the present study. Microglia are the resident macrophages of the central nervous system (CNS) as microglia and macrophages, both being cells of the monocyte phagocytic system, have similar biochemical characteristics^[16]. In addition, recent findings suggest that infectious agents may increase the risk of ALS and infected migratory mononuclear phagocytes may play an important role in the infection process^[17]. Therefore mouse peritoneal macrophages as an accessible source of mononuclear phagocytes and neurotoxicity were used. NSC34 cells, a hybrid cell line obtained by fusion of motor neuron-enriched embryonic mouse spinal cord cells with mouse neuroblastoma N18TG cells, were used as the target motor neuronal cells^[18]. Lipopolysaccharide (LPS), a cell wall component of gram-negative bacteria, can activate macrophages. Interferon (IFN)- γ is another important stimulant which can enhance cytokine production. A

combination of LPS and IFN- γ was used to activate monocytes^[19,20].

In the present study, we further verified the injured motor neuronal model by evaluating the neuroprotective effect of celecoxib, which prolongs the survival of ALS transgenic mice. In addition, the release of PGE₂, NO, ROS, inflammatory cytokines and the expression of relevant inflammatory genes in macrophages was studied to explore the possible mechanism of the neuroprotective effect of a COX-2 inhibitor against the toxicity of microglia activation on motor neuron viability.

Materials and methods

Drugs and reagents Celecoxib was kindly provided by Dr Yu-she YANG, Shanghai Institute of Materia Medica, Chinese Academy of Sciences, Shanghai, China. LPS (*Escherichia coli* 055:B5) was purchased from Sigma (St Louis, USA). IFN- γ was obtained from Clonbiotech (Shanghai, China). A radioimmunoassay (RIA) kit for PGE₂ was obtained from China PLA General Hospital (Beijing, China). Enzyme-linked immunosorbent assay (ELISA) kits for TNF- α and IL-1 β were obtained from BD Biosciences (San Diego, CA, USA).

Cell culture Macrophages were obtained from the peritoneal exudates of female BALB/c mice (Grade II, Shanghai Experimental Animal Center, Shanghai, China; Certificate No 003) 4 d after intraperitoneal injection with 0.5 mL 3% thioglycollate (WAKO, Tokyo, Japan). The cells were harvested using cold peritoneal lavage with phosphate-buffered saline (PBS, pH 7.4) containing 1% fetal calf serum (FCS; PAA, Pasching, Austria), washed twice with PBS and resuspended in Dulbecco's modified eagle medium (DMEM)-F12 medium (Gibco, NY, USA) supplemented with 5% FCS, 0.1 g/L streptomycin, and 100 kU/L penicillin. The cells were seeded at a density of 1×10^6 cells/mL at 37 °C in a humidified atmosphere of 5% CO₂ and 95% air in an incubator. After adhering for 2 h, the cells were washed 3 times with warm PBS and incubated in DMEM-F12 medium supplemented with 5% FCS for the formal experiments. The viability of each cell preparation was more than 95%, as assessed by trypan blue staining (0.1% solution).

The mouse motor neuronal NSC-34 cell line was a gift from Dr Jin REN (Shanghai Institute of Materia Medica). NSC34 cells were maintained at 37 °C and 5% CO₂ in DMEM (Gibco) supplemented with 10% FCS, 0.1 g/L streptomycin and 100 kU/L penicillin.

Measurement of cell viability NSC34 cell viability was measured using the MTT assay as described by Hansen *et*

al^[21]. Briefly, MTT (Sigma) was added to cell cultures to reach a final concentration of 0.2 g/L. Following a 4-h incubation at 37 °C, the dark crystals formed were collected and dissolved in 200 µL/well dimethylsulfoxide in 24-well plates. Subsequently, optical densities were measured at 570 nm by transferring 100 µL/well to 96-well plates and recording the values using a plate reader (POLARstar®; BMG, Victoria, Australia). The number of viable NSC34 cells was calculated as a percentage of the value obtained from the control NSC34 cells incubated with media only.

Measurement of nitric oxide Nitric oxide was determined by assaying for nitrite using Greiss reagent (1% sulfanilamide, 0.1% *N*-(1-naphthyl) ethylenediamine dihydrochloride in 5% H₃PO₄)^[22]. Briefly, 100 µL of the supernatant from each well (24-well plates) was incubated for 5 min with 100 µL Griess reagent in 96-well plates. Optical densities of the samples were then obtained by reading absorbance at 540 nm.

Measurement of reactive oxygen species The ROS assay was modified from the fluorescence assay described by Gunasekar *et al*^[23]. Briefly, 90 µL of supernatant from each well (24-well plates) was transferred to 96-well fluorescence assay plates, incubated to 37 °C, and then added 10 µL Krab's Ringer buffer (127 mmol/L NaCl, 5.5 mmol/L KCl, 2 mmol/L MgSO₄, 1 mmol/L CaCl₂, 20 mmol/L HEPES, 10 mmol/L dextrose, pH 7.4) with 50 µmol/L 2',7'-dichlorofluorescein diacetate (DCFH-DA; Sigma) and 20 IU/mL horseradish peroxidase (SABC, Shanghai, China). The fluorescence value of each well was read at 30 s intervals for 5 min at 485 nm excitation wavelength and 520 nm emission wavelength. The ROS value of each sample was calculated as the slope of its time-fluorescence value curve.

Measurement of PGE₂, TNF-α and IL-1β The concen-

trations of PGE₂, TNF-α and IL-1β were determined by RIA and ELISA according to the manufacturer's instructions.

Measurement of mRNA The mRNA levels of COX-2, iNOS, TNF-α and IL-1β were detected by real-time quantitative reverse transcription-polymerase chain reaction (RT-PCR) using β-actin mRNA as an internal control. Briefly, macrophages from various treatments in 6-well plates were washed twice with ice-cold PBS. Total RNA was extracted from the cells in each well with RNazol (Dingguo Biotechnology, Beijing, China) according to the manufacturer's instructions. First-strand cDNA synthesis was carried out using 2 µg total RNA and M-MLV reverse transcriptase (Promega, Madison, USA). The reaction mix was incubated at 42 °C for 60 min, and then heated at 70 °C for 10 min. Each reaction mixture was diluted 4 times with 0.1% diethyl pyrocarbonate (DEPC)-treated H₂O. A 2-µL aliquot from each diluted reaction mixture was used for real-time PCR amplification. The primer sequences and PCR cycle parameters for β-actin^[24], COX-2^[24], iNOS^[25], TNF-α^[26], and IL-1β^[27] are listed in Table 1.

Real-time quantitative RT-PCR was carried out as described by Livak^[28]. Each reaction contained 2 µL of the cDNA sample with 1 IU *Taq* DNA polymerase (Dingguo Biotechnology) and 0.5 µL Sybr Green (OPE, Shanghai, China) in a total volume of 20 µL in a real-time quantitative PCR cycler (DNA Engine Opticon® Continuous Fluorescence Detection System; MJ Research, USA). The mRNA level was estimated as a relative value by normalizing with β-actin mRNA. Reaction products were also separated on a 1.5% agarose gel, stained with ethidium bromide, and photographed to validate the reliability of the objective genes.

Statistical analysis Data were presented as mean±SD of the values from 3 independent experiments and the

Results

Toxicity of LPS+IFN- γ -stimulated macrophages toward NSC34 cells and inhibitory effect of celecoxib on cytotoxicity The supernatant of the macrophages stimulated with a combination of LPS and IFN- γ significantly inhibited the viability of motor neuron NSC34 cells (Figure 1). Adding celecoxib enhanced the survival of these NSC34 cells (Figure 1). The neuroprotective effect of celecoxib was due to an effect on macrophage neurotoxic secretions because celecoxib showed no neuroprotective effect on NSC34 cells if it was added to the supernatant of NSC34 cells directly (data not shown).

Figure 1. Inhibitory effect of celecoxib on the cytotoxicity of lipopolysaccharide (LPS)/interferon (IFN)- γ -stimulated macrophages toward NSC34 cells (MTT assay). Data (mean \pm SD) from 3 independent experiments (each done in 2 wells, *n*=6) are expressed as a percentage of each control. ^c*P*<0.01 vs control. ^d*P*<0.05, ^e*P*<0.05, ^f*P*<0.01 vs celecoxib 0 μmol/L.

Effect of celecoxib on the production of PGE₂, NO, ROS, TNF- α and IL-1 β on LPS+IFN- γ -stimulated macrophages To confirm that the production of PGE₂, NO, ROS, TNF- α and IL-1 β was increased in LPS+IFN- γ -stimulated macrophages, their concentrations were measured in the macrophage supernatants. Compared with resting macrophages, LPS+IFN- γ -stimulated macrophages significantly increased the release of PGE₂, NO, ROS, TNF- α , and IL-1 β (Figure 2A–2E). To determine whether celecoxib regulates PGE₂, NO, ROS, TNF- α , and IL-1 β release from activated macrophages, macrophages were preincubated with celecoxib for 30 min prior to the addition of LPS+ IFN- γ . After the macrophages were stimulated for 12 h or 24 h, the concentrations of PGE₂, NO, ROS, TNF- α , and IL-1 β in the macrophage supernatants were measured. The increased productions of PGE₂, NO, TNF- α , and IL-1 β were attenuated by preincubation with celecoxib (Figure 2A–2E). However, pre-treatment with celecoxib had no effect on the level of ROS in macrophage supernatants (Figure 2C).

Figure 2. Effect of celecoxib on the release of prostaglandin E₂ (PGE₂), nitric oxide (NO), reactive oxygen species (ROS), tumor necrosis factor- α (TNF- α) and interleukin-1 β (IL-1 β) in lipopolysaccharide (LPS)/interferon (IFN)- γ -stimulated macrophages. Data (mean \pm SD) from 3 independent experiments (each done in 2 wells, *n*=6) are expressed as a percentage of the values from the 12 h LPS/IFN- γ treatment. ^a*P*>0.05, ^b*P*<0.05, ^c*P*<0.01 vs control. ^d*P*>0.05, ^e*P*<0.05, ^f*P*<0.01 vs celecoxib 0 μmol/L.

Effect of celecoxib on mRNA levels of COX-2, iNOS, TNF- α and IL-1 β in LPS+IFN- γ -stimulated macrophages

To determine whether LPS stimulation increases the mRNA levels of COX-2, iNOS, TNF- α , and IL-1 β in macrophages, the mRNA levels of these genes were determined by real time RT-PCR. Stimulated macrophages strongly expressed mRNA of COX-2, iNOS, TNF- α and IL-1 β following treatment with LPS+IFN- γ (Figure 3A–3D), whereas resting macrophages expressed these mRNA very weakly. Furthermore,

preincubation with celecoxib inhibited the increases of the mRNA levels of iNOS, TNF- α and IL-1 β , which were induced by LPS+IFN- γ in macrophages and had no effect on the mRNA level of COX-2 (Figure 3).

Discussion

In the present study, we demonstrated that the supernatant of macrophages stimulated with LPS 0.5 mg/L plus IFN- γ 1.5×10^5 IU/L caused a loss of NSC34 cells following either a 24-h or 72-h exposure. In consisten with the previous results^[19,20,29], no neurotoxicity was observed when the supernatant from unstimulated macrophages was transferred to NSC34 cells, and LPS (0.0005–5.0 mg/L) increased the neurotoxicity of the supernatant of macrophages on NSC34 cells dose-dependently. LPS did not show toxic effects on NSC34 cells when it was added to the supernatant of NSC34 cells directly (data not shown). These results indicate that NSC34 cells injured by the supernatant of LPS-stimulated macrophages can be used to develop an injured motor neuronal model, whose neurotoxicity was due mainly to inflammatory secretions of macrophages. In the present investigation, Celecoxib was used to verify the model because of its beneficial effects on ALS transgenic mice. It was shown that celecoxib significantly enhanced the survival of NSC34 cells. These results indicate that this model may have valuable applications for drug screening and further research the mechanisms involved. No improvement in NSC34 cell viability was observed when celecoxib was added

directly to NSC34 cells (data not shown). This suggests that the target cells of celecoxib are macrophages rather than motor neurons and that the action of celecoxib on macrophages is likely a reduction of neurotoxic macrophage secretions. Another COX-2 selective inhibitor, NS398, has been reported to have neuroprotective effects on neuronal-like SH-SY5Y cells by suppressing the toxic actions of human monocytic THP-1 cells^[20,29].

PGE₂ is an important mediator involved in a variety of inflammatory processes and COX-2 has been shown to be primarily responsible for the synthesis of PGE₂. COX-2 is rapidly induced by various proinflammatory agents, including LPS, cytokines and mitogens^[30]. In the present study, exposure of LPS to macrophages resulted in an increase in the level of PGE₂ released and an induction of COX-2 expression at the mRNA level (Figure 3). Results from previous studies have also shown that proinflammatory stimuli induce PGE₂ release and COX-2 expression^[30]. Our results showed that PGE₂ release was inhibited by the addition of celecoxib in LPS-stimulated macrophages (Figure 2), suggesting that celecoxib exerts neuroprotective effects on motor neuron NSC34 cells by inhibiting COX-2 activity and the subsequent production of PGE₂ in LPS-stimulated macrophages.

The expression and activity of iNOS plays a pivotal role in sustained and elevated NO release^[31]. It has previously been reported that microglial cells are the main source of LPS-induced iNOS/NO both in neuron-glia culture and *in vivo*^[32]. In addition, there is “cross-talk” between iNOS/NO

Figure 3. Effect of celecoxib on the mRNA levels of cyclooxygenase-2 (COX-2), inducible nitric oxide synthase (iNOS), tumor necrosis factor- α (TNF- α) and interleukin-1 β (IL-1 β) in lipopolysaccharide (LPS)/interferon (IFN)- γ -stimulated macrophages. Data (mean \pm SD) are from 3 independent experiments and are expressed as a percentage of the 6 h control. ^c $P < 0.01$ vs control, ^d $P > 0.05$, ^e $P < 0.05$, ^f $P < 0.01$ vs celecoxib 0 μ mol/L.

and COX-2/PGE₂^[33]. In the present study, we demonstrated that celecoxib significantly inhibits LPS-stimulated iNOS expression and NO release in macrophages. These results suggest that downregulation of iNOS/NO by celecoxib might be involved in the neuroprotective effect of celecoxib against LPS-induced motor neuronal death^[32].

Although one previous study found that LPS-induced ROS was increased in neurons, not microglial cells, in neuron-glia coculture^[33], the most abundant source of oxygen free radicals in the CNS is the respiratory burst system of activated microglia^[2]. A recent study reported that LPS treatment increased intracellular ROS in rat microglia in a dose-dependent manner and ROS played a regulatory role in the expression of COX-2 and the subsequent production of PGE₂ during the process of microglial activation^[34]. On the other hand, Gunasekar *et al* reported that pretreatment with NS398 significantly decreased potassium cyanide (KCN)-induced ROS generation in cerebellar granule cells. The results indicated the involvement of COX-2 in KCN-induced oxidant generation^[23], which further suggests a level of “cross-talk” between ROS and COX-2 in activated microglia. The present studies showed that extracellular ROS levels from LPS-stimulated macrophages were upregulated. However, celecoxib showed no effect on the extracellular ROS level in our study. The results suggest that celecoxib exerts its neuroprotective effect against the toxicity of LPS-stimulated macrophages probably not by the regulation of extracellular ROS.

TNF- α is a potent proinflammatory cytokine that plays an important role in immunity and inflammation. The present study showed that LPS-stimulation increases TNF- α secretion from macrophages. A previous study found that LPS-stimulation increases TNF- α secretion in microglia such as BV-2 cells^[19]. We further demonstrated that celecoxib significantly downregulates TNF- α mRNA level and TNF- α secretion induced by LPS in macrophages. The results suggest that inhibition of TNF- α secretion from the LPS-activated macrophages probably participates in the neuroprotective effect of celecoxib on motor neurons.

Interleukin-1 β is an important cytokine in the inflammation process, and microglia are an important source of IL-1 in the human CNS^[35]. The release of IL-1 plays a critical role in the effect of microglial activation on motor neuron viability and IL-1 is amongst a wide range of factors that upregulate the expression of COX-2 and the subsequent production of proinflammatory cytokines and PGE₂^[9]. Previous studies reported that LPS increases the secretions of IL-1 β in monocytic THP-1 cells^[35]. In addition, another study indicated that celecoxib decreases the secretion of IL-1 β in rats^[36]. The data from the present study show that celecoxib inhibits the

level of IL-1 β , which is increased in LPS-stimulated macrophages. Therefore, the inhibitory effect of celecoxib on the level of IL-1 β may be involved in the mechanism of its neuroprotective effect.

In summary, an injured motor neuronal model was established. The selective COX-2 inhibitor celecoxib showed beneficial effects against motor neuronal death induced by inflammatory reaction. The neuroprotective effect of celecoxib might be associated with downregulation of the levels of PGE₂, NO, TNF- α and IL-1 β as well as gene expression of iNOS, TNF- α and IL-1 β . Since PGE₂^[12], NO^[37-39] and TNF- α ^[19,40] have been reported to be upregulated in ALS, indicating COX-2 inhibitors would be promising candidates for the treatment of ALS.

Abstract

Aim: To demonstrate and compare hemodynamic phenotypes of blood pressure (BP), blood pressure variability (BPV) and baroreflex sensitivity (BRS) in genetic hypertensive rats. **Methods:** BP was recorded continuously in conscious, freely moving rats using a computerized technique. BPV was expressed as the standard deviation of beat-to-beat BP values during a 1-h period. BRS was determined by measuring the heart period prolongation in response to the elevation in BP produced by an intravenous injection of phenylephrine. **Results:** Body weight and heart period were not different between spontaneously hypertensive rats (SHR) and stroke-prone spontaneously hypertensive rats (SHR-SP) at the age of 15 weeks. The BP level was markedly higher in SHR-SP than SHR, whereas there were no significant differences in BPV and BRS. Quantitatively, systolic, diastolic and mean BP were significantly elevated by 36.9%, 42.9% and 39.5%, respectively, in SHR-SP compared with SHR ($P < 0.01$). However, their variabilities were elevated only by 14.0%, 0.4% and 10.1%, respectively, without statistical significance ($P > 0.05$). **Conclusion:** BPV and BRS were not changed in parallel with the BP alterations in SHR and SHR-SP.

Introduction

Blood pressure (BP) is not constant. Spontaneous variations exist in BP. The extent of the variation in BP is defined as the blood pressure variability (BPV). This new parameter of cardiovascular function can be determined through continuous ambulatory BP monitoring using a computerized technique^[1,2], which can provide beat-to-beat BP tracings. It is understood that BPV is independent of BP^[2,3], and high BPV is a novel risk factor for cardiovascular damage, such as aortic hypertrophy and renal lesions^[2,4,5]. In the post-genome era, attaching physiology and pharmacology to the genome has become more and more important, as the combined physiological, pharmacological and genomic information should facilitate the development of new therapeutics^[6]. To obtain genomic information on BPV, one of the strategies is to use linkage analysis in segregating populations produced by crossbreeding of inbred strains^[7]. The first step of this strategy is to select two parental strains for cross-

breeding. It is generally realized that the greater the difference in phenotype between two parental strains, the better for the linkage study.

Spontaneously hypertensive rat (SHR), an inbred strain for genetic hypertension, has a higher BPV compared with normotensive controls, such as Wistar-Kyoto rats and Sprague-Dawley rats^[1,5]. Stroke-prone spontaneously hypertensive rat (SHR-SP), a sub-strain of SHR, has a much higher BP level than SHR^[8,9]. However, little is known about the BPV of SHR-SP. We hypothesized that SHR-SP had a higher BPV than SHR in parallel with their BP changes, and thus would be more appropriate as a parental strain crossbred with another parental strain of normal rats. To test this hypothesis, hemodynamics were compared between SHR and SHR-SP in the present study.

Materials and methods

Animals Male SHR and SHR-SP were provided by the

Animal Center of the Second Military Medical University, Shanghai, China. Animals were housed at controlled temperature (23 °C–25 °C) and lighting (8:00–20:00) and with free access to tap water and rat chow. At the age of 15 weeks, hemodynamic parameters, including BP, BPV, and baroreflex sensitivity (BRS), were measured in conscious, freely moving rats. All procedures were in accordance with the guidelines for animal care of the Second Military Medical University.

Measurement of blood pressure and its variability Rats were anesthetized with an injection of ketamine (50 mg/kg, ip) and diazepam (5 mg/kg, ip). A catheter was placed into the lower abdominal aorta via the left femoral artery for measurement of BP and heart period (HP), and another catheter was inserted into the left femoral vein for drug administration. Both catheters were tunneled subcutaneously and exteriorized between the scapulae. After a 2-d recovery, animals were placed in individual cylindrical cages. The aortic catheter was connected to a BP transducer (PT14M2, Fudan University, Shanghai, China) via a rotating swivel that allowed the animal to move freely in the cage. After approximately 14 h habituation, the BP signals were digitized and processed by a microcomputer, which calculated systolic BP (SBP), diastolic BP (DBP), mean BP (MBP), and HP values on-line for 2 h–3 h. These values were sampled beat-to-beat at 1000 Hz. In off-line analysis, the mean values of SBP, DBP, MBP, and HP over a 1-h period (10:00–11:00) were calculated and served as SBP, DBP, MBP, and HP, respectively. The standard deviation values of SBP, DBP, and MBP over the 1-h period were calculated and defined as systolic BPV (SBPV), diastolic BPV (DBPV), and mean BPV (MBPV), respectively^[1,3–5].

Measurement of baroreflex sensitivity After BP and BPV measurement, BRS was determined using a method described previously^[10]. The principle of this method is to measure the HP prolongation in response to an elevation in blood pressure. A bolus intravenous injection of phenylephrine was used to raise SBP to between 30 mmHg and 40 mmHg. HP was plotted against SBP for linear regression analysis; the slope of the linear regression equation was expressed as BRS (ms/mmHg).

Statistical analysis Data are expressed as mean±SEM. The differences between 2 groups were evaluated using the two-tailed Student's unpaired *t*-test. Statistical significance was judged at $P<0.05$.

Results

Blood pressure and its variability Body weight and heart

period were not significantly different between SHR and SHR-SP at the age of 15 weeks (Table 1). BP was markedly higher in SHR-SP than SHR, whereas there was no significant difference in BPV. To show clearly that BPV was not changed in parallel with the BP changes in SHR and SHR-SP, BP and BPV were compared quantitatively using percentage difference (Table 1). Systolic, diastolic and mean BP were elevated significantly by 36.9%, 42.9%, and 39.5%, respectively, in SHR-SP compared with SHR ($P<0.01$). However, their variabilities were elevated only by 14.0%, 0.4%, and 10.1%, respectively, without statistical significance ($P>0.05$). Figure 1 shows the representative values of systolic blood pressure tracings during a 1-h period in SHR and SHR-SP.

Discussion

In the present study, 15-week-old rats were used for comparisons of hemodynamic phenotypes, including BP, BPV, and BRS. This is because BP levels reach a plateau at this adult age^[9,11]. It is well known that BP level is markedly higher in SHR-SP than SHR in both conscious and anesthetized states^[8,9,12]. Our present data are in accordance with previous results^[8,9].

In contrast to our hypothesis, there was no significant difference in BPV between SHR-SP and SHR. In other words, BPV was not elevated in parallel with the remarkable elevations in BP in SHR-SP compared with SHR. The BPV data combined with the shorter life span of SHR-SP (about 45 weeks)^[9] compared with SHR (about 75 weeks)^[13] lead us to the unequivocal conclusion that SHR is more appropriate as a parental strain than SHR-SP for crossbreeding in BPV linkage studies.

Blood pressure variability is increased in almost all hypertensive patients and animals^[1,14]. This often leads to the deduction that alterations in BP and BPV occur in parallel. The present study showed that SHR-SP, a sub-strain of SHR, had a markedly higher BP level without a significant increase

in BPV, when compared with SHR. These provide a good example to delineate that BPV is not necessarily dependent on BP level. The facts were also demonstrated in other previous studies. Under physiological conditions, rabbits are known for their unstable BP, and when compared with rats, rabbits exhibit a higher BPV and a lower BP level^[15]. In pathological states of baroreflex interruption, BPV is increased markedly with no change in the average BP level after sinoaortic denervation or nucleus tractus solitarii lesions^[2,4,5,16]. Frequent ventricular premature beats in myocardial infarction rats cause high BPV with unchanged BP level^[3]. Finally, in pharmacological studies, BPV is reduced significantly by simultaneous infusion of phenylephrine and adenosine when the BP level maintains unchanged^[17]. All of the above results confirm that BPV may not be associated with BP level.

Two reports have analyzed the BRS data of SHR and SHR-SP within the same study. In these previous studies, BRS was estimated either in an anesthetized state using intravenous infusion of phenylephrine for 30 min^[12] or in a conscious state using cross-spectral analysis^[9]. In the present study, BRS was determined in conscious, freely moving rats using a bolus intravenous injection of phenylephrine. These three studies provide similar evidence showing that the impairment of baroreflex function, expressed as decreased BRS, is not significantly different between SHR and SHR-SP.

In summary, the current study demonstrated and compared the hemodynamic phenotypes of BP, BPV and BRS in SHR and SHR-SP. For the first time, we have provided evidence that in addition to BRS, BPV is not changed in parallel with BP changes in SHR-SP and SHR. Together with the short life span of SHR-SP, these findings indicate that SHR is more appropriate than SHR-SP for crossbreeding in future linkage studies on BPV and BRS. The data are meaningful in attaching the physiological variables of BPV and BRS to the genome, especially as the rat has become researchers' favorite laboratory animal due to the recent availability of its genome sequence^[6,18,19].

Abstract

Aim: To investigate the effects of bone morphogenetic protein-7 (BMP7)-expressing recombinant adeno-associated virus (AAV) vector on the differentiation of C2C12 cells. **Methods:** AAV-BMP7 was packaged by infecting the stable cell clone BHK-21 (integrated with recombinant AAV vector plasmid pSNAV-BMP7) with recombinant herpes simplex virus type 1, which expresses AAV-2 Rep and Cap and possesses AAV packaging functions. Following infection with AAV-BMP7 at multiplicities of infection of 1×10^5 vector genomes per cell and subsequent culture, C2C12 cells were assessed qualitatively for BMP7 production, alkaline phosphatase activity, osteocalcin production and Cbfa1 and MyoD expression. **Results:** C2C12 cells transduced with AAV-BMP7 could produce BMP7 protein until d 28. Alkaline phosphatase in the cultured C2C12 cell lysate was elevated. Secreted osteocalcin in the culture medium was detectable at d 12 and Cbfa1 mRNA expression level was upregulated, coinciding with downregulation of MyoD in a temporal manner. **Conclusion:** The present *in vitro* study demonstrated that AAV-BMP7 could infect and efficiently convert C2C12 cells from myoblasts into osteoblast lineage cells.

Introduction

Currently, the repair of massive segmental bone defects and non-healing fractures remains a challenging problem in orthopedic surgery. Bone morphogenetic proteins (BMP) are known to possess strong osteoinductive properties and BMP gene therapy plays an important role in modulating bone regeneration^[1]. However, more efficient and safe delivery vectors must be obtained before clinical trials can be carried out successfully. Previous work with recombinant adeno-associated virus (AAV) vector for gene therapy has shown some outstanding advantages and has made it an attractive candidate for clinical trials in recent years^[2]. However, there have only been a small number of experiments using AAV vectors carrying BMP to induce bone healing^[3–5]. Previous studies have indicated that the C2C12 myoblast cell line may be a useful model to investigate osteoblast differentiation during bone formation in muscular tissues^[6–8]. Although it has been reported that continuous exposure of

C2C12 cells to BMP7 protein could inhibit myotube formation and induce osteoblastic differentiation^[6], it is not known whether transfer of the *BMP7* gene into C2C12 cells using a BMP7-harboring AAV could also produce consistent results. This committed osteoblastic differentiation would be important for AAV-BMP7 *in vivo* gene therapy for bone healing. In addition, because recombinant AAV does not cause disease in humans and does not contain coding sequences necessary to trigger inflammatory or immune responses^[2–4], we speculate that the AAV-BMP7 vectors could be injected into the fracture sites or segmental bone defects to induce bone formation by direct local gene therapy. To investigate the feasibility of *BMP7* gene transfer into C2C12 cells using the AAV vector, we constructed an AAV vector carrying the *BMP7* gene, designated AAV-BMP7. C2C12 cells were infected with AAV-BMP7 and their committed differentiation was examined *in vitro*. This study provides fundamental understanding and a platform for future applications of AAV-BMP7 local gene therapy.

Materials and methods

Cells HEK293, BHK-21 and C2C12 cells (all from ATCC, Manassas, VA, USA) were cultured in Dulbecco's modified Eagle's medium (DMEM) (Gibco BRL, Grand Island, NY, USA) containing 10% fetal bovine serum (FBS) (Hyclone, Logan, UT, USA) and penicillin/streptomycin at 37 °C in humidified 5% CO₂ atmosphere.

Plasmids The recombinant AAV2 packaging plasmid pSNAV^[9] was constructed by deleting all viral open reading frames and introducing the sequences for human cytomegalovirus promoter/enhancer, a multiple-cloning site, a neomycin-resistant gene, a simian virus 40 promoter and a polyadenylation signal, retaining the 2 inverted terminal repeats (ITR), which contain the palindromic sequences necessary in cis for replication of the intact viral genome. The AAV plasmid pSNAV-BMP7 (Figure 1) was constructed by inserting full-length human BMP7 (*hBMP7*) cDNA (1.3 kb) into the restriction sites between *KpnI* and *BgIII* of the multiple-cloning site. The *BMP7* cDNA was cloned by reverse transcription-polymerase chain reaction from HEK293 cells using the following set of primers: forward, 5'-GTG GTA CCG ATGCACGTGCGCTCACTG-3'; reverse, 5'-AGA AGATCT CTC GGA GGA GCT AGT GGC AG-3' (introduced *KpnI* and *BgIII* restriction sites are underlined).

Figure 1. Schematic representation of the adeno-associated virus (AAV) vector used in this study. CMV, human cytomegalovirus promoter; ITR, inverted terminal repeat; MCS, multiple cloning site; PolA, polyadenylation signal.

Adeno-associated virus vector packaging, purification and titration BHK-21 cells were transfected with the purified pSNAV-BMP7 plasmid according to a standard calcium phosphate precipitation method. The cells were then cultured in selection media containing 500 µg/mL G418 (Gibco/BRL). G418-resistant BHK-21 cell clones were isolated and the integrity of *hBMP7* gene was determined by polymerase chain reaction (PCR) using the above PCR primers. To package the virus, stably transfected BHK-21 cells were subsequently infected with recombinant herpes simplex virus type 1 (rHSV-1)^[10], which can express the AAV-2 Rep and Cap genes of wild-type AAV and possesses packaging functions for recombinant AAV. For large-scale recombinant AAV production and purification, BHK-21 cells were incubated in 6 roller bottles (Ø 110 mm×480 mm; Wheaton, Millville, NJ, USA) at 37 °C at 1 roll/min. Confluent cells in a volume of 10 mL medium were infected with helper virus rHSV-1 at mul-

tiplicities of infection (MOI) of 0.1 for 2 h. The collected cells were processed by chloroform treatment, PEG8000/NaCl precipitation and chloroform extraction for purification^[11]. The titer was determined using quantitative DNA dot blots^[12] and the purity was examined by sodium dodecyl sulphate-polyacrylamide gel electrophoresis^[11]. Titers averaged approximately 2×10¹² vector genomes (v.g.) per mL and purity was >97%. Recombinant AAV-enhanced green fluorescence protein (EGFP) was also constructed using the same procedure.

Adeno-associated virus vector transduction C2C12 cells were placed in monolayer culture in 6-well plates at a density of 2×10⁵ cells per well in DMEM containing 10% FBS. Subconfluent cells were incubated with either AAV-BMP7 or AAV-EGFP at an MOI of 1×10⁵ v.g. per cell, or as a control, left alone in a total volume of 500 µL serum-free medium for 1 h at 37 °C. The medium was then aspirated and 1 mL growth medium (DMEM supplemented with 5% FBS, 50 mmol/L sodium butyrate) was added. An MOI of 1×10⁵ was chosen as a result of pilot studies demonstrating that an MOI of 1×10⁵ produced the highest level of EGFP transgene expression. Morphological changes were monitored with a phase contrast microscope. All experiments were carried out in triplicate.

Determination of bone morphogenetic protein-7 production To quantify BMP7 levels, culture medium of C2C12 cells was collected for enzyme-linked immunosorbent assay (ELISA) every 2 d up to 28 d after transduction. ELISA was carried out according to the manufacturer's recommendations (ADL, San Antonio, TX, USA). Briefly, standards and culture media were incubated at room temperature with sample buffer in 96-well plates for 90 min and then with biotin-labeled anti-human BMP7 detection antibody for 60 min. Finally, a streptavidin-horseradish peroxidase conjugate was added at room temperature for 30 min. Bound BMP7 was detected by adding tetramethylbenzidine substrate solution for 15 min and the plates were read at 450 nm.

Gene expression of *Cbfa1* and *MyoD* A total of 2 µg cellular RNA from C2C12 cells was reverse transcribed using Mouse Moloney murine leukemia virus reverse transcriptase and oligo(dT) 15 primer (both from Promega, Madison, Wisconsin, USA). PCR were carried out for 25 cycles (94 °C for 1 min, 55 °C for 1 min, 72 °C for 1 min) for *MyoD* and glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*), and 30 cycles for *Cbfa1* (annealing temperature 62 °C). Primers were: *MyoD* (expected product size 275 bp): upstream, 5'-TCCAAGTCTCTGATGGCA-3'; downstream, 5'-GTTCCC-TGTTCTGTGTCGCT-3'; *Cbfa1* (expected product size 330 bp)^[13]: upstream, 5'-CTTCATTCGCCTCACAAAC-3'; downstream, 5'-CACGTCGCTCATCTTGCCGG-3'. *GAPDH*

was used as an internal control (expected product size 413 bp): upstream, 5'-GGAAAGCTGTGGCGTGATGG-3'; downstream, 5'-GTAGGCCATGAGGTCCACCA-3'. The PCR products were subjected to electrophoresis on 1.5% agarose gels, scanned, and semiquantitated using Image-Quant software (Kodak ID V3.53; Kodak, Tokyo, Japan).

Alkaline phosphatase activity assay and osteocalcin production C2C12 cells were rinsed twice with phosphate-buffered saline, then collected into 50 mmol/L Tris-HCl, 0.1% Triton X-100, pH 7.5, and sonicated for 10 s at 4 °C. The samples were centrifuged for 5 min at 13400×g. Alkaline phosphatase (ALP) activity was measured using an ALP assay kit (Zhongsheng Biochemical, Beijing China) at 37 °C. The enzyme activity was normalized against the protein concentration and expressed as U·g⁻¹·L⁻¹[14]. Protein concentration was measured using the bicinchoninic acid protein assay kit (Pierce Biotechnology, Rockford, IL, USA) using bovine serum albumin as a standard. The amount of osteocalcin secreted into the culture medium was determined by radioimmunoassay using a mouse osteocalcin assay kit following the manufacturer's recommendations (Biomedical Technologies, Stoughton, MA, USA).

Statistical analysis Data (mean±SD) were analyzed using two-tailed Student's *t*-test with a level of significance of 0.05.

Results

Bone morphogenetic protein-7 expression in C2C12 cells The *in vitro* release kinetics of BMP7 from AAV-BMP7-infected C2C12 cells was evaluated over the course of 28 d using ELISA. No detectable BMP7 was produced by the uninfected and AAV-EGFP-treated C2C12 cells. However, cells transduced with AAV-BMP7 produced low levels of BMP7 by 48 h (12±8 ng/10⁶ cells per 48 h), followed by an increase in production with a mean of 165±10 ng/10⁶ cells per 48 h from d 6 to d 28 (Figure 2).

Effect of bone morphogenetic protein-7 on C2C12 cell morphology After cultured in DMEM with 5% FBS for 6 d, the phenotype of C2C12 cells displayed obvious changes. Elongated and multinucleated thin myotubes formed by cells fusing with each other were observed in uninfected C2C12 cells and cells infected with AAV-EGFP. In contrast, most cells infected with AAV-BMP7 revealed an unfused, mononuclear round-cell morphology, resembling that of osteoblastic cells (Figure 3).

Differentiation of C2C12 cells treated with AAV-BMP7 In order to further investigate the function of BMP7 expression, we examined the gene expression changes for osteoblast-specific genes, and also measured ALP activity

Figure 2. The time course of bone morphogenetic protein-7 (BMP7) production in C2C12 cells in 48 h after infected with adeno-associated virus (AAV)-BMP7 by enzyme-linked immunosorbent assay quantitative analysis. *n*=3. Mean±SD.

Figure 3. Morphological changes in C2C12 cells on d 6. (A) Uninfected C2C12 cells. (B) C2C12 cells transduced with adeno-associated virus (AAV)-enhanced green fluorescence protein (EGFP). (C) C2C12 cells transduced with AAV-bone morphogenetic protein-7 (BMP7). ×100.

and osteocalcin production, in C2C12 cells infected with AAV-BMP7. In AAV-BMP7-treated C2C12 cells the mRNA expression level of *Cbfa1* (an osteoblast specific transcription regulatory factor^[15]) was upregulated after 4 d of treatment, a significant increase was detected at d 6 and its level continued to increase until d 12 (Figure 4). In contrast, the expression level of muscle-specific regulatory factor *MyoD* was reduced dramatically after 8 d of treatment and became undetectable by d 12.

Figure 4. The expression changes of osteoblastic and myoblastic markers in adeno-associated virus (AAV)-bone morphogenetic protein-7 (BMP7)-treated C2C12 cells. The expression of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as an internal control. Results of the (A) electrophoretic and (B) semiquantitative analyses are shown. *n*=3. Mean±SD.

The uninfected and AAV-EGFP-infected C2C12 cells were found to have low levels of ALP activity with no significant change at all time points (Figure 5). A significant upregulation of ALP activity was observed in AAV-BMP7-treated cells, starting from d 2 and peaking at d 8. Osteocalcin production was detected at d 12 as 35±6 ng/mL (Figure 6); no detectable osteocalcin was found in non-treated and AAV-EGFP-treated cells.

Figure 5. Time course of alkaline phosphatase (ALP) activity in the lysates of C2C12 cells. *n*=3. Mean±SD. ^b*P*<0.05 vs the uninfected and adeno-associated virus (AAV)-enhanced green fluorescence protein (EGFP)-treated groups.

Figure 6. Comparison of osteocalcin production in C2C12 cells treated with adeno-associated virus (AAV)-enhanced green fluorescence protein (EGFP) or AAV-bone morphogenetic protein-7 (BMP7) at d 12. *n*=3. Mean±SD. ^b*P*<0.05 vs the uninfected and AAV-EGFP-treated groups.

Discussion

Our *in vitro* experiments demonstrated that C2C12 cells infected with AAV-BMP7 were able to generate BMP7 protein and showed a concomitant shift from myoblastic to osteoblastic differentiation. In addition, the highly efficient recombinant adeno-associated viral vector packaging system, rHSV-1/AAV hybrid helper viral system^[10], provided us with high-titer purified AAV-BMP7 for further experiments. Our subsequent AAV-BMP7 transduction analysis suggested that recombinant AAV vector could mediate efficient transduction in C2C12 cells. At the same time, the amount of secreted BMP7 protein could reach the level of protein needed for cellular responses. The elevated ALP activity and osteocalcin production, together with osteoblast-like morphology, confirmed that the AAV-BMP7-infected C2C12 cells displayed differentiation to an osteoblastic phenotype.

Previous studies have shown that BMP7 at 200 ng/mL can completely inhibit myogenic differentiation of C2C12 cells

and successfully induce expression of both important early and late osteoblastic differentiation markers (ALP and osteocalcin, respectively)^[6]. Although BMP7 protein could satisfactorily induce C2C12 cell differentiation into osteoblastic cells *in vitro*, it requires supra-physiological amounts of BMP7 to overcome rapid clearance due to its short life span, in order to accelerate fracture healing, bridge segmental bone defects and generate spine fusion in animal models^[16]. Hence, protein therapies are hampered by high manufacturing costs, unpredictable side effects and the lack of an ideal matrix to deliver protein in a continuous manner over times^[16]. Local BMP7 gene therapy provides an alternative method for the delivery of BMP7 protein to stimulate bone regeneration^[17–20]. Recent studies have demonstrated that recombinant AAV vector is an ideal vector to deliver therapeutic factors. Recombinant AAV vector is non-pathogenic and elicits no inflammatory response. It is also an advantage that recombinant AAV vector often leads to efficient long-term expression of secreted proteins *in vivo* and *in vitro*^[21]. However, whether AAV-BMP7 could induce bone formation *in vitro* and *in vivo* remains unclear. In this study, a recombinant AAV-BMP7 vector was constructed successfully. The sustained secretion of BMP7 protein was detected in culture medium up to d 28 by C2C12 cells infected with AAV-BMP7. Mouse myoblast C2C12 cells displayed an osteoblastic phenotype. It has been reported that C2C12 cells are pluripotent mesenchymal precursor cells, capable of differentiating into myoblasts, adipocytes and osteoblasts under appropriate stimulation conditions^[22,23]. Further studies demonstrated that BMP7 protein was a potent inducer of osteoblastic differentiation of C2C12 cells by upregulating *Runx2/Cbfa1* gene transcription^[24]. The core binding factor *Runx2/Cbfa1* is a specific transcriptional activator and a molecular switch of osteoblast differentiation^[25]. Thus, C2C12 cells infected with AAV-BMP7 could be finally restricted to give rise to one terminally differentiated cell type expressing the markers of osteoblasts (eg ALP and osteocalcin). This osteogenic committed differentiation mediated by genetic modification is safe as it gives the desired cell type and avoids the possibility of giving rise to unlimited cell growth or unwanted cell types. The committed differentiation could also be controlled by using tissue-specific promoters or the “tet switch system”.

In this study, we found an interesting feature of the AAV vector, namely delayed transgene expression. The production of BMP7 protein reached a peak as late as 6 d after infection, compared with adenovirus-mediated gene delivery in C2C12 cells in which the desired BMP2 protein could be produced as early as 24 h after infection^[7]. This difference

may be due to the fact that AAV is a single-stranded DNA virus; there is, therefore, a rate-limiting step of second-strand DNA synthesis in the nucleus of infected cells^[21]. However, the delayed BMP7 protein expression using the AAV vector did not affect the osteogenic biological function of BMP7 in our study. Some *in vivo* examinations have also demonstrated the same delayed transgene expression^[26,27]. From a clinical standpoint, it seems that the short period of delayed osteoinductive protein production does not hamper the treatment of relative longer-term and non-emergency cases of fracture healing or spinal fusion. Furthermore, delayed transgene expression might protect secreted therapeutic proteins from immunologic attack induced by destruction of the vascular barrier at the time of virus injection^[28].

We first report that AAV-based BMP7 gene transfer could represent a new and feasible way to induce a committed osteoblast differentiation in an *in vitro* culture system using C2C12 cells. This approach would be preferred in a great range of applications for some orthopedic disorders in which it is necessary to increase the formation of bone. Unlike the adenoviral-based vectors that are limited by their non-specific immune response^[1], the AAV-BMP7 vectors could be injected directly into the segmental bone defect that does not heal spontaneously to promote bone formation by recruiting locally responsive cells to differentiate into osteoblasts. In addition, the AAV-BMP7 vectors could be added to autologous bone grafts to serve as an osteoinductive agent to augment bone regeneration at the fusion site and decrease the need for extensive harvesting of autograft from the iliac crest. Furthermore, direct injection of these vectors into the spine could generate spine fusion in a less invasive way. For some systemic and metabolic bone diseases such as osteoporosis, the efficient long-term secretion of BMP7 proteins mediated by AAV is another outstanding advantage. The advantages of direct gene therapy strategy also include relatively simple technique requirements, minimized invasion and the potential for lower costs.

Although the detailed mechanisms of C2C12 cells differentiating into osteoblasts remains unclear, our current study suggests that AAV-BMP7 may be a valuable viral vector in the treatment of orthopedic disorders. Further *in vivo* studies are under consideration.

Acknowledgements

The authors thank AGTC Gene Technology Company (Beijing, China) for their technical assistance in packaging the AAV vector. We also thank Dr Jason WONG from Cambridge University (Cambridge, UK) for his help in the prepa-

ration of this manuscript.

Abstract

Aim: To investigate the mitochondria-initiated apoptosis pathway involved in Carbon tetrachloride (CCl₄) hepatotoxicity *in vitro*. **Methods:** Several cytotoxicity endpoints, including WST-8 metabolism, lactate dehydrogenase leakage and morphological changes, were examined. The 5,5'-dithio-bis(2-nitrobenzoic acid) reaction was used to measure reduced glutathione level, and the malondialdehyde level was determined using the thiobarbituric acid assay. The release of cytochrome c and Bcl-X_L was detected by Western blot. Caspase-3 activity was measured using the fluorogenic substrate Ac-DEVD-AMC. DNA fragmentation was used to evaluate cell apoptosis. **Results:** A time- and dose-dependent decrease in cellular glutathione content was observed, along with a concomitant increase in malondialdehyde levels following the application of CCl₄. Caspase 3 activity was stimulated at all doses of CCl₄, with the most significant activation at 3 mmol/L. Cytochrome c was released obviously after CCl₄ treatment. A time-dependent decrease in Bcl-X_L expression was observed. DNA fragmentation results revealed apoptosis and necrosis following CCl₄ treatment. **Conclusion:** Oxidative damage is one of the essential mechanisms of CCl₄ hepatotoxicity, which triggers apoptosis via the mitochondria-initiated pathway.

Introduction

Apoptosis is a genetically encoded form of cell suicide central to the development and homeostasis of multicellular organisms^[1–3]. Once researchers assumed that the activation of endonucleases and specific proteases (such as caspases) reflect the key mechanism of apoptosis^[4,5]. However, a number of studies disclose that mitochondria play a key role in apoptosis^[1,4,6]. The mitochondrial pathway is partly dependent on the release of cytochrome c. After release from mitochondria to the cytosol, cytochrome c binds to apoptosis-activating factor-1 (Apaf-1), ATP (or dATP), and possibly a cytosolic protein (Apaf-3), and activates caspase 9, which in turn stimulates caspase 3 activity. Caspase 3 cleaves and activates DNA fragmentation factor (DFF), resulting in DNA degradation^[2,4,7].

Bcl-2 proteins act on mitochondria to regulate apoptosis. The Bcl-2 family consists of both cell death promoters and

preventers, including the anti-apoptotic proteins Bcl-2, Bcl-X_L, Mcl-1, A1/Bfl-1 and Bcl-W, and the pro-apoptotic members Bax, Bcl-X_s, Bak, Bad, Bik, Bim, Bid, Hrk and Bok^[8]. Bcl-2 and Bcl-X_L prevent cytochrome c from entering the cytosol, either by blocking release or binding to the cytochrome in a direct or indirect fashion, and consequently inhibiting activation of the downstream caspase cascade^[4].

Reactive oxygen species (ROS), which induce the onset of the mitochondrial permeability transition (MPT), play an important role in mitochondrial apoptosis. Activation of MPT is a major controlling mechanism in some apoptotic systems, and also contributes to the release of cytochrome c and other apoptogenic proteins^[4,9]. However, the mechanisms of ROS generation and its relationship with the well-documented caspase activation remain to be elucidated. In the present investigation, the levels of reduced glutathione (GSH) and malondialdehyde (MDA) are measured as reliable markers of oxidative stress.

Carbon tetrachloride (CCl₄) is a typical poison that induces severe oxidative stress followed by activation of caspase 3 in rat liver^[10]. Moreover, GSH depletion and MDA induction by CCl₄ are evident in rat primary hepatocytes and HepG2, a human hepatoma cell line^[11]. However, it is currently unclear whether both oxidative stress and apoptosis occur in rat primary hepatocytes induced by CCl₄.

Mitochondrial damage by CCl₄ is involved in the apoptotic process *in vivo*, during which caspase 3 is activated^[10]. A histological study suggests that apoptosis is additionally induced by CCl₄ in liver^[12]. However, the pathway by which CCl₄ mediates apoptosis in rat primary hepatocytes is currently unknown.

In the present report, CCl₄ mediation of the expression and activation of different proteins involved in apoptotic cell death is investigated. Moreover, the relationship between peroxidative damage and apoptosis induced by CCl₄ in rat primary hepatocytes is explored.

Materials and methods

Materials and culture of hepatocytes CCl₄ and Me₂SO were purchased from Shanghai Chemical Reagent Company (Shanghai, China). CCl₄ was dissolved in 10% Me₂SO HBS solution (in mmol/L: HEPES 33, NaCl 160.8 mmol/L, KCl 3.15 mmol/L, Na₂HPO₄·12H₂O 0.7 mmol/L) and diluted to final concentration of 0.1 mmol/L, 0.3 mmol/L, 1 mmol/L, 3 mmol/L, and 9 mmol/L, respectively.

Hepatocytes were isolated from Sprague-Dawley male rats (180 g–220 g) by 2-step collagenase perfusion, as described previously^[13–15], with some modifications. Collagenase IV was purchased from Sigma Chemical Company (St Louis, USA). Hepatocytes were seeded on collagen-coated plastic dishes at a density of 3×10⁵ viable cells/mL, and cultured in Ham's F-12/Dulbecco's modified Eagle's medium (DMEM) (Invitrogen, Carlsbad, CA, USA) (1:1) medium supplemented with 15% fetal bovine serum (PAA Laboratories, Linz, Austria), 0.1 g/L penicillin (Shanghai Fourth Pharmaceuticals, Shanghai, China), 0.07 g/L streptomycin (Shanghai Fourth Pharmaceuticals, Shanghai, China) and 0.2% bovine serum albumin (Roche, NJ, USA). After 3 h, the medium was altered. Cells were incubated in medium containing different concentrations of CCl₄ solution.

Cell viability and lactate dehydrogenase leakage assay Rat primary hepatocytes were treated with CCl₄ for 20 h, and the general viability of cultured cells was assayed at 450 nm with the Cell Counting Kit-8 (Dojindo Laboratories, Tokyo, Japan).

Hepatocytes were seeded on collagen-coated 96-well

microtiter plates at a density of 3×10⁴ cells/well. After treatment with increasing concentrations of CCl₄ for 20 h, lactate dehydrogenase (LDH) released into the culture supernatants was measured in a 3-min coupled enzymatic assay that results in the conversion of a tetrazolium salt (NBT) into a formazan product^[16]. The amount of color formed is proportional to the number of lysed cells. Visible wavelength absorbance data at 490 nm were collected using a standard 96-well plate reader (SOFTmax[®] PRO, Molecular Devices, Sunnyvale, CA, USA).

General morphology of cultured cells Hepatocytes were cultured with CCl₄ for 20 h, and cell morphology was examined using inverted microscopy.

Intracellular glutathione content assay Hepatocytes were treated separately with CCl₄ for 4 h, 8 h, 12 h, 16 h, or 24 h. Cells in monolayers were gently washed 3 times with phosphate-buffered saline (PBS) (pH 7.4), scraped in ice-cold PBS, and sonicated intermittently 3 times. Cell homogenates were added to solution containing 10% trichloroacetic acid and 20 mmol/L EDTA-Na₂. The mixture was centrifuged for 5 min at 3000×g. The suspension was mixed with buffer (0.4 mmol/L Tris-HCl, 20 mmol/L EDTA-Na₂) and 5,5'-dithio-bis(2-nitrobenzoic acid) (DTNB), and measured at a wavelength of 412 nm within 5 min. Reduced pure GSH was used to obtain a standard curve.

Lipid peroxidation assay for malondialdehyde Malondialdehyde levels were measured spectrophotometrically using a thiobarbituric acid (TBA) fluorescence assay. Cell homogenates were mixed with solution (20 mmol/L TBA/glacial acetic acid, 1:1), and heated for 60 min at 100 °C in a water bath. After cooling down, the mixture was extracted in methanol and centrifuged for 10 min at 5000×g. The suspension was measured in a fluorimeter with excitation at 515 nm and emission at 550 nm.

Western blot analysis Hepatocytes were scraped in ice-cold PBS obtained by centrifugation at 300×g for 5 min. Cells were gently lysed for 30 s in 75 μL ice-cold buffer containing 250 mmol/L sucrose, 1 mmol/L edetic acid, 0.05% digitonin, 25 mmol/L Tris, pH 6.8, 1 mmol/L dithiothreitol, and protease inhibitor (10⁻³ g/L leupeptin and aprotinin, and 0.1 mmol/L phenylmethylsulfonyl fluoride). Lysates were then homogenized through a 26-gauge needle for 30 passages and centrifuged twice at 800×g for 20 min at 4 °C. The pooled supernatant was centrifuged at 10 000×g for 10 min at 4 °C to collect the mitochondria fractions. This supernatant was then transferred to fresh tubes and centrifuged at 16 000×g for 20 min at 4 °C to remove any residual mitochondria. The supernatant was stored as the cytosolic fraction of hepatocytes. Cytosolic and mitochondria fractions were

subjected to 15% sodium dodecyl sulphate-polyacrylamide gel electrophoresis. The gel was transferred to a PVDF membrane. Monoclonal rat anti-cytochrome c antibody was purchased from Neomarkers (Lab Vision & NEOMARKERS, UK) and polyclonal rat anti-bcl-X_L antibody was from Cell Signaling Technology (Beverly, MA, USA). Following incubation with horseradish peroxidase-conjugated secondary antibody (Rockland, Gilbertsville, PA, USA), the blot was developed using the enhancing chemiluminescence detection system.

Caspase 3 activity assay Following incubation of hepatocytes in the absence of CCl₄ for the indicated times, caspase 3 activation was measured with the Caspase 3 assay kit (BD Biosciences Pharmingen, San Diego, CA, USA). In brief, culture cells were washed with ice-cold PBS (pH 7.4), and lysed in buffer provided by the kit for 30 min on ice. Reaction mixtures containing Ac-DEVD-AMC and cell lysates in buffer were incubated for 1 h at 37 °C. AMC liberated from Ac-DEVD-AMC was measured in a fluorimeter with excitation at 380 nm and emission at 460 nm.

DNA gel electrophoresis assay Cultured cells were washed 3 times with ice-cold PBS, scraped in the same PBS, and collected by centrifugation for 5 min at 600×g. Cells were resuspended in 10 mmol/L EDTA and 50 mmol/L Tris-HCl (pH 8.0) containing 0.5% sodium lauryl sarcosinate and 0.5 g/L proteinase K, and incubated for 60 min at 50 °C. Next, 10 mmol/L EDTA containing 0.25% bromophenol blue and 40% sucrose was mixed with each DNA extract. Individual extracts were loaded into the wells of a 2% agarose gel containing 3×10⁻³ g/L ethidium bromide. Electrophoresis was carried out in 40 mmol/L Tris-HCl containing 40 mmol/L acetic acid and 1 mmol/L EDTA.

Statistical analysis Data were entered into a database and analyzed using SPSS software. Group mean values and standard deviations were calculated. After homogenetic analysis, homogeneous data were analyzed with one-way analysis of variance and a *post hoc* test of least significant difference. Heterogeneous data were analyzed using the *t*-test. *P*<0.05 was considered statistically significant.

Results

Cytotoxicity induction by CCl₄ in rat primary hepatocytes Cells were exposed to 0.1–9 mmol/L CCl₄ for 20 h, and viability was measured. Cell viability decreased in a dose-dependent manner (Table 1).

Intracellular LDH release as a result of plasma membrane breakdown and alteration of permeability was evaluated. A dose-dependent increase in LDH release in rat primary hepa-

tocytes was observed in the presence of CCl₄ (Table 2).

Hepatocyte morphology Cultured cell morphology examination revealed that 9 mmol/L CCl₄ significantly inhibited the confluence of cultured hepatocytes (Figure 1).

Glutathione depletion CCl₄ induced a dose- and time-dependent depletion of GSH in rat primary hepatocytes. The GSH level was significantly reduced after cell incubation with 1 mmol/L CCl₄ for 8 h, 12 h, 16 h, and 24 h, but not at 4 h. The exhaustion of GSH was observed initially with 3 mmol/L CCl₄ after a 16-h incubation (Figure 2).

Malondialdehyde formation We observed dose- and time-dependent induction of MDA formation in the presence of CCl₄ in rat primary hepatocytes. CCl₄ induced significant amounts of MDA at concentrations of 3 mmol/L and 9 mmol/L after a 12-h incubation and at 0.3–9 mmol/L after 20 h. There was no evident MDA induction after 4 h of CCl₄ treatment at all the doses tested (Table 3).

Cytochrome c release Cytochrome c was detected in the cytosolic fractions of hepatocytes. Hepatocytes were treated with 0.3, 1, 3 and 9 mmol/L CCl₄ up to 16 h. CCl₄ induced time-dependent cytochrome c release in rat primary hepatocytes. Evident dose-dependent release of cytochrome c was observed at 4 h and 8 h (Figure 3A). In contrast, a dose- and time-dependent decrease in mitochondria cyto-

Bcl-X_L analysis Bcl-X_L protein levels were analyzed in cultured hepatocytes treated with different concentrations of CCl₄. Hepatocytes were exposed to CCl₄ for 4 h, 8 h and 16 h (Figure 4). No significant dose-dependent change was observed, but a time-dependent decrease in Bcl-X_L expression was observed.

Figure 4. Effect of CCl₄ on Bcl-X_L expression in rat primary hepatocytes treated with 0.3 mmol/L, 1 mmol/L, 3 mmol/L, and 9 mmol/L CCl₄ for up to 16 h.

DNA fragmentation To confirm whether CCl₄ induces DNA fragmentation in rat primary hepatocytes, DNA was extracted from treated cells. No ladder was observed in control cells at 0 h, 8 h, or 20 h of CCl₄ treatment. Apoptosis was initially observed in the presence of 9 mmol/L CCl₄ after 8 h treatment, followed by 3 mmol/L and 1 mmol/L CCl₄ after 20 h treatment (Figure 5).

Figure 5. DNA fragmentation in rat primary hepatocytes treated with CCl₄ 1 mmol/L, 3 mmol/L and 9 mmol/L CCl₄ for 8 h and 20 h.

Discussion

Carbon tetrachloride is a typical hepatotoxin used in liver injury research. Early studies showed that the damage induced by CCl₄ in liver is partly involved in the apoptosis pathway *in vivo*. At least 2 different apoptosis pathways – the mitochondrial pathway and the death-receptor pathway – lead to caspase activation^[17]. Although past reports have disclosed caspase 3 activation and other histopathological changes in CCl₄-induced apoptotic hepatocytes^[10,12], little is known about the precise molecular mechanisms of apoptosis induction. In this study, we investigated the molecular mechanism of CCl₄-induced apoptosis in rat primary hepatocytes. Release of cytochrome c first occurred at 4 h and then up to 16 h (Figure 3A). On the other hand, cytochrome c remaining in the mitochondria was found to decrease in a dose- and time-dependent manner (Figure 3B). In addition, it was found that caspase 3 was significantly activated after 8 h at all doses (Table 4). As a result of caspases cascade activation, DNA fragmentation first appeared at 9 mmol/L after 8 h and formed at all concentrations after 20 h (Figure 5). It is well known that cytochrome c released from mitochondria into the cytosol triggers the activation of caspase 9 and caspase 3 in the mitochondrial pathway. In view of this, we propose the involvement of the mitochondrial pathway via cytochrome c release in CCl₄-induced apoptosis.

In the present study, we investigated the level of Bcl-X_L, an anti-apoptotic protein, in CCl₄-induced apoptosis in rat

primary hepatocytes. Bcl-X_L, the only member of the Bcl-2 family present in hepatocytes, is one of the markers used to identify apoptosis in rat primary hepatocytes^[18]. Bcl-X_L exerts an anti-apoptosis function by interacting with cytochrome c, either directly or indirectly via Apaf-1, which binds to both Bcl-X_L and cytochrome c^[2,4,19,20]. Therefore, decreased Bcl-X_L levels and increased cytochrome c release are specific biomarkers for the mitochondrial pathway of apoptosis^[18]. In our experiments, cytochrome c levels increased markedly after a 8-h CCl₄ treatment with a concomitant decrease in Bcl-X_L protein expression. Bcl-X_L may not execute its anti-apoptotic function once large amounts of cytochrome c are released from the mitochondria when the cell is over-exposed to stimuli, for example, lipid peroxidation induced by CCl₄ in this system. These findings strongly suggest the involvement of cytochrome c release from mitochondria accompanied by Bcl-X_L regulation in CCl₄-induced apoptosis in rat primary hepatocytes.

Hepatic injury through CCl₄-induced lipid peroxidation is used extensively in experimental models to elucidate the cellular mechanisms behind oxidative damage^[11,21–23]. In the present study, we confirm time- and dose-dependent depletion in the intracellular GSH content after CCl₄ treatment. MDA, an important lipid peroxidation product, increased in a time- and dose-dependent manner in our system. The data suggest that oxidative damage is one of the essential mechanisms of hepatotoxicity induced by CCl₄ *in vitro*.

The relationship between ROS and apoptosis has been under investigation for a number of years^[4,9]. ROS play important roles in apoptosis initiated in mitochondria^[24,25]. It has been documented that GSH depletion and MDA increase, events observed frequently during oxidative damage, are inducers of mitochondrial permeability transition (MPT)^[11,26]. Triggering of MPT leads to the release of several different factors relevant to apoptosis, such as cytochrome c, Apoptosis-inducing factor (AIF), and endonuclease G^[2,8,9,27]. In this study, we demonstrated GSH depletion, MDA increase and apoptosis initiated from mitochondria of CCl₄-treated rat primary hepatocytes. Our results collectively indicate that CCl₄ induces apoptosis partly via a mitochondria-dependent pathway, dependent on ROS production in rat primary hepatocytes.

To elucidate other possible mechanisms of CCl₄-induced apoptosis, we analyzed the expression of endonuclease G, a caspase-independent apoptotic protein released from mitochondria that translocates to the nucleus during apoptosis^[28,29]. Western blot analysis of endonuclease G revealed no evident release in rat primary hepatocytes treated with CCl₄ (data not shown). The finding implies that endonu-

lease G does not participate in apoptosis induced by CCl₄.

In summary, our results confirm that oxidative damage is one of the essential mechanisms of hepatotoxicity induced by CCl₄. Moreover, mitochondria-initiated apoptosis triggered by ROS plays an important role in this hepatotoxicity in rat primary hepatocytes.

Abstract

Aim: To investigate the expression of feeding-related peptide receptors mRNA in GT1-7 cell line and roles of leptin and orexins in the control of GnRH secretion. **Methods:** Receptors of bombesin₃, cholecystokinin (CCK)-A, CCK-B, glucagon-like peptide (GLP)1, melanin-concentrating hormone (MCH)1, orexin1, orexin2, neuromedin-B, neuropeptide Y (NPY)1 and NPY5, neurotensin (NT)1, NT2, NT3, and leptin receptor long form mRNA in GT1-7 cells were detected by reversed transcriptase-polymerase chain reaction. GT1-7 cells were treated with leptin, orexin A and orexin B at a cohort of concentrations for different lengths of time, and GnRH in medium was determined by radioimmunoassay (RIA). **Results:** Receptors of bombesin₃, CCK-B, GLP1, MCH1, orexin1, neuromedin-B, NPY1, NPY5, NT1, NT3, and leptin receptor long form mRNA were expressed in GT1-7 cells, of which, receptors of GLP1, neuromedin-B, NPY1, and NT3 were highly expressed. No amplified fragments of orexin2, NT2, and CCK-A receptor cDNA were generated with GT1-7 RNA, indicating that the GT1-7 cells did not express mRNA of them. Leptin induced a significant stimulation of GnRH release, the results being most significant at 0.1 nmol/L for 15 min. In contrast to other studies in hypothalamic explants, neither orexin A nor orexin B affected basal GnRH secretion over a wide range of concentrations ranging from 1 nmol/L to 500 nmol/Lat 15, 30, and 60 min. **Conclusion:** Feeding and reproductive function are closely linked. Many orexigenic and anorexigenic signals may control feeding behavior as well as alter GnRH secretion through their receptors on GnRH neurons.

Introduction

Reproduction including mating, pregnancy, and lactation is an energy-demanding process. In normal circumstances, energy intake and expenditure from food is used for essential life activities such as maintenance of basal body temperature, cellular metabolism, fertility and storage of energy in fat tissue. When the food intake is limited or when an inordinate fraction of the available energy is diverted to other uses such as exercise or fattening, reproductive attempts are sacrificed in favor of more critical life activities^[1,2]. The negative energy balance, as typified by fasting, anorexia nervosa or exercise-induced amenorrhea, is associated with a sup-

pression of reproductive function and ovarian cyclicity. Appropriate regulation of reproduction, energy intake and energy expenditure, and thus maintenance of body weight and fertility, relies on complex hypothalamic neuro-circuitry, which serve as key signals to integrate and/or coordinate the status of energy balance and the neuroendocrine reproductive axis. Many neuropeptides that have been shown to play a role in the regulation of food intake have overlapping functions in the regulation of reproductive function^[3].

Successful reproduction and thus survival of the species in mammals is dependent on the GnRH pacemaker. The network of neurons that controls GnRH secretion is not yet defined, but it is thought to be the final common pathway

through which many factors influence gonadal activity, including metabolic status^[4]. GT1-7 cells, a subclone of the GT1 cell line, were developed by targeting expression of the potent oncogene, SV40 T-antigen, with the regulatory region of GnRH gene, has been shown to faithfully exhibit many of the known characteristics of GnRH neurons. To date, the GT1 cells have proven to be the best characterized cell model available to study biology of the hypothalamic GnRH neurons^[5].

In the last few years, the receptors for several families of neurotransmitters known to modify GnRH secretion have been identified on GT1 cells, and the stimulatory or inhibitory activity of the corresponding ligands on GnRH secretion has been documented^[6-8]. Here we used the GT1-7 cells to investigate the expression of some feeding-related peptide receptors mRNA and the effects of leptin and orexins on GnRH secretion.

Materials and methods

Cell culture and reagents GT1-7 cells kindly provided by Dr KNOBIL (University of Texas-Houston Medical School, Houston, Texas, USA), were maintained in high-glucose Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal calf serum at 37 °C in an atmosphere of 5% CO₂+95% air. GnRH antiserum was the generous gift of Dr KNOBIL. GnRH, chloramine T, sodium pyrosulfite, leptin, bacitracin, orexin A, and orexin B were purchased from Sigma-Aldrich (St Louis, MO, USA). TRIZOL Reagent was purchased from GIBCO-BRL (Gaithersburg, Maryland, USA). SuperScript II reverse transcriptase was obtained from Life

Technologies (Rockville, USA). All oligodeoxynucleotides were synthesized from Biosia Co Ltd (China).

RT-PCR analysis Total RNA was isolated from GT1-7 cells and rats hypothalamus by the TRIZOL extraction method. The first-strand cDNA was synthesized from 1–10 µg deoxyribonuclease treated RNA using SuperScript II reverse transcriptase. The RT reaction was primed with oligo. The specificity of each amplification reaction was monitored by control reactions with RT omission reaction. Because all these receptors have previously been reported in the hypothalamus, we used the rat hypothalamic tissue as a positive control. Polymerase chain reaction (PCR) amplifications were performed with 1.25 U *Taq* polymerase from Sangon in a 50-µL reaction for 35 cycles (1 min at 94 °C, 45 s at 55–60 °C, 1 min at 72 °C). The primers selected were shown in Table 1. PCR products were electrophoresed in 1.5% agarose and visualized by ethidium bromide staining.

Static incubation For GnRH secretion studies, GT1-7 cells were plated in 24-well multiwell plates at a density of 2×10⁵ cells/well and grown in culture for 3–4 d, the medium was replaced by DMEM with 0.2% BSA 16 h before the experiments. Confluent cells were washed three times with Locke's mediums (NaCl 154 mmol/L, KCl 5.6 mmol/L, CaCl₂ 2.2 mmol/L, MgCl₂ 1 mmol/L, NaHCO₃ 6 mmol/L, glucose 10 mmol/L, HEPES 2 mmol/L) containing 0.2% bovine serum albumine (BSA), 20 µmol/L bacitracin and then were treated with or without leptin, orexin A and B at a cohort of concentrations for 15, 30, and 60 min in Locke's medium. At the end of incubation period, media were stored at -80 °C until radioimmunoassay (RIA) for GnRH.

dium (1 mL/well) was measured by RIA in duplicate. GnRH was iodinated by chloramine T technique as described^[9]. Purification was achieved on a sephadex G25 column, using 0.1 mol/L acetic acid with 0.25% BSA as eluant. Aliquots of medium (150 μ L) were cultured with 50 μ L polyclonal antiserum (1: 24 000) for 24 h at 4 °C. The antigen-antibody complex was precipitated with a goat anti-rabbit g-globulin and ethanol. The limit of detection was 0.5 pg/tube, and the intra-assay coefficient of variation was 6.7%.

Statistical analysis For assessment of statistical significance, data were analyzed using analysis of variance. Comparisons between individual pairs were determined using Student's *t*-test. Statistical significance was defined as *P*<0.05.

Results

RT-PCR analysis of the feeding-related peptide receptors transcript in GT1-7 cells Feeding-related peptide is known to have a profound effect on the regulation of reproductive function through the GnRH neuron, however, it is not yet known whether the GnRH neuron itself contains receptors for them. The expression of orexin, neurotensin, neuropeptide Y (NPY), glucagon-like peptide 1 (GLP-1), melanin-concentrating hormone (MCH), cholecystokinin (CCK), leptin, neuromedin B and bombesin receptor mRNA were analyzed. Our results confirmed that bombesin3, CCK-B, GLP1, MCH1, orexin1, neuromedin-B, NPY1, NPY5, NT1, NT3 and leptin long form receptor mRNA were expressed in GT1-7 cells, the amplified fragments were identical in size to those amplified by total RNA derived from the rat hypothalamus, which was used as the positive control. No amplification fragment was obtained from RNA samples when the incubation with RT was omitted, a fact that excludes contamination of the samples with genomic DNA and the pseudo-positive bands, in which, GLP1, neuromedin-B, NPY1, and NT3 receptor were highly expressed in GT1-7 cell line. Additionally,

though the primers designed for orexin2, NT2, CCK-A receptor cDNA amplified the fragments of the expected size with rat hypothalamic RNA (data not shown), no amplified fragment was generated with GT1-7 RNA, indicating that the GT1-7 cells did not express mRNA for them (Figure 1).

Dose-response effect of leptin on GnRH release from GT1-7 cells In experiments conducted under static conditions, GT1-7 cells were treated with leptin for 15, 30, and 60 min, and GnRH peptide levels in the medium were measured by RIA (Figure 2). Exposure of GT1-7 cells to leptin resulted in dose-dependent stimulation of GnRH release at concentrations of 0.1, 1, 10, and 100 nmol/L with rapid effect. The most profound changes of GnRH release were induced at the dose of 0.1 nmol/L after 15 min, with an increased extension of 1.5 fold (*vs* basal release, 2.69 \pm 0.49 pg/tube *vs* 1.87 \pm 0.33 pg/tube). However, as mentioned above, the release of GnRH was routinely measured after 30 and 60 min, extending leptin treatment in GT1-7 cells did not further increase the stimulation of GnRH secretion.

Figure 2. Effect of leptin on the release of GnRH by GT1-7 cells (static incubation). GT1-7 cells were treated with leptin (0.01–100 nmol/L) for 15, 30, or 60 min. GnRH released into the medium was assayed by RIA. *n*=8–10. Mean \pm SEM. ^b*P*<0.05, ^c*P*<0.01 *vs* control (Tukey test).

Figure 1. Expression of the feeding-related peptide receptors mRNA in GT1-7 cells. 1: bombesin3 receptor; 2: CCK-A receptor; 3: CCK-B receptor; 4: GLP1 receptor; 5: MCH1 receptor; 6: orexin1 receptor; 7: orexin2 receptor; 8: neuromedin-B receptor; 9: NPY5 receptor; 10: NPY1 receptor; 11: NT2 receptor; 12: NT3 receptor; 13: NT1 receptor; 14: leptin long form receptor. Note the presence of the receptor of bombesin3, CCK-B, GLP1, MCH1, orexin1, neuromedin-B, NPY 1 and 5, NT1 and 3, leptin long form PCR products of the appropriate size in GT1-7 cells, and no amplified fragments of receptor of orexin 2, NT2, and CCK-A cDNA were generated.

Effect of orexin A and B on release of GnRH from GT1-7 cells Using RT-PCR, we observed readily detectable orexin 1 receptor mRNA in GT1-7 cells. To verify whether orexin receptors play a physiological role in these cells, the effects of orexin A and B on the release of GnRH were subsequently investigated. GnRH secretion has previously been shown to be stimulated by orexin A from hypothalamic explants in male rats and females at proestrus. However, in GT1-7 cells, we were unable to detect a similar stimulated effect, neither orexin A nor orexin B affected basal GnRH secretion over a wide range of concentrations ranging from 1 nmol/L to 500 nmol/L for 15, 30, and 60 min. The positive control (56 mmol/L KCl) significantly increased GnRH release in this study.

Figure 3. Neither orexin A nor orexin B cause a significant change in GnRH release levels in GT1-7 cells. GT1-7 cells were incubated for 15, 30, and 60 min in 1 mL Locke’s medium with increasing concentrations of either orexin A (A) or orexin B (B). None of the values analyzed reached statistical significance ($P>0.05$).

Discussion

In mammals, hypothalamic control of food intake involves counter-regulation of appetite by orexigenic peptides and anorexigenic peptides, which are produced in the central nervous system and periphery. Several major orexigenic signals have been identified including NPY, the orexins, MCH, endorphins, galanin, growth hormone-releasing hormone, γ -aminobutyric acid, and agouti-related protein, similarly, a few major anorexigenic signals of recent interest include

bombesin, glucagon-like peptide-1 (GLP-1), corticotropin-releasing hormone, CCK, cocaine and amphetamine-regulated transcript, serotonin, neurotensin, neuromedin α -melanocyte-stimulating hormone, leptin, ciliary neurotrophic factor, urocortin and dopamine^[2], these essential messenger molecules serve as a communication bridge between neural processes that regulate reproduction and energy homeostasis.

The expression of feeding stimulant receptors mRNA of MCH, NPY, the orexins were detected first. Previous studies have shown that the GnRH-releasing effect of MCH is estrous-cycle stage dependent and it takes place only in proestrous rats^[10]. MCH has been shown to bind and activate two G-protein-coupled receptors, called MCH receptor 1 and MCH receptor 2, expressed in the human brain and other tissues, but several non-human species (ie, rat, mouse, hamster, guinea pig, and rabbit) did not have functional MCH receptor 2 receptors, or encode a nonfunctional MCH receptor 2 pseudogene while retaining MCH receptor 1 expression^[11]. We detected MCH receptor 1 mRNA in the GT1-7 cell line by RT-PCR, suggesting that MCH released from the median eminence might act directly on GnRH nerve terminals through MCH receptor 1. The NPY1 and NPY5 receptor subtypes are believed to play a role in appetite control^[12,13]. There was evidence that NPY stimulated GnRH release from GT1-7 cells through a direct, Y1-like receptor-mediated action on the GnRH neuron itself^[14], further research is needed to verify whether the NPY5 receptor exerts its effects at the hypothalamic level by regulating the release of GnRH.

Orexin A and B were first discovered in rats and found to increase feed intake in these animals when administered directly into the brain. Orexins orchestrate their actions by orexin-1 receptor and orexin-2 receptor. Orexin-2 receptor is a nonselective receptor that binds both orexin A and B, and orexin-R1 is highly selective for orexin A^[15]. It was found that about 75%–85% of GnRH neurons contacted by orexin fibers and approximately 85% of GnRH neurons were colocalized with the orexin receptor 1, which provided the basis for a functional neuroanatomical pathway^[16]. In whole hypothalamic tissue, orexin A stimulated GnRH release harvested from male rats and from females at proestrus, with no effect at estrus or metestrus^[17]. To further investigate the mechanism underlying the orexins stimulating the release of GnRH, we used the GnRH immortalized cell line GT1-7 cells. However, we were unable to detect a similar stimulating effect of orexin A and B. the different effects observed in hypothalamic explants and GT1-7 cells could be explained by differences between GnRH neurons from animal tissue and cultured GnRH neurons.

The receptors of feeding suppressant including CCK,

bombesin, GLP-1, neuromedin, neurotensin and leptin were also observed. CCK is involved in the modulation/control of multiple central functions, these actions are mediated by at least two distinct receptors (CCK-A and CCK-B). The CCK-B receptor antagonist L-365,260, but not the CCK-A receptor antagonist L-364,718 infused into the medial preoptic area of recently mated females blocked pregnancy. These findings implicated CCK acting on CCK-B receptors in the medial preoptic area as a mediator of olfactory influenced on reproductive physiology^[18], and was further supported by our findings that provided the first evidence of the presence of CCK-B receptor but not CCK-A receptor mRNA in total RNA isolated from GT1-7 cells.

The central GLP-1 system has been implicated in the control of feeding behavior. GLP-1 receptor has been identified in the medial and lateral preoptic areas, regions rich in GnRH neurons. The GLP-1 receptor knock-out mouse had delayed puberty^[19]. We showed that GLP-1 receptor was highly expressed in GT1-7 cells, suggesting that GLP-1 may have a permissive role in the regulation of the reproductive axis.

Bombesin, neuromedin, and neurotensin are known to be essential to the regulation of feeding behavior. Neurotensin exerts its effects through at least three receptors that have been cloned and designated NT1 (high affinity), NT2 and NT3^[20]. Dual-label in situ hybridization revealed that NT1 mRNA was expressed in some GnRH neurons in the OVLT/rPOA region, the percentage of dual-labeled neurons varied significantly depending on the stage of the cycle surge^[21]. We demonstrated that NT1 and NT3 but not NT2 receptor sub-types were in fact expressed in GT1-7 cells. Bombesin and its structurally related peptide neuromedin-B belonged to negative regulators of appetite^[22,23], the present study provided the first evidence of the presence of bombesin receptor 3 and neuromedin-B receptor mRNA in GT1-7 cells, strongly supporting the possibility that hypothalamic LHRH neurons in situ might also express these receptors. Studies are continuing to determine whether the receptors encoded by these mRNA mediate the actions of their neuropeptides on GnRH release from GT1-7 cells.

Leptin, a fat-derived anorexigenic hormone, has been described to be an important peripheral signal that indicates body fat stores to the hypothalamus and thus links nutrition and reproductive processes. Leptin treatment corrected infertility, hyperinsulinemia, and hyperglycemia of ob/ob mice, however, diet restriction alone is ineffective in restoring fertility to either female or male ob/ob mice, suggesting that obesity is not the sole cause of infertility and that leptin may be essential for normal reproductive function^[24]. Our

results seem to agree with others studies, reporting that treatment of GT1-7 cells with leptin stimulated the release of GnRH. Moreover, we found a rapid stimulation of leptin after 15 min of incubation, at concentrations of 0.1–100 nmol/L with moderate, but significant increments, which suggested a more direct and immediate modulation of GnRH release.

In summary, our results suggested that feeding-related peptide receptors of bombesin3, CCK-B, GLP1, MCH1, orexin1, neuromedin-B, NPY1, NPY5, NT1, NT3 and leptin long form mRNA were expressed in GT1-7 cells, in which, receptor of GLP1, neuromedin-B, NPY1 and NT3 were highly expressed. Additionally, no amplified fragments of orexin2, NT2 or CCK-A receptor cDNA were generated, indicating that the GT1-7 cells did not express mRNA for them. Leptin showed a rapid stimulating effect on GnRH release after 15 min incubation, and neither orexin A nor orexin B affected basal GnRH secretion from GT1-7 cells. The different effects of orexin A observed in hypothalamic explants and GT1-7 cells could be explained by differences between GnRH neurons from animal tissue and cultured GnRH neurons. These results, in accordance with previous findings, suggest that in addition to any indirect actions, feeding-related peptides may also exert their effects directly on hypothalamic GnRH neurons as a results of expression of their receptors mRNA. Feeding and reproductive function are closely linked.

Abstract

Aim: Increased expression of c-fos, c-jun and type IV collagen (CoIV) in glomerular mesangial cells (GMC) are important characteristics of diabetic nephropathy. Both c-fos and c-jun regulate the gene expression of extracellular matrix components, and CoIV is the main component of the extracellular matrix. It has been reported that puerarin inhibits aggregation of the extracellular matrix in diabetic rats by an as yet unknown mechanism. The aim of this study is to investigate the effect of puerarin on c-fos, c-jun and CoIV expression in GMC cultured in medium containing 5.6 or 27.8 mmol/L glucose. **Methods:** The expressions of c-fos and c-jun were measured at the protein level using flow cytometry. CoIV content was detected using radioimmunoassay. Protein kinase C (PKC) activity was measured using liquid scintillation counting. **Results:** Puerarin (10⁻⁵ mmol/L) significantly ameliorated the high-glucose effect on c-fos, c-jun and CoIV expression. This effect is accompanied by a reduced PKC activity in these cells. **Conclusion:** Our results suggest that reduced PKC activity and expression of c-fos and c-jun in GMC might participate in the mechanisms underlying the therapeutic effect of puerarin on diabetic nephropathy.

Introduction

Glomerular mesangial cells (GMC), the major cell type synthesizing and excreting extracellular matrix (ECM) components and various cellular factors, are one of the major indispensable glomerular cells. GMC proliferation can lead to the excess production and accumulation of ECM, whose progressive accumulation is an important character of diabetic nephropathy in its early stages, which can lead to glomerulosclerosis^[1]. Recent data suggest that progressive ECM accumulation can be detected by increasing levels of *c-fos* and *c-jun* oncogene mRNA in the early stages of diabetic rats. The expression products of *c-fos* and *c-jun* form a steady dimer (activated protein-1, AP-1), which translocates from the cytosol to the cell membrane and binds to specific sequences of certain ECM gene promoters, regulating the transcription and expression of ECM components^[2]. AP-1 activity can be regulated by various protein kinases as well as protein modulation after its synthesis and translocation. Protein kinase C (PKC) is an important molecule in cellular

signaling transcription pathways, where it is located upstream of c-fos and c-jun. Diabetes-induced PKC activation can induce diabetic nephropathy, for example, by modifying cytoskeleton proteins, regulating ECM gene expression and promoting growth factor transcription^[3,4].

Puerarin is one of the major effective extract from the radix of *Puerarin Lobata (wild) ohwi* and *P thomsonii Benth.* Modern pharmacology has demonstrated that puerarin can activate blood and eliminate stasis, improve micro-circulation, inhibit aldose reductase activity and decrease blood glucose. Furthermore, it has been shown to have clinical applications in the treatment of coronary heart disease, angina, myocardial infarction and diabetic nephropathy^[5]. In the diabetic nephropathy rat model where the kidney is unilaterally removed, hypertrophy of the glomerular basement membrane and increased PKC activity of the glomerular membrane have been reported^[3]. Puerarin can inhibit aggregation of the ECM and improve translocation of PKC to the cell membrane. However, it is not known whether high glucose regulates protein expressions of c-fos and c-jun by activating PKC,

nor has the underlying mechanism by which puerarin preventing against diabetic nephropathy been fully demonstrated. In the present study, we investigate changes in protein expressions of c-fos and c-jun, CoIV synthesis and PKC activity of GMC cultured under high glucose conditions. We also investigated puerarin's effect on these changes in order to explain the underlying mechanism by which diabetic nephropathy occurs and develops.

Materials and methods

Chemicals and reagents Puerarin was purchased from Guangdong Yantang Biochemistry (2 mL/100 mg, No. 040310; Guangdong, China). Cell culture medium RPMI-1640 (containing 5.6 mmol/L or 27.8 mmol/L glucose) was purchased from Gibco (USA). Ethidium bromide and bromophenol blue were the products of Sigma (USA). CoIV radioimmunoassay analysis kit was the product of Shanghai Haiyan Medical Bio-tech Institute (No. 20040328; Shanghai, China). Breaking membrane reagent, and c-fos and c-jun rabbit anti-rat monoclonal antibodies and goat anti-rabbit IgG-fluorescein-isothiocyanate (FITC) were purchased from Santa Cruz Inc (USA). PKC protein kinase assay kit was purchased from Gibco (No. 20040220; USA).

Cell culture The rat GMC cell line^[6] purchased from the Nephropathy Laboratory of the Second Military Medical University Changzheng Hospital (Shanghai, China) was plated in 10% RPMI-1640 containing 10% fetal bovine serum (FBS, Gibco), averaged into 2 culture containers (5 mL in each container), and cultured in a humidified atmosphere of 95% air and 5% CO₂ at 37 °C. Before the experiment, cells were pre-incubated with RPMI-1640 culture medium without FBS. After 48 h, GMC were cultured and divided into five groups: (i) RPMI-1640 containing 5.6 mmol/L glucose; (ii) RPMI-1640 containing 27.8 mmol/L glucose; (iii) RPMI-1640 containing 27.8 mmol/L glucose+puerarin (10⁻⁵ mol/L); (iv) RPMI-1640 containing 27.8 mmol/L glucose+puerarin (1×10⁻⁶ mol/L); (v) RPMI-1640 containing 27.8 mmol/L glucose+puerarin (1×10⁻⁷ mol/L). Each group was incubated in 5% CO₂ at 37 °C.

Detection of c-fos and c-jun protein expression in GMC using flow cytometry Glomerular mesangial cells (2×10⁶) were collected after they were cultured for 24 h, 48 h, or 96 h. Breaking membrane reagent 1 (Santa Cruz Inc, USA) was added to cell pellets, which were homogenized, fixed at 25 °C for 15 min, washed with phosphate-buffered saline (PBS) and centrifuged at 300×g for 5 min, and the supernatant was removed. Breaking membrane reagent 2 was then added to the remaining pellet, which was homogenized, dissolved at 25 °C for 5 min and incubated with rabbit anti-rat c-fos or c-

jun protein polyclonal antibodies for 30 min at 25 °C. The first antibody was then washed out using PBS, and cells were incubated at 25 °C for 20 min with goat anti-rabbit IgG-FITC. After the second PBS washes, cells were suspended in 0.5% formaldehyde and detected using a flow cytometer (Becton Dickinson Co, USA). The Cell Quest™ analysis system was used to detect c-fos and c-jun positive cells

Type IV collagen content in the supernatant of GMC

After GMC (1×10⁶) were cultured for 24 h, 48 h or 96 h, the supernatants from the cell cultures were collected to measure CoIV content using a competitive radioimmunoassay. Samples were homogenized with type-IV-collagen labeled by ¹²⁵I, incubated at 4 °C overnight. The secondary antibody was then added to the assay system and incubated at 4 °C for 60 min. The supernatant was removed by centrifugation at 10 000×g for 10 min and the radioactivity in the pellet was counted.

Protein kinase C activity After GMC (2×10⁶) had been treated for 24 h, the homogenate was prepared with 2 mL PBS, and centrifuged at 100 000×g (4 °C) for 1 h. The supernatant containing PKC from the cytosol, was collected and stored separately. PBS containing 0.1% Triton X-100 was added to the pellet. The mixture was bathed in ice, extracted for 30 min, centrifuged at 100 000×g (4 °C) for 30 min, and the remaining particles are PKC. The protein content was measured using a coomassie brilliant blue assay (to quantify PKC activity), and PKC activity was measured using a liquid scintillation counter (LS2000; Beckman Coulter, USA). The units are presented as pmol·min⁻¹·mg⁻¹ protein.

Statistical methods Differences between groups were analyzed by one-way ANOVA with SPSS 10.0 software, and the results were expressed as mean±SD. *P*<0.05 was considered to be statistically significant.

Results

Protein expressions of c-fos and c-jun in different GMC groups

Of the GMC cultured in RPMI-1640 for 24 h, 48 h and 96 h, protein expression of c-fos and c-jun was higher in the 27.8 mmol/L glucose group than in the 5.6 mmol/L glucose group (*P*<0.01). At 24 h and 48 h, protein expression of c-fos and c-jun in cells cultured in RPMI-1640 containing 27.8 mmol/L glucose+puerarin (1×10⁻⁵ mol/L) decreased significantly compared with those cultured in 27.8 mmol/L glucose alone (*P*<0.05). At 96 h, protein expression of c-jun was still increased, but protein expression of c-fos decreased. At 48 h, protein expression of c-fos and c-jun in the 27.8 mmol/L glucose+puerarin (10⁻⁶ mol/L) group decreased markedly compared with cells cultured in RPMI-1640 containing 27.8 mmol/L glucose alone (*P*<0.05). These results suggest that

protein expression of c-fos and c-jun in GMC may be increased at an early stage after treatment with high concentrations of glucose (27.8 mmol/L), but the increase in c-jun expression was sustained for longer than that of c-fos, Puerarin can inhibit GMC protein expression of c-fos and c-jun under high concentrations of glucose (27.8 mmol/L) (Tables 1, 2)

Type IV collagen synthesis in different GMC groups At 24 h, 48 h and 96 h of the investigation, CoIV synthesis in the 27.8 mmol/L glucose group was higher than in the 5.6 mmol/L glucose group ($P<0.05$). CoIV synthesis in the 27.8 mmol/L glucose group was also higher than in the 27.8 mmol/L glucose+puerarin (10^{-5} and 10^{-6} mol/L) groups ($P<0.05$). These results indicate that high glucose concentrations (27.8 mmol/L) can increase CoIV synthesis in GMC, which can be partly inhibited by puerarin (Table 3).

Protein kinase activity in different GMC groups At 24 h and 48 h of the investigation, the PKC activity in the cytosol decreased. However, in the granule (which included membrane and nucleolus) of the high glucose concentration

Glucose (27.8 mmol/L) +puerarin (10^{-6} mol/L)	17.79 \pm 0.91	13.67 \pm 0.85 ^e	17.43 \pm 0.81 ^f	12.99 \pm 0.82 ^f	15.96 \pm 1.21	11.76 \pm 0.81
Glucose (27.8 mmol/L) +puerarin (10^{-7} mol/L)	18.24 \pm 0.69	14.22 \pm 0.69	18.75 \pm 0.94	13.83 \pm 1.09	16.35 \pm 1.36	12.58 \pm 0.48

(containing 27.8 mmol/L glucose)+puerarin (10^{-5} mol/L) group decreased significantly compared with the high glucose concentration group (containing 27.8 mmol/L glucose). These results suggest that PKC can translocate from the cytosol of GMC to the membrane under conditions of high glucose concentrations, resulting in a sustained increase in PKC activity in the membrane. Puerarin can apparently inhibit such membrane translocation (Table 4).

Table 4. Effect of puerarin on protein kinase C (PKC) activity in glomerular mesangial cells. *n*=6. Mean±SD. ^b*P*<0.05, ^c*P*<0.01 vs 5.6 mmol/L glucose. ^e*P*<0.05, ^f*P*<0.01 vs 27.8 mmol/L glucose.

Discussion

Recent studies demonstrate that abnormalities in GMC protein metabolism in various cells play a key role in the occurrence and development of diabetic nephropathy. GMC, the major cell type synthesizing and excreting ECM components and various cell factors, are a key factor in the occurrence and development of many diseases. The present study focused on GMC and discussed the excretion of CoIV, a main component of the ECM, on a cellular level when cells are exposed to high glucose concentrations. The results demonstrated that high glucose concentrations significantly increased CoIV content in GMC, which could be effectively inhibited by puerarin. These results are also supported by previous animal experiments^[7].

We investigated the effect of high glucose on the protein expressions of c-fos and c-jun in mesangial cells. The results suggest that when GMC are treated with a high concentration of glucose (27.8 mmol/L) for 24 h and 48 h, nuclear protein expression levels are higher than following treatment with a low concentration of glucose (5.6 mmol/L). However, when treated with a high concentration of glucose (27.8 mmol/L) for 96 h, c-fos nuclear protein level is approximately the same as that in the low glucose concentration (5.6 mmol/L) group, while c-jun nuclear protein content continues to

increase, which is the same result as in other studies^[8]. This suggests that high concentrations of glucose can induce increases in c-fos and c-jun nuclear protein translocation.

In the condition of diabetes mellitus, hyperglycemia results in a series of metabolic disorders and plays a key role in the degeneration of nephrosis. There are many mechanisms by which high glucose concentrations exert pathological and physiological effects, one of which is the PKC signaling pathway. PKC normally exists in an inactive form in cytosol, and in an active form in the cell membrane and nucleus. An increase in PKC activity therefore suggests that PKC is translocated and activated. Various middle products, not involved in the progression of high blood glucose metabolism, can synthesize diacylglycerol (DAG), the main activator of PKC. Through a series of intracellular signaling pathways, such PKC activation can upregulate gene expression of ECM components, and further promote its protein expression^[3,9,10]. When signals are translocated to the nucleolus, the transcription of certain genes is upregulated immediately. Most of these genes are protooncogenes whose expression products exert effects within the nucleolus. They can also encode certain key regulatory proteins and be distributed in various tissues and cells. The most important protooncogenes are the c-fos and c-jun gene expression products, all of which are phosphorylated proteins of middle molecular weight^[4,11]. In cellular signaling pathways, PKC is an important molecule located upstream of c-fos and c-jun, both of which can participate in regulating gene expression of ECM components, such as CoIV, Fibronectin and laminin. In the promoter regions of the CoIV, FN and LN genes there are similar sites that can combine with c-fos and c-jun heterodimers. We chose GMC to investigate the effect of high glucose on c-fos and c-jun protein expression, and examine PKC activity in the membrane and cytosol of GMC under high glucose concentrations. The results indicate that at the early stage of high glucose treatment, protein expression products of c-fos and c-jun increase at the same time. However the duration of increased c-jun protein expression was longer than that of c-fos, as shown in the study of Shankland and Scholey^[8]. At 24 h and 48 h of investigation, protein expression of c-fos and c-jun in GMC in the high concentration glucose+puerarin group was less than that of the high concentration glucose group, indicating that puerarin may inhibit the increase in c-fos and c-jun protein expression in GMC under the influence of high glucose concentrations. At 48 h, PKC activity in the cytosol of the high concentration glucose group was lower than that of the low concentration glucose group, but in the membrane fraction of the high concentration glucose group, PKC

activity was higher than that of the low concentration glucose group. As PKC activation involves translocation from the cytosol to the membrane, the total PKC activity increase indicated that high glucose concentrations could not only promote PKC activation, but also up-regulate PKC protein expression. Our results demonstrate that after the addition of high concentration glucose+puerarin into GMC culture, puerarin inhibits PKC activity increases in GMC membranes at high glucose concentrations, consistent with diabetic nephropathy rats PKC membrane translocation in animal experiments^[7]. All of these results further suggest that protein expression of c-fos and c-jun is up-regulated in GMC at high glucose concentrations, and CoIV synthesis is increased, both of which could be induced by PKC activation. Puerarin effectively inhibits this upregulation.

In summary, high glucose concentrations could induce PKC membrane translocation in GMC leading to the up-regulation of c-fos and c-jun gene products, an increase in CoIV synthesis and aggravating the occurrence and development of diabetic nephropathy, all of which could be inhibited by puerarin. Undoubtedly, these results will provide a molecular and pharmacological basis for puerarin's development as a new drug against diabetic nephropathy.

Abstract

Aim: To evaluate the protective role of membrane cofactor protein (MCP, CD46) on complement-dependent injury. **Methods:** MCP was separated by ion exchange chromatography on a DEAE sephadex A-50 column from pig erythrocyte ghosts. Its protective effect was tested in models such as cobra venom factor (CVF)-induced platelet metamorphosis and aggregation, human serum-induced injury in isolated working guinea pig heart and reverse passive Arthus reaction. **Results:** MCP inhibited CVF-induced platelet metamorphosis with an IC_{50} of $56.7 \text{ mg/L} \pm 2.6 \text{ mg/L}$, and prevented injury induced by activated complement in isolated working guinea pig hearts. In the rat model of reverse Arthus reaction, MCP relieved the skin lesions induced by immune complexes. **Conclusion:** MCP has a protective effect against complement-dependent injury.

Introduction

The first barrier to a successful xenograft is the hyperacute rejection (HAR), that is initiated by the activation of complement on the graft vessel walls. The fragments of activated complement, such as C3a, C5a and membrane attack complex (MAC), promote blood coagulation and induce endothelial cell injury. Although drugs with anti-complement activity, such as heparin and FUT-175, have been used to prevent thrombosis, their clinical application is limited because they interfere with host blood coagulation or have other toxic effects. If the activation of complement is blocked, intravascular coagulation can be prevented effectively.

Membrane cofactor protein (MCP, CD46) belongs to the complement regulator protein family. It is located on the cellular membrane of all nucleated cells. MCP inhibits the activation of complement by combining with C3b/C4b and serves as a cofactor in their proteolytic cleavage by complement serine protease factor I. Generally, MCP function downregulates complement activation. Therefore, it is possible to prevent lesions caused by abnormal activated complement^[1].

In this study, cobra venom factor (CVF), zymosan A and the ovalbumin (OVA)–anti-OVA complex were used as complement activators to observe the protective effect of MCP on complement-dependent lesions.

Materials and methods

Reagents and animals Cobra venom factor (CVF) was isolated and purified by successive column chromatography from the venom of *Naja naja atra*, as described previously^[2]. DEAE-sephadex A-50 was purchased from Pharmacia, USA; β -mercaptoethanol, Coomassie brilliant blue R-250 and Nonidet P-40 were from Fluka, USA; acrylamide and *N,N*-methylene bisacrylamide was from Bio-Rad, USA; sodium azide, Evans blue dye, zymosan A and OVA were from Sigma, USA; rabbit anti-OVA from Chemicon; and benzanidine and phenylmethyl sulfonyl fluoride (PMSF) were from Amresco, USA. All chemicals were of analytical grade.

Blood was freshly obtained from pigs or sheep. O-type human plasma was purchased from the blood bank of the First Affiliated Hospital of Sun Yat-Sen University. Sprague-Dawley rats (Grade II, Certificate No. 99A005), and New Zealand rabbits and guinea pigs (Certificate No. 99A016, 99A015 conferred by the Medical Animal Management Committee, Guangdong Province) were provided by the Experimental Animal Center of Sun Yat-Sen University.

Isolation of membrane proteins from pig erythrocyte ghosts Pig erythrocytes were washed 3 times with phosphate buffered solution (PBS, in mmol: Na_2HPO_4 10.1, KH_2PO_4 1.7, NaCl 137, KCl 2.7; pH 7.4) and resuspended (1/10) in lysis buffer [in mmol: Na_2HPO_4 5, edetic acid (EDTA) 2,

benzimidazole 1, Phenylmethylsulfonyl Fluoride (PMSF) 1, sodium azide 0.05%; pH 7.4]. After being stirred overnight at 4 °C, the erythrocyte ghosts were concentrated (12 000×*g*, 4 °C, 45 min), and washed again with lysis buffer (1:1) and centrifuged (12 000×*g*, 4 °C, 45 min). The erythrocyte ghosts were then diluted 1/5 in PBS and extracted with 0.1% Nonidet P-40 at 4 °C for 1 h. After centrifugation (12 000×*g*, 4 °C, 30 min), the erythrocyte ghost extract was added to the top of a DEAE sephadex A-50 column (Ø: 2.6 cm; L: 25 cm) and washed with PBS containing a NaCl concentration gradient from 0 to 1 mol/L. The flow-rate was 24 mL/h. The fraction corresponding to the second ultraviolet absorbance peak, which possessed anti-complement activity, was collected and stored.

Identification of MCP The molecular weight of MCP was determined according to R_f on reduced SDS-PAGE, stained with Coomassie brilliant blue R-250. CH_{50} was determined according to the absorbance of sensitized sheep erythrocytes incubated with fresh guinea pig plasma, to which a series of concentrations of MCP were added. Protein concentrations were determined by using the Coomassie brilliant blue R-250 method.

Platelet metamorphosis and aggregation The metamorphosis and aggregation of male guinea pig platelets in platelet rich plasma (PRP) were recorded by an aggregometer (Chrono-Log, USA) linked to a computer with an A/D converter. Platelet poor plasma (PPP) was used for a control. After the baseline was steady, MCP (0, 20, 40, 80, and 160 mg/L) was added to PRP 3 min before CVF (80 mg/L) to observe the aggregation line changes.

Isolated working guinea pig heart Male guinea pigs weighing 380 \pm 35 g ($n=15$) were divided randomly into three groups. The guinea pig hearts were removed quickly and then perfused in a retrograde manner with modified Krebs-Henseleit buffer (in mmol: NaCl 11.2, KCl 5.7, MgCl₂ 1.2, CaCl₂ 2.5, NaHCO₃ 26.2, Na₂-EDTA 0.5, glucose 11.0; pH 7.2) at 37 °C, saturated by a mixture of 95% O₂ and 5% CO₂. After the heart began to beat again, a plastic cannula was inserted into the left atrium, and retrograde perfusion was changed to anterograde. Left ventricular pressure (LVP) was detected by a pressure transducer connected to the canal, which was inserted into the left ventricular cave. LVP, dp/dt , and heart rate (HR) were recorded by a polygraph (LMS-2A, Shanghai, China). Aortic flow (AF) was measured by an electromagnetic flowmeter (MFV-1200, Nihon Kohden, Japan), and coronary flow (CF) was measured manually. Cardiac output (CO) was defined as the sum of AF and CF.

After the CF became steady at 8 to 9 mL per min, we carried out the following treatment: 56 °C preheated human

plasma was added into perfusate in the negative control group. Human plasma pre-incubated with zymosan A was used for the positive control group. In group 3, human plasma was incubated with both MCP and zymosan A before being added.

Reverse passive Arthus reaction Anesthetized female rats (140 g–170 g, $n=10$) were given 0.6 mL of 0.9% NaCl solution *iv*, which contained 5 mg OVA and 2% Evans blue dye. Five minutes later, 0.1 mL PBS containing 0.5 mg rabbit-anti-OVA IgG with or without 0.4 mg MCP was injected *sc* on both sides of the back. Six hours later, rats were killed, and the area of dye leakage was measured. Skin samples were dissected, fixed with formalin, and then stained with hematoxylin and eosin.

Statistical analysis Statistical tests were performed using the *t*-test of SigmaPlot software. $P<0.05$ was considered to be statistically significant.

Results

Isolation of MCP A total of 2.1 mg MCP was gained from 100 mL pig erythrocytes. The molecular weight of MCP was determined to be 51 kDa according to the R_f value from SDS-PAGE. One anti-complement activity unit (CH_{50}) of MCP was $39.8\pm 0.7 \mu\text{g}$

Inhibition of CVF-induced platelet metamorphosis and aggregation MCP, at concentrations from 20 mg/L to 160 mg/L, dose-dependently inhibited the rat platelet metamorphosis induced by CVF (Figure 1). The linear regression equation was $Y=89.31\text{lg}X-106.6$ (where Y is the inhibitory ratio percentage, and X is the concentration of MCP; $r=0.98$, $n=20$, $P<0.05$). The IC_{50} was $56.7\pm 2.6 \text{ mg/L}$. MCP had little effect on CVF-induced platelet aggregation.

Protection of human complement-induced lesions on isolated working hearts Cardiac function parameters, namely LVP, dp/dt , CO, CF, AF, and HR, remained relatively stable for about 2 h in 56 °C inactivated complement treatment (negative control group). In positive control group, hearts quickly became non-functional after zymosan A (16.7 mg/L) activated complement was added. CF, CO, LVP and dp/dt decreased markedly after 5 min (Figure 2; $P<0.05$ vs negative control group, $n=5$), and declined to their lowest levels at 30 min. Yet when 1.3 mg/L MCP was co-incubated with zymosan A and complement, no change was seen in the first 20 min ($P<0.05$ vs negative control group, $n=5$).

Reverse passive Arthus reaction In our study, vigorous infiltration of polymorphonuclear cells, perivascular cuffing and mini clots were seen in the skin lesions under light microscopy (Figure 3A,3B), and the skin lesion area (dye

leakage indicating edema) was 330 mm²±15 mm² in size (*n*=5). The skin lesion area in the MCP-treated group, 149 mm²±10 mm² in size, was smaller (*P*<0.05 vs control, *n*=5). The inflamma-

tory reaction (cellular infiltrate) was less than that in the control group and no clotting or perivascular cuffing was found (Figure 3C, 3D), which suggests that MCP signifi-

cantly reduced the extent of inflammatory injury.

Discussion

MCP is widely distributed on epithelial and endothelial cells, cells originating from fibroblasts, and all animal blood cells except human erythrocytes^[3]. Because it is more abundantly expressed on erythrocytes from pigs than on those from other animals, the MCP used in this study was derived from pig erythrocytes. Structurally, pig-derived MCP amino acid sequence has 43% homology with human-derived MCP^[4], and it has no *N*-glycosylation site in the second repeated motif (short consensus repeat, SCR), which serves as a measles receptor. Because it is a safer complement inhibiting factor than human-derived MCP, pig-derived MCP was worth testing for its protective action in complement-dependent injury. The DEAE sephadex A-50 anion exchange column is able to separate proteins by both their charge and molecular weight. Although one-step anion exchange separation can result in only impure proteins, in our study, the pig-derived MCP did show the complement regulation ability, more importantly, the high yield made continuation of our experiment possible.

CVF can activate complement through an alternative

pathway: its terminal product MAC can induce platelet metamorphosis and express binding sites for the coagulation factors Va and Xa on platelet membranes, triggering coagulation^[5]. In the present study, MCP inhibited the platelet metamorphosis induced by MAC. Thus, MCP can be used to prevent the intravascular coagulation initiated by activated complement. Decay-accelerating factor (DAF, CD59), another complement-regulating protein, has been reported to have a similar effect^[2].

We further investigated the anti-complement effect of MCP *in vivo* and *in vitro*. The isolated working heart was an *in vitro* model of HAR. When zymosan A-treated serum reached the coronary vessel wall, the complement was activated and then cascade responses initiated the HAR, causing the hearts to fail quickly. However, when MCP was pre-incubated, it inhibited the complement activation by zymosan A. Thus, hemodynamic indexes such as LVP, dp/dt , HR, CO and CF, were well maintained. This observation shows that MCP protects the isolated working heart from complement injury. DAF has also been found to have a similar protective effect^[6]. The above facts show that downregulating complement activation is an effective way to alleviate the HAR.

The reverse passive Arthus reaction is an *in vivo* model

of HAR, and it refers a type III immune complex mediated hypersensitivity reaction that occurs following the intradermal injection of antigen in the presence of a high level of circulating antibody. In that process, antigen-antibody complex also activated complement. The histological lesions in the MCP-treated group were smaller than those in the control group, suggesting that MCP blocks the classical pathway of complement activation. This finding corresponds with that of an earlier report about blockades preventing monocyte activation and anaphylatoxin damage^[7].

Because of its antigenicity, MCP is not completely safe for clinical uses. To improve its safety, further research and chemical modifications are required. Recently, a human transgenic pig model has been established, and it has been shown that HAR in xenotransplantation is suppressed to a large degree^[8,9].

In summary, we showed that MCP alleviated complement-mediated injury. Preventing the activation of complement is an effective method to ameliorate such complement-mediated injury.

Abstract

Aim: To assess the effects of *L*-arginine (*L*-Arg) supplementation on pulmonary oxidative stress and antioxidant defenses in rats after exhaustive exercise. **Methods:** Rats were randomly divided into four groups: sedentary control (SC), sedentary control with *L*-Arg treatment (SC+Arg), exhaustive exercise with control diet (E) and exhaustive exercise with *L*-Arg treatment (E+Arg). Rats in groups SC+Arg and E+Arg received a 2% *L*-Arg diet. Rats in groups E and E+Arg underwent an exhaustive running test on a motorized treadmill. Pulmonary oxidative stress indices [xanthine oxidase (XO), myeloperoxidase (MPO), and malondialdehyde (MDA)] and antioxidant defense systems [superoxide dismutase (SOD), catalase (CAT), glutathione peroxidase (GPX), glutathione reductase (GR), and glutathione (GSH)] were investigated in this study. **Results:** *L*-Arg supplementation significantly reduced exercise-induced elevations of XO and MPO activities in lung. *L*-Arg reversed the exercise-induced increase in SOD and GR activities, but increased CAT and GPX activities. *L*-Arg administration also significantly increased the GSH levels in plasma. **Conclusion:** *L*-Arg supplementation can prevent elevations of XO and MPO activities in the lung and favorably influence pulmonary antioxidant defense systems after exhaustive exercise.

Introduction

In recent years, it has been shown that *L*-arginine (*L*-Arg) serves as a precursor to the synthesis of NO and may participate in amino acid metabolism^[1]. Most pharmacological actions of *L*-Arg are attributed to nitric oxide (NO), and NO has various physiological properties including vasodilatation, inhibition of platelet aggregation and neutrophil adhesion, scavenging superoxide (O₂⁻) formation and suppression xanthine oxidase (XO)^[2,3]. More recently, *L*-Arg has shown protective role against reactive oxygen radical (ROS) attack as a result of its interaction with O₂⁻ *in vitro*^[4]. There is evidence that *L*-Arg is closely linked to protective properties against oxidative stress^[5,6]. Furthermore, *L*-Arg administration to rats prevented pulmonary neutrophil accumulation and preserved pulmonary endothelial function after endotoxin^[7]. The XO activity of pulmonary

artery endothelial cells decreased using *L*-Arg, suggesting that NO generated in the endothelial cells negatively regulates this enzyme^[8].

Strenuous physical exercise may be associated with a 10- to 20-fold increase in whole body oxygen consumption and oxidative stress shown in both human and experimental animal studies^[9,10]. The mitochondrial electron transport chain, XO and neutrophils of inflammatory response have been identified as major sources of intracellular free radical generation during exercise^[11]. XO, a metalloflavoprotein, is an important source of ROS. The enzyme catalyzed the reduction of O₂, leading to the formation of O₂⁻ and H₂O₂, and it has been proposed as a major mechanism of oxidative injury^[12]. Reddy *et al* reported that XO activity and lipid peroxides increased in the lung tissue after exhaustive swimming exercise^[13]. In addition, the activity of glutamine synthetase and reactive carbonyl derivatives enhanced in the

rat lung during exhaustive running^[14]. Similarly, activated neutrophils are known as a major source of ROS^[15]. Neutrophils are capable of further generation of ROS through NADPH oxidase and producing hypochlorous acid from H₂O₂ through MPO reaction^[16]. The NADPH oxidase system has been shown to be activated in response to various stimuli that can be provoked by strenuous exercise^[17]. However, the lung tissue presents a significant first target of free radical species and gas exchange function of the respiratory system during exercise. Thus, the lung may be more vulnerable to oxidative damage as a result of exercise. Nevertheless, the pulmonary system has a series of defense mechanisms including SOD, CAT, GPX, GR, and GSH to protect the cell against these toxic oxygen metabolites, such as O₂⁻, H₂O₂ and hydroxyl radicals (OH[•]). Strenuous exercise generated ROS seems to increase the activity of antioxidant enzymes and decrease GSH levels in the muscle and heart^[18], possibly as a compensatory mechanism to cope with oxidative stress induced by exhaustive running.

However, the roles of *L*-Arg administration in exhaustive exercise-induced oxidative damage and inflammatory response in lung tissues are still not clear. Therefore, we studied whether *L*-Arg administration can protect lung tissue and have beneficial effects on ameliorating exercise-induced oxidative stress and reserve antioxidant defense capability in the lung of rats.

Materials and methods

Animals and treatment Adult male Sprague-Dawley rats ($n=32$), weighing 280–300 g and aged 8 weeks old, were purchased from the National Laboratory Animal Breeding and Research Center (Taipei). All rats were given standard rat chows and tap water *ad libitum* and housed at 23±2 °C on a 12:12-h dark-light cycle in the first week. This experiment was approved by the Fu-Jen Catholic University Animal Care and Usage Committee and followed the guidelines established by the National Laboratory Animal Breeding and Research Center in Taiwan. In the second week, in order to adapt to the experimental standard diet, all rats were fed AIN-93 purified diet^[19]. Rats were then randomly divided into four groups: sedentary group with control AIN-93 diet (SC, $n=8$); sedentary group with AIN-93 containing 2% *L*-Arg diet (SC+Arg, $n=8$); exhaustive exercise with control AIN-93 diet (E, $n=8$); and exhaustive exercise with AIN-93 containing 2% *L*-Arg diet (E+Arg, $n=8$). Rats were fed diets for 30 d beginning from the third week. Both diets were identical in calorie content (Table 1)^[19,20].

were introduced to treadmill running with 15–20 min exercise bouts at 15–30 m/min for 6 d to accustom them to running. In the formal run, the rats were warmed up for 15 min running at a speed of 15 m/min. They then progressed to running for 15 min at 20 m/min and 30 min at 25 m/min. They were then made to run to exhaustion at a final speed of 30 m/min, 10% grade, approximately 70%–75% VO_{2max}^[21]. The treadmill was equipped with an electric shock grid on the rear barrier to provide the animal with exercise motivation (using a T510E treadmill device; DR Instrument, Taipei). The point of exhaustion was determined by the loss of righting reflex when turned on its back. To eliminate diurnal effects, the experiments were performed at the same time (09:00–12:00 h). It is also well known that exercise performance is limited by the increase of body temperature during exercise. In order to eliminate this complicating factor, all running tests were conducted in an environmental chamber at 10–12 °C to reduce undue rise in body temperature caused by sustained exercise. All animals were anesthetized with ethyl ether and killed immediately after exhaustive exercise. Blood was collected through the abdominal aorta, and lung tissues were stored at -80 °C for further analysis. All chemicals used in this study were purchased from Sigma Chemical (St Louis, MO, USA) unless otherwise stated.

Plasma parameters Blood samples were centrifuged at 1400×g at 4 °C for 10 min. The supernatants (plasma) were used for determination of uric acid (UA) with an automatic analyzer (Hitachi 7170; Hitachi, Tokyo, Japan). In addition,

nitrate/nitrite (NO_x) levels in plasma were quantified by using the Griess reagent to measure nitrite ion concentration^[22]. NO_x concentrations in plasma were measured spectrophotometrically at 550 nm according to a previous study^[23].

Total protein concentration of lung tissues In order to express the antioxidant enzyme activities per gram of protein, total protein concentration of tissue samples was spectrophotometrically estimated using a Bio-Rad DC protein assay kit (Cat No 500-0116; Bio-Rad Laboratories, Hercules, CA, USA).

Assay of xanthine oxidase activity in lung tissues XO (EC.1.2.3.2) activities of tissue samples were determined using the method outlined by Westerfeld *et al*^[24]. A diluted sample was added to 0.1 mmol/L xanthine (dissolved in 50 mmol/L sodium phosphate buffer, pH 7.5). XO activity was measured at 25 °C on a Hitachi U-2000 Spectrophotometer at 290 nm for 3 minutes. A unit of XO activity was to form one mmol of urate per minute at 25 °C. XO activity was expressed as U·g protein⁻¹ for specific activity.

Assay of myeloperoxidase activity in lung tissues MPO (EC.1.11.1.7) activities of tissue samples were determined as a marker enzyme for measuring neutrophil accumulated in tissue samples, because correlates closely with the number of neutrophils present in the tissue^[25]. MPO activity was determined using the method described by Schierwagen *et al*^[26]. Fifty microlitre of diluted sample was added to 1 mL of mixed substrate containing 3 mmol/L hydrogen peroxide dissolved in 3,3',3,5'-tetramethylbenzidine (R&D Systems, Minneapolis, MN, USA). MPO activity was measured at 37 °C on a Hitachi U-2000 Spectrophotometer at 655 nm for 3 min. One unit of MPO activity was defined arbitrarily as the amount of enzyme necessary to catalyze an increase in absorbance of 1.0 at 655 nm per minute at 37 °C. MPO activity was expressed as U·mg protein⁻¹ for specific activity.

Lipid peroxidation in plasma and lung tissues The malondialdehyde (MDA) concentrations of plasma and tissue samples were assessed colorimetrically at 586 nm using a commercial kit (Calbiochem 437634; Calbiochem-Novabiochem, La Jolla, CA, USA). The concentration was expressed in μmol/L in plasma and in μmol·mg protein⁻¹ in lung tissues.

Assay of superoxide dismutase activity in lung tissues SOD (E.C.1.15.1.1) activities of tissue samples were measured with a commercial kit (SD 125; Randox Laboratories, Antrim, UK). Fifty microlitre of diluted sample was added to 1.7 mL of mixed substrate (50 μmol/L xanthine and 25 μmol/L 2-(4-iodophenyl)-3-(4-nitrophenol)-5-phenyltetrazolium chloride, INT). Two hundred and fifty microlitre of XO were added to the mixture and SOD was measured at 37 °C on a Hitachi U-2000 Spectrophotometer at 505 nm for 3 min. Activity was

expressed as U·mg protein⁻¹ for specific activity.

Assay of catalase activity in lung tissues CAT (EC.1.11.1.6) activities of tissue samples were determined at 25 °C with Hitachi U-2000 Spectrophotometer UV-VIS spectrophotometer using the method described by Beers and Sizel^[27]. A diluted sample was added to 59 mmol/L hydrogen peroxide (dissolved in 50 mmol/L potassium phosphate buffer, pH 7.0) and CAT was measured at 240 nm for 3 min. One unit of CAT activity was defined as the H₂O₂ degraded (mmol·min⁻¹·mg protein⁻¹). Activity was expressed as U·mg protein⁻¹ for specific activity.

Assay of glutathione peroxidase activity in lung tissues GPX (EC.1.11.1.9) activities of tissue samples were determined with a commercial kit (RS 504; Randox Laboratories, Antrim, UK). Twenty microlitre of diluted sample was added to 1 mL of mixed substrate. Forty microlitre of cumene hydroperoxide (diluted in deionized water) was added to the mixture and GPX was measured at 37 °C with a Hitachi U-2000 Spectrophotometer at 340 nm for 3 min. Activity was expressed as U·mg protein⁻¹ for specific activity.

Assay of glutathione reductase activity in lung tissues GR (E.C.1.6.4.2) activity of tissue samples was measured with a commercial kit (Calbiochem 359962; Calbiochem-Novabiochem). Two hundred mL of diluted sample was added to 400 μL of 2.4 mmol/L GSSG buffer (dissolved in 125 mmol/L potassium phosphate buffer, pH 7.5, 2.5 mmol/L EDTA). Four hundred mL of 0.55 mmol/L NADPH (dissolved in deionized water) was added to the mixture and GR activity was measured at 340 nm for 5 min on a Hitachi U-2000 Spectrophotometer. The activity was expressed in mU·g protein⁻¹ in tissue samples.

Assay of glutathione levels in plasma and lung tissues The concentrations of GSH in plasma and tissue samples were measured spectrophotometrically at 400 nm using a commercial kit (Calbiochem 354102; Calbiochem-Novabiochem, La Jolla, CA, USA). The concentration was expressed in μmol/L in plasma and in μmol·mg protein⁻¹ in tissue samples.

Statistical analysis Values were expressed as mean±SEM. To evaluate differences between the groups, two-way analysis of variance (ANOVA) with Fisher's *post hoc* test was used. The SAS software (version 8.2, SAS Institute, NC, USA) was used to analyze all data. Differences were considered statistically significant when *P*<0.05.

Results

Bodyweight and endurance time On d 30, bodyweight in the groups SC, SC+Arg, E and E+Arg were 446±7, 446±10,

447±6, and 451±8 g, respectively. There was no significant difference in bodyweight between the 4 groups. The mean endurance time of treadmill running to exhaustion was 81±4 min for the group E and 87±5 min for the group E+Arg, which showed no significant difference between the 2 groups.

XO and MPO activities of lung tissues The XO and MPO activities of lungs in group E were significantly elevated by 113% and 55%, respectively, compared to those in the SC group ($P<0.05$). In contrast, the XO and MPO activities of lungs in the E+Arg group were significantly reduced by 65% and 24%, respectively, compared with those in the E group ($P<0.05$). Furthermore, there was no difference between the SC+Arg and E+Arg groups (Figure 1).

Uric acid and nitrite/nitrate concentrations of plasma

The UA concentration of plasma in the E and E+Arg groups were significantly increased by 268% and 41%, respectively, compared with those in the SC and SC+Arg groups ($P<0.05$). Although, the UA concentration of plasma in the SC+Arg group was significantly increased compared with the SC group. This indicated that exogenous L-Arg may elevate UA in the plasma, and reduce UA excretion. However, L-Arg supplement might ameliorate UA concentration in plasma after exercise (Table 2). The NOx concentrations of plasma in the E and E+Arg groups were significantly increased by 93% and 82%, respectively, compared with those in the SC and SC+Arg groups ($P<0.05$). However, there was no difference between the SC and SC+Arg or E and E+Arg groups (Table 2).

MDA levels of plasma and lung tissues

of the plasma and lung showed no changes between SC+Arg and E+Arg groups. In contrast, the MDA levels of plasma and lung in the E group were significantly increased by 81% and 32%, respectively, compared to those in the SC group ($P<0.05$). There was a slight but not significant decrease in the MDA level of plasma in the E+Arg group compared to that in the E group ($P>0.05$) (Table 3).

Antioxidant enzymes activities of lung tissues Table 4 shows the antioxidant enzyme activities. The E+Arg group had significantly higher GPX and CAT activities by 19% and 25%, respectively, than the group E ($P<0.05$), but showed no difference when compared with the SC+Arg group. Furthermore, the GRD and SOD activities of the E group were significantly elevated by 44% and 96%, respectively, compared with those of the SC group ($P<0.05$), but they were significantly reduced by 35% and 58%, respectively, in the E+Arg group compared with the E group ($P<0.05$).

GSH concentrations of plasma and lung tissues The GSH concentration of plasma showed no change between

SC+Arg and E+Arg groups. In contrast, the GSH concentration of plasma in the E group was significantly decreased by 25% compared with the SC group (*P*<0.05). Moreover, the GSH concentration of plasma in the E+Arg group was significantly increased by 31% compared with the E group (*P*<0.05). However, there was no difference in the GSH concentration of lungs in any group (Table 5).

Discussion

The lung represents the front line of defense against a number of airborne toxicant and oxidant stress because it is directly exposed to higher oxygen tensions. In this study, we investigated whether *P*-Arg supplementation attenuates exhaustive exercise-induced pulmonary oxidative stress. More recently, there has been some evidence to show that strenuous exercise simulates the condition of heart I/R and may activate the XO pathway^[28,29]. Hypoxanthine and UA are known to elevate in plasma during high intensity exercise^[30]. Our results indicate that in exhaustive exercise with higher anaerobic components, the lactate concentrates in the plasma of the E group (E: 76±6 mg/dL vs SC: 55±4 mg/dL, *P*<0.05), but not in the E+Arg group. XO activity in the lung and plasma UA levels was also significantly increased in group E (*P*<0.05). Our data are consistent with previously published reports^[30,31].

According to Yokoyama *et al*^[32], the XO that is formed by the inadequate supply of oxygen to exercising muscles might have generated oxidative damage in other organs including the lung by causing an increase in the circulating level of XO, which binds in the lung to provide a pulmonary source of O₂⁻. This is a possible mechanism that could explain increased XO activity in the lung under the current study. Lipid peroxidation causing tissue damage has been estimated by an extensively used indicator, such as MDA. The present study showed that after exhaustive running MDA levels (*P*<0.05) were significantly increased in the lung and plasma of the E group, compared to the SC group. However, the extent of the increase in pulmonary and plasma MDA levels in the E+Arg group was comparatively low as compared to the non-Arg group with exercise. This may suggest that the XO derived ROS exert some toxicant effect on lung tissue. In contrast, a smaller increase in XO and MDA concentration activity was observed in *L*-Arg fed rats in response to exhaustive exercise. This result in *L*-Arg fed rats could be responsible for protecting oxidative damage in the E+Arg group.

Numerous studies have shown that *L*-Arg is a precursor of NO, which can increase coronary vasodilation, scavenge various free radicals, inactivate Fe-S centers of XO and suppress XO activity as well as inhibit platelet and neutrophil adhesion to the endothelium^[33,34]. Hence, the protective role of NO is probably a result of its ability to scavenge free radicals, reduce lipid peroxidation, and inhibit XO, which are in accordance with our results for the E+Arg group.

The current study showed that MPO activity in lungs from E group significantly increased after exhaustive exercise (*P*<0.05). However, there was no significant difference between E+Arg and SC groups. Hence, *L*-Arg supplementation to rats is successful in reducing post-exercise lung MPO activity and oxidative damage in lungs. These results are in accordance with previous studies about protecting the role of NO^[12].

In the present study, our results indicate that both the E and E+Arg groups significantly increase plasma NOx after exhaustive exercise compared to the control. NO, however,

is also a free radical and hence the toxicity of NO (excess product of NO) is markedly enhanced by its reaction with O_2^- from peroxynitrite ($ONOO^-$), which is extremely cytotoxic^[35]. However, Rubbo *et al*^[36] recently reported that NO actually inhibits peroxynitrite-induced lipid peroxidation. This report demonstrated that NO will significantly enhance lipid peroxidation only when rates of NO production approach or are equivalent to rates of O_2^- production by XO. In the current study, we measure the effect of exhaustive exercise on the rate of NOx synthesis in plasma in both exercised groups. Although *L*-Arg supplementation affects animals subjected to exhaustive exercise on levels of NOx production, so the results cannot be distinctly different between both exercise groups in our study. This is likely to be related to the following two mechanisms. First, *L*-Arg serves as a precursor to the synthesis of NO that may act as an indirect antioxidant role by scavenging O_2^- and inhibiting XO activity from exercise-induced stress^[37]. Our results suggest that *L*-Arg protection is generated through NO. NO has the capacity to inhibit reactive oxygen metabolites, including O_2^- and XO to prevent cellular damage, but in presence of the NO synthase inhibitor *L*-NAME, this protection was abolished, which suggests that the protection *L*-Arg is through the generation of NO^[38]. Second, *L*-Arg has some protective roles against ROS attack possibly because of its direct chemical property interaction with O_2^- , thus suggesting a protective effect for *L*-Arg involving antioxidant mechanisms^[4]. Obviously, the E group does cause a significant increase in XO and MPO activities, as well as MDA levels that are a result of oxidative stress in lung tissues. This means that the enhanced production of O_2^- by XO, may possibly be the combined work of higher level NO and O_2^- to form cytotoxic $ONOO^-$ after exhaustive exercise. In contrast with the E+Arg group, when NO concentrations are increased the protective role of NO is probably be a result of its ability to scavenge free radicals and possibly inhibit XO and inflame neutrophils. Therefore, this study suggests that the E+Arg group has higher levels of NO to inhibit $ONOO^-$ formation leading to lipid peroxidation and it is unlikely that $ONOO^-$ may have a role in this process.

In this study, SOD activity in the lung was significantly increased in response to exercise in the E group. As SOD is known to be an enzyme induced by its O_2^- substrate, the increase in the E group indicates an increased production of O_2^- . This finding was in agreement with Reddy *et al*^[13], that SOD activity in the lung tissue significantly increased after strenuous swimming exercise. However, the SOD activity in the lung tissue of *L*-Arg-fed animals after exhaustive exercise was well below the control level, suggesting reduced

generation of O_2^- and protection offered by *L*-Arg.

Furthermore, the CAT enzyme works on cooperating with GPX to scavenge excess H_2O_2 as well as lipid peroxides in response to oxidative stress. Under this situation, when O_2^- production through XO and neutrophils becomes an overwhelming compensatory mechanism, inadequate consequences take place. Possible mechanisms that could explain excess O_2^- are the inhibition of the activity of CAT by reduction of the Fe III center and inactivated GPX activity by oxidation of the selenium active site^[39,40]. This interaction suggests SOD, CAT and GPX constitute a mutually supportive team of enzymes that provide a defense against the intermediaries of ROS. This study confirms Kono *et al*'s and Blum *et al*'s hypothesis, because overproducing O_2^- may speculate an inactive CAT and GPX activities and reciprocally influence these enzymes^[39,40]. In contrast with the E+Arg group, the increased CAT and GPX activities seem to be an adaptive response of the lung to oxidative stress generated by exercise. An increase in activity of those enzymes is possibly a result of exposure to various oxygen toxicants. GR catalyzes the reduction of oxidized glutathione (GSSG) to GSH at the expense of NADPH and maintains high GSH/GSSG ratios in the cell. In the present study, GR activity of lung tissue was significantly increased after exhaustive running ($P<0.05$). The increase in GR activity of the lung suggested that the pulmonary antioxidant defense system of exercised rats reacted positively to combat ROS toxicity giving the tissue an adaptive response to oxidative stress. However, our data showed that GR maintains the same levels in the *L*-Arg-fed animals at rest and after exercise, indicating that *L*-Arg supplementation has beneficial effects on attenuating the oxidative stress and maintaining GSH levels. GSH is the first line of defense against various types of chemicals^[41]. As described, the GSH levels decreased in the liver and muscles after exhaustive exercise in rats^[11]. In the current study, our data showed a depletion in pulmonary GSH and a significant decrease in plasma GSH in the E group compared with the SC group. However, in the E+Arg group the levels of GSH were restored, suggesting that the mechanism of protective action by *L*-Arg may involve maintenance of the thiol group of GSH. Our data correspond with previous reports that exhaustive exercise causes GSH oxidation in blood in both animals and in human beings^[42,43].

Other possible mechanisms for an increase in GSH in lung tissue are that GSH synthesized primarily in the liver and was then transported to different organs of the body through the blood during prolonged exercise in order to maintain GSH homeostasis to cope with oxidative stress^[44].

In conclusion, an acute bout of exhaustive exercise causes

oxidative stress, tissue damage and antioxidant responses in the lungs. This study suggests that *L*-Arg supplementation can prevent elevations of XO and MPO activities in the lungs and can favorably influence pulmonary antioxidant defense systems after exhaustive exercise.

Abstract

Aim: To define the *in vitro* cytotoxic activities of 4-demethyl-picropodophyllotoxin 7'-O-β-D-glucopyranoside (4DPG), a new podophyllotoxin glucoside. **Methods:** Antiproliferation activity was measured in several tumor cell lines by using the microculture tetrazolium MTT assays. Cell cycle distribution was analyzed using flow cytometry and mitosis index assays. Furthermore, transmission electron microscopy, TUNEL, DNA agarose electrophoresis, and activated caspase-3 were used to analyze the induction of apoptotic cell death. Moreover, intracellular changes in the cytoskeleton were detected using immunocytochemistry. **Results:** 4DPG effectively inhibited the proliferation of cancer cells (HeLa, CNE, SH-SY5Y, and K562 cell lines). For the K562 cell line, the antiproliferation effect of 4DPG was much more potent than that of etoposide (IC₅₀ value: 7.79×10⁻⁹ mol/L for 4DPG vs 2.23×10⁻⁵ mol/L for etoposide). Further, 4DPG blocked the cell cycle in the mitotic phase. The induction of apoptosis and elevated levels of activated caspase-3 were confirmed in cells treated with 4DPG. The microtubule skeleton of HeLa cells was disrupted immediately after treatment with 4DPG. **Conclusion:** The cytotoxicity of 4DPG is due to its inhibition of the microtubule assembly of cancer cells at a low concentration, thus inducing apoptosis. These properties qualify 4DPG to be a potential antitumor drug.

Introduction

Natural products have long been an important source of treatments for cancer. At present, there are more than one thousand plants that have been found to possess significant anticancer properties. Although many molecules obtained from plants have been shown to have antineoplastic activity, a huge number of molecules still remain to be isolated or studied in detail. Recently, traditional Chinese medicines have attracted much interest, and evaluations of potential antineoplastic herbal ingredients are currently being carried out in laboratories^[1-3].

Of the natural compounds with anticancer properties, podophyllotoxin occupies a very important position^[4]. Podophyllotoxin is a naturally occurring lignan, which is isolated from the dried roots and rhizomes of *Podophyllum* plants,

and has been proven to possess antineoplastic properties. Although its unacceptable levels of cytotoxicity precluded the use of podophyllotoxin as an anticancer drug, subsequent research aimed to abstract and synthesize new analogues of podophyllotoxin, and analyzed podophyllotoxin's structure-function relationship and its mechanism of action. Several decades' efforts have proven that the cytotoxicity of podophyllotoxin is due to its interaction with β-tubulin, because it disrupts microtubule organization and leads to mitotic arrest, in a manner that is similar to the action of colchicines^[5-8]. Meanwhile, many analogues of podophyllotoxin have been determined, and most exhibit pronounced biological activity as strong antiviral or antineoplastic agents^[4,9-11]. Among these molecules, etoposide is a notably successful derivative of podophyllotoxin^[12,13], with demonstrated efficacy against a broad spectrum of human

malignancies, including testicular, germ cell, lung, and other cancers^[14–17]. Etoposide arrests cancer cell growth prior to mitosis as a DNA topoisomerase II inhibitor^[18–21], whereas podophyllotoxin has no inhibitory effect on this enzyme^[22]. Conversely, an isomer of podophyllotoxin, picropodophyllotoxin, has no inhibitory effect on microtubules and apparently lacks cytotoxicity^[4,22–26]. After these observations were made, little or no attention was paid to picropodophyllotoxin. However, some recent studies on picropodophyllotoxin produced different and exciting results. Some derivatives of picropodophyllotoxin have high levels of antiproliferation activity against the L1210 cell line because they inhibit microtubule assembly^[27]. The cyclolignan podophyllotoxin and picropodophyllotoxin inhibit tyrosine phosphorylation of the insulin-like growth factor-1 receptor (IGF-1R), but have no effect on the highly homologous insulin receptor (IR) or tyrosine kinases that are related to other major cancer-relevant growth factor receptors, so they specifically inhibit malignant cells^[28,29]. These results could cause more research interest to be focused on the analogues of podophyllotoxin, in order to identify the derivatives with the most potent and specific antitumor activity (ie, to optimize the structure), or to develop an alternative and renewable source of podophyllotoxin.

Sinopodophyllum emodi (Wall) Ying, mainly distributed over the Western region of the Qinling mountains of China, is a type of *Podophyllum*. In the area in which it grows, *S emodi* has been used as a folk medicine to treat cancer and various types of verrucosis, but the pharmacology of its constituent ingredients has not been investigated. Our previous study revealed that 4-demethyl-picropodophyllotoxin 7'-*O*- β -*D*-glucopyranoside (4DPG) (Figure 1) is a novel podophyllotoxin glucoside isolated from *S emodi*^[30]. A significant structural characteristic of 4DPG is that it belongs to the picropodophyllin family. Therefore, as a herbal medicine ingredient and a podophyllotoxin analogue with a quite different structure, we wondered what the biological activity of this molecule would be.

In this study, we demonstrate that 4DPG is a highly potent inhibitor of microtubule assembly, leading to mitotic arrest, induction of apoptosis, and inhibition of the proliferation of malignant cells.

Materials and methods

Chemicals 4DPG was isolated from *Sinopodophyllum emodi* (Wall) Ying (Berberidaceae) by our group^[30]. The extracted 4DPG was dissolved in methanol (0.01 mol/L) and stored at room temperature.

Cell lines and cell culture A human cervical carcinoma

Figure 1. Chemical structure of 4DPG.

cell line (HeLa), a human nasopharyngeal carcinoma cell line (CNE) and a human neuroblastoma cell line (SH-SY5Y) were grown in Dulbecco's MEM (Hyclone, Logan, USA) and a human chronic myelogenous leukemia cell line (K562) was maintained in RPMI-1640, supplemented with 10% heat-inactivated fetal calf serum (FCS), 100 U/mL penicillin and 100 μ g/mL streptomycin in a humidified atmosphere (37 $^{\circ}$ C, 5% CO_2).

Cytotoxicity assay The MTT assay to determine the cytotoxicity of 4DPG was performed as described previously^[31]. Briefly, cells were plated onto 96-well plates at 2×10^3 cells per well for the HeLa, CNE, and SH-SY5Y cell lines or at 5×10^3 cells/well for the K562 cell line. After incubation with medium containing 0.1% methanol, 2×10^{-5} mol/L 4DPG and etoposide (VP-16) for 48 h, MTT (Sigma Chemical Co, St Louis, USA) was added to cell cultures to a final concentration of 0.5 mg/mL and incubated at 37 $^{\circ}$ C for 4 h. Then, the adherent cells were solubilized with 200 μ L dimethyl sulfoxide (Me_2SO , Sigma), and K562 cells were exposed to 100 μ L 0.04 N 2-propanolic hydrochloric acid. Absorbance at 570 nm was measured on a multiplate reader (Bio-Rad 550, Hercules, USA).

In the same way, K562 cells treated with gradient concentrations of 4DPG and etoposide for 48 h were tested. The drug concentration required to inhibit cell growth by 50% (IC_{50}) was determined by interpolation from dose-response curves. All assays were carried out in quadruplicate. The inhibition rate of cell proliferation was calculated by:

$$\text{Inhibition rate (\%)} = \frac{OD_{\text{control}} - OD_{\text{treated}}}{OD_{\text{control}}} \times 100\%$$

Cell cycle analysis K562 cells were treated with 1×10^{-9} mol/L, 1×10^{-8} mol/L, 1×10^{-7} mol/L, and 1×10^{-6} mol/L 4DPG, respectively. After incubation for 48 h, cells were collected and fixed with 70% ethanol at 4 °C for 24 h, then stained with 50 μ g/mL propidium iodide (Sigma). The cell cycle distribution from 10 000 cells was collected by using the Epics flow cytometer (Coulter Electronics, Fullerton, USA). Cell cycle analysis was performed by using Multicycle software (Phoenix Flow Systems, San Diego, USA).

The mitotic index was determined by Giemsa staining. K562 cells were incubated with or without 1×10^{-6} mol/L 4DPG for 48 h. Then, fixed cells were stained with Giemsa solution and mitotic cells were counted per visual field. Quadruplicate fields were measured.

DNA fragmentation assay K562 cells were exposed to 0.01% methanol, 1×10^{-6} mol/L 4DPG and 1×10^{-6} mol/L etoposide for 48 h, and then cells were collected by centrifugation. Total DNA was purified with a DNA isolation kit (R&D Systems, Minneapolis, USA) according to the manufacturer's protocol. The DNA was separated in 1.5% agarose gel and visualized by ultraviolet illumination after staining with ethidium bromide.

TUNEL assay After incubation with 1×10^{-6} mol/L 4DPG for 12 h, 24 h, and 48 h, cells were rinsed three times with phosphate-buffered saline (PBS) and fixed with methanol. Based on the TUNEL protocol (Roche, Basel, Switzerland), cells were permeabilized with 0.1% Triton X-100 in 0.1% sodium citrate and then rinsed twice with PBS. The DNA nick-labeling reaction was performed using 50 μ L TUNEL reaction mixture, including 45 μ L enzyme solution and 5 μ L nucleotide mix at 37 °C for 60 min. Then the samples were rinsed three times with PBS and analyzed under a fluorescence microscope.

Morphology analysis by transmission electron microscopy K562 cells treated with 1×10^{-6} mol/L 4DPG were washed with PBS, centrifuged, and pre-fixed with 2.5% glutaraldehyde in 0.1 mol/L phosphate buffer at 4 °C for 2 h. The cells were then rinsed thoroughly in phosphate buffer and post-fixed in 1% OsO_4 at 4 °C for 30 min. After being fixed, the cells were pelleted in 2% agar, then cell blocks were prepared, dehydrated through a graded ethanol series, and embedded in Epon 812 (Spi supplies, West chester, USA). The ultrastructure of cells was analyzed in ultrathin sections in a transmission electron microscope (Hitachi H-600, Tokyo, Japan) after the sections were stained with uranyl acetate and lead citrate.

Caspase-3 cleavage assay After the K562 cells were treated with 10^{-6} mol/L 4DPG as described above, the cells were fixed and incubated with cleaved caspase-3 (Asp175)

antibody (Cell Signaling, Beverly, USA) as a primary antibody, which specifically recognizes activated caspase-3 resulting from cleavage adjacent to Asp175, and then with biotinylated goat antirabbit IgG as a secondary antibody. Finally, the cells were incubated with the ABC kit (Vector, Peterborough, England) and visualized by incubation with the colorigenic substrates (DAB, Promega, Madison, USA).

Indirect immunofluorescence staining Exponentially growing HeLa cells were seeded into 96-well plates, then after 12 h, the medium was replaced with complete medium containing 10^{-6} mol/L 4DPG. After treatment with 4DPG for 1 h, 2 h, 3 h, 12 h, 24 h, or 48 h, immunofluorescence staining was performed. The cells were incubated with anti- α -tubulin antibody (ZSBO, Beijing, China) as a primary antibody, which was followed by a secondary antibody, TRITC-conjugated rabbit antimouse IgG. After being washed three times with PBS, the labeled cells were observed and photographed with a fluorescence microscope (Olympus IX70, Tokyo, Japan).

HeLa cells plated onto cover slips were treated with the 10^{-6} mol/L 4DPG for 24 h. As per the procedure described earlier, the cytoskeletons of the adherent and suspension cells were photographed on a confocal laser scanning biological microscope (Olympus Fluoview FV300).

Statistics Data were expressed as mean \pm SD and analyzed using two-way analysis of variance (ANOVA). The differences between two groups were determined by using the *t*-test, and statistical significance was set at $P < 0.05$.

Results

Chemical structure of 4DPG 4DPG, as a congener of podophyllotoxin, has the same multiple ring structure; however, it differs with respect to the composition and minor modifications of the podophyllotoxin rings, including the steric orientation of a carbon-carbon bond and substitution on the ring. 4DPG has a hydroxy group in the 4-carbon position, but podophyllotoxin has a methoxy group at this position. Another site that differs is the 7'-carbon position, which is substituted in podophyllotoxin with an unmodified glucoside. Among the analogues of podophyllotoxin reported previously, 4DPG is the isomer of the 4'-demethylpodophyllotoxin glucoside DMPG^[22].

Effect of 4DPG on proliferation of tumor cells As shown in Figure 2, 4DPG induced a significant inhibition of proliferation in the tested cell lines (SH-SY5Y, CNE, HeLa and K562). Compared with etoposide, 4DPG had much more potent cytotoxic effect on CNE and K562 cells.

After a 48 h-treatment, 4DPG had maximal cytotoxic effect on K562 cells at a concentration of 1×10^{-8} mol/L. The

Figure 2. The inhibitory effect of 4DPG on the proliferation of four tumor cell lines (SH-SY5Y, CNE, HeLa, K562) was measured by MTT assays after treatment with 4DPG for 48 h. *n*=4. Mean±SD. ^c*P*<0.01 vs VP-16.

maximal inhibition rate was 72.82%, and the IC₅₀ value was 7.79×10⁻⁹ mol/L (Figure 3). Under the same conditions, the maximal effect on cell proliferation inhibition was observed with etoposide at a concentration of 2.5×10⁻⁴ mol/L, which inhibited 95.25% of cells, with an IC₅₀ value of 2.23×10⁻⁵ mol/L (data not shown).

Mitotic arrest was induced by 4DPG treatment As shown in Figure 4, 4DPG caused a significant dose-dependent accumulation of K562 cells in the G2/M and sub-G0 phases, and a decrease in the G0/G1 and S phases from 1×10⁻⁹ mol/L to 1×10⁻⁶ mol/L at 48 h. The differences in cell cycle distribution between vehicle-treated K562 cells and 1×10⁻⁸ mol/L, 1×10⁻⁷

Figure 4. The effect of 4DPG on G2/M phase arrest and induction of apoptosis in K562 cells was dose-dependent. K562 cells were treated with 1×10⁻⁹ mol/L, 1×10⁻⁸ mol/L, 1×10⁻⁷ mol/L or 1×10⁻⁶ mol/L 4DPG for 48 h. The negative control was the vehicle-treated sample.

mol/L, 1×10⁻⁶ mol/L treatment are statistically significant (*P*<0.01).

To further characterize the cell cycle distribution, mitotic index detection was performed. We found that approximately 50% of cells treated with 10⁻⁶ mol/L 4DPG for 48 h were blocked in mitosis, which was consistent with the result from flow cytometry, but for vehicle-treated cells, only 6.8% were in mitosis (*P*<0.01).

4DPG induced apoptosis in K562 cells 4DPG treatment resulted in the formation of a DNA ladder in K562 cells at 48 h (Figure 5), but etoposide did not produce the same result. Additionally, as shown in Figure 6, the longer K562 cells were exposed to 1×10⁻⁶ mol/L 4DPG, the more cells that had DNA strand breaks were labeled by TUNEL.

Figure 3. Dose-response curve for the inhibition of cell proliferation. K562 cells were incubated with gradient concentrations of 4DPG for 48 h. *n*=4. Mean±SD. The inhibition value was calculated using the means of *OD*_{control} and *OD*_{treated}.

Figure 5. DNA fragmentation in K562 cells treated with 4DPG for 48 h. Lane A: 1 kb marker; lane B: normal control; lane C: treated with 1×10^{-6} mol/L etoposide for 48 h; lane D: treated with 1×10^{-6} mol/L 4DPG for 48 h.

Observations of ultrastructure showed that K562 cells displayed the characteristics of apoptosis after the incuba-

tion of 1×10^{-6} mol/L 4DPG for 24 h and 48 h, respectively. That is, some slim protuberances packed with the unit membrane and numerous substances were released around the cell; this was followed by increases of the structure of the membrane in the cytoplasm, and the cytoplasm was separated into several units in which a few vacuoles could be seen; then, the nuclear membrane became unclear, and the chromatin condensed and turned into single chromosome spots (Figure 7).

4DPG induced the activation of caspase-3 As shown in Figure 8, after incubation with 1×10^{-6} mol/L 4DPG for 12 h, the number of activated caspase-3-positive cells had changed little; however, the number had increased greatly after 24 h, and further increased after 48 h.

4DPG inhibited microtubule polymerization At 1 h after 1×10^{-6} mol/L 4DPG treatment, a marked inhibition of microtubule assembly in HeLa cells was observed. Compared with the vehicle-treated cells, the most significant change was the disappearance of the bipolar mitotic spindles in the cell division phase (Figure 9). Additionally, the results from confocal fluorescent microscopy further confirmed that 4DPG

Figure 6. DNA breaks induced by 1×10^{-6} mol/L 4DPG were detected by TUNEL. (A) Vehicle-treated K562 cells (only cells involved in mitosis were positively labeled); (B) after 12 h exposure, the chromatin in a few cells condensed and broke; (C) after 24 h exposure, many more cells were positively labeled; (D) after 48 h exposure, condensed and separated chromatins were dispersed in the cytoplasm ($\times 400$).

Figure 7. Ultrastructural photomicrographs of K562 cells after treatment with 1×10^{-6} mol/L 4DPG, visualized by transmission electron microscopy. (A) Normal control, the nucleolus and nuclear membrane were clear, chromatin was dispersed and uncondensed ($\times 5000$); (B) after 4DPG treatment for 24 h, the nucleolus disappeared and the nuclear chromatin was condensed ($\times 3500$); (C) after treatment with 4DPG for 48 h, the nuclear membrane was becoming unclear, and the chromatin was condensed and separated. Cells displayed the characteristics of apoptosis and mitosis ($\times 5000$).

Figure 8. The percentage of activated caspase-3 in K562 cells increased greatly with increased exposure to 1×10^{-6} mol/L 4DPG. $n=4$. Mean \pm SD. $^c P < 0.01$ vs 0 h.

disrupted normal microtubule polymerization (Figure 10).

Discussion

By screening new potential antitumor agents using a cytotoxicity assay, we identified 4DPG as an agent that possessed antiproliferative properties. 4DPG has been found to have an extensive and significant inhibitory effect on the proliferation of various carcinoma cell lines. In this study, we found that compared with etoposide, 4DPG is much more potent in some cell lines, such as HeLa and K562. The IC_{50} value of 4DPG on K562 cells was 2–3 orders of magnitude lower than that of etoposide. The cytotoxic effect of 4DPG on K562 cells is dose-dependent. Furthermore, regarding the effect of 4DPG on the cell cycle distribution, 4DPG was found to cause significant mitotic arrest in K562 cells. These

findings regarding the picro derivatives are different from those reported previously, which considered that these compounds lacked biological activity and that the C-8 α , C-8 β trans configuration is of crucial importance for biological activity^[4]. However, recent studies on a new derivative of picropodophyllotoxin, 4-amino-4 deoxypicropodophyllotoxin, have proven that it exerts antitumor activity through inhibiting microtubule assembly^[27]. These results suggest that the modification of picropodophyllotoxin with a free hydroxy group in the 4-position or substitution at the 7'-position can also produce molecules with high levels of biological activity. Moreover, the specific inhibitive effect of tyrosine phosphorylation of IGF-1R and malignant cell growth by picropodophyllotoxin that was observed by Girnita and coworkers provide another perspective on this molecule^[28,29]. These new discoveries suggest that picro derivatives retain a high biological activity and could become an important family of anticancer agents.

In the podophyllotoxin family, there are two well-investigated mechanisms that cause cytotoxicity^[4]. The first is the inhibition of microtubule polymerization (eg, podophyllotoxin^[5,6]) and the second is the inhibition of topoisomerase II (eg, etoposide^[18]). As shown in Figure 8, after just 1 h exposure to 4DPG, the fibroid microtubule skeleton in normal HeLa cells was broken and the tubulin- α tagged by TRITC was distributed in the cytoplasm homogeneously. These observations indicate that the cytotoxicity of 4DPG is caused by disrupting the microtubule assembly, which interferes with mitosis at low concentrations. This property is similar to that of podophyllotoxin, indicating that 4DPG is a new antimicrotubule agent. However, reports regarding the effectiveness of podophyllotoxin and picropodophyllotoxin

Figure 9. Observations of the course of microtubule depolymerization in the 4DPG-treated HeLa cells (0 h–48 h) by using immunofluorescence techniques. The microtubule skeleton of HeLa cells after being treated with 10^{-6} mol/L 4DPG for 0 h, 1 h, 2 h, 3 h, 12 h, 24 h and 48 h, respectively (A–G). The microtubules of cells were almost totally depolymerized in the first 2 h and TRITC-labeled tubulin- α was dispersed in the cytoplasm ($\times 400$, HeLa cells).

as inhibitors of IGF-1R suggest that there is another possible mechanism by which podophyllotoxin inhibits malignant cell proliferation at the same time as it interferes with microtubule assembly^[28]. It could be necessary to carry out a study to determine whether 4DPG also possesses this activity.

Microtubules are important cytoskeletal components involved in the regulation of cell proliferation, differentiation,

and apoptosis^[32]. Microtubule-targeted agents, in particular taxanes^[33], have been shown clinically to exert a high level of anticancer activity, and they have also been shown to be promoters of apoptosis in cancer cells^[34]. In the present study, the apoptosis-inducing effects of 4DPG were also proven by several observations, including ultrastructure changes, DNA strand breaking and fragmentation, and a subdiploid peak. Apoptosis induced by antimicrotubule

Figure 10. Comparison of the changes in the microtubules of HeLa cells in the control and the 4DPG-treated groups by using confocal immunofluorescence microscopy. (A) The microtubules of normal cells were fibroid and interweaved. (B) When treated with 1×10^{-6} mol/L 4DPG for 24 h, the microtubules of the adherent cells were depolymerized. (C) When treated with 1×10^{-6} mol/L 4DPG for 24 h, most of the suspension cells also disappeared (HeLa cells).

agents is a very complex process. Many proteins involved in these signal pathways have yet to be identified, and many questions about the process remain unanswered^[35,36-38]. It is conceivable that different microtubule binding sites and different disruptions caused by antimicrotubule agents trigger different protein kinase signal pathways. The present study demonstrated clearly that activated caspase-3 increased greatly after treatment with 4DPG for 24 h. This result is quite consistent with the observations gained from TUNEL, suggesting that 4DPG causes the induction of apoptosis through a caspase-3-dependent signaling pathway. The other proteins involved in this apoptotic signaling pathway also need to be determined.

In summary, our results demonstrate that 4DPG has a powerful cytotoxic activity at very low concentrations (<0.01 $\mu\text{mol/L}$), through interrupting microtubule assembly. It is worth noting that 4DPG is a natural podophyllotoxin glucoside with a unique structure. These findings about the biological activity and mechanism of 4DPG are not only valuable additions to the body of information regarding the structure-activity relationships in the podophyllotoxin family, but also suggest a way forward for exploring natural antitumor products.

Abstract

Aim: To investigate the reversal effects of curcumin on multidrug resistance (MDR) in a resistant human gastric carcinoma cell line. **Methods:** The cytotoxic effect of vincristine (VCR) was evaluated by MTT assay. The cell apoptosis induced by VCR was determined by propidium iodide (PI)-stained flow cytometry (FCM) and a morphological assay using acridine orange (AO)/ethidium bromide (EB) dual staining. P-glycoprotein (P-gp) function was demonstrated by the accumulation and efflux of rhodamine123 (Rh123) using FCM. The expression of P-gp and the activation of caspase-3 were measured by FCM using fluorescein isothiocyanate (FITC)-conjugated anti-P-gp and anti-cleaved caspase-3 antibodies, respectively. **Results:** Curcumin, at concentrations of 5 $\mu\text{mol/L}$, 10 $\mu\text{mol/L}$, or 20 $\mu\text{mol/L}$, had no cytotoxic effect on a parent human gastric carcinoma cell line (SGC7901) or its VCR-resistant variant cell line (SGC7901/VCR). The VCR-IC₅₀ value of the SGC7901/VCR cells was 45 times more than that of the SGC7901 cells and the SGC7901/VCR cells showed apoptotic resistance to VCR. SGC7901/VCR cells treated with 5 $\mu\text{mol/L}$, 10 $\mu\text{mol/L}$, or 20 $\mu\text{mol/L}$ curcumin decreased the IC₅₀ value of VCR and promoted VCR-mediated apoptosis in a dose-dependent manner. Curcumin (10 $\mu\text{mol/L}$) increased Rh123 accumulation and inhibited the efflux of Rh123 in SGC7901/VCR cells, but did not change the accumulation and efflux of Rh123 in SGC7901 cells. P-gp was overexpressed in SGC7901/VCR cells, whereas it was downregulated after a 24-h treatment with curcumin (10 $\mu\text{mol/L}$). Resistant cells treated with 1 $\mu\text{mol/L}$ VCR alone showed 77% lower levels of caspase-3 activation relative to SGC7901 cells, but the activation of caspase-3 in the resistant cell line increased by 44% when cells were treated with VCR in combination with curcumin. **Conclusion:** Curcumin can reverse the MDR of the human gastric carcinoma SGC7901/VCR cell line. This might be associated with decreased P-gp function and expression, and the promotion of caspase-3 activation in MDR cells.

Introduction

Although progress has been made in the treatment of patients with gastric cancer over the last two decades, a significant percentage of these patients fail to achieve complete remission or they relapse due to the phenomenon of multidrug resistance (MDR). In tumor cell lines, MDR is often associated with the overexpression of ATP-dependent

drug efflux proteins belonging to the superfamily of ATP-binding cassette (ABC) transporters: the 170 kDa P-glycoprotein (P-gp) encoded by the MDR1 gene and the 190 kDa multidrug resistance-associated protein-1 encoded by the MRP-1 gene^[1,2]. These proteins bind to and transport various structurally unrelated compounds to maintain their intracellular concentrations below cytotoxic levels.

Over the last two decades, considerable efforts have been

made to circumvent the problem with multidrug resistance. One approach is to use various resistance modulators to reverse MDR mechanisms and thus sensitize MDR tumor cells to anticancer drugs. Several compounds can reverse MDR, such as calcium channel blockers, CsA, MK571, buthionine sulfoximine (BSO) and genistein. However, the use of effective doses of these agents for systemic chemotherapy has been difficult because of their side effects and dose-limiting toxicity. Therefore, it is necessary to find new reversing agents that do not have the undesirable toxicological effects^[3].

Curcumin is a natural phenolic coloring compound that is found in the rhizomes of *Curcuma longa* L, commonly called turmeric. It has been widely used as a spice, to color cheese and butter, as a cosmetic^[4], and in some medicinal preparations^[5]. Curcumin has a wide range of biological and pharmacological activities, including antioxidant properties^[6], anti-inflammatory properties^[5], anti-mutagenic activity^[7], and anti-carcinogenic^[8], hypocholesterolemic^[9] and hypoglycemic effects^[10]. The safety of *C longa* and its derivatives has been studied in various animal models^[11], and it is clear that turmeric is not toxic even at high doses in laboratory animals. A single feeding of a 30% turmeric diet to rats did not produce any toxic effects. In a 24-h acute toxicity study, mice were fed doses of 0.5 g/kg, 1.0 g/kg, and 3.0 g/kg of turmeric extract daily. There was no increase in the mortality rate when compared with the controls in either study.

Because of its wide range of biological and pharmacological effects, and a lack of toxicity in animal models, curcumin has been examined to determine whether it interacts with MDR. *In vitro* studies have demonstrated that curcumin is able to modulate both the expression and function of P-gp in multidrug-resistant KB cells^[12,13] and primary cultures of rat hepatocytes^[14]. It is not clear whether curcumin can reverse the P-gp-mediated MDR of resistant gastric cancer cells. This led us to evaluate the effect of curcumin on the MDR of a vincristine (VCR)-resistant gastric cancer cell line (SGC7901/VCR). We found that treatment of drug-resistant SGC7901/VCR cells with curcumin increased their sensitivity to vincristine, which was consistent with decreased P-gp function and expression. In addition, curcumin was able to promote VCR-stimulated caspase-3 activation in SGC7901/VCR cells. It is possible that curcumin could be useful in the treatment of drug resistant gastric cancer cells as a MDR modulator.

Materials and methods

Reagents Curcumin, MTT, ethidium bromide (EB), acridine orange (AO) and rhodamine123 (Rh123) were obtained

from Sigma (St Louis, MO, USA); vincristine (VCR) was obtained from Farmitalia Carlo Erba (Milan, Italy); the anti-cleaved caspase-3 antibody was purchased from Cell Signaling Technology (Beverly MA); the anti-P-gp antibody and FITC-conjugated goat antimouse IgG were bought from Beijing Zhongshan Biological Technology Co (Peking, China).

Cells and cell cultures Gastric cancer cell line SGC7901 and VCR-resistant gastric cancer SGC7901/VCR cells were kindly provided by the Department of Gastroenterology, Xijing Hospital, the Fourth Military Medical University (Xi'an China). The MDR subline SGC7901/VCR was developed by exposing the parental SGC7901 cells to increasing concentrations of the anticancer drug VCR. All cells were cultivated in RPMI-1640 supplemented with 10% heat-inactivated fetal bovine serum at 37 °C in a 5% CO₂ atmosphere. The medium for SGC7901/VCR cells was further supplemented with VCR (0.25 μmol/L). Before their use in experiments, the SGC7901/VCR cells were cultured in a drug-free medium for 2 weeks.

Cytotoxicity assay by MTT Cells were seeded into 96-well plates at densities of 1×10⁴ SGC7901/VCR cells per well and 0.5×10⁴ SGC7901 cells per well, and incubated in a humidified atmosphere of 5% CO₂+95% air overnight, then normal cell medium containing either test compounds or solvents at the desired concentration were added. After 72 h incubation, 20 μL MTT (5 g/L in phosphate buffered saline, PBS) were added. The plates were incubated for 4 h and the blue dye formed was dissolved in 100 μL dimethyl sulfoxide (DMSO or Me₂SO). The absorbance at 570 nm was recorded using an ELISA reader. The survival rate was calculated as follows:

$$\text{Survival rate (\%)} = (T - B) / (U - B) \times 100\%$$

where T is the absorbance of treated tumor cells when exposed to drugs, U is the absorbance of untreated cells, B is the absorbance when neither the drug nor MTT was added (blank).

The 50% inhibitory concentration (IC₅₀) of 3 d exposure for a particular agent was defined as the drug concentration that causes in a 50% reduction in the number of cells compared with the untreated control. The IC₅₀ values were determined by Bliss software.

Apoptosis assay by flow cytometer using propidium iodide staining Cells were treated with various concentrations of VCR and curcumin for 24 h, and then harvested with 0.25% trypsin and washed with PBS. Cells (2×10⁵) were fixed in 70% ice-cold EtOH/PBS for 20 min on ice, and then washed with PBS and incubated in propidium iodide (PI) solution (69 mmol/L PI, 388 mmol/L sodium citrate, 100 μg/mL RNase A)

for 15 min at 37 °C. Cells were immediately analyzed with FAC scan flow cytometry (Becton Dickinson, San Jose, CA).

Apoptosis detection by morphological observation after AO/EB staining Cells were treated with various concentrations of VCR and curcumin for 24 h, and then harvested with 0.25% trypsin and resuspended in RPMI-1640 medium. After staining for 10 min with 4 mL of an AO (100 mg/mL)/EB (100 mg/mL) dye mixture, cells were visualized immediately under a fluorescence microscope.

Accumulation and efflux of Rh123 as measured by flow cytometry The measurement of Rh123 accumulation was performed as previously described^[15]. Briefly, cells (5×10^5 per sample) were incubated with 1 $\mu\text{g/mL}$ of Rh123 in the dark at 37 °C in 5% CO_2 for 120 min. Curcumin (dissolved in 0.1% DMSO) was added to cultures at the same time as Rh123. A final concentration of 0.1% Me_2SO (v/v) was used for all experiments and controls. Following Rh123 accumulation, cells were washed twice with ice-cold Hanks' Balanced Salt (HBSS) (without phenol red), placed in HBSS with 10% fetal bovine serum on wet ice. The green fluorescence of Rh123 was measured by using a FAC scan flow cytometer (Becton Dickinson).

For determination of Rh123 efflux, cells were loaded for 60 min with Rh123 in the absence of curcumin, and then the medium was replaced with Rh123-free medium containing curcumin, or the vehicle (Me_2SO). Following efflux intervals of 60 min, the medium was removed, and the cells were washed twice with ice-cold HBSS and prepared for flow cytometry as described earlier. As measured by Trypan blue exclusion, the cells remained viable during the Rh123 accumulation and efflux studies with curcumin.

Flow-cytometric analysis of the expression of P-gp and the activation of caspase-3 The cells were collected and adjusted to a concentration of 1×10^6 cells per mL and centrifuged at $1500 \times g$ for 5 min at 20 °C. The cell pellet was resuspended in 20 mL anti-P-gp or anti-active caspase-3 antibody (1:400), and then incubated at 4 °C for 30 min while being protected from light. After three washes with cold PBS containing 1% fetal calf serum (FCS), cells were incubated while being protected from light at 4 °C for 30 min with FITC-conjugated goat antimouse IgG (1:1000). Then cells were centrifuged at $1500 \times g$ for 5 min at 20 °C and were resuspended with PBS. The fluorescence intensity of cells was then analyzed by using a flow cytometer (Becton Dickinson).

Statistical analysis Data were expressed as mean \pm SD. Student's *t*-test was used to assess the statistical significance of differences. $P < 0.05$ was considered to be statistically significant.

Results

Cytotoxic effect of curcumin on SGC7901 and SGC7901/VCR cells We found that 1–20 $\mu\text{mol/L}$ curcumin was not obviously cytotoxic to gastric cancer cell line SGC7901 or VCR-resistant gastric cancer SGC7901/VCR cells (survival rate $>85\%$). However, 40–160 $\mu\text{mol/L}$ curcumin caused significant cytotoxicity in SGC7901 and SGC7901/VCR cells (Figure 1). Because treatment of the cells with 5 $\mu\text{mol/L}$, 10 $\mu\text{mol/L}$, and 20 $\mu\text{mol/L}$ curcumin had no significant effect on cell viability, we used these concentrations for further analysis.

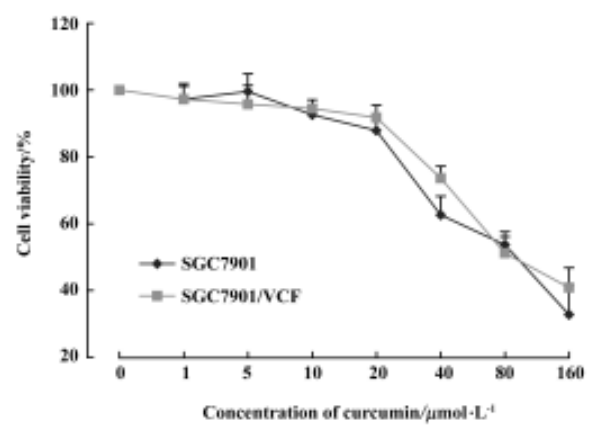

Figure 1. Effects of curcumin on SGC7901 and SGC7901/VCR cells growth. Cells were treated with various curcumin concentrations for 3 d. $n=3$ independent experiments. Mean \pm SD.

Effect of curcumin on VCR resistance in SGC7901/VCR cells The IC_{50} values of VCR were 0.49 $\mu\text{mol/L}$ and 22.27 $\mu\text{mol/L}$ in the sensitive and resistant lines, respectively, which indicated that the SGC7901/VCR cell line was 45 times more resistant to VCR than the parent SGC7901 cell line. As shown in Figure 2, when 5 $\mu\text{mol/L}$, 10 $\mu\text{mol/L}$, or 20 $\mu\text{mol/L}$ curcumin was added, the IC_{50} value of VCR in the SGC7901/VCR cell line significantly decreased from 22.27 $\mu\text{mol/L}$ to 11.60 $\mu\text{mol/L}$, 3.28 $\mu\text{mol/L}$, and 1.53 $\mu\text{mol/L}$, respectively, in a dose-dependent manner. After treatment with 20 $\mu\text{mol/L}$ verapamil (positive control), the IC_{50} value of VCR in the SGC7901/VCR cell line only decreased from 22.27 $\mu\text{mol/L}$ to 3.13 $\mu\text{mol/L}$.

Effect of curcumin on the apoptotic resistance of SGC7901/VCR cells Apoptotic cells were quantified as the proportion of cells that had a DNA content of less than 2N (sub- G_1 DNA content)^[16]. As shown in Figure 3, after treatment with 1 $\mu\text{mol/L}$ VCR for 24 h, the apoptosis of SGC7901/VCR cells was only 12.5%, but significant apoptosis was observed in the parental cells (61.4%, $P < 0.01$) at the same

Figure 2. Effect of curcumin on VCR resistance in SGC7901/VCR cells. The SGC7901/VCR cells were grown in medium with 0.1% Me₂SO (vehicle control), 5 μmol/L, 10 μmol/L, 20 μmol/L curcumin or 20 μmol/L verapamil (positive control) in the presence of different concentration of VCR. The cell viability was determined by MTT assay and the IC₅₀ of VCR was analyzed by Bliss software. *n*=3 independent experiments. Means±SD ^a*P*>0.05, ^c*P*<0.01 vs control group.

Figure 3. Effect of curcumin on the apoptosis of SGC7901/VCR cells. A, B: SGC7901/VCR cells were treated by 0.1% Me₂SO and 10 μmol/L of curcumin for 24 h, respectively; C, D: SGC7901 and SGC7901/VCR cells were treated by 1 μmol/L of VCR for 24 h, respectively; E, F, G: SGC7901/VCR cells were treated with 1 μmol/L of VCR combination with 5, 10, 20 μmol/L of curcumin for 24 h, respectively. The percentage of apoptotic cells was assayed by flow cytometer using propidium iodide staining.

drug concentration, indicating that SGC7901/VCR cells had apoptotic resistance to VCR. Curcumin, at concentrations of 5 μmol/L, 10 μmol/L, and 20 μmol/L for 24 h, promoted the VCR-mediated apoptosis of SGC7901/VCR cells from 12.3% to 20.5%, 32.7%, and 43.7%, respectively, in a dose-dependent manner. Moreover, AO/EB staining also revealed that curcumin promoted VCR-induced apoptosis in SGC7901/VCR cells (Figure 4). These results demonstrate that curcumin is able to overcome the apoptotic resistance of SGC7901/VCR cells to VCR.

Effect of curcumin on P-gp functions To examine the function of P-gp on the surface of viable cells, Rh123 accumulation and efflux studies were chosen because they appear to be sensitive indicators of P-gp activity when assayed by FAC scans^[17,18]. As shown in Figure 5A, Rh123 accumulation in SGC7901/VCR cells was obviously less than that in SGC7901 cells after being incubated with Rh123 for 120 min (*P*<0.01). After treatment with curcumin (10 μmol/L), Rh123 accumulation in SGC7901/VCR cells was increased by 40%; however, there was no change in SGC7901 cells. The effect of curcumin on the P-gp-mediated efflux of Rh123 in SGC7901 and SGC7901/VCR cells was also examined. As shown in Figure 5B, Rh123 retention in SGC7901/VCR cells was obviously less than that in SGC7901 cells. When SGC7901/VCR cells were treated with curcumin (10 μmol/L) for 60 min, Rh123 retention increased by 80% compared with the vehicle control (0.1% Me₂SO), indicating that curcumin could cause a significant decrease in Rh123 efflux. However, in SGC7901 cells, there was no change in Rh123 retention in the presence of curcumin.

Effect of curcumin on P-gp expression Cells were plated at a concentration of 6×10⁴ cells per mL in supplemented RPMI-1640. At 24 h after plating, the medium was replaced with fresh medium containing 0.1% Me₂SO (vehicle control) or 10 μmol/L curcumin. After 24 h, cells were collected to examine the expression of P-gp by flow cytometry. The expression rate of P-gp was 42.73% in SGC7901/VCR cells and 2.03% in SGC7901 cells. Treatment with curcumin (10 μmol/L) for 24 h led to downregulation of P-gp expression in MDR cells. The expression rates of P-gp in SGC7901/VCR cells decreased from 42.73% to 17.69% after curcumin treatment (Figure 6).

Effect of curcumin on the activation of caspase-3 in SGC7901/VCR cells The activation of caspase-3 was assessed by examining the expression of cleaved caspase-3 by flow cytometry. SGC7901/VCR cells treated with VCR (1 μmol/L) alone for 24 h showed 77% lower levels of caspase-3 activation than did SGC7901 cells (Figure 7). When cells were treated with VCR (1 μmol/L) in combination with

Figure 4. Apoptosis of SGC7901 and SGC7901/VCR cells detected by AO/EB staining. A, SGC7901 cells; B, SGC7901 cells treated by 1 $\mu\text{mol/L}$ of VCR for 24 h; C, SGC7901 /VCR cells; D, SGC7901 /VCR cells treated by 1 $\mu\text{mol/L}$ of VCR for 24 h; E, SGC7901/VCR cells treated by 1 $\mu\text{mol/L}$ of VCR combination with 20 $\mu\text{mol/L}$ of curcumin for 24 h. Apoptotic cells detected by morphological observation after AO/EB staining.

Rh123 (1 $\mu\text{g/mL}$) was added, and the cells were incubated for 120 min. (B) Cells were incubated with Rh123 for 60 min, washed, and resuspended in medium with 10 $\mu\text{mol/L}$ curcumin or vehicle control (0.1% Me_2SO) for 60 min. Rh123 fluorescence was measured using FAC scan. Means \pm SD from three independent experiments. ^c $P < 0.01$ vs SGC7901 cells. ^f $P < 0.01$ vs vehicle control.

Figure 6. Effect of curcumin on the expression of P-gp in SGC7901/VCR cells. The level of P-gp expression, following treatment with 0.1% Me₂SO (vehicle control) or curcumin (10 $\mu\text{mol/L}$) for 24 h, was determined in cells by flow cytometer. Means \pm SD from three independent experiments. ^c P <0.01 vs SGC7901 cells. ^f P <0.01 vs vehicle control.

Figure 7. Effect of curcumin on the activation of caspase-3 in cells. The level of caspase-3 activation, following treatment with VCR (1 $\mu\text{mol/L}$) in the presence or absence of 0.1% Me₂SO (vehicle control) and curcumin (10 $\mu\text{mol/L}$) for 24 h, was determined by flow cytometer. Means \pm SD from three independent experiments. ^c P <0.01 vs SGC7901 cells. ^f P <0.01 vs VCR treatment alone.

curcumin (10 $\mu\text{mol/L}$) for 24 h, the activation of caspase-3 was increased by 44% (P <0.01) in the SGC7901/VCR cell line.

Discussion

The development of P-gp-dependent multidrug resistance in tumors is a major obstacle for successful chemotherapy^[19]. For this reason, there is an increasing search for new reagents that inhibit the expression and/or function of P-gp to overcome MDR. Recent studies have shown that curcumin is able to modulate the expression and function of P-gp, and therefore it might be an possible new agent for the chemosensitization of cancer cells^[12-14]. VCR-resistant gas-

tric cancer SGC7901/VCR cells have been shown to express P-gp at a high level, but P-gp was not expressed in the drug-sensitive cells (SGC7901)^[20]. Thus, in the present study, we wanted to demonstrate the possibility of using curcumin in gastric cancer as an MDR modulator.

We showed that curcumin enhanced the toxicity of VCR in the MDR cell line SGC7901/VCR. The SGC7901/VCR cell line was 45 times more resistant than the parental SGC7901 cell line. Curcumin, at concentrations of 5.0 $\mu\text{mol/L}$, 10.0 $\mu\text{mol/L}$ and 20.0 $\mu\text{mol/L}$, is able to decrease the IC₅₀ of VCR to SGC7901/VCR cells in a dose-dependent manner. These data indicate that curcumin is able to reverse MDR in the SGC7901/VCR cell line.

The potent MDR-reversing capacity of curcumin in tumor cells was further confirmed by its ability to enhance VCR-induced apoptosis in MDR SGC7901/VCR cells. Apoptotic and anti-apoptotic character are also strongly related to drug sensitivity and resistance. A number of tumor cells have been reported to undergo apoptotic cell death when treated with such chemotherapeutic agents as etoposide, camptothecin, cisplatin, Ara-C, mitomycin C, adriamycin, and vincristine. These findings indicate that apoptosis in tumor cells plays a critical role in chemotherapy-induced tumor cell killing, and also suggest that blockade of the apoptosis-inducing pathway could be another mechanism for MDR to chemotherapy^[21]. VCR, at a concentration of 1 $\mu\text{mol/L}$, did not induce apoptosis in SGC7901/VCR cells, but significantly induced apoptosis in the parental cells, which indicated that the MDR SGC7901/VCR cell line was also apoptosis-resistant. In our study, we found that curcumin could promote the VCR-mediated apoptosis of MDR SGC7901/VCR cells, which suggests that curcumin could overcome the apoptosis-resistance of MDR cells.

The experiment for evaluating the effect of curcumin treatment on P-gp expression determined that curcumin clearly inhibited P-gp expression in SGC7901/VCR cells. The uptake and/or efflux of Rh123 is frequently used for assays of P-gp in tumor cells^[22,23]. In the present study, we also investigated the effects of curcumin on the P-gp function of SGC7901/VCR cells. Curcumin caused a substantial increase in the accumulation of Rh123 in SGC7901/VCR cells, and inhibited the efflux of Rh123, but had no effect on drug-sensitive cells (SGC7901), which do not overexpress P-gp. Because Rh123 is known to be a good substrate for P-gp, we suppose that curcumin modulates intracellular Rh123 level by inhibiting P-gp. It is unlikely that curcumin acts by downregulating P-gp expression because the time of exposure of cells to curcumin in these experiments was short (1–2 h). Taken together, our data indicate that treatment of

drug-resistant SGC7901/VCR cells with curcumin increased their sensitivity to VCR, which is consistent with an increase in intracellular drug concentration by decreasing P-gp function and expression.

Although P-gp is best known for its ability to efflux a variety of amphiphilic substances across plasma membranes, new functions are emerging. Transfected MDR1 in Chinese hamster ovary fibroblasts results in a decrease in growth factor withdrawal-induced apoptosis^[24]. P-gp has been shown to inhibit apoptosis induced by anti-fas, ultraviolet radiation, and tumor necrosis factor in both lymphoid and myeloid cell lines^[25,26], to resist spontaneous apoptosis in acute myeloid leukemia (AML) blasts^[27,28], and is implicated in the inhibition of ceramide-induced apoptosis in TF-1 cells^[29]. P-gp has also been shown to protect kidney proximal tubule cells from cadmium- and oxygen species-induced apoptosis^[30]. Therefore we suggest that, besides exporting a wide range of xenobiotics from cells, the multidrug transporter P-gp may also confer resistance to apoptosis from different stimuli. Our results suggest that the ability of curcumin to promote VCR-induced apoptosis in drug-resistant SGC7901/VCR cells might be associated with a decrease in P-gp function and expression.

Recent studies have shown that functional P-gp plays a role in regulating cell death not only by removing drugs from the cell, but also by inhibiting the activation of proteases involved in apoptotic signaling (caspase-8)^[25] and execution (caspase-3)^[25,26]. In agreement with this, our data indicate that SGC7901/VCR cells inhibited VCR-induced caspase-3 activation. However, treatment of drug-resistant SGC7901/VCR cells with curcumin promoted VCR-induced caspase-3 activation. The results of a previous study have demonstrated that curcumin overcomes P-gp-mediated multidrug resistance through induction of caspase-3 activation^[31]. Our results indicate that the MDR reverse function of curcumin may be associated with promoting anticancer agent-induced caspase-3 activation.

Summing up, our results suggest that curcumin could be considered a promising chemosensitizer of MDR in gastric cancer.

Abstract

Aim: To search genes sensitivity to the anti-cancer drugs navelbine (NVB) and docetaxel (DOC) in small-cell lung cancer (SCLC) and non-small-cell lung cancer (NSCLC) cell strains. **Methods:** The sensitivity of 4 strains of SCLC and 6 strains of NSCLC to NVB and DOC was evaluated using the MTT assay. The expression of 1291 sensitive-related genes to the anti-cancer drugs in 10 lung cancer cell strains was measured using cDNA macroarrays and the relationship was analyzed. **Results:** In total, there were 56 ($r \geq 0.4$) genes sensitive to NVB and DOC. For NVB: 36 genes were sensitive to NVB, 20 co-expressed genes between the SCLC+NSCLC set and the NSCLC set; 27 expressed genes and 7 specially expressed genes in the SCLC+NSCLC set; and 29 expressed genes and 9 specially expressed genes in the NSCLC set. For DOC, 50 genes were sensitive to DOC, 12 co-expressed genes between the SCLC+NSCLC set and the NSCLC set; 24 expressed genes and 12 specially expressed genes in the SCLC+NSCLC set; and 38 expressed genes and 26 specially expressed genes in the NSCLC set. The genes sensitive to NVB and DOC in lung-cancer cell stains were mainly divided into the following 4 categories: signal transduction molecules, cell factors, transcription factors and metabolism-related enzymes and inhibitors. **Conclusions:** There were obvious differences in genes related to NVB and DOC between SCLC and NSCLC cell strains, but the same as categories of function.

Introduction

Chemotherapy failure in lung cancer is usually caused by multidrug resistance. Discovering ways to overcome resistance to chemotherapeutic drugs is the main problem to be resolved. There are different mechanisms of resistance to different drugs, while various mechanisms can produce resistance to the same drug. Many of these mechanisms, such as drug transition protein (CABC and lung cancer resistant protein), change the molecular target, the state of detoxifying enzymes, the obstruction of apoptosis, the repairing ability of DNA or the activity of oncogenes. Much work has been reported on the function of drug resistant genes in lung cancer using calcium antagonists and the MTT assay, as well as other methods, but there are few reports about the relationship between anticancer drug sensitivity and related genes.

Gene chip technology has provided a powerful tool to study the expression profile of genes and their related genes, providing much better data than the previous gene-monitoring techniques. The cDNA gene chip techniques can be divided into 2 types according to the different density of hybridized genes: (i) macroarrays^[1]; and (ii) microarrays^[2]. Macroarrays are better than microarrays in that they are economical, have a high level of repeatability and therefore accuracy, and they do not require special instruments. We therefore used macroarrays to measure the gene expression profiles of 10 lung cancer cell strains. We also measured drug sensitivity to navelbine (NVB) and docetaxel (DOC) in 10 lung cancer cell strains using the MTT assay, and analyzed the relationship between them. The precision of our results was then confirmed by reverse transcription-polymerase chain reaction (RT-PCR). This outcome has significance for clinical therapy.

Materials and methods

Cell strains There were 11 cell strains used in the experiments, of which 6 were NSCLC strains (LK-2, PC-7, PC-9, PC-14, A549 and Lu65) and 4 were SCLC strains (H69, N231, Lu135 and SBC-3); BET2A was used as a control. All cell strains were cultured in RPMI 1640 supplemented with 5% fetal bovine serum at 37 °C in humidified air containing 5% CO₂.

Concentration adjustment of anticancer drugs The concentration of NVB was adjusted to within the range 0.005 µg/mL–10 µg/mL using RPMI 1640, and DOC was adjusted to within the range 0.005 µg/mL–50 µg/mL using dimethylsulphoxide (DMSO).

Measurement of cell sensitivity to anticancer drugs Sensitivity to the anticancer drugs was assessed using the MTT assay^[3]. The IC₅₀ was calculated using the Reed-Muench method^[4], while the index of sensitivity was calculated as: IC₅₀/peak plasma concentration (PPC).

Anticancer drug sensitivity-related genes Genes related to anticancer drug sensitivity were assessed using cDNA microarray.

Isolation of mRNA from total RNA Total RNA was isolated from 1×10⁸ cells, which were grown in suspension, at A₂₆₀/A₂₈₀ ratio∈[1.8, 2.0]. mRNA was isolated by incubation with oligo-dT-magnetic beads (Toyobo Co, Osaka, Japan), followed by washing to remove non-specific binding.

Reverse transcription-polymerase chain reaction and labeling of the mRNA polyA⁺RNA 0.8 µg was picked and RT-PCR was carried out using the RT, Rever TraAce (Toyobo Co, Osaka, Japan). The probes were labeled with biotin by incorporation of biotin-16-dUTP during the synthesis of cDNA.

Making the filters Gene Navigator cDNA Array System-Cancer Selected (Geneticlab, Sapporo Co, Osaka, Japan) was used. Anti-cancer drug-sensitivity genes (1291 species) were spotted onto the filter in duplicate. There were 280 non-mammalian genes and 49 housekeeping genes as negative controls^[5]. A list of the set of genes on the filter is shown on the web site(<http://www.toyobo.co.jp/seihin/xr/product/genenavi/genenavigator.html>).

cDNA array hybridization Filters were preincubated in 30 mL Perfect Hyb (Toyobo Co, Osaka, Japan) at 68 °C for 30 min. Biotin-labeled probes (100 µL) were denatured at 100 °C for 5 min before being added to the prehybridization solution. The filters were incubated in the hybridization mixture at 68 °C for 20 h, then the filters were washed 3 times at 68 °C for 10 min using 30 mL 2×SSC/0.1% sodium dodecylsulfate (SDS) and 0.1×SSC/0.1% SDS.

Signal measuring After washing the filters, specific signals on the filters were detected using the Imaging High Chemifluorescence Detection Kit (Toyobo Co, Osaka, Japan). Vistra ECF substrate (AttoPhos) (Amersham Pharmacia Biotech, Uppsala, Sweden) was used as the chemifluorescence substrate. Substrate images were acquired by Fluorimager (Amersham Pharmacia Biotech, Uppsala, Sweden).

Measuring gene expression The drugs were clustered on the basis of Pearson correlation coefficients relating their patterns across the 10 cell strains to the expression patterns of genes. These correlation coefficients were calculated for each combination of gene and drug by taking the level of expression of the gene in each cell line, enhancing it by the corresponding sensitivity of the cell to the drug, summing the results over all of the cell strains and renormalizing. This produced 1291 correlation coefficients (1 for each gene and target) for each of the 2 drugs. We then clustered the 2 drugs on the basis of these correlation coefficients.

Computer soft analysis “A” was designed as a drug active model (the drug sensitivity of 10 lung cancer cell strains to NVB and DOC-IC₅₀), Tr was the related data model of the level of mRNA expression (the expression of 1291 genes from 10 lung cell strains), and gene expression data included the rate of expression intensity of measuring gene and BET2A cells.

Statistical analysis The AT-clustered image map (CIM; Figure 1 and Figure 2) summarizes the relationship between drug activity and gene expression by means of the clustering method. In this CIM, drugs were together with related genes, and genes were also together with related drugs. Each color reflects the connection of one gene and one drug. For example, a red point (high positive Pearson correlation coefficient) indicates that cell strains with more expressed genes tend to be more sensitive to the agent; a blue point (high negative Pearson correlation coefficient) indicates the opposite; a yellow point and a green point indicate a lower correlation.

Expression of clusterin, galectin-1 mRNA Following RT-PCR, Gernerunner software was used to design specific primers (Table 1), and the specificity of the primer was proved through the BLAST(Basic Local Alignment Search Tool) internet database. Total RNA was extracted from LK-2 and A549 cell lines according to methods described previously and the first chain was finished through RT-PCR. b-Actin was used as an internal control.

The PCR amplification products were visualized by bromide-ethyl pastille following sodium dodecyl sulphate-polyacrylamide gel electrophoresis with the DL-2000 molecular weight standard (Generunner).

Figure 1. Comparison of the effects of docetaxel (DOC) and navelbine (NVB) on the clustered image map in 10 lung cancer cell strains.

Figure 2. Comparison of the effects of docetaxel (DOC) and navelbine (NVB) on the clustered image map in NSCLC. Gene expression analysis for genes sensitive to DOC and NVB in lung cancer cell strains is detailed in Table 3 and Table 4.

Results

Comparison of the sensitivity of the lung cancer cell strains to navelbine and docetaxel The anti-cancer drug sensitivity of the lung cancer cell strains to NVB was greater than that to DOC (Table 2).

Comparing the clustered image map of the drugs with the clustered image map of genes The study related the 1291 gene expression profiles from the CIM of the lung cancer cell strains to NVB and DOC (Figure 1 and Figure 2). In the 10 lung cancer cell strains, there were more genes positively correlated to DOC than to NVB, but there were more genes negatively related to NVB than to DOC. Of the 6 NSCLC cell strains, there were more genes that expressed either positive or negative correlations to DOC than to NVB.

NSCLC (PC7, PC14, PC9, A549, LK-2, LU65)

SCLC (Lu135, N231, H69, SBC-3)

Figure 3. Gene expression of *Clusterin*, *Galectin-1*, *TIMP-1* and *metallothionein* in NSCLC (PC7, PC14, PC9, A549, LK-2, LU65) cell lines were verified by reverse transcription polymerase chain reaction. 1, PCR marker, M; 2, normal lung, NL; 3–10, NSCLC. (A) PCR product of β -actin. Reaction conditions: 94 °C, 3 min; 94 °C, 20 s; 56 °C, 30 s; 72 °C, 50 s; 72 °C, 10 min for extension. After 23 cycles, expression could be seen in NL and 8 NSCLC. (B–E) PCR products of *TIMP-1*, *Clusterin*, *Galectin-1* and *metallothionein*, with β -actin as an internal control. Reaction conditions: 94 °C, 3 min; 94 °C, 40 s; 60 °C, 40 s; 72 °C, 40 s, 72 °C, 10 min for extension. 22, 26, 26 and 32 cycles, respectively. (B) *Clusterin* was not expressed in the A549 and LK-2 cell lines, but was expressed weakly in the GLC and PG cell lines. (C) *Galectin-1* was not expressed in the A549 and LK-2 cell lines, but was expressed weakly in the 95C cell line.

- 5 The *MDM2* gene was positively related to NVB in the NSCLC and SCLC. The *CaMKK* gene was positively related to NVB only in the NSCLC, *MDM2* and *CaMKK* were both positively related to DOC in the SCLC.
- 6 *GSK-3 β* and *VHL2* were both negatively related to NVB

- and DOC in the SCLC.
- 7 *Elongin A*, *MMP-7* and *Galectin-3* were negatively related to NVB in the SCLC. *Elongin A*, *MMP-7*, *Galectin-3* were negatively related to DOC in the NSCLC, but the *AT2* gene was positively related to NVB in the SCLC.

- 8 8 genes positively related to DOC in the SCLC. They were *TAK1*, *IFN- γ* , *Phospholipase D*, *ENA-78*, *GSTT1*, *Id4*, *CD8 α* and *GCP-2*.
- 9 9 genes negatively related to DOC in the NSCLC. They were *Rak*, *XO*, *P300*, *LIFR*, *C/EBP γ* , *GSTMIB*, *Smad4*, *Thymosin b* and *CD29*.
- 10 *ICAM-2* and *Ataxia Telangiectasia Group D-Associated Protein* were positively related to DOC in the NSCLC.
- 11 *ICAM-2* and *Ataxia Telangiectasia Group D Associated Protein* and NSCLC were positively related to DOC.

The classification of gene sensitivity to NVB and DOC in lung cancer cell strains is shown in Table 7. They were divided into 4 types: signal transduction molecules, cell factors, transcription factors, and metabolism-related enzymes and inhibitors.

Verification In order to verify the reliability of hybridization, GLC, L18, 95C, PG, PAa, 95D, A549 and LK-2 cell lines were chosen. cDNA of *Galectin-1*, and *Clusterin*, which were downregulated in expression and selected with cDNA macroarray, was used in semi-quantitative RT-PCR. The results are shown in Figure 3A–3C.

Discussion

The morbidity of lung cancer is higher now than in the past, and lung cancer therapy is less sensitive to chemotherapy than other kinds of cancer. Because most patients are in the middle or late stages when cancer is found, the rate of surgical success is low. Therefore, chemotherapy is a commonly integrated treatment for lung cancer patients. NVB and Doc are both new anticancer drugs act on microtubules^[6–9]. NVB can inhibit the assembly of tubulin and act on the mid-stage of mitosis, leading to stasis of cancer cell growth. Because of its special anticancer function, in December 1994 the FDA (Food and Drug Administration) approved NVB in combination with CDDP for use as a first-line therapy for advanced NSCLC patients^[10]. As for DOC, its mechanism is to promote the aggregation of tubulin and to inhibit its disassembly, preventing cells from entering into the growth phase. It is widely used in cancer treatments, mainly for lung cancer and breast cancer in advanced stages^[11].

In clinical cases there are usually different sensitivities to anticancer drugs. The same chemotherapeutic medicine is often used for patients with different types of cancer cells, even for different individuals with the same type of cancer cells. This is due to such factors as the different biological characters of tumors, different patients and different drug responses.

There are many methods to determine sensitivity to anti-

cancer drugs by analyzing gene expression. Only 1 gene at a time can be tested through northern blotting, which has an obvious disadvantage in automation. Other methods include differential display, cDNA sequence analysis and SAGE, but they also have many disadvantages. For any organism, we can analyze many different drug responses by means of DNA gene chip technology, and obtain more reliable results than with other methods. We conclude that other single element methods are less advantageous than the DNA gene chip technique^[12–15].

A recent study showed that drug sensitivity to DOC is concerned with P-GP (P Glucose protein), and changes in target molecules, changes in signal transduction system, cell-control factors and apoptosis-related factors. In addition, the metabolism of DOC in the body is primarily through the sub-family of CYP3A proteins. The activity of enzyme in this family varies greatly among individuals, and the factors sensitive to NVB have not yet been reported.

We have examined the genes sensitive to DOC and NVB in 10 lung cancer cell strains using cDNA macroarrays. The results showed that there were 56 genes significantly related to NVB and DOC ($r \geq \pm 0.4$). Among them, 36 were related to NVB, 20 were co-expressed in the NSCLC set and the NSCLC+SCLC set; 27 were related in the NSCLC+SCLC set and 7 were specifically related genes; 29 were related genes in the NSCLC set, and 9 were specifically related genes. There was a total of 50 genes related to DOC and 12 co-expressed genes related in the NSCLC and NSCLC+SCLC sets; 24 related genes in the NSCLC+SCLC set and 12 specifically related genes. In the NSCLC set there were 38 related genes and 26 specifically related genes.

The genes described above are mainly signal transduction molecules, metabolism-related enzymes and inhibitors, cell factors and transcription factors. At the same time, *Clusterin* and *Galectin-1* genes, which were downregulated in expression in LK-2, were tested using RT-PCR. The results were in agreement with those obtained through cDNA macroarray. However, with the A549 cell line, the cDNA macroarray did not show the same downregulated expression as with RT-PCR. Genes screened by cDNA macroarray therefore need to be further tested using other methods.

In this study, we identified the relationship among the gene expression profiles of 10 lung cancer cell strains, which focused on 1291 genes and drug sensitivity to DOC and NVB. This study may help to explain the mechanisms of action of NVB and DOC, provide theoretical evidence in the search for new ways to overcome drug resistance, discover new anticancer drugs by providing new targets, and facilitate individualized therapy regimens and increased response

rates. The aim of our future work is to identify and analyze these new genes screened for drug sensitivity, especially those not known to us previously.

Abstract

Hepatocellular carcinoma (HCC) is one of the most common cancers in the world. Surgical resection has been considered the optimal treatment approach, but only a small proportion of patients are suitable candidates for surgery, and the relapse rate is high. Approaches to prevent recurrence, including chemoembolization before and adjuvant therapy after surgery, have proven to have a limited benefit; liver transplantation is successful in treating limited-stage HCC because only a minority of patients qualify for transplantation. Therefore, new therapeutic strategies are urgently needed. Because in addition to the classical genetic mechanisms of deletion or inactivating point mutations, epigenetic alterations, such as hyperacetylation of the chromatin-associated histones (responsible for gene silencing), are believed to be involved in the development and progression of HCC, novel compounds endowed with a histone deacetylase (HDAC) inhibitory activity are an attractive therapeutic approach. In particular, pre-clinical results obtained using HA-But, an HDAC inhibitor in which butyric acid residues are esterified to a hyaluronic acid backbone and characterized by a high affinity for the membrane receptor CD44, indicated that this class of compounds may represent a promising approach for hepatocellular carcinoma treatment.

Introduction

Hepatocellular carcinoma (HCC) is currently the fifth most common solid tumor worldwide and the fourth most common cause of cancer-related death^[1]. The incidence of HCC is approximately 1 000 000 cases worldwide; and although in Europe and the USA the incidence of HCC is 4/100 000, it is 120/100 000 in Asia and Sub-Saharan Africa^[2]. In particular, statistical data from the last decade show that HCC is the second most prevalent cause of cancer deaths in men and the third most prevalent cause in women in mainland China, with more than 500 000 new cases every year^[3,4]. Moreover, a rise in the incidence of disease and mortality from HCC, most likely reflecting the increased prevalence of hepatitis C virus (HCV), has recently been observed also in Japan, Western Europe and the USA^[5,6].

The major etiologies of HCC are well defined, and some of the steps in its molecular pathogenesis have been elucidated. HCC arises commonly, but not exclusively, in

the context of liver injury, which leads to inflammation, hepatocyte regeneration, liver matrix remodeling, fibrosis and, ultimately, cirrhosis. In fact, cirrhosis represents the most important risk factor for HCC (70%–90% of cases of HCC develop in cirrhotic liver) and it is principally imputable to chronic viral hepatitis B and/or C (HBV, HCV), although other risk factors are alcohol abuse, metabolic liver disease (such as hemochromatosis, α_1 -antitrypsin deficiency and steatosis), androgenic steroid use and aflatoxin exposure^[7]. In particular, chronic HBV infection is strongly associated with hepatocellular cancer in China^[8], while HCV infection and subsequently cirrhosis is the leading cause of chronic hepatitis and HCC in Japan and Western countries^[9].

Current trends in the management of HCC

The rates of early detection, treatment and prevention of HCC are poor, and a majority of patients (70%–85%) are affected by advanced or unresectable disease. Despite the

many treatment options, the prognosis of HCC remains dismal. In fact, even for those patients who undergo resection, the recurrence rate can be as high as 50% at 2 years^[10,11] and a meta-analysis that evaluated the results of 37 randomized clinical trials of systemic and regional chemotherapy in more than 2000 HCC patients concluded that non-surgical therapies were ineffective or minimally effective^[12]. In addition, most published studies of systemic chemotherapy report a response rate ranging from 0% to 25%; treatment failure is most likely due to the particular resistance to cytostatic agents displayed by HCC cells^[12,13], which are known to express the multidrug-resistant gene MDR-1^[14]. Liver-directed therapies, such as transarterial chemoembolization or percutaneous ethanol injection, are palliative treatments, with encouraging results only for patients with small HCC^[15,16].

Alternative therapeutic approaches have been investigated, but with disappointing results. The effectiveness of hormone therapy with anti-estrogens, anti-androgens or somatostatin analogues has been studied in several trials^[17,18], but these treatments were found to be generally ineffective or to not produce reproducible results^[19].

At present, orthotopic liver transplantation is considered the only curative treatment option for HCC, bringing about an increase in the 5-year survival rate from the historical 20%–36% to the recent 61%, which is likely related to adoption of the Milan criteria at US transplantation centers^[23,24]. However, most patients with cirrhosis are not generally considered good candidates for liver transplantation, or they remain on the waiting list until they die from tumor progression or cirrhosis-related complications.

An understanding of tumor biology and the key molecular events leading to HCC development is therefore fundamental for identifying new therapeutic strategies that are effective against HCC but not toxic to normal cells, and are well-tolerated by the typical patient with underlying cirrhosis.

HCC biology and targeted therapies

In most types of cancer, hepatocarcinogenesis is a multi-step process involving different genetic alterations, including cellular oncogene activation, tumor suppressor gene inactivation (possibly in cooperation with genomic instability), DNA repair defects, overexpression of growth and angiogenic factors, and telomerase activation, which ultimately lead to malignant transformation of the hepatocyte^[20]. For a more comprehensive review of the complex molecular pathogenesis of HCC the reader may refer to some excellent papers including those by Ozturk^[21], Moradpour and Wands^[22], Thorgeirsson and Grisham^[7] and Suriawinata and Xu^[23].

On the basis of knowledge of the molecular pathways that are associated with the malignant phenotype, new and promising agents, which are specifically targeted to tumor cell receptors or signaling events, are emerging. This is the case for the selective growth factor receptors, tyrosine kinase inhibitors, the fundamental role of which is to block signal transduction^[24,25], or farnesyltransferase inhibitors, which counteract oncogene *ras*-mediated signaling^[26]. Moreover, to stimulate an immunological response against liver tumors, other agents have been tested, for example interferon- α , which can significantly prolong the survival of HCC patients when given at high doses^[27], interleukin-2, which can produce objective remission when given alone^[28] or in combination with melatonin^[29], or tumor necrosis factor- α -related apoptosis-inducing ligand (TRAIL), which has not yet been tested in humans, but has been found to be effective in pre-clinical experiments^[30].

Gene therapy is a new and promising therapeutic strategy that is based on the introduction of genetic material, for example natural genes, chimeric genes or subgenomic molecules, into cells in order to generate a beneficial effect against disease^[31]. So far, a variety of gene therapy approaches have been designed to treat liver cancer, including the replacement of functional tumor suppressor genes^[32], inhibition of oncogenes^[33], selective prodrug activation within the tumor^[34], stimulation of antitumor immunity^[35] and inhibition of tumor vascularization^[36], although encouraging results have been mostly only obtained in pre-clinical models.

Histone acetylation status and HCC development

In addition to the classical genetic alterations (chromosomal deletions and rearrangements, and gene amplifications and mutations) first recognized as being responsible for hepatocarcinogenesis, molecular approaches have recently been used to identify alterations in the epigenetic control of gene transcription that positively mediate cellular proliferation or inactivate tumor suppressor genes^[37]. In particular, acetylation, methylation and phosphorylation of the N-terminal lysine tails of the chromatin core histones have been found to play a critical role in post-translational modifications, suggesting the hypothesis of a histone “code”^[38]. Among these modifications, the acetylation status of the histones constitutes the major epigenetic alteration, and is fundamentally involved in transcriptional regulation^[39].

The acetylation level of histones is determined by the equilibrium between the activities of two groups of enzymes, histone acetyltransferases (HAT) and histone deacetylases

(HDAC), which respectively add or remove acetyl groups from the lysine tails^[40]. Hypoacetylated histones are associated with a more packaged chromatin structure and with suppression of gene transcription, whereas highly acetylated histones activate gene transcription by releasing the chromatin structure^[41]. At present, eleven mammalian HDAC have been identified, and these have been ordered into 3 classes^[42]. Class I deacetylases (HDAC 1, 2, 3, and 8) share homology in the catalytic sites; class II includes HDAC 4, 5, 6, 7, 9, 10, and 11, of which HDAC 4, 5, 7, and 9 share homology in the C-terminal catalytic domain and N-terminal regulatory domain, whereas HDAC11 contains conserved residues in the catalytic core regions shared by both classes I and II, and HDAC6 and HDAC10 have two regions that are homologous with the class II catalytic site. The third class of HDAC is the conserved nicotinamide adenine dinucleotide-dependent Sir2 family. Increasing evidence indicates that HDAC are not redundant in function and distribution: class I HDAC are found exclusively in the nucleus, whereas class II HDAC shuttle between the nucleus and cytoplasm in response to certain cellular signals^[43]. HDAC do not bind directly to DNA, but are recruited by protein complexes that can differ in their subunit composition.

The balance between HAT and HDAC activity in regulating DNA folding and gene transcription can be disrupted

by HDAC inhibitors, which act by blocking HDAC enzymes; HDAC inhibition leads to lysine residue hyperacetylation and to DNA conformation changes (Figure 1). Inaccessible promoter regions thus become available targets for transcription factors, which activate the re-expression of several genes, including those involved in cell growth arrest, differentiation and apoptosis^[44,45].

HDAC inhibitors and cancer treatment

Several lines of evidence suggest that inappropriate transcriptional activation commonly occurs in the formation of many types of cancer and that an imbalance between HAT and HDAC activity may be responsible for the alteration. Because HDAC dysregulation has been demonstrated in many solid cancers, including hepatocellular carcinoma, HDAC inhibitors have been investigated for their therapeutic potential to reprogram transcription and inhibit tumor cell growth and progression^[46]. Historically, sodium butyrate (NB), which is normally present in the human colon as a product of the metabolic degradation of complex carbohydrates by colonic bacteria, was the first compound found to cause an increase in histone acetylation^[47] and to regulate the physiological differentiation of colonocytes^[48], suggesting its possible use in the prevention of colorectal cancer

Figure 1. Schematic diagram of the activity of the histone acetyltransferase (HAT) and histone deacetylase (HDAC) enzyme inhibitors, which lead to chromatin hyperacetylation or hypoacetylation, respectively. HDAC inhibitors such as phenylbutyrate (BPA), trichostatin A (TSA) and HA-But act by restoring the re-expression of several genes, including those involved in cell growth arrest, differentiation and apoptosis.

and the treatment of premalignant and neoplastic lesions. Many other HDAC inhibitors have since been identified, which belong to several chemical structure classes: 1) short-chain fatty acids, of which NB represents the prototype; 2) hydroxamic acids, including trichostatin A (TSA)^[49] and a series of hydroxamic acid-based hybrid polar compounds, such as suberoylanilide hydroxamic acid (SAHA)^[50]; 3) cyclic tetrapeptides, which may or may not contain the 2-amino-8-oxo-9,10 epoxy-decanoyl moiety (trapoxins A and B^[51], FK228/depsipeptide^[52] and apicidin^[53]); and 4) benzamides (MS-275)^[54] and others, such as valproic acid^[55] and oxamflatin^[56].

Several of these compounds, including SAHA, MS-275 and FK228/depsipeptide, are undergoing phase I and II clinical trials to examine their potential use as anticancer drugs for solid and hematological tumor treatment either as monotherapies or in combination with other cytotoxic and differentiation agents. For example, in a phase I clinical trial, SAHA was well tolerated when administered either intravenously or orally, and it was found to have antitumor activity in heavily pre-treated patients with advanced solid and hematological tumors. Furthermore, SAHA has good bioavailability when administered orally and it induces objective responses in patients with prior therapy-resistant cutaneous T cell lymphomas^[57]. Similarly, a phase II trial demonstrated that FK228/depsipeptide was active against refractory neoplasms^[58] and chronic lymphocytic and acute myeloid leukemia^[59]. MS-275 is also well-tolerated when orally administered in patients with refractory or relapsed hematological malignancies, and it is biologically active in terms of histone acetylation^[60]. However, none of these studies have been specifically focused on hepatocellular carcinoma, and in addition, despite the encouraging results obtained for several types of tumors, these drugs do not achieve the major goal in cancer therapy: to selectively target anti-cancer molecules to organs or compartments that harbor tumor cells.

HA-But as an HDAC inhibitor target delivery

As mentioned earlier in this paper, NB was the first compound found to cause an increase in histone acetylation^[50], so given its antiproliferative and differentiation activities, together with a relative absence of systemic toxicity, it was a candidate for the prevention of colorectal cancer and a therapeutic agent for the treatment of pre-neoplastic and neoplastic lesions. Unfortunately, the first clinical study undertaken using high doses of NB resulted in only a partial and temporary remission, principally due to the relatively low potency of the drug and a low plasma concentration that

was not sufficient to inhibit cell growth, but high enough to induce side-effects^[61]. Both to overcome chemical constraints that restrict the clinical application of NB, and to specifically target the compound to cancer cells, a bioconjugate (HA-But), in which a hyaluronic acid backbone was used as a suitable carrier for butyric residues, was developed^[62].

Hyaluronic acid (HA), also referred to as hyaluronan, is a polysaccharide molecule whose repeated disaccharide motif comprises *D*-glucuronic acid and *D*-*N*-acetylglucosamine linked together through alternating β -1,4 and β -1,3 glycosidic bonds. HA is present in all vertebrates and is a major constituent of the extracellular matrix, where it is organized, by specific interactions, with other matrix macromolecules^[63]. HA has a high rate of turnover (in the bloodstream its half-life is 2–5 min) because it is rapidly captured by receptors on hepatic sinusoidal endothelial cells, which internalize it, and subsequently catabolize it in lysosomes. Sinusoidal endothelial cells actively remove almost 90% of the circulating HA, even though the spleen is also involved in its degradation^[64]. The chemical properties of HA determine its physiological role as an essential structural element in the extracellular matrix, where it regulates the retention of water molecules in the interstitial space. In addition, HA provides support for cell orientation through some specific cell surface receptors, including CD44^[65]. CD44 is a single-pass transmembrane glycoprotein consisting of 4 functional domains: the distal extracellular domain (responsible for the binding of HA), the membrane-proximal extracellular domain (whose sequence depends on the alternative CD44 mRNA splicing), the transmembrane domain (similar to that of many other single-pass proteins), and the cytoplasmic domain (which has protein motifs that either interact with the cytoskeletal proteins or are responsible for intracellular signaling)^[68]. Although physiologically expressed by some normal human epithelial and mesenchymal cells, where it plays an important role in immune recognition, cell-cell aggregation and cell-matrix-cell signaling, CD44 is overexpressed in most human cancers, including hepatic carcinoma, and is associated with tumor progression^[66,67]. In fact, clinical evidence indicates that in comparison with normal hepatocytes, HCC is frequently associated with an increased expression of CD44 receptors^[73,74], an overexpression that provides them with an essential migration-promoting advantage as demonstrated by Lara-Pezzi *et al*^[68]. In their interesting pre-clinical study, these authors demonstrated a link between CD44 expression and HBV infection. In fact, a CD44-dependent migratory phenotype was induced by the stable transfection of Chang liver cells with the gene coding for the hepatitis B virus X protein (HBx), which was able to

enhance cell motility by altering the cellular morphology and inducing the formation of pseudopodal protrusions and cytoskeletal rearrangements together with the polarization of cell-surface adhesion molecule CD44. This finding is particularly relevant because it supports the relationship between HBV infection and hepatocarcinogenesis, underlining the role of HBx protein in the transformed phenotype.

In developing HA-But synthesis, we took advantage of some molecular properties of HA that satisfy some important biochemical concerns. In fact, HA can make stable bonds with butyric residues, increasing their *in vivo* half-life without affecting their pharmacological activity. In addition, we exploited its high affinity with the CD44 receptor, which is generally overexpressed on tumor cell membranes, to selectively target the butyric residues directly to neoplastic lesions, with minimal effects on normal cells. In fact, in agreement with data in the literature^[69], we found that in normal cells such as fibroblasts, which express a percentage of CD44-positive cells (as evaluated by flow cytometry) similar to that of tumor cells, HA-But had no effect, suggesting that it

is only really effective in actively proliferating cells, such as tumor cells (Figure 2).

HA-But: pre-clinical *in vitro* results

When we analyzed the antiproliferative effect of HA-But on two hepatocellular carcinoma cell lines, namely Hep3B and HepG2, which both expressed CD44 receptors (although to different extents), we found that after 6 days of treatment it exerted a dose-dependent effect, almost completely inhibiting the CD44-rich Hep3B (90%) cells, and moderately (but significantly) inhibiting (60%) the CD44-poor HepG2 cells; furthermore, this growth arrest corresponded to a block in the G₀/G₁ phase of the cell cycle^[70]. As shown in Figure 3, the progression of the cell cycle is regulated by cyclin/cyclin-dependent kinase (cdk) complexes and cdk inhibitors, such as p16^{ink4}, p21^{waf1}, and p27^{kip1} proteins. Because it is known that overexpression of cdk inhibitors leads to cell-cycle arrest and apoptosis, we investigated the effect of HA-But on the expression of some of the molecules responsible for

Figure 2. A: Cell surface CD44 expression on fibroblasts, and HepG2 and Hep3B cell lines as evaluated by flow cytometry. Cells (1×10^6) were first incubated with mouse antihuman CD44 antibody, and then with goat FITC-labeled antimouse secondary antibody. Negative controls (gray or black) and stained samples (white) are shown. B: Antiproliferative effect of scalar doses of HA-But on the growth of fibroblasts (▲), and HepG2 (■) and Hep3B (●) cell lines, after 6 d of treatment. Briefly, cells (1000 cells per well) were seeded in 96-well plates in RPMI-1640 medium supplemented with 10% fetal calf serum and allowed to adhere for 24 h. The seeding medium was removed and replaced with experimental medium supplemented with increasing concentrations of HA-But. At the end of the experiments the antiproliferative effect was evaluated by using the 3-(4,5-dimethyl-2-thiazoyl)-2,5-diphenyl-2H-tetrazolium bromide (MTT) method. Results are expressed as percentage of inhibition with respect to control (cells maintained in the presence of culture medium alone). Each point represents the mean value from 3 independent experiments. The variation coefficient was $<5\%$ and therefore error bars are not shown.

Figure 3. Schematic representation of cell cycle phases. In proliferating cells, the cell cycle consists of 4 phases. Gap1 (G1) is the interval between mitosis and DNA replication, which occurs during the synthesis (S) phase. The S phase is followed by a second gap phase (G2), during which growth and preparation for cell division occurs. Mitosis and the production of 2 daughter cells occur in M phase. Passage through the 4 phases of the cell cycle is regulated by a family of cyclins that act as regulatory subunits for cyclin-dependent kinases (cdks). The activity of the various cyclin/cdk complexes that regulate the progression through the G1-S-G2 phases of the cell cycle is controlled by the synthesis of the appropriate cyclins during a specific phase of the cell cycle. In addition, there are several proteins, including p16^{ink4}, p21^{waf1}, and p27^{kip1} (termed cdk inhibitors) that can inhibit the cell cycle in G1 when an adverse event, such as DNA damage, has occurred.

growth arrest, including cyclin D1, which is involved in the regulation of the G₁ phase of the cell cycle, and whose gene is found amplified in 10%–20% of HCC,^[71] but leads, when combined for example with p16^{ink4} amplification, to a loss of growth control in more than 30% of HCC. Experimental findings indicated that as in other types of tumors, such as lung cancer^[65], and in agreement with the effect of other HDAC inhibitors on hepatoma cells^[72,73], HA-But increased cdk-inhibitor expression (ie, the protein level of p27^{kip1} and p21^{waf1}), while decreasing cyclin D1 protein levels, suggesting that the HA backbone does not interfere with the activity of butyric residues, which maintain their biological properties. In fact, as previously demonstrated in lung cancer^[65], and similarly to NB, HA-But induces a hyperacetylation of histone H4, a dose-dependent overexpression of p27^{kip1} and p21^{waf1}, and a block of cell growth in the G₀/G₁ phase of the cell cycle. In addition, cytometric analysis showed that CD44 receptor turnover was not affected by treatment with HA-But, which is a finding of great pharmacological relevance, because the stable presence of the receptors on plasma membranes guar-

antees a continuous internalization of the drug.

cDNA microarray analysis is a technical approach that enables investigators to measure the expression of thousands of mRNAs simultaneously in a biological specimen, providing comprehensive information that is useful for diagnosis and therapeutic intervention. Data gathered using this technique have further confirmed the previous experimental findings regarding the mechanism of action of HDAC inhibitors, and demonstrated that almost all HDAC inhibitors exerted their antiproliferative effects by modulating a small set of genes that regulate key cellular activities such as proliferation and differentiation. In particular, it has been shown that TSA, SAHA, depsipeptide are able to modulate genes involved in apoptosis and cell cycle pathways, among which are cdk inhibitors such as p16^{ink4}, p21^{waf1}, and bcl-2^[74,75]. In addition, gene expression profiling of hepatocellular carcinomas has provided qualitative and quantitative evidence that the genes involved in the development and progression of a HCC correlate with the dysregulation of pathways associated with cell cycle regulation^[76], apoptosis^[77], signal transduction^[78], cellular adhesion and angiogenesis^[79,80]. Thus, the finding that HDAC inhibitors, including HA-But, can restore growth control and induce differentiation is particularly exciting.

HA-But: pre-clinical *in vivo* results

There are very few studies that have aimed to investigate the *in vivo* effect of HDAC inhibitors on tumor growth or the metastatic spread of liver tumors. Among the studies that have been conducted, a study using 4-phenylbutyrate, a derivative of the short-chain fatty acid butyrate, found that when administered via intratumor catheter, the compound reduced the growth of xenograft tumors derived from hepatocarcinoma cell lines, most likely by the induction of p21^{waf1} expression and the activation of apoptosis^[78].

The *in vivo* capability of HA-But to inhibit primary tumor growth and metastatic spread has been investigated in several animal models^[65,75], and evaluation of the drug biodistribution, by using the compound labeled with ^{99m}Techneium, found that a few minutes after iv administration, there was a substantial accumulation of the compound in the liver, uniformly distributed in both lobes^[75]. These results have been confirmed by the evaluation of the *ex vivo* distribution of HA-But, which showed that the liver was the organ of preferential accumulation, in agreement both with the finding obtained by using native HA^[81] and with the observation that circulating hyaluronan is physiologically degraded by hepatic sinusoidal endothelial cells

via CD44 receptors^[82]. All these findings clearly suggest that iv injection can be appropriately exploited to treat intrahepatic lesions. In fact, when we explored the therapeutic potential of HA-But for the treatment of intrahepatic lesions induced in the mouse by intrasplenically inoculated Lewis lung carcinoma cells (LL3) and B16/F10 melanoma cells (two cell lines known for their particular aggressiveness^[83,84], and which express high percentages of CD44-positive cells), we found that a prolonged iv administration of HA-But affected the survival time of tumor-bearing animals, reducing the number of intrahepatic metastatic lesions. In addition, prolonged treatment with low doses of HA-But significantly increased the survival time of treated mice relative to untreated controls. It is noteworthy that 90 d after tumor implantation, 80% of HA-But treated animals were still alive versus approximately one-third in the untreated group^[75].

Conclusions and future perspectives

Experimental evidence and preliminary clinical phase I and II trials indicate that HDAC inhibitors acting on a pivotal mechanism of gene transcription such as histone acetylation may represent an innovative therapeutic approach for solid and hematological cancer. In particular, recent findings indicate that in pre-clinical studies HA-But is able to inhibit hepatocellular carcinoma cell growth, and that this antiproliferative activity is due to an increase in some cell-cycle related proteins, such as p21^{waf1} and p27^{kip1}, and a decrease in some others, including cyclin D1. Furthermore, the results provide experimental evidence for the clinical use of HA-But as a promising agent for the treatment of hepatocellular carcinoma, a tumor that is otherwise particularly resistant to chemotherapy. The treatment exploits the overexpression of CD44 receptors on tumor cell membranes, which allows selective targeting of the compound to the neoplastic lesion.

In addition to DNA acetylation, which hampers gene transcription, aberrant DNA hypermethylation of cytosine residues in the promoter region can cause growth-controlling gene silencing, a frequently observed phenomenon for several genes in HCC^[7]. Therefore, the additional inhibition of DNA methyltransferase (DNMT), the enzyme responsible for such hypermethylation (the activity of which can be reversed using specific DNMT inhibitors, such as 5-aza-2-deoxycytidine, 5-AZA) could be an interesting candidate for further study. Therefore, a promising development for HA-But could be a new chemical compound in which HA-But is simultaneously esterified with 5-AZA. Such a molecule should be able to reactivate silenced genes and enhance the re-expression of specific genes involved in cell

growth arrest, terminal differentiation and apoptosis in aggressive tumors such as hepatocellular carcinoma.

Acknowledgements

The authors wish to thank Drs I Scarlata, C Pellizzaro, and S Zorzet, who contributed to the HA-But synthesis, *in vitro*, and *in vivo* experiments, respectively.

Abstract

Aim: To investigate the effect of chronic morphine exposure on the receptive field properties of lateral geniculate nucleus (LGN) neurons in cats. **Methods:** Cats were injected with morphine (10 mg/kg) or saline twice daily, for 10 d. Subsequently, extracellular single-unit recording techniques were used to examine the sensitivity of LGN neurons to visual stimuli in chronic morphine-treated and saline-treated cats. **Results:** Compared with saline-treated cats (as controls), LGN neurons in morphine-treated cats had decreased signal-to-noise ratios (1.9 vs 3.1), and orientation and direction sensitivity (0.103 vs 0.135 and 0.074 vs 0.10, respectively), accompanied by significant increases in spontaneous (27.4 vs 17.5) and evoked activity (preferred: 42.2 vs 38.1; average: 28.1 vs 22.3). **Conclusion:** Chronic morphine exposure can lead to the functional degradation of LGN neurons in cats, which might result from the effects of chronic morphine exposure on inhibitory neurotransmission.

Introduction

The brain is rich in opiate receptors, and significant concentrations of opiate receptors are observed in the visual systems of cats^[1], macaques^[2], and rats^[3]. It has been suggested that the visual system is subject to opiate modulation. Previous studies have shown that morphine-like drugs decrease visual sensitivity in humans^[4], affect visual discrimination performance in rats^[5], and evoke cortical potentials by stimulating the optic chiasm in cats^[6].

Repeated use of addictive drugs leads to multiple adaptive neuronal responses^[7,8]. Increasingly, research suggests that chronic exposure to opiates significantly changes glutamatergic synaptic transmission and neuronal plasticity in many brain regions^[9,10]. Similarly, GABAergic synaptic transmission is also influenced by opiates^[11–13]. However, normal excitatory and inhibitory synaptic transmission is crucial for the development and maintenance of visual function. These findings indicate that opiates might influence the performance of neurons in the lateral geniculate nucleus (LGN). In the present study, we tested this possibility by using extracellular single-unit recording techniques to

examine the stimulus sensitivity of LGN neurons in chronic morphine-treated cats.

Materials and methods

Subjects and drug exposure The experiments were performed on 8 healthy adult male cats (2–3 kg), 4 of which were allocated to the morphine treatment group and 4 of which were used as controls. All animals were treated strictly in accordance with the Chinese National Institutes of Health's Guide for the Care and Use of Laboratory Animals. The method of morphine treatment was similar to that used by other researchers^[9]. Morphine HCl (10 mg/kg) was administered by cervical subcutaneous injection twice per day at 9:00 and 21:00 for 10 d before the electrophysiological experiments. Control cats were treated similarly with saline instead of morphine.

All cats were examined ophthalmoscopically before the experiment to confirm that they had no optical problems or obvious retinal problems that would impair the visual function.

Preparation for extracellular recording On the 11th

day of morphine administration, animals were prepared for extracellular single-unit recording as described previously^[14,15]. A typical recording session lasted for 3 d. During recording, morphine or saline was injected in the same way as described in the previous section.

Visual stimulation The receptive fields of cells were first plotted by using manually controlled stimuli displayed on the tangent screen. Computer-controlled visual stimuli consisting of drifting sinusoidal gratings were presented on a CRT (cathode-ray tube) monitor (1024×768, 85 Hz), placed 57 cm away from the animals' eyes. The program to generate the stimulus was written in MATLAB, using the extensions provided by the high-level Psychophysics Toolbox^[16] and the low-level Video Toolbox^[17]. The time frequency of drifting gratings was set at 3 Hz. At first, a tuning curve of spatial frequency was plotted. We selected a high spatial frequency where cells' responses were approximately half of that at peak frequency to compile the orientation and direction tuning curves. Before each stimulus presentation, 5 s spontaneous activities were obtained while the mean luminance was shown on the display. Additional stimuli were used to identify a cell as X- or Y-type, and on- or off-center. The contrast of the stimulus was set at 80%. The mean luminance of the display was 19 cd/m², and the environment luminance on the cornea was 0.1 lux.

Data collection and analysis After the neuronal signal was amplified with a microelectrode amplifier (Nihon Kohden, Tokyo, Japan) and a differential amplifier (FHC, Bowdoinham, USA), action potentials were fed into a window discriminator with an audio monitor. The original voltage traces were digitized using an acquisition board (National Instruments, Austin, USA) controlled by IGOR software (WaveMetrics, Portland, USA). The original data were saved for online and offline analysis. The post-stimulus time histograms (PSTH) of neuronal responses with a bin width of 10 ms were obtained for further analysis. The responses of cells to the sinusoidal gratings were treated using a fast Fourier transform and the amplitude was defined as the resultant fundamental Fourier component (FFT1) of the PSTH. The FFT1 value of each stimulus orientation (direction) was used to draw the spatial frequency and orientation (direction) tuning curves. The method for calculation of orientation bias (OB) and direction bias (DB) has been described elsewhere^[18,19]. A cell with bias=0.1 was considered significantly biased for orientation or direction. A cell with bias=0.2 was considered strongly biased for orientation or direction. A cell's signal-to-noise ratio (STN) was defined as the ratio of the cell's visual evoked response (FFT1 value in preferred orientation and direction) to spontaneous response.

To avoid data skewing or overestimation, all spontaneous activities below 1 spike per second were set equal to 1 spike per s for signal-to-noise analysis.

Statistical comparisons between morphine-treated and saline-treated cat data were carried out using *t*-test. All mean values were presented as mean±SEM.

Results

The results described here were obtained from 168 cells in 4 morphine-treated cats (abbreviated to MCs) and 173 cells in 4 saline-treated cats (abbreviated to control) in LGN. Our chief findings were that chronic morphine exposure led to a decrease in the signal-to-noise ratio and a degradation in the orientation and direction sensitivity of LGN cells, which was accompanied by an increase in spontaneous and evoked response. Our analysis revealed that there was a consistent effect of chronic morphine exposure on different types of LGN cells (X or Y; on or off), so comparisons of data between two groups ignore the type of cell.

Orientation and direction sensitivity As an example, we show here the response of an LGN cell to a drifting sinusoidal grating (Figure 1A) and its PSTH (Figure 1B). Figure 1C and 1D illustrate the tuning curve of a cell from controls (OB=0.2, DB=0.01) and MCs (OB=0.1, DB=0.08), respectively. MCs have a decrease in orientation and direction sensitivity relative to controls. The average OB and DB values varied individually in both MCs and controls. The OB were significantly smaller in MCs (0.103±0.068) than in control cats (0.135±0.084, *P*<0.01; Figure 1E). Sixty-three percent of LGN cells in controls and 50% of cells in MCs had significant orientation sensitivity (OB=0.1). In MCs, the percentage of cells (10%) with strong orientation sensitivity (OB=0.2) was half of that in controls (20%). Similarly, the direction sensitivity of LGN cells was also affected by chronic morphine exposure. The DB of LGN cells were significantly less for MCs (0.074±0.059) than for controls (0.100±0.064, *P*<0.01; Figure 1F). As with the orientation bias, the percentages of cells having significant and strong direction bias in MCs (30% and 6%, respectively) were less than those in controls (47% and 10%, respectively).

Visually evoked activity To explore whether the sensitivity decrease of cells in MCs resulted from an increase of responsiveness to previously non-preferred orientations and directions or from a reduction of responsiveness to the previously preferred orientations and directions, or both, we compared the average response (AR) to all stimulating grating orientations of LGN cells in MCs and controls. Cells in MCs showed a tendency for an increase in the AR compared

Figure 1. (A) An example of the responses of a neuron to the drifting sinusoidal grating. Ten cycles of the neuron’s original response are superimposed in one stimulus period. A spike above the broken horizontal line is counted as an action potential. (B) The PSTH derived from (A) for further analysis. Bin width was 10 ms. (C, D) The neuron’s orientation tuning curve from saline-treated (C) and morphine-treated cats (D). The responses were defined as the fundamental Fourier components (FFT1). The FFT1 at each stimulus direction was computed from the PSTH such as the one shown in (B). (E, F) Comparison of orientation (E) and direction (F) biases of LGN cells between morphine-treated ($n=4$) and saline-treated ($n=4$) cats. The data were expressed as mean \pm SEM. $^{\circ}P<0.01$ vs saline.

with controls (Figure 2A). Half of the cells (50.3%) in MCs had an AR value of more than 25 spikes per second. In contrast, most cells (63.2%) in controls had an AR value of less than 25 spikes per second. A statistical analysis showed that the mean AR value in MCs (28.1 ± 16.1) was significantly larger than that in controls (22.3 ± 11.3 , $P<0.01$). Moreover, we also compared the response of LGN cells to their preferred orientation and direction in MCs and controls. For

convenience, we call this the preferred response (PR). Similar to the AR, the PR value in MCs was also increased relative to that in controls (Figure 2B). The t -test indicated that the mean PR value (42.2 ± 19.1) for MCs was significantly higher compared with that for controls (38.1 ± 16.2 , $P<0.05$). Therefore, LGN cells in MCs have increased responsiveness to both preferred and non-preferred stimuli.

Spontaneous activity and signal-to-noise ratio LGN cells

Figure 2. Percentage of cells with different average response (AR) and preferred response (PR) values for morphine-treated and saline-treated cats. (A) Percentage of cells with different AR values for all stimulus orientations. (B) Percentage of cells with different PR values. The mean AR and PR values are significantly different between the two groups.

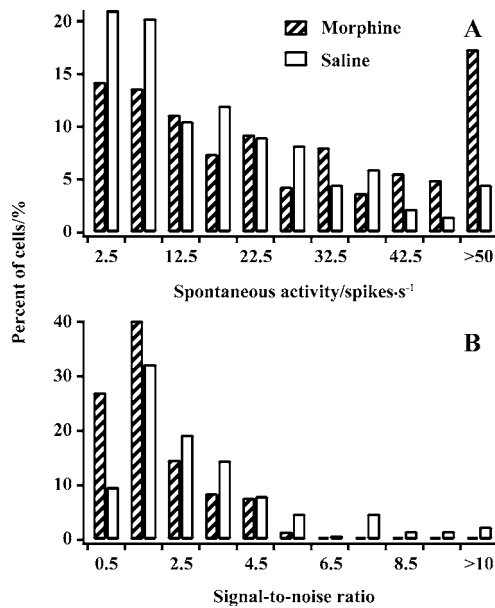

Figure 3. Comparison of spontaneous activity (A) and signal-to-noise ratio (B) between morphine-treated and saline-treated cats. Neurons in morphine-treated cats had decreased signal-to-noise ratio, which is mainly attributable to increased spontaneous activity.

in controls trended to have a small spontaneous response (SR) value, whereas cells in MCs had a more extensive distribution. Most cells (63.9%) in controls had an SR value of less than 20 spikes per second. In contrast, approximately half of the cells (53.4%) in MCs had an SR value of more than 20 spikes per second. The average SR value (27.4 ± 22.5) in MCs was significantly higher than that in controls (17.5 ± 14.3 , $P < 0.01$; Figure 3A).

Figure 3B presents the distribution of various signal-to-noise ratios (STN=PR/SR) for cells in MCs and controls. The number of cells with lower STN was much more for MCs than for controls. Almost all cells (98.4%) in MCs had an STN value of less than 5. However, quite a number of cells (16.1%) had an STN value of more than 5 in controls. A comparison of the averaged STN for controls (3.1 ± 2.3) versus MCs (1.9 ± 1.2) showed that the difference was statistically significant ($P < 0.01$). Taken together, these data suggest that chronic morphine exposure results in an increase in spontaneous activity and a decrease in signal-to-noise ratio in LGN cells in MCs.

Discussion

We found significant degradation in the receptive field properties of LGN neurons in MCs. The morphine-derived

degradation in orientation and direction sensitivity in LGN neurons was accompanied by an unspecific increase in responsiveness. The average response across all orientations of stimulus gratings for MCs increased by 26.0% compared with controls, whereas the response to preferred stimuli increased by only 11.2%. Thus, the increased responsiveness to non-preferred orientations and directions appears to be an important mechanism mediating the reduction in cells' sensitivity to stimuli in MCs. On the other hand, the spontaneous activity of LGN neurons in MCs increased by 56.6% compared with controls. This increase was much higher than the increase in preferred response. As a result, the ratio of preferred response to spontaneous activity (signal-to-noise ratio) in MCs was much lower than in controls. The decrease in signal-to-noise ratio in MCs thus appears to mainly reflect the large increase in spontaneous activity.

Orientation and direction sensitivity is a well-known receptive field property of neurons in the mammalian visual cortex^[20]. However, it is quite controversial whether orientation and direction sensitivity exists in LGN neurons. Many tests beyond the peak spatial frequency have shown that a lot of LGN cells are sensitive to stimulus orientation or direction^[14,21]. The results of the present study also show this. It has been proposed that an elliptical shape of the receptive-field center and asymmetry in the inhibitory surrounds contribute to the orientation and direction sensitivity of LGN cells. Previous investigations suggest that microiontophoresis of bicuculline (an antagonist of the GABA_A receptor) affects the orientation and direction sensitivity of neurons in LGN of cats^[22,23]. Moreover, LGN cells also have increased spontaneous and evoked activity when GABAergic inhibition is blocked^[22,24]. In the present study, LGN cells in MCs had decreased orientation and direction sensitivity accompanied by increased spontaneous and evoked activity. Furthermore, research on drug abuse suggests that the decline of inhibitory neurotransmission actually happens in many brain regions^[11-13]. In view of the extensive expression of opiate receptors throughout the visual system, reduced GABAergic inhibition might be a reasonable explanation for the degradation of receptive field properties of LGN cells in MCs. Nevertheless, some studies have shown that drug abuse also affects glutamatergic and other transmitter systems, indicating that these transmitter systems might affect the sensitivity of LGN cells to visual stimuli following chronic morphine exposure. Additionally, LGN neurons reflect the properties of the center-surround organized retinal receptive fields and convey them to the cortex in a way that does not significantly alter their spatial structure^[24]. Therefore, the action of chronic morphine exposure on the

retina might be one factor resulting in the degradation of the receptive field properties of LGN cells in MCs.

In summary, our results suggest that chronic morphine exposure can lead to the degradation of the receptive field properties of LGN cells in cats. Morphine-derived decreases of GABAergic inhibition together with other factors might contribute to the functional degradation of LGN cells in MCs. All in all, much remains to be learned about the role of opiate receptors in the visual system and the morphine-derived decay of receptive field properties of LGN neurons.

Abstract

Aim: To investigate effect of the nociceptin/orphanin FQ (OFQ) on hypothalamus gonadotropin-releasing hormone (GnRH) release in ovariectomized (OVX) rats. **Methods:** GnRH radioimmunoassay (RIA) was used to study the effect of OFQ on GnRH release in hypothalamus slices *in vitro*. Push-pull perfusion and intracerebroventricular (icv) injection were used to examine the effect of OFQ on GnRH release in the hypothalamus medial preoptic area (POA) *in vivo*. Ovariectomies were performed on female Sprague-Dawley rats, and their plasma luteinizing hormone (LH) levels were measured after icv injection of OFQ with or without [Nphe¹]NC(1-13)NH₂, a competitive antagonist of opioid receptor-like 1 receptor (ORL1 receptor). Reverse transcription-polymerase chain reaction (RT-PCR) was used to investigate the expression of the ORL1 receptor in rat pituitary. **Results:** GnRH release from hypothalamus slices was inhibited 90 min after the administration of 2 mmol/L and 20 mmol/L OFQ ($P < 0.05$). Accordingly, GnRH release from hypothalamus POA was also significantly reduced by the injection of 0.2 mmol/L and 2 mmol/L OFQ. Plasma LH levels were also decreased significantly 2 h after icv injection of 20 nmol OFQ in OVX rats ($P < 0.05$) and this effect could be abolished by pretreatment with 20 nmol [Nphe¹]NC(1-13)NH₂, that is, NC13. More interestingly, plasma LH levels in OVX rats increased markedly 2 h after icv injection of 100 nmol and 200 nmol NC13. RT-PCR analysis further revealed that the ORL1 receptor was not expressed in the pituitary of OVX rats. **Conclusion:** Central administration of nociceptin/orphanin FQ might inhibit the release of hypothalamic GnRH and decrease the plasma LH levels through ORL1 receptors in OVX rats.

Introduction

Nociceptin/orphanin FQ (OFQ) is a heptadecapeptide that has high amino acid sequence homology to the endogenous opioid peptides, especially dynorphin A^[1,2]. OFQ is the putative endogenous ligand for the opioid receptor-like 1 receptor (ORL1 receptor)^[2,3]. The ORL1 receptor has structural and functional homology with the δ , κ , and μ classic opioid receptors. Despite its close similarity to opioid receptors, the ORL1 receptor does not selectively bind opioids and opioids antagonists^[3]. A number of physiological effects of OFQ have been reported, including nociceptive modulation, and cardiovascular and renal physiological

functions^[2,4,5].

The classic opiates are involved in the regulation of anterior pituitary hormone secretion. Opiate administration increases prolactin and growth hormone^[6], while decreasing the release of luteinizing hormone in a naloxone-reversible manner^[7]. The homology between the opiate peptides and OFQ as well as between their receptors, coupled with the localization of OFQ in the hypothalamus suggest a neuroendocrine role for OFQ^[8,9].

GnRH, as an important hypothalamic decapeptide, plays a key role in the functions of the hypothalamic-pituitary-ovary axis (HPOA) by modulating the secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH)

from the anterior pituitary^[10]. Endogenous opioid peptides, particularly β -endorphin, constitute an important inhibitory component of the neural circuitry that regulates GnRH secretion and a significant decrease in the inhibitory opioid tone is critical for the generation of a LH surge during the estrous cycle^[11].

OFQ and the ORL1 receptor are densely localized in the preoptic area (POA), ventralmedial hypothalamus (VMH) and arcuate nucleus (ARC), all of which have been identified as the chief hypothalamic nuclei regulating GnRH release^[8]. It has been demonstrated that OFQ activates the G protein-coupled inwardly rectifying K^+ channel (GIRK) and hyperpolarizes many hypothalamic neurosecretion cells, especially in the ARC^[12]. Recent studies have revealed that OFQ potently and dose-dependently inhibits forskolin-induced GnRH release from rat hypothalamic fragments^[13]. We postulated that OFQ might play a role in the regulation of GnRH release in rat hypothalamus. To test the hypothesis, the effects of the central administration of OFQ on rat hypothalamus GnRH release and plasma LH levels were observed in the present study.

Materials and methods

Animals and drugs Female Sprague-Dawley rats weighing 200–220 g obtained from the Animal Center of Shanghai Medical School of Fudan University had both ovaries surgically removed under aseptic conditions. They were kept in an air-conditioned room with controlled lighting (light 12 h: dark 12 h) and given free access to laboratory chow and tap water. Experiments were carried out 4–6 weeks after the ovariectomies. Nociceptin/orphanin FQ (MW 1810) and [$Nphe^1$]NC(1-13)NH₂ (NC13; MW=1382) were purchased from Phoenix Pharmaceutical Company (St Joseph, MD, USA). The compounds were dissolved in artificial cerebrospinal fluid (ACSF; 128 mmol/L NaCl, 2.5 mmol/L KCl, 1.4 mmol/L CaCl₂, 1.0 mmol/L MgCl₂ and 1.2 mmol/L Na₂HPO₄; pH 7.4)^[14]. All other reagents and solvents were of analytical grade.

Incubation of hypothalamus slices Animals were killed by decapitation in a period of less than 30 min and medial basal hypothalamus slices were quickly dissected at 4 °C as described by Lamar *et al*^[15]. The slices were placed into 2 mL ice-cold ACSF in a chamber made from a 5 mL plastic syringe specially modified for incubation. The slices were maintained at 37 °C in an atmosphere of 5% CO₂ and 95% O₂ with gentle agitation for 30 min preincubation. The slices then were treated with ACSF or 0.2, 2, and 20 mmol/L OFQ and incubated for 2 h. Every 30 min, 200 μ L medium was extracted, then 200 μ L fresh ACSF was added to the system. The incu-

bation medium was collected in tubes and stored at -20 °C for GnRH radioimmunoassay.

Push-pull perfusion Animals were anesthetized with sodium pentobarbital (40 mg/kg, ip) and placed on a stereotaxic instrument. A push-pull cannula with a removable inner stylette constructed in our laboratory was implanted towards the hypothalamus POA (Bregma AP: 0.4 mm; L: 0.8 mm; H: 8.5 mm)^[16]. The device was fixed onto the rat skull with an anchor screw and dental cement, and the animals were given a minimum recovery period of 7 d. On the day of perfusion, the inner stylette was removed and replaced with the inner cannula perfusion assembly. ACSF was infused through the push cannula and collected from the pull cannula at a flow rate of 10 μ L/min. After a 30 min equilibration period, 0.02, 0.2, or 2 mmol/L OFQ solution was perfused. The perfusate was collected every 20 min over a total period of 2 h and stored at -80 °C for GnRH radioimmunoassay.

Intracerebroventricular injection Implantation of the cannula was performed stereotaxically under anesthesia with sodium pentobarbital (40 mg/kg, ip). Stereotaxic surgical procedures were used to implant one 22 gauge stainless steel guide cannula with a removable 28 gauge inner stylette to the left lateral ventricle (Bregma AP: 1.0 mm; L: 1.5 mm; H: 3.0 mm)^[16]. Experiments with icv injection were performed at least 7 d after operation. The OFQ solution was added with protease inhibitor (1 g/L) for preventing proteolysis after injection. Two, 20 or 200 nmol OFQ dissolved in 10 μ L ACSF was infused through a 28 gauge cannula extended 0.5 mm beyond the guide cannula. The needle was connected to a 10- μ L syringe by a polyethylene tube and the drug solutions were delivered by infusion pump at a flow rate of 5 μ L/min. The injection needle was maintained in place for an extensive period of 10 min after the injection. Under anesthesia conditions, OVX rats were injected with ACSF, OFQ (2, 20, or 200 nmol OFQ in 10 μ L ACSF) or NC13 (20, 50, 100, and 200 nmol NC13 in 10 μ L ACSF). Blood samples of 400 μ L were withdrawn from the rat tail vein every hour over a total period of 4 h after icv injection. Blood plasma (200 μ L) was separated from each blood sample by centrifugation and stored at -20 °C until LH radioimmunoassay.

RT-PCR analysis Total cytoplasmic RNA was isolated from the medial basal hypothalamus, hippocampus and pituitary of ovariectomized rats using the Trizol reagent (Life Technologies, Rockville, MD, USA). Total RNA (4 μ g) was digested with DNase RNase-free enzyme to eliminate genomic DNA, and then converted to complementary DNA (cDNA) using 200 U Moloney murine leukemia virus reverse transcriptase (Promega, Madison, WI, USA) in 20 μ L of buffer containing 0.4 mmol/L deoxynucleotide triphosphates, 20 U

RNase inhibitor and 0.8 μg oligo (deoxythymidine)₁₅ (Sino-American Biotechnology Company, Shanghai, China). Specific primers were 5'-CAGGCTGTTAATGTGGCCATATG-3' and 5'-GAGCCTGAAAGCAGACGGACACC-3' (synthesized in Shanghai Sangon Biological Engineering Technology and Service Company), which annealed to bases 493–515 and 743–721 of the ORL1 receptor^[17]. Twenty-eight cycles under the following PCR conditions were carried out: denaturation at 94 °C for 45 s, annealing at 60 °C for 45 s and elongation at 72 °C for 60 s with *Thermus aquaticus* DNA polymerase (Promega, Madison, WI, USA). The RT-PCR products (5 μL) were electrophoresed in a 1.6% agarose ethidium bromide gel and visualized using the SYNGENE imaging system (GeneSnap Software, London, UK).

GnRH and LH radioimmunoassay GnRH in perfusate was assayed by using a commercial RIA kit (Sigma) and measurements were performed according to the manufacturer's instructions. Plasma LH was measured by using an LH RIA kit (Shanghai Institute of Biologic Products, Shanghai, China), and the sensitivity of the assay was 0.4 pg/mL. The intra-assay coefficient of variation was 3.5% and the inter-assay variation was 4.8%.

Statistical analysis All results are expressed as mean±SD and were analyzed by the Statistical Package for the Social Sciences (SPSS) statistical software. The data in Figures 1–3 were analyzed by using a two-way repeated measures analysis of variance (ANOVA) with time as the repeated measure. The other results were analyzed by one-way ANOVA and the significance of difference was determined by the Newman-Keuls test. When only two treatment groups were being compared, Student's *t*-test was used. A probability of *P*<0.05 was considered to be statistically significant.

Results

Effect of OFQ on GnRH release from hypothalamus slices It was apparent that GnRH release began to decrease 60 min after OFQ administration. In the 2 mmol/L and 20 mmol/L OFQ groups, GnRH concentrations in the medium were significantly decreased (*P*<0.05) at 90 min (21.01±3.77 pg/mL and 15.78±3.02 pg/mL) after OFQ administration compared with the control group at the same time (31.49±3.34 pg/mL). OFQ at a concentration of 0.2 mmol/L did not affect GnRH release during the 120 min incubation time (Figure 1).

Effect of OFQ on GnRH release from POA OFQ evoked a dose-dependent inhibitory effect on POA GnRH release in ovariectomized rats (*P*<0.05). GnRH release stayed at approximately the same level over 120 min in the control group. The administration of 0.2 mmol/L and 2.0 mmol/L

Figure 1. Dose-response curves for the effect of OFQ on GnRH release from medial basal hypothalamic slices from OVX rats. OFQ and ACSF were administered at *t*=0. *n*=5. Mean±SD. ^b*P*<0.05 vs control.

OFQ caused a significant decrease in GnRH release at 40 min (19.83±2.35 pg/mL and 14.77±2.31 pg/mL, respectively), which lasted approximately 20 min, as compared with the control group (31.79±6.19 pg/mL). OFQ at a concentration of 0.02 mmol/L had no significant effect on GnRH release over 120 min (Figure 2).

Figure 2. Dose-response curves for the effect of OFQ on GnRH release in the medial preoptic area of the hypothalamus. OFQ or ACSF was administered at *t*=0. The concentrations of GNRH in perfusates were measured every 20 min for 2 h. *n*=5–6. Mean±SD. ^b*P*<0.05 vs control.

Effect of icv injection of OFQ and NC13 on plasma LH levels A dose-dependent decreasing effect on plasma LH levels was observed 2 h after icv injection of OFQ. The plasma LH levels in the control group ranged from 3.08±0.33 ng/mL to 3.27±0.37 ng/mL and were not significantly

different from those of the 2 nmol OFQ group at any time point over 4 h. Administration of 20 nmol and 200 nmol OFQ significantly decreased pituitary LH secretion ($P<0.05$). The strongest effect was achieved at 2 h after injection in the 20 nmol and 200 nmol OFQ groups (2.47 ± 0.30 ng/mL and 2.12 ± 0.32 ng/mL), as compared with the control group (3.11 ± 0.31 ng/mL). The LH decrease occurred at 2 h after injection for both doses and persisted until 3 h (Figure 3).

Figure 3. Time course study for the effect of OFQ on plasma LH levels of OVX rats. OFQ or ACSF was administered at $t=0$. The plasma LH levels were measured every hour for 4 h. $n=8$. Mean \pm SD. ^b $P<0.05$ vs control. ^c $P<0.05$ vs before administration.

A significant decrease in plasma LH level (2.47 ± 0.30 ng/mL) induced by 20 nmol OFQ was abolished by pretreatment with 20 nmol NC13, a competitive antagonist of the ORL1 receptor (3.02 ± 0.39 ng/mL). No change in plasma LH level was observed with a single icv injection of 20 nmol NC13 (Figure 4).

Effect of icv injection of NC13 at different doses on plasma LH levels The plasma LH levels in the 20 nmol and

Figure 4. Effect of pretreatment with NC13 on the decrease of plasma LH levels induced by OFQ. The plasma LH levels were measured 2 h after icv injection. $n=8$. Mean \pm SD. ^b $P<0.05$ vs control.

50 nmol NC13 groups (3.18 ± 0.36 ng/mL and 3.78 ± 0.46 ng/mL) were not significantly different from those of the control group (3.13 ± 0.34 ng/mL) 2 h after administration. Interestingly, 100 nmol and 200 nmol NC13 stimulated a significant increase in plasma LH levels (4.27 ± 0.51 ng/mL, 4.95 ± 0.53 ng/mL) 2 h after icv infusion ($P<0.05$) and the effect was dose-dependent. This reveals that a single high-dose icv injection of NC13 produces a significant increase in plasma LH levels in OVX rats (Figure 5).

Figure 5. Dose-dependent study for the effect of NC13 on plasma LH levels in OVX rats. The plasma LH levels were measured 2 h after icv injection. $n=8$. Mean \pm SD. ^b $P<0.05$ vs control.

RT-PCR analysis RT-PCR analysis to check for ORL1 receptor expression revealed that the ORL1 receptor transcript was expressed in the hypothalamus and hippocampus of OVX rats, but not in the pituitary (Figure 6).

Figure 6. RT-PCR analysis for the expression of the ORL1 receptor in rat hippocampus, pituitary, and hypothalamus. The RT-PCR product of 250 bp, corresponding to the ORL1 receptor, was detected in rat hippocampus and hypothalamus but not in the pituitary. Discussion

OFQ and its receptor are densely distributed in several nuclei in the hypothalamus, suggesting that OFQ might mediate and modulate hypothalamic functions^[2,8]. There is evidence that OFQ is involved in the regulation of some important hypothalamic functions, such as feeding behavior, temperature control and sexual behavior^[18-20]. OFQ has been

shown to stimulate prolactin and growth hormone secretion in male and female rats as an endogenous opioid peptide^[21]. Our results show that central administration of OFQ can inhibit the release of GnRH in the hypothalamus *in vitro* and *in vivo* and decrease the plasma LH level, suggesting that OFQ might play a role in the modulation of hypothalamic GnRH secretion and pituitary LH release. Recent data from our laboratory and from other investigators indicate a neuroendocrine role for OFQ in mechanisms of the hypothalamus governing reproduction^[13,21].

It is known that GnRH is the key central regulator in the estrous cycle. Despite intensive investigation, the mechanism underlying GnRH secretion remains poorly understood^[10]. GnRH cell bodies form a loose continuum from the medial septum to the ventral anterior hypothalamus. GnRH is released from nerve terminals in the median eminence, where it is transported to the anterior pituitary to act on gonadotropes to stimulate LH and FSH secretion to the blood^[22]. The ovariectomy performed in our experiments was intended to remove the effects of the estrous cycle on the hypothalamus GnRH and plasma LH secretion in female rats. Our results show that 2 mmol/L and 20 mmol/L OFQ inhibits GnRH release from rat medial basal hypothalamus slices in a dose-dependent manner, which is in agreement with previous reports^[13]. Moreover, by using push-pull perfusion, we demonstrated that OFQ could also inhibit GnRH release from rat hypothalamus POA *in vivo*, further indicating the pharmacological effect of OFQ on hypothalamic GnRH release.

It was observed in our study that central injection of 20 nmol OFQ significantly decreased plasma LH levels, and the strongest effects occurred 2 h after administration. Pretreatment with 20 nmol selective ORL1 receptor antagonist NC13 can reverse the inhibitory effect that is induced by icv injection of 20 nmol OFQ. These results further confirm that the decrease of pituitary LH secretion induced by OFQ administration is mediated by the ORL1 receptor in the brain. We found that the ORL1 receptor was not expressed in rat pituitary by using RT-PCR analysis, indicating that OFQ might have no direct effect on pituitary hormone secretion. There has been no evidence of OFQ receptors on the anterior pituitary gland until now. These results strongly suggest that by interacting with its own receptor, the ORL1 receptor, OFQ elicits its inhibitory effect on hypothalamus GnRH release, thus decreasing the plasma LH level.

Time course studies reveal that the strongest effect of OFQ on GnRH release occurred at 40 min after OFQ administration *in vivo*, but it takes 2 h before any significant effects are seen on LH levels. The apparent discrepancy is probably due to the interval required by neuroendocrine

transduction. The neural signal of GnRH decrease evoked by OFQ is transduced from the medial basal hypothalamus to the median eminence and then to the anterior pituitary, resulting in a decrease of LH secretion. Likewise, the time discrepancy in these results could also offer support for this postulation.

The effect of OFQ on GnRH secretion is likely to be due to an indirect mechanism of action, because OFQ has no such inhibitory effect when applied directly to immortalized GnRH (GT-1) neurons *in vitro*^[13]. There is accumulating evidence that OFQ is able to inhibit the K⁺-evoked release of glutamate and suppress glutamate transmission in the central nervous system of various species^[23-25]. There is a general agreement that the glutamatergic pathway is a major excitatory element in the regulation of GnRH release^[26]. We speculate that hypothalamic glutamate might mediate the inhibitory effects of OFQ on GnRH secretion. Therefore, we are currently investigating the effects of NMDA or non-NMDA antagonists on the decrease of GnRH and LH secretions induced by OFQ. Undoubtedly, our hypothesis needs to be supported by more experimental evidence, and at this stage we could not exclude the possibility that OFQ has a direct effect on GnRH neurons *in vivo*.

Several studies have indicated that OFQ has an anti-opioid effect in nociceptive modulation because OFQ can induce hyperalgesia and antagonize opioid analgesia mediated by the μ and δ receptors in the brain^[27,28]. Morphine and endogenous opioid peptides such as β -endorphin decrease the release of GnRH and LH in a naloxone-reversible manner^[7,29]. Our data suggest that OFQ also plays a negative neuroendocrine role in the modulation of GnRH and LH release as classic opioids.

As the first identified selective ORL1 receptor antagonist, NC13 has allowed us to characterize some biological effects that are clearly mediated through the ORL1 receptor *in vitro* and *in vivo*^[4]. It is shown in our work that NC13 can antagonize the inhibitory effect of OFQ on LH secretion. Nevertheless, we also observed that icv injection of 100 nmol and 200 nmol NC13 alone enhanced the plasma LH levels of ovariectomized rats. The present study reveals an unexpected function of NC13, that is, it can also act as a potent stimulator of LH release at a higher concentration. This suggests that OFQ has a tonic physiological role in the control of pituitary LH secretion. Our next study will focus on elucidating the mechanism for the involvement of the endogenous OFQ/ORL1 receptor system in regulating GnRH and LH release in male and female rats.

In summary, these results demonstrate that central administration of OFQ might inhibit the release of hypothalamic

lamic GnRH and decrease the level of plasma LH via the ORL1 receptor in OVX rats. In addition, our work implies that hypothalamic OFQ might participate in the neuroendocrine regulation of GnRH and LH secretion in female rats. Although the neuroendocrine role of OFQ remains to be explored more directly, our results provide evidence for novel mechanisms for hypothalamic OFQ regulation of GnRH and LH secretion.

Abstract

Aim: The spinal cord is pivotal in immobility induced by volatile anesthetics because the anesthetics depress the activity of motor neurons in the spinal cord. The aim of this study was to observe the effects of sevoflurane on pain processing at the spinal level. **Methods:** The firing of the gastrocnemius muscle was evoked by electrical stimulation to the ipsilateral hindpaw in rats. The nociceptive C response of electromyography (EMG) was selected to study. The GABA_A receptor antagonist bicuculline (0.1 mg/kg) and opioid receptor antagonist naloxone (0.4 mg/kg) were administered intravenously, either in the presence or in the absence of 1.0% sevoflurane. **Results:** In rats with transected spinal cord, sevoflurane produced a profound reduction in the C response in a dose- and time-dependent manner. In the presence of 1.0% sevoflurane, the C responses were increased after injections of bicuculline and naloxone. **Conclusion:** Sevoflurane is a volatile anesthetic that acts directly on the spinal cord to suppress the nociceptive reflex. The sevoflurane-induced suppression of the C response is antagonized by either bicuculline or naloxone. The results suggest that spinal GABA_A receptors and opioid peptide receptors are involved in the sevoflurane-induced suppression of spinal nociception.

Introduction

Gamma-aminobutyric acid (GABA) and opioid peptides are the major inhibitory transmitters in the central nervous system, and both transmitter systems are likely to play important roles in anesthetic mechanisms. For example, a common property of a wide spectrum of general anesthetics, including barbiturates and propofol, is enhancement of the action of GABA_A receptors^[1–4].

Increasing evidence have indicated that the spinal cord is pivotal in the immobility induced by volatile anesthetics because the anesthetics depress the activity of α -motoneurons in the spinal cord^[5,6], in which process spinal GABA receptors and opioid peptide receptors may be involved^[7–10]. However, there has been few study on the effects of sevoflurane on pain processing in the spinal cord. Given the

high density of GABA receptors and opioid peptide receptors located in the dorsal horn of the spinal cord, in the present study we examine whether the suppression of nociceptive effects by sevoflurane is mediated by actions at GABA_A and opioid receptors in the spinal cord.

Materials and methods

Animals and surgical preparation This study was approved by animal experimentation committee of Xinhua hospital. The experiments were performed on 37 male Sprague-Dawley rats weighing 215–345 g (provided by the Animal Center of the Chinese Academy of Sciences). Animals were divided into 5 groups according to the different tests. Group I ($n=6$) animals were used to test the effects of sevoflurane after transection of the spinal cord. Anesthesia for surgical preparation was induced by 2.5% sevoflurane in

95% O₂–5% N₂ and maintained by 0.8%–1.5% sevoflurane through a tightly fitting mask. Group II ($n=11$) animals were used to test the time course of sevoflurane in the spinally transected rats; Group III ($n=9$), group IV ($n=6$) and group V ($n=5$) animals were used to test the effect of bicuculline (GABA_A receptor antagonist), phaclofen (GABA_B receptor antagonist) and naloxone (opioid receptor antagonist), respectively. Animals in groups II–V were anesthetized with urethane (1.0 g/kg, ip). The trachea, left internal jugular vein and carotid artery were cannulated for artificial ventilation, drug administration and blood pressure monitoring, respectively.

Following laminectomy, the spinal cord was transected at T₉–T₁₀ with 2.0% lidocaine surface anesthesia. The experiments were started at least 2 h after transection. During experiments, core body temperature was maintained at 37–39 °C by a warm blanket and a heat lamp. In order to maintain effective circulation, 0.5–1 mL 5% glucose was injected into the internal jugular vein every 1–2 h.

Electrophysiological recording Electromyographic measurements were taken in the gastrocnemius muscles. Two stainless steel needles were separately inserted into the two toes of the ipsilateral hindpaw for electrical stimulation. The intensity of electrical stimulation (1 ms, 50 V, 3 pulses, 1 Hz) was sufficient to excite the C-fiber nociceptors. Two components of the electromyographic response, the A- and C-responses, were evoked by the electrical stimulation. The C response was an indication of nociceptive reflex. An averaged C response was analyzed by a signal processing system (SMUP-PC, Fudan University).

Drug administration In group I, sevoflurane was delivered at concentrations of 0.8%, 1.0%, 1.5%, 2.0%, and 2.5%. Electromyographic measurements were taken 25 min after inhalation of sevoflurane. In group II, 1.0% sevoflurane was given, and electromyographic measurements were taken every 3 min. In groups III, IV, and V, as a control, bicuculline (0.1 mg/kg), phaclofen (0.6 mg/kg) or naloxone (0.4 mg/kg) were first intravenously administered without inhalation of sevoflurane. Two hours later, bicuculline, phaclofen, or naloxone at the same doses was administered, respectively, 15 min after inhalation of 1.0% sevoflurane.

Data analysis The effects of drugs, dose dependence, and time course were analyzed by using the paired *t*-test. Differences between groups were determined to be statistically significant if $P<0.05$. All data are shown as mean±SD.

Results

Consistent with our previous study^[11], the strong cur-

rent-induced electromyographic responses from the gastrocnemius muscle consisted of two components: first, a primary myelinated afferent fiber-mediated A response with a latency of 5–10 ms, and second, the unmyelinated fiber-mediated C response with latency of >100 ms. Given that primary afferent C fibers conduct nociceptive information, this study focused on the change in C responses.

Effect of sevoflurane on the spinal cord To examine whether inhalation of sevoflurane affects the spinal cord neurons, the spinal cord was transected at the T_{9–10} segment. Following inhalation of sevoflurane at concentrations of 1.0%, 1.5%, 2.0%, and 2.5%, C responses were reduced to 36.1%±17.4%, 11.7%±8.6%, 2.2%±5.2% and 0% of control ($P<0.01$), respectively (Figure 1). The inhibition occurred in a time-dependent manner. When 1.0% sevoflurane was inhaled, C responses were 60.0%±18.1%, 50.4%±13.5%, 42.0%±14.5%, 33.2%±13.5%, and 31.5%±13.8% at 1 min, 4 min, 7 min, 10 min, and 13 min after inhalation, respectively, compared with the group without sevoflurane (Figure 2). C responses recovered almost completely within 9 min of ceasing inhalation.

Figure 1. Inhalation of sevoflurane dose-dependently reduces the C response in rats with transected spinal cords. Before inhalation of sevoflurane, the baseline area of the C response is considered to be 100%. $n=6$. Mean±SD. ^c $P<0.01$ vs baseline.

Reversal of sevoflurane-induced inhibition by bicuculline and naloxone As shown in Figure 3, bicuculline (0.1 mg/kg, iv) failed to alter the C response in the absence of sevoflurane. Following 20 min of inhalation of 1.0% sevoflurane, bicuculline at the same dose significantly increased the C responses at the time points of 1 min, 4 min, 7 min, 10 min, and 13 min ($P<0.05$). However, phaclofen (0.6 mg/kg) failed to alter the C response in the absence or presence of sevoflurane.

Although the C responses appeared to be slightly

Figure 2. Time course of 1.0% sevoflurane-induced depression of C responses in rats with transected spinal cords. Before inhalation of sevoflurane, the baseline area of the C response is considered to be 100%. ↑ indicates the time point at which inhalation of sevoflurane was terminated. *n*=11. Mean±SD. ^c*P*<0.01 vs baseline.

enhanced by naloxone alone (0.4 mg/kg, iv) in the absence of sevoflurane, this effect was not statistically different from the control (Figure 4). After the rats inhaled 1% sevoflurane, naloxone significantly increased their C responses at time points of 1 min, 4 min, 7 min, 10 min, 13 min, and 16 min (*P*< 0.05).

Figure 3. Effects of bicuculline on C responses evoked in spinally transected rats in the presence or absence of 1.0% sevoflurane. SS indicates the steady-state area of the C response before administration of bicuculline (0.1 mg/kg, iv). Before SS, the baseline area of the C response is considered to be 100%. All rats were given bicuculline at the steady-state time point. *n*=9. Mean±SD. ^b*P*<0.05, ^c*P*<0.01 vs steady-state.

Discussion

Several studies have shown that the mechanisms underlying the suppression of noxious stimuli-induced motor reactions by volatile anesthetics, including sevoflurane, are

Figure 4. Effect of naloxone on the C response evoked in spinally transected rats in the presence or absence of 1.0% sevoflurane. SS indicates the steady-state area of the C response before the administration of naloxone (0.4 mg/kg, iv). Before SS, the baseline area of the C response is considered to be 100%. All rats were given bicuculline at the steady-state time point. *n*=5. Mean±SD. ^b*P*<0.05, ^c*P*<0.01 vs steady-state.

likely to be spinal in nature rather than involving supraspinal structures^[5,6,12]. Apart from immobility mediated by reducing the activity of spinal α-motoneurons, studies on the effects of sevoflurane on nociceptive sensory neurons in the spinal cord are generally lacking. The C-fiber-induced response recorded in the peripheral nerve or muscle is commonly used to characterize spinal processing and is considered to be an acute pain model^[11]. By means of this model, the present work for the first time shows that inhalation of sevoflurane produces a dose-dependent reduction of primary sensory afferent C-fiber-mediated nociceptive responses in the rat after transection of the spinal cord at T₉₋₁₀. This indicates that sevoflurane not only suppresses excitation in α-motor neurons but also inhibits the activity of pain-sensitive neurons in the dorsal horn of the spinal cord, in the absence of supraspinal input.

It is well-known that GABA receptors exist in the spinal cord and, when activated, cause decreased excitability of the neurons in which they exist^[13]. A recent report showed that the intrathecal administration of GABA_A or glycine receptor antagonists increased the MAC (minimum alveolus concentration) value of isoflurane by approximately 40% in rats^[14]. Yamauchi *et al* also observed an approximately 50% reversal of halothane depression^[15]. Similarly, in the present study, the sevoflurane-induced inhibition of nociceptive C responses was reversed by the intravenous administration of 0.1 mg/kg bicuculline, a GABA_A receptor antagonist. This

reversal effect by bicuculline seems unlikely to be involved in a release of a GABA-mediated tonic inhibition, given that 0.1 mg/kg bicuculline in the absence of sevoflurane did not increase nociceptive C responses significantly. Previous studies have revealed that the sevoflurane-induced inhibition of field potentials evoked from CA1 of the hippocampus is partially antagonized by phaclofen, a competitive antagonist of the GABA_B receptor^[16]. However, the antinociceptive effect of halothane was not affected by the intrathecal administration of GABA_B receptor antagonist CGP 35348^[7]. Similarly, our preliminary results show that intravenous administration of 0.6 mg/kg phaclofen failed to affect nociceptive C responses (data not shown). Taken together, these results suggest that the antinociceptive effect of sevoflurane might be mainly mediated by GABA_A receptors in the spinal cord rather than GABA_B receptors.

Opioid receptors are densely localized presynaptically and postsynaptically on pain-sensitive neurons in the spinal cord, which play a critical role in spinal antinociception. It has been reported that intravenous or intrathecal morphine is able to reduce the minimum alveolar concentration of halothane^[8-10]. In the present study, the fact that naloxone blocked the sevoflurane-induced inhibition of nociceptive C responses provides further support for the involvement of spinal opioid receptors in antinociception mediated by sevoflurane.

In conclusion, the volatile anesthetic sevoflurane can directly depress spinal transmission of nociceptive information in the spinal cord, by a mechanism that may involve GABA receptors and opioid receptors.

Abstract

Aim: To investigate the blood pressure (BP), baroreflex sensitivity (BRS), and organ damage in hybrids of spontaneously hypertensive rats and Sprague-Dawley rats. **Methods:** Spontaneously hypertensive rats and Sprague-Dawley rats were crossbred, and the F₁ hybrids were inbred randomly to produce an F₂ generation. At the age of 52 weeks, the F₁ and F₂ hybrids were tested to determine BP and BRS in a conscious state. Histopathological examinations were carried out after BP recording and BRS studies. **Results:** BP and BRS were not different in F₁ and F₂ hybrids. BRS was inversely related to systolic BP (SBP) in male, female, or whole populations of hybrids. Quantitatively, BRS values were one-third determined by SBP level (the determinant coefficient was 0.326). The indexes for left ventricular hypertrophy, aortic hypertrophy, and renal damage were all positively related to BP, and negatively related to BRS. In multiple-regression analysis, left ventricular and aortic hypertrophy and glomerulosclerosis score were all most significantly associated with lower BRS and higher systolic BP. The contribution of BRS to left ventricular and aortic hypertrophy and glomerulosclerosis was greater than that of SBP. **Conclusion:** The present work with hybrid rats demonstrated quantitatively that the BRS value was one-third determined by SBP level. Both BP level and BRS value contributed greatly to the hypertensive organ damage. However, the contribution of BRS to the hypertensive organ damage was greater than that of BP level in these rats.

Introduction

Arterial baroreflex (ABR) plays a crucial role in cardiovascular regulation. It was found that ABR function, expressed by baroreflex sensitivity (BRS), was impaired in hypertensive patients and animals^[1–4]. This impairment of BRS is attributed mainly to the high blood pressure (BP) level based on the following observations. (i) In renovascular hypertensive rats, BRS decreased significantly 1 d and 7 d after renal artery clipping^[5,6]. One day after removal of a left renal artery clip, BRS was inversely related to the BP level. BRS was restored as early as renovascular hypertension was reversed^[7]. (ii) In spontaneously hypertensive rats (SHR), many antihypertensive drugs lower BP and restore BRS at the same time^[8,9]. On the other hand, it was found that BRS

might be lower in normotensive children with hypertensive parents or in young spontaneously hypertensive rats (SHR) before hypertension^[10,11]. Therefore, it is not yet clear how important BP level is in influencing BRS. To answer quantitatively this question was the first aim of the present work.

It is well known that BP level is an important determinant for end-organ damage (EOD) in hypertensive patients and hypertensive animals. However, it is certainly not the only determinant for EOD. In our previous work, it was found that BRS was related to the severity of EOD in SHR^[12]. The second aim of the present work was to ascertain whether BRS was as important as BP level in determining the severity of EOD.

Hybrid offspring of SHR and normotensive rats are used widely to analyze the relationship between BP level and other

parameters. The present work was designed to study the features of BP, BRS, and EOD, and the relationships between these parameters in hybrid offspring of SHR and Sprague-Dawley (SD) rats.

Materials and methods

Animals Sprague-Dawley rats were purchased from the Sino-British SIPPR/BK Lab Animal Ltd (Shanghai, China). SHR were provided by the Animal Center of the Second Military Medical University (Shanghai, China). SHR and SD rats were crossbred, and the F₁ hybrids were inbred randomly to produce F₂ hybrids. All rats were housed at controlled temperature (23 °C–25 °C) and lighting (8:00–20:00 light: dark cycle) with free access to food and tap water. All animals used in this work received humane care in compliance with institutional animal care guidelines.

Blood pressure measurement At the age of 52 weeks, the F₁ and F₂ hybrids were tested to determine BP in a conscious state. Systolic BP (SBP), diastolic BP (DBP), and heart period (HP) were recorded continuously using techniques described previously^[13,14]. The BP signal was digitized by a microcomputer. SBP, DBP, and HP values from every heartbeat were determined on line. The mean values of these parameters during a period of 24 h were calculated, and served as SBP, DBP, and HP.

Baroreflex sensitivity measurement To determine the function of ABR in conscious rats, the methods widely used are derived from that of Smyth, which was first applied to humans^[15]. The principle of this method is to measure the prolongation of HP in response to an elevation of BP. With some modifications, this method has been used in conscious rats^[16,17]. A bolus injection of phenylephrine was used to induce an elevation of BP. The dose of phenylephrine was adjusted to raise SBP to between 20 mmHg and 40 mmHg. HP was plotted against SBP for linear regression analysis and the slope of SBP-HP was expressed as BRS (ms/mmHg). As there exists a delay between the stimulus and response (approximately 1 s), the slopes were calculated by computer with 1–10 beats of shift for linear regression analysis, and the slope with the highest correlation coefficient was used as BRS. A correlation analysis with 5 beats of shift, for example, means that values of HP₆/SBP₁, HP₇/SBP₂, and HP₈/SBP₃ were used.

Morphological examination Morphological examinations were carried out after BP recording and BRS studies. The animals were weighed and killed by decapitation. The thoracic and peritoneal cavities were opened immediately. The right kidney, aorta, and heart were excised and rinsed in

cold physiological saline. The right kidney was blotted and weighed. The left ventricle was isolated, blotted, and weighed. At the same time, the aorta was cleaned of adhering fat and connective tissue. Just below the branch of the left subclavicular artery, a 30 mm-long segment of thoracic aorta was harvested, blotted, and weighed. Ratios of left ventricular weight to body weight (LVW/BW), right ventricular weight to body weight (RVW/BW), ventricular weight to body weight (VW/BW), left ventricular weight to right ventricular weight (LVW/RVW), and aortic weight to the length of aorta (AW/length) were calculated^[18,19]. Histopathological observation was also carried out using our conventional method^[20]. Briefly, immediately after gross detection, all samples of left ventricles in 2 mm-thick to 3 mm-thick slices, aortae, and kidney were immersed in formalin solution for more than 1 week, dehydrated in ethanol, cleared in dimethylbenzene and embedded in paraffin. The 5 μm-thick sections were then prepared and stained with hematoxylin and eosin for light microscopic evaluation.

Glomerulosclerosis score For the semiquantitative evaluation of glomerular damage, the glomerulosclerosis score (GSS) was defined as described previously^[21]. From the light microscopic specimens, approximately 50 glomeruli from the outer cortex and the same number of glomeruli from the inner cortex of each kidney were graded according to the degree of sclerosis: 0, no mesangial expansion; 1, mild mesangial expansion (less than 30% of a glomerular area); 2, moderate mesangial expansion (30%–60% of a glomerular area); 3, marked mesangial expansion (more than 60% of a glomerular area); and 4, global sclerosis. This was carried out by one observer in a blind fashion using coded slides. A weighted composite sclerosis score was then calculated for each kidney according to the following formula: glomerulosclerosis score = [1 × (number of grade 1 glomeruli) + 2 × (number of grade 2 glomeruli) + 3 × (number of grade 3 glomeruli) + 4 × (number of grade 4 glomeruli)] × 100 / (number of glomeruli observed).

Statistical analysis Data were expressed as mean ± SEM. Comparisons between 2 groups were made by Student's *t*-test. The relationships between hemodynamic parameters and organ damage parameters were analyzed by classic univariate correlation analysis. Stepwise multiple-regression analysis was used to study the independent effect of hemodynamic parameters on organ damage. *F* to enter and *F* to remove were set to *P* < 0.05 and *P* > 0.10, respectively. *P* < 0.05 was considered statistically significant. Statistical analysis was carried out using software SPSS 11.0.0 (SPSS, Chicago, Illinois, USA).

Results

Blood pressure and baroreflex sensitivity in the F₁ hybrids with different parenthood Blood pressure, HP, and BRS values in the F₁ hybrids are shown in Figure 1. BP was slightly higher in H×S offspring rats (hybrids derived from male SHR and female SD rats) than in S×H offspring rats (hybrids derived from male SD and female SHR rats). This difference reached a significant level only for DBP in males and in the whole F₁ hybrid group. Male H×S rats possess significantly higher DBP than female H×S rats, but this sex difference in DBP of S×H rats was not significant. A similar sex-difference tendency was found in SBP but never reached statistical significance. No obvious sex or strain differences in HP or BRS were found in F₁ hybrids.

Blood pressure and baroreflex sensitivity in the F₁ and F₂ hybrids As shown in Figure 2, no obvious difference was found between F₁ (including H×S and S×H offspring rats) and F₂ hybrids with respect to BP, HP, and BRS. In F₁ and F₂ hybrids, male rats tended to have slightly higher BP than female rats. However, these sex differences in SBP and DBP did not reach statistical significance. The distribution of SBP and BRS in F₁ and F₂ hybrids is shown in Figure 3. No obvious difference between F₁ and F₂ was noted.

Relationship between systolic blood pressure and baroreflex sensitivity in the F₁ and F₂ hybrids It was found

that BRS was significantly and inversely related to SBP in both F₁ ($r=-0.599, n=96, P<0.01$) and F₂ offspring ($r=-0.510, n=36, P<0.01$) (Figure 4A,4B). When the whole population (F₁+F₂) were analyzed, the correlation coefficient (r) was -0.571 ($n=132, P<0.01$) (Figure 4C) and the determinant coefficient (r^2) was 0.326. This value means that the BRS value is 33% determined by SBP level. In accordance with this result, it was found that lower BRS was not always linked to higher BP in the hybrid offspring rats. In the hybrids studied (Figure 4), we found some normotensive animals with a lower BRS (SBP<140 mmHg, BRS<0.4 ms/mmHg; $n=5$) and hypertensive animals with a higher BRS (SBP>150 mmHg, BRS>0.7 ms/mmHg; $n=22$). Two examples for BRS obtained from the hybrids are shown in Figure 5A, a normotensive animal with a lower BRS; and Figure 5B, a hypertensive animal with a higher BRS.

Organ damage in the F₁ and F₂ hybrids The average values of LVW/BW, AW/length, and GSS are presented in Figure 6. No obvious difference between F₁ and F₂ hybrids was found.

Relationships between blood pressure, baroreflex sensitivity, and organ damage in hybrids The relationships between BP, HP, BRS, and organ damage in the hybrids were shown in Table 1. It was found that LVW/BW, an index for left ventricular hypertrophy, AW/length, an index for aortic hypertrophy, and GSS, an index for renal damage, were all

related positively to BP, and related negatively to BRS. There was no significant relationship between HP and organ dam-

age parameters (Table 1). Some examples for important correlations were shown in Figure 7.

	LVW/BW	AW/length	GSS
SBP	0.492°	0.464°	0.465°
DBP	0.416°	0.303°	0.411°
HP	-0.162	-0.074	-0.164
BRS	-0.646°	-0.559°	-0.590°

AW, aortic weight; BW, body weight; DBP, diastolic blood pressure; GSS, glomerulosclerosis score; LVW, left ventricular weight; SBP, systolic blood pressure.

The relative dependencies of organ damage on hemodynamic parameters were assessed by stepwise multiple-regression analysis. LVW/BW, AW/length, and glomerulosclerosis score were all most significantly associated with lower BRS ($\beta=-0.542, P<0.01$; $\beta=-0.436, P<0.01$; and $\beta=-0.482, P<0.01$, respectively) and higher SBP ($\beta=0.183, P<0.01$; $\beta=0.216, P<0.01$; and $\beta=0.191, P<0.01$, respectively). After comparing the standardized partial regressive coefficients, it was found that the contribution of BRS to left ventricular, aortic hypertrophy, and glomerulosclerosis was greater than

that of SBP.

Discussion

The main contributions of the present work may be summarized as follows:

(i) It is well known that the BRS value is closely related to and importantly determined by BP level. The present work is the first to demonstrate quantitatively that BRS value is one-third determined by SBP level (the determinant coefficient was 0.326).

(ii) Both BRS and SBP level contributed to organ damage. This report is the first to show that the contribution of BRS to organ damage is greater than that of SBP.

(iii) F₁ hybrid offspring are suitable for studying the relationships between BP level and other parameters.

Figure 5. Schematic presentation of baroreflex sensitivity obtained from the hybrids. See Figure 1 for abbreviations. (A) A normotensive rat with lower baroreflex sensitivity. (B) A hypertensive rat with normal baroreflex sensitivity. Slope of the regression is expressed as baroreflex sensitivity.

Many abnormalities or changes have been reported to relate to high BP level in hypertension. Among these abnormalities or changes, some are intrinsically related to hypertension and some are only accompanying phenomena in hypertension. Hybrid offspring of hypertensive and normotensive rats are often used to distinguish these 2 sorts of changes found in hypertension. Using these hybrid offspring, it was found that the genes responsible for the hypertensive trait and those responsible for the hyperactivity trait are not tightly linked^[22,23]. The relationships between BP and other parameters, such as salt appetite^[24], temperature^[25], and sensitivity to stress^[26], have also been studied in the hybrids rats derived from hypertensive and normotensive rats. Recently, hybrid rats derived from a hypertensive and normotensive strain were produced to study genetic markers for blood pressure using statistical techniques for quantitative trait loci analysis^[27]. It has been noted that BRS is lower in hypertensive patients and hypertensive animals. However, no study has been carried out using hybrid rats to analyze the relationship between BP and BRS. This may be due to the large quantity of work that it entails; the measurement of BRS in conscious and unrestrained rats requires a computerized BP monitoring system and more than 100 rats are

Figure 6. Organ damage in the F₁ and F₂ hybrids. AW, aortic weight; BW, body weight; GSS, glomerulosclerosis score; LVW, left ventricular weight. The numbers of rats used were 49 and 16 in male (M), 47 and 20 in female (F), and 96 and 36 in total (M+F) F₁ and F₂ rats, respectively.

needed for such a study. Investigating the relationship between BP and BRS using hybrid offspring rats was the first aim of the present work.

To analyze the links between BP and other parameters previous studies have used hybrid rats derived from a cross between SHR and Wistar-Kyoto (WKY) rats^[22–26], stroke-prone SHR (SHRSP) and WKY rats^[28], Dahl/Iwai salt-sensitive rats and WKY rats^[29], New Zealand genetically hypertensive rats and Wistar rats^[23], and SHR and Donryu rats^[30]. In the present study, SHR were crossbred with SD rats, but not with WKY rats. This is based on the following considerations: (i) WKY rats possess a relatively higher BP level than SD rats; and (ii) compared with WKY rats, the genetic background of SD rats is more different from that of SHR. Therefore, using SD rats may help to produce hybrid rats exhibiting wider range of BP levels or BRS values, which would be expected for the correlation analysis.

It was found in previous studies that the BP of hybrid offspring derived from SHR and WKY rats depended on the

Figure 7. Examples of the correlation between hemodynamic parameters and organ damage parameters in hybrids. $n=132$. See Table 1 for abbreviations.

strain of the male progenitor of the cross; male offspring with an SHR male progenitor had significantly higher BP (SBP, +20 mmHg) than male offspring with a WKY male progenitor^[31]. The same results were also found in hybrids of SHRSP and WKY rats (SBP/DBP, +20/15 mmHg)^[28]. These observations showed strong evidence for a locus or loci on the SHR or SHRSP Y chromosome that contributed to hypertension in these models. Some subsequent studies confirmed the Y-chromosome effect on BP^[27,32]. In accordance with previous reports, the current work showed that the male F₁ hybrids with hypertensive fathers had higher BP levels than those with normotensive fathers (SBP/DBP, +12/14 mmHg). The difference reached a significant level only for DBP. These differences found in the present work were slightly lower than those in previous studies. This might be due to the difference in BP measurement: we measured BP continuously for 24 h while others measured BP either once by tail sphygmomanometry^[31] or by using average values sampled every 5 min for 10 s over a 4 d period using the radiotelemetry system^[28]. However, in our study, the F₁ hybrids with different parenthood had similar HP and BRS values.

In previous studies concerning hybrid offspring rats, F₁, F₂ or the whole population of F₁ and F₂ were used^[22–26,30]. The use of F₂ hybrids is based on the expectation of obtaining a wider distribution range in the parameters studied. In the present work, no obvious differences in the average val-

ues of SBP and BRS were found between F_1 and F_2 hybrids. In addition, the distribution of SBP and BRS values was similar in F_1 and F_2 hybrids. It is known that BP and BRS phenotypes are not controlled by only one gene, but rather by many genes^[27]. This may explain the wide distribution range of SBP and BRS values. Accordingly, we propose that F_1 hybrids may be suitable for these kinds of studies.

Abnormalities in baroreflex have been demonstrated in numerous studies in both experimental and human hypertension^[15,33], and the impairment in baroreflex is thought to be the result of elevated BP or reduced arterial distensibility^[6,7]. In agreement with previous studies, we found that BRS was significantly and inversely related to SBP in the hybrid offspring rats. However, in the hybrids studied, we also found some normotensive animals with a lower BRS and hypertensive animals with a higher BRS. These results indicate that lower BRS is not always linked to higher blood pressure in the hybrid offspring rats. Previous studies have shown that impairment of BRS may be present early in the course of, or may precede the development of, hypertension. BRS has been shown to be diminished in the early phase of hypertension in SHR as well as in borderline essential hypertension in humans; impairment of BRS is thought to be genetically determined in part^[10,34]. In addition, it was found that other factors, such as alterations in endothelial prostaglandins and opioid peptides, might also contribute to the impairment of BRS^[35,36]. Therefore, BP is not the only determinant of BRS. However, it is not clear how important BP level is in influencing BRS. Our study, for the first time, demonstrated quantitatively that BRS was one-third determined by SBP level (the determinant coefficient was 0.326).

It is well known that high BP level induces organ damage, while decreasing BP level can prevent EOD. Our present study showed that both SBP and DBP were significantly and positively related to LVW/BW, AW/length, and GSS. These results indicate that elevated BP has a major effect on EOD in hybrid offspring rats. However, BP level is not the only determinant for EOD. Our previous study proposed that BRS was one of the independent variables related to EOD score^[12]. In the present work, BRS was significantly and negatively related to LVW/BW, AW/length, and GSS. Multiple-regression analysis showed that the contribution of BRS to left ventricular, aortic hypertrophy, and glomerulosclerosis was greater than that of SBP. The present study is the first to show that BRS makes a greater contribution to hypertensive organ damage than does BP level.

In conclusion, the present work with hybrid rats demonstrated quantitatively that BRS value was one-third determined by SBP level. Both BP level and BRS value contrib-

uted to the hypertensive organ damage. However, the contribution of BRS to the hypertensive organ damage was greater than that of BP level in these rats.

Abstract

Aim: To explore the relationship between differential leucocyte count and coronary atherosclerosis. **Methods:** The study population consisted of 507 consecutive patients (376 male and 131 female) who underwent coronary angiography for suspected or known coronary atherosclerosis. The patients' smoking and drinking habits were investigated, and anthropometric measurements, serum measurements, and hematological measurements were conducted for every patient. The severity of coronary atherosclerosis was defined by using Gensini's score system. One-way ANOVA, Spearman's correlation analysis, and multivariate stepwise linear regression analysis were employed to explore the relationship between differential leucocyte count and coronary atherosclerosis. **Results:** One-way ANOVA indicated that the diastolic blood pressure, glucose, urea, creatinine, leukocyte count, neutrophil count, monocyte count, hemoglobin, and platelet count differed among the groups according to Gensini's score, the tertile values of which were used as cutoff points. Spearman's correlation analysis suggested that Gensini's score was significantly correlated with age, diastolic blood pressure, glucose, urea, creatinine, leukocyte count, neutrophil count, monocyte count, hemoglobin, and erythrocyte count, respectively. Multivariate stepwise linear regression analysis show that neutrophil count ($\beta=0.247$, $P=0.000$), age ($\beta=0.141$, $P=0.001$), glucose ($\beta=0.173$, $P=0.000$), creatinine ($\beta=0.088$, $P=0.063$), hemoglobin ($\beta=-0.168$, $P=0.013$) and sex (men were coded as 1 and women were coded as 2; $\beta=-0.121$, $P=0.012$) were significantly independently associated with the Gensini's score. **Conclusion:** The independent association of neutrophil count with the angiographical characteristics of coronary atherosclerosis, as estimated by Gensini's score, strongly suggests that granulocytosis may play a role in the development of coronary atherosclerosis.

Introduction

Inflammation is a key feature of atherosclerosis, and leukocyte count is a marker of inflammation that is widely available in clinical practice. Numerous epidemiological and clinical studies have shown leukocytosis to be an independent predictor of future cardiovascular events, both in healthy individuals free of coronary heart disease, and in patients with stable angina, unstable angina, or a history of myocardial infarction. This relationship has been observed in pro-

spective and retrospective cohort studies, as well as in case-control studies^[1]. The relationship is strong, consistent, temporal, dose-dependent, and biologically plausible. Elevated differential cell counts, including eosinophil, neutrophil, and monocyte counts, also predict the future incidence of coronary heart disease^[2]. Clinical studies suggest that neutrophil infiltration is actively associated with acute coronary events. The high number of neutral endopeptidase-positive neutrophils in ruptured plaques, compared

with eroded plaques, may reflect differences in the underlying pathophysiological mechanisms^[3]. However, there is little information available about the association between the angiographical characteristics of coronary atherosclerosis as estimated by conventional coronary angiography and circulating leukocyte count.

Gensini's scoring system assigns a severity score for a stenosed vessel depending on the degree of luminal narrowing and the importance of its location^[4]. Therefore, we evaluated the association between the angiographical characteristics of coronary atherosclerosis and circulating leukocyte count.

Materials and methods

Study subjects The study population consisted of 507 consecutive patients who underwent coronary angiography for suspected or known coronary atherosclerosis at the First Affiliated Hospital of Nanjing Medical University, Nanjing, China, from 2004 to 2005. Patients with spastic angina pectoris (ie, acetylcholine-positive) were excluded. Patients with 2-week infectious processes before catheterization, heart failure (Killip class =2 after acute myocardial infarction), hepatic dysfunction, vascular disease (aortitis treated with prednisolone), familial hypercholesterolemia, thyroid dysfunction, or adrenal dysfunction were also excluded. This study was approved by the Ethics Committee of the First Affiliated Hospital of Nanjing Medical University and informed consent was obtained from all patients.

Coronary angiography Coronary arteries were cannulated by using the Judkins technique^[5] with 5F catheters, and recorded on Kodak, 35 mm Cinefilm at a rate of 30 frames per second. When stenotic coronary arteries were found, the presence of stenosis was determined by using a computer-assisted coronary angiography analysis system (Mipron 1; Kontron) after the direct intracoronary injection of isosorbide dinitrate (ISDN; 2.5 mg in 5 mL solution over 20 s). One minute after the injection of ISDN through the Judkins catheter, coronary angiography was performed from several projections. The severity of coronary atherosclerosis was measured by using Gensini's scoring system, based on the hypothesis that the severity of coronary heart disease is a consequence of the functional significance of vascular narrowing and the extent of the area perfused by the involved vessel or vessels. In this scoring system, a greater reduction of the lumen diameter is assigned a higher score than a distal lesion^[4].

Cigarette smoking and alcohol intake The subjects' cigarette smoking and alcohol intake habits were assessed

by means of a standardized questionnaire. Past or current smokers were asked about the number of cigarettes smoked per day, and those who reported smoking at least 1 cigarette per day during the preceding year were classified as current smokers. With regard to smoking status, subjects were classified as "never a smoker" and "smoker" (including "formerly a smoker" and "currently a smoker"). Subjects who reported consuming at least 50 g alcohol/week were regarded as "current drinkers". Subjects were classified as "never a drinker" and "drinker" (including "formerly a drinker" and "currently a drinker").

Anthropometric measurements Anthropometric measurements were taken after the patients had removed their shoes and upper garments and had donned an examining gown. Each measurement was performed twice and the average was used in the analysis. Height was measured to the nearest 0.1 cm using a wall-mounted stadiometer. Weight was measured to the nearest 0.1 kg using a hospital balance beam scale. Body mass index (BMI) was calculated as weight (kg) divided by the square of height (m²). Blood pressure was measured in the right arm with the participant seated and the arm bared. Three readings were recorded for each individual, and the average was recorded.

Hematological measurements Blood samples from every patient were taken at admission to the coronary unit and measurements including total leukocyte count, neutrophil count, eosinophil count, lymphocyte count, monocyte count, basophil count, hemoglobin, erythrocyte count, and platelet count were carried out by an automated blood analyzer.

Laboratory measurements The 12-h fasting blood samples were taken in the morning and the sera were stored at -70 °C immediately after centrifugation until being assayed. All laboratory measurements were conducted at the Central Clinical Laboratory at the First Affiliated Hospital of Nanjing Medical University. Total cholesterol, triglyceride, fasting blood glucose, urea, creatinine, and uric acid were determined by enzymatic procedures on an automated autoanalyzer (AU 2700 Olympus, 1st Chemical Ltd, Japan). The laboratory was monitored for the precision and accuracy of glucose and lipid measurements by the surveillance program. Measurements of agency-assigned quality control samples showed no consistent bias over time within or between surveys.

Statistical analysis Data analysis was performed using the Statistical Package for the Social Sciences (SPSS for Windows, version 10.0; SPSS, Chicago, IL, USA). Patients were classified into 3 groups with low, intermediate, and high Gensini's scores using the tertile values as cutoff points, so that each group had an approximately equal number of pa-

tients to minimize any bias that may have been produced in the statistical analysis. Results for continuous variables are expressed as mean±SD and comparisons of continuous variables were analyzed by the one-way analysis of variance (ANOVA). Categorical variables were compared among the groups of patients by a chi-squared analysis. The Spearman two-way test was used to assess the relationship between 2 quantitative variables. We assessed independent predictors of Gensini's score with multiple regression analysis. Differences were considered to be significant if the null hypothesis could be rejected with >95% confidence. All *P* values are 2-tailed.

Results

Clinical and biochemical characteristics in patients grouped according to Gensini's score Table 1 show the clinical and biochemical characteristics in patients grouped according to Gensini's score, tertile values of which were used as cutoff points. Patients in tertiles I, II, and III had an increasingly higher Gensini's score. The frequency distribution of sex (*P*=0.009) and smoking status (*P*=0.000) were different among the 3 groups, and drinking status was simi-

lar among the 3 groups. The distribution levels of BMI, systolic blood pressure, total cholesterol, triglyceride, uric acid, eosinophil count, basophil count, and lymphocyte count were similar among the 3 groups (*P*>0.05), whereas those of age (*P*=0.000), diastolic blood pressure (*P*=0.011), fasting blood glucose (*P*=0.000), urea (*P*=0.012), creatinine (*P*=0.005), leukocyte count (*P*=0.000), neutrophil count (*P*=0.000), monocyte count (*P*=0.000), hemoglobin (*P*=0.000), erythrocyte count (*P*=0.008) and platelet count (*P*=0.019) differed among the groups.

Spearman correlations between Gensini's score and leukocyte count, anthropometric measurements, and biochemical characteristics in patients Table 2 shows the results of Spearman correlations between Gensini's score and leukocyte count, anthropometric measurements, and biochemical characteristics in patients. The Spearman correlation analysis indicated that the level of Gensini's score was significantly correlated with age (*r*=0.225, *P*=0.000), DBP (*r*=-0.106, *P*=0.017), fasting blood glucose (*r*=0.195, *P*=0.000), urea (*r*=0.137, *P*=0.002), creatinine (*r*=0.165, *P*=0.000), leukocyte count (*r*=0.303, *P*=0.000), neutrophil count (*r*=0.326, *P*=0.000), monocyte count (*r*=0.253, *P*=0.000), hemoglobin (*r*=-0.133, *P*=0.003), and erythrocyte count (*r*=-0.094, *P*=

0.035), whereas a significant correlation was not found between Gensini's score and Body Mass Index, SBP, total cholesterol, triglyceride, uric acid, eosinophil count, basophil count, lymphocyte count, or platelet count.

Multiple linear regression analysis with Gensini's score as dependent variable To examine the independent associations between Gensini's score and leukocyte count, multiple linear regression analysis was performed. In this model, Gensini's score was used as the dependent variable and the independent variables included age, sex, smoking status, drinking status, body mass index, SBP, DBP, total cholesterol, triglyceride, fasting blood glucose, urea, creatinine, uric acid, leukocyte count, neutrophil count, eosinophil count, basophil count, lymphocyte count, hemoglobin, erythrocyte count, and platelet count. In the final model (Table 3), neutrophil count ($\beta=0.247, P=0.000$), age ($\beta=0.141, P=0.001$), glucose ($\beta=0.173, P=0.000$), creatinine ($\beta=0.088, P=0.063$), hemoglobin ($\beta=-0.168, P=0.013$) and sex (men were coded as 1 and women were coded as 2; $\beta=-0.121, P=0.012$) were significantly independently associated with Gensini's score.

Discussion

Cardiovascular disease is the leading cause of death in

the world^[6]. One of its most insidious forms is coronary heart disease due to atherosclerosis^[7]. Although many risk factors for coronary heart disease have been identified, they do not fully account for all cases of the disease. Thus, searches are underway for additional biological markers and especially inflammatory markers for the disease. Numerous epidemiological and clinical studies have shown leukocyte count to be an independent risk factor for coronary heart disease, a risk factor for future cardiovascular events in individuals apparently without cardiovascular disease, and a prognostic marker of future events in patients who already have cardiovascular disease^[1]. Although leukocyte count appears to be an independent predictor of cardiovascular events, some of its predictive ability can be explained by its interdependence with smoking. Therefore, further studies are needed to clarify just how prominent a role leukocytes play in the pathogenesis of coronary heart disease, as well as the clinical implications. Obviously, there is a need to determine the degree to which leukocyte count is independent of smoking and other risk factors^[2].

The present study was conducted to evaluate the association between the angiographical characteristics of coronary atherosclerosis and leukocyte count in patients with suspected coronary heart disease. The main finding of the present study is that the neutrophil count is significantly associated with Gensini's score according to one-way ANOVA, the Spearman correlation, and multiple linear stepwise regression analysis in these 507 Chinese subjects. This finding is consistent with results from previous studies, in which leukocytosis has been consistently shown to be an independent risk factor for coronary heart disease regardless of disease status^[2]. Furthermore, this study suggests a link between inflammatory and coronary atherosclerosis.

Our study is the first to document the independent association of neutrophil count with the angiographical characteristics of coronary atherosclerosis, which were approximated by using Gensini's score in Chinese subjects, and which is in agreement with the results of previous studies. In a meta-analysis of 1764 cases of coronary heart disease from 7 long-term prospective studies, involving a total of 30 374 participants, the association of coronary heart disease with neutrophil count was somewhat stronger than that with other specific leukocyte components^[8]. In a prospective cohort study of 55 patients with non-ST segment elevation acute coronary syndromes and angiographically documented coronary disease, acute inflammatory markers such as neutrophil count were higher among patients with multiple angiographically complex plaques than among those without^[9]. The results from an immunohistochemical study

Table 3. Predictors of Gensini’s score from multiple linear regression among patients.

on coronary artery segments suggest that neutrophil infiltration is actively associated with acute coronary events^[3]. Granulocytosis affects the development of coronary atherosclerosis through multiple pathological mechanisms that mediate inflammation, cause proteolytic and oxidative damage to the endothelial cells, plug the microvasculature, induce hypercoagulability, and promote infarct expansion^[2].

Moreover, another finding of this study is that age ($\beta=0.141, P=0.001$), creatinine (μ mol/L; $\beta=0.088, P=0.063$), glucose (mmol/L; $\beta=0.173, P=0.000$), hemoglobin (g/L; $\beta=-0.168, P=0.013$), and sex (men were coded as 1 and women were coded as 2, $\beta=-0.121, P=0.012$) were significantly associated with Gensini’s score after adjusting for the other cardiovascular risk factors. The results of the Atherosclerosis Risk in Communities study, a community-based study of risk factors for coronary heart disease (CHD) in middle-aged people indicated that high serum creatinine was associated with almost a 3-fold risk of coronary heart disease among middle-aged people with anemia (anemia was defined as hemoglobin <130 g/L in men and <120 g/L in women), whereas no increased risk was found in people with high serum creatinine in the absence of anemia^[10]. Another study found a relationship between low hemoglobin level and adverse cardiovascular outcomes in women with suspected ischemia^[11]. Several investigations as well as prospective studies have shown a significant correlation between glucose metabolism and atherosclerosis in patients without diabetes, and have shown that the glycemic milieu correlates with the cardiovascular risk according to a linear model^[12]. In addition, the present study demonstrated that age and being male were independent risk factors for coronary atherosclerosis, which was consistent with results from other studies^[13].

A limitation of the present study is that the subjects were from one center rather than multiple centers, which may result in selective bias; however, given the large size sample of this study, it may minimize the bias. In fact, the present

study is only a cross-sectional study rather than a retrospective study. And the other limitation of the study is that it provides no information regarding the cause and effect relationship between neutrophil count and coronary atherosclerosis. Although the correlation between neutrophil count and coronary atherosclerosis is significant in the present study, the clinical significance of this finding requires further investigation.

In conclusion, the independent association of neutrophil count with the angiographical characteristics of coronary atherosclerosis as approximated by Gensini’s score strongly suggests that granulocytosis may play a role in the development of coronary atherosclerosis. Thus, it may prove to be an equally informative, but less expensive and more readily available risk marker than other currently available risk factors. Further studies are required, however, to determine the implications of using the leukocyte count to predict clinical risk and outcome.

SCI Impact Factor of Acta Pharmacologica Sinica increased to 1.125

According to the latest Journal Citation Report 2004 (JCR 2004) published by Institute for Scientific Information (ISI, USA), we are greatly pleased to announce that the Science Citation Index (SCI) Impact Factor of Acta Pharmacologica Sinica (APS) has risen from 0.884 to **1.125**, ranking the 132nd out of 187 journals in the category of PHARMACOLOGY & PHARMACY, and the 49th out of 125 journals in the category of CHEMISTRY, MULTIDISCIPLINARY. APS is continued to be the only journal listed in the SCI in Chinese Pharmacology and Pharmacy and the latest impact factor is ranking the 8th out of 71 Chinese journals listed in SCI.

Here we would like to share the good news with all our authors, reviewers, and readers. Without your long-term contribution, APS cannot achieve such a progress! Hope to have your support continuously!

Full-length article

Honokiol inhibits arterial thrombosis through endothelial cell protection and stimulation of prostacyclin

Abstract

Aim: To study the effect of honokiol on arterial thrombosis and endothelial cells. **Methods:** Rabbit platelet aggregation was performed with Born's turbid method. Thrombosis was produced by the endothelial injury stimulated with electric current. Rat aortic endothelial cells (RAEC) were cultured and cell viability was assessed using the MTT assay. Nitric oxide (NO) concentrations in serum-free media of RAEC were determined using the kinetic cadmium-reduction method. The stable metabolite prostacyclin was measured in serum-free media of RAEC by radioimmunoassay. **Results:** Honokiol (37.6–376 $\mu\text{mol/L}$) decreased rabbit platelet aggregation *in vitro* in a concentration-dependent manner, while intravenously injection of honokiol (0.12–12 $\mu\text{g/kg}$) significantly inhibited rabbit platelet aggregation induced by collagen *ex vivo*. In the electrical current-stimulated carotid thrombosis model in rats, honokiol (5–50 $\mu\text{g/kg}$, iv) prolonged the thrombus occlusion time in a dose-dependent manner. *In vitro* honokiol (0.376–37.6 $\mu\text{mol/L}$) effectively protected cultured RAEC against oxidized low density lipoprotein (ox-LDL) injury, and significantly increased 6-keto-PGF_{1 α} (the stable metabolite of prostacyclin) in serum-free media of RAEC. Honokiol also increased NO level in RAEC serum-free medium at a lower concentration range (0.0376–0.376 $\mu\text{mol/L}$), but honokiol 3.76 $\mu\text{mol/L}$ decreased NO level. **Conclusion:** Honokiol is a potent arterial thrombosis inhibitor. Endothelial cell protection and the stimulation of prostacyclin release may be its main anti-thrombosis mechanism. Stimulation of NO release in endothelial cells may play a role, but it is not a key factor.

Introduction

Platelet activation and aggregation play essential roles in thromboembolic disorders^[1]. When platelets are activated they adhere to the injured blood vessel walls. This results in the formation of an occlusive thrombus in the lumen of the vessel^[2,3]. These thrombi are the source of many thromboembolic cerebral vascular diseases, including strokes^[4].

Honokiol is the main biphenyl neolignan isolated from Hou pu, the cortex of *Magnolia officinalis* (Magnoliaceae), which has been used for treatment of acute enteritis, bacterial or amebic diarrhea, chronic gastritis, etc, in traditional Chinese medicine. The pharmacological effects of honokiol

included inhibition of platelet aggregation by blocking thromboxane A₂ (TXA₂) generation and intracellular calcium mobilization^[5], protection of the myocardium against ischemic injury^[6], and suppression of ventricular arrhythmia^[7]. Recently honokiol was found to protect rat brain from focal cerebral ischemia–reperfusion injury by inhibiting neutrophil infiltration and reactive oxygen species production^[8]. However, the effects of honokiol on thrombosis and its influence on endothelial cells have not yet been reported. The aim of this study was to investigate the effects of honokiol on arterial thrombosis and endothelial cells to explore its potential mechanism of action.

Materials and methods

Chemicals and reagents Honokiol injection was prepared by the Department of Natural Medicinal Chemistry, School of Pharmaceutical Sciences, Peking University (Beijing, China). This water-soluble preparation of honokiol contains polyvinyl and other auxiliary materials. Before use it was diluted with normal saline to different concentrations for intravenous injection (0.5 $\mu\text{g/mL}$, 5 $\mu\text{g/mL}$, 50 $\mu\text{g/mL}$ for rats; 0.12 $\mu\text{g/mL}$, 1.2 $\mu\text{g/mL}$, 12 $\mu\text{g/mL}$ for rabbits; concentrations vary with surface area of the animals). Acetylsalicylic acid (ASA) was the product of Astra (Wuxi, China) and was dissolved in normal saline by sonication before use. Collagen was purchased from Sigma (St Louis, MO, USA) and dissolved in normal saline before use. Oxidized low density lipoprotein (ox-LDL) was the product of Beijing Union Sanyou Science and Technology Development Co (Beijing, China). 6-keto-PGF_{1 α} [the stable metabolite of prostacyclin (PGI₂)] immunoassay kits and nitric oxide (NO)/nitrate assay commercial kits were products of the Radioimmunity Institute of People Liberation Army General Hospital (Beijing, China). α -Tocopherol (VE) was the product of Beijing Double-Crane Pharmaceutical Co (Beijing, China). MTT was the product of Sigma. The control was normal saline plus defined proportion of auxiliary materials.

Experimental animals Male Sprague-Dawley rats and male New Zealand rabbits were obtained from the Experimental Animal Center of Peking University. The experimental procedures were approved by the Local Committee on Animal Care and Use.

Platelet aggregation study *in vitro* Blood samples were obtained from the auditory arteries of Male New Zealand rabbits weighing 3.0–4.0 kg into a syringe containing a 1:10 volume of 3.8% sodium citrate. Platelet-rich plasma (PRP) and platelet-poor plasma (PPP) were prepared by centrifugation of blood samples at 120 \times g and 850 \times g, respectively, for 15 min. The platelet count was adjusted to 1.8×10^9 platelets/mL with PPP. Platelet aggregation was measured using the 490 optical aggregometer (Chrono-log Co. Harvertown, PA USA) as described by Born^[9]. Collagen was used as an inducer with a final concentration of 40–50 $\mu\text{g/mL}$.

Platelet aggregation study *ex vivo* Male rabbits weighing 3.0–3.5 kg were used after overnight fasting. The rabbits were administered intravenously with either control, honokiol 0.12, 1.2, and 12 $\mu\text{g/kg}$ or ASA 1.2 mg/kg. Blood samples were then collected from the auditory arteries of the rabbits into a syringe containing a 1:10 volume of 3.8% sodium citrate at 10 min after administration. PRP and PPP were prepared as above. The platelet count was adjusted to 1.8×10^9 platelets/

mL with PPP and platelet aggregation was measured with the Chrono-log mode 490 optical aggregometer. Collagen was used as an inducer with a final concentration of 40–50 $\mu\text{g/mL}$.

Carotid thrombosis model in rats induced by electric current Male Sprague-Dawley rats (280–320 g) were anesthetized with urethane (1.5 g/kg, ip) after overnight fasting. The left carotid arteries were then isolated carefully and treated intravenously with either control, honokiol 0.5, 5, 50 $\mu\text{g/kg}$ or ASA 5 mg/kg. Carotid thrombus formation was induced using the modified Hladovec method^[10] on an Electric Thrombosis Stimulator (BT87-3, Baotou Medical College, Baotou, China) by delivering a current of 3 mA for 3 min at 10 min after treatment. Occlusion time (OT) of the arteries was measured through a timer linked to the temperature sensor on the Thrombosis Stimulator.

Culture of rat aortic endothelial cells Endothelial cells were isolated from rat aorta by gentle scraping with vertical ophthalmic forceps. The rat aortic endothelial cells (RAEC) were then grown in T75 polystyrene flasks in the presence of antibiotics (100 U/mL penicillin G and 100 mg/mL streptomycin) and subcultured as described by Centra *et al*^[11]. The endothelial cells were allowed to grow undisturbed for several days and thereafter the media were changed every 2 d for a total culturing period of 8–10 d. Cell culture purity (99%) was assessed by staining for factor VIII antigen, as described by Jaffe *et al*^[12] and by visual inspection of their typical morphology. After mechanical disruption of cell monolayers by gentle scraping and triturating, the cells were subcultured. Experiments were carried out using confluent cultures between passages 5 and 7.

Cultured rat aortic endothelial cell injury induced by ox-LDL Rat aortic endothelial cells of passage 5 were seeded at 1×10^5 cells/mL in 96-well plates and grown to confluence. The cells were treated with control or honokiol (final concentration 0.0376 $\mu\text{mol/L}$, 0.376 $\mu\text{mol/L}$ or 3.76 $\mu\text{mol/L}$) or Vitamin E for 30 min in serum-free medium, and then incubated with ox-LDL (final concentration 50 $\mu\text{g/mL}$) for 24 h as described previously^[13]. The viability of cells was assayed using the MTT assay.

Measurement of 6-keto-PGF_{1 α} levels in serum-free medium of injured rat aortic endothelial cells by ox-LDL The culture medium was removed after RAEC were grown to confluence, and cells were washed twice with phosphate-buffered saline and pre-incubated with the serum-free medium for 30 min. After the cells were treated with control, honokiol 0.376, 3.76, 37.6 $\mu\text{mol/L}$, or VE 100 mg/L at 37 °C for 30 min, the cultures were incubated with ox-LDL (final concentration 50 $\mu\text{g/mL}$) for 24 h to induce injury. Incubations were terminated by placing them in an ice bath. Culture

fluids were saved for the determination of 6-keto-PGF_{1α}, and cells were collected for protein content measurement. 6-keto-PGF_{1α} was determined using immunoassay kits, and protein content was measured using the Bradford method^[14].

Determination of nitric oxide levels in serum-free medium of injured rat aortic endothelial cells by ox-LDL Cells were cultured and treated as described above. The level of NO in culture fluid was determined using a kinetic cadmium-reduction method^[15] with NO/nitrate assay commercial kits.

Statistical analysis The data were expressed as mean±SD and represent data from 5 repeated assays. Statistical evaluation was carried out using the Dunnet *t*-test to compare the differences between treated groups and control groups. *P*<0.05 was considered to be statistically significant.

Results

Effects of honokiol on rabbit platelet aggregation *in vitro* and *ex vivo* As shown in Figure 1, honokiol displayed a concentration-dependent inhibitory effect on platelet aggregation *in vitro*. Honokiol at 0.376 μmol/L did not influence platelet aggregation, but honokiol 37.6 μmol/L decreased the platelet aggregation from 78.0%±5.7% to 13.5%±5.9%, and an almost complete inhibition was observed when 376 μmol/L honokiol was used (from 78.0%±5.7% to 0.6%±1.1%). At 15 min after bolus intravenous administration, honokiol significantly inhibited platelet aggregation induced by collagen. The maximum aggregation rates were 70.0%±7.4% for the control group, 22.9%±17.0 % for the 0.12 μg/kg group, 18.4%±19.8% for the 1.2 μg/kg group and 14.5%±19.0% for the 12 μg/kg group. It was evident that honokiol inhibited collagen-induced platelet aggregation in a dose-dependent manner. ASA, a typical anti-platelet agent, also inhibited collagen-induced platelet aggregation at 1.2 mg/kg under the same conditions (Figure 2). It is evident that honokiol has a

Figure 1. Inhibitory effects of honokiol on collagen-induced platelet aggregation *in vitro*. Platelet aggregation of rabbits was induced by collagen as described by Born. *n*=4 from 4 rabbits. Mean±SD. ^c*P*<0.01 vs control.

Figure 2. Inhibitory effects of honokiol on collagen-induced rabbit platelet aggregation *ex vivo*. PRP and PPP were prepared from blood samples of rabbits at 15 min after the intravenous administration and platelet aggregation was induced by collagen as described by Born. *n*=6 samples from 6 rabbits. Mean±SD. ^c*P*<0.01 vs control.

potent inhibitory effect on collagen-induced platelet aggregation *ex vivo*; its effective dose is lower than that of ASA.

Effect of honokiol on electrical current-stimulated carotid thrombosis in rats The effects of honokiol on the carotid thrombus model in rats were measured at 10 min after bolus intravenous injection. The OT for the control group was 534 s±66 s, and for the 0.5 μg/kg, 5 μg/kg and 50 μg/kg of honokiol groups the OT were 654 s±204 s, 684 s±186 s and 954 s±282 s, respectively, while the OT for the 5 mg/kg ASA group was 804 s±318 s (Figure 3). It indicated that honokiol dose-dependently inhibited thrombosis induced by endothelium injury *in vivo*. ASA at 5 mg/kg also significantly inhibited thrombosis.

Figure 3. Effects of honokiol on carotid thrombosis. Endothelial injured-thrombus formation in SD rats was stimulated by electric current at 10 min after treatment with control vehicle, honokiol or ASA intravenously. *n*=10 samples from 10 rats. Mean±SD. ^b*P*<0.05, ^c*P*<0.01 vs control.

Effect of honokiol on viability of normal cultured rat aortic endothelial cells Honokiol 0.376–3.76 μmol/L significantly increased cell viability. However, honokiol 37.6 μmol/L and VE 100 mg/L did not influence cell viability. This

suggested that low concentrations of honokiol could stimulate normal endothelial cell proliferation (Figure 4).

Figure 4. Effect of honokiol on normal rat aortic endothelial cells. The viability of cells was measured using MTT reduction assay. $n=4$ tests. Mean \pm SD. [§] $P<0.01$ vs normal control cells.

Protective effect of honokiol against cultured rat aortic endothelial cell injury induced by ox-LDL The ox-LDL-injured cells showed an obvious decrease in *OD* values compared with control-treated uninjured cells. Treatment of injured cells with honokiol 0.376–3.76 $\mu\text{mol/L}$ significantly enhanced *OD* values in a concentration-dependent manner. Honokiol 37.6 $\mu\text{mol/L}$ also increased *OD* value but no further increase was obtained compared with honokiol 3.76 $\mu\text{mol/L}$. It indicated that honokiol could protect endothelial cells against ox-LDL injury and increase cell viability. VE 100 mg/L also significantly increased cell viability (Figure 5).

Figure 5. Effect of honokiol on ox-LDL-induced rat aortic endothelial cell injury. The viability of cells was measured using MTT assay. $n=4$ tests. Mean \pm SD. [§] $P<0.01$ vs control cells. ^f $P<0.01$ vs ox-LDL injured cells.

Influence of honokiol on 6-keto-PGF_{1 α} concentration in serum-free medium of rat aortic endothelial cells ox-LDL injury significantly decreased the PGI₂ level in serum-free medium. Honokiol 0.376–36.7 $\mu\text{mol/L}$ concentration-dependently increased 6-keto-PGF_{1 α} concentration in medium of injured rat aortic endothelial cells, which was significantly

higher than that of injured cells and normal cells. VE 100 mg/L showed a similar result (Figure 6). These results demonstrated that both honokiol and VE were potent PGI₂-release enhancers.

Figure 6. Effect of honokiol on the level of 6-keto-PGF_{1 α} in cultured fluid of rat aortic endothelial cells. 6-keto-PGF_{1 α} was determined with immunoassay kits. $n=4$ tests. Mean \pm SD. [§] $P<0.01$ vs control. ^f $P<0.01$ vs ox-LDL.

Effect of honokiol on nitric oxide concentration in serum-free medium of rat aortic endothelial cells Honokiol 0.0376–0.376 $\mu\text{mol/L}$ significantly increased NO levels in serum-free medium of rat aortic endothelial cells. However honokiol 3.76 $\mu\text{mol/L}$ did not increase NO level but slightly decreased its level. This result showed that appropriate concentrations of honokiol could promote NO release from rat aortic endothelial cells (Figure 7).

Figure 7. Effect of honokiol on the level of NO in cultured fluid of ox-LDL-injured rat aortic endothelial cells. NO was measured using a kinetic cadmium-reduction method with NO/nitrate assay commercial kits. $n=4$ tests. Mean \pm SD. [§] $P<0.01$ vs control. ^f $P<0.01$ vs ox-LDL.

Discussion

Other authors have demonstrated that honokiol inhibits platelet aggregation in rabbits^[5]. It has protective effects against myocardial ischemia^[6,7] and cerebral infarction^[8]. We

have also found that honokiol can prevent cerebral injury caused by middle cerebral artery occlusion and cerebral ischemia reperfusion injury^[16]. This study demonstrated that honokiol significantly inhibited arterial thrombosis induced by endothelium injury in rats, and the results on platelet aggregation *in vivo* and *in vitro* were basically consistent with those described previously^[5]. We observed that the effective dose of honokiol was much lower than ASA, suggesting that honokiol is a potent platelet aggregation and thrombosis inhibitor. A previous study indicated that the anti-platelet aggregation activity of honokiol was due to its inhibitory effect on TXA₂ formation and intracellular calcium mobilization^[5]. In our preliminary study, honokiol significantly inhibited endothelium-injured thrombosis in rats, and its concentration for inhibiting platelet aggregation *in vitro* was 10 times higher than that for anti-thrombosis. We hypothesize that there is another mechanism mediating its anti-thrombotic effects.

Endothelial cell structure and functional integrity are important in the maintenance of blood vessel walls and circulatory function. They produce and release a variety of vasoactive substances, such as PGI₂ and NO^[17]. PGI₂ is a potent endogenous platelet aggregation inhibitor and produces vasodilatation of all vascular beds studied^[18,19]. We found that honokiol protected cultured RAEC from ox-LDL injury, and it potently increased PGI₂ concentration in cell media in a concentration-dependant manner. The PGI₂ level in cell media treated with honokiol and VE were much higher than that in normal cells, suggesting that both honokiol and VE not only protect cells from injury but also stimulate PGI₂ release from normal RACE. This increase in PGI₂ release may play a crucial role in the anti-thrombotic effect of honokiol. Simultaneously, we have observed that lower concentrations of honokiol 0.376–3.76 μmol/L stimulate normal RACE proliferation, and this effect may be important for maintaining vascular normal state and integrity as well as the concrescence of injured vessels. However, this effect of honokiol needs to be studied further.

At honokiol 37.6 μmol/L, the cell viability is not maximum but PGI₂ level is highest. The reason for this phenomenon is not clear but it is indeed a fact that we confirmed with three separate experiments. We observed that cell shape had a little change at this concentration. Maybe honokiol at this concentration slightly inhibits cell growth or damages cell function. Under this condition the increase of PGI₂ may be a response of cell to injurious stimulation^[20]. This fact suggested that ideal effective concentration of honokiol should be less than 37.6 μmol/L.

According to Teng *et al*, honokiol inhibited TXA₂ forma-

tion in platelets^[5]. This may be due to inhibition of enzymes involved in TXA₂ synthesis, including cyclooxygenase (COX) and TXA₂ synthase in platelets. But our findings suggested that honokiol stimulated PGI₂ release from endothelial cells. A possible explanation for this is that honokiol inhibits TXA₂ synthase in platelets but activates PGI₂ synthase in endothelial cells. However, definitive evidence needs to be provided.

The continuous release of NO from the endothelium has an important role in blood flow modulation. NO may also modulate interactions between inflammatory cells and the endothelium. It reduces platelet, monocyte, macrophages, and neutrophils adhesion to endothelial cells and inhibits platelet aggregation^[21–25]. This study showed that honokiol 0.0376–0.376 μmol/L stimulated NO release, but honokiol 3.76 μmol/L did not and caused a slight decrease in NO level. The effective concentration range of honokiol in stimulating NO release is 10 times lower than that in increasing cell viability. Thereby NO release may not play an important role in the anti-thrombotic effect of honokiol. Accordingly, protection of endothelial cells and stimulation of PGI₂ release from endothelial cells may be the main mechanism by which honokiol inhibited thrombosis, apart from its inhibitory effect on platelet arachidonic acid pathway as described by Teng *et al*^[5]. However, honokiol and VE showed similar effects in cell protection and PGI₂ release under present condition. Whether these effects are the results of their anti-oxidative properties or they themselves have a stimulatory effect on PGI₂ release is not clear yet. In addition, the results of this study cannot explain whether honokiol stimulates PGI₂ generation in endothelial cells. The limitation of this study is that it did not supply direct evidence of the importance of PGI₂ on anti-thrombosis caused by honokiol.

In conclusion, this study showed that honokiol is a potent arterial thrombosis inhibitor. Protection of endothelial cells and stimulation of PGI₂ release may be the main mechanism. NO release from endothelial cells may play some roles but is not a key factor. The detailed mechanism by which honokiol stimulates PGI₂ release and promotes endothelial cell proliferation requires further study.

Abstract

Aim: To investigate the hypothesis that transplantation with expanded autologous endothelial progenitor cells (EPC) could enhance neovascularization. **Methods:** Peripheral blood mononuclear cells (PB-MNC) isolated from New Zealand White rabbits were cultured *in vitro*. At d 7, the adherent cells were collected for autologous transplantation. Rabbits with severe unilateral hind limb ischemia were randomly assigned to receive phosphate-buffered saline or expanded EPC in phosphate-buffered saline, administered by intramuscular injection in 6 sites of the ischemic thigh at postoperative d 7. Neovascularization was monitored by using the calf blood pressure ratio to indicate tissue perfusion, digital subtraction angiography to identify collateral vessel development and histological analysis of capillary density in the ischemic limb at d 35 after surgery. **Results:** Autologous EPC transplantation produced significant amelioration in ischemic hind limbs, as indicated by a greater calf blood pressure ratio (0.52 ± 0.04 vs 0.42 ± 0.05 , $P < 0.01$), angiographic score (1.44 ± 0.06 vs 0.98 ± 0.08 , $P < 0.01$) and capillary density in muscle ($195.2 \pm 5.4/\text{mm}^2$ vs $169.4 \pm 6.4/\text{mm}^2$, $P < 0.05$), than controls. **Conclusion:** Transplantation of autologous expanded EPC can promote neovascularization in ischemic hindlimbs.

Introduction

The maintenance of constant tissue perfusion is necessary for physiological organ function. Under certain pathological conditions, however, vascular supply can be reduced to such an extent that tissue necrosis results. Various angiogenic approaches have already been widely explored to revascularize ischemic tissue in animal models of ischemia and in clinical trials^[1–5]. Most interventions involve the delivery of angiogenic growth factors such as vascular endothelial growth factor, basic fibroblast growth factor genes encoding these proteins to the ischemic tissue to stimulate the growth of new vessels. In recent years, ample evidence has established that bone marrow-derived endothelial progenitor cells (EPC) are present in the systemic circulation,

are augmented in response to certain cytokines and/or tissue ischemia, and home to as well as incorporate into sites of neovascularization (which is defined as postnatal vasculogenesis)^[6–9]. Experimental studies have shown that bone marrow-derived or blood-derived EPC may contribute to the regeneration of ischemic tissues and enhance the neovascularization of ischemic hind limbs or myocardium^[10–14]. Therapeutic vasculogenesis in which EPC are actively involved is a new strategy for ischemic disease. Allogeneic or heterogeneic transplantation of EPC into ischemic animals has produced promising results, and thus brought attention to the possibility of using such treatments clinically.

To use EPC safely in a clinical setting for ischemic disease, autologous EPC are the first choice. Circulating EPC are at a very low level in adults, and the number is insufficient for

transplantation unless they are enriched in some way^[15,16]. The use of expanded EPC is one solution to the problem. Therefore, we investigated the feasibility of using intramuscular injections of autologous expanded endothelial progenitor cells to treat rabbits with hind limb ischemia.

Materials and methods

Hind limb ischemia model Twelve male New Zealand white rabbits (weighing 2.8–3.2 kg) were used for this study. The initial surgery to induce hind limb ischemia has been described by others^[17]. Briefly, the rabbits were first anesthetized with sodium pentobarbital (30 mg/kg, iv), then under sterile surgical conditions, a longitudinal incision was made on the medial thigh of one hind limb, extending from the inguinal ligament to a point just proximal to the patella. After the skin incision, the entire femoral artery and all its major branches including the inferior epigastric, deep femoral, lateral circumflex and superficial epigastric arteries were dissected free. The external iliac artery and all of the arteries listed were ligated. Finally, the femoral artery was excised from its proximal origin as a branch of the external iliac artery, to the point distally where it bifurcates into the saphenous and popliteal arteries. As a consequence, blood flow to the ischemic limb became completely dependent upon collateral vessels issuing from the internal iliac artery. The incision was closed in three layers with 3.0 silk. All rabbits were closely monitored by veterinary staff and received an antibiotic (20 mg/kg gentamycin sulfate, im) for 3 d. The experimental protocols were approved by the Institutional Animal Care and Use Committee of Shanghai Second Medical University, Shanghai.

Mononuclear cell isolation and culture Samples of peripheral blood (12–15 mL) from the central auricular artery of rabbits were harvested 1 h before surgery and anticoagulated with heparin. The isolation and culture of mononuclear cells has been described previously^[18]. In brief, peripheral blood mononuclear cells (PB-MNC) were isolated by density-gradient centrifugation and resuspended in Iscove's Modified Dulbecco's Medium (IMDM, Gibco Invitrogen, Shanghai, China) supplemented with 20% fetal calf serum (FCS; CCT, Cansera International, Ontario, Canada). The cells were then seeded into 48-well plates (Sumilon, Sumitomo Bakelite, Osaka City, Japan) at a density of 1×10^6 cells per well and cultured at 37 °C and 5% CO₂. The medium was replaced completely at d 3 or d 4.

To confirm EPC phenotype, the adherent cells were incubated with 1,1'-dioctadecyl-3,3',3'-tetramethyl-indocarbocyanine perchlorate-labeled acetylated low density lipopro-

tein (LDL) (DiI-Ac-LDL, 10 mg/mL; Biomedical Technologies, Stoughton, USA) at 37 °C for 2 h at d 7 in culture. Then the cells were fixed with 2% paraformaldehyde for 10 min and incubated with fluorescein isothiocyanate-labeled *Ulex europaeus* agglutinin (UEA-1 lectin, 10 mg/mL; Sigma, St Louis, USA) for 1 h. The lectin binding is a marker of endothelial cell (EC) lineage and the incorporation of acLDL is a characteristic function of EC^[13]. Nearly all adherent cells (>97%) were DiI-acLDL(+) UEA-1-lectin(+) as analyzed by a fluorescence-activated cell sorter (FACS).

Experimental groups and EPC transplantation After femoral artery excision, the rabbits were randomly assigned to one of 2 groups: (a) control group ($n=6$, receiving vehicle PBS); (b) EPC group (receiving expanded EPC, $n=6$).

At d 7, EPC in culture were trypsinized and collected for transplantation. EPC in 0.6 mL of phosphate-buffered saline (PBS) were injected im into 6 different sites of the ischemic thigh skeletal muscles (100 mL to each site) with a 22-gauge needle. The control group received 0.6 mL PBS. Overall, a mean of $2.11 \times 10^6 \pm 0.51 \times 10^6$ EPC were injected per rabbit.

To elucidate *in vivo* differentiation to endothelial lineage, 2×10^6 EPC from autologous PB-MNC were labeled with fluorescent carbocyanine 1,1'-dioctadecyl-3,3',3'-tetramethyl-indocarbocyanine perchlorate (DiI, Molecular Probes (Eugene, Oregon, USA) and were injected via a 22-gauge needle to the ischemic thigh muscles 7 d after surgery. Four weeks after cell transplantation, 5 mg of UEA-1 lectin (Sigma) was infused intravenously before the rabbits were killed by an overdose of pentobarbital. Ischemic hind limb thigh muscles were embedded in OCT compound and snap-frozen for fluorescence microscopy to examine the incorporation of transplanted cells into foci of neovascularization.

Calf blood pressure ratio Calf blood pressure was measured at the posterior tibial artery before surgery and at 7, 14, 21, 28, and 35 d in both hind limbs using a Doppler Flowmeter (Model ALF 2100, Advance Advance Co, Tokyo, Japan) and a cuff (PC 2.5 cm \times 12 cm, Hokanson, Bellevue, USA) connected to a pressure manometer as described by others^[2]. The calf blood pressure ratio (BPR) was defined for each rabbit as the ratio of systolic pressure of the ischemic hind limb to that of the normal hind limb.

Intra-iliac arterial angiography The collateral arteries in the medial thigh region of the ischemic limb originate from the internal iliac artery^[19,20]. Digital subtraction angiography (DSA; Model Advantx-LC-DLX, General Electronic) of the hind limb was performed on postoperative d 35 to obtain an anatomical measurement of the growth and development of the larger conduit vessels in the medial portion of the upper limb. Each animal was anesthetized, and the right

common carotid artery was exposed. A 4-F polyethylene catheter (Cordis, Corporation, Miami Lakes, USA) was introduced into the right common carotid artery through a small cutdown and the tip of the catheter was positioned just proximal to the point where it bifurcates into the right and left common iliac arteries under fluoroscopic guidance. Immediately following an intra-arterial bolus injection of the vasodilator sodium nitroprusside (300 μ g in 1 mL saline), iodinated contrast media (Huaihai Pharmaceutical Company, Shanghai, China) was infused intra-arterially at a rate of 1 mL/s for 5 s using an automated angiographic injector (LF, Liebel-Flarsheim Co, Cincinnati, OH, USA). Perfusion of the hind limb was observed on a monitor in real time and a series of angiographic images were taken after the start of contrast media infusion.

The angiograms at 4 s were quantified by image analysis using Qwin software (Leica, Bensheim, Germany). In brief, the area occupied by all small visible arteries in the medial thigh, including the branches of the femoral artery and collateral vessels from the intra-iliac artery (excluding the intra- and extra-iliac, femoral, saphenous and popliteal arteries) was calculated. The angiographic score was calculated by a single observer who was blinded to the treatment regimen, and the score was defined for each rabbit as the ratio of the area occupied by vessels of the ischemic thigh to that of the normal thigh.

Histological determination of capillary density Immediately after angiography, the rabbits were killed, then the hind limbs were dissected, and samples of the adductor muscle and the semimembranous muscle were removed for histological evaluation. The tissues were placed in plastic cassettes and covered with OCT compound (Tissue-Tek, Sakura Finetechnical Co, Tokyo, Japan) before being snap frozen in liquid nitrogen. Multiple frozen sections were cut (10 mm thickness) on a cryostat (CM 3050, Leica) and placed on glass slides. Tissue sections were stained for alkaline phosphatase using the indoxyl-tetrazolium method^[21] to detect capillary endothelial cells, and were counterstained with eosin. The number of capillaries was counted under a 20 \times objective lens using an image analysis system (Qwin, Leica) by a single observer blinded to the treatment regimen. Capillaries in 15 randomly selected fields were analyzed. Capillary density was calculated as the number of capillaries per mm² of muscle.

Clinical assessment All rabbits were clinically evaluated for the incidence of distal limb ulcers and necrosis by macroscopic examination during the study; this was considered significant if a skin ulcer or necrosis was observed at the leg, foot or ankle.

Statistical analysis All data are reported as mean \pm SEM. Differences between control and EPC groups were analyzed by using the paired Student's *t*-test. A value of $P<0.05$ was considered statistically significant.

Results

Characterization of EPC expanded *ex vivo* Freshly isolated PB-MNC were round and small, but became larger with more cytoplasm on the second day. Large round adherent cells appeared from d 2–d 3, then they assumed a spindle-shaped, endothelial cell-like morphology. Significant proliferation was observed from d 3, and the adherent cells were almost convergent at d 6–d 7. The morphology of the adherent cells is shown in Figure 1A, 1B; >97% of the adherent cells had taken up acetylated LDL (red fluorescence) and had bound the lectin (green fluorescence) (Figure 1C, 1D). The percentage of EPC in freshly isolated PB-MNC was much less than that in the adherent cells in culture (data not shown).

The incubation of PB-MNC *in vitro* resulted in a 100- to 200-fold increase in differentiating EPC which were DiI-acLDL (+) UEA 1-lectin (+). This calculation is based on our findings that freshly isolated PB-MNC had much fewer (about 0.06%) EPC (data not shown). We were able to obtain $1.07\times 10^5\pm 0.33\times 10^5$ EPC/ 1×10^6 MNC after 7 d of the *ex vivo* culture, thus yielding a 100- to 200-fold increase in EPC number.

Effect of transplanted autologous EPC on neovascularization

Calf blood pressure ratio The systolic blood pressure of the ischemic hind limb showed a tendency to increase after surgery in both the EPC and control groups. EPC transplantation promoted the recovery of blood perfusion to the ischemic hind limb, as by the greater ischemic/normal calf blood pressure ratio than that observed in the control group. The ischemic/normal calf blood pressure ratio measured at d 28 and d 35 was 0.47 ± 0.02 and 0.52 ± 0.02 , respectively, for the EPC group, which are significantly higher than those of the control animals (0.38 ± 0.01 and 0.42 ± 0.03 ; Figure 2). Thus, EPC transplantation significantly increased the ischemic/normal calf blood pressure ratio, suggesting augmented perfusion in the EPC-treated group compared to control rabbits.

Angiographic analysis Collateral vessel development in the medial thigh was assessed by digital subtraction angiography as described earlier. There were more collateral vessels in the EPC group compared with the control. The angiographic score at d 35 in the EPC group was significantly higher than that of the control group (control= 0.98 ± 0.08 ; EPC= 1.44 ± 0.06 ; $P<0.01$; Figure 3).

Figure 1. Characteristics of peripheral blood EPC in culture at (A) d 4 and (B) d7 ($\times 10$). Cultivated EPC were incubated with DiI-acLDL (red fluorescence) and stained with lectin (green fluorescence), viewed by (C) confocal microscopy and (D) analyzed by FACS.

Figure 2. Time-course of the calf blood pressure ratio in the hind limbs of rabbits treated with transplanted EPC. Results are presented for animals receiving PBS (control) or transplanted EPC at d 7, 14, 21, 28, and 35 post-surgery. $n=6$. Mean \pm SEM. ^c $P<0.01$ vs control.

Histological evaluation of capillary density Histological staining of alkaline phosphatase was performed to identify capillaries in ischemic muscles on d 35 after surgery. Tissue sections retrieved from the medial thigh muscles of the ischemic hind limbs showed a marked increase in capillary number in EPC-treated animals. Capillary density in the EPC group was significantly greater than that in the controls (control= $169.4\pm 6.4/\text{mm}^2$; EPC= $195.2\pm 5.4/\text{mm}^2$; $P<0.05$; Figure 4).

Transplanted autologous EPC incorporate into foci of neovascularization Four weeks after autologous EPC transplantation, tissue sections from the ischemic thigh muscles were examined under fluorescence. Transplanted autologous EPC marked with DiI fluoresced red, whereas

Figure 3. Effect of transplanted endothelial progenitor cells (EPC) on collateral vessel development in ischemic hind limbs of rabbits at d 35 post-surgery. (A) Representative angiograms of ischemic hind limbs. (a) Control rabbits receiving PBS; (b) Rabbits receiving EPC transplantation. (B) Effect of EPC transplantation on angiographic score compared with control (angiographic score is defined in the text). $n=3$. Mean \pm SEM. ^c $P<0.01$ vs control.

Figure 4. Histological evaluation of capillary density in ischemic hind-limb muscle on d 35 post-surgery. (A) Representative images of alkaline phosphatase-stained capillaries (×20). the rabbit vasculature, stained by a premortem administration of UEA-1 lectin, were identified by green fluorescence in the same tissue section. DiI-labeled EPC were distributed principally in the ischemic area of the hind limb neovascularization and incorporated into tubular structures and capillaries, which is consistent with neovascularization (Figure 5). Thus, locally transplanted EPC were incorporated into the foci of neovascularization and differentiated into mature endothelial cells in the ischemic hind limbs.

Figure 5. Histological identification of epithelial progenitor cells (EPC) incorporation *in vivo*. Tissue sections were retrieved from ischemic muscles. (A) Red fluorescence marks autologously transplanted DiI-labeled EPC. (B) Green fluorescence indicates UEA-1 lectin binding identifying endothelial cells (×10).

Clinical assessment All animals were conscious within 1 h of the surgery, and they developed a limp in their hind limbs. Two animals from the control group developed skin ulcers at the knees of the ischemic limb. Animals from the EPC group did not have any skin ulcers or necrosis.

Discussion

The present study describes for the first time autologous transplantation with expanded EPC from peripheral blood in hind limb ischemia. We found that the transplantation of EPC was associated with a significant increase in the calf blood pressure ratio, collateral vessel development, and muscle capillary density, suggesting a beneficial effect on neovascularization.

Postnatal EPC have been implicated in the neovascularization associated with postnatal vasculogenesis. In animal experiments, allogeneic or heterogeneic transplantation of blood-derived cells containing EPC into ischemic animals have been shown to regenerate infarcted myocardium and coronary capillaries, thus limiting functional impairment after myocardial ischemia. Enhanced neovascularization by EPC was also observed in animals with hind limb ischemia.

After favorable results were found in studies of allogeneic and heterogeneic transplantations of EPC, studies were carried out to investigate the efficiency of autologous transplantation of EPC in animals and humans^[15,16,22–28] to overcome the limitations of immunorejection, but these studies did not answer the crucial questions such as cell populations for transplantation, delivery method, and therapy time for cell transplantation, which are important for efficient transplantation.

In the present study, we used expanded EPC for transplantation based on the following considerations. First, the number of EPC after expansion greatly exceeds the number of EPC in freshly isolated cells, which need mononuclear cell apheresis to enrich the EPC-containing cell population. Second, expanded EPC are pure and uncontaminated, and are exempt from the potential inflammatory response induced by other cells from a hematopoietic lineage. In the present study, EPC expanded 100- to 200-fold in number after 7 d of culture *in vitro*. Kalka *et al* reported a 80- to 90-fold expansion of EPC when cultured in a fibronectin-coated dish in a commercial medium (EBM-2) supplemented with a cocktail of growth factors including VEGF, bFGF, insulin-like growth factor (IGF), and epidermal growth factor (EGF)^[13]. Our study used a simple medium supplemented with FCS, but which did not compromise the expansion potential. The culture conditions used in the present study are much more economical and accessible than those used by Kalka *et al*. Our findings regarding autologous expanded EPC transplantation are consistent with those of Shintani *et al*, in which autologous expanded EPC from bone marrow promoted neovascularization in hind limb ischemia^[22]. However, expanding EPC from peripheral blood is clearly less invasive than aspirating bone marrow. The culture-expanded EPC

may consist of EPC at different stages of differentiation depending on the culture conditions or duration. Recently, Hur *et al* sequentially cultured total mononuclear cells from a source of adult peripheral blood and found 2 types of EPC: early and late EPC. However, there was no difference in the contributions of the 2 types to neovascularization in ischemic limbs^[29].

The incorporation rate of transplanted cells is greatly influenced by the delivery method. When infused intravenously, the number of infused cells incorporated in ischemic vasculature was much less than that being injected near the ischemic zone. To deliver the EPC efficiently, we directly injected the cells into the ischemic thigh muscle to ensure a maximum available concentration of EPC at the site of the ischemic hind limb. The optimal time for cell transplantation is also a primary concern; to mimic ischemic events in a clinical setting, and using the course of events after myocardial ischemia for reference, we set the time point for EPC injection at d 7 after ischemia.

A limitation of the present study is that no control cells were used to demonstrate the advantage of expanded EPC. In a heterogenetic transplantation study with human EPC, Murasawa and Aahara used either human microvascular EC (HMVEC) or medium as a control in a nude mouse model of hind limb ischemia. They found that the outcomes in the mice receiving control cells (HMVEC) and those receiving the medium were similar^[30]. The appropriate control cells for the present study would have been mature vascular EC. However, preparation of vascular EC for autologous transplantation is not feasible, so we had to use saline for the control.

In conclusion, we found that neovascularization was enhanced by autologous expanded EPC from peripheral blood when injected intramuscularly at the site of ischemia at d 7 after hind limb ischemia in rabbits. Our data indicate that autologous expanded EPC from peripheral blood may be an important and novel therapeutic approach for ischemic disease via enhancing neovascularization.

Abstract

Aim: To explore whether overexpression of the small heat shock protein HSP20 in rat cardiomyocytes protects against simulated ischemia/reperfusion (SI/R) injury. **Methods:** Recombinant adenovirus expressing HSP20 was used to infect rat H9c2 cardiomyocytes at high efficiency, as assessed by green fluorescent protein. H9c2 cells were subjected to SI/R stress; survival was estimated through assessment of lactate dehydrogenase and cell apoptosis through caspase-3 activity. **Results:** Overexpression of HSP20 decreased lactate dehydrogenase release by 21.5% and caspase-3 activity by 58.8%. Pretreatment with the protein kinase C inhibitor Ro-31-8220 (0.1 $\mu\text{mol/L}$) for 30 min before SI/R canceled the protective effect of HSP20. The selective mitochondrial K^+_{ATP} channel inhibitor 5-hydroxydecanoate (100 $\mu\text{mol/L}$) had a similar effect. However, the non-selective K^+_{ATP} channel inhibitor glibenclamide (100 $\mu\text{mol/L}$) had no significant effect. **Conclusion:** These data indicate that the protective effect of HSP20 *in vitro* is primarily due to reduced necrotic and apoptotic death of cardiomyocytes, possibly via the protein kinase C/mitochondrial K^+_{ATP} pathway.

Introduction

Heat shock proteins (HSP) are highly conserved molecules that fulfill a range of functions, including cytoprotection and the intracellular assembly, folding, and translocation of oligomeric proteins^[1]. Expression of these proteins can be induced by a range of cellular insults, which include high temperature, oxidative stress, viral infection, and nutritional deprivation^[2].

Previous studies have demonstrated that increased expression of various HSP, such as HSP70, HSP60, HSP10, and HSP90, protected against stress insult. Recently, the cytoprotective properties of small HSP have drawn increased attention. Small HSP, including HSP20, HSP25, HSP27, αB -crystallin, and myotonic dystrophy kinase binding protein, are a group of proteins expressed in muscle tissues and share sequence homology of approximately 80–100 amino acids at the C terminus, known as the α crystallin domain^[3,4]. It was reported that overexpression of HSP27 by transfection into rodent and Chinese hamster cell lines directly correlated with

survival from hyperthermia^[5–7]. Overexpression of αB -crystallin has a similar effect^[8–10]. It was also reported that overexpression of both HSP27 and αB -crystallin protected against ischemic injury in cardiac myocytes^[11].

HSP20 is a newly discovered small HSP that was co-purified with αB -crystallin and HSP27 from skeletal muscle by affinity chromatography^[12]. Previous reports demonstrated that HSP20 redistributed from the cytosol to insoluble fractions and dissociated from the aggregated form to the small form when rat diaphragm was exposed to heat stress *in vitro*^[13]. Stable overexpression of HSP20 in Chinese hamster ovary cells results in enhanced survival after heat shock, which is similar to the results for αB -crystallin^[14]. However, the effect of HSP20 on ischemia-mediated injury in cardiac myocytes has not been explored.

In our previous study, we showed that overexpression of HSP20 in rat heart *in vivo* protected against simulated ischemia/reperfusion (SI/R) injury, the mechanism of which related to the reduction of necrosis and apoptosis of ventricular cardiomyocytes (unpublished data). In the present

study, our aim was to determine whether increased expression of HSP20 exerted a protective effect against SI/R injury in cardiac myocytes. We demonstrated, for the first time, that overexpression of HSP20 protected against ischemic damage in rat H9c2 cardiomyocytes, the protective effect of HSP20 *in vitro* being due primarily to reduced necrotic and apoptotic cell death, possibly via the protein kinase C (PKC)/mitochondrial K^+_{ATP} channel (mito K^+_{ATP}) pathway.

Materials and methods

Construction of recombinant adenovirus The recombinant adenovirus encoding HSP20 (Ad.HSP20) and adenovirus encoding GFP (Ad.GFP) were prepared as described previously^[15]. Adenovirus was propagated in 293 cells and purified by 2 rounds of CsCl density ultracentrifugation (4 °C, 13000×g for 105 min and 16 h, respectively). Viral stocks were desalted through a PD-10 desalting column (Amersham Biosciences UK, Buckinghamshire, UK) into a Tris-buffered solution (10 mmol/L Tris, pH 8.0, 2 mmol/L $MgCl_2$ and 4% sucrose)^[16], plaque-titered, aliquoted, and stored at -80 °C with 4% sucrose until use.

Cell culture and simulated ischemia/reperfusion H9c2 cells were purchased from ATCC, the Global Bioresource Center (No CRI-1446; Hong Kong, China) and were cultured in Dulbecco's modified Eagle's medium (DMEM) supplemented with 10% fetal bovine serum (FBS). Cells were infected with Ad.HSP20 or Ad.GFP at a multiplicity of infection of 50 in no-serum DMEM when the confluence was 60%. After 2 h, the medium was removed and supplemented with DMEM containing 1% FBS for 24 h. Infected cells and the efficiency of infection were monitored by GFP expression with the use of fluorescent microscopy. After 24 h of infection, cells underwent 8 h of simulated ischemia and 24 h of reperfusion. Simulated ischemia was achieved by placing cells in a hypotonic balanced salt solution consisting of 1.3 mmol/L $CaCl_2$, 5 mmol/L KCl , 0.3 mmol/L KH_2PO_4 , 0.5 mmol/L $MgCl_2$, 0.4 mmol/L $MgSO_4$, 69 mmol/L $NaCl$, 4 mmol/L $NaHCO_3$, and 0.3 mmol/L Na_2HPO_4 without glucose or serum, and hypoxia was induced for 8 h at 37 °C^[17]. Hypoxia was attained with an airtight jar from which the oxygen was exhausted through the oxygen-consuming GasPak System from BBL Microbiology Systems (Cockeysville, MD)^[17]. At the end of the experiment, the dishes were removed from the chamber with the medium, and cells were reperfused in no-serum DMEM for 24 h. The control H9c2 cells were cultured in DMEM supplemented with 10% FBS, and cells were cultured in no-serum DMEM when the confluence was 60%. After 2 h, the medium was removed and cells were supple-

mented with DMEM containing 1% FBS. After 24 h, the medium was removed and cells were supplemented with a balanced salt solution at 37 °C for 8 h. The medium was then removed and the cells were cultured in no-serum DMEM for 24 h at 37 °C. The supernatant and cells were assayed separately for both lactate dehydrogenase (LDH) or caspase-3 activity.

Evaluation of necrosis and apoptosis by flow cytometry After SI/R, cells were harvested, washed, and double-stained using an annexin V-fluorescein-isothiocyanate (FITC) apoptosis detection kit. This kit is based on the observation that soon after initiating apoptosis most cell types translocate the membrane phospholipid phosphatidylserine from the inner face of the plasma membrane to the cell surface. Annexin V has a strong affinity for phosphatidylserine and therefore serves as a probe for detecting apoptosis. Cells that have lost membrane integrity will show red staining (propidium iodide) throughout the nucleus and therefore will be easily distinguishable from apoptotic cells. Samples were incubated for 15 min in the dark with annexin V and propidium iodide, and flow cytometry was carried out using a FACScan (Becton Dickinson, Heidelberg, Germany). Annexin V-FITC and propidium iodide-related fluorescence were recorded using FL1-H (525 nm) and FL2-H (575 nm) filters, respectively.

Lactate dehydrogenase (LDH) release assay Lactate dehydrogenase activity released into the medium or remaining in the cells was determined with the use of an LDH assay kit (Roche Diagnostics, Basel, Switzerland). The LDH activity is determined in an enzymatic test. In the first step, NAD^+ is reduced to $NADH/H^+$ by the LDH-catalyzed conversion of lactate to pyruvate. In the second step the catalyst transfers H/H^+ from $NADH/H^+$ to the tetrazolium salt INT, which is reduced to formazan, and the absorbance of the samples is measured at 490 nm using an enzyme-linked immunosorbent assay reader. Necrosis of cardiomyocytes was evaluated by the percentage of LDH release, which was calculated by the LDH activity in the medium divided by the total enzyme activity (medium and remaining activity in the cells) after reperfusion for 24 h.

Measurement of caspase-3 activity Cardiomyocytes were examined for apoptosis after simulated reperfusion for 24 h. Caspase-3 activity was determined by use of the caspase-3 Colorimetric Assay (R&D Systems, Minneapolis, MN, USA). Cells that were suspected to be or had been induced to undergo apoptosis were first lysed to collect their intracellular contents. The cell lysate was then tested for protease activity by the addition of a caspase-specific peptide that was conjugated to the color reporter molecule *p*-nitroanilide (*p*-NA). Cleavage of the peptide by caspase released the

chromophore *p*-NA, which was quantitated spectrophotometrically at a wavelength of 405 nm.

Statistical analysis Data are expressed as mean±SD. Difference was analyzed for significance by one-way repeated-measures ANOVA and further analyzed with the use of the Newman-Keuls test for multiple comparisons between treatment groups. The results were considered significant at $P<0.05$.

Results

Gene transfer of Hsp20 inhibits necrosis and apoptosis of H9c2 cells We infected H9c2 cells with Ad.HSP20 or Ad.GFP. The infection efficiency was $94.7\% \pm 2.1\%$ ($n=5$) with Ad.HSP20 and $95.2\% \pm 2.6\%$ ($n=5$) with Ad.GFP, as indicated by GFP fluorescence (Figure 1). Importantly, there was no apparent morphological alteration or difference in the number of adherent cells between control cells, Ad.HSP20-infected cells, and Ad.GFP-infected cells. We determined the levels of necrosis and apoptosis of H9c2 cells double-stained by annexin V-FITC and propidium iodide after SI/R by flow cytometry. The lower-left quadrants of the cytograms showed the viable cells, which excluded propidium iodide-stained cells and

Figure 1. Typical light microscope (A) and fluorescence (B) images of H9c2 cells infected with Ad.HSP20 for 24 h were observed in a high-power field ($\times 40$).

cells that were negative for annexin V-FITC binding. The lower-right quadrants represented the apoptotic cells, annexin V-FITC-positive cells, and propidium iodide-negative cells. The upper-right quadrants contained necrotic and late-apoptotic cells, positive for annexin V binding and for propidium iodide uptake. The upper-left quadrants represented cells damaged during the procedure. For each treatment group, 10 000 cells were analyzed. In the control group, most of the cells were healthy (93.0%) (Figure 2A). Of the H9c2 cells exposed to SI/R, 22.3% were propidium iodide negative (lower-right quadrant) while 23.7% were propidium iodide positive (upper-right quadrant), which indicated early apoptosis and late apoptosis/necrosis, respectively (Figure 2B). Overexpression of HSP20 significantly reduced the number of cells labeled with annexin-V. The percentage of early apoptotic and late apoptotic/necrotic cells was significantly decreased to 5.1% and 1.0%, respectively (Figure 2C). H9c2 cells infected with control virus had no such result (Figure 2D).

We also detected necrosis and apoptosis by LDH release and caspase-3 activity, respectively. Cellular damage was measured by the amount of cytosolic LDH release after SI/R. Cell apoptosis was quantitated by caspase-3 activity. Overexpression of HSP20 in cardiomyocytes resulted in a 21.5% reduction in the proportion of cytosolic LDH release and a 58.8% reduction in caspase-3 activity, compared with Ad.GFP-treated cells (Figure 3B).

Protein kinase C inhibitor and mitochondrial K^+ channel inhibitor reversed the protective effect of HSP20 Pretreatment with the PKC inhibitor Ro-31-8220 (0.1 $\mu\text{mol/L}$) for 30 min prior to SI/R reversed the protective effect of HSP20 on LDH release and caspase-3 activity (Figure 3). Pretreatment with the selective mitochondrial K^+ channel inhibitor 5-hydroxydecanoate (5-HD, 100 $\mu\text{mol/L}$) for 30 min prior to SI/R also canceled the protective effect of HSP20, whereas pretreatment with the non-selective K^+ channel inhibitor glibenclamide (100 $\mu\text{mol/L}$) had no significant effect (Figure 3). These data suggest that the protective effect of HSP20 *in vitro* is due to reduced necrotic and apoptotic death of cardiomyocytes, possibly via the PKC/mito K^+ pathway.

Discussion

Our previous study demonstrated that overexpression of HSP20 in rat heart protected against ischemia/reperfusion, the protective effect relating to the reduction of necrosis and apoptosis of ventricular cardiomyocytes. In the present study, we used H9c2 cardiomyocytes, which originated from rat embryonic cardiac tissue and retained certain features of

Figure 2. Flow cytometric histograms of H9c2 cells induced by simulated ischemia/reperfusion (SI/R). Cells were infected with Ad.HSP20 or Ad.GFP 24 h before the SI/R. Control cells were not infected with adenovirus or exposed to SI/R. After SI/R, cells were harvested and labeled with a combination of annexin V-fluorescein-isothiocyanate and propidium iodide. Mean \pm SD. ^b $P<0.05$ vs control. ^e $P<0.05$ vs SI/R. ^h $P<0.05$ vs SI/R+Ad.HSP20. 5-HD, 5-hydroxydecanoate; GLB, glibenclamide.

cardiac specificity^[18,19], to investigate the mechanism of the protective effect of HSP20.

By detecting annexin V-FITC and propidium iodide double-stained H9c2 cells after SI/R by flow cytometry, we detected the necrosis and apoptosis of cells. We also de-

tected the necrosis and apoptosis of H9c2 cells by LDH release and caspase-3 activity. Similar to the *in vivo* experiments, our results *in vitro* suggest that the protective effect of HSP20 also relates to the reduction of necrosis and apoptosis, which is indicated by flow cytometry, LDH re-

lease and caspase-3 activity (unpublished data).

Myocardial ischemia is frequently followed by reperfusion. Reperfusion and the resultant reoxygenation lead to the generation of oxygen radicals that can cause reperfusion injury. In the present study, we used H9c2 to mimic *in vivo* ischemia/reperfusion injury. We used LDH to evaluate the cell damage *in vitro*. The overexpression of HSP20 protected H9c2 cells against SI/R injury by reducing the LDH level. These data indicate that HSP20 reduces necrosis of cardiomyocytes. Our *in vitro* results also showed that H9c2 cells with overexpressed HSP20 had reduced caspase-3 activity. These data indicate that the anti-apoptotic effect of HSP20 in cardiomyocytes is mediated through reduced caspase-3 activity. In addition, Fan *et al*^[15] showed that the protective effects of HSP20 were further increased by the constitutively phosphorylated HSP20 mutant (S16D). In our study, the PKC inhibitor Ro-31-8220 (0.1 $\mu\text{mol/L}$) and selective mitochondrial K^+_{ATP} channel inhibitor 5-HD (100 $\mu\text{mol/L}$) blocked the HSP20-induced protective effect. Our results are similar to those of previous reports showing that the PKC inhibitor blocks the cardioprotective effect of the mitochondrial K^+_{ATP} channel^[20,21], which indicates that PKC lies upstream of the mitochondrial K^+_{ATP} channel.

Our results suggest that the protective effect of HSP20 is attributed to a reduction of necrosis and apoptosis in cardiomyocytes. Therefore, the cardioprotective effect of HSP20 *in vitro* might be mediated mainly by inhibiting cardiomyocyte necrotic and apoptotic cell death, possibly via the PKC/mito K^+_{ATP} pathway.

Abstract

Aim: To examine the effect of daidzin, genistin, and glycitin on the osteogenic and adipogenic differentiation of bone marrow stromal cells (MSC) and the adipogenic transdifferentiation of osteoblasts. **Methods:** MTT test, alkaline phosphatase (ALP) activity measurement, Oil Red O stain and measurement were employed. **Results:** Daidzin, genistin, and glycitin 1×10^{-8} , 5×10^{-7} , 1×10^{-6} , 5×10^{-6} , and 1×10^{-5} mol/L all promoted the proliferation of primary mouse bone MSC and osteoblasts. Daidzin 5×10^{-7} mol/L and genistin 1×10^{-6} mol/L promoted the osteogenesis of MSC. Genistin 1×10^{-8} , 5×10^{-7} , 1×10^{-6} , 5×10^{-6} , and 1×10^{-5} mol/L and glycitin 1×10^{-8} , 1×10^{-6} , and 1×10^{-5} mol/L inhibited the adipogenesis of MSC. Daidzin, genistin, and glycitin 1×10^{-8} , 5×10^{-7} , 1×10^{-6} , 5×10^{-6} , and 1×10^{-5} mol/L all inhibited the adipocytic transdifferentiation of osteoblasts. **Conclusions:** Daidzin, genistin, and glycitin may modulate differentiation of MSC to cause a lineage shift toward the osteoblast and away from the adipocytes, and could inhibit adipocytic transdifferentiation of osteoblasts. They could also be helpful in preventing the development of osteonecrosis.

Introduction

Bone metabolism is regulated by functions of osteoblasts and osteoclasts, which are localized in bone tissues. Osteoblasts stimulate bone formation and calcification while osteoclasts promote bone resorption. Many experimental results on the action of isoflavones on the differentiation and/or function of osteoblasts and/or osteoclasts have been reported^[1].

Bone marrow stromal cells (MSC) are pluripotent cells that have the capacity to differentiate into osteoblasts, adipocytes, chondrocytes, myoblasts, or fibroblasts^[2,3]. Thus, lineage determination between osteoblasts and adipocytes could be a critical component in the regulatory pathways of osteoblastogenesis^[4]. Consistently, an increased lipid accumulation in the bone marrow has been reported in association with age-related bone loss implying an

inverse relationship between osteoblastogenesis and adipogenesis. Indeed, it is now hypothesized that an increase in the number of adipocytes occurs at the expense of osteoblasts in osteopenic disorders. Furthermore, there is more and more evidence that suggest a large degree of plasticity exists between osteoblasts and adipocytes and that this transdifferentiation is reciprocal^[5]. It was reported that there was a therapeutic opportunity to either prevent or treat osteopenic disorders by inhibiting marrow adipogenesis^[6]. Therefore, it is possible that the inhibition of marrow adipogenesis with a concomitant increase in osteoblastogenesis could provide a therapeutic target with which to either prevent further increases in adipocyte formation or divert existing adipocytes to become more osteoblasts with a resulting increase in functional bone cells^[7]. Moreover, recent studies *in vitro* have demonstrated that 17β -estradiol suppresses

the expression of lipoprotein lipase (LPL), a marker of adipocyte differentiation in an extramedullary preadipocytic cell line, 3T3L1^[8]. Okazaki *et al* reported that 17 β -estradiol directly modulated differentiation of bipotential stromal cells into the osteoblast and adipocyte lineages, promoting osteoblast differentiation and inhibiting adipocyte differentiation, causing a lineage shift toward the osteoblast^[9]. Such effects will lead to direct stimulation of bone formation and thereby contribute to the protective effects of 17 β -estradiol on bone.

So far, the effect of daidzin, genistin, and glycitin on the osteogenic and adipogenic differentiation of MSC and the adipogenic transdifferentiation of osteoblasts was not reported. The aim of the present investigation was to address the question of whether daidzin, genistin and glycitin had effects on osteogenic and adipogenic differentiation of primary mouse MSC and to investigate the adipogenic transdifferentiation of primary mouse osteoblasts compared with 17 β -estradiol.

Materials and methods

Materials Kunming (KM) mice were purchased from the Guangming Weiwu Biological Product Factory (Shenzhen, China). Dulbecco's modified Eagle's medium (DMEM) and fetal bovine serum were purchased from Gibco (Carlsbad, CA, USA). The 17 β -estradiol, benzylpenicillin, streptomycin, MTT, β -glycerophosphate, dexamethasone, ascorbic acid, insulin, oil red O stain were obtained from Sigma Chemical Co (St Louis, MO, USA). Demethyl sulfoxide (Me₂SO) was purchased from Sangon (Shanghai, China). Genistin, daidzin, and glycitin were from Shanghai TAUTO Biotech Co (Shanghai, China). An alkaline phosphatase (ALP) activity kit was obtained from Nanjing Jiancheng Biological Engineering Institute (Nanjing, China), micro-protein assay kit was purchased from Beyotime Biotechnology (Haimen, China).

Isolation and culture of primary bone MSC The mouse bone MSC were obtained from adult KM mice (4–6 weeks) using the method previously reported^[10] with minor modification. Mice were killed by decapitation. Femora and tibiae were aseptically harvested, and the whole bone marrow was flushed using DMEM in a 1 mL syringe and a 25-gauge needle. The cells were collected and cultured in a culture flask. After a 3-d incubation in a 37 °C, 5% CO₂ humidified incubator, the nonadherent cells were removed from the cultures by gentle aspiration and the medium replaced with fresh DMEM. The medium was changed every 3 d in all the experiments.

Isolation and culture of primary osteoblasts The mice osteoblasts were isolated mechanically from newborn mice skull using a modification of the method previously reported^[11]. Briefly, the skull (frontal and parietal bones) was dissected from KM mice, the endosteum and periosteum were stripped off, and the bone was cut into approximately 1–2 mm² pieces and digested with trypsin (2.5 g/L) for 30 min, and the digestion was discarded. The bone was then digested twice with collagenase A (2.0 g/L) for an 1 h each time. The cells were collected and cultured in a culture flask. After being placed overnight in a 5% CO₂ humidified incubator at 37 °C, the DMEM was removed. The medium was then changed every 3 d in all the experiments.

Assessment of primary mouse bone MSC and osteoblast growth The protocol described by Mosmann was followed with some modifications^[12]. Briefly, MSC (3 \times 10⁶ cells per well) and osteoblasts (1 \times 10⁴ cells per well) were plated in 96-well culture plates and cultured overnight at 37 °C in a 5% CO₂ humidified incubator. Daidzin, genistin, glycitin, and 17 β -estradiol were then added to the wells at final concentrations of 1 \times 10⁻⁸, 5 \times 10⁻⁷, 1 \times 10⁻⁶, 5 \times 10⁻⁶, and 1 \times 10⁻⁵ mol/L. Control wells were prepared with the addition of DMEM. Wells containing DMEM without cells were used as blanks. The plates were incubated at 37 °C in a 5% CO₂ incubator for 48 h. Upon completion of the incubation, stock MTT dye solution (20 μ L, 5 g/L) was added to each well. After 4-h incubation, the supernatant was removed and Me₂SO (100 μ L) was added to solubilize the MTT. The optical density of each well was measured on a microplate spectrophotometer (Bio-Rad Model 680, Hercules, CA, USA) at a wavelength of 570 nm. The proliferation rate/% of control was calculated according to the formula: $OD_{\text{treated}}/OD_{\text{control}}\times 100\%$.

Measurement of ALP activity The bone MSC were isolated as above. MSC (3 \times 10⁶ cells per well) were plated in 48-well culture plates, after being induced by an osteogenic supplement (1 \times 10⁻⁷ mol/L dexamethasone, 5.0 mmol/L β -glycerophosphate, 50 mg/L ascorbic acid) and treated with daidzin, genistin, glycitin and 17 β -estradiol at final concentrations of 1 \times 10⁻⁸, 5 \times 10⁻⁷, 1 \times 10⁻⁶, 5 \times 10⁻⁶, 1 \times 10⁻⁵ mol/L for 7 d. The plates were washed thrice with ice-cold PBS and lysed by two cycles of freezing and thaw. Aliquots of supernatants were subjected to alkaline phosphatase activity and protein content measurement using an alkaline phosphatase kit and a micro-Bradford assay kit, respectively. The osteogenic differentiation rate was calculated according to the formula: $ALP\ activity_{\text{treated}}/ALP\ activity_{\text{control}}\times 100\%$.

Oil red O stain and measurement The bone MSC and osteoblasts were isolated as above. MSC (3 \times 10⁶ cells per well) and osteoblasts (1 \times 10⁴ cells per well) were plated in 48-

well culture plates, after being induced by adipogenic supplement (10 mg/L insulin, 1×10^{-7} mol/L dexamethasone and treated with daidzin, genistin, glycitin, and 17β -estradiol at final concentrations of 1×10^{-8} , 5×10^{-7} , 1×10^{-6} , 5×10^{-6} , 1×10^{-5} mol/L for 14 d and 9 d, respectively. Fat droplets within differentiated adipocytes from MSC and transdifferentiated adipocytes from osteoblasts were observed using the oil red O staining method described by Ichiro *et al.* with some modification^[13]. Cell monolayers were fixed in 4% formaldehyde, washed in water and stained with a 0.6% (w/v) oil red O solution (60% isopropanol, 40% water) for 15 min at room temperature. For quantification, cell monolayers were then washed extensively with water to remove unbound dye, then 1 mL of isopropyl alcohol was added to the stained culture dish. After 5 min, the absorbance of the extract was assayed by a spectrophotometer at 510 nm. The adipogenic differentiation rate and adipocytic transdifferentiation rate were calculated according to the formula: $OD_{treated}/OD_{control} \times 100\%$.

Statistical analysis Data were expressed as mean \pm SD of at least three separate experiments. The statistical differences were analyzed using Student *t*-test.

Results

Effect of daidzin, genistin and glycitin on the MSC proliferation MTT tests showed that daidzin, genistin, and glycitin significantly promoted MSC proliferation and all the promotion rates were less than that of 17β -estradiol at the same concentrations (Figure 1).

Effect of daidzin, genistin, and glycitin on osteoblast proliferation The daidzin, genistin, and glycitin significantly promoted osteoblast proliferation and the promotion rate of

daidzin was greater than those of genistin and glycitin at the same concentrations (Figure 2).

Figure 2. Effect of daidzin, genistin, and glycitin on the proliferation of osteoblasts. *n*=5. Mean \pm SD. ^b*P*<0.05, ^c*P*<0.01 vs control.

Effect of daidzin, genistin, and glycitin on the osteogenic differentiation of MSC ALP activity measurements at d 7 showed that neither daidzin, genistin, and glycitin inhibited the osteogenic differentiation of MSC. Daidzin at concentration of 5×10^{-7} mol/L and genistin at concentrations of 1×10^{-6} , 5×10^{-6} , and 1×10^{-5} mol/L promoted the osteogenic differentiation and all the promotion rates were less than those of 17β -estradiol at the same concentrations (Figure 3).

Effects of daidzin, genistin, and glycitin on the adipogenic differentiation of MSC Oil red O stain and measurement on

Figure 1. Effect of daidzin, genistin, and glycitin on the proliferation of bone MSC. *n*=5. Mean \pm SD. ^b*P*<0.05, ^c*P*<0.01 vs control.

Figure 3. Effect of daidzin, genistin, and glycitin on the osteogenic differentiation of MSC. *n*=5. Mean \pm SD. ^b*P*<0.05, ^c*P*<0.01 vs control.

d 14 showed that the effect of daidzin, genistin and glycytin on adipogenic differentiation depended on concentrations. Genistin inhibits adipogenic differentiation at concentrations of 1×10^{-8} – 1×10^{-5} mol/L, and the effect was stronger than that of 17β -estradiol (Figure 4). The morphologic observation was in accordance with this result (Figure 5).

Figure 4. Effect of daidzin, genistin, and glycytin on the adipogenic differentiation of MSC. $n=5$. Mean \pm SD. ^b $P<0.05$, ^c $P<0.01$ vs control.

Effect of daidzin, genistin, and glycytin on adipocytic transdifferentiation of osteoblasts Oil red O stain and measurement showed that daidzin, genistin and glycytin inhibited adipocytic transdifferentiation of osteoblasts at all concentrations in a dose-independent manner. The effects of these were stronger than that of 17β -estradiol (Figure 6). The morphologic observation was in accordance with the results (Figure 7).

Discussion

Adipocytic and osteogenic cells are believed to be derived from multipotential stromal cells in the marrow, and *in vitro* studies have shown an inverse relationship between the differentiation of adipocytic and osteogenic cells^[5].

Figure 5. Effect of daidzin, genistin, and glycytin on adipogenic differentiation of MSC. (A) Adipogenic supplement; (B) Adipogenic supplement+ 5×10^{-7} mol/L daidzin; (C) Adipogenic supplement+ 5×10^{-7} mol/L glycytin; (D) Adipogenic supplement+ 5×10^{-7} mol/L genistin. $\times 100$.

Besides having a passive role of space-filling in bone marrow cavity, recent data suggest that medullary adipocytes are secretory cells that may influence hematopoiesis and osteogenesis^[14]. A variety of peptide and nonpeptide compounds are synthesized and released by adipocytes^[15]. Adipocytes also secrete cytokines such as tumor necrosis factor- α (TNF- α) and interleukin (IL-6), and the main effect of these cytokines is a stimulation of bone resorption^[16]. In addition, Benayahu *et al* reported that preadipocytes had the potential to stimulate osteoclast differentiation^[17]. On the relationship between adipogenesis and the ability to support osteoclast formation, Sakaguchi *et al* have demonstrated that adipocyte-enriched stromal cells also support osteoclast formation^[18]. It has been reported that preadipocytes isolated from mouse marrow may regulate the activity and final differentiation of marrow precursors of osteoblasts. The condition medium harvested from mouse stromal preadipocytes decreased the alkaline phosphatase activity of a mouse stromal osteoblastic cell line^[19]. So a reversal of adipogenesis will also be important as a therapeutic approach to treat age-related osteoporosis.

Osteonecrosis is a disabling condition that can be defined as the death of the cell components of the bone (including osteocytes and bone marrow cells). Possible pathogenesis of osteonecrosis is an increased size of marrow fat cells, a high intraosseous pressure, an accumulation of lipids within the osteocytes, and fat embolisms. Cui *et al* reported that steroid-induced adipogenesis by bone progenitor cells in the marrow might influence the development of osteonecrosis^[20]. Lipid clearing agents, such as lovastatin, which promote osteogenic differentiation and inhibit adipogenic differentiation of MSC, might be helpful in preventing the development of steroid induced osteonecrosis.

In the present study we have examined the effects of daidzin, genistin, and glycitin on osteogenic and adipogenic differentiation of MSC and the adipogenic transdifferentiation of osteoblasts in an *in vitro* assay employing isolated mouse primary bone marrow stromal cells and osteoblasts. The results indicate that daidzin, genistin, and glycitin promoted osteogenic differentiation and inhibited adipogenic differentiation of MSC. It also inhibited adipocytic transdifferentiation of osteoblasts at appropriate concentrations similar to 17 β -estradiol. These results were further supported by the fact that daidzin, genistin and glycitin did not inhibit proliferation of the MSC and osteoblasts. This suggests that daidzin, genistin and glycitin regulate a dual differentiative process of bone MSC into the osteogenic and adipogenic lineages, and transdifferentiation process of primary osteoblasts into the adipocyte lineages, causing a

lineage shift toward osteoblasts. So, we deduced that the protective effects of daidzin, genistin, and glycitin on bone might be mediated by decreasing adipocytic cell formation from MSC. This may promote osteoblast proliferation, differentiation and mineralization, and secrete less cytokines, which may inhibit osteoclast formation and activation. In addition, the results also indicate that daidzin, genistin, and glycitin may be helpful in preventing the development of steroid induced osteonecrosis. The mechanisms of the effects of daidzin, genistin, and glycitin on the osteogenic and adipogenic differentiation of bone MSC, and the adipogenic transdifferentiation of osteoblasts, need to be studied further.

Important Announcement: the Online Manuscript Submission and Review System was Launched!

Acta Pharmacologica Sinica announced that its online manuscript submission and review system based on ScholarOne Manuscript Central (<http://mc.manuscriptcentral.com/aphs>) was launched on May 25, 2005.

As the leading web-based peer-review system applied by many journals, Manuscript Central is a complete, database-driven software for the online submission and review of full-text manuscripts and graphics. The system provides fully electronic workflow and will speed up the time from submission to decision.

Acta Pharmacologica Sinica strongly recommend its authors to submit manuscript via this system, which enables this journal to handle the manuscript quickly and efficiently. Please read the User Guide before submitting manuscript online. For more detailed submission instruction, please consult the Manuscript Central Online User Guide (<http://mcv3help.manuscriptcentral.com/tutorials/>). You may also contact the Editorial Office who will be pleased to help you.

Abstract

Aim: To examine the antimicrobial spectrum and functional structure of high mobility group nucleosomal binding domain 2 (HMGN2). **Methods:** OMIGA protein structure software was used to analyze the two-dimensional structure of HMGN2. Synthetic short peptides were generated for studying the relationship between function and structure. Prokaryotic expression vectors were constructed for the holo-HMGN2 and its helical domain. Their *E coli*-based products were also prepared for antimicrobial testing. The antimicrobial assay included minimal effective concentration, minimal inhibitory concentration, and minimal bactericidal concentration. **Results:** OMIGA protein structure software analysis revealed a transmembrane α -helical structure (the putative antimicrobial domain) located from position 18 to 48 of the HMGN2 protein sequence. The antimicrobial assay showed that the MIC of the recombinant holo-HMGN2 against *E coli* ML-35p (an ampicillin-resistance strain), *Pseudomonas aeruginosa* ATCC 27853 and *Candida albicans* ATCC 10231 were 12.5, 25, and 100 mg/L, respectively. Against the same microorganisms, the MIC of the synthetic HMGN2 α -helical domain were 12.5, 25, and 100 mg/L, respectively, that is, the same as with the recombinant form of HMGN2. In contrast, recombinant holo-HMGN2 was inactive against *Staphylococcus aureus* ATCC 25923. The synthetic N-terminal and C-terminal fragments of HMGN2 had no antimicrobial activity against *E coli* ML-35p, *P aeruginosa* ATCC 27853 or *C albicans* ATCC 10231. **Conclusion:** HMGN2 showed potent antimicrobial activity against *E coli* ML-35p, *P aeruginosa* ATCC 27853 and, to some extent, against *C albicans* ATCC 10231, but was inactive against *S aureus* ATCC 25923 in these assay systems. Its α -helical structure may be essential for the antimicrobial activity of HMGN2.

Introduction

Cationic antimicrobial peptides play a crucial role in the host defense against infections^[1]. It has been shown that the antimicrobial activity of human mononuclear leukocytes originates from natural killer (NK) cells^[2], T cells^[3] and monocytes^[4]. Several antimicrobial peptides or proteins have been described in NK and T cells. Granulysin is a recently characterized antimicrobial polypeptide from T and NK cells^[5]. The porcine counterpart of granulysin (NK-lysin) was characterized as an antimicrobial and cytotoxic polypeptide expressed

by NK and T cells^[6]. The antimicrobial peptides LL-37 and human neutrophil defensins (HNP1-HNP3) were found in the supernatant of enriched T and NK cells^[7]. We isolated and characterized an antimicrobial polypeptide from human circulatory mononuclear leukocytes. Its N-terminal sequence was identical to high mobility group nucleosomal binding domain 2 (HMGN2)^[8]. HMGN2 was identified as a non-histone chromosomal protein in invertebrates and vertebrates and may play a role in gene transcription and organogenesis^[9–12]. However, the biological role of this protein has not

been fully defined. In this study, we prepared recombinant holo-molecule, recombinant or synthetic helical domain, N-terminal and C-terminal fragments to further determine the antimicrobial spectrum and functional structure of HMGN2.

Materials and methods

Synthetic peptide Synthetic N- and C-terminal fragments, and the α -helical domain of HMGN2, were prepared by Shanghai Genebase Gen-Tech (Shanghai, China). Their amino acid sequences are as follows:

Fragment 1: MPKRKAEGDA KGDKAKV (position 1-17 of the HMGN2 amino acid sequence)

Fragment 2: KDEPQRSSARLSAKPAPPKPEPKPKKAPAK K (position 18-48 of the HMGN2 amino acid sequence)

Fragment 3: GEKVPKGGKGGKADAGKEGNNPAENGDA-KTD QAQKAEGAGD AK (position 49-90 of the HMGN2 amino acid sequence)

High-performance liquid chromatography (HPLC) and mass spectroscopy analysis of these peptides revealed a purity of >95%. The peptides were dissolved in 10 mmol/L potassium phosphate buffer (PPB, pH 7.0) to a final concentration of 10 g/L.

Antimicrobial activity assay Rabbit neutrophil defensin (NP-1) and HNP1-3 were used as the control antimicrobial peptides, and were prepared as described elsewhere^[13,14].

Evaluation of minimal effective concentration The minimal effective concentrations (MEC) were tested using a radial diffusion assay. Briefly, soy broth (*E coli* ML-35p, *Pseudomonas aeruginosa* ATCC 27853, *Staphylococcus aureus* ATCC 25923) or sabouraud dextrose broth (*Candida albicans* ATCC 10231) underlay gel mixture containing 1×10^6 colony-forming units (CFU)/mL of organisms was decanted into a dish. Sample wells of 3-mm diameter were punched and 5 μ L of serial dilutions of the peptides (200, 100, 50, 25, 12.5, 6.25, and 3.125 mg/L) were added to the wells. After 3 h of incubation, overlay soy broth (for growing *E coli* ML-35p, *P aeruginosa* ATCC 27853, *S aureus* ATCC 25923) or sabouraud dextrose broth (for growing *C albicans* ATCC 10231) gels were poured and incubated continuously at 37 °C overnight, the resulting clear zones were measured and expressed in units (1 mm=10 U) after subtracting the well diameter. A linear regression analysis of peptide concentration (x-axis) against the zone diameter (y-axis) was carried out to determine the x-intercept, whose value represented the MEC.

Evaluation of minimal inhibitory concentration and minimal bactericidal concentration The minimal inhibitory concentration (MIC) and minimal bactericidal concentration

(MBC) of the peptides were examined using bacteria at 1×10^6 CFU/mL in the soy broth and serial dilutions of the peptides (500, 250, 200, 150, 100, 50, 25, 12.5, and 6.25 mg/L). Inhibition of growth was determined by measuring optical density (OD) at 492 nm on a UV/VIS spectrometer after incubation at 37 °C for 12-16 h. Antimicrobial activity was expressed as the MIC, the concentration at which 100% inhibition of growth was observed, and the MBC, the concentration at which no CFU were observed after incubation for 12-16 h on soy broth (for growing *E coli* ML-35p, *P aeruginosa* ATCC 27853, and *S aureus* ATCC 25923) or sabouraud dextrose broth (for growing *C albicans* ATCC 10231) solid media.

***E coli*-based production of recombinant human holo-HMGN2 and its α -helical domain** Total RNA was isolated with Trizol Reagent (Gibco BRL, Washington, USA) from the stimulated mononuclear leukocytes. The full-length HMGN2 cDNA was amplified by reverse transcription-polymerase chain reaction (RT-PCR) and ligated to pMD-18T vector (TakaRa, Tokyo, Japan) for DNA sequencing. Generation of DNA of holo-HMGN2 and the HMGN2 α -helical domain was carried out by PCR amplification. Primers containing *Bam*H I and *Eco*R I restriction sites were designed as follows: P1 (5'-ACGGATCCCCCAAGAGAAAGGCTG-3') and P2 (5'-TAGAATTCCTTGGCATCCTCCAGCAC-3') for amplifying holo-HMGN2 cDNA; P3 (5'-CAGGATCC AAGGACGAACCACAG-3') and P4 (5'-GCGAATTC CTTCTTTGCAGGGGCCT-3') for synthesizing DNA encoding HMGN2 α -helical domain. *Bam*HI and *Eco*RI restriction sites are underlined. After digestion with *Bam*HI and *Eco*RI, the PCR products were inserted into the pGEX-1 λ T vector (Amersham Biosciences, Uppsala, Sweden). DNA sequencing of the recombinant prokaryotic expression vectors pGEX-1 λ T-HMGN2 and pGEX-1 λ T-HMGN2 α was carried out to confirm the insert sequences.

The transformed *E coli* JM109 carrying pGEX-1 λ T-HMGN2 and pGEX-1 λ T-HMGN2 α were cultured in Luria-Bertani (LB) medium for 12 h in the presence of isopropylthio- β -D-galactoside (IPTG) to induce protein expression. The induced cultures were washed with phosphate-buffered saline and cell lysates were obtained by freezing/thawing in the presence of lysozyme. After centrifugation (10000 r/min, 4 °C, 5 min), the fusion proteins were purified from the supernatants using Bulk Glutathione Sepharose 4B columns (Amersham Biosciences). The purified fusion proteins were cleaved by thrombin digestion. Holo-HMGN2 and its α -helical domain were obtained by acid-urea polyacrylamide gel electrophoresis (AU-PAGE) elution and HPLC purification.

Results

Analysis of the HMGN2 two-dimensional structure OMIGA protein structure software analysis revealed a transmembrane α -helical structure, the putative antimicrobial domain, located from position 18 to 48 of the HMGN2 protein sequence (Figure 1).

Figure 1. OMIGA protein structure software analysis of high mobility group nucleosomal binding domain 2 (HMGN2). (A) Hydrophobicity analysis using the Janin method. (B) Transmembrane helices analysis using the Argos Method.

Antimicrobial activity of the synthetic peptide fragments Sodium dodecyl sulphate-polyacrylamide gel electrophoresis of the synthetic fragments of HMGN2 is shown in Figure 2. The agar radial diffusion assay indicated that the α -helical domain of HMGN2 had strong antimicrobial activity against an antibiotic-resistant strain of *E coli*. In contrast, no antimicrobial activity was observed for its

Figure 2. Tricine sodium dodecyl sulphate-polyacrylamide gel electrophoresis of synthetic N- and C-terminal fragments and the α -helical domain of high mobility group nucleosomal binding domain 2 (HMGN2). M, protein marker; 1, C-terminal fragment; 2, α -helical domain; 3, N-terminal fragment.

N-terminal or C-terminal fragments using this assay system (Figure 3).

Figure 3. Antimicrobial activity against *E coli* of the synthetic peptide fragments of high mobility group nucleosomal binding domain 2 (HMGN2). A1, Lysozyme (10 g/L); A2, lysozyme (5 g/L); B1, α -helical domain (1 g/L); B2, N-terminal fragment (1 g/L); B3, C-terminal fragment (1 g/L).

Construction of holo-HMGN2 and HMGN2 α -helical domain prokaryotic expression vectors The cDNA encoding mature holo-HMGN2 and its α -helical domain were obtained by PCR (Figure 4), and their corresponding prokaryotic expression vectors were constructed. Sequence analysis indicated that the insert sequences and their orientation were correct in the recombinant vectors.

Figure 4. The cDNA fragments of high mobility group nucleosomal binding domain 2 (HMGN2) and its α -helical domain. A, Full length of HMGN2 cDNA; B, HMGN2 α -helical domain cDNA fragment.

***E coli*-based production of human holo-HMGN2 and its α -helical domain** pGEX-1 λ T-HMGN2 or pGEX-1 λ T-HMGN2 α -transformed *E coli* produced bulk amounts of the HMGN2 and HMGN2 α fusion proteins. The fusion proteins

were purified by glutathione *S*-transferase (GST) affinity chromatography. The purified recombinant holo-HMGN2 and its α -helical domain were obtained using AU-PAGE elution from thrombin-digested fusion proteins and reverse-phase HPLC (Figure 5).

Antimicrobial properties of human holo-HMGN2 and its α -helical domain As shown in Table 1, the MIC, MEC, and

MBC assays indicated that the recombinant human HMGN2 and its transmembrane α -helical domain (synthetic and recombinant) had potent antimicrobial activity against *E coli*, *P aeruginosa* and, to some extent, against *C albicans*. However, human HMGN2 was inactive against *S aureus* in this assay system (data not shown). All experiments were repeated 3 times.

Discussion

High mobility group (HMG) proteins have been described as an abundant family of non-histone proteins in the cell nucleus of vertebrate and invertebrate organisms^[15]. In the narrowest traditional sense, this HMG protein family consists of 6 proteins and is subdivided into 3 subfamilies: the HMG-box (HMGB) (formerly HMG-1/-2), the HMG AT-hook (HMGA) (formerly HMG-I/Y/C), and the HMG nucleosomal binding domain (HMGN) (formerly HMG-14/-17) subfamilies. Each of these classes seems to have a distinct function in the nucleus^[16]. HMGN has a cell cycle-related cellular location^[17]. The functional gene is located on chromosome 1p36.1^[9], and it contains 6 exons, with an extremely high GC content and a “HTF” island, indicative of a housekeeping gene that could be crucial for regulating the function of cells^[9]. However, up to now, the biological role of this protein has not been clear. A variety of experiments have shown that HMGN2 is preferentially associated with chromatin subunits contain-

ing transcribed genes and enhances the transcriptional potential of corresponding genes^[10,11]. Other experiments indicate that HMGN2 maintains the timing of early embryonic development in the mouse, and shows developmental regulation during organogenesis^[12]. Furthermore, abnormal gene or protein expression of HMGN2 is related to some diseases such as neoplasms and autoimmune diseases^[18,19]. The significance of HMGN2 in the host defense against infection is unclear. Frohm and colleagues attempted to identify antimicrobial polypeptides from human wound and blister fluid. Several known antimicrobial peptides or proteins, eg defensins HNP1–3, lysozyme, FALL-39 and histone H2B fragments, were found. Although HMGN2 was isolated, its antimicrobial property was not determined^[20]. More recently, Fernandes *et al* have described a potent antimicrobial peptide isolated from the skin mucus secretions of fish^[21], that is a member of the HMG protein family. In our experiment we observed the antimicrobial activity of the HMGN2 protein.

Many cationic antibiotic peptides are suggested to be membrane-active, assembling to form channels^[22]. Alternatively, certain peptides cluster at the membrane surface cause a cooperative permeabilization by the carpet effect^[23–25]. On the other hand, apidaecins function through a receptor-activated non-pore-forming mechanism involving stereospecificity^[25]. PR-39 kills bacteria by interrupting both DNA and protein synthesis and the DNA binding property of tachyplexin I has also been implicated in antimicrobial activity^[26]. By protein structure analysis of HMGN2, a transmembrane α -helical structure located at residues 18–48 was found, and this location is related to the DNA binding domain of this protein. As such, we prepared a recombinant α -helical domain and confirmed its antimicrobial activity. Thus, the transmembrane α -helical domain may be essential for the antimicrobial activity of HMGN2. The antimicrobial mechanisms of HMGN2 should be further studied.

Abstract

Aim: To prepare new pharmaceutical forms with sustained delivery properties of recombinant human bone morphogenetic protein-2 (rhBMP₂) for tissue engineering and guided tissue regeneration (GTR) use. **Methods:** rhBMP₂-loaded dextran-based hydrogel microspheres (rhBMP₂-MPs), which aimed to keep rhBMP₂ bioactivity and to achieve long-term sustained release of rhBMP₂, were prepared by double-phase emulsified condensation polymerization. The physical, chemical performances and biological characteristics of those microspheres were studied both *in vitro* and *in vivo*. **Results:** The microspheres' average diameter was 30.33±4.32 μm with 75.4% ranging from 20 μm to 40 μm and the drug loading and encapsulation efficiency were 7.82% and 82.25%, respectively. The rhBMP₂-releasing profiles *in vitro* showed that rhBMP₂ release could be maintained more than 10 d. The rhBMP₂-MPs, with good swelling and biodegradation behavior, could be kept for 6 months at below 4 °C without significant characteristic change or bioactivity loss. Cytology studies showed that rhBMP₂-MPs could promote the proliferation of periodontal ligament cells (PDLs) approximately 10 d, while the bioactivity of concentrated rhBMP₂ solution could keep no more than 3 d. Scanning electron microscope showed that rhBMP₂-MPs could be enmeshed into the porous structure of calcium phosphate ceramic (CPC) and the eugenic growth of PDLs in CPC/rhBMP₂-MPs scaffolds. Animal experiments indicated that using CPC/rhBMP₂-MPs scaffolds could gain more periodontal tissue regeneration than using rhBMP₂ compound firsthand with CPC (CPC/rhBMP₂). **Conclusion:** By encapsulating rhBMP₂ into dextran-based microspheres, a small quantity of rhBMP₂ could achieve equivalent effects to the concentrated rhBMP₂ solution and at the same time, could prolong rhBMP₂ retention both *in vitro* and *in vivo*.

Introduction

Tissue engineering is one of the biomedical technologies used to induce tissue regeneration or repair body defects. The goal is to isolate adult stem cells in the tissue, then grow them in experimental devices into types of tissue that can be placed into injured regions to promote regeneration of tissue in and around injured areas of the body^[1,2]. Drug delivery is an area in which chemical engineers have had a major impact, particularly for controlled delivery of

pharmaceuticals to specific target sites such as tumors. Gene therapy is really metabolic engineering combined with drug delivery. It is a quantitative problem requiring a systems analysis. The right genes need to be delivered to the desired tissues, and proteins from that gene need to be made at the right time in the right amount. The lack of success with gene therapy is, at least in part, due to the inability of medical scientists to deal with these issues of well-controlled gene delivery and gene expression. This is a broad area that includes materials that are produced using biological processes

and biologically compatible materials that are used for drug delivery and other medical applications. However, questions pertaining to the scarce resources and the potential risk of seed cells, the biomaterials of scaffold and the methods used to design the cell and scaffold complex remain unresolved, which have resulted in their limited clinical application^[3-5]. So far, several research approaches – both in animal experiments and in clinical treatment – have been attempted to promote tissue regeneration by bioactive agents, including members of the bone morphogenic protein, transforming growth factor, and insulin-like growth factor families, which are important to the maintenance and repair of most tissue defects^[6-8]. Since periodontal tissue defects typically remain unhealed and often lead to further tissue degeneration and the loss of teeth, understanding the physiological role of these proteins in the wound-healing cascade and tissue regeneration is of critical importance in advancing the treatment of periodontal tissue loss and in enhancing periodontal tissue regeneration. Most of the research in this field has centered on examining the therapeutic effects that these molecules have on hard or soft tissues with the presence of 1 or more growth factors^[9-16]. However, as the fields of tissue engineering and biomaterials merge with molecular and cellular biology, new drug delivery vehicles can be utilized to study the *in vivo* effect of these molecules on periodontal tissue regeneration or periodontal defect repair. Accordingly, this paper details the design and development of a genus of new composite scaffolds with the sustained delivery property of recombinant human bone morphogenetic protein-2 (rhBMP₂).

Bone morphogenetic proteins (BMPs) have been shown to modulate the wound-healing response in both hard and soft tissues. During the past decade, many investigators have demonstrated the anabolic effects of these wound-healing molecules on the promotion of periodontal attachment structures, namely alveolar bone, periodontal ligament and tooth root cementum^[6-8,10-13]. However, because of their drawbacks such as short-term BMP retention and losable BMP biological activity *in vivo*, using agents for BMPs sustained release is of great importance. Although many agents such as calcium phosphate cement (CPC), collagen, bioactive glass ceramic (BGC), hydroxyapatite (HA) and more recently, some hydrogels have been used to enhance tissue regeneration and have gained good results. The actual effect is still uncertain considering the time BMP bioactivity might keep *in vivo*, as those materials themselves could not preserve BMPs from humoral dilution, metabolized and degraded action. There is evidence that the continuous presence of some growth factors at the periodontal tissue interface to provide

a tangible effect is essential, which can accelerate the soft and hard tissue regeneration^[6-8,17]. Therefore, it is rather inviting to search for new pharmaceutical forms that can sustain elevated growth factor levels and increase or improve tissue regeneration in periodontal diseases treatment or periodontal defect repair^[18-20].

Microspheres as drug carriers have the advantage of sustained or controlled release, passive or active drug targeting to specific tissues, which notably reduce the side effects of drugs and improve their bioavailability. Therefore, microspheres as a drug delivery system have drawn much attention in the pharmaceutical field and have been successfully used in tumor chemotherapeutics and in the treatment of diabetes. Dextran-based hydrogels are widely used polymers in pharmaceutical products. The good biocompatibility, the degradation to non-toxic and readily excreted products were the main attractive characteristics of dextran-based hydrogels, which suggest its use in the drug delivery field^[21]. In addition, dextran is relatively cheap and dextran-co-gelatin hydrogels have putative bioadhesive properties that allow the drug delivery systems, designed in different forms, to meet the need of periodontal tissues and mucosal tissues, as well as other especial tissues, such as the eye, nasal, gastrointestinal and urinary epithelial tissues^[22-24]. In order to improve the therapeutic efficiency and to prolong BMP retention in periodontal bone defects, and to explore the possibility of preparing targeted rhBMP₂ delivery devices, this study was aimed at developing a new kind of rhBMP₂ delivery system: rhBMP₂-loaded dextran-based microspheres (rhBMP₂-MPs). The results indicated that using this delivery system could result in a long-term release of rhBMP₂ and could enhance periodontal tissue regeneration continually when compounded with tissue engineering scaffold materials.

Materials and methods

Materials Dextran (M_r 69 800 with 5% branches) was purchased from Xia-si Biomaterial Inc (Beijing, China), Gelatin G-6650 was obtained from Sigma (Sigma Chemicals, Saint-Louis, MO, USA) and dried at 60 °C in a vacuum oven for 2 d. Span-80 and Dextranase (400–800 U/mg protein) was also purchased from Sigma. Triethylamine, 2,20-dimethoxy-2-phenyl acetophenone (DMAP), dimethyl formamide (DMF), *N*-methyl pyrrolidone (NMP) and *N,N,N',N'*-tetramethylethylene diamine (TEMED) were obtained from E Merck (Mumbai, India). Glycidyl methacrylate (GMA) was purchased from Bioengineering Inc (Boston, MA, USA). All these materials were dried overnight at 70 °C in a vacuum oven. RhBMP₂ were obtained from the Academy of Military

Medical Science (Beijing, China), acrylic acid (AA, Merck) was used after vacuum distillation. Water was double distilled. All other chemicals and solvents were used without further purification.

Preparation of rhBMP₂-MPs Using dextran and GMA, we synthesized the dex-GMA precursor as the method we reported recently with some modifications^[25]. The synthesized procedure was as follows: Dextran was dissolved in a dimethyl sulphoxide (Me₂SO) solvent system (60 mL with Span-80 0.4 mL and TEMED 0.2 mL, DMAP 1.5 g, DMF 0.2 g and NMP 0.2 g) at 60 °C under N₂ gas and stirred for 15 min. After dissolving, the solution was cooled down to 35 °C and GMA was then slowly added to the dextran solution. The reaction was conducted at 35 °C for 72 h under N₂ gas. The reaction product was precipitated with cold isopropyl alcohol, filtered, washed several times with isopropyl alcohol, and then freeze-dried in a vacuum oven. The degree of substitution (DS) of the dex-GMA precursor was estimated by the ¹H-NMR method. There is an anomeric proton attached to the C1 position of the dextran glucose ring that appears at 4.5–5.5 ppm in the NMR spectrum, where the protons of the hydroxyl groups appear. This proton does not react during the GMA substitution reaction, while some of the other protons of other hydroxyl groups are substituted by GMA. So, we can use the ratio of the normalized, integrated intensities of the sum of the hydroxyl group peaks to the normalized, integrated intensities of the anomeric proton peak to estimate the DS. For unsubstituted pure dextran, the ratio should be 3; while for GMA-substituted dextran, this ratio should be less than 3, and the magnitude would depend on the number of substitution. Thus, the DS could be calculated from the ratio: 3×(difference of the NMR proton intensity between dextran and dextran derivatives)/dextran. The dex-GMA precursor synthesized in this study had a DS of 2.6, that is, 2.6 hydroxyl groups per dextran glucose ring were substituted by GMA. Using dex-GMA, we synthesized a species of biodegradable poly (dex-GMA-co-gelatin) hydrogel microspheres, which were used as the carrier of rhBMP₂. The rhBMP₂-MPs were prepared by double-phase emulsified condensation polymerization method and optimal preparation parameters were obtained by the orthogonal design. The technique was as follows: 3 cuvettes of equivalent homogeneous aqueous dex-GMA and gelatin solution (10%, w/v) of 6 mL, each containing 0.6 g dex-GMA and 0.15 g gelatin, were preheated to 30 °C and dropped into 3 different reactor systems comprising of 30 mL paraffin liquid, 0.2 mL Span-80 and 0.01 mL, 0.02 mL, or 0.03 mL TEMED. The 3 reactor systems were at 30 °C in a water bath, forming a water-in-oil emulsion by stirring with a two-paddle stirrer.

Ten minutes later, as the emulsion was obtained, concentrated rhBMP₂ solution (containing 0.08 g rhBMP₂) was dropped into the reactor systems. The resulting microspheres were washed 3 times with cool isopropanol, ethyl ether to remove the residual paraffin, washed with rhBMP₂ saturation water and then lyophilized, sized by passing through sieves of different apertures. The collected loaded microspheres were preserved in a desiccator. Unloaded microspheres were synthesized by the same procedure, with the exception of the concentrated rhBMP₂ solution added and rhBMP₂ saturation water washing.

Morphology, size, and swelling analysis Freeze-dried microspheres were sprinkled onto a piece of electric-glue paper, gold-sprinkled in a vacuum and then examined by scanning electron microscopes (SEM, S-520, Hitachi, Japan). Size and size distribution were calculated by 500 microparticles during SEM and the roundness of the microspheres were determined by a particle size analyzer (BI-90, Brookhaven Co, California, USA). At the same time, freeze-dried microspheres (5 mg) were suspended in aqueous solution (4 mL) for 5 min using an ultrasonic bath and then dropped onto a sheet glass. The morphology of swelling microspheres was observed by photomicroscope (XI 70, Olympus, Tokyo, Japan). Another solidified rhBMP₂-MPs powder (weight W₀ of 5 mg) was dipped in aqueous solution for approximately 30 min, then using filtered paper absorbed the water and weighed the weight of the swollen microspheres (W_s). The swelling ratio (Rs) of the microspheres was calculated by the following formula:

$$Rs (\%) = (W_s - W_0) / W_0 \times 100\%$$

Determination of drug loading and drug encapsulation efficiencies Drug encapsulation efficiencies (DE) and drug loading (DL) are 2 main indexes of pharmaceutical forms. DE reflects the pharmaceutical form's ability to encapsulating drugs and high DE means little drug wasted during preparation, while DL reflects the effectual drug component in a pharmaceutical form and high DL means high therapeutic component available. They are all of great importance. The determination methods included an exact weighed amount of rhBMP₂-MPs (100 mg); unloaded microspheres (100 mg) were treated with 50 mL NaOH (10%, w/v) water solution at 80 °C for 20 min. Fully degraded dex-GMA/gelatin solution were adjusted to neutral solution with 3 mol·L⁻¹ HCl and centrifugated for 5 min. The supernatants were mixed with total-ionic-strength adjusting buffer (TISAB II) and made into 50 mL of solution. Drug content in the solution were conducted by means of High Performance Liquid Chromatography (HPLC) (94-09SC, Orion Research Inc, Boston, MA, USA). The actual weight of rhBMP₂ found loaded should be

equal to the remainder of the rhBMP₂ contents between rhBMP₂-loaded and unloaded microspheres.

DE (%)=(Weight of rhBMP₂ found loaded)/(Weight of rhBMP₂ input)×100%

DL (%)=(Weight of rhBMP₂ found loaded)/(Weight of rhBMP₂-loaded microspheres)×100%

Biodegradation of rhBMP₂-MPs Reports have been found to show that dextran-based biomaterials could be biodegraded in any liquid with presence a very tiny quantity of dextranase. Thirty-six exact weighed amounts of rhBMP₂-MPs (100 mg) were dipped in 0.9% physiological saline (containing 0.05 μg/mL, 0.1 μg/mL and 0.2 μg/mL dextranase, respectively) and divided into 4 groups at certain time intervals of 10 d, 20 d, 30 d, and 40 d; three of each group were collected and freeze-dried. The morphology of the biodegraded microspheres was observed by SEM and weight loss was also studied.

Stability and biological activities of rhBMP₂-MPs Dry rhBMP₂-MPs were sealed and deposited in a 4 °C refrigerator or at room temperature for 6 months respectively. Their appearance, morphology, DE and DL were checked as routine procedure. The bioactivity of the microspheres were evaluated by the biological effects they had on the cultured cells *in vitro*, and at the same time, we investigated the biological effects of loaded microspheres compared to the equivalent concentrated rhBMP₂ solution. Human periodontal ligament cells (PDLCs) were obtained from premolars extracted for orthodontic reasons from a 14-year-old patient, using cultured methods as previously described by Somerman *et al*^[26]. The protocol was approved by the Ethical Committee in Research from the Fourth Military Medical University. The cell growth assay was performed by MTT (purchased from Sigma, Saint-Louis, MO, USA) methods^[27]. Generally, PDLCs were placed in a 96-well culture plate (Nunc A/S, Roskilde, Denmark) at a density of 30,000 cells/well in 2 μL of DMEM containing 10% FBS and antibiotics. After 16 h, the cells were washed with PBS and cultured in serum-free (CT)-FBS/DMEM supplemented with 100 μg/mL rhBMP₂ (group I) or 782 μg/mL rhBMP₂-MPs synthesized within 3 d (equal to 100 μg/mL rhBMP₂; group II), or 782 μg/mL rhBMP₂-MPs deposited in a 4 °C refrigerator for 6 months (group III), or at room temperature for 6 months (group IV), the control group (group IV) served as the control supplemented with nothing. After 1, 2, 3, 5, 7, 10, 12 d, absorbance was read at 570 nm according to routine MTT methods. The cellular proliferation was calculated as the amount of MTT uptake.

Drug release study *in vitro* *In vitro* drug release profiles were obtained by a dynamic dialysis method simulating the temperature *in vivo*. Briefly, 3 groups of rhBMP₂-MPs (50

mg), according to different quantity of TEMED (0.01 mL, 0.02 mL and 0.03 mL) when prepared, were poured into a dialysis tube (IL61105, Rockford, USA), then placed at 37.0±0.5 °C into phosphate buffer solution (PBS) of 150 mL (pH=7.0), respectively, and continuously stirred with a magnetic stirrer at 200 r/min. At specific time intervals of 5 h, 20 h, 30 h, 60 h, 90 h, 120 h, 150 h, 190 h, and 250 h, 10 mL of samples were removed from the release medium and the same volume and temperature of PBS was added back to the release medium. The samples were then assayed for drug content according to intraday standard curve. Results of triplicate test data were used to calculate accumulated drug release. Cumulative release profiles of different rhBMP₂-MPs were studied respectively.

CPC/rhBMP₂-MPs scaffolds preparation The calcium phosphate ceramic (CPC) was purchased from Rui Bang Biomaterial Inc (Shanghai, China) and CPC/rhBMP₂-MPs was obtained by a physical concoction mechanism using CPC, PBS, and rhBMP₂-MPs with the inverse proportion being 1:3:0.01, and then solidified in a vacuum desiccator. Human PDLCs cultured *in vitro* were collected and seeded on the concreting compound, the cell growth in the scaffolds and CPC/rhBMP₂-MPs framework were observed by SEM.

Animal experiment After receiving approval from the Committee of Research Facilities for Laboratory Animal Science, Fourth Military Medical University, 12 female beagle dogs weighing 10 to 14 kg and aged 12 to 20 months were used in this study. Good oral health was established by scaling and mechanical tooth-brushing. All surgical procedures were performed under general anesthesia with sodium pentobarbital (40 mg/kg), and local infiltrated anesthesia with 2% lidocaine with 1:80 000 noradrenaline. Experimental Class III furcation defects prepared in this study were based on the model described by Lindhe *et al*^[28]. The second, third, and fourth premolars (P2, P3, and P4) in each dog were selected for experimentation (Figure 1A). Following sulcular incisions, mucoperiosteal flaps were raised, and Class III furcation defects were created surgically at P2, P3, and P4. The Class III defect height from the cemento-enamel junction to the reduced alveolar crest was 5.00±0.20 mm. Denuded root surfaces were prepared to remove all periodontal ligament and cementum. The roots were denuded only in the area within the furcation and extending to the mesial line angle for the mesial root and to the distal line for the distal root. Reference notches were placed around the circumference of the mesial and distal roots at the bottom of the bone level. All teeth were divided into 4 sub areas: maxillary left and right, submaxilla left and right, and then divided into 2 groups stochastically (to avoid the interaction of defects in

Figure 1. Animal experiment (A) Lindhe's model of Class III furcation defects; (B) Presurgical view of the mandibular premolar area and Class III furcation defects circumscription demarcation; (C) After defect preparation; (D) After transplantation of CPC/rhBMP₂-MPs scaffolds; (E) After repositioning of gingival flaps and suturing; (F) Schematic drawing of percentage of new cementum length and percentage of new bone.

one subarea): the experimental group and the control group. The experimental group was transplanted with CPC/rhBMP₂-MPs scaffolds while the control group was transplanted with CPC concreting compound soaked with the commensurate quantity of concentrated rhBMP₂ compared with rhBMP₂-MPs. In another words, the actual rhBMP₂ quantity transplanted into each Class III furcation defects was exactly same (Figure 1B, 1C, 1D, 1E). One or 2 months after transplantation, anesthetized animals were perfused with 1% glutaraldehyde in a sodium cacodylate buffer containing 0.05% calcium chloride (pH 7.3). The periodontal tissue regeneration was evaluated by unaided eye and X-ray. After that, the mandibles and maxillas were dissected and immersed in the same fixative. After decalcification with hydrochloride for 3 to 5 d, the mandibles and maxillas were dehydrated in paraffin. Serial section (5 μm) were cut in the mesial-distal plane throughout the buccal-lingal extension of the tooth. The sections were stained with hematoxylin and eosin (HE) or the Azan method, and observed using a light microscope. The center-most section and the immediate section on either side were subjected to morphometric analysis. The percentage of new cementum (NC) length and percentage of new bone (NB) area were measured on digitized photomicrographs captured in a computer. The lengths of NC formed along the denuded root surface on each specimen were added, and the percentage of the lengths to the total root surface length from one notch to the next notch was calculated. The area of NB on each specimen was calculated as a percentage of the area surrounded with reference notches at mesial and distal root

surfaces space is present in normal periodontal tissue (Figure 1F). All data were statistically analyzed using the Mann-Whitney U test.

Results

Morphology and particle size The SEM photomicrographs of dried rhBMP₂-MPs showed a smooth and uniform surface (Figure 2A). The roundness of microspheres was 1.020±0.005. The average diameter was (30.33±4.32) μm with 75.4% ranging from 20 μm to 40 μm, The swelling ratio for solidified and dried microspheres was 4.18±0.06, and the size of the soggy microspheres size was approximately 5–10 times larger (Figure 2B). The morphology and particle size analysis showed no difference between loaded and unloaded freeze-dried or swelling microspheres, but when the swelling microspheres were sprinkled onto a piece of glass, half freeze-dried and then observed through a photomicroscope (XI 70, Olympus), the loaded microspheres were found to be a little fuscous. The unloaded microspheres were briefly translucent (Figure 2C, 2D), which was perhaps caused by the increase of the microspheres' density when drugs were encapsulated into the microspheres. Thus, we could presume that drug encapsulation was the primary drug association mechanism of dex-GMA-co-gelatin microspheres.

DL and DE The calculated results of DL and DE were 7.82% and 82.25%, respectively. In the present study, we achieved optimal preparation parameters using the orthogonal design, which was rhBMP₂ (0.5 mmol·L⁻¹), dex-GMA/gelatin solution (20%, *m/v*), emulsifying agent (1%, *m/v*), and 1:5

Figure 2. Micrographs of rhBMP₂-MPs. (A) SEM micrographs of dried rhBMP₂-MPs ($\times 400$); (B) Optical micrographs of soggy rhBMP₂-MPs ($\times 100$); (C) Loaded microspheres ($\times 100$); (D) Unloaded microspheres ($\times 100$).

(*v/v*) of water phase to oil phase. During the experiment we discovered that the concentration of rhBMP₂ affected the quality of the microspheres. When the content of rhBMP₂ exceeded 1 mmol/L, the microspheres' morphology was not uniform, and was prone to sticking. When the concentration was lower than 0.1 mmol/L, the drug content was also too low and thus, unfit for practical application. In order to reduce the loss of rhBMP₂ during the process of preparation, and improve the encapsulation efficiencies, presolidification was introduced and microspheres were washed with concentrated rhBMP₂ solution. Glutaraldehyde (25%, *v/v*) was used to solidify; the solidification time was over 24 h. The encapsulation efficiencies of rhBMP₂-MPs reached 86.73%, which was much higher than other biomaterials that have been reported^[29].

Biodegradation of rhBMP₂-MPs rhBMP₂-MPs could completely degrade within 30–40 d by dextranase action (Figure 3). The weight at specific time intervals was shown in Figure 4, and the microspheres eventually dissolved. However, Figure 4 also shows that the degraded speed in-

Figure 4. Weight of rhBMP₂-MPs at certain time intervals when degraded under conditions with different quantities of dextranase which showed significant difference. $n=4$. Mean \pm SEM. ^b $P<0.05$, ^c $P<0.05$ vs dextranase 0.05 µg/L. ^{ce} $P<0.05$, ^{cf} $P<0.05$ vs dextranase 0.1 µg/L.

terrelated closely to the consistence of dextranase. This might have important clinical meanings. In periodontal diseases such as periodontitis, especially rapidly progressive periodontitis, when the prolific nosogenetic bacteria and organisms in local environment (which cause excessive dex-

Figure 3. SEM of rhBMP₂-MPs biodegradation in certain time intervals. (A) After 10 d, rhBMP₂-MPs begin to be felted and dissolution can be seen ($\times 200$); (B) After 20 d rhBMP₂-MPs were felted diffusely and many rhBMP₂-MPs degraded ($\times 100$); (C) After 30 d most of rhBMP₂-MPs degraded ($\times 1500$); (D) After 40 d most of rhBMP₂-MPs disappeared and the surface of residuary rhBMP₂-MPs became scraggly ($\times 4000$).

tranas biosynthesis and the biodegradation of rhBMP₂-MPs more rapidly), rapid releasing rhBMP₂ from microspheres is beneficial for tissue repair and at the same time, can prevent tissue loss. It could be hypothesized that when rhBMP₂-MPs are topically applied, their presence in the periodontal environment, even at low concentrations, can prevent demineralization as well as promote remineralization of incipient lesions through rhBMP₂ release which are quickened under more dextranase conditions.

Stability of rhBMP₂-MPs The rhBMP₂-MPs were stable when sealed and stored below 4 °C for 6 months without obvious physical and chemical characteristics change. However, when stored at room temperature, rhBMP₂-MPs biomorphic characteristic could not keep unchangeable and with a configuration of conglutination and abnormality (Figure 5). The proliferation curves of PDLCs in different groups are shown in Figure 6. Cytology studies showed that there was no significant differences between groups II and III ($P > 0.05$), indicating no significant bioactivity loss of rhBMP₂-MPs when stored below 4 °C for 6 months. On the other hand, after 6 months of being stored at room temperature, rhBMP₂-MPs would no longer have any biological activity ($P < 0.01$). In addition, the rhBMP₂-MPs could enhance the proliferation of PDLCs for more than 12 d continuously, while the pure rhBMP₂ bioactivity could function only in 3 d, which also showed the sustained delivery property of rhBMP₂-MPs (Figure 6).

In vitro release studies The release profiles of rhBMP₂ from microspheres as a function of time showed that rhBMP₂-

releasing kinetics *in vitro* fitted to first-order and Higuchi equations. From Figure 7 we could see that the drug release from rhBMP₂-MPs mainly consisted of 2 components with an initial rapid release followed by a slower exponential stage. The release profile *in vitro* was in accord with 2-phase kinetics law and more than 80% of the drugs were released during the first 10 d. Furthermore, changing the quantity of TEMED could influence drug release; rhBMP₂ release from rhBMP₂-MPs was slower when the quantity of TEMED was increased during preparation, which could be caused by the DS of microspheres increase followed with TEMED increased. During the initial stages, the microspheres were absorbed and the sphere enlarged rapidly; the drugs were rapidly released from the microspheres through the exoteric micro-aperture; When swelling was counterpoise, the drug release slowed down and was determined by drug pervasion and microsphere biodegradation. Thus, we can speculate that rhBMP₂ release from rhBMP₂-MPs might be controlled by some preparation technique change.

Cells growth on CPC/rhBMP₂-MPs scaffolds A scanning electron microscope showed that the porous structure

Figure 7. Cumulative release profiles of different rhBMP₂-MPs prepared with different quantities of TEMED. $n=4$. Mean±SEM. ^b $P < 0.05$, ^c $P < 0.05$ vs TEMED 0.03 mL. ^e $P < 0.05$, ^f $P < 0.05$ vs TEMED 0.02 mL.

of CPC/rhBMP₂-MPs compound and rhBMP₂-MPs could be adhered in the porous structure (Figure 8A). After 3 d, human PDLCs could grow on CPC/rhBMP₂-MPs compound both in the porous structure (Figure 8B) and on the material's surface (Figure 8C).

Animal experiment When observed with unaided eye in the experimental group, the defect was well regenerated after 1 month (Figure 9A) and was almost completely regenerated after 2 months (Figure 9B). The control group gained less tissue regeneration than the experimental group even after 2 months (Figure 9C). The X-ray observation results were shown in Figure 10. In the experimental group, a significant amount of new bone and an adequate width of periodontal ligament were observed (Figure 11A). The denuded root

surface was almost completely covered with NC, and regenerated periodontal ligament separated the NB from the cementum. On the denuded root surfaces of the furcation area, newly formed cementum covered the surface, and the Sharpey's fibers inserted into the cementum were frequently observed (Figure 11B). In the control group, no cementum regeneration was observed (Figure 11C) and epithelial cells invaded into the top of the furcation in the area (Figure 11D). Less bone regeneration was observed in this group compared to the experimental group. The percentages of NC length in the experimental group after 1 and 2 months were $93.9\% \pm 14.2\%$ and $96.7\% \pm 5.29\%$, respectively, compared to $70.4\% \pm 12.1\%$ and $72.8\% \pm 9.2\%$ in the control group. The results showed significant difference ($P < 0.01$). Accordingly,

Figure 8. SEM of CPC/rhBMP₂-MPs scaffolds and cell growth. (A) CPC/rhBMP₂-MPs scaffolds ($\times 400$); (B, C) Cell growth on CPC/rhBMP₂-MPs scaffolds ($\times 1000$).

Figure 9. Tissue regeneration observed with unaided eye. (A) After 1 month experimental group; (B) After 2 months experimental group; (C) After 2 months control group.

Figure 10. Tissue regeneration observed with X-ray after 2 months. (A) Tooth in mandible experimental group, well-regeneration in the Class III furcation defect area could be seen and the radiograph was on the verge of normal dental film; (B) Tooth in mandible control group, shadow in the furcation area was still obvious; (C) Tooth in maxilla experimental group, bone image in the furcation defect area showed well bone regeneration; (D) Tooth in maxilla control group, compared to experimental group, little new bone could be observed.

Figure 11. Histological analysis of periodontal tissue regeneration after 2 months. (A) HE×13 experimental group. After 2 months, there was a significant amount of NB and NC; (B) Azan method ×100 experimental group. An adequate width of periodontal ligament can be observed; (C) HE×13 control group. Less NB and NC can be observed; (D) HE×100 control group. Epithelial cells invaded the top of the furcation.

the percentages of NB were $62.6\% \pm 13.5\%$ and $68.7\% \pm 9.73\%$ in the experimental group and $54.7\% \pm 10.73\%$ and $57.3\% \pm 11.2\%$ in the control group also showed significant difference ($P < 0.01$).

Discussion

Biodegradable hydrogel microspheres are attractive devices for drug release because they combine good tissue biocompatibility with the possibility of manipulating the permeability for solutes. In particular, their use in pharmaceuticals shows promise since recent advancements in biotechnology have led to a great variety of pharmacologically active peptides and proteins that are not adequately released from systems that are not biodegradable. Degradation of the hydrogel microspheres not only allows a tailored release of entrapped molecules, but also circumvents the removal of the empty device from the body^[30–32]. Although the use of biodegradable hydrogel microspheres related to prolonged and/or controlled drug delivery has been widely investigated, the need for the development of hydrogels using simpler and more feasible methods still exists. Among the starting materials, polysaccharides and polyaminoacids represent good candidates to prepare biodegradable hydrogels by photocrosslinking reactions. Besides their biocompatibility and biodegradability, these polymers can also have functional groups incorporated into their structures. These functional groups include acrylic or methacrylic ones, which can easily lead to the formation of inter- and intra-chain bonds by UV irradiation. In this context, the synthesis and characterization of dextran-co-gelatin hydrogel microspheres show good biocompatibility and biodegradability. Dextran is a natural polysaccharide that is widely used in the phar-

ma- ceutical field^[33–37]. It is water soluble, inert in biological systems and does not affect cell viability. The characteristic α -1,6-glucosidic linkage is hydrolyzed by dextranases, enzymes produced by various molds and certain bacteria as well as by mammalian cells. It has also been found that dextranases are produced by anaerobic Gram-negative intestinal bacteria^[38]. The use of hydrogels based on dextran represents a strategy to release drug molecules in the colon after hydrolysis of the polysaccharide microspheres^[39]. After sucking and swelling *in vivo*, rhBMP₂-MPs can keep rhBMP₂ concentrations over prolonged periods of time, which might be explained by the sustained-release of rhBMP₂ from rhBMP₂-MPs and dextran-based microspheres' bioadhesive properties to mouth parenchyma. Experiments conducted using rhBMP₂-MPs and rhBMP₂ solution as control revealed that rhBMP₂-MPs maintained rhBMP₂ elevation above baseline for about 10 d, but rhBMP₂ maintained for less than 3 d. This indicated the possibility that rhBMP₂-MPs could meet clinical intermittent administration by prolonging rhBMP₂ retention time significantly.

Many biomaterials such as Chitosan, polylactic acid (PLA), polyglycolic acid (PGA), PGA-co-PLA polymers (PLGA), poly(ethylene glycol) (PEG), gelatin, and polybutylcyanoacrylate (PBCA) were all reported to prepare growth factor-sustained release systems recently, but a lot of questions remain unanswered. The outstanding obstacle in the clinical application of growth factor carriers to promote tissue regeneration and control release of growth factors is still unrealized, which results in the growth factors not being able to maintain enough time or concentration during the tissue regenerated period. To meet the need of periodontal regeneration, new biomaterials used to prepare controlled release system of growth factors have become increasingly

important. From this study, we prepared a new carrier for the sustained release of rhBMP₂, which can be used to synthesize guided tissue regeneration biomembranes and build functional scaffolds in tissue engineering. In summary, for the first step in developing a new type of rhBMP₂ agent, we chose dextran-based microspheres as sustained release carriers for topical rhBMP₂ applications. We proved the ability of rhBMP₂-MPs in prolonging rhBMP₂ release and their potential in prohibiting demineralization and enhancing the rhBMP₂ retention both *in vitro* and *in vivo*. This work offered a new method in contributing growth factors, not only BMPs, but also other growth factors for clinical use, which can be popularized with further evaluation both in animal experiment and in clinical cases. However, some limitations of using the microsphere-carrier combination, including the potential difficulty in manufacturing the carrier, and the expensive price considering the costly price of growth factors themselves. Moreover, the manufacture procedure and the application of this pharmaceutical form still require further study both experimentally and clinically.

Abstract

Aim: The antihyperglycemic effects of the total ginsenosides in Chinese ginseng (TGCG), extracted from leaves and the stem, were evaluated in diabetic C57BL/6J *ob/ob* mice. **Methods:** Animals received daily intraperitoneal injections of TGCG (100 and 200 mg/kg) or oral administration (150 and 300 mg/kg) for 12 d. Fasting blood glucose levels and body weight were measured after fasting the animals for 4 h. Peripheral glucose use was also measured using an intraperitoneal glucose tolerance test. **Results:** In the injection group, a high dose of TGCG (200 mg/kg) significantly lowered the fasting blood glucose levels in *ob/ob* mice on d 12 (153 ± 16 mg/dL vs 203 ± 9.8 mg/dL, $P < 0.01$, compared to vehicle-treated group). In the oral group, blood glucose decreased notably with a dose of TGCG (300 mg/kg) on d 12 (169.1 ± 12.6 mg/dL vs 211.6 ± 13.8 mg/dL, $P < 0.05$, compared to the vehicle-treated group). Glucose tolerance was also improved markedly in *ob/ob* mice. Furthermore, a significant reduction in bodyweight ($P < 0.05$) was observed after 12 d of TGCG (300 mg/kg) treatment in mice from the oral group. **Conclusion:** The results indicated that in a diabetic *ob/ob* mouse model TGCG was endowed with significant anti-hyperglycemic and anti-obesity properties. Therefore, the total ginsenosides extracted from Chinese ginseng leaves and the stem may have some potential for treating diabetes.

Introduction

Diabetes mellitus is a devastating disease affecting approximately 8% of the total population in the USA and 3% of the population world wide, 90% of which suffer from type 2 diabetes^[1]. Diabetes is a chronic metabolic disease that has a significant impact on the patients' quality of life as well as on the health care system. The incidence of diabetes is increasing rapidly, which will lead to a worldwide increase in the cost of management of the disease and its complications. Generally, diabetes is classified into two major categories: type 1 diabetes (formerly known as insulin-dependent diabetes mellitus, or IDDM), and type 2 diabetes (formerly known as non-insulin dependent diabetes mellitus, or NIDDM)^[1,2]. Although the two types of diabetes have distinct pathogeneses, hyperglycemia and various life-threatening complications resulting from long-term hyperglyce-

mia are common to both^[3–7].

The drugs currently available for type 2 diabetes have a number of limitations, such as significant side effects and high rates of secondary failure. As the knowledge of the heterogeneity of this disorder increases, there is a need to look for more effective agents with fewer side effects^[8]. This has led to the search for alternative therapies that may have a similar degree of efficacy without the troublesome side effects associated with conventional drug treatment. The identification of compounds with antihyperglycemic activity from medicinal plants may provide an opportunity to develop a new class of antidiabetic agents. According to previous reports, ginseng is one of the most important and valuable plants with antidiabetic properties^[9].

Ginseng is a perennial herb of the *Araliaceae* family, cultivated in China, Japan, Korea, and Russia, as well as in the

USA and Canada. Ginseng has been used as a tonic remedy in traditional Chinese medicine for several thousands of years^[10]. The pharmacological properties of ginseng are mainly attributed to ginsenosides, the active constituents that are found in the extracts of different species of ginseng^[11,12]. Over 80 years ago, Japanese scientists observed that ginseng root extracts had antidiabetic properties^[13,14]. Subsequently, the blood glucose-lowering effect of ginseng root was investigated by other researchers^[15-19]. It has been reported that both Chinese ginseng (*Panax ginseng* C A Meyer) and American ginseng (*Panax quinquefolium* L) roots possess antihyperglycemic properties^[18,20,21]. A limitation of using ginseng root, however, is its high cost. Other parts of the ginseng plant, namely; berries, leaves, and the stem, can also be harvested and could yield additional herbal material and improve the cost-efficiency of ginseng cultivation. Recently, we have demonstrated the antihyperglycemic properties of Chinese ginseng berry and root extract, American ginseng berry and leaf extract, polysaccharide fractions from American ginseng berry, and ginsenoside Re in diabetic *ob/ob* mice^[22-28]. Moreover, our past data indicated that American ginseng leaf extract, with its high ginsenoside yield, could be an inexpensive alternative to the root in the treatment of diabetes^[27]. In the present study, the total ginsenosides in Chinese ginseng (TGCG) were evaluated for antihyperglycemic and antiobesity properties in order to further examine the antidiabetic properties of the Chinese ginseng plant.

Materials and methods

Animals Adult male, diabetic C57BL/6J *ob/ob* mice were used in the present study, and were purchased from Jackson Laboratory (Bar Harbor, ME, USA). The study protocol was approved by the Institutional Animal Care and Use Committee of the University of Chicago. Animals were housed under controlled conditions with a 12-h light/dark cycle. Animals had free access to standard rodent pellet food (Zeigler Bros, Gardners, PA, USA) and water *ad libitum*, except when fasted before experiments. After 2–3 weeks of acclimation under these conditions, animals were grouped for the experiment.

Thirty-four diabetic *ob/ob* mice, 10–16 weeks old, weighing 58.2 ± 0.6 g, were randomly divided into two groups used for the experiments: Group 1, Injection Group (*ip*) including high-dose TGCG group (200 mg/kg, $n=7$), low-dose TGCG group (100 mg/kg, $n=6$), and vehicle group ($n=6$); and Group 2, Oral Group (*ig*) including high-dose TGCG group (300 mg/kg, $n=5$), low-dose TGCG group (150 mg/kg, $n=5$), and vehicle group ($n=5$). Dose selection was based on previous reports^[22].

The TGCG solution was injected intraperitoneally or orally administered once a day. Vehicle group animals received an equivalent volume of saline. No irritation or restlessness was observed following administration of the test solutions. All mice were housed in the same conditions during all experiments.

TGCG preparation The dried TGCG extracts were a gift from Mr Qing-hua ZHANG at Nankai University in Tianjin, China. Leaves and stems of *Panax ginseng* were purchased from Jilin Province in China. TGCG was analyzed using HPLC in our laboratory. The dried TGCG were dissolved in saline and vortexed for 2 min at room temperature before use.

Blood glucose levels As in our previous studies^[22,23,27], fasting blood glucose levels (measured by Glucose Analyzer, Hemocue, Angelholm, Sweden) and bodyweight were measured after fasting the animals for 4 h (starting from 09:00) on d 0 (before treatment), d 5, and d 12. Blood glucose levels were determined from tail vein blood samples at 13:00 using the Glucose Analyzer.

Glucose tolerance test To evaluate the peripheral glucose use, an intraperitoneal glucose tolerance test (IPGTT) was performed on d 0 and d 12. On the test days, animals were fasted for 4 h starting from 09:00 followed by an *ip* administration of glucose (2 g/kg). Blood glucose levels were determined in blood samples from the tail vein at 0 (prior to glucose administration), 30, 60 and 120 min after glucose administration.

Statistical analysis Data are expressed as mean \pm SEM. Statistical significance between vehicle-treated versus drug-treated mice, and between before treatment versus after treatment were determined by a paired Student's *t*-test. A value of $P < 0.05$ was considered statistically significant.

Results

HPLC assay Figure 1 shows the HPLC-UV (202 nm) chromatogram of TGCG. The analyzed results were Rb1 (0.32%), Rb2 (1.45%), Rc (1.68%), Rd (2.60%), Re (20.42%), Rg1 (14.60%), and Rg2 (4.64%). The rank order of the quantity of ginsenoside was Re > Rg1 > Rg2 > Rd > Rc > Rb2 > Rb1. The results show that ginsenosides Re and Rg1 in TGCG are much higher than other ginsenosides.

Effect of TGCG on blood glucose levels in injection group Blood glucose levels in C57BL/6J *ob/ob* mice after 4 h fasting were measured on d 0, d 5, and d 12 after daily *ip* administration of TGCG or vehicle. As shown in Figure 2, diabetic *ob/ob* mice had remarkably high baseline fasting blood glucose levels (>200 mg/dL), which decreased significantly after administration of high-dose of TGCG. For example, on d 5 blood glucose levels were 179.0 ± 12.7 mg/dL

Figure 1. Chromatogram of total ginsenosides of Chinese ginseng (TGCG) extracted from leaves and stem.

($P < 0.05$) compared to the vehicle group, 192.0 ± 10.7 mg/dL. On d 12, the high-dose group were normoglycemic (153.0 ± 16.8 mg/dL) compared to the vehicle group (203.0 ± 9.8 mg/dL, $P < 0.01$). At the low-dose (100 mg/kg), however, the blood glucose decreased from 203.0 ± 15.0 mg/dL to 189.0 ± 20.0 mg/dL on d 5 and 170.0 ± 9.0 mg/dL on d 12 ($P < 0.05$). Figure 2 also indicates that mice in the vehicle group did not show any remarkable changes in blood glucose levels. In contrast, TGCG inhibited blood glucose level in a dosage-dependent manner. The blood glucose lowering effect of TGCG was comparable to Chinese and American ginseng berry extracts and ginseng leaf extracts^[22–28].

Figure 2. Effect of total ginsenosides of Chinese ginseng (TGCG; 200 mg/kg, ip, $n=7$) and vehicle ($n=6$) on fasting blood glucose in *ob/ob* mice. ^b $P < 0.05$, ^c $P < 0.01$ vs vehicle group.

Effects of TGCG on glucose tolerance test in injection group Glucose tolerance was evaluated by IPGTT, prior to and 12 d after treatment with TGCG. As shown in Figure 3A (high-dose group, 200 mg/kg) and Figure 3B (vehicle group), on d 0, *ob/ob* mice demonstrated basal hyperglycemia. This

hyperglycemia was exacerbated by the ip glucose load and failed to return to baseline after 120 min, indicating glucose intolerance. After 12-d treatment with TGCG 200 mg/kg the overall glucose tolerance was improved remarkably. Figure 3A also shows that the area under the curve (AUC) decreased by 42% (from 830.4 mg·mL⁻¹·min⁻¹ on d 0 to 486.3 mg·mL⁻¹·min⁻¹ on d 12, $P < 0.01$) after treatment. In the vehicle group (Figure 3B), however, the AUC decreased less than 10% (from 590.6 mg·mL⁻¹·min⁻¹ on d 0 to 533.9 mg·mL⁻¹·min⁻¹ on d 12, $P > 0.05$).

Effect of TGCG on blood glucose levels in oral group We also evaluated the effects of orally administered (oral gavage) TGCG (150 and 300 mg/kg) on blood glucose in *ob/ob* mice. As shown in Table 1, after the TGCG high-dose treatment (300 mg/kg), fasting blood glucose levels significantly decreased from 209.8 ± 16.7 mg/dL (d 0) to 186.2 ± 11.0 mg/dL (d 5, $P < 0.05$), and 169.1 ± 12.6 mg/dL (d 12, both $P < 0.05$, compared to vehicle group). In the low-dose group (150 mg/kg), blood glucose was lowered significantly on d 12 (183.5 ± 10.9 mg/dL, $P < 0.05$ vs vehicle group). The results showed that TGCG (150 and 300 mg/kg) caused anti-hyperglycemic effects after oral administration.

Effect of TGCG on body weight in oral group The aver-

Table 1. Effects of oral administration of total ginsenosides in Chinese ginseng (TGCG) on fasting blood glucose in *ob/ob* mice. ^b $P < 0.05$ vs vehicle group.

	<i>n</i>	Blood glucose/mg·dL ⁻¹		
		d 0	d 5	d 12
TGCG 150 mg/kg	5	214.0 ± 21.1	201.7 ± 16.1	183.5 ± 10.9^b
TGCG 300 mg/kg	5	209.8 ± 16.7	186.2 ± 11.0^b	169.1 ± 12.6^b
Vehicle	5	210.3 ± 14.6	212.5 ± 10.8	211.6 ± 13.8

Figure 3. Effect of total ginsenosides in Chinese ginseng (TGCG) and vehicle on intraperitoneal glucose tolerance test in *ob/ob* mice before (d 0) and after a 12-d treatment (d 12). (A) TGCG (200 mg/kg, ip, *n*=7); (B) vehicle (*n*=6).

age bodyweight of adult *ob/ob* mice is almost twice as great as their lean littermates. As shown in Figure 4, the body weight of *ob/ob* mice in the oral vehicle group had a tendency to increase from d 0 (57.9±2.3 g) to d 12 (59.1±1.1 g). In contrast, in the oral administration of TGCG high-dose group (300 mg/kg), the body weight decreased from 60.8±0.5 g (d 0) to 57.2±1.0 g (*P*<0.05 compared to d 0) after 12-d TGCG

Figure 4. Effect of total ginsenosides of Chinese ginseng (TGCG; 300 mg/kg, ig, *n*=5) and vehicle (*n*=5) on body weight by oral administration in *ob/ob* mice. ^b*P*<0.05 vs d 0.

treatment. On d 5, however, the bodyweight was not significantly reduced (*P*>0.05 compared to d 0). The data indicated that TGCG (300 mg/kg, ig) possessed the effect of lowering the bodyweight in *ob/ob* mice. The body weight reduction activity of TGCG by oral administration was similar with Chinese and American ginseng berry extracts and ginseng leaf extracts by ip administration^[22–28].

Discussion

Diabetes mellitus is a serious and chronic disease. Although oral antihyperglycemic agents and insulin are often successful in diabetes treatment, they have prominent side effects and fail to significantly alter the course of diabetic complications^[8,29]. Therefore, there is an urgent need to look for more effective agents with fewer side effects, especially in medicinal plants. Previous records reveal that ginseng possesses anti-hyperglycemic properties^[9]. The blood glucose-lowering effect of ginseng root has been studied^[15–20,30]. According to our recent results, Chinese ginseng and American ginseng root, berry, and leaf extract, American ginseng berry polysaccharide fractions and their major active constituent ginsenoside Re, show anti-hyperglycemic properties in diabetic animals^[22–28]. For a thorough study of the ginseng plant, other parts of ginseng should be analyzed for chemical composition, studied for biological activity and compared with ginseng root^[31]. Recently in our laboratory, a comparison of constituent analyses among American ginseng root, berry, and leaf extract, using HPLC indicated that total ginsenosides (%) were different in ginseng berries, roots, and leaves. The total ginsenosides (%) in leaves are much higher than those in roots, and the content of ginsenoside Re in leaves is much higher than that in roots. The rank order of the quantity of total ginsenoside Re was leaves, berries, then roots^[22–28]. Therefore, the ginseng leaf extract, with its high ginsenoside yield, has a promising potential to be an inexpensive alternative to the root in the treatment of diabetes. The major findings in the present study are as follows: (1) TGCG (200 and 100 mg/kg by ip and 300 and 150 mg/kg by ig) decreased fasting blood glucose levels significantly; (2) TGCG (200 mg/kg by ip) improved glucose tolerance; and (3) TGCG (300 mg/kg by ig) lowered the body weight in our experimental conditions.

As previous studies have shown the blood glucose lowering effects of ginseng root, berry, and leaf extracts individually^[22–28], the results from the present study indicate that TGCG also possesses an anti-hyperglycemic property. Both injection and oral administration of TGCG can decrease blood glucose. The results of IPGTT indicated that TGCG increased the peripheral glucose use and lowered blood glu-

cose levels. There are considerable amounts of data indicating that the chronic elevation of blood glucose causes many of the major complications of diabetes, including nephropathy, retinopathy, neuropathy, and macro- and microvascular damage^[32]. Effective control of the blood glucose level, therefore, is a key step in preventing or reversing diabetic complications and improving the quality of life in both type 1 and type 2 diabetic patients^[3-6]. Sustained reductions in hyperglycemia will decrease the risk of developing microvascular complications, and most likely reduce the risk of macrovascular complications^[7]. The present data show TGCG not only lowers blood glucose in diabetic *ob/ob* mice, but also improves glucose tolerance. The anti-hyperglycemic effect and body weight reduction activity of TGCG may prove to be of clinical importance in improving the management of type 2 diabetes.

The mechanisms for improved blood glucose levels associated with ginseng part extract, including TGCG, and its major active components, ginsenosides, may be multifaceted and remain unclear so far. According to previous studies, there are several plausible hypotheses that may work independently or concurrently.

First, inhibition digestion and increase of energy expenditure may be involved. Our results have demonstrated that ginseng berry extract significantly decreased food intake activity, which reduced the source of carbohydrates^[22]. Energy expenditure values were obtained in *ob/ob* mice treated with vehicle or Chinese ginseng berry extract. After the 12-d treatment, there was a significant increase in energy expenditure in *ob/ob* mice ($P < 0.01$). However, we also showed that ginseng berry extract increased body temperature significantly in *ob/ob* mice. Increases in body temperature suggested that the carbohydrate metabolism in mice was enhanced, consistent with the increased basal metabolic rate.

Second, there can be improvement in sensitivity to insulin and changes in blood insulin levels. Prospective studies of populations at high risk for type 2 diabetes suggest that in most patients, the initial inherited damage is insulin resistance^[33,34]. The *ob/ob* mice mimic these characteristics of type 2 diabetes and demonstrate insulin resistance and hyperinsulinemia by 6 weeks of age^[35]. Our study confirmed these characteristics, and showed reduced glucose disposal rates during the glucose clamp study in vehicle-treated *ob/ob* mice, which suggested insulin resistance was partly caused by reduced insulin receptor sensitivity. Treatment with ginseng extract improved peripheral insulin action as suggested by the significantly improved insulin-stimulated glucose disposal. Improvement in peripheral insulin sensitivity should increase tissue glucose uptake, lower blood

glucose levels towards normal^[23], and should also result in reduced insulin requirements. This is consistent with our present data, which demonstrate a significant reduction in serum insulin levels following treatment with ginseng extract, accompanied by improved peripheral insulin action.

While we have indicated a decreased serum insulin level with ginseng treatment, there are reports in the published literature that ginseng treatment increases serum insulin. Kimura *et al* indicated that administration of ginseng to alloxan-treated rats resulted in increased serum insulin levels^[36,37]. Obviously, the effect of ginseng on the serum insulin level is dependent on the animal model used. The *ob/ob* mice show typical characteristics similar to type 2 diabetes mellitus, where impaired glucose tolerance is caused by decreased peripheral insulin sensitivity and a compensatory excess insulin release, which is corrected by ginseng treatment. However, alloxan-treated diabetic animal models are characterized by chemical destruction of pancreatic islets and a decreased insulin level. Ginseng treatment in this model caused stimulation of the residual islets and increased serum insulin and glucose-stimulated insulin secretion^[38].

Because ginsenosides were shown to release nitric oxide (NO) from vascular tissues^[39], and NO is known to stimulate glucose-dependent secretion of insulin in rat islet cells^[40], ginseng extract may affect glucose transport, which is mediated by NO and thus modulates NO-mediated insulin secretion^[41,42]. Ginseng may act through both mechanisms in exerting its antidiabetic effect; however, the more relevant mechanism in the type 2 diabetic model would be improved insulin sensitivity, thereby reducing insulin requirements and decreasing serum insulin.

The last hypothesis addresses the importance of antioxidants. It is clear that antioxidants are important in diabetes and circulating levels of radical scavengers were impaired throughout the progression of diabetes^[43]. Therefore, the antioxidant character of ginseng extract may be a significant mechanism of antidiabetic properties. Recently, we used a cardiomyocyte culture model to measure the antioxidant effect of American ginseng berry extract^[44] and ginsenoside Re (unpublished data). The results demonstrated that American ginseng berry extract and Re attenuated oxidant stress and protected cells from lethal oxidant damage. Therefore, American ginseng berry extract and ginsenoside Re have antioxidant properties. The antioxidant character of ginseng extract may be an important mechanism in the antidiabetic action.

In summary, our results have demonstrated that TGCG possesses anti-hyperglycemic and anti-obesity properties in diabetic *ob/ob* mice *in vivo*. We conclude that the total ginsenoside fraction of the leaf and stem extract could po-

tentially be developed into newer anti-diabetic agents subject to confirmation of its efficacy in clinical trials.

Abstract

Aim: To investigate the possible association of Q89R, N740N and A1330V polymorphisms in low-density lipoprotein receptor-related protein 5 (LRP5) gene with bone mineral density (BMD) in postmenopausal Chinese women. **Methods:** Q89R, N740N and A1330V genotypes were determined by polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) in 647 unrelated healthy postmenopausal Han Chinese women aged 43–76 years in Shanghai. BMD at lumbar spine 1–4 and the left proximal femur including the femoral neck, trochanter and Ward's triangle were measured by dual-energy X-ray absorptiometry in all subjects. **Results:** The distribution of the Q89R, N740N and A1330V genotypes in this population was as follows: QQ 80.5%, QR 18.7%, and RR 0.8%; TT 66.9%, TC 31.1%, and CC 2.0%; AA 68.0%, AV 29.7%, and VV 2.3%. The frequencies of the Q89R, N740N and A1330V genotypes and alleles did not deviate from the Hardy-Weinberg equilibrium. We found that the Q89R and A1330V polymorphisms were in linkage disequilibrium in our population ($\chi^2=13.50, P<0.01$). Both before and after adjusting for age, years since menopause, height, and weight, the Q89R or N740N genotypes were significantly associated with BMD at the femoral neck ($P<0.05$). Subjects with the Q89R QQ genotype or the N740N TT genotype had a significantly higher BMD at the femoral neck, compared with those with the QR/RR or TC/CC genotypes, respectively. No significant association was found between A1330V polymorphism and BMD at any site. **Conclusion:** Our findings suggest that the LRP5 gene is a candidate for the genetic determination of BMD in postmenopausal Chinese women.

Introduction

Osteoporosis is characterized by a decrease in bone mass as well as a deterioration of the bone architecture, resulting in an increased risk of fracture. The disease is multifactorial, and it depends on environmental and genetic factors. Twin studies have shown that genetic factors account for 60%–80% of the variance in bone mineral density (BMD)^[1–3], which is the best predictor of the risk of osteoporosis. Several candidate genes that may contribute to BMD have been identified. Vitamin D receptor (VDR), estrogen receptor- α (ER- α), and collagen type I α 1 (COL1A1) genes

are three important candidate genes that could potentially regulate BMD. Association and linkage studies have been performed in order to identify these candidate genes in the pathogenesis of osteoporosis^[4–8]. However, their effect on the variation of BMD in the general population is controversial^[9–11].

Recently, osteoporosis-pseudoglioma (OPPG), an autosomal recessive disease characterized by low bone mass, childhood fractures and abnormal eye development, has been shown to be due to an inherited loss of function of the gene for low-density lipoprotein receptor related protein 5 (LRP5)^[12]. Moreover, two independent studies have sug-

gested that a mutation (G171V) in the LRP5 gene is associated with high bone mass (HBM)^[13,14]. In addition to the above mentioned G171V mutation in the LRP5 gene, Gong *et al*^[12] identified three potential disease-associated missense mutations in regions encoding the LRP5 extracellular domain: R494Q, R570W and V667M. More recently, mutation analysis have identified seven novel sequence variants in the human LRP5 gene^[15]. Two of them are missense mutations (c.314A>G: Q89R and c.4037C>T: A1330V). Although Koller *et al*^[16] found the evidence that a quantitative trait locus (QTL) contributed to normal variation in BMD on chromosome 11q12–13 (the chromosome region where LRP5 is located), only a few studies have investigated the association between LRP5 gene polymorphisms and variation in BMD in the general population^[17–20]. However, these studies yielded inconsistent reports of the association between candidate loci and BMD, and only small groups of subjects were studied in the Japanese and Korean studies. In the present study, we investigated the association between BMD and Q89R, A1330V, and N740N polymorphisms in the LRP5 gene in 647 postmenopausal Chinese women.

Materials and methods

Study population The study population comprised of 647 unrelated, postmenopausal, healthy volunteers aged 43–76 years (mean±SD, 60.1±6.3 years) living in Shanghai, China. All participants were of the Han ethnic group. The clinical data taken included questions on medical history, including medication, and a survey of the incidence of disease. A physical checkup was carried out on all subjects, and all were found to be in good health. No participant had

medical complications or was undergoing treatment for conditions known to affect bone metabolism, such as hyperthyroidism, diabetes mellitus, primary hyperparathyroidism, renal failure, pituitary and adrenal disease, or rheumatic disease. Postmenopausal women who had experienced early menopause (before 40 years of age) and those who had undergone ovariectomy or who were receiving estrogen replacement therapy were excluded. The study protocol was approved by the Committee on the Ethics of Human Research of Shanghai Jiaotong University Affiliated Sixth People's Hospital.

BMD measurements A total of 647 subjects were measured for BMD. The BMD of the lumbar spine 1–4 (L1–4) and the left proximal femur including femoral neck, trochanter, and Ward's triangle was measured by dual-energy X-ray absorptiometry (DXA) on a Hologic QDR 2000 (Hologic, Bedford, MA, USA). The machine was calibrated daily, and the coefficient of variation (CV) values of the DXA measurements (which were obtained from 7 individuals repeatedly measured 5 times) at L1–4, the femoral neck, trochanter, and Ward's triangle were 0.9%, 1.93%, 1.48% and 2.85%, respectively^[6,21]. The long-term reproducibility of our DXA data during the trial based on weekly repeated phantom measurements was 0.45%.

Genotyping DNA was isolated from peripheral blood leukocytes using conventional methods. Using the methods described by Okubo *et al*^[15], we genotyped subjects with the LRP5 Q89R, N780N and A1330V polymorphisms. Genomic DNA (0.1 µg) was carried out in 30 µL buffer solution (10 mmol/L Tris-HCL, 50 mmol/L KCl, 1.5 mmol/L MgCl₂, 200 µmol/L of each of the four deoxyribonucleotides [dNTPs], 2.5 U of *Taq* polymerase, and 0.25 µmol/L of each primer).

Table 1. Three LRP5 gene polymorphisms were identified in this study.

Location	Sequence alteration	Amino acid change	PCR primer for RFLP detection	Restriction enzyme	Fragment size /bp
Exon 2	c.314 A>G	Q89R	Forward: 5'-TCTGGGCATAGTGCTCCATC-3' Reverse: 5'-TTCCGGGATGTGCCATTGAG-3'	<i>Ava</i> II	Wild (Q): 436 Variant (R): 274+162
Exon 10	c.2268 T>C	N740N	Forward: 5'-CTACTGGGCGGACACTGGGATTAA-3' Reverse: 5'-ACAGCTCTAATCACTGAGGG-3'	<i>Ase</i> I	Wild (t): 216+21 Variant (c): 237
Exon 18	c.4037 C>T	A1330V	Forward: 5'-GACTGTCAGGACCGCTCACACG-3' Reverse: 5'-AAGGTTTTTCAGAGCCCCTAC-3'	<i>Dra</i> III	Wild (A): 143 Variant (V): 119+24

The polymerase chain reaction (PCR) was performed by using the following steps: 94 °C for 5 min and then 94 °C for 1 min, 56 °C for 1 min, 72 °C for 1 min, for 30 cycles, and 72 °C for 7 min. The PCR primers and restriction endonucleases used for genotyping are summarized in Table 1. The PCR products were digested with *Ava*I, *Ase*I, and *Dra*III restriction endonucleases, respectively. The Q89R genotypes were separated by electrophoresis in 1.5% agarose gel. The QQ genotype produces a 436 bp fragment, the RR genotype produces 274 bp and 162 bp fragments, and the heterozygous QR genotype produces 436 bp, 274 bp and 162 bp fragments. The N740N and A1330V genotypes were separated by electrophoresis on 8.0% polyacrylamide gel electrophoresis gels. The N740N CC genotype produces a 237 bp fragment, the TT genotype produces 216 bp and 21 bp fragments, and heterozygous TC genotypes produce 237 bp, 216 bp and 21 bp fragments. The A1330V AA genotype produces a 143 bp fragment, the VV genotype produces 119 bp and 24 bp fragments, and the heterozygous AV genotype produces 143 bp, 119 bp and 24 bp fragments.

Statistical analysis Allele frequencies were estimated by using the gene counting method, and the chi-squared test was used to identify significant departures from the Hardy-Weinberg equilibrium and linkage disequilibrium between genotypes. The relationship between various LRP5 genotypes and BMD was analyzed by using the unpaired Student's *t*-test. All associations were further evaluated

using multiple linear regression analysis to adjust for risk factor. BMD was a dependent variable and the independent variables included age, height, weight, years since menopause, and LRP5 Q89R genotype (0=QQ, 1=QR+RR), N740N genotype (0=TT, 1=TC+CC), and A1330V genotype (0=AA, 1=AV+VV). *P*<0.05 was considered to be statistically significant. All statistical calculations were performed using the SPSS 9.0 program (SPSS, Chicago, IL, USA).

Results

Frequency distribution of LRP5 gene polymorphisms

The genotype distribution and allele frequencies of polymorphisms of the LRP5 gene are shown in Table 2. Frequencies of the Q89R, N740N, and A1330V genotypes and alleles did not deviate from Hardy-Weinberg equilibrium. Strong linkage disequilibrium was found between Q89R and A1330V polymorphisms in our population ($\chi^2=13.50, P<0.01$; Table 3). However, no linkage disequilibrium was found between Q89R and N740N or between A1330V and N740N polymorphisms in these subjects.

Association between BMD and LRP5 genotype Because the frequencies of the Q89R RR, N780N CC and A1330V VV genotypes were all very low, we compared the background parameters and BMD in the QQ and QR/RR, TT and TC/CC, and AA and AV/VV groups for further analysis. The association between BMD and LRP5 genotype was analyzed us-

Table 2. Genotype distribution and allele frequencies of polymorphisms of the LRP5 gene in 647 postmenopausal Chinese women.

Polymorphism	Genotype frequencies			Allele frequencies	
Q89R	QQ	QR	RR	Q	R
	521 (80.5%)	121 (18.7%)	5 (0.8%)		
N740N	TT	TC	CC	T	C
	433 (66.9%)	201 (31.1%)	13 (2.0%)		
A1330V	AA	AV	VV	A	V
	440 (68.0%)	192 (29.7%)	15 (2.3%)		

Table 3. Frequency of LRP5 genotypes by combination of Q89R and A1330V polymorphisms. Values represent the observed number of subjects with the combined genotypes of Q89R and A1330V; in parentheses are the expected numbers under linkage equilibrium. $\chi^2=13.50; P<0.01$ for linkage disequilibrium.

		A1330V polymorphic site		
Q89R polymorphic site		AA	AV	VV
		QQ	389 (355.61)	124 (155.17)
	QR	48 (79.90)	66 (34.87)	7 (2.72)
	RR	3 (4.49)	2 (1.96)	0 (0.15)

ing the unpaired Student's *t*-test (Table 4). BMD at the femoral neck was significantly higher in subjects with the Q89R QQ genotype than in the combined group with QR/RR genotypes ($P<0.05$). A similar finding was observed for the N740N genotype; that is, that subjects with the N740N TT genotype had significantly higher BMD at the femoral neck compared with those with TC/CC genotypes ($P<0.05$). Moreover, we further used multiple linear analysis to adjust for age, years since menopause, height, and weight. We found that BMD at the femoral neck was significantly associated with the Q89R polymorphism and the N740N polymorphism

($P<0.05$; Tables 5, 6). However, no significant association was found between the A1330V genotype and BMD at any site according to the unpaired Student's *t*-test or multiple linear analysis (Tables 4, 7).

Discussion

In this cross-sectional study of postmenopausal Chinese women, we found that differences existed in the frequencies of the Q89R, N740N and A1330V LRP5 polymorphisms compared with frequencies in Caucasian people; in particular,

Table 4. BMD and other characteristics according to Q89R, N740N and A1330V polymorphisms in the LRP5 gene in postmenopausal Chinese women. Mean \pm SD. ^c $P<0.05$ vs QR/RR genotypes. ^e $P<0.05$ vs TC/CC genotypes.

the Q89R polymorphism is very rare in Caucasian people^[22,23]. However, the frequencies of genotypes and alleles of Q89R, N740N and A1330V LRP5 polymorphisms in Chinese women are similar to those found in Japanese and Korean subjects^[15,17]. We found that the prevalent frequencies of the Q, T and A alleles in Chinese women were 89.9%, 82.5%, and 82.8%, respectively, as compared with 92%, 81%, and 82%, respectively, in Japanese subjects; furthermore, the frequencies of the Q89R Q and A1330V A alleles were 92% and 85% in Korean subjects. Therefore, LRP5, similar to other candidate genes (eg, VDR and COL1A1) had significantly different frequencies of genotypes and alleles in various ethnic groups^[9,24].

In the present study, a significant association was observed between the Q89R genotype or the N740N genotype and BMD at the femoral neck both before and after adjusting for confounding factors, and subjects with the QQ genotype or the TT genotype had significantly higher BMD. Our findings are consistent with those of Koh *et al*^[17], who recently reported that the Q89R polymorphism was significantly associated with BMD at the femoral neck and Ward's triangle in 219 young Korean men. After adjusting for age, weight, and height, a marginal association was observed at the femoral neck ($P=0.098$). However, the N740N polymorphism was not investigated in Korean men. The Q89R and A1330V polymorphisms are located in exon 2 and exon 18 in the LRP5 gene, respectively. The Q89R and A1330V polymorphisms were in linkage disequilibrium in our study population. This finding is similar to that for a Korean population^[17], but differs from that for a European population^[22]. Although the A1330V polymorphism is a functional mutation, no significant association was observed between the A1330V polymorphism and BMD either in postmenopausal Chinese women or in young Korean men. Similarly, Ferrari *et al*^[18] failed to find a significant association between c.4037C>T (A1330V) polymorphism and lumbar bone mineral content and bone area in 889 healthy Caucasian people of both sexes.

LRP5 is a single pass membrane receptor whose extracel-

lular domain contains four modules consisting of six YWTD repeats followed by an epidermal growth factor (EGF)-like motif and an LDLR-like ligand-binding domain^[25,26]. Recent studies have shown that LRP5 and its closely related LRP family member, LRP6, are Wnt co-receptors that are capable of interacting with several key components of the Wnt pathway, and research regarding the signaling mechanisms involved in bone regulation by LRP5 has focused on this pathway^[27-29]. The LRP5 gene has 23 exons. In addition to the G171V substitution in HBM, nine disease-causing mutations in exons encoding the LRP5 extracellular domain have been identified in patients with OPPG^[12,13]. We found that the Q89R and N740N polymorphisms were only associated with BMD at the femoral neck, and were not associated with BMD at the lumbar spine in this large group of postmenopausal Chinese women, which suggests that the Q89R and N740N polymorphisms can influence the attainment of peak bone mass. Although the molecular mechanisms that underlie the association of the Q89R and N740N polymorphisms of the LRP5 gene with BMD remain unclear, we consider that the Q89R and N740N or related linked polymorphisms in the region might alter LRP5 protein function and might be associated with BMD.

In conclusion, we found a significant association between the Q89R and N740N polymorphisms in the LRP5 gene and BMD at the femoral neck in postmenopausal Chinese women, but we failed to observe a significant association between the A1330V polymorphism and BMD at any site. Our findings suggest that the LRP5 gene is a candidate for the genetic determination of BMD in postmenopausal Chinese women. Further studies will be needed to determine an association between the LRP5 gene polymorphisms and the risk of osteoporosis in the general population.

Abstract

Aim: To investigate effects of CpG oligodeoxynucleotide (CpG ODN) on the mRNA expression of transcription factors GATA binding protein 3 (GATA-3) and T-box expressed in T cells (T-bet) in asthmatic mice. **Methods:** An asthmatic mouse model was established and treated with CpG ODN. Total inflammatory cells and eosinophils in bronchoalveolar lavage fluid (BALF) were counted and inflammatory cell infiltration in lung tissue was evaluated. Interferon- γ and interleukin-4 concentrations in BALF and splenocyte culture supernatants were detected using an enzyme-linked immunosorbent assay. Transcription factor GATA-3 and T-bet mRNA expression in splenocytes and lung tissue were detected by reverse transcription-polymerase chain reaction. **Results:** Total inflammatory cells and eosinophils in BALF were reduced in the CpG ODN-treated group compared with the asthma group, and inflammatory cell infiltration in lung tissue was also significantly alleviated. CpG ODN treatment increased the interferon- γ concentration but decreased the interleukin-4 concentration in both BALF and splenocyte culture supernatants. GATA-3 mRNA expression was reduced in both lung tissue and splenocytes in the CpG ODN-treated group, while the mRNA ratio of T-bet to GATA-3 in splenocytes was increased. **Conclusion:** CpG ODN treatment inhibits airway inflammatory cell infiltration and regulates interferon- γ /interleukin-4 synthesis in asthmatic mice, possibly through a mechanism of downregulation of GATA-3 mRNA expression in both lung tissue and splenocytes.

Introduction

Asthma is a chronic airway inflammatory disease involving multiple inflammatory cells and cytokines. T-helper type 2 cells (Th2) are considered to play central role in the pathogenesis of asthma by producing a variety of cytokines such as interleukin (IL)-4, IL-5, IL-9, and IL-13^[1,2]. These cytokines promote IgE synthesis and mediate airway inflammatory cells (such as eosinophil, mast cell, T lymphocyte and neutrophil) infiltration. On the other hand, T-helper type 1 cells (Th1) inhibit Th2 function by producing interferon (IFN)- γ . Recent studies show that bacterial DNA containing unmethylated CpG motifs, or immunostimulatory sequences (ISS), can induce strong Th1-polarized immune responses

both *in vivo*^[3] and *in vitro*^[4,5]. The induction of Th1 responses is thought to result from the ability of ISS (containing CpG) to induce activation and secretion of IL-12 and IL-18 by macrophages and dendritic cells^[6,7], which promote IFN- γ production and polarize T-helper type 0 cells (Th0) to Th1. Studies also show that T-box expressed in T cells (T-bet) and GATA binding protein 3 (GATA-3) are 2 T cell-specific transcription factors. T-bet promotes Th1 polarization while GATA-3 enhances Th2 polarization. In the present study, we investigated the effects of the CpG oligodeoxynucleotide (ODN) on the mRNA expression of transcription factors GATA-3 and T-bet in splenocytes and lung tissue in a mouse model of asthma.

Materials and methods

Mice and reagents Thirty-six male BALB/c mice (approximately 6–10 weeks old, purchased from the Shanghai Experimental Animal Center of the Chinese Academy of Sciences, Shanghai, China) were maintained in specific pathogen free (SPF) animal facility at Renji Hospital, Shanghai Second Medical University (Shanghai, China). The CpG ODN consisted of 20 bases containing 2 CpG motifs: TCCATGACGTT-CCTGACGTT was synthesized and purified by Sangon Biological Engineering and Technology (Shanghai, China), and ovalbumin (OVA) was purchased from Sigma (St Louis, MO, USA). IL-4 and IFN- γ enzyme-linked immunosorbent assay (ELISA) kits were purchased from JingMei Biotech (Shenzhen, China). Trizol reagent was purchased from Invitrogen (Carlsbad, CA, USA). Oligo(dT)₁₈ primer and 2 \times Master Mix were purchased from MBI Fermentas (Hanover, MD, USA).

OVA sensitization and challenge Mice were divided into 3 groups: (i) group A, control group; (ii) group B, OVA-sensitized and -challenged; and (iii) group C, OVA-sensitized and challenged, CpG ODN-treated. Mice were sensitized and challenged with chicken OVA as described previously^[8]. Briefly, on d 0, d 7, d 14, and d 21, all animals were injected with 0.2 mL phosphate-buffered saline (PBS) containing 100 μ g OVA and 2 mg aluminum hydroxide (alum). On d 26, d 30, d 36, and d 37, animals were challenged with 2% OVA aerosol for 30 mins. Control mice (group A) received a saline-only aerosol.

Administration of CpG oligodeoxynucleotide On d 24, d 28, and d 32, mice in group C were injected with 0.1 mL PBS containing 50 μ g CpG ODN. Mice were assessed for pulmonary cellular infiltration histopathology on d 38.

Cellular count in bronchoalveolar lavage fluid and lung histology Bronchoalveolar lavage (BAL) was carried out as in Kline *et al*^[9]. After euthanasia, the trachea was cannulated and the lungs underwent lavage 3 times with 0.5 mL PBS. The lavage samples were processed immediately for total and differential cell counts. BAL fluid (BALF; 10 μ L) was used for counting total inflammatory cells. The residual BALF was centrifuged (10 min, 2000 \times g) and the supernatant was stored at -30 °C for cytokine detection. The precipitated cells were used to prepare cell slides, which were stained with hematoxylin and eosin (HE), and 200 cells were counted for differential cell counting. The right lung was preserved in liquid nitrogen for mRNA extraction, while the left lung was fixed with 10% formalin and embedded in paraffin. Sections 4- μ m thick were used to prepare slides, which were stained with HE.

Measurement of cytokines Approximately 5 \times 10⁶ single suspended splenocytes were stimulated with 20 μ g/mL OVA

for 72 h, centrifuged (10 min, 2000 \times g) and the supernatant was preserved for cytokine detection. The concentrations of IL-4 and IFN- γ in BALF and splenocyte culture supernatants were determined by using ELISA kits according to the manufacturer's recommendations.

Reverse transcription-polymerase chain reaction Total RNA was extracted from lung tissue and splenocytes using Trizol reagent, according to the manufacturer's instructions. Reverse transcription (RT) was carried out with 2 μ g of total RNA using an oligo (dT)₁₈ primer, and polymerase chain reaction (PCR) was carried out using 2 \times Master Mix. The T-bet primer was designed according to Chakir *et al*^[10], while the GATA-3 primer was designed according to Ise *et al*^[11]. The primer sequences were as follows: β -actin, sense 5'-GTGGGC-CGCTCTAGGCACCA-3', antisense 5'-CGTTGGCCTTAGGGTTCAGGGGG-3'; GATA-3, sense 5'-GAAGGCATCCAGACCCGAAAC-3', antisense 5'-ACCCATGGCGGTGACCATGC-3'; T-bet, sense 5'-AACCAGTATCCTGGTCCCA-GC-3', antisense 5'-TGTCGCCACTGGAA GGATAG-3'. PCR were run for 35 cycles and the annealing temperatures were as follows: GATA-3 and β -actin, 55 °C; T-bet, 57 °C. Semiquantitative RT-PCR was carried out using β -actin as an internal control to normalize gene expression for the PCR templates. The PCR product sizes were as follows: T-bet, 436 bp; GATA-3, 255 bp; β -actin, 245 bp. PCR products were electrophoresed in 2% agarose gel and the net intensity of the corresponding bands was analysed using Tian-Neng gel image software (Shanghai Tian-neng Technology Corporation, Shanghai, China).

Statistical analysis All data were expressed as mean \pm SD. Using Prism software, one-way ANOVA analysis was used to assess statistical significance between the different groups. $P < 0.05$ was considered to be significant.

Results

CpG oligodeoxynucleotide reduced the total number of inflammatory cells and the percentage of eosinophils in bronchoalveolar lavage fluid The total number of inflammatory cells and the percentage of eosinophils were (100.4 \pm 7.1) \times 10⁵/mL and 43.3% \pm 2.5%, respectively, in BALF from the asthma group of mice (group B). CpG ODN treatment reduced the total number of inflammatory cells and the percentage of eosinophils to (40.5 \pm 2.9) \times 10⁵/mL and 10.2% \pm 0.5%, respectively (Table 1).

CpG oligodeoxynucleotide inhibited infiltration of airway inflammatory cells In asthma-group mice, lung pathological slides showed significant bronchial epithelial proliferation and shedding, bronchoconstriction and mucus production, as well as abundant inflammatory cell infiltra-

the CpG ODN-treated group, although no difference was found in T-bet mRNA expression between the 2 groups. However, the mRNA ratio of T-bet to GATA-3 was increased in the CpG ODN-treated group compared with the asthma group (Figure 2). In lung tissue, CpG ODN treatment also decreased mRNA ratio of GATA-3 to β -actin compared with the asthma group (0.19 \pm 0.04 vs 0.35 \pm 0.04, $P<0.02$). T-bet mRNA was not detected under the same conditions.

Discussion

Airway eosinophil infiltration is one of the most prominent characteristics of asthma^[12-14]. In the present study, a typical asthmatic mouse model was established, as evidenced by increased total inflammatory cells, increased percentage of eosinophils in BALF, and obvious bronchoconstriction, mucus secretion, epithelial proliferation and shedding, and inflammatory cell infiltration in the lungs in the asthma group compared with the control group.

Prior studies have demonstrated that CpG ODN treatment inhibits asthmatic airway inflammation and increases Th1 cytokine IFN- γ while decreasing Th2 cytokine, IL-4 and IL-5 levels in asthmatic mouse models^[15-17]. In the present study, our data showed that CpG ODN treatment reduced total inflammatory cells and the percentage of eosinophils in BALF when CpG ODN was administered (ip) after allergen sensitization. Lung tissue pathological slides showed that inflammatory cell infiltration were significantly alleviated in CpG ODN treated group compared with asthma group. The inhibitory effect of CpG ODN on lung inflammation was accompanied by increased IFN- γ levels but decreased IL-4 levels in both BALF and splenocyte culture supernatants. IL-4-producing Th2 cells are considered to play an important role in the immune reaction of local tissue inflammation^[18]. Xie *et al* demonstrated that in a rat asthma model, the decrease in IFN- γ level was accompanied by an increase in IL-4 level, which resulted in a decreased IFN- γ /IL-4 ratio in the BALF after the sensitized rats were challenged with aerosol anti-

Figure 2. gen^[19]. These results suggest that the inhibitory effect of CpG ODN on airway inflammatory cell infiltration maybe the result of a downregulation of Th2 cytokine synthesis with an upregulation of Th1 cytokine synthesis.

Recent studies have shown that T-bet and GATA-3 are 2 major T helper-specific transcription factors that regulate the expression of Th1 and Th2 cytokine genes, and play a crucial role in T-helper cell differentiation. T-bet is thought to initiate Th1 development while inhibiting Th2 cell differentiation^[20]. GATA-3 plays a pivotal role in the development of the Th2 phenotype while inhibiting Th1 cell differentiation^[21]. Because asthma is a Th2-mediated airway inflammatory disease, both T-bet and GATA-3 may play an important role in the pathogenesis of asthma by directing Th0 differentiation. Finotto *et al* demonstrated that expression of T-bet in T cells from airways of patients with asthma was reduced compared with that in T cells from airways of non-asthmatic patients, suggesting that loss of T-bet might be associated with asthma^[22]. Nakamura *et al* demonstrated that GATA-3 mRNA expression was increased significantly in the airways of asthmatic subjects and the number of cells expressing GATA-3 mRNA correlated significantly with reduced airway caliber and airway hyperresponsiveness^[23]. Furthermore, GATA-3 mRNA-positive cells correlate significantly with the number of cells expressing IL-5 mRNA, and double *in situ* hybridization demonstrates that approximately 76% of GATA-3 mRNA-positive cells coexpress IL-5 mRNA and 91% of IL-5 mRNA-positive cells coexpress GATA-3 mRNA^[23]. Blockade of GATA-3 mRNA expression by GATA-3 antisense oligonucleotides in lung tissue significantly inhibits Th2 cytokine production and airway inflammatory cells infiltration in an asthmatic mouse model^[24].

Most studies have focused on the effect of CpG ODN on the Th1/Th2 cytokine balance in a murine model, but data regarding the effect of CpG ODN on the mRNA expression of transcription factors GATA-3 and T-bet have not been reported. In the present study, we first investigated the effects of CpG ODN on GATA-3 and T-bet mRNA expression in a mouse model of asthma. Our data showed that, compared with the asthma group, CpG ODN treatment reduced GATA-3 mRNA expression and increased the mRNA ratio of T-bet to GATA-3 in splenocytes, although no difference was found in T-bet mRNA expression between the 2 groups. In lung tissue, GATA-3 mRNA expression was also decreased in the CpG ODN-treated group compared with the asthma group. Chakir *et al* demonstrated that T-bet and GATA-3 gene expression reflected changes in Th1-specific cytokine IFN- γ and Th2-specific cytokine IL-4 in DO11.10 CD4⁺ T cells as well as in a mixed population of BBc rat splenocytes, and

the T-bet/GATA-3 ratio reflects the Th1/Th2 differentiation status^[10].

Our data demonstrated that CpG ODN downregulated GATA-3 mRNA expression both in lung tissue and in splenocytes, which may be an important mechanism for reducing Th2 cytokine synthesis in asthmatic mouse model. Moreover, as the mRNA ratio of T-bet to GATA-3 in splenocytes was increased in the CpG ODN-treated group compared with the asthma group, CpG ODN may also regulate T cell differential status by promoting Th0 differentiation to Th1. In summary, our data have shown that reducing GATA-3 mRNA expression both in lung tissue and in splenocytes may be an important mechanism for CpG ODN to regulate Th1/Th2 cytokine synthesis, thereby alleviating airway eosinophilia in an asthmatic mouse model.

Abstract

Aim: To investigate the effects of inhaled nitric oxide (NO) on pulmonary inflammation, apoptosis, peroxidation and protein nitration in a rat model of acute lung injury (ALI) induced by meconium. **Methods:** Twenty-four healthy male Sprague-Dawley rats were randomly divided into 3 groups ($n=8$): meconium-induced ALI with intratracheal instillation of 1 mL/kg saline (Mec/saline group), continuous inhalation of NO at 20 μ L/L (Mec/iNO), and the control group (control). Electromicroscopic examination was used to determine the extent of epithelial apoptosis. TUNEL was used to detect DNA fragmentation in pulmonary apoptotic cells, expressed as the apoptosis index (AI). Western blotting was used to detect pulmonary inducible NO synthase (iNOS) expression. RT-PCR was used to detect interleukin (IL)-1 β mRNA expression. Cell count in bronchoalveolar lavage (BAL), myeloperoxidase (MPO) activity, as well as malondialdehyde (MDA) and nitrotyrosine formation, the markers of toxic NO-superoxide pathway in rat lung parenchyma specimens, were also examined. **Results:** Expression of iNOS protein and IL-1 β mRNA were increased significantly in the Mec/saline group (both $P<0.01$) compared with the control group. BAL cell count, MPO activity, lung injury score, pulmonary AI, MDA level and nitrotyrosine formation were also increased significantly (all $P<0.01$). The meconium-induced iNOS protein and IL-1 β mRNA expression were inhibited significantly by NO inhalation when compared with the Mec/saline group (both $P<0.01$). BAL cell count, MPO activity and lung injury score were also decreased significantly ($P<0.01$ or $P<0.05$). However, there were no statistical differences in MDA level, nitrotyrosine formation or pulmonary AI between the Mec/saline and Mec/iNO groups. Electromicroscopic examination revealed a significant degree of epithelial apoptosis in both the Mec/saline and Mec/iNO groups. **Conclusions:** Early continuous inhalation of NO 20 μ L/L may protect the lungs from inflammatory injury, but does not decrease epithelial apoptosis or lung nitrotyrosine formation. Inhalation of NO alone is not associated with a detectable increase in oxidant stress.

Introduction

Meconium aspiration syndrome (MAS) remains a significant cause of morbidity and mortality in term newborn infants with intrauterine hyperoxia, despite improvements in obstetric care. The pathophysiology of lung injury in MAS

is very complicated. The complex nature of MAS contributes to its poor response to many therapeutic interventions^[1-4]. Clinical and experimental evidence suggest that inhaled nitric oxide (NO) reduces pulmonary hypertension, improves systemic oxygenation and inhibits the transendothelial migration of activated neutrophils in a variety of patho-

logical conditions of the lungs, including meconium aspiration^[3,5,6].

As a free radical, however, NO inhalation is potentially toxic. NO induces apoptosis in various cell lines^[7]. NO inhalation can cause damage to the lung tissue through its reaction with superoxide anions, resulting in the production of peroxynitrite anion (ONOO⁻). Nitrotyrosine is a marker of ONOO⁻ production, which provides evidence for therapy-induced iNO toxicity^[8]. A previous study showed that NO inhalation during the early phase of inflammation did not increase, but rather decreased nitrotyrosine formation^[8,9]. However, nitrotyrosine formation in meconium-induced acute lung injury (ALI) with or without inhalation of NO has not been investigated. The anti-inflammatory effect of iNO in meconium-induced ALI is still controversial^[3].

The aims of our present study were to explore the mechanism of anti-inflammatory effects and to investigate the possible toxic role of iNO in meconium-induced ALI. A rat model of ALI following meconium aspiration was established. The pulmonary inducible NO synthase (iNOS) protein and interleukin (IL)-1 β mRNA expression, nitrotyrosine formation, pulmonary apoptosis, as well as lung injury score, bronchoalveolar lavage (BAL) cell count, myeloperoxidase (MPO) activity and malondialdehyde (MDA) level were measured.

Materials and methods

Meconium preparation First-passed meconium was taken from urine-free diapers of healthy term neonates. The meconium was placed in a sterile jar and frozen for less than 7 d and then lyophilized, pooled and diluted with sterile saline to a final concentration of 20% suspension^[10]. This meconium slurry was frozen at -70 °C until use.

Animal management Twenty-four 30–45 d old Sprague-Dawley rats weighing 130–170 g were studied. A rat model of meconium-induced ALI was established as previously described^[10,11]. Briefly, rats were anesthetized with sodium pentobarbital (40 mg/kg, ip). After tracheotomy, an endotracheal tube was placed through the incision, and then stabilized. Prior to meconium instillation, rats were given vecuronium bromide (2 mg/kg, ip). After 15 min, the rats were randomized into 3 groups ($n=8$ each). Sixteen of the rats were instilled intratracheally with meconium (1 mL/kg) followed by a 3 mL bolus of air to disperse the meconium into the lung to establish the model of ALI. Half of the dose was given with the rat lying on one side and the other half with the rat lying on the other side and then randomized into the Mec/saline group, with intratracheal instillation of 1 mL/kg saline, or the Mec/iNO group, with continuous inhalation of

NO at 20 μ L/L. The remaining 8 rats were given 1 mL/kg sterile saline intratracheally followed by a 3 mL bolus of air as control. At 60 min after surgery, skin and tracheal incisions were closed with a 4–0 nylon suture. The rats in the Mec/saline group and in the control group were allowed to breath spontaneously in room air.

Nitric oxide exposure Immediately after the skin and tracheal incisions were closed, the rats in the Mec/iNO group were housed for 24 h in a sealed Plexiglas chamber that was flushed continuously with a precise dilution of NO gas (800 μ L/L) and medical air (4 mL/kg) to achieve a final NO concentration of 20 μ L/L NO concentration in the chamber was continuously monitored by a NO/NO₂ monitor confirming that the NO concentration was maintained at 20 \pm 1 μ L/L and that the NO₂ concentration was consistently <2 μ L/L.

Sample collection and storage The animals were killed 24 h after treatment. The chest was opened by a midline incision. The lungs were isolated and left lung lavage was carried out. Tissue samples from the right lung were obtained. Apoptosis of lung tissue cells was evaluated using electron microscopy and a terminal deoxynucleodityl transferase-mediated dUTP nick-end labeling (TUNEL) assay was carried out.

Bronchoalveolar lavage total cell count The left lung was lavaged using 31 mL aliquots of cold sterile saline following tracheotomy. Each lung was instilled and cleared 3 times. The recovered amount was always more than 90%. A total BAL cell count was obtained within 4 h.

Pulmonary myeloperoxidase activity and malondialdehyde assay Myeloperoxidase (MPO) activity was assessed as a measure of pulmonary neutrophil influx and activity. Pulmonary MPO activity and malondialdehyde (MDA) levels were assayed in duplicate on homogenized lung samples, according to the manufacturer's manual. One unit of MPO activity was expressed as units per gram of wet lung tissue. MDA levels were standardized for tissue protein concentration determined by the Bradford protein assay^[12].

Reverse transcription-polymerase chain reaction (PCR) analysis of pulmonary IL-1 β mRNA expression Total RNA was isolated with Trizol Reagent (Sangon, Shanghai, China) in accordance with the manufacturer's instructions. Complementary DNA (cDNA) was prepared by reverse transcription (RT) of 10 μ g total RNA using oligo dT18 and 200 u MmuLV reverse transcriptase (Sangon) at 37 °C for 90 min according to the manufacturer's manual. cDNA was used as a template in the PCR, which was run in *Tag*-polymerase buffer, supplemented with 1.5 mmol/L MgCl₂, 5 μ g/mL of each primer, 4 μ L of 10 mmol/L dNTPs, and 1 U of *Tag*-polymerase (TaKaRa, Dalian, China). The total reaction volume

was 50 μ L. The primers used for IL-1 β in RT-PCR were coding, 5'-GAAGCTGTGGCA GCTACCTATGTCT-3' and uncoding, 5'-CTCTGCCTTGAGAGGTGCTGATGTAC-3', which yielded a PCR product of 520 bp. The primers for β -actin (200 bp) were coding, 5'-ATG CCA ACA CAG TGC TGT CT-3' and uncoding, 5'-CTG CTT GCT GAT CCA CAT CT-3'. Amplification was carried out for 30 cycles at 94 °C for 1 min, 65 °C for 45 s, 72 °C for 45 s, followed by a 7 min extension at 72 °C. Gene expression was determined by the size of the PCR product in 1.6% agarose gels (in Tris-buffer, pH 8.0), stained with 0.1% μ g/mL ethidium bromide and observed under ultraviolet light. The data of the IL-1 β mRNA levels was normalized against the housekeeping gene β -actin. Molecular weight markers were run in parallel.

Western blot analysis of pulmonary nitrotyrosine formation and inducible nitric oxide synthase expression Frozen lung tissues were homogenized in protein extraction buffer. The homogenate was left on ice for 30 min before centrifugation at 10 000 \times g. Protein content was estimated^[12], and aliquots of 50 μ g homogenate protein were run on 10% (w/v) sodium dodecylsulfate (SDS)-polyacrylamide gel electrophoresis (PAGE) gels. Proteins were subsequently transferred to nitrocellulose membranes and stained with Coomassie blue to verify the equivalent transfer of samples. Membranes were blocked by incubation with 3% (w/v) fat dry milk in PBS for 1 h at room temperature, with shaking. Thereafter, the membranes were incubated overnight at 4 °C with either mouse monoclonal anti-nitrotyrosine (Calbiochem-Novabiochem, San Diego, CA, USA) or rabbit polyclonal anti-iNOS or rabbit polyclonal anti-actin (Santa Cruz, California, USA). The primary antibody was used at dilutions from 1:500 to 1:1000. The blots were washed 4 times (10 min each time) with Tris-buffered saline Tween-20 (TBST), comprising 50 mmol/L Tris-HCl (pH 7.6), 150 mmol/L NaCl and 0.1% Triton X-100, and subsequently incubated for 2 h at room temperature in Tris-buffered saline with horseradish peroxidase-conjugated anti-rabbit or anti-mouse IgG antibody (1:5000; Pierce, Rockford, IL, USA). Immunoreactive bands were visualized using the enhanced chemiluminescence system (Pierce) and quantified by densitometric analysis using Scion image software (Kodak, EDAS290 Imager Analysis). Results were calculated as the relative ratio of the specific band compared with actin.

Histological examination Pulmonary tissue samples from the right lower lobe were fixed in 10% buffered formalin, embedded in paraffin, and stained with hematoxylin and eosin for determination of the severity of lung injury. Samples were assessed by a blinded pathologist who was unaware of the group of the rats. A score from 0 to 4 represented the

percentage of affected area on the lung section (0=0%, 1=1%–25%, 2=26%–50%, 3=51%–75%, and 4=76%–100%) and was assigned for 3 different characteristics: (i) extension of pulmonary leukocyte infiltration; (ii) amount of intra-alveolar leukocytes; and (iii) amount of exudative debris and edema fluid. The calculated total injury score represents the sum of these scores^[3].

Quantification of apoptosis in lung tissues by TUNEL The semiquantification of apoptotic cells in lung tissue was carried out by in situ TUNEL using the Apop Tag Peroxidase *In Situ* Cell Death Detection Kit (Roche Diagnostic GmbH Mannheim, Germany) according to the manufacturer's protocol. The number of positive signals in each section was evaluated by 3 independent pathologists using light microscopy. The apoptosis index (AI) was calculated. AI is a measure of the number of positive cells in each 100 cells counted in 5 different blocks in the same section^[13].

Electron microscopy Small pieces of lung tissue (1 mm³) from the left lower lobe were obtained for ultrastructural analysis of apoptotic pulmonary cell death by electron microscopy.

Statistical analysis Data are expressed as mean \pm SD. Statistical significance among sample groups was analyzed with ANOVA. The Mann-Whitney test was used to analyze the data from lung injury score. A level of $P<0.05$ was considered statistically significant.

Results

The meconium-instilled group showed increased BAL cell count, pulmonary MPO activity and lung injury score when compared with the control group (all $P<0.01$; Table 1). The expression of IL- β mRNA and iNOS protein was also increased significantly (both $P<0.01$; Figures 1,2). Pulmonary nitrotyrosine, a marker of ONOO⁻ formation as an index of pulmonary peroxidation, and MDA, a marker of lipid peroxidation, were increased significantly as well (both $P<0.01$; Table 1; Figure 3). Pulmonary AI, demonstrated by TUNEL staining, was significantly elevated at 24 h after the treatment ($P<0.01$; Figure 4). This was confirmed by the electron microscopic finding that apoptotic change occurred in pulmonary epithelium in the meconium-instilled rat lungs (Figure 5).

Inhalation of NO (20 μ L/L) significantly inhibited meconium-induced iNOS protein and IL-1 β mRNA expression when compared with the Mec/saline group (both $P<0.01$; Figures 1, 2). BAL cell count, MPO activity, and lung injury score were also decreased ($P<0.01$, $P<0.01$, and $P<0.05$, respectively; Table 1). However, there were no statistical

Discussion

The present study shows that meconium aspiration in meconium-induced ALI, compared with NO inhalation, is associated with increased MPO activity, lung injury score,

Figure 4. Representative lung sections from (A) control, (B) acute lung injury with intratracheal instilled saline (Mec/saline) or (C) with 20 μ L/L. nitric oxide (NO) inhalation (Mec/iNO), showing stained brown nuclei of apoptotic cells with terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling. high numbers of neutrophils in BAL, and increased iNOS protein and IL-1 β mRNA expression. It demonstrates that early NO inhalation at a dose of 20 μ L/L. inhibits the pulmonary inflammatory injury, but does not increase pulmonary MDA and nitrotyrosine formation in meconium induced-ALI. These findings indicate that NO inhalation may protect the

lung tissue against the meconium-induced pulmonary inflammatory response and that at the present dosage, the oxidative effects of iNO are not clinically significant.

Meconium contains variable amounts of proinflammatory substances, such as IL-1 β , IL-6, IL-8, TNF- α , and heme, which may activate lung inflammatory cells to produce cytokines and elicit inflammatory reactions^[11,14]. This is also demonstrated in the rat lungs in our study by induction of pulmonary IL-1 β mRNA expression. As previously reported, high expression of iNOS might lead to overproduction of NO^[15,16]. NO is an important mediator in inflammation and high levels of NO produced by iNOS can mediate lung injury^[8]. During inflammatory conditions, meconium is able to activate macrophages to produce oxygen radicals, including superoxide anions^[4]. Reaction of NO with superoxide anions produces

peroxynitrite, which is a highly oxidative species and is capable of nitrating tyrosine residues of numerous proteins, leading to the formation of nitrotyrosine that may result in protein inactivation and lipid and DNA degradation. Nitrotyrosine is a product of the peroxynitrite pathway that has been used as a probe to detect NO-mediated oxidative reactions^[8]. Our findings show that meconium aspiration results in the expression of iNOS and the production of MDA and nitrotyrosine, indicating that meconium-induced ALI is associated with pulmonary inflammatory and oxidative/nitrosative injury.

Findings from earlier studies suggest that inhaled NO can decrease inflammatory reactions in neonatal and adult lungs^[6,17]. In the present study, we showed an attenuation in pulmonary inflammatory injury after NO treatment, similar to earlier findings. Evidence from our study shows that the mechanism of the anti-inflammatory effects of NO inhalation may be associated with inhibited expression of pulmonary iNOS protein and IL-1 β mRNA. On the other hand, during inflammatory conditions, inhaled NO might increase the reaction between superoxide and NO to enhance tissue nitration and exacerbate injury. Nitrotyrosine has been found in the lungs of patients with acute respiratory distress syndrome who have received inhaled nitric oxide^[18,19]. In newborn piglets the formation of peroxynitrite may be enhanced in lungs exposed to high doses of inhaled NO or hyperoxia^[20]. However, inhaled NO might have contradictory effects on lung tissue: first, an increase in nitration as a result of increased amounts of NO and nitrite, thereby enhancing the production of peroxynitrite and the reaction via peroxidase as a source of nitrite^[19]; and second, a decrease in nitration by inhibiting leukocyte accumulation in the lungs, thereby reducing the production of NO and superoxide^[9,21]. In the present study, inhaled NO at 20 μ L/L does not further increase pulmonary nitrotyrosine formation. Some studies have also shown that early inhalation of NO in severe respiratory failure is not associated with increased NO toxicity. In the rat model of lipopolysaccharide-induced ALI, NO inhalation during the early phase of inflammation did not increase, but rather decreased tyrosine nitration and chlorination, possibly by reducing neutrophil sequestration^[9]. Inhaled NO at 100 μ L/L was shown to increase the survival of rats with hyperoxia^[22]. Inhaled NO at 20 μ L/L with concurrent hyperoxia did not increase intracellular or intercellular nitrotyrosine in a mouse model^[23]. According to evidence from this and from previous studies, the oxidative effects of iNO are not clinically significant.

There is some indirect evidence suggesting that apoptosis may play an important role in ALI. Aspirated meconium

may cause apoptotic cell death of the airway epithelium, supposedly through the action of bile salt or pulmonary inflammatory cells. Increased release of reactive oxygen and nitrogen species by pulmonary inflammatory cells may be associated with apoptotic cell death in the lung. Previous studies indicate that NO may function as an inhibitor of the apoptotic death program. An earlier study showed that NO inhalation inhibited pulmonary apoptosis in porcine meconium aspiration^[3]. However, there was a bulk of evidence indicating that NO induced apoptosis in different cell lines^[7]. In this study we found that NO inhalation did not protect the lung from meconium-induced apoptosis, despite the positive effect on pulmonary inflammatory injury.

In summary, meconium-induced ALI is associated with inflammatory oxidant injury and epithelial apoptosis. Early inhalation of NO at a dose of 20 μ L/L does not seem to prevent epithelial apoptosis caused by meconium aspiration. Inhalation of NO at the present dose is not associated with any detectable increase in oxidative or nitrosative damage. The results presented here suggest a lack of toxicity of inhaled NO due to oxidant injury and further justify therapeutic trials on inhaled NO in clinical respiratory failure. Caution with regard to pulmonary toxicity is still required.

Abstract

Aim: To study the effects (and the mechanisms thereof) of *Ganoderma lucidum* polysaccharides (*Gl*-PS) on the proliferation and the anti-tumor activity of cytokine-induced killer (CIK) cells, and to make use of CIK cells as a means to investigate the interactions between *Gl*-PS and cytokines. **Methods:** CIK cells were prepared by using the standard protocol as a positive control. Experimental groups also underwent the standard protocol, except that *Gl*-PS (400 mg/L or 100 mg/L) was added and the dose of anti-CD3 and interleukin-2 they received was reduced by 50% and 75%, respectively. For negative controls, *Gl*-PS in the experimental protocol was replaced with soluble starch or methylcellulose (400 mg/L or 100 mg/L). CIK cell proliferation, cytotoxicity, and phenotype were determined by using the Trypan blue exclusion method, MTT assay, and flow cytometry. **Results:** By synergizing cytokines, *Gl*-PS (400 mg/L or 100 mg/L) could decrease the amount of cytokine in lymphokine activated killer (LAK) cells and CIK cells culture, but had no significant effect on the proliferation, cytotoxicity, or phenotype of LAK cells, or CIK cells induced by cytokines at higher doses alone, in which CIK cells expanded about 80-fold and the main effectors, CD3⁺NK1.1⁺ cells, expanded by more than 15%. The cytotoxicity of CIK cells in experimental groups was 79.3% ± 4.7%, 76.9% ± 6.8% versus the positive control 80.7% ± 6.8% against P815 ($P > 0.05$) and 88.9% ± 5.5%, 84.7% ± 7.9% versus the positive control 89.8% ± 4.5% against YAC-1 ($P > 0.05$). The activity of *Gl*-PS could mostly be blocked by anti-CR3. **Conclusion:** *Gl*-PS was shown to be a promising biological response modifier and immune potentiator. The effect of *Gl*-PS on CIK cells is possibly mediated primarily through complement receptor type 3.

Introduction

The fungus *Ganoderma lucidum* (Leyss, ex Fr) Karst (known in China as “lingzhi” and in Japan as “reishi”) has a long history of use in traditional Chinese medicine. Polysaccharides from *Ganoderma lucidum* have been reported to have promising immune modulating effects; for example, they have been shown to promote the function of the mononuclear phagocyte system, antigen-presenting cells and cytotoxic T lymphocytes (CTL) induced by dendritic cells^[1–3], to enhance lymphocyte proliferation and antibody production^[4–6], to potentiate cytokine production by splenocytes and macrophages^[7], and to inhibit spontaneous and Fas-mediated

apoptosis in neutrophils^[8]. The antitumor effect of *Gl*-PS is reportedly due to its effects on the immune system, and there is reportedly no associated toxicity in humans^[9].

Over the past 20 years or so, investigators have attempted to develop adoptive cellular immunotherapy for cancer treatment. Cytokine-induced killer (CIK) cells have been shown to generate effector cells with higher proliferative capacity, increased cytotoxicity and fewer side effects than lymphokine activated killer (LAK) cells^[10,11]. Some reports have demonstrated that *Gl*-PS can enhance the cytotoxicity of CTL and natural killer (NK) cells^[1], but little is known about the effects of *Gl*-PS on the development and cytotoxic

activity of CIK cells. The present study was undertaken to elucidate the effects (and mechanisms thereof) of *GI*-PS on LAK cells and CIK cells induction and anti-tumor activity.

Materials and methods

Animals and drugs Male C57BL/6j mice 6–8-week-old were purchased from the Department of Experimental Animals, Health Science Center, Peking University, Beijing, China. *GI*-PS were isolated from *Ganoderma lucidum* (Leyss, ex Fr) Karst by placing the fungus in boiling water, followed by ethanol precipitation, dialysis, and protein depletion using the Sevag method. The isolated molecule was a polysaccharide peptide with a molecular weight of 584 900, and a ratio of polysaccharides to peptides of 93.61%:6.49%. The polysaccharides included *D*-rhamnose, *D*-xylose, *D*-fructose, *D*-galactose, *D*-mannose and *D*-glucose with a molar ratio of 0.793:0.964:2.944:0.167:0.389:7.94, linked together with β -glycosidic linkages. The peptides contained 16 kinds of amino acids^[2]. *GI*-PS was isolated as a water-soluble powder that was dissolved in serum-free RPMI-1640 medium (Gibco BRL, NY, USA), then filtered through a 0.22 μ m filter and stored at 4 °C. This solution was further diluted to the required concentrations before assay.

Isolation and culture of LAK cells LAK cells were generated as previously described^[9]. Briefly, mice were killed by cervical dislocation. Suspensions of spleen single cells were pooled in serum-free RPMI-1640 medium by filtering the suspension through mesh with the aid of a glass homogenizer to exert gentle pressure on the spleen fragments. Erythrocytes were lysed with an ammonium chloride solution [0.15 mol/L NH₄Cl, 10 mmol/L KHCO₃, 0.1 mmol/L edetic acid (EDTA), pH 7.2]. Obtained cells were washed twice with phosphate-buffered saline (PBS) and resuspended in the complete RPMI-1640 medium [RPMI-1640 medium supplemented with 10% inactivated fetal calf serum (FCS), 2 mmol/L *L*-glutamine, 25 mmol/L NaHCO₃, 1 mmol/L sodium pyruvate, 25 mmol/L *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES), 100 kU/L penicillin G, and 100 mg/L streptomycin]. Adherent cells were removed via adherence to glass surfaces. Nonadherent mononuclear cells were obtained and the percentage of viable cells was >95%. Murine recombinant interleukin-2 (rIL-2) (300 kU/L) was added on d 0. Cells were incubated at 37 °C in a humidified atmosphere of 5% CO₂ at a concentration of 1×10⁹ cells/L. Cell density was determined every 4 d, and cells were subcultured in fresh complete medium containing 150 kU/L IL-2. LAK cells were cultured in complete medium with 300 kU/L IL-2 for the positive control, with 75 kU/L IL-2 plus 400 mg/L or 100 mg/L *GI*-PS for experimental groups 1 and 2, respectively, and with 75

kU/L IL-2 plus 400 or 100 mg/L soluble starch (SS) or methylcellulose (MC) as negative controls 1–4, respectively.

Isolation and culture of CIK cells CIK cells were generated as previously described^[10]. Nonadherent splenocytes were suspended in complete RPMI-1640 medium at a concentration of 1×10⁹ cells/L. Murine γ -interferon (IFN- γ ; 1000 kU/L) was added on d 0. After 24 h of incubation, 50 mg/L monoclonal antibodies (mAb) against CD3 (dilution of supernatant from hybridoma 145-2C11), 300 kU/L IL-2, and 100 kU/L murine rIL-1 were added. Fresh IL-2 (150 kU/L) and fresh medium were added every 3 d to maintain a cell density of 1.5×10⁹–2.0×10⁹ cells/L for 14–21 d. All the cytokines were purchased from PeproTech EC, London, UK. CIK cells were prepared by using the standard protocol described earlier for the positive control. Experimental groups 1 and 2 were prepared according to the standard protocol except that *GI*-PS (400 or 100 mg/L) was added, and the dose of anti-CD3 and IL-2 was decreased by 50% and 75%, respectively. For negative control groups 1–4, *GI*-PS in the experimental protocol was replaced with SS or MC (400 or 100 mg/L).

LAK and CIK cell proliferation assay Cell density was assessed every 3 d, and cells were subcultured in fresh complete medium containing IL-2 as described previously^[10]. Viable cell numbers were determined by the Trypan blue dye exclusion method at each time point. LAK and CIK cell proliferation was analyzed by cell growth curves.

Preparation of target cells P815 (NK-resistant) and YAC-1 (NK-sensitive) cells proliferating in a logarithmic manner were used as target cells for the cytotoxicity assay. Cells (2×10⁸ cells/L) were maintained in complete RPMI-1640 medium as described earlier. On the day of testing, cells were washed once with PBS and re-suspended in a complete medium at a concentration of 2×10⁸ cells/L.

Cytotoxicity assay The MTT colorimetric assay was used for testing cytotoxic activity *in vitro*^[12]. LAK cells or CIK cells were used as effectors, and were coincubated with P815 or YAC-1 cells as targets for 4 h at effector:target ratios of 20:1. Cells were plated in triplicate in 96-well microculture plates (Corning Costar, MA, USA). MTT (Sigma, St Louis, MO, USA) was dissolved at 5 g/L in PBS and filtered through a 0.22 μ m filter. MTT solution (20 μ L) was added to each well, and the microplates were further incubated at 37 °C for 4 h. The 96-well microplates were centrifuged at 200×g for 15 min, then supernatants were discarded, and 150 μ L of Me₂SO was added into each well. The tray was gently shaken thoroughly for 10 min to dissolve the dark blue crystals of formazan that could be measured spectrophotometrically. Data are expressed as mean absorbance value (optical density, *OD*) of samples±SD. Percentage-specific cytotox-

icity (% C) was calculated as follows: % C = $\{1 - [(OD \text{ of effectors} + \text{targets}) - OD \text{ of effectors}] / OD \text{ of targets}\} \times 100\%$.

Flow cytometric assays Effector cells were harvested and washed twice with ice cold FACScan buffer (PBS containing 2% FCS and 0.1% sodium azide). To block nonspecific antibody binding, 20% mixed mouse and rat serum was used and then cells were stained with mAb against CD3 coupled to fluorescein isothiocyanate (FITC) and/or mAb against NK1.1 coupled to phycoerythrin (PE) (antibodies from Santa Cruz, CA, USA or Pharmingen, CA, USA) for 45 min at 4 °C in the dark. The stained cells were washed twice and fixed with 1% paraformaldehyde in FACScan buffer and then analyzed by using a FACScan flow cytometer (Becton Dickinson, NJ, USA). Dead cells and debris were gated out.

Antibody block experiment CIK cells were induced by using the standard protocol described earlier for the positive control, except that *GI-PS* (400 or 100 mg/L) was added and the dose of anti-CD3 and IL-2 was decreased by 50% and 75% (experimental groups 1 and 2, respectively) or *GI-PS* in the experimental group protocol was replaced by SS (400 mg/L or 100 mg/L) or MC (400 mg/L or 100 mg/L) as negative controls 1–4, respectively. Anti-CR3 (eBioscience, San Diego, CA, USA) or its isotype immunoglobulin G (IgG) was added 30 min prior to *GI-PS* in the experimental group protocol, in anti-CR3 groups 1 or 2 and isotype antibody groups 1 or 2. Cells were harvested on d 7. The proliferation and cytotoxicity of different groups were determined by MTT colorimetric assay.

Statistical analysis Data were analyzed using general linear models (2-way ANOVA) in SPSS statistical software (version 10.0) with a significance level of $\alpha=0.05$. Comparisons between means were made using the least significant difference multiple comparisons *t*-test of Dunnett's *t*-test. Results are presented as the mean \pm SD. Values of $P < 0.05$ were considered to be statistically significant.

Results

Effects of *GI-PS* on LAK cell proliferation Nonadherent splenocytes were incubated at 1×10^9 cells/L in complete medium with IL-2 alone or IL-2 at different concentrations plus *GI-PS* at different concentrations. Cells were harvested after 4 d to generate LAK cells. Statistical tests of the between-subject effects showed that there were significant differences according to univariate analyses of variance (two-way ANOVA). The interaction between IL-2 and *GI-PS* was significant, which suggests a synergy between IL-2 and *GI-PS*. The effect of IL-2 was bigger than that of *GI-PS*. For the factor "IL-2", there was no statistically significant difference between neither the 150 kU/L nor the 75 kU/L level when compared with the 300 kU/L level ($P > 0.05$). For the factor "*GI-PS*", the 400 mg/L and 100 mg/L levels were significantly different from the 0 mg/L level ($P < 0.01$). The combination of 75 kU/L IL-2 and 400 mg/L or 100 mg/L *GI-PS* was optimal for the least usage of IL-2 (75 kU/L), and LAK cell proliferation induced by the combination was not less than that of the positive control, in which only IL-2 (300 kU/L) was added (Table 1). Compared with only 75 kU/L IL-2 in the LAK cell culture, the effects of SS or MC in different concentrations plus 75 kU/L IL-2 were not significant, therefore SS and MC were chosen as negative controls (data not shown).

Cells in different groups were harvested and viable cell numbers were determined on d 1, 4, 8, and 12. The difference in cell numbers across groups was not significant on d 1. Following 4 d of culture, the number of viable cells of the positive control and experimental groups increased 2-fold in comparison to the negative controls, but the difference between experimental groups and the positive control was not significant at that time. The number of viable cells in the positive control and experimental groups increased markedly compared with negative controls on d 8. However, at that time, there was no significant difference between the

IL-2 (300 kU/L) was added alone in complete medium as a positive control.

positive control and experimental groups. After 8 d of culture, cells in all groups no longer proliferated, died gradually, and decreased on d 12 relative to the number present on d 1 (Figure 1).

Effects of *GI*-PS on CIK cell proliferation With respect to the synergistic interaction of *GI*-PS (400 mg/L or 100 mg/L)

Figure 1. Effects of *GI*-PS on the expansion of LAK cells. LAK cells were cultured in complete medium with 300 kU/L IL-2 as a positive control, with 75 kU/L IL-2 plus 400 mg/L or 100 mg/L *GI*-PS for experimental groups 1 and 2, respectively, and with 75 kU/L IL-2 plus 400 or 100 mg/L SS or MC for negative controls 1–4, respectively. *n*=9. Mean±SD.

and IL-2 (75 kU/L), experimental groups 1 and 2 were the same as the positive control except for the addition of 400 or 100 mg/L *GI*-PS and a reduction in the doses of anti-CD3 and IL-2 by 50% and 75%, respectively. For negative controls 1–4, *GI*-PS was replaced with SS or MC (400 mg/L or 100 mg/L) in the protocol used in the experimental groups. We observed that the proliferation of CIK cells in the experimental groups was also similar to that of the positive control. The reduction of cell numbers in the negative controls was significant compared with the positive control on d 6 to d 21. The number of CIK cells in the positive control and experimental groups peaked at d 21 and was expanded about 80-fold relative to the beginning culture. Their increase in activity was much larger than that observed in LAK cells (LAK proliferation peaked at d 4–8 and the cell number increased 2-fold relative to the initial culture). This suggests that 400 mg/L or 100 mg/L *GI*-PS decreased the usage of IL-2 and anti-CD3 by 75% and 50%, respectively, and that the influence on CIK cell proliferation was almost equal to that of cytokines alone at higher doses (Figure 2).

Effects of *GI*-PS on cytotoxicity of LAK Compared with induction by 300 kU/L IL-2 alone, no significant difference in the cytotoxicity of LAK cells induced by 75 kU/L IL-2 plus

Figure 2. Effect of *GI*-PS on CIK cell proliferation. CIK cells were induced by using a standard protocol as described in the text (positive control). Experimental groups 1 and 2 were treated in the same way as the standard protocol except that *GI*-PS (400 mg/L or 100 mg/L) was added, and the dose of anti-CD3 and IL-2 was reduced by 50% and 75%, respectively. For the negative control groups 1–4, *GI*-PS was replaced with SS or MC (400 mg/L or 100 mg/L) using the same protocol as the experimental group. *n*=9. Mean±SD.

400 mg/L or 100 mg/L *GI*-PS was observed, but cytotoxicity induced by 75 kU/L IL-2 plus SS or MC instead of *GI*-PS in the negative controls was reduced. This suggests that a certain concentration of *GI*-PS increases the cytotoxicity of LAK cells (Figure 3).

Effects of *GI*-PS on cytotoxicity of CIK cells Compared with the standard protocol for preparing CIK cells, the cytotoxicity of CIK cells in the experimental groups was not significantly different, but was higher than that in the negative control groups. We found that CIK cells in every group achieved higher cytotoxicity than LAK cells. This suggests that 400 mg/L or 100 mg/L *GI*-PS decreases the usage of IL-2 and anti-CD3 by 75% and 50%, respectively, but has no influence on CIK cell cytotoxicity induced by cytokines alone at higher doses (Figure 4).

Immunophenotype of effector cells in the presence of *GI*-PS Flow cytometric assays showed that LAK cells represented a heterogeneous population, in which the major effector cells generally had an NK1.1⁺ cell surface phenotype. Compared with LAK cells in the positive control groups, the phenotype of LAK cells in the experimental groups was not significantly different. Most CIK cells expressed CD3, a sur-

Figure 3. Effect of *Gl-PS* on the cytotoxicity of LAK cells. LAK cells were induced by different protocols and tested for cytotoxicity at an effector:target ratio of 20:1. 1: Positive control, 300 kU/L IL-2; 2,3: experimental groups 1 and 2, 75 kU/L IL-2 plus 400 or 100 mg/L *Gl-PS*, respectively; 4–7: negative controls 1–4, 75 kU/L IL-2 plus 400 or 100 mg/L SS or MC, respectively. $n=9$. Mean \pm SD. ^b $P<0.05$ vs negative controls against P815. ^a $P<0.05$ vs negative controls against YAC-1.

Figure 4. Evaluation of effects of *Gl-PS* on the cytotoxicity of CIK cells. CIK cells induced by different protocols were harvested on d 15 and tested for cytotoxicity. Effector:target ratio is 20:1. 1: Positive control, standard protocol described in text; 2,3: experimental groups 1 and 2 received the standard protocol except that *Gl-PS* (400 mg/L or 100 mg/L) was added and the doses of anti-CD3 and IL-2 were reduced by 50% and 75%, respectively; 4–7: negative controls 1–4, *Gl-PS* in the experimental protocol was replaced with SS or MC (400 mg/L or 100 mg/L), respectively; LAK, LAK cells. $n=9$. Mean \pm SD. ^b $P<0.05$, ^c $P<0.01$ vs every group of CIK cells against P815. ^e $P<0.05$, ^f $P<0.01$ vs every group of CIK cells against YAC-1.

face marker of T cells. Treatment with 400 mg/L or 100 mg/L *Gl-PS* in the experimental groups did not alter the phenotype of CIK cells (Table 2).

Effect of anti-CR3 on proliferation and cytotoxicity of CIK cells induced by stimuli containing *Gl-PS* CIK cell proliferation and cytotoxicity were reduced to <40% of that in the experimental groups by the addition of anti-CR3 30 min prior to the addition of *Gl-PS* in CIK cell culture, but not by nonspecific isotype IgG (Figures 5, 6).

Discussion

Polysaccharides isolated from *Ganoderma* are high-

LAK and CIK cells were induced by different protocols as described in the text. Group 1: LAK cells in the positive control group; groups 2 and 3: LAK cells in experimental groups 1 and 2; group 4: CIK cells in the positive control group; groups 5 and 6: CIK cells in experimental groups 1 and 2.

molecular-weight polysaccharides linked together by β -glycosidic linkages. These polysaccharides exhibit immunological activity, for example promoting cellular immunity and humoral immunity^[1–8,13–15]. Biological and immunopharmacological activities depend on the conformation of polysaccharides, molecular mass, solubility in water and triple-helical structure. Soluble starch is an α -(1,4)-bonding glucose polymer, and methylcellulose links by uniform β -(1,4) glycosidic linkages^[16]. Because they lack a helical structure, neither of these compounds have the immunological activity, so they served as negative controls. Flow cytometry indicated that LAK and CIK cells populations were heterogeneous. Effector cells in LAK cell culture generally have the CD3⁺NK1.1⁺ cell surface phenotype^[17]; however, most CIK cells express T-cell markers. Earlier studies have shown that cytotoxicity correlates with the expansion of CD3⁺NK1.1⁺ lymphocytes, which are the main effector cells in CIK cell cultures^[18]. The present study demonstrated that the optimal combination of *Gl-PS* (400 mg/L or 100 mg/L) and certain cytokines did not alter the phenotype of LAK cells or CIK cells, and had no effect on the percentage of effector cells. For this reason, the cytotoxicity of LAK cells and CIK cells in the experimental groups was similar to that of the positive control, which contained cytokines alone at higher doses.

CIK cells with enhanced cytotoxicity and a higher proliferative capacity relative to LAK cells were described first by Schmidt-Wolf and colleagues in 1991. They reported that treatment of tumor cells from bone marrow with CIK cells effectively reduced the tumor cell burden, allowing animals to survive^[10]. As demonstrated here, LAK and CIK cells

Figure 5. Effect of anti-CR3 on the proliferation of CIK cells induced by *GI-PS* and cytokines. CIK cells were induced by using the standard protocol for the positive control group, by using the standard protocol plus the addition of *GI-PS* (400 mg/L or 100 mg/L) and a decreased dose of anti-CD3 and IL-2 by 50 % and 75 %, respectively, for experimental groups 1 and 2, and by replacing *GI-PS* in the experimental group protocol with SS or MC (400 mg/L or 100 mg/L) for negative controls 1–4, respectively. Anti-CR3 (10 mg/L) or its isotype IgG were added 30 min prior to *GI-PS* in the experimental group protocol for anti-CR3 groups 1 and 2 and isotype antibody groups 1 and 2, respectively. Cells were incubated only in complete medium without any stimuli for medium group. $n=9$. Mean \pm SD. ^b $P<0.05$ vs positive control, experimental groups and isotype antibody groups. ^f $P<0.01$ vs the every other group.

Figure 6. Effect of anti-CR3 on cytotoxicity of CIK cells induced by *GI-PS* and cytokines. CIK cells were induced by using the standard protocol for the positive control group, by using the standard protocol plus the addition of *GI-PS* (400 mg/L or 100 mg/L) and a decreased dose of anti-CD3 and IL-2 by 50 % and 75 %, respectively, for experimental groups 1 and 2, and by replacing *GI-PS* in the experimental group protocol with SS or MC (400 mg/L or 100 mg/L) for negative controls 1–4, respectively. Anti-CR3 (10 mg/L) or its isotype IgG were added 30 min prior to *GI-PS* in the experimental group protocol for anti-CR3 groups 1 and 2 and isotype antibody groups 1 and 2, respectively. Effector:target ratio is 20:1. $n=6$. Mean \pm SD. ^b $P<0.05$ vs positive control, experimental groups and isotype antibody groups against P815. ^e $P<0.05$ vs standard group, experimental groups and isotype antibody groups against YAC-1.

possess cytotoxic effects against both NK-sensitive and NK-resistant tumor cells, and CIK cells are more cytotoxic than LAK cells. Previous studies have shown that CIK cells ex-

press both the Fas receptor and FasL. Fas-sensitive and previously activated T cells are eliminated in the early stages of CIK cell culture through either IFN- γ , activation-induced

cell death or both. To generate CIK cells, splenocytes are stimulated with IFN- γ 24 h prior to anti-CD3 and IL-2 treatment. This combination of cytokines might select for a population of Fas-resistant cells^[19]. In the present study, the CIK cell growth curve decreased in the initial stages, then increased. The initial decrease might be related to the downregulation of cell proliferation caused by IFN- γ . In the present study, a synergistic interaction between IL-2 (75–300 kU/L) and *Gl*-PS (400 mg/L or 100 mg/L) enhanced LAK cell development and cytotoxicity. In combination with 1000 kU/L IFN- γ , 75 kU/L IL-2, 25 mg/L anti-CD3 and 100 kU/L IL-1, *Gl*-PS (400 mg/L or 100 mg/L) decreased the dose of IL-2 and anti-CD3 by 75% and 50% respectively, but did not influence CIK cell proliferation and cytotoxicity. These results show that only intermediate concentrations (not too high or too low) of *Gl*-PS enhance immunocyte development; and the results also suggest that a certain concentration of *Gl*-PS could be an immune potentiator to reduce the dose of cytokine inducing LAK and CIK cells. Previous studies have shown that *Gl*-PS can stimulate splenocytes and macrophages to produce cytokines, including IL-1, IL-2, IFN- γ and tumor necrosis factor^[5,20–23]. Whether *Gl*-PS exerts its activity by promoting the release of cytokines by the precursors of CIK cells is currently under investigation.

β -Glucans are known to bind to receptors, for example CR3. The binding site of CR3 has a broad specificity for certain polysaccharides containing glucose and mannose, as well as *N*-acetyl-*D*-glucosamine^[24]. *Gl*-PS is a heteroglycan that contains primarily glucose^[2], and CR3 is expressed mostly by activated lymphocytes, NK cells, macrophages and granulocytes^[25]. Our results demonstrated that the activity of CIK cells mediated by *Gl*-PS was drastically inhibited (60%–70%) by prior treatment of murine splenocytes with anti-CR3. These results correspond with those of Xia *et al*, who found that β -Glucans bound to CR3 on macrophages, neutrophils, and NK cells in humans and mice, and cytotoxicity mediated by β -glucans can be blocked by anti-CR3 added before or after β -glucan treatment^[25]. It has been confirmed that anti-CR3 had no effect on the cytotoxic activity of CIK cells^[26]. These results suggest that the immune-modulating effect of *Gl*-PS on CIK cells is mediated primarily through CR3. Our study provides useful data for the use of *Gl*-PS in combination with other immunomodulators.

Abstract

Aim: To investigate the mechanism underlying the killing effects of a novel amphipathic photosensitizer, disulfonated diphthalimidomethyl phthalocyanine zinc (ZnPcS₂P₂), mediated photodynamic therapy (ZnPc-PDT) in human myelogenous leukemia HL60 cells. **Methods:** After incubation for 5 h with 0.5 μmol/L ZnPcS₂P₂, the HL60 cells were exposed to a light source of 670 nm wavelength. Thereafter, the cells were detected at different time intervals after PDT. The characteristics of apoptosis were detected by observation of ultrastructure assay, DNA fragmentation assay and terminal deoxynucleotidyl transferase deoxyuridine nick-end labeling method (TUNEL). Mitochondria-dependent apoptosis was determined by the detection of mitochondrial membrane potential (Δψ_m), activities of caspase family protease and of caspase-3, cytosol cytochrome c. Proteins Bcl-2 and Bax were detected by immunoblot analysis. **Results:** Evident characteristics of apoptosis were observed post-ZnPc-PDT with ultrastructure assay, DNA fragmentation assay and TUNEL staining. TUNEL assay showed that apoptotic rates in the cells collected from 6 h, 12 h and 24 h after PDT were 9.6%, 24.4%, and 33.0%, respectively. HL60 cells underwent mitochondria-dependent apoptosis as a result of cytochrome c release from mitochondria into cytosol accompanied by a reduction of Δψ_m. The activities of caspase family protease and of caspase-3 were elevated. Furthermore, ZnPc-PDT could remarkably down-regulate the Bcl-2 pro-apoptotic protein and up-regulate the anti-apoptotic Bax protein. **Conclusion:** ZnPc-PDT could induce mitochondria-dependent apoptosis in HL60 cells.

Introduction

Photodynamic therapy (PDT), a promising cancer therapeutic approach, utilizes a photosensitizing agent followed by illumination at a specific “activating” wavelength of light. PDT produces singlet oxygen and other reactive oxygen species (ROS), leading to lipid peroxidation and damage to membranes, DNA, cytoskeleton, and other sites, and eventual cell death^[1–3]. Individually, photosensitizers and light are nontoxic, but tumoricidal when combined. Electron microscopy, histological and biochemical studies have shown that PDT with different photosensitizers induces apoptotic or necrotic cell death in different cell types^[4–8]. Photosensitizers are key factors for PDT. According to previous studies^[9,10], ZnPcS₂P₂ presents 4 advantages over conventional photosensitizers such as hematoporphyrin derivatives (HpD)

or other porphyrin derivatives. The first advantage is that the wavelength of suitable excited light for ZnPcS₂P₂ is 670 nm, which is good for penetrating into tissues. The second advantage is that ZnPcS₂P₂ has no obvious absorption in the visible part as with HpD with the result of decreased skin phototoxicity from natural light to a larger extent. The third advantage is that the excited triplet state of ZnPcS₂P₂ has a larger quantum yield and longer lifetime. The fourth advantage is that the amphipathic structure of ZnPcS₂P₂ results in the increase of selective uptake of sensitizers by tumor cells. Our previous investigation manifested that leukemic cell lines exhibited higher susceptibility to ZnPc-PDT than normal hematopoietic cells and ZnPc-PDT could eliminate the residual leukemia cells in normal bone marrow mononuclear cells^[11]. However, the mechanism underlying the killing ef-

fects of ZnPc-PDT on leukemic cells is still unknown. In the present paper, we studied the death pathway of HL60 cells induced by ZnPc-PDT and the mechanism of its action.

The mitochondrion plays a central role in the control of apoptosis by releasing the apoptogenic proteins apoptosis-inducing factor (AIF) and cytochrome c into the cytosol. The released proteins activate pathways essential for carrying out the morphological and biochemical changes. For example, cytochrome c, normally residing between the mitochondrial outer and inner membranes and serving as a diffusible electron carrier in the intermembrane space, has been demonstrated to be a co-activator of caspase-9, which in turn activates caspase-3. The active caspase-3 then activates caspase-activated DNA (CAD). Active CAD initiates chromatin and DNA fragmentation^[12-22]. Therefore, in the present study, we investigate the relationship between the death mechanism induced by ZnPc-PDT and the mitochondria-dependent apoptosis. Furthermore, it is well known that Bcl-2 serves to inhibit apoptosis by antagonizing the release of mitochondrial cytochrome c, whereas Bax promotes apoptosis^[24,25]. The Bcl-2 protein was reported to be a damage target of PDT and contributes to PDT-efficient induction of apoptosis^[25]. Therefore, we also detect the kinetic change of Bcl-2 and Bax expression following ZnPc-PDT.

Materials and methods

Cell line Human myelogenous leukemia HL60 cells provided by the Shanghai Institute of Cytobiology (Institute of Chinese Academy of Sciences, China) were maintained in continuous culture in RPMI-1640 (GIBCO BRL), supplemented with 10% (v/v) heat-inactivated fetal calf serum (FCS), penicillin 100 U/mL, 100 µg/mL streptomycin, and 0.25 mmol/L L-glutamine at 37 °C under 5% CO₂ humidified air. The viability of cells was determined by Trypan blue dye exclusion. Cells were maintained in log phase with viability greater than 95%.

Photosensitizer ZnPcS₂P₂ was a gift from the Department of Chemistry, Institute of Research on Functional Materials, Fuzhou University, China. It was dissolved in a solution comprised of Cremophor EL 2% (v/v), propylene glycol 20% (v/v), NaCl 0.9% (w/w) and stored in the dark at 4 °C.

Photodynamic treatment HL60 cell suspensions (5 × 10⁶/mL in RPMI-1640) were incubated with 0.5 µmol/L of ZnPcS₂P₂ for 5 h. The cell suspensions were then photoirradiated using a LD-670 semi-conductor laser (Laboratory of Laser Medicine, Tianjin Medical University, China) emitting red light at a 670 nm wavelength. The power density at the illumination area was 53 mW/cm² and total light dose was

2.1 J/cm². A control group (cells incubated with same volume of saline for 5 h) was established. Thereafter, cells were harvested at 6 h, 12 h, and 24 h, respectively.

Apoptosis assays Ultrastructure was analyzed under a HU-12A electron microscope. DNA fragmentation assay was followed as described^[26]. TUNEL stains were carried out according to the manufacture's instructions (Promega) and the apoptotic cells characterized with brown nuclei were counted under microscope and photographed.

Assays for mitochondrial membrane potential ($\Delta\psi_m$), caspase-family protease activity and caspase-3 activity The procedure was carried out according to the manufacture's instructions (Biovision). The results were then analyzed by flow cytometry (BD). The $\Delta\psi_m$ detection kit utilized MitoCaptureTM (BioVision), a cationic dye that fluoresces differently in healthy cells and apoptotic cells. In healthy cells, MitoCapture accumulated and aggregated in the mitochondria, giving off a bright red fluorescence. In apoptotic cells, MitoCapture could not aggregate in the mitochondria due to the altered $\Delta\psi_m$, and thus it remained in the cytoplasm in its monomer form, emitting green fluorescence. The fluorescent signal could be analyzed by flow cytometry FITC channel for green monomers and PI channel for red aggregates. The assay for caspase activity was based on the cleavage of (aspartyl)₂-Rhodamine 110 (D₂R), a reported substrate for members of caspase family proteases. D₂R was non-fluorescent, however, upon cleavage of the substrate by cellular caspases, the released rhodamine 110 resulted in a green fluorescence. The caspase-3 activity detection kit utilized the caspase-3 inhibitor DEVD-FMK, conjugated to FITC as the fluorescent *in situ* marker. FITC-DEVD-FMK was cell-permeable, nontoxic, and irreversibly binds to activated caspase-3 in apoptotic cells.

Assay for cytochrome c Western blotting was performed according to previously published methods^[27], with minor modification. In brief, cell pellets were washed once with ice-cold phosphate-buffered saline (PBS) and lysed in lysis buffer (in mmol/L: 20 Hepes-KOH, 250 sucrose, pH 7.5, 10 KCl, 1.5 MgCl₂, 1 sodium ethylene diaminetetraacetic acid (EDTA), 1 dithiothreitol, and 0.1 phenylmethylsulfonyl fluoride). The cells were homogenized on ice for 15 min and the homogenates were centrifuged twice at 1000 × g for 10 min. The supernatants were centrifuged at 12000 × g for 15 min at 4 °C, and the supernatants were cytosol without mitochondria. Protein concentration of cell extracts was determined with Bradford protein assay (Coomassie Brilliant Blue G-250 obtained from BBI). Cytosol protein was loaded and separated on 12% sodium dodecyl sulfate (SDS) polyacrylamide gel and transferred to a nitrocellulose membrane

by standard electric transfer protocol. The chemiluminescent detection of membrane-bound proteins was performed according to the manufacture's instructions (KPL, Kirkegaard & Perry Laboratories). In brief, the membranes were blocked in blocking buffer for 1 h at room temperature and then incubated with anti-human cytochrome c mouse monoclonal antibody (Neomarkers) in blocking buffer overnight at 4 °C. After washing, the membranes were incubated with anti-mouse secondary antibody horseradish peroxidase conjugate and then detected by enhanced chemiluminescent detection system. Finally, the bands were visualized by autoradiography using X-ray film and scanned and quantified by Imager Quant (Alpha Innotech Corporation, San Leandro, USA). The relative levels of cytochrome c were obtained after normalization with β -actin values in the same lane. At the same time, the distribution of cytochrome c was detected by immunohistochemistry staining and the signals were visualized with an alkaline phosphatase-linked assay system (DAKO LSAB labeled streptavidin-biotin, DakoCytomation Inc). The proteins were detected under microscope and photographed.

Assay for Bcl-2 protein and Bax protein To prepare lysates, cells were initially washed once with ice-cold PBS.

Cell pellets were treated with lysis buffer [1% Nonidet P-40 detergent (NP-40), 50 mmol/L Tris-HCl buffer, pH 8, 0.1% SDS, 0.1 mmol/L phenylmethylsulphonyl fluoride (PMSF), 0.02% sodium azide] for 15 min on ice. Lysates were centrifuged at $12\,000\times g$ 4 °C for 15 min. Protein concentration of cell extracts was determined with Bradford protein assay. The detergent-soluble proteins were detected using the same procedure as cytochrome c. The intensities of the bands were determined with the utilization of the ratios of Bax (21 kDa) to Bcl-2 (26 kDa). The anti-human monoclonal antibodies were purchased from NeoMarkers.

Statistical analysis All data were presented as mean \pm SD of 3 independent experiments. Statistical significance was determined with Student's unpaired two-tailed *t*-test (SPSS 10.0 software, SPSS Inc, Chicago, USA). $P < 0.05$ was considered statistically significant.

Results

Characteristics of apoptosis in HL60 cells after ZnPc-PDT Electron microscopy studies showed that in ZnPc-PDT group, the features of HL60 cells appeared obviously as following: the cell size decreasing, cell membrane blebbing,

Figure 1. ZnPc-PDT induced apoptosis in HL60 cells. Electron micrographs of HL60 cells in control group (A, $\times 6000$) or in ZnPc-PDT group (B–D, incubated with 0.5 $\mu\text{mol/L}$ of ZnPcS_2P_2 for 5 h and then exposed to 670 nm light source of total light dose of 2.1 J/cm^2). B: nuclear chromatin condensation ($\times 4800$, 6 h post-PDT); C: nuclear chromatin cleavage ($\times 7000$, 24 h post-PDT); D: formation of apoptotic bodies ($\times 7000$, 24 h post-PDT).

cytoplasm shrinkage, nuclear chromatin condensation or cleavage and formation of apoptotic bodies (Figure 1). And characteristic chromosomal DNA fragmentation appeared in the cells after ZnPc-PDT. By contrast, no DNA ladder existed in the control groups (Figure 2). TUNEL staining analysis showed many apoptotic cells which nuclei stained brown existed in ZnPc-PDT groups and the average apoptosis rates significantly increased in a time-dependent manner. At the 3 different time points after PDT, the mean TUNEL-positive rates were 9.6%, 24.4%, and 33.0%, respectively (Figure 3). However, few apoptotic cell was detected in the control group. The results indicated that ZnPc-PDT could induce evident apoptosis in HL60 cells.

Figure 2. DNA electrophoresis of HL60 cell extracts. Control group: No DNA ladder existed. Post-PDT: HL60 cells were incubated with 0.5 $\mu\text{mol/L}$ of ZnPcS₂P₂ for 5 h and then exposed to 670 nm light source of total light dose of 2.1 J/cm². The cells were harvested at 6 h, 12 h and 24 h post-PDT. Characteristic DNA ladder appeared. (Original magnification \times 1.5)

Characteristics of mitochondria-dependent apoptosis in HL60 cells after ZnPc-PDT In the control group, the positive rates of assays for $\Delta\psi_m$, activities of caspase family proteases and caspase-3 were all less than 1%. In the ZnPc-PDT groups, compared with the control group, the positive rates of the 3 indexes increased remarkably ($P<0.01$) as shown in Figure 4. In the ZnPc-PDT groups, $\Delta\psi_m$ altered significantly and the positive rates increased in a time-dependent manner. When detecting caspase-3 activity, approximately 75.4% cells presented proteases activities at 6 h post-PDT. Caspase family proteases were activated comparatively slightly and slowly after PDT.

Compared with the control groups, in the ZnPc-PDT

Figure 3. TUNEL staining analysis. A: Control group. B: 24 h post-PDT (HL60 cells were incubated with 0.5 $\mu\text{mol/L}$ of ZnPcS₂P₂ for 5 h and then exposed to 670 nm light source of total light dose of 2.1 J/cm²). (Original magnification \times 400.)

Figure 4. Time course of changes in $\Delta\psi_m$, activities of caspase and caspase-3 post-PDT (HL60 cells were incubated with 0.5 $\mu\text{mol/L}$ of ZnPcS₂P₂ for 5 h and then exposed to 670 nm light source of total light dose of 2.1 J/cm²). $n=3$. Mean \pm SD. ^c $P<0.01$ vs control.

groups the ratio of cytosol cytochrome c (15 kDa) to β -actin (43 kDa) assessed by Western blot analysis increased significantly ($P<0.01$). Significant difference existed between 6 h and 12 h post-PDT ($P<0.01$). However the difference between 12 h and 24 h points was minor ($P>0.05$) (Figure 5A). Immunocytochemistry assay showed that after ZnPc-PDT, cytochrome c translocated from its original location adjacent to nucleus and dispersed into cytosol and the positive particles were stained obviously darker (Figure 5B). The 2 indexes showed that ZnPc-PDT induced evident release of cytochrome c from the mitochondria into the cytosol.

Summing up the results from different observations as

Figure 5. Results of the detection of cytosol cytochrome c. A: Western blotting showed that the intensity of cytochrome c bands strengthen remarkably after ZnPc-PDT (HL60 cells were incubated with 0.5 $\mu\text{mol/L}$ of ZnPcS₂P₂ for 5 h and then exposed to 670 nm light source of total light dose of 2.1 J/cm²). (Original magnification $\times 2$) B: Immunohistochemistry assay showed that after PDT, cytochrome c translocated from its original location adjacent to nucleus to cytosol ($\times 1000$).

previously discussed, we concluded that ZnPc-PDT could induce HL60 cells apoptosis through mitochondria-dependent ways.

Effects of ZnPc-PDT on the expression of Bcl-2 and Bax

Western blot assays showed that ZnPc-PDT could down-regulate Bcl-2 expression and up-regulate Bax expression. After PDT, the ratio of Bax to Bcl-2 increased significantly in a time-dependent manner (Figure 6).

Discussion

PDT has emerged as a promising therapeutic procedure for the treatment of many tumors. The cytotoxic efficacy relies on a bimodal protocol comprised of chemical-photosensitizer and light-irradiation. Separately, neither the photosensitizer nor the light is toxic^[1,11]. The mechanism of the PDT-mediated cytotoxic effects is not well defined. However it is generally believed that the apoptotic response of PDT is critical for its therapeutic efficacy and the generation of ROS is essential for PDT effects^[2,3,25]. Some results have demonstrated that PDT could induce the permeability tran-

Figure 6. Western blot analysis of Bax and Bcl-2. Bcl-2 expression decreased and Bax expression increased after ZnPc-PDT (HL60 cells were incubated with 0.5 $\mu\text{mol/L}$ of ZnPcS₂P₂ for 5 h and then exposed to 670 nm light source of total light dose of 2.1 J/cm²). (Original magnification $\times 2$)

sition pore open and the opening leads to the loss of integrity of the outer mitochondrial membrane, thus releasing the inter-membrane proteins, such as cytochrome c, into the cytosol^[12-16]. When released from the mitochondria, cytochrome c combines with an inactive protease precursor, procaspase-9, to form the “apoptosome”. The apoptosome attacks procaspase-3 and cleaves it to form active caspase-3, which can lead to DNA breakage, nuclear chromatin condensation, then cause cell death^[20,21].

A number of studies have documented that cell death response to PDT varies due to the physical properties of the photosensitizer employed, PDT dose and the cell type^[4-8]. Different subcellular localization of the photosensitizer results in different responses^[6,7]. Even the same photosensitizer-mediated PDT could lead to different outcomes. At low doses, the cellular machinery for apoptosis is activated, however, higher doses lead to the inhibition of apoptosis with cell death via a necrotic process^[4,8]. In the present study, a novel photosensitizer agent, ZnPcS₂P₂, developed in China, was employed. Our previous studies have demonstrated that ZnPc-PDT could exert significant photodamage to HL60 cells^[11]. In the present study, 0.5 $\mu\text{mol/L}$ drug level was selected as the experimental condition. Under the condition, ZnPc-PDT could inhibit the proliferation of HL60 cells at 51%.

It is well known that there are two major pathways that are involved in the initiation of apoptosis: the “extrinsic” death receptor pathway and the “intrinsic” mitochondrial pathway. The present study provides direct evidence for the role of mitochondria in HL60 cells apoptosis induced by ZnPc-PDT. Cytochrome c appeared in the cytosol 6 h following light activation of ZnPcS₂P₂. The main cytochrome c release occurred later, between 6 h and 12 h after PDT. However, caspase-3 could be quickly activated by ZnPc-PDT. Remarkable activity of caspase-3 was observed 6 h post-PDT in almost all cells. According to recent studies^[28],

during genotoxic stress-induced apoptosis, the release of cytochrome c from mitochondria occurs in 2 distinct stages. The early release of low levels of cytochrome c into the cytosol precedes the activation of caspase 9 and 3. The late stage cytochrome c release results in a drastic loss of mitochondrial cytochrome c and the activities of caspases contribute to the late cytochrome c release mentioned earlier. In the present study, PDT induced the early release of low levels of cytochrome c into the cytosol in the first 6 h. The cytochrome c then combined with procaspase-9 to form the "apoptosome". The apoptosome activated caspase-3 that induced the late cytochrome c release. Therefore, between 6 h and 12 h post-PDT, the main cytochrome c release occurred. At the time of cytochrome c release and remarkable caspase-3 activation (6 h after PDT), only a 12.6% fraction of the cells detected disruption of $\Delta\psi_m$. The data are in agreement with the previous conclusion^[19] that the dissipation of $\Delta\psi_m$ is not required for the release of cytochrome c from the mitochondria. Also, the up-regulation of pro-apoptotic protein Bax, and the down-regulation of anti-apoptotic protein Bcl-2 by ZnPc-PDT appeared significantly and could result in activating mitochondria-mediated apoptosis. The results coincide with those of other previously published studies^[25,29]. It is also reported that in many cell types, there is delicate coordination and cross talk between the extrinsic and intrinsic pathways that leads to the activation of the executioner caspase cascade^[30,31]. Therefore, the study of the role of the death receptor pathway in the apoptosis induced by ZnPc-PDT should be pursued.

Thus, we conclude that the main mechanism for the apoptosis in HL60 cells induced by ZnPc-PDT appeared to be mitochondria-mediated pathway accompanied with cytochrome c release from the mitochondria into the cytosol followed by the activation of caspase-3. Our findings would provide a fundamental basis for the clinical application of ZnPc-PDT.

Abstract

Aim: To investigate the influence of dosage forms on the pharmacokinetics of daidzein and its main metabolite daidzein-7-*O*-glucuronide in Wistar rats. **Methods:** After administration of two typical dosage forms (daidzein solution and suspension), the concentrations of daidzein and daidzein-7-*O*-glucuronide were determined by an LC-MS-MS method. The pharmacokinetic parameters were calculated and analyzed statistically using the Student's *t*-test. **Results:** Absorption of daidzein after administration of daidzein solution ($t_{\max}=0.46$ h) was more rapid than that of the suspension ($t_{\max}=5.00$ h). The peak plasma concentrations of daidzein after administration of daidzein solution and suspension were 601.1 $\mu\text{g/L}$ and 127.3 $\mu\text{g/L}$, respectively, and those of daidzein-7-*O*-glucuronide were 3000 $\mu\text{g/L}$ and 192.6 $\mu\text{g/L}$, respectively. The absolute bioavailabilities of free daidzein in rats after administration of daidzein solution and suspension were 12.8% and 6.1%, respectively, which were calculated to be 47.0% and 12.2%, respectively, in the form of total daidzein (free plus conjugated daidzein). **Conclusion:** Absorption of daidzein solution was better than absorption of suspension ($P<0.05$).

Introduction

Daidzein [7-hydroxy-3-(4-hydroxyphenyl)-4*H*-1-benzopyran-4-one, CAS 486-66-8, Figure 1] is one of the naturally occurring isoflavones present mainly in leguminous plants, especially in soybeans, soy foods and *Pueraria lobata* Ohwi (Leguminosae). Several epidemiological studies in humans have suggested that daidzein intake is inversely associated with the incidence of hormone-dependent diseases, especially breast and prostate cancer^[1]. In addition to its putative anticarcinogenic effects, daidzein has also been investigated as an antihyperlipidemic agent and a

therapeutic substance to combat osteoporosis^[2,3].

After oral administration, daidzein is subject to glucuronidation at the 7-hydroxyl position, and daidzein-7-*O*-glucuronide is its main metabolite in human^[4] and rat^[5] plasma and urine. The pharmacokinetics of daidzein in humans has been the subject of several studies^[6–10], but there have been no reports about the pharmacokinetics of its main metabolite daidzein-7-*O*-glucuronide. Due to its poor hydrophilicity and lipophilicity, the pharmacokinetics of daidzein may be influenced by the dosage form. However, the influence of dosage forms on the pharmacokinetics of daidzein

Figure 1. Chemical structures of daidzein (I), genistein (II, internal standard) and daidzein-7-*O*-glucuronide (III).

and its main metabolite daidzein-7-*O*-glucuronide have not been investigated previously. Furthermore, the extent of the influence of dosage forms remains unknown.

In the present study, the influence of two typical dosage forms (solution and suspension) on the pharmacokinetics of daidzein and its main metabolite daidzein-7-*O*-glucuronide was investigated after oral administration of 20 mg/kg purified daidzein to rats.

Materials and methods

Chemicals and reagents Daidzein and genistein (internal standard) were purchased from Huike Botanical (Xi'an, Shaanxi, China). The purities of these 2 compounds were 99.3% and 98.9%, respectively, which was verified using high-performance liquid chromatography (HPLC) methods. β -Glucuronidase (EC 3.2.2.21, 542 200 units/g of solid) was purchased from Sigma (St Louis, MO, USA). CMC-Na was purchased from Shenyang Chemical Factory (Shenyang, Liaoning, China). Acetonitrile and methanol (Yuwang Chemical Factory, Shandong, China) were of HPLC grade. Other chemicals were of analytical grade. Distilled water, prepared from demineralized water, was used throughout the study.

Preparations of dosage forms A transparent solution of daidzein was prepared by dissolving an appropriate amount of daidzein in 0.9% NaCl solution (water was used as solvent) and adjusting the pH to 7.0 by the addition of 1 mol/L NaOH. A daidzein suspension with good physical stability was achieved by dispersing grinded daidzein in 0.5% CMC-Na solution (water was used as solvent and CMC-Na was used as co-suspension reagent). The concentrations of daidzein in both dosage forms were determined to be 2.0 g/L by a validated HPLC-UV method. The 2 dosage forms were prepared freshly for animal administration.

Instrumentation A Finnigan TSQ API II tandem mass spectrometer equipped with an atmospheric pressure chemical ionization (APCI) source (San Jose, CA, USA), an Agilent 1100 autosampler (Agilent, Wilmington, DE, USA) and a Shimadzu LC-10AD pump (Kyoto, Japan) were used for LC-MS-MS analyses. Analytical data were acquired using Xcalibur 1.1 software (Finnigan) and quantitative processing was carried out using LCQuan software (Finnigan).

LC-MS-MS conditions The LC-MS-MS method used for the determination of daidzein and daidzein-7-*O*-glucuronide was a slightly modified version of one described previously^[11]. The LC separation was carried out using a Diamonsil C₁₈ column (200 mm×4.6 mm ID, 5 mm; Dikma, Beijing, China) and a SecurityGuard C₁₈ guard column (4 mm×3.0 mm ID; Phenomenex, Torrance, CA, USA). The

isocratic mobile phase consisted of acetonitrile-water-formic acid (80:20:1, v:v:v) at a flow rate of 0.75 mL/min. The column temperature was maintained at 20 °C.

The mass spectrometer was operated in positive APCI mode with the corona discharge current set at 4.00 μ A. Nitrogen was used as the sheath gas (0.6 MPa) and auxiliary gas (3 L/min) for nebulization. The heated capillary and vaporizer temperatures were set to 280 °C and 450 °C, respectively. For collision-induced dissociation (CID), argon was used as the collision gas at a pressure of 0.19 Pa. Quantification was carried out using selected reaction monitoring (SRM) of the transitions m/z 255→199 for daidzein and m/z 271→153 for genistein, with a scan time of 0.3 s/transition. The optimized collision energies of 30 eV and 35 eV were chosen for daidzein and genistein, respectively.

Sample preparation To determine free (unconjugated) daidzein, 50 μ L internal standard solution (genistein, 50 mg/L in methanol) and 50 μ L water were added to 50 μ L of each rat plasma sample. $\text{NH}_4\text{H}_2\text{PO}_4$ buffer (pH 5.0; 200 μ L of 0.05 mol/L) was added. The mixture was vortexed for 10 s and extracted with 2 mL *n*-hexane-diethyl ether (1 : 4, v/v) by shaking for 10 min. After centrifugation at 2000×g for 10 min, the organic phase was transferred into another tube and evaporated to dryness at 40 °C under a stream of nitrogen. The residue was reconstituted in 100 μ L of the mobile phase and vortexed for 1 min. A 20- μ L aliquot of the solution was injected onto the LC-MS-MS system.

To determine total daidzein (free plus conjugated daidzein), 100 μ L β -glucuronidase enzyme solution (1084 U/mL in 0.05 mol/L $\text{NH}_4\text{H}_2\text{PO}_4$ buffer, pH 5.0) was added to a 50 μ L aliquot of rat plasma. The mixture was incubated in a water bath at 37 °C for 16 h. After enzymatic hydrolysis, 50 μ L internal standard and 50 μ L water were added. The mixture was treated as described above.

Those plasma samples whose concentrations were higher than the highest calibration point were diluted appropriately with blank rat plasma in order to make the concentration within the range of the standard curve before sample preparation.

The concentration of daidzein-7-*O*-glucuronide was calculated using the following formula:

$$C_{\text{DG}} = (C_t - C_f) \times 430/254,$$

where C_{DG} was the mass concentration of daidzein-7-*O*-glucuronide (conjugated daidzein), C_t was the total mass concentration of daidzein, C_f was the mass concentration of free (unconjugated) daidzein, and 254 and 430 were the molecular weights of daidzein and daidzein-7-*O*-glucuronide, respectively.

Study design Eighteen Wistar rats (Grade II, Certificate

No 042; 9 males and 9 females; Laboratory Animal Center of Shenyang Pharmaceutical University, Shenyang, China) weighing 200 g–250 g were divided into 3 groups at random in the studies. Each group contained 3 male and 3 female rats. All experimental procedures were carried out in accordance with the guidelines of the Experimental Animal Care and Use Committee of Shenyang Pharmaceutical University. The rats were housed under standard conditions and had *ad libitum* access to water and a standard laboratory diet (isoflavone free). All rats were dosed following an overnight fast; food was returned 0.5 h after dosing. Water was available *ad libitum* throughout the experiments.

Polyethylene cannulas were implanted in the femoral vein 2 d before the experiment while the rats were anesthetized with pentobarbital (50 mg/kg, ip). The cannulas were externalized at the back of the neck and filled with heparinized saline (20000 U/L). One group of 6 rats weighing 224±13 g were dosed orally with daidzein solution at 20 mg/kg (10 mL/kg, 2 g/L), the second group of 6 rats weighing 230±16 g were dosed orally with daidzein suspension at 20 mg/kg (10 mL/kg, 2 g/L), and the third group of 6 rats weighing 227±10 g were dosed intravenously with daidzein solution at 20 mg/kg (10 mL/kg, 2 g/L). Serial blood samples (0.25 mL) were collected at 0 h, 5 min, 10 min, 30 min, 1 h, 3 h, 5 h, 8 h, 12 h, 24 h and 48 h post dose. Plasma was separated by centrifugation at 2000×g for 10 min and stored frozen at -20 °C until analysis.

Data analysis Plasma concentrations were subjected to an appropriate pharmacokinetic analysis on mean data points. Values below the quantification limit were considered to be zero. The peak concentration (C_{max}) and the corresponding peak times (t_{max}) were determined by visual inspection of the mean data. The elimination half-life ($t_{1/2}$) was calculated using the non-compartmental model of the TOPFIT program on a personal computer. The area under the plasma concentration-time curve (AUC) from time zero to the last measurable plasma concentration point ($t=48$ h) (AUC_{0-48h}) was calculated using the linear trapezoidal rule. Extrapolation to time infinity ($AUC_{0-\infty}$) was calculated as follows:

$$AUC_{0-\infty} = AUC_{0-48h} + C_{48h} / k_e,$$

where C_{48h} was the last measurable plasma concentration and k_e was the elimination rate constant. The bioavailability (F) of free daidzein was calculated as follows:

$$F = AUC_{0-\infty, po} / AUC_{0-\infty, iv},$$

where $AUC_{0-\infty, po}$ and $AUC_{0-\infty, iv}$ were the AUC values of free daidzein after oral and intravenous administration of daidzein. The bioavailability (F) of total daidzein (free plus conjugated daidzein) was calculated as follows:

$$F = AUC_{0-\infty, po} / AUC_{0-\infty, iv},$$

where $AUC_{0-\infty, po}$ and $AUC_{0-\infty, iv}$ were the AUC values of total daidzein after oral and intravenous administration of daidzein.

The main pharmacokinetic parameters, including $t_{1/2}$, k_e , t_{max} , C_{max} , AUC_{0-48h} , $AUC_{0-\infty}$, and F , were analyzed using the Student's *t*-test. A probability level of $P < 0.05$ was defined as being statistically significant.

Results

Mass spectrometry Using the positive APCI mode, the analyte and internal standard formed predominately protonated molecules $[M+H]^+$ in full-scan spectra. To determine daidzein using the SRM mode, full-scan and product-ion spectra of daidzein and internal standard were investigated under the present HPLC conditions. Figure 2 shows the product ion spectra of $[M+H]^+$ ions of daidzein and genistein. Several fragment ions were observed in the product-ion spectra. The major fragment ions at m/z 199 and 153 were chosen in the SRM acquisition for daidzein and genistein, respectively.

Method validation Selectivity was assessed by comparing the chromatograms of 6 different batches of blank rat plasma with the corresponding spiked plasma. Figure 3

Figure 2. Full-scan product-ion spectra of $[M+H]^+$ of (A) daidzein and (B) genistein.

Figure 3. Representative selected reaction monitoring chromatograms of daidzein plasma samples determined using the LC-MS-MS method. (A) Blank plasma sample; (B) Blank plasma sample spiked with daidzein at the LLOQ of 0.24 $\mu\text{g/L}$ and genistein (IS, 50 mg/L); (C) Rat plasma sample collected at 30 min after oral administration of daidzein (20 mg/kg). Peak I, daidzein; peak II, genistein.

shows the typical chromatograms of a blank plasma sample, a blank plasma sample spiked with daidzein at the LLOQ and genistein, and a plasma sample from a Wistar rat 30 min after oral administration. No significant interference from endogenous substances with analyte or genistein were detected. The typical retention times for daidzein and genistein were 2.7 min and 2.9 min, respectively.

Calibration standards were prepared by spiking 50 µL of the appropriate standard solutions of daidzein to 50 µL of blank rat plasma. Plasma concentrations were 0.24 µg/L, 0.50 µg/L, 1.5 µg/L, 20 µg/L, 100 µg/L, 500 µg/L and 1000 µg/L for daidzein. The linear regression of the peak area ratios versus concentrations was fitted over the concentration range of 0.24 µg/L–1000 µg/L in rat plasma. A typical equation of the calibration curve was as follows:

$$y=3.888 \times 10^{-4} + 6.030 \times 10^{-4} x \quad (r=0.9981),$$

where *y* is the peak area ratio of daidzein to genistein, and *x* is the concentration of daidzein. The present assay method had an LLOQ of 0.24 µg/L with an accuracy of 14.3% and a precision of 12.7% (*n*=5), which was sufficient for monitoring daidzein plasma levels over a period of 48 h after a single oral administration.

Table 1 summarizes the intra-day and inter-day precision and accuracy for daidzein from QC samples. In this assay, the intra-day and inter-day precisions ranged from 3.4% to 7.1% and from 6.3% to 13.2% for each QC level. The accuracy ranged from -0.5% to 2.4%. The results, calculated using a one-way ANOVA, indicated that the values were within the acceptable range and that the method was accurate and precise^[12].

Table 1. Precision and accuracy of the LC-MS-MS method in determining daidzein concentrations in rat plasma.

Concentration/µg·L ⁻¹		RSD/%		RE/%
Added	Found	Intra-day	Inter-day	
0.50	0.51	7.1	10.7	2.0
50.0	51.2	6.5	13.2	2.4
800.0	796.0	3.4	6.3	-0.5

RE, relative error. RSD, relative standard deviation.

The extraction recovery of daidzein, determined at 3 concentrations (0.50 µg/L, 50 µg/L, 800 µg/L), were 73.8%, 75.1% and 76.3% (*n*=6), respectively. The extraction recovery of genistein was also investigated as 64.2% (*n*=6).

Daidzein in the plasma was shown to be stable for at least 30 d stored at -20 °C. The relative error (RE%) of daidzein

between the initial concentrations and the concentrations of the following 3 freeze–thaw cycles ranged from -6.7% to 2.4%, which indicated the stability of daidzein during freeze–thaw. Processed samples were also found to be stable in the reconstituted solution of acetonitrile–water–formic acid (80:20:1, v:v:v) for at least 24 h at room temperature. These data are summarized in Table 2.

Table 2. Stability of daidzein in rat plasma (*n*=6).

Stability	Daidzein concentration/µg·L ⁻¹		
	0.50	50.0	800.0
Storage (≤-20 °C, relative error, %)			
0 d	2.6	-1.1	2.9
30 d	-4.7	-5.8	3.5
Freeze-thaw (relative error, %)			
0 cycles	-0.4	2.4	-2.1
3 cycles	-2.7	-5.6	-6.7
Processed plasma samples at room temperature (relative error, %)			
0 h	0.7	-3.2	0.3
24 h	-2.6	1.9	-3.8

Pharmacokinetics The mean plasma concentration versus time curves of daidzein and daidzein-7-*O*-glucuronide after oral administration of 2 different dosage forms (daidzein solution and suspension) are given in Figure 4. The mean plasma concentration versus time curves of daidzein and daidzein-7-*O*-glucuronide after intravenous administration of daidzein solution are given in Figure 5. Table 3 summarizes the pharmacokinetic parameters of daidzein and daidzein-7-*O*-glucuronide after administration of 2 different dosage forms. The pharmacokinetic parameters of daidzein and daidzein-7-*O*-glucuronide after intravenous administration of daidzein solution are given in Table 4.

Pharmacokinetics of daidzein After oral administration of 2 different dosage forms, the absorption of daidzein after administration of daidzein solution (*t*_{max}=0.46 h) was more rapid than that of suspension (*t*_{max}=5.00 h). The peak plasma concentration after administration of daidzein solution was 601.1 µg/L, which was approximately 4 times higher than that of suspension (127.3 µg/L). The absolute bioavailability of daidzein in rats after administration of daidzein solution was 12.8%, but the absolute bioavailability of daidzein after administration of daidzein suspension was only 6.1%.

There are significant differences of daidzein parameters in the values of *t*_{max} and *C*_{max} (*P*<0.05) between daidzein solution and suspension.

Pharmacokinetics of daidzein-7-*O*-glucuronide After

oral administration of 2 different dosage forms, absorption of daidzein after administration of daidzein solution (t_{max} =

0.40 h) was more rapid than that of suspension (t_{max} =3.67 h). The peak plasma concentration after administration of

Table 4. Pharmacokinetic parameters of daidzein and daidzein-7-*O*-glucuronide after intravenous administration of daidzein solution to rats (20 mg/kg, *n*=6). Each value represents the mean±SD for 6 individual values.

Parameter	Unit	Daidzein	Daidzein-7- <i>O</i> -glucuronide
$t_{1/2}$	h	6.40±2.45	11.4±3.93
k_e	h ⁻¹	0.13±0.07	0.07±0.02
AUC _{0-48h}	mg·h·L ⁻¹	26.5±7.20	20.8±12.8
AUC _{0-∞}	mg·h·L ⁻¹	26.5±7.20	21.4±13.2
CL _{TOT}	mL·min ⁻¹ ·kg ⁻¹	13.4±3.63	18.8±6.46
V_z	L·kg ⁻¹	7.65±4.64	17.5±6.37
MRT	h	2.00±1.00	8.09±3.41
V_{ss}	L·kg ⁻¹	1.45±0.47	9.58±5.66

daidzein solution was 3000 µg/L, which was approximately 14 times higher than that of suspension (192.6 µg/L). The absolute bioavailability of total daidzein (free plus conjugated daidzein) in rats after administration of daidzein solution was 47.0%, but the absolute bioavailability of total daidzein (free plus conjugated daidzein) after administration of daidzein suspension was only 12.2%.

In general, there are significant differences between the main pharmacokinetic parameters of daidzein and daidzein-7-*O*-glucuronide after administration of 2 different dosage forms (*P*<0.05). There is better absorption following administration of daidzein solution than after administration of suspension.

Discussion

Daidzein shows poor hydrophilicity and lipophilicity due to the typical plane structure of the isoflavones. However, it can be dissolved in weak alkaline solution and form a sodium salt at the hydroxyl groups; as a result its water solubility is greatly increased to 2 g/L. Daidzein solution was found to be stable during a period of at least 24 h (data not shown).

In present study, we choose solution and suspension as the 2 representative dosage forms. Daidzein suspension has similar *in vivo* processes to solid preparations, while daidzein solution is a typical liquid preparation. As a compound with poor solubility, the form of administration may have a great influence on its absorption and pharmacokinetics.

After oral administration, daidzein is subject to glucuronidation at its 7-hydroxyl group, and glucuronide conjugate is its main metabolite and the form in which it mainly exists

in vivo. The pharmacological effects of daidzein-7-*O*-glucuronide have not been reported in the literature. Daidzein can transform into daidzein-7-*O*-glucuronide as a substrate of glucurotransferases, and daidzein-7-*O*-glucuronide can transform back into daidzein by the action of a hydrolase. As a result, it is necessary to determine the concentrations of free daidzein and daidzein-7-*O*-glucuronide in order to study its absorption and pharmaco-kinetics.

Previous studies, which focused on the pharmacokinetics after consumption of known amounts of soy foods or limited purified isoflavones (solid preparations), found that daidzein was absorbed poorly^[6-10]. In our investigations, there are significant differences in pharmacokinetic parameters of daidzein and daidzein-7-*O*-glucuronide between solution and suspension. After administration of daidzein solution, daidzein is absorbed well and is mostly metabolized into daidzein-7-*O*-glucuronide. The reason for the significant differences was the poor solubility of daidzein.

Wojcicki *et al*^[13] reported that there were no statistically significant differences in the pharmacokinetics and bioavailability of flavonoid glycosides of *Ginkgo biloba* (quercetin, kaempferol and isorhamnetin) after a single oral administration of 3 formulations to healthy volunteers, which seems to contradict the results of the present study. However, the 3 formulations adopted in that report were capsules, drops and tablets, which were all solid formulations, while in present study, solution and suspension (solid) formulations were prepared to investigate their pharmacokinetics. In fact, there does exist significant differences in the pharmacokinetic parameters of solid and liquid formulations.

Pharmacokinetic parameters varied a great deal among individuals, indicating great inter-individual variability of daidzein disposition *in vivo*, which is in accordance with the results found in the literature^[9]. There were more factors to affect the pharmacokinetic behavior of daidzein and daidzein-7-*O*-glucuronide after oral administration compared with using an intravenous dose, and this may be the reason that larger RSD values of AUC_{0-48h} were achieved after oral administration (88.2% for oral solution and 50.9% for oral suspension; 27.3% for intravenous solution). Furthermore, different distribution amounts of β-glucuronidase *in vivo* and strong hepatic-intestinal cycles may also account for the large differences in the amounts of daidzein and its main metabolite daidzein-7-*O*-glucuronide *in vivo*.

In conclusion, dosage forms have a great influence on the bioavailability of daidzein. Solution preparations are more bioavailable than solid preparations. As a result, the solution preparations of daidzein are recommended for development in order to improve its oral bioavailability.

Abstract

Single-particle electron microscopy has now reached maturity, becoming a commonly used method in the examination of macromolecular structure. Using a small amount of purified protein, isolated molecules are observed under the electron microscope and the data collected can be averaged into a 3D reconstruction. Single-particle electron microscopy is an appropriate tool for the analysis of proteins that can only be obtained in modest quantities, like many of the large complexes currently of interest in biomedicine. Whilst the use of electron microscopy expands, new methods are being developed and improved to deal with further challenges, such as reaching higher resolutions and the combination of information at different levels of structural detail. More importantly, present methodology is still not robust enough when studying certain “tricky” proteins like those displaying extensive conformational flexibility and a great deal of user expertise is required, posing a threat to the consistency of the final structure. This mini review describes a brief outline of the methods currently used in the 3D analysis of macromolecules using single-particle electron microscopy, intended for those first approaching this field. A summary of methods, techniques, software, and some recent work is presented. The spectacular improvements to the technique in recent years, its advantages and limitations compared to other structural methods, and its future developments are discussed.

Introduction

Transmission electron microscopy (TEM) is a structural technique that has existed for many years in biology to study the ultra-structure of cells. However, it has only been more recently that outstanding technical advances have consolidated the prospect of observing single protein molecules at the electron microscope level with such sufficient structural details to use these data to reconstruct the molecule in three dimensions (3D). These methodological improvements lie at the level of the instrument itself, that is, better microscopes, but most significantly, more powerful algorithms and software platforms, and, importantly, dramatically increased speed of computers to deal with the noisy images of proteins obtained with the microscope. As a result of these advances, analysis of macromolecules using single-particle

electron microscopy (EM) can be widely noticed in a fast-increasing number of publications. Hence, the need rapidly emerged to store and make accessible all of this 3D information to the scientific community, and the Macromolecular Structure Data Base (at the European Bioinformatics Institute, Cambridge, UK) has been created to this end (<http://www.ebi.ac.uk/msd/>). Most scientific journals now make mandatory the deposition of any 3D structure obtained by EM into this data base, importantly using standard formats to guarantee the interchange of the data. This will certainly stimulate both the flow of EM structures among scientists (as already happens with atomic coordinates) as well as the quality of the EM work deposited.

As EM spreads out, its interaction and dependence on other structural techniques has deepened. A modern ap-

proach to the exploration of macromolecular structures requires a wise combination of molecular biology, biochemistry, biocomputing, X-ray crystallography, nuclear magnetic resonance (NMR), EM and any other structural technique (ultracentrifugation, small-angle neutron scattering, *etc.*). An important challenge will therefore be to develop methods to combine all of this multi-resolution information in a comprehensive way.

In the following sections, I will describe the major methods that EM employs today, how relevant structural information is extracted, and the present limitations of these approaches. Supplementary and more in-depth information can be found elsewhere^[1-9] and on the web (eg the 3D-electron microscopy data base at <http://3dem.ucsd.edu/index.html>, the Electron Microscopy Yellow Pages at <http://cimewww.epfl.ch/EMYP/comp.html>, or the SPIDER web site at http://www.wadsworth.org/spider_doc/spider/docs/spider.html).

Basics of single-particle electron microscopy

The protein of interest must be purified to homogeneity prior to any EM analysis, as image processing is most generally based on the assumption that every single image we take derives from the same specimen (Figure 1A). The sample is then applied to EM grids covered by a thin carbon support film (which can contain small holes in the case of cryo-EM, where specimens are vitrified) and visualized under the electron microscope (Figure 1B). Molecules of the protein adsorb to the carbon film in orientations determined by the charges on their surface and their overall shape. Ideally, a random distribution of orientations is desirable, because this will allow recording images of the protein from many different angles, a requirement to obtain a correct 3D reconstruction. Before insertion into the microscope, the sample must be prepared to withstand the incident radiation (electrons). For this purpose, the protein on the EM grid can be either stained with heavy-atom salts, known as negative staining (uranyl acetate, uranyl formate and ammonium molybdate, as the most widely used staining agents), or quickly vitrified into liquid ethane and kept under liquid nitrogen temperatures (cryo-EM). Each method has its own advantages and limitations widely discussed before and beyond the scope of this review^[5,7,10]. Briefly, negative staining provides a higher contrast at the expense of resolution and only the surface or topography of the molecule is actually defined. Performing cryo-EM experiments is technically more demanding for the microscopist, but perfectly preserves the structure of the protein at high resolution within the vitrified buffer.

Nevertheless, contrast is strongly reduced, thus small proteins might only be analyzed with the help of staining agents^[10-12].

Images obtained with the electron microscope are projections of the molecules along the direction of the electron beam. In a very simplified view, we can state that as the beam encounters more atoms along its path within the protein, the fewer electrons get into the detector, either photographic film or CCD, therefore integrating the 3D information of the molecule along the beam direction. Large collections of images from single molecules are selected and boxed out from each micrograph (after digitalization) or CCD frames (Figure 1C), which become the starting data set for image processing. These single particle images are always noisy, because low levels of electrons are used during imaging to reduce radiation damage and so minimize the destruction of the structural information. Furthermore, single particle images are intentionally under focus to secure sufficient contrast of the protein over the background, so molecules can be identified within the micrographs. Both the high noise levels and the under focus of the micrographs are responsible for the experimental limitations to reach high resolution in 3D reconstructions using EM. Consequently, the aims of image processing (Figure 1D) are 2-fold: first, to reduce the noise present in the images by averaging similar projections in 2 dimensions and, later on, into a 3D volume; second, to correct the consequences of under focus and other optical effects during the generation of images in the microscope (globally known as contrast transfer function, CTF). This second aspect of image processing will not be discussed in this review, but it has been nicely introduced elsewhere^[7,13,14]. Generally speaking, image processing in 2D is required at some stage in order to classify those images corresponding to similar projections of the molecules (therefore, similar "shape") and to align them in 2D, this is, to place them into register, so that they can be averaged pixel-by-pixel to improve their signal-to-noise ratio. How is a 3D structure then reconstructed from the 2D data recorded? It is demonstrated that 2D projections along a 3D object contain sufficient information to restore the original object if the orientation angles of each projection are known, and several algorithms and approximations can easily perform this task. For instance, in medical tomography a radiation source is used to acquire projections of the patient along a set of established directions and then a 3D reconstruction is generated. Just a word of caution to point out that several algorithms exist to reconstruct a 3D structure from its projections at known orientations and the mathematics behind them and its relevance to the correctness of the resulting structure is

Figure 1. Basic procedures used in single-particle electron microscopy (EM) and 3D reconstruction. The work carried out by our group on DNA-PKcs, a kinase implicated in DNA repair, is shown as an example throughout the whole set of figures^[33,76]. (A) Proteins must be purified to homogeneity before attempting an EM experiment because most methods are based on the assumption that the majority of collected images originate from the same specimen. (B) Proteins are adsorbed onto EM grids and observed under the electron microscope. Images from single molecules are detected over the noisy background (asterisks). (C) Micrographs are scanned and thousands of single images extracted (only a small gallery shown) and they constitute the starting data set. (D) To generate a 3D reconstruction of the target protein, the input raw images must be subjected to 2D and 3D image processing. The main purpose of image processing is the assignment to each input particle of its orientation angles, so all particles can be merged and averaged in 3D. Angular assignment is performed by a process known as “angular refinement” where projections of preliminary volumes are used as templates for alignment, classification or angular assignment. Preliminary assignments permit reconstruction of an improved 3D volume that functions as the source of more accurate template projections for the next round of refinement. As this process is repeated iteratively, angular assignment is improved and the correct 3D structure can be calculated.

not insignificant^[15-17]. In single-particle EM, different views of the same protein are contained within each micrograph as, frequently, molecules interact with the support film or are enclosed within the vitrified ice (in cryo-EM) at many different orientations. In order to generate a “correct” 3D structure, all these projections of the molecule must evenly fill Fourier space, meaning we are merging in 3D images from all possible angles. Nevertheless, there are cases where the shape of the molecule can make it mathematically redundant to collect all possible views. For instance, GroEL, a molecular chaperon made up of 2 back-to-back stacked rings can be reconstructed just from its side views because the protein

rotates along its longitudinal axis filling all Fourier space without the need to incorporate top views during image processing^[18,19]. Therefore, once a sufficient data set is collected, the only requirement to resolve the 3D structure of the protein is to establish the orientation of each projection image with respect to a common set of reference coordinates. The problem of reconstructing a volume from projections is mostly reduced to that of angular assignment. This is actually the most time- and effort-consuming task during single particle EM and the heart of the image processing itself (Figure 1D). Several software platforms are commonly used, each one with a specific vision on how to approach the problem of

angular assignment and 3D reconstruction, which in all cases incorporates some type of iterative refinement of the data (Figure 1D).

These procedures described above require images from the same molecule at the same conformation taken in several orientations. In some cases, such data cannot be collected either because the protein binds to the grid in a preferred view, or because conformational flexibility exists in the protein, and therefore different views cannot be unambiguously assigned to a specific conformation. In such situations, the random conical tilt method can deliver a 3D structure for each type of view and generate a volume without a template^[20-22].

Several commonly used software packages can do the job

Along the already relatively extended history of electron microscopy and image processing, several groups have deposited a lot of effort into the development of theory, methodological approaches, algorithms and complete platforms for the analysis of single-molecule images taken under the electron microscope. It is an outstanding effort that all microscopists should thank because they provide us with the tools we need in our everyday work. Original work by Crowther and colleagues developed the first methods to combine images of the same specimen lying at different orientations and applied them to icosahedral viruses^[23,24]. Moreover, works performed on the structural determination of viral capsids have led the way in the possibilities of 3D EM. Accordingly, in 1997 2 groups, led by Crowther at Cambridge (UK) and Steven at the National Institutes of Health in Bethesda (USA), managed to visualize secondary structural elements in the 3D structure of hepatitis B viral cores at 7.4 Å and 9 Å^[25,26], a major breakthrough at the time and the beginning of today's improvements in the EM field.

At present, some kind of implicit standard has been reached and most EM work is performed using 1 of 3 distinct software platforms: SPIDER^[27], IMAGIC^[28] and EMAN^[16]. As a note of prudence, other popular platforms and programs exist, many of them dedicated to the processing of particles with icosahedral symmetry^[29], which will not be discussed in this review. SPIDER was developed by the group of Joachim Frank in Albany (NY, USA), IMAGIC by Marin van Heel's group in London (UK) and EMAN by Steve Ludtke and Wah Chiu in Houston (TX, USA). EMAN is the most recent platform and it is available completely free of charge. More information about each package is found on their respective web sites: SPIDER (http://www.wadsworth.org/spider_doc/spider/docs/spider.html), IMAGIC (<http://www.imagescience.de/imagi/>) and EMAN (<http://ncmi.bcm.tmc.edu/ncmi/>).

Other research groups are also intensively contributing to software development and implementation for EM analysis, whose strength lies in that they mostly attend to aspects or approaches in image processing not sufficiently looked after by the previous platforms. This software can therefore add force to the potential of the most commonly used packages. This is the case with XMIPP, which includes a good repertoire of classification and alignment algorithms^[30-32] (<http://www.cnb.uam.es/~bioinfo/>), FREALIGN (<http://emlab.rose2.brandeis.edu/grigorieff/downloads.html>) designed for extracting high-resolution features at the final stages of refinement, and BSOFT (<http://www.niams.nih.gov/labbranch/labr/software/bsoft>) containing, among other tools, a good algorithm to estimate and correct the CTF of the micrographs. To this day, the most common way for EM groups to make use of all of these computational possibilities is to choose 1 or 2 of the above main platforms while using other software to complement them for specific tasks.

It is as well worth mentioning that these efforts in software development for EM processing have been matched by spectacular improvements in the programs needed to render and visualize the 3D data. Many different programs are now available, all of them very good, each displaying advantages in specific features. Just a few of the most typically used by the EM community are AMIRA (<http://www.amiravis.com/>), CHIMERA (<http://www.cgl.ucsf.edu/chimera/>), VMD (visual molecular dynamics; REF; <http://www.ks.uiuc.edu/Research/vmd/>) or PYMOL (<http://pymol.sourceforge.net/>).

In the following paragraphs I will summarize the basic features of each one of the main platforms (SPIDER, IMAGIC and EMAN)^[16,27,28], pointing out those aspects that make each software package exceptional (Figure 2). Globally, the main differences among them center on (i) the use of either single particles or their 2D averages to build the volumes; and (ii) the means for angular assignment, either "angular reconstitution" or "projection matching"^[7]. With respect to the first point, all 3 platforms use the images from single particles as input data, but only SPIDER directly utilizes these to reconstruct the volume, because both IMAGIC and EMAN classify and average single images from similar views of the protein in order to produce a 2D average with improved signal-to-noise ratio. These averages then constitute the input to reconstruct the 3D structure. With respect to the second point, and as mentioned earlier, the fundamental aspect of image processing corresponds to the determination of the orientation angle of each image (or average) with respect to

a common set of coordinates. SPIDER and EMAN define these angles by comparison with projections of preliminary volumes that act as templates of known angles. Within each cycle of refinement the reconstructed volumes and their projections are improved, so that angular assignment is also iteratively improved. This strategy is known as “projection matching”. Alternatively, IMAGIC defines orientation angles using “common lines”, an algorithm that can potentially find the angular relation between projections without additional input. I will not get into the principles that underlie common lines but this requires a high signal-to-noise ratio to diminish false solutions and, consequently, IMAGIC spends much of its efforts in particle classification, alignment and averaging. Its great conceptual advantage is that angles come directly from the data, thus the name “angular reconstitution”^[7]. Model bias in the assignment of angles is therefore greatly reduced, though some bias still exists because projections from iteratively improved 3D models are used to increase the accuracy in particle alignment and classification. It is imperative to point out that, besides these differences in the general approaches among several platforms, each of these contains the tools required to perform almost any operation with the images from the electron microscope, and are consequently intrinsically very flexible. Therefore, for instance, a “projection matching” strategy can be perfectly carried out using tools provided by IMAGIC.

Figure 2 outlines a generalised flow-through during image processing with each platform. SPIDER^[27] initiates from a rough starting model to generate projections of defined angular spacing (Figure 2A). Each single particle is compared with all projections so that it receives those angles of that template with which it better fits. This preliminary angular assignment is used to build a new 3D model that acts as a new source for projections. As this process is repeated iteratively (“angular refinement”), projections better match the real data and, at the end, the angles assigned to the particles allow reconstruction of the structure. Refinement in IMAGIC^[28] (Figure 2B), on the other hand, makes use of the projection templates just to align the particles, so classification and averaging can be iteratively improved, but angles are defined using the 2D averages and common lines. Finally, EMAN^[16] (Figure 2C) has adopted a scheme somehow in between those of SPIDER and IMAGIC. Angular assignment for each particle in EMAN is defined based in their correlation with projection templates, as with SPIDER. But instead of using particles directly to build the volumes, all particles with a similar orientation constitute a group or class to be averaged, and only these averages are then used to reconstruct a volume. The process of averaging in EMAN

incorporates a very good set of parameters that can be tuned to improve averaging and discard “bad” particles. An especially interesting feature of EMAN is that particles within a class are actually “refined” during averaging so that model bias is strongly minimised and single images with a standard deviation above a certain threshold are not incorporated into the final average. Common to all 3 systems is that either mechanism of angular assignment is repeated iteratively (angular refinement) until the angles assigned to the particles and the resulting 3D structure are stabilised. At the end, if correctly used, any of these 3 software platforms can construct an accurate structure. Nevertheless, it is extremely important to note that image processing is far from a fully automated method that does not require user intervention. On the contrary, each processing platform just provides a large number of computing tools to deal with the data from the microscope, but evaluation of the output results and decisions during processing are completely user dependent. Consequently, an inexperienced user could end up with a wrong structure.

The resolution problem or how to solve the resolution gap

Once we have the final 3D reconstruction of our macromolecule, the last stage of the research involves the in-depth inspection and description of the structure. This is a crucial step because interpretation of the 3D data is the source for the extraction of biologically relevant information, and therefore the source of our conclusions about the processes we are studying. In single-particle EM this task is problematic because the structures are solved to resolutions above those required to trace the polypeptide chain, due to the difficulties still present during averaging and alignment of the noisy images obtained with the microscope. Typically, EM analysis provides structures ranging from 8 Å–10 Å to 30 Å–40 Å resolution, and the consequences of these resolutions for the way in which a macromolecule is visualized can be perceived in Figure 3C, where I have used as an example the recent atomic model of DNA-PKcs, a kinase implicated in DNA repair^[33]. While at a resolution of 9 Å secondary structural elements, such as alpha helices, can still be distinguished in favorable cases^[19,34], at poorer resolutions (>15 Å), rarely anything more than the overall shape of the protein is apparent (Figure 3C).

To bridge the gap between the atomic information we would wish to have in our structure and the medium or low resolution of the actual EM reconstructions, 3 “multi-resolution” methods have been proposed^[35–39]. These suggest

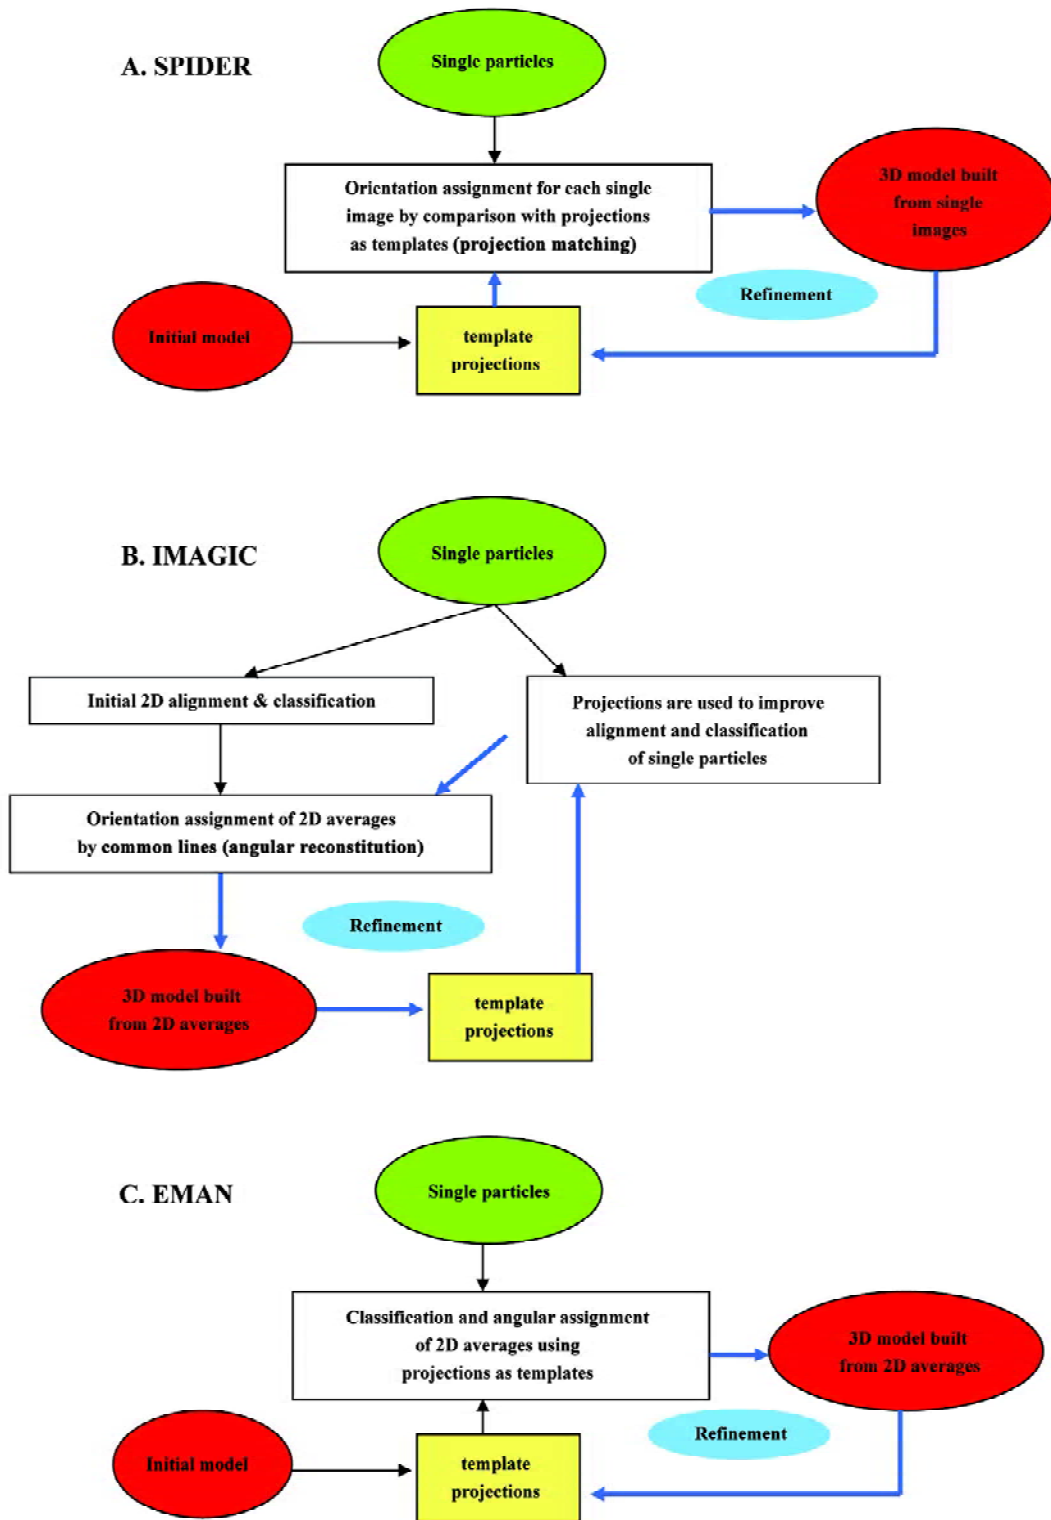

Figure 2. Several software packages exist for single-particle image processing, the 3 most widely used being: (A) SPIDER, (B) IMAGIC and (C) EMAN. Each platform deals with input images from electron micrographs as the source to build the 3D structures, but each one uses slightly different approaches to reach that goal, which have been summarized in this figure (and the text).

combining information at different levels of resolution in order to investigate complex systems.

Rigid-body fitting A medium-resolution EM structure can be depicted as a convolution of its atomic features; hence a pseudo-atomic model can be obtained by computationally placing (“fitting”) atomic coordinates into the EM map^[36]. The atomic structure is considered to be a rigid body with no conformational changes, whose density has to be located and placed within the 3D reconstruction. Rigid-body fitting is a very appropriate mode to map domains into a larger complex that contains several domains or proteins, and it has been extensively used already to propose pseudo-atomic models of macromolecular complexes. However, it is important to bear in mind that the accuracy of this computational approach can be seriously hampered by a lack of resolution of the target 3D model and by the size, shape and conforma-

tional flexibility of the fitted atomic structure. Figure 3 shows a recent example from our group where the 3D structure of the DNA-PKcs kinase^[33] was fitted with atomic structures of individual domains (Figure 3A) to produce a pseudo-atomic model for some portions of the molecule (Figure 3B). This atomic model, when filtered to the resolution experimentally obtained by EM, very much resembles the corresponding segments of the 3D structure (Figure 3C). Many other examples can be found in the recent literature where these methods have been applied^[40–42].

Several algorithms have been developed that consider different sides of the problem^[35,36], but this is still a very active field where a consensus about the best approaches has not yet been reached. Some of the most commonly used tools are those implemented in SITUS^[43] (<http://situs.biomachina.org/>), EMAN^[16] (<http://ncmi.bcm.tmc.edu/ncmi/>)

Figure 3. Multi-resolution fitting. (A) Medium- or low-resolution maps obtained by electron microscopy (EM) do not provide atomic information of macromolecules, but (B) atomic structures of parts of the proteins can be fitted into the EM density to generate a likely model at atomic resolution for parts of the macromolecule (usually referred to as “pseudo-atomic models”). (C) The consequences of the loss of resolution on the structural details that are observed in 3D EM can be shown after low-pass filtering of the atomic model in (B) at different resolutions. When the pseudo-atomic model is rendered at resolutions compatible to those of the experimentally obtained EM maps, structural resemblance between the model and the 3D reconstruction should be evident.

and EM fit^[44]. Nevertheless, other algorithms are also frequently used^[45–47]. At low resolution, several solutions could comply with our fitting criteria, so one must be cautious with the results, which, if much uncertainty persists, should ideally be supported or validated with external information.

Flexible fitting It is very likely that an atomic structure will not perfectly match one solved by EM, especially when the portion represented by the atomic structure is part of a larger complex solved by EM or it is at a different stage of its functional cycle. In such cases, and if sufficiently good resolution is present, the atomic coordinates can be modified so that they better fit into the EM density. By doing so, we can not only place a domain within a larger structure (as in rigid-body fitting), but we can also actually identify a new conformation of the protein. A nice example has been shown recently in the 6 Å structure of GroEL, where some displacement of helices were found compared to its atomic coordinates^[19]. Both SITUS^[48] and EMAN^[16] contain algorithms to perform flexible fitting.

Prediction of secondary structure elements and protein folds In those cases where the resolution of an EM map is very good (usually anything below 8 Å), instead of fitting known atomic structures, a more powerful approach can be carried out, and the actual recognition of secondary structure elements within the map can be achieved. The AIRS platform in EMAN has several commands (helixhunter, ssehunter) to look for sheets and helices in the maps. A score is supplied to help discriminate real from spurious findings. In favorable cases, a whole fold type can be defined and consequently a sufficiently realistic atomic model. A brilliant example has been recently published describing a pseudo-atomic model for the capsid of phi29 phage^[34]. Other groups are also currently working on fold predictions from EM reconstructions^[49]. Importantly, results in the area of secondary structure prediction need to be handled with great care due to the still innovative nature of this field.

Some notable recent electron microscopy studies

The last 2–3 years have been characterized by a rapid increase in EM publications. I wish to point out some significant works recently published, which have been dealing with some challenging applications of single-particle EM. These works shed light on where the field is going in the very near future. I strongly apologize to all whose work has not been reflected in this review.

Small, asymmetric and flexible proteins Certainly, EM has clear limitations with respect to the smallest size of the

molecules it can analyze. Proteins must be visualized above a noisy background to be extracted and processed, and only large macromolecules can therefore fit this criterion. There are also deeper conceptual reasons that do not allow reconstruction of very small molecules^[50]. As a result, proteins targeted by EM studies are usually above 200 kDa–300 kDa. Having said that, some recent outstanding works have challenged these difficulties and studied small proteins, many with molecular weights around, or even below, 100 kDa, and these have been reconstructed at decent resolutions (around 20 Å–30 Å): geminin^[51], separase^[11], the Arp2/3 complex^[52] and the mammalian fatty acid synthase^[53], to name a few.

A common feature of many of these proteins is that they participate in very relevant pathways in the biology of the cell (eg signaling pathways, DNA repair, oncogenes and tumor suppressors), and though they are not extremely large, they are still difficult to purify in large quantities for X-ray studies. This is the case, for instance, with Vav, an activator of Rho/Rac GTPases, whose 3D structure has been solved in the inactive and active conformations, plus a ~85 kDa truncated mutant with oncogenic potential^[12], providing insights into its regulatory mechanisms. Another remarkable example is the structure of the tetrameric KvAP voltage-dependent K⁺ channel^[54] with a mass of 100 kDa, which the authors deliberately increased up to 300 kDa by addition of 4 Fab fragments.

Generally speaking, all of these works have the challenging difficulty of collecting good microscopy data and being able to correctly align images of small molecules, which, on top of that, frequently display no symmetry at all. But an even further twist to these already difficult experiments comes when the protein under study is flexible; several conformations are present in the same micrographs whose identification is not always straightforward. In some of these cases, the method called “random conical tilt”^[20,22] (developed some time ago to obtain 3D structures from proteins bound to the EM grids with preferential views) might be the only tactic available to solve these structures without mixing several conformations. In this regard, it is worth taking a look at some recent excellent works by Tomas Waltz’s group^[55,56]

Structures of the ribosome The complex structure of the ribosome and the process of mRNA translation have been extensively studied by several groups in the last decade. These authors regularly provide structures at resolutions better than 12 Å and the wealth of biological information obtained by combining EM and X-ray crystallography of the ribosome is unprecedented. Two groups have been leading this research: Joachim Frank at Albany (NY, USA)^[57–61] and Marin van Heel at London (UK)^[62–64].

Multi-protein macromolecular complexes or “molecular machines” The natural targets of EM are those complexes that contain several proteins, are very large in size, are heterogeneous in their composition, have complex functional cycles and are difficult to purify; all of these qualities making complicated a traditional analysis by crystallography or NMR. Interestingly, these large and transient complexes, sometimes named “molecular machines”, have been admitted by modern biology to comprise the basics for a major number of cellular processes, and are therefore a subject of great interest. Some EM works have started to obtain 3D information on some of these complexes, such as the spliceosome (implicated in mRNA splicing)^[65–68], the SAGA complex from *Saccharomyces cerevisiae*^[69], the apoptosome involved in procaspase-9 binding and activation during apoptosis^[70], and several complexes between chaperonins with their substrates and co-chaperons^[71–74].

DNA-bound protein complexes Determination of the 3D structure of complexes between proteins and DNA substrates has been accomplished, for instance, the large T antigen bound to the simian virus 40 origin of replication^[75], the DNA-PKcs kinase bound to a double-stranded DNA fragment that simulates a DNA repair signal^[33,76], and the clamp-loading complex for DNA replication^[77].

High resolution structures Averaging of the noise images from single-particle EM has the potential to deliver 3D structures with a resolution sufficient to trace the polypeptide chain^[50]. A Nature paper published in 2003 on the flagellar structure^[78] demonstrated that if good single images can be accurately aligned, they are able to deliver atomic information. The authors made use of a trick to align the images according to their regular arrangement within the flagella. Nevertheless, the outstanding merit of the work was that no diffraction information was used during their processing. It seems clear that reaching very high resolution will only be possible for adequate specimens of large size, high symmetry and by means of high-quality (ie high signal-to-noise ratio) images, derived probably from helium-cooled microscopes. However, the race is on to increase the resolution of single-particle reconstructions both with improved equipment and better algorithms. Some recent examples are the GroEL structure at 6 Å^[19] using EMAN, the *Escherichia coli* large ribosomal subunit at 7.5 Å^[79], and the 8 Å resolution structure of microtubules^[41] using SPIDER.

Other noteworthy works Other recent studies of special interest have been the definition of the structural basis of pore formation by the bacterial toxin pneumolysin, by the group of Helen Saibil^[80], and the pseudo-atomic model of the capsid of phage phi29^[34].

Future prospects and limitations of single-particle electron microscopy

Single-particle EM analysis has become a trendy structural tool in biology despite not providing atomic resolution information. This is due to some of the great advantages of this method in comparison to more established atomic resolution techniques: (i) small amounts of purified protein are required, compatible with those ordinarily obtained for large macromolecules or multi-subunit protein complexes, possibly its key advantage when compared to crystallography and NMR as EM can deliver biological information from modest quantities of material; (ii) macromolecules are trapped in their native conformation in physiological buffers; and (iii) preparations containing mixed populations or contaminated samples could be potentially analyzed whenever the distinct populations can be separated, either visually or computationally. Consequently, single-particle EM is a technique very suitable for determining the 3D structure of large macromolecule complexes (“molecular machines”), which are now known to be implicated in many cellular processes. This is so because macromolecular complexes can be very large and challenging to crystallize; they can frequently be purified only in modest quantities, while at the same time being very flexible and of variable composition.

Future developments of the technique are being directed toward improved resolution and a more profound examination of the volumetric data by either the fitting of atomic structures or the identification of folds. All of these advances will require new methods now under development^[7,13,81]. Automation of data collection and analysis is also becoming an important goal for EM. The long learning process needed to properly operate a modern electron microscope, to collect good-quality data and to perform a flawless image processing means that only those with extended experience in EM can really do the job. Hence, making as many of those processes as automatic as possible is a great need for the future development of EM, especially when collecting the many thousands of single images needed when high resolutions are the goal. Some interesting approximations are already under development^[82–87], and there are no serious conceptual reasons why automation of the most repetitive microscope tasks should not be achieved in the near future. However, one of the more important challenges for the future will be to deal with conformational flexibility and the heterogeneity of large protein complexes. As resolution increases, more data on identical conformations must be averaged, but the better the resolution, the more likely it is that molecules will differ in their exact conformation.

Suggested solutions implicate the refinement of the data into more than one possible 3D volume and the exploration of the conformational space of a protein using normal-mode analysis^[88–91].

Still, EM analysis presents some important limitations that are essential to keep in mind. To begin with, the methods we use today are still very much dependent on the expertise of the user to deliver the correct structure, especially when dealing with small and low-symmetry molecules or heterogeneous samples. Things can be done wrong, and an inexperienced user can end up in local minima not representing the real 3D structure. Consequently, a great challenge for the near future should be to standardize methods and controls as is done in modern X-ray crystallography. A further limitation to the method is that, in some cases, structures of macromolecular complexes are solved only to moderate resolutions, which might provide few or no biologically relevant information, especially when no atomic data of any part of a complex is known. Nevertheless, in these cases, EM structures can still be interpreted by calculating difference maps among several reconstructions to then determine the position of components in the complex. Besides these limitations, single-particle EM will certainly cope with its future challenges to become a widespread method to study the 3D structures of macromolecules in conjunction with other structural techniques.

Acknowledgement

I greatly acknowledge the constant support by Laurence H Pearl at the Institute of Cancer Research (London, UK) in the DNA-PK work presented in the figures of this review. I am also very thankful for the work of Angel Rivera-Calzada and Ernesto Arias-Palomo in my lab. I apologize to all those groups working in the EM field whose studies have not been reflected in this mini review, which was just intended as an initiation for those outside of our discipline.

Abstract

AIDS is presently treatable, and patients can have a good prognosis due to the success of highly active antiretroviral therapy (HAART), but it is still not curable or preventable. High toxicity of HAART, and the emergence of drug resistance add to the imperative to continue research into new strategies and interventions. Considerable progress in the understanding of HIV attachment and entry into host cells has suggested new possibilities for rationally designing agents that interfere with this process. The approval and introduction of the fusion inhibitor enfuvirtide (Fuzeon) for clinical use signals a new era in AIDS therapeutics. Here we review the crucial steps the virus uses to achieve cell entry, which merit attention as potential targets, and the compounds at pre-clinical and clinical development stages, reported to effectively inhibit cell entry.

Introduction

Acquired immunodeficiency syndrome (AIDS) was recognized in 1981, and the first human immunodeficiency virus (HIV) was isolated 2 years later, heralding a new era in the fight against pathogenic viruses^[1,2]. Since then, HIV infection has become a major public health problem worldwide, with an estimated 39.4 million infected people as at the end of 2004 (Table 1)^[3]. According to the Joint United Nations Programme on HIV/AIDS (UNAIDS) epidemic update, in 2004 there were more than 3.1 million AIDS deaths, including 500 000 children under 15 years of age^[4]. The prevalence of HIV-1 is greater in developing countries, and especially in Sub-Saharan Africa, where the infrastructure to prevent and treat the infection is limited^[5]. These “hotspots” absorb most of the attention of international committees and organizations, and a significant part of the funding for AIDS prevention and treatment goes towards attempting to scale up antiretroviral (ARV) therapy in developing and transitional countries^[6].

HIV is a lentivirus that is predominantly transmitted by sexual contact, as virus particles can cross the mucosal epithelium and infect specific cells^[7,8] expressing the CD4 receptor. Cells bearing CD4 receptors on their membrane belong to the macrophage/monocyte lineage and to a subset of T-cells^[9,10]. Initial indications were that HIV-1 used

only CD4 to identify and enter the target cells. Soon, however, it became apparent that additional co-receptors were probably required in order for the virus to complete cell entry. Subsequently, several such potential co-receptors were proposed^[11,12], but the CCR5 and CXCR4 chemokine receptors are today considered to be the major co-receptors for HIV-1 entry^[13–15]. T-cell tropic HIV strains use mainly CXCR4 as a co-receptor and are called X4 strains, whereas macrophage-

Table 1. Worldwide distribution of estimated number of people living with HIV^[4].

Region	Estimated number ¹⁾
North America	1.0 million (540 000–1.6 million)
Caribbean	440 000 (270 000–780 000)
Latin America	1.7 million (1.3–2.2 million)
Western and Central Europe	610 000 (480 000–760 000)
Eastern Europe and Central Asia	1.4 million (920 000–2.1 million)
North Africa and Middle East	540 000 (230 000–1.5 million)
Sub-Saharan Africa	25.4 million (23.4–28.4 million)
East Asia	1.1 million (560 000–1.8 million)
South and South-East Asia	7.1 million (4.4–10.6 million)
Oceania	35 000 (25 000–48 000)

¹⁾The ranges around the estimates define the boundaries within which the actual numbers lie based on the best available information^[4].

tropic strains, responsible for host-to-host transmission, use CCR5 as a co-receptor, and are referred to as R5 strains. Thus, macrophages are the principal targets for the establishment of the infection in new individuals^[16]. Although it is not always the case^[17,18], the transition from viral isolates that use the CCR5 receptor to isolates that use the CXCR4 receptor has been linked with the transition from the latent asymptomatic phase to the clinical manifestations associated with AIDS^[19,20].

The most striking feature of HIV-1 infection is the gradual depletion of circulating CD4⁺ T cells, which leads to increased sensitivity of the patient to opportunistic and chronic infections and to oncogenesis. The cause of the CD4⁺ T cell depletion is still under debate^[21–23]. It is generally accepted, however, that during the asymptomatic phase the daily replenishment rate of CD4⁺ T cells is much higher than the turnover of infective virus particles for the cytopathicity model to explain the progressive depletion of CD4⁺ T cells from circulation^[24]. An alternative hypothesis proposes that certain viral components contribute to dysfunction of a vital immune mechanism^[25].

Over the past 23 years, the main objective in the field of HIV research has been the discovery of drugs that will combat the disease. Satisfactory progress has already been made and there are now more than 20 anti-HIV drugs approved by the American Food and Drug Administration (FDA)^[26]. ARV drugs are categorized according to their mode of action into three main groups: 1) the nucleoside reverse transcriptase inhibitors (NRTI); 2) the non-nucleoside reverse transcriptase inhibitors (NNRTI)^[27,28]; and 3) the protease inhibitors (PI)^[29]. ARV drugs from these categories are now administered in combination (as cocktails) to produce more efficient treatment^[30]. This type of therapy, termed “highly active antiretroviral therapy” or HAART, has markedly decreased mortality and morbidity in the developed world. Efforts have been made by the World Health Organization (WHO) and UNAIDS

to substantially increase the number of people on HAART in developing and transitional countries^[6].

Despite the fact that current antiviral treatments have improved prognosis, drug resistance and high toxicity are serious limitations to current treatments that justify the continuation of research efforts for new strategies and interventions^[31,32]. Today, AIDS is treatable, and patients can have a good prognosis, but it is still not curable. A new generation of drugs was recently introduced that inhibit viral cell entry (to be discussed later). HIV entry inhibitors appear to be a rational step forward in ARV therapy, because they prevent the virus from infecting new host cells, and may potentially stop or significantly limit HIV transmission^[33–35]. In order to rationally design effective drugs, the pathophysiology of HIV must be better understood for ARV therapy research to target specific events in the biology of the virus within the host cell^[36,37].

HIV entry

HIV-1 predominately infects cells that have the CD4 receptor on their surface membrane, although this is not always the case^[38,39]. Achievement of infection of these cells involves three discrete steps: viral attachment, then co-receptor binding, and finally fusion (see Figure 1). Recognition of the “correct” target cell and attachment to it is primarily achieved through envelope glycoprotein gp120, which binds to CD4 molecules. Gp120 is generated within the infected host cell after cleavage of gp160 by cellular proteases into two functional proteins: gp120 and gp41. It consists of 5 variable (V1–V5) and 5 conserved (C1–C5) regions^[40]. Gp120 and gp41 are glycosylated in the Golgi apparatus, and then transported to the membrane that is later incorporated in the viral envelope during the budding of the viral particles to form mature viruses^[41]. The envelope membrane is studded with trimers of gp120-gp41 heterodimers, where gp41 forms

Figure 1. Schematic representation of the mechanism for HIV-1 cell entry.

the cytosolic part and gp120 the extracellular part^[42].

Binding of viral gp120 to host cell CD4 is achieved through interactions of several conserved gp120 residues with the second complementarity-determining region (CDR2) of CD4^[43,44]. This interaction alone is not sufficient to achieve cell entry, but it is necessary in order to identify the target cell and also to increase the affinity of other viral components for the co-receptor molecules. Indeed, binding of gp120 to CD4 causes conformational changes to the variable loop regions V1/V2 and V3 of gp120, causing the V3 loop to evaginate, thus becoming exposed to the co-receptors^[45] (Figure 1). The major co-receptors that HIV-1 uses are the CCR5 and CXCR4 chemokine receptors. The exact mechanism of interaction between the variable loop regions V1/V2 and V3 and the chemokine receptors is not well understood and it merits a more detailed investigation. It has been suggested, however, that the interaction between V3 and CCR5 is ionic in nature, and results in enhancement of the process of activation-induced cell death of responding effector CD4⁺ T cells during antigen presentation^[22,46,47].

The final step for viral entry requires fusion of the viral envelope components with the target surface membrane; this is achieved with the use of gp41, which is a glycoprotein consisting of 3 main domains: an intracellular domain (endodomain), a transmembrane anchor and an extracellular domain (ectodomain). The ectodomain is the key structure responsible for fusion and consists of a hydrophobic fusion peptide sequence at the N-terminal, two hydrophobic heptad repeats (HR1 and HR2) at the C-terminal, and a hinge region, where a disulfide-bond loop is formed between the two heptad repeats during fusion^[48,49]. On binding of gp120 to CD4 and subsequently to the co-receptor, further conformational changes occur that lead to gp41 dissociation from gp120. The gp41 unfolds and the hydrophobic fusion peptide sequence extends out of the viral membrane towards the host cell membrane. Insertion of the fusion peptide into the host cell membrane leads gp41 to fold into a hairpin-like structure where the two hydrophobic heptad repeats (HR1 and HR2) lie antiparallel, forming a 6-helix bundle^[50,51]. This hairpin structure is believed to be responsible for the fusion of the HIV envelope to the host cell membrane.

Enfuvirtide: the first FDA-approved fusion inhibitor

Enfuvirtide (formerly known as T-20) is the first fusion inhibitor approved by the FDA and the European Commission for the Treatment of AIDS, and is available under the trade name Fuzeon (Trimeris and Roche). It is a 36 amino

acid synthetic peptide homologous to the HR2 region of gp41 (residues 127-162)^[52,53], that has the ability to interfere with the fusion pathway by mimicking the HR2 domain^[54]. The accepted mode of action proposes that enfuvirtide targets conformational changes during fusion by binding to the HR1 domain. Recent evidence indicates that enfuvirtide interacts with multiple sites in gp41 and gp120^[55]. This binding prevents the formation of the 6-helix bundle by preventing HR2 from refolding antiparallel to HR1^[56,57]. Thus, inhibition of fusion of the viral envelope to cell membranes is achieved by blocking a critical step in the fusion pathway (Figure 2).

In the initial stages of discovery, enfuvirtide appeared to inhibit HIV-1 replication very effectively in various cell types and clinical trials proved to be very promising. Phase I/II trials provided proof that HIV entry was inhibited after treating patients with 100 mg enfuvirtide twice daily for 14 d. The levels of plasma HIV RNA after 14 d of treatment demonstrated a 1.96 lg median decline^[58]. Phase II clinical trials were performed on 71 HIV-infected individuals who were treated with 50 mg enfuvirtide together with other ARV drugs for 48 weeks. There was a 1.0 log₁₀ decline from baseline in HIV RNA and a median gain of CD4 cell counts of 84.9 cells/ μ L, with no significant toxicity^[59].

Furthermore, two TORO (T-20 vs Optimized Regimens Only) Phase III clinical trials were performed in America (TORO 1) and in Europe and Australia (TORO 2). The trials had similar protocols: they compared the efficacy and safety of enfuvirtide plus an optimized antiretroviral regimen with the efficacy and safety of an optimized antiretroviral regimen alone^[60,61]. In both studies the least-squares mean change from baseline in the plasma viral load indicated a significant difference in the decrease in the enfuvirtide group compared with the control ($P < 0.01$). In the same way, the mean count of CD4 cells/mL was significantly greater in the enfuvirtide group compared with the controls ($P < 0.01$).

Further studies are currently being performed on the exact metabolic pathway of enfuvirtide, potential drug resistance problems, and identification of synergistic interactions with other drugs. Several reports concluded that enfuvirtide does not appear to interfere with the activities of cytochrome P450, probably because it is a peptide and is easily hydrolyzed in the body^[62,63]. Enfuvirtide was found to act synergistically with other potential entry inhibitors *in vitro*, such as AMD3100 and PRO542, producing results that encouraged the use of combinations of entry inhibitors as part of a new generation of ARV strategies^[64,65]. However, HIV resistance has been reported in patients treated with enfuvirtide, indicating a hotspot from codons 36 to 38 of the HR1 domain^[66],

Figure 2. Mechanism of inhibition of HIV fusion to the cell membrane by enfuvirtide.

as well as other sites in gp41^[67–69]. Additionally, primary resistance has been reported, which appears to be more frequent than predicted^[70], indicating that more research is needed in this field.

Enfuvirtide obtained accelerated approval by the FDA in 2003 and became the 17th licensed ARV drug and the first to inhibit HIV entry. The drug is supplied as a lyophilized powder in single-dose vials containing 108 mg of the drug. Reconstitution of the powder in 1.1 mL sterile water for injection produces a single dose of 90 mg/mL^[71] that is injected subcutaneously. Enfuvirtide has two currently known major drawbacks. First, being a peptide, it can only be administered by injection and not orally. This makes usage more difficult, because patients must be educated for self-administration. Second, the cost of enfuvirtide is high, because it is a synthetic peptide that is manufactured by a highly complicated process involving large amounts of raw materials^[72,73]. It is estimated that the annual cost of enfuvirtide therapy is approximately US\$20 000 per patient, and if taken in combination with other ARV drugs then the cost of therapy could approach US\$30 000.

Potential drugs targeting entry and fusion

Attachment inhibitors Current novel antiretroviral drugs aim to interfere with the crucial HIV entry steps: viral attachment, co-receptor binding and fusion. One approach for interfering with viral attachment involves the use of a tetravalent fusion protein construct, consisting of a human

IgG2 in which the Fv portions of both the heavy and light chains have been replaced with the D1 and D2 domains of human CD4^[74,75]. This CD4-immunoglobulin fusion construct, called PRO 542, is suggested to bind to the viral gp120 and thus prevent the virus from interacting with CD4-bearing host cells. Phase I clinical trials indicated that PRO 542 has a half-life of 3–4 d when a relatively high dose was used (10 mg/kg), and no dose-limiting toxicities were observed^[76]. In addition, in phase II clinical trials, 12 HIV-infected patients were treated with 25 mg/kg single-dose PRO 542. The drug was well tolerated and the acute reduction caused in the HIV-1 RNA was statistically significant, even in patients with advanced AIDS^[77].

In the same way, several other compounds target either the gp120 or the CD4 receptor and interfere with HIV attachment. FP-21399 is a bis(disulfonaphthelene) derivative that binds to gp120, most probably near the third variable domain, because interactions with antibodies against the V3 loop region were blocked^[78]. A phase I study showed that it caused an increase in CD4 cell counts, and a significant decrease in viral load and minor side effects^[79]. BMS-378806, a 4-methoxy-7-azaindole derivative, is a compound that can be administered orally, and was developed by Bristol Myers Squibb^[80,81]. Despite the fact that phase I and II studies showed promising results, Bristol Myers Squibb decided to investigate similar drugs such as BMS-488043, an analogue of BMS-378806, in order to optimize its effectiveness^[82]. A series of polyanionic compounds, for example dextrin-2-sulfate, Carraguard and PRO 2000 are in clinical trials, and

are designed to be topically administered^[83–85]. Finally, TNX-355, a humanized anti-CD4 mAb that binds to CD4 without interfering with its biological function, significantly decreased viral load and increased CD4 cell counts in a phase I trial^[86].

Co-receptor binding inhibitors The most interesting target in HIV entry is the co-receptor binding phase. Current drug research is focused on designing compounds that prevent the virus interacting with the chemokine receptors. The CCR5 receptor is the principal target, and a number of potential drugs are currently being studied. SCH-C is a small molecule that inhibits the binding of gp120 to CCR5, and initial *in vitro* experiments have indicated good inhibitory activity against R5 viruses as well as synergistic effects with several ARV drugs, including enfuvirtide^[87,88]. Although it can be administered orally and clinical studies showed decreased viral loads, electrocardiographic anomalies due to arrhythmias were reported at high dosages^[89]. Another compound, SCH-D, has been found to have greater *in vitro* and *in vivo* antiviral properties, with no apparent side effects. Clinical studies for this drug are still ongoing^[90]. Interestingly, it was recently reported that V3-like peptides from X4 strains with more electropositive V3 domains were effective antagonists and potential infectivity blockers of R5 variants^[91].

TAK-779 was the first non-peptidic molecule found to inhibit co-receptor attachment by binding to CCR5 at transmembrane helices 1, 2, 3, and 7^[92,93]. It has the disadvantage of intravenous administration and because of irritations observed at the injection site, its development was discontinued. It was replaced by another compound, T-220, which can be administered orally, and shows promising anti-R5 HIV activity^[94]. Similarly, UK-427,857 is a novel CCR5 inhibitor that has acceptable pharmacokinetic and metabolic rates in mice, rats, dogs and humans, and can be administered orally^[95]. Finally, PRO 140 is one of the few monoclonal antibodies that has been used as an entry inhibitor and has been reported to block co-receptor attachment without down-modulating or inducing signaling of the CCR5 chemokine receptor^[96,97].

CXCR4, the second major HIV co-receptor, is also a target for current drug research. AMD-3100, one of the first entry inhibitors, was found to inhibit viral entry well before the discovery of co-receptor usage by HIV^[98]. It is a bicyclam compound of low molecular weight that inhibits the electrostatic interaction between CXCR4 and gp120 by ionic binding to the second extracellular loop (ECL2) and the adjacent membrane-spanning domain (TM4) of the CXCR4 receptor^[99]. Despite the fact that in phase I and II clinical trials, intravenous administration of AMD-3100 significantly reduced the

viral load^[100], it was later replaced by an orally available compound, AMD-070. A non-peptidic compound, KRH-1636, which is absorbed through the duodenum, had similar efficacies to AMD-3100^[101]. Finally, T-22 and ALX40-4C are positively charged peptides that occupy the V3 region and competitively inhibit binding of gp120 to the negatively charged amino acid residues on CXCR4^[102–104].

In conclusion, the role of the V3 region in the mechanism of cell attachment and entry in relation to the major co-receptors is being actively pursued. In addition to biological studies, physicochemical studies on the interacting protein domains are being carried out in an attempt to decipher the interface conformations between the virus and the cell^[105].

Fusion inhibitors Understanding the mechanism of fusion of the viral envelope with the host membrane played a crucial role in the development of new generation ARV drugs. This became apparent when enfuvirtide was licensed as the first viral entry inhibitor, and it is currently used in HAART. Resistance to enfuvirtide has been reported, which has led to the design of a second generation HR2 mimetic peptide. T-1249 is a 39-L-amino acid synthetic peptide that contains a pocket-binding sequence that makes the HR1 and HR2 interaction more stable. Studies on T-1249 showed that it has greater efficacy and longer half-life than enfuvirtide. Additionally, efficacy against enfuvirtide-resistant viruses has been reported, indicating that this second generation fusion inhibitor is a step forward^[106,107]. However, Roche and Trimeris decided to halt clinical development due to formulation concerns^[108].

5-Helix is a newly designed recombinant C-peptide that consists of 5 of the 6 helices that are formed during the fusion phase. A CHR domain is missing for the 6-helix bundle formation, and thus there is one exposed groove. This groove binds to a CHR domain in gp41 and inhibits fusion of the viral membrane to the host membrane^[109]. Because it is a recombinant peptide, it has a much lower cost of production compared with the synthetic enfuvirtide. Initial studies demonstrated potent antiretroviral activity, with IC₅₀ values in the low nanomolar range^[110].

Finally, N-peptides represent another group of peptides with potential inhibitory effects against HIV entry. Initial studies have indicated that they are weaker inhibitors than the C-peptides, with IC₅₀ values in the micromolar range. However, chimeric molecules composed of soluble trimeric coiled coils have shown promising results. IQN17 is one of the first such peptides with potent inhibitory effects, and the current most potent chimeric N-peptide, IQN23, is reported to have an IC₅₀ value of 15 nmol/L^[111].

Conclusion

Antiretroviral chemotherapy has recently acquired a new “weapon” in the fight against AIDS. Enfuvirtide is the first HIV entry inhibitor that was approved by FDA, and it is currently used in combination with other ARV drugs. Results from clinical trials indicated that it had potent activity against HIV strains that are resistant to other ARV drugs, although some resistance to enfuvirtide has been reported. The design of other entry inhibitors has moved forward, and every phase of HIV entry is actively pursued as a target for potential inhibitors. Probably the most exciting prospect is potential interference with co-receptor usage, particularly that of CCR5.

ARV drug development aims to produce drugs with potent antiretroviral activity, with IC_{50} values in the nanomolar range, with no or limited toxicity and that can be administered orally. Several compounds are currently in clinical trials, and we are optimistic that new, more effective drugs will be added to the ARV armory.

Perfect high throughput screening assay: a crucial technique for drug discoveryGuan-hua DU¹*Institute of Materia Medica, Peking Union Medical College & Chinese Academy of Medical Sciences, Beijing 100050, China*¹ Correspondence to Prof Guan-hua DU. Since being developed approximately 20 years ago, high throughput screening (HTS) has become one of the key techniques used in drug discovery^[1]. However, three main problems are recognized with the use of HTS; namely, with the compound library, drug targets, and assay methods. Until now, the compound library has evolved based on the techniques of combinatorial chemistry and modern phytochemistry. Several functional proteins have emerged following the advance of genomics and proteomics. However, although many functional proteins have been discovered recently, they are not, as sometimes claimed, real drug targets; at best, they might be potential drug targets. The ideal targets selected for drug screening should qualify as drug targets^[2]. The selection of targets for drug screening is a crucial procedure in drug screening.

However, the main problem for drug discovery is in finding drugs or candidates based on the targets and compounds^[3]. There are many different techniques used in drug discovery, such as virtual screening, and computer aid molecular design. However, all of the active compounds should be evaluated using biological methods. Therefore, establishing a novel biological assay is very important for drug screening in HTS. The assays used in HTS require high sensitivity and high stability, and must be performed automatically. The homogeneous assay is a simple and useful method for drug screening. It is suitable for automatic performance and can enhance the efficiency of screening, especially in HTS. Therefore, the homogenous system has become the favored technique in HTS.

The basic goal of small-molecule screening is to identify chemically "interesting" starting points for elaboration towards a drug^[4]. The establishment of new screening assays will promote the discovery of lead compounds or candidates^[5]. The HTS has been used in China since 1998 and, since then, experts have attempted to resolve some key problems with

HTS, such as with target validation, compound collection, and assay establishment^[6]. In the current issue of *Acta Pharmacologica Sinica*, Dr Ming-wei WANG *et al.* introduced a homogeneous high throughput drug screening assay based on scintillation proximity assay technology for the identification of ligands of subunit acetylcholine receptors^[7]. This assay is not only in a homogeneous system, but has a new target, a subunit of the acetylcholine receptor. The assay of homogeneous binding for $\alpha 4\beta 2$ nicotinic acetylcholine receptor is a new assay for HTS to screen for ligands of $\alpha 4\beta 2$ nicotinic acetylcholine receptors. This assay, with state-of-the-art design and interesting targets can be performed easily and automatically. The lead compound is valuable for new drug development and might also be used for validating the functions of the $\alpha 4\beta 2$ nicotinic acetylcholine receptor. Screening with this assay might help us find new drugs with new mechanisms.

Abstract

Aim: To develop a homogeneous high-throughput screening (HTS) assay based on scintillation proximity assay (SPA) technology for identification of novel $\alpha 4\beta 2$ nicotinic acetylcholine receptor (nAChR) modulators. **Methods:** Membrane preparation of HEK293 cells expressing $\alpha 4\beta 2$ nAChR, [³H]cytisine and wheat germ agglutinin (WGA)-coupled microbeads were used to develop an HTS assay based on SPA technology. This method was validated against a conventional filter binding approach and applied to large-scale screening of a library containing 32 000 synthetic compounds. Intracellular calcium measurement was carried out to verify the bioactivities of the hits found by the SPA assay. **Results:** IC₅₀ values of 2 reference compounds (epibatidine and RJR 2403) determined by SPA and filter binding methods were comparable and consistent with those reported elsewhere. A total of 54 compounds, showing more than 60% competitive inhibition on [³H]cytisine binding to $\alpha 4\beta 2$ nAChR, were identified initially following an HTS campaign. Secondary screening confirmed that 17 compounds with novel chemical structures possessed relatively high binding affinity to $\alpha 4\beta 2$ nAChR ($K_i < 2 \mu\text{mol/L}$). Eight compounds displayed antagonistic effects with >50% inhibition on ABT-594-induced calcium mobilization while none showed any agonist activity. **Conclusions:** This homogeneous binding assay is a highly efficient, amenable to automation and robust tool to screen potential $\alpha 4\beta 2$ nAChR modulators in an HTS setting. Its application may be expanded to other membrane receptors and ion channels.

Introduction

Nicotinic acetylcholine receptors (nAChR) are excitatory ligand-gated ion channels mainly distributed in the central and peripheral nervous systems, neuromuscular junctions and adrenal glands^[1]. The nAChR channel complex is composed of 5 protein subunits, which form a pore that is permeable to Na⁺, K⁺, and Ca²⁺. To date, α , β , γ , δ , and ϵ subunits have been cloned, with 9 different α and 4 varieties of β subunits identified^[2]. The $\alpha 4\beta 2$ is the predominant nAChR subtype in the mammalian brain and has a high affinity for nicotine. nAChR consisting of $\alpha 4$ and $\beta 2$ subunits modulates neurotransmitter release and plays a direct role in nico-

tine addiction. This group of nAChR was implicated in the pathological pathways of Alzheimer disease, Parkinson disease, schizophrenia, epilepsy and pain^[3].

The anti-nociceptive effects of (–)-nicotine have been known for over 60 years. This non-selective nAChR agonist could not be applied as an analgesic agent due to serious adverse events. Although (–)-epibatidine is a highly selective $\alpha 4\beta 2$ nAChR agonist that displays a more potent analgesic activity than morphine in nociceptive tests^[4], toxicities in the cardiovascular and central nervous systems rendered it unsuitable for therapeutic use^[5]. Therefore, a primary goal in the development of novel analgesic agents based on $\alpha 4\beta 2$ nAChR is to discover subtype-specific ago-

nists with less liability.

An accurate and robust receptor-binding assay is highly desirable to screen a large collection of chemical entities. Associated techniques are generally based on absorbance, fluorescence and radiometric assays. Scintillation proximity assay (SPA), because of its simplicity and high-throughput nature, has broad applications in measuring receptor-ligand interactions and enzyme reactions. Conventional filter binding assays involve 1 or more separation steps and, thus, are laborious, non-homogeneous and not suitable for automation. SPA technology^[6], on the other hand, provides a homogeneous screening approach that does not require post-reaction liquid handling steps and is well suited to automation and high-throughput screening (HTS). Briefly, the receptor is anchored to a scintillant-impregnated microbead. When an isotope (eg, [³H]) is brought very close to the microbead by binding to its surface, it activates the scintillant leading to light emission. Because the emitted β particles or auger electrons can only travel short distances in the bulk solution, the microbead preferentially captures electrons from the bound radiolabeled ligand. Therefore, the amount of light emitted from the scintillant in the microbead is directly proportional to the amount of bound radiolabeled ligand. In the present paper, we describe a simple SPA method to assess specific binding properties of various known ligands to $\alpha 4\beta 2$ nAChR. It was further validated and optimized in the context of HTS for a library containing 32 000 synthetic compounds. More than a dozen compounds with novel chemical structures were found to have relatively high binding affinity to $\alpha 4\beta 2$ nAChR and 8 of them showed significant antagonist activities in a functional assay.

Materials and methods

Reagents Potassium chloride, sodium phosphate monobasic anhydrous, and magnesium chloride hexahydrate were purchased from Shanghai Chemical Co (Shanghai, China). Aprotinin and leupeptin were purchased from Merck KGaA (Darmstadt, Germany). RJR 2403 and epibatidine were purchased from Sigma-Aldrich (St Louis, MO, USA). [³H] Cytisine (37 Ci/mmol) was obtained from Amersham Biosciences UK (Buckinghamshire, UK). FlashBlue™ GPCR beads, Isoplate™ and Filtermat B made of glass fiber were bought from PerkinElmer Life and Analytical Sciences (Boston, MA, USA).

Cell culture and membrane preparation The full-length cDNA of the $\alpha 4$ (GenBank Accession No. U62437) and $\beta 2$ (GenBank Accession No. U62437) subunits of nAChR were cloned into pcDNA3.1 (Invitrogen, Carlsbad, CA, USA) and

pIRESpuro2 (BD Clontech, Mountain View, CA, USA), respectively. They were subsequently cotransfected into HEK293 cells and clones stably expressing $\alpha 4\beta 2$ nAChR were selected and characterized by calcium mobilization assay^[7]. The cells were maintained in Dulbecco's modified Eagle's medium (DMEM) (Sigma) containing 10% fetal calf serum (FCS) in the presence of penicillin (100 mg/L), streptomycin (100 mg/L), G418 (400 mg/L) and puromycin (5 mg/L) at 37 °C in a humidified atmosphere of 5% CO₂. For membrane preparation, cells were treated with 0.25% trypsin (Sigma) for 5 min and centrifuged at 1000×g for 10 min. The pellets were resuspended in hypotonic buffer [50 mmol/L Tris-HCl, pH 7.5, 5 mmol/L ethylenediaminetetraacetic acid (EDTA)] and homogenized with a BioNeb® cell disruption system (Glas-Col, Terre Haute, IN, USA) followed by centrifugation at 1200×g, 4 °C for 20 min to precipitate nuclear debris. The supernatant was then centrifuged at 20 000×g for 30 min to pellet the membrane. The latter was resuspended in 50 mmol/L Tris-HCl, pH 7.5, 5 mmol/L EDTA with 30% (w/v) sucrose. The protein content was determined using a spectrophotometer (Thermo Electron, Waltham, MA, USA).

Filter binding assay Various amounts of the above membrane receptor preparation, 3 nmol/L [³H]cytisine and different concentrations of known ligands to $\alpha 4\beta 2$ nAChR were added to the binding buffer (50 mmol/L Tris HCl, 120 mmol/L NaCl, 5 mmol/L KCl, 1 mmol/L MgCl₂, 2.5 mmol/L CaCl₂, pH 7.4) to give a final volume of 0.1 mL. After incubation at 4 °C for 8 h, the membrane fraction was harvested on the Filtermat B presoaked with a solution consisting of the washing buffer (50 mmol/L Tris HCl, pH 7.4) and 0.5% (v/v) polyethyleneimine. The Filtermat B was washed 3 times with the washing buffer and dried at 55 °C for 45 min before counting on a Microbeta scintillation counter (PerkinElmer). Non-specific binding activity was determined in the presence of 2 μ mol/L epibatidine.

SPA binding assay Various amounts of the above membrane receptor preparation, 3 nmol/L [³H]cytisine, FlashBlue™ GPCR beads (62.5 μ g/well) and different concentrations of known ligands to $\alpha 4\beta 2$ nAChR were added to the binding buffer to give a final volume of 0.1 mL. The plates were incubated at 4 °C for 12 h and centrifuged for 3 min at 2500×g before counting on the Microbeta scintillation counter.

Calcium mobilization assay The above cells expressing $\alpha 4\beta 2$ nAChR were detached and loaded with 5 μ mol/L Fluo-4 (Molecular Probes, Eugene, OR, USA) in culture medium supplemented with 2.5 mmol/L probenecid (Sigma) for 45 min. They were then washed twice with solB buffer containing: 10 mmol/L HEPES, 5 mmol/L NaCl, 5 mmol/L KCl, 2 mmol/L

CaCl₂, 140 mmol/L *N*-methyl-D-glucamine and 10 mmol/L glucose (pH 7.4). The cells were resuspended in solB buffer, plated onto 96-well plates at a density of 60 000 cells in 80 μL per well, and reattached by centrifugation. Effects of the hit compounds on calcium influx were analyzed by FlexStation™ (Molecular Devices, Sunnyvale, CA, USA) with excitation wavelength 485 nm and emission wavelength 525 nm. An α4β2 nAChR agonist, ABT-594^[8], was used as a positive control.

HTS campaign The compound library used for screening consisted of 32 000 pure synthetic compounds. A 10-compound pool per well mix was applied to the primary screening, with an average concentration of 7 μmol/L for each compound dissolved in 100% dimethylsulphoxide (Me₂SO) solution. This matrix system maximizes the advantage of HTS and allows duplicate screening of each compound^[9]. In each 96-well Isoplate™, 16 wells were used as positive controls (epibatidine) and samples showing greater than 60% inhibition were considered as “hits”.

Data analysis Data were analyzed using GraphPad Prism software (GraphPad, San Diego, CA, USA). Non-linear regression analyses were performed to generate dose-response curves. *K_i* values were calculated from IC₅₀ using the equation of Cheng and Prusoff^[10].

$$K_i = \frac{IC_{50}}{1 + \frac{[radioligand]}{K_d}}$$

Results

Assay optimization For HTS purposes, 96-well microtiter plates were used and reaction volume was adjusted to 100 μL/well. At a concentration equivalent to the previously reported *K_d* value (~0.5 nmol/L)^[11], more than 25% of [³H]cytisine added was bound to the receptor (data not shown). To avoid excessive ligand depletion, the concentration was increased to 3 nmol/L, in which the bound form accounted for less than 10%. The best signal-to-background (S/B) ratio was observed in a matrix experiment when 62.5 μg/well microbeads and 10 μg/well membrane preparation were used. However, 5 μg/well was selected for the HTS campaign to conserve the membrane preparation. Under these assay conditions, a sound S/B ratio (~30) was achieved (Figure 1). Me₂SO, at concentrations below 3%, did not affect the assay performance (data not shown).

Binding saturation A serial titration of [³H]cytisine was prepared to study binding characteristics of the SPA assay (Figure 2). The *B_{max}* and *K_d* values calculated from the SPA and filter binding assays were strikingly similar: 2.26 pmol/mg vs 2.31 pmol/mg and 0.65 nmol/L vs 0.70 nmol/L,

Figure 1. Assay optimization. Different concentrations of FlashBlue™ GPCR beads and membrane preparation were mixed in the presence of 3 nmol/L of [³H]cytisine. Unlabeled epibatidine was included at a concentration of 2 μmol/L to determine non-specific binding. The signal was measured after 12 h incubation using a MicroBeta scintillation counter. The arrow indicates the conditions to be optimised.

Figure 2. Saturation study in the scintillation proximity assay. A series titration of [³H]cytisine was made to determine receptor binding characteristics in the presence and absence of 2 μmol epibatidine. *n*=3. Mean±SD.

respectively.

Assay performance As shown in Figure 3, the average *Z'* value for the SPA binding assay was 0.78 with a S/B ratio of 29, indicating that the system was adequately optimized for HTS. Assay stability was evaluated by incubating the plates overnight at 4 °C and both the *Z'* factor and the S/B ratio remained unchanged. Two known α4β2 nAChR ligands, namely, epibatidine and RJR2403, were used to compare the 2 assay methods and the binding affinities measured were within the same range (Figure 4).

HTS campaign Of the 32 000 samples initially screened, 54 hits (0.17%) showing greater than 60% competitive inhibition on [³H]cytisine binding to α4β2 nAChR were discov-

Figure 3. Z' factor determination. Assays were performed at optimized conditions (62.5 μ g beads+5 μ g membrane preparation). Forty-eight replicates of total and non-specific signals were studied. Dashed lines indicate means and mean \pm 3SD of 48 data points.

Figure 4. Dose-response curves of epibatidine and RJR 2403 measured by the (A) scintillation proximity assay or (B) filter binding method from which respective K_d values were calculated. $n=3$. Mean \pm SD.

ered (Figure 5). Secondary (single compound per well) screening confirmed that 17 of the above hits displayed consistent inhibitory effects with K_i values below 2 μ mol/L. These active compounds are of different chemical structures including thiophene, piperidine, azole and other types of heterocyclic derivatives. The HTS campaign was high quality in na-

Figure 5. High-throughput screening of 32 000 compounds using the scintillation proximity assay. Results are expressed as percentage inhibition of [3 H]cytisine binding to α 4 β 2 nicotinic acetylcholine receptor.

ture with a Z' factor and S/B ratio equaling 0.73 and 29, respectively. The bioactivities of the confirmed hits were further evaluated with a functional assay. Eight compounds displayed antagonistic effects with >50% inhibition at 6.7 mg/L on ABT-594-induced calcium mobilization while none showed any agonist activity (Figure 6).

Discussion

Taking advantage of our prior experience in the development of a SPA-based nuclear receptor binding HTS method^[12], efforts were made to expand the knowledge to membrane receptors such as α 4 β 2 nAChR described in this paper. Although similar SPA approaches have been employed to study ligand-binding characteristics of a variety of G protein-coupled receptors^[6,13-15], its application in α 4 β 2 nAChR is novel and may be expandable to other ligand-gated ion channels.

When developing a SPA-based receptor-binding assay, many factors have to be considered in order to maximize the S/B ratio. The optimization procedure may include scintillant-impregnated microbead selection, assay buffer and volume determination, or protein/bead ratio verification. While the assay buffer could be readily transferred from a conventional filter binding assay, the amount of receptor protein and its relative ratio to the quantity of beads used are critical to assay performance. An adequate amount of beads is required to saturate the protein in order to achieve a maximal binding signal. However, excessive beads will lead to undesired exposure of bead surface to non-specific ligand binding. Therefore, the amount of beads applied should be kept to a minimum where protein saturation is still achievable.

Figure 6. Inhibition of $\alpha 4\beta 2$ nicotinic acetylcholine receptor agonist ABT-594-induced calcium mobilization by 16 hit compounds (6.7 mg/L). One compound was not included due to auto-fluorescence. Cells were pretreated with test compounds or dimethylsulphoxide (control) for 2 min and calcium influx was stimulated by ABT-594 (166 nmol/L). $n=3$. Mean \pm SEM.

On the other hand, stable signal is highly dependent on protein stability and its coating ability on the beads. In the assay system reported here, no signal shift was observed for more than 48 h, indicating a very stable interaction among various reagents.

It was learned from other membrane receptor screening settings that assay sensitivity can be improved by choosing a radiolabeled ligand concentration at or below its K_d to permit effective competition by an unlabeled ligand^[14]. In the present study, we selected a relatively higher concentration of [³H]cytisine (ie, 3 nmol/L) as opposed to the K_d value (0.6 nmol/L) of unlabeled ligand. This arrangement allowed us to accurately measure K_i values of the 2 reference compounds as well as to confirm hits identified from the HTS campaign, while keeping [³H]cytisine bound to the receptor to a minimum (<10%). Conceivably, such a practice would compromise assay sensitivity thereby reducing the hit rate. Considering our initial intention of finding hits with K_i values below 2 μ mol/L from primary screening, this purpose was well served as evidenced by a confirmed hit rate of 0.05% and the identification of 1 highly active compound (23 nmol/L; data not shown). In addition, the bioactivities of the hits discovered by the SPA method were confirmed with a cell-based functional assay where 8 compounds were found to demonstrate significant antagonistic effects on ABT-594-induced calcium mobilization.

In comparison with conventional filter binding techniques, the SPA method omits steps such as pre-coating, pre-incubation, separation and excessive washing, and thus, simplifies the assay protocol, mitigating labor intensity and

reducing systemic error. It is also readily adaptable to HTS and automation, as demonstrated in this study. When deduced to practice, both approaches yielded similar K_i values for 2 known $\alpha 4\beta 2$ nAChR ligands (epibatidine and RJR2403), which are not only consistent with those reported elsewhere^[16] but also exhibited the same affinity rank order and pK_i features (in agreement within 1/2 log unit). In addition, the cost and amount of wastage are significantly less if SPA technology is employed. This advantage could be further explored by utilizing high-density plate formats (eg, 384-well plate) where filtering assays clearly show their limitations.

The Z' factor is a useful tool for evaluating bioassay qualities^[17]. In general, a Z' value above 0.5 suggests that an assay is robust enough for HTS. The SPA system described herein consistently displayed a Z' value between 0.73 and 0.78. This, and in conjunction with other parameters such as S/B ratio, B_{max} and K_d values, indicate that the assay is high quality in nature.

In summary, a simple and SPA-based HTS binding assay was developed and validated for identification of compounds with specificity and functionality for $\alpha 4\beta 2$ nAChR. Receptor coating onto the beads and ligand binding are achieved in 1 mixing step and the procedure is homogeneous. Its application may be expanded to other membrane receptors and ion channels.

Abstract

Aim: To establish a cell-based assay to screen human dopamine D1 and D5 receptor agonists against compounds from a natural product compound library. **Methods:** Synthetic responsive elements 6×cAMP response elements (CRE) and a mini promoter containing a TATA box were inserted into the pGL3 basic vector to generate the reporter gene construct pCRE/TA/Luci. CHO cells were co-transfected with the reporter gene construct and human D1 or D5 receptor cDNA in mammalian expression vectors. Stable cell lines were established for agonist screening. A natural product compound library from over 300 herbs has been established. The extracts from these herbs were used for human D1 and D5 receptor agonist screenings. **Results:** A number of extracts were identified that activated both D1 and D5 receptors. One of the herb extracts, SBG492, demonstrated distinct pharmacological characteristics with human D1 and D5 receptors. The EC₅₀ values of SBG492 were 342.7 µg/mL for the D1 receptor and 31.7 µg/mL for the D5 receptor. **Conclusion:** We have established a cell-based assay for high-throughput drug screening to identify D1-like receptor agonists from natural products. Several extracts that can activate D1-like receptors were discovered. These compounds could be useful tools for studies on the functions of these receptors in the brain and could potentially be developed into therapeutic drugs for the treatment of central nervous system diseases.

Introduction

The dopamine receptors fall into two families called D1-like and D2-like receptors, based on their structural and pharmacological features^[1]. The D1 family includes D1- and D5-receptor subtypes, and the D2 family consists of D2-, D3- and D4-receptor subtypes. Dopamine receptors are mainly expressed in the central nervous system and control motor function, emotional state and endocrine physiology^[2,3].

Many central nervous system (CNS), cardiovascular and renal diseases have been shown to be associated with alterations in dopamine receptors. These diseases include Parkinson disease, schizophrenia, migraine, drug dependence, depression and Gilles de la Tourette syndrome^[4]. Dopamine is one of the principal neurotransmitters in the basal ganglia, and plays a critical role in motor control and cognitive func-

tion through interactions with dopamine receptors. The possible role of dopamine D1-like receptors in brain function, especially in learning and memory, has recently been studied extensively^[5-7]. Indeed, D1-like receptors play essential roles in working memory^[8] and other forms of cognition activity^[9]. The abnormality of these receptors also contribute to Parkinson disease^[10,11]. In addition, the D5 receptor subtype is involved in modulating the release of hippocampal acetylcholine, a neurotransmitter implicated in a variety of cognitive processes^[12].

Much evidence has been accumulated to indicate that dopamine receptor agonists or antagonists can be developed into therapeutic drugs for the treatment of CNS diseases. It has been reported that D1-like receptor agonists improve learning and memory in different animal models^[13,14]. Furthermore, D1-like receptor agonists or antagonists are

potential therapeutic drugs for addiction and Parkinson disease^[15–18]. Receptor agonists and antagonists also provide essential tools for pharmacological and functional characterization of the receptors.

Several high throughput screening methods to screen agonists and antagonists of G-protein coupled receptors (GPCR) have been developed^[19–22]. Recently, we developed a universal functional assay for GPCR^[23]. In the present report, we further modified this functional assay for human D1-like agonist screening. A number of natural compounds were identified that can specifically activate both human D1 and D5 receptors. Detailed pharmacological analysis demonstrated that one of the agonists had distinct pharmacological properties for these 2 receptors.

Materials and methods

Plasmid construction Human D1 and D5 receptors were cloned by polymerase chain reaction (PCR). The primers used for the PCR were: DIR5', 5'-GCT GGA TCC GTG CCC AAGACAGTGACCT-3'; DIR3', 5'-GGGAGCTCCGAGGG GTACAAACATCA-3'; D5R5', 5'-GGC GAATTC GCGTGT GTGTGCGTGCTTGTCACTGT-3'; and D5R3', 5'-GGGAAG CTTCTGAAGTTGGACCGCGCACAGACCG-3'. PCR products were digested with *EcoRI* and *HindIII* and subcloned into the *EcoRI/HindIII*-digested mammalian expression vector pCDNA3.1 (Invitrogen) to generate pCDNA3.1/D1 and pCDNA3.1/D5. The 6×CRE and a mini promoter with 49 bps, containing a TATA box, were synthesized and inserted into the pGL3 basic vector (Promega) to produce pCRE/TA/Luci as a reporter gene. All plasmids were confirmed by DNA sequencing.

Cell culture, transfection and stable cell line generation CHO cells were maintained in RPMI-1640 medium containing 10% fetal calf serum at 37 °C. Cells were transfected with dopamine D1 and D5 receptors and the reporter construct using Lipofectin (Invitrogen). Stably transfected cells were generated in the presence of 0.8 mg/mL G418.

Natural product extracts Traditional Chinese Medicines (TCM) were purchased from a local pharmacy in Chongqing, China. Fifty grams of each TCM were extracted twice with 500 mL water at 80 °C for 2 h. The extracts were concentrated to 100 mL by evaporation under low pressure at 80 °C. Using this method, we prepared more than 300 samples for human dopamine receptor agonist screening.

Luciferase assay Aliquots of 90 μ L cells (3×10^5 cells/mL) were seeded into each well of 96-well plates and incubated overnight at 37 °C. A natural product sample (10 μ L) was added to each well and incubated at 37 °C for 6 h–10 h.

Bright-Glo™ Luciferase assay reagent (100 μ L; Promega) was then added to each well, and the luciferase activity was measured using Analyst™ HT (Molecular Device).

Results

Characterization of the CRE/TA/Luci reporter gene in CHO cells We generated a reporter gene construct for human dopamine D1 and D5 agonist screening. The construct contained 6 copies of CRE and a TATA box linked to the luciferase gene. The reporter gene construct was stably transfected into CHO cells to generate the CRE/TA/Luci/CHO cell line. This cell line was treated with forskolin (an adenylyl cyclase activator) at different concentrations, and luciferase activity was measured. Our results showed that forskolin stimulated reporter gene luciferase expression in a dose-dependent manner (Figure 1). This result indicated that increasing intracellular cAMP levels led to the activation of CRE and TATA promoter and suggested that this assay could be used for Gs-coupled receptor agonist screening. To examine whether there was any endogenous dopamine receptor in the CHO cells, we tested several dopamine receptor agonists in the stable reporter gene cell line. Our results demonstrated that none of the dopamine receptor agonists had any effect on the cell line, indicating that no dopamine receptor was expressed in CHO cells.

Figure 1. The activity of forskolin and D1-like receptor agonists in CRE/TA/Luci/CHO cells. The cells were incubated with different concentrations of D1 agonists and forskolin for 6 h, and luciferase activity was measured.

Development of reporter gene assay for D1-like receptor agonist screening Mammalian expression vectors containing human dopamine D1 or D5 receptors were transfected into the reporter gene cell line. Activation of the receptors

leads to the elevation of cAMP and activates the cAMP response element, and therefore induces the expression of the reporter gene luciferase. We tested the natural ligand dopamine and two other D1-like receptor agonists, dihydroxidine and chloro-APB, in the stable cell lines expressing both dopamine receptors and the reporter gene. The results are shown in Figure 2. The rank order of potency, dopamine>dihydroxidine>chloro-APB, agreed with the ligand-receptor binding analysis^[24,25].

Figure 2. The activities of D1-like receptor agonists in cell lines expressing human D1 or D5 receptors. (A) D1/CRE/TA/CHO cells were incubated with D1-like receptor agonists for 6 h; (B) D5/CRE/TA/CHO cells were incubated with D1-like receptor agonists for 6 h.

Optimization of the reporter gene assay conditions We carried out a series of experiments to optimize the reporter gene assay for drug screening. First, we examined the incubation time for the D1-like receptor agonist in the assay. Different concentrations of dihydroxidine were used for the experiment. Our results showed that approximately 8 h incubation with the agonist gave the highest response at all concentrations (Figure 3). Therefore, we used an 8-h incubation time for all of our experiments, unless otherwise indicated.

Figure 3. The effects of dihydroxidine on the activity of luciferase in the D5/CRE/TA/Luci/CHO cells at different incubation times. The concentrations of dihydroxidine were 10 nmol/L, 30 nmol/L and 300 nmol/L. Cells were incubated with D1-like receptor agonist dihydroxidine for 6 h and luciferase activity was measured.

Second, because the compounds were in dimethylsulphoxide (Me₂SO) solution, we tested the effects of Me₂SO at different concentrations in the assay. Me₂SO concentrations of 1% or less had no effect on the signal (data not shown). In our compound screen assays, the final concentration of Me₂SO was adjusted at 1% or less. Finally, we found that the number of cells in each well may influence the reporter gene assay. Figure 4 shows that although increasing cell number gave a better signal after agonist stimulation, the background was also higher. The best number of cells to use was

Figure 4. The effects of cell number on the luciferase activity in D5/CRE/TA/Luci/CHO cells in the presence of dopamine. D5/CRE/TA/Luci/CHO cells were treated with either saline or 100 nmol/L dopamine for 6 h, and luciferase activity was measured.

between 2×10^5 cells/mL and 4×10^5 cells/mL. Therefore, we used 3×10^5 cells/mL in all compound screens using the reporter gene assay. In addition, we calculated the coefficient of variation (CV) for the assay in a standard 96-well plate. The CV values were 6.5% for non-activated cells and 5.8% for dopamine-stimulated cells. The Z' factor^[26] was 0.58. These results suggest that the reporter gene assay system was suitable for dopamine receptor agonist screening.

Identification of extracts active for the D1-like receptor More than 300 herb extract samples were used for the D1-like receptor agonist screening. From our previous experiences for other G-protein coupled receptor agonist or antagonist screens, we found that it was necessary to use different concentrations of the raw extracts for the screen. Therefore, in the D1-like receptor agonist screen, the extract samples were screened twice at different concentrations. One was at the original concentration and the other was a 5-fold dilution of the sample. The samples that gave signals larger than the mean value +3SD were selected as agonist candidates (Figure 5). To eliminate the possibility that the agonist candidates activated the reporter gene expression through intracellular pathways other than the D1-like receptor, we tested the samples in a cell line expressing the reporter gene alone, without the D1-like receptor. We found that some of the agonist candidates, such as Chinese ester pillar fungus, could stimulate the reporter gene luciferase expression in the reporter gene cell line (Figure 6). In contrast, sample SBG492 activated the expression of the reporter gene in the D1-like receptor expressing cell line, but had no effect in the reporter gene cell line. This result suggested that SBG492

Figure 5. D1-like receptor agonist screening. Reporter gene cell line expressing human D1-like receptor was treated with herb extracts and luciferase activity was measured. The solid line indicates basal activity of luciferase without treatment. The dotted line represents mean \pm SD.

Figure 6. The activity of SBG492 and Chinese ester pillar fungus in D5/CRE/TA/Luci/CHO and TA/Luci/Luci/CHO cell lines. The cells were treated with 100 μ g/mL extracts for 8 h and luciferase activity was measured.

activated the reporter gene expression through human D1-like receptor (Figure 6). Furthermore, we tested the sample in more than 20 different GPCR using the same reporter gene assay system (data not shown). Our results demonstrated SBG492 could not activate other GPCR, suggesting that the sample contained specific human D1-like receptor agonist. We further analyzed the pharmacological properties of SBG492 for human D1 and D5 receptors. The EC_{50} values of SBG492 were 342.7 μ g/mL for the D1 receptor and 31.7 μ g/mL for the D5 receptor (Figure 7).

Discussion

Dopamine receptors are a subclass of the superfamily of GPCR. Within the dopamine receptor family, both D1 and D5 are Gs-coupled receptors. Interaction of the receptors with the natural ligand dopamine or other agonists leads to the activation of adenylyl cyclase and increases the intracellular concentration of cAMP. The cAMP second messenger system ultimately activates CRE and induces gene expression. This is the basis of our reporter gene assay, which contains 6 \times CRE linked to the reporter gene luciferase.

The D1 and D5 dopamine receptors are genetically distinct, sharing over 80% sequence homology within the highly conserved 7 transmembrane-spanning domains, but display only 50% overall homology at the amino acid level^[27]. The D1-like dopamine receptors, including D1 and D5, have similar pharmacological properties^[28]. Indeed, it is often difficult to pharmacologically distinguish between dopamine D1 and D5 receptors using the same ligands. Therefore, identification of agonists that have distinct pharmacological

Figure 7. Pharmacological characterization of SBG492 on luciferase activity of D5/CRE/TA/Luci/CHO and D1/CRE/TA/Luci/CHO cells. (A) D5/CRE/TA/Luci/CHO cells were treated with different concentrations of SBG492 for 8 h and luciferase activity was measured. (B) D1/CRE/TA/Luci/CHO cells were incubated with SBG492 for 8 h and luciferase activity was measured.

properties for these 2 receptors should provide a useful tool for their functional studies.

In our previous agonist or antagonist screening for GPCR and other targets, we have successfully isolated active components from crude extracts of herbs^[29-31]. Subsequent purification of the active components lead to the identification of a single effective compound. The advantage of using the crude extract is that the samples are easy to prepare and a large amount of herbs can be screened in a short period of time. On the other hand, since the crude extracts contain hundreds of different compounds, some of them may have negative effects on the targets or may even be harmful to cells. Indeed, we found that in some cases, high concentrations of the extracts in our cell-based assay had no effects,

while after dilution the samples showed agonist or antagonist activity. Therefore, we used 2 concentrations of each extract for the screening to increase the chances of identifying D1-like receptor agonists. A number of extracts were isolated as potential receptor agonists using the reporter gene assay.

There are several other possible ways in which that the extracts can activate the reporter gene expression other than as human D1-like receptor agonists. For example, the extracts may activate or inhibit other components in the cAMP signal pathway, such as adenylyl cyclase, protein kinase A, cAMP-dependent phosphodiesterase or CRE binding protein, and eventually lead to the activation of the reporter gene. It is also possible that the extracts may activate other endogenous GPCR in the cell and lead to the induction of reporter gene expression. To examine these possibilities, we tested the activity of the herb extracts in a reporter gene cell line that did not express human D1-like receptors. We found that SBG492 did not induce the expression of the reporter gene in the cell line, indicating that the extract activated the reporter gene through the receptor. It is interesting to note that SBG492 is approximately 10 times more potent for human D1 receptor than for D5 receptor. Further characterization of the agonist could provide important information for pharmacological and functional studies on human D1-like receptors.

Abstract

Aim: The 3-azabicyclo(3,3,1)nonanyl-9- α -yl- α -cyclopentyl- α -phenyl- α -glycolate (DM-phencynonate hydrochloride, DMCPG) is a demethylated metabolite of 3-methyl-3-azabicyclo(3,3,1)nonanyl-9- α -yl- α -cyclopentyl- α -phenyl- α -glycolate (phencynonate hydrochloride, CPG). (\pm)DMCPG had one chiral center and two enantiomers [R(-) and S(+)]DMCPG]. Here we carried out a comparative study of the pharmacological profiles of these optical isomers. **Methods:** Affinity and relative efficacy were tested using a radioligand-binding assay with muscarinic acetylcholine receptors from the rat cerebral cortex. Pharmacological activity was assessed in three individual experiments: (1) potentiating the effect of a sub-threshold hypnotic dose of sodium pentobarbital; (2) inhibiting oxotremorine-induced salivation; and (3) inhibiting the contractile response to carbachol. **Results:** In the competitive binding assay, R(-)DMCPG ($K_i=763.75$ nmol/L) was 4- and 2-fold more potent than (\pm)DMCPG ($K_i=3186$ nmol/L) and S(+)]DMCPG ($K_i=1699$ nmol/L) in inhibiting the binding of [³H]QNB. The R(-) and S (+) configurations showed positive cooperation ($n_H>1$) with the muscarinic receptor, whereas (\pm)DMCPG had a negative cooperation ($n_H<1$) relationship with the muscarinic receptor in a radio-binding assay. Both the R(-) and S(+)] configurations could potentiate the effect of sub-threshold hypnotic dose of sodium pentobarbital in a dose-dependent manner (the ED_{50} values were 2.53 and 18.65 mg/kg, respectively), but (\pm)DMCPG did not display significant central depressant effects at doses from 10 to 29.15 mg/kg ($P>0.05$). (\pm)DMCPG and its optical isomers suppressed the guinea pig ileum contractile response to carbachol. The IC_{50} values were 7.78×10^{-9} , 1.88×10^{-7} , and 1.03×10^{-7} nmol/L, respectively. In the anti-salivation study, (\pm)DMCPG and its enantiomers depressed oxotremorine-induced salivation in a dose-dependent manner, and the order of potency was R(-)DMCPG ($ED_{50}=0.44$ mg/kg) $>$ (\pm)DMCPG ($ED_{50}=2.88$ mg/kg) $>$ S(+)]DMCPG ($ED_{50}=5.05$ mg/kg). **Conclusion:** (\pm)DMCPG and its optical isomers have differences in their pharmacological potencies as anticholinergic agents, and the R(-) configuration is more active than the S(+)] configuration.

Introduction

In order to develop more potent drugs for muscarinic intervention in disorders of the central and peripheral nervous system, a series of heterocyclic compounds including esters, alkanes, and ether derivatives were designed and synthesized in our institute. One of the compounds, CPG,

has been developed as a novel anti-motion-sickness drug with higher efficacy and lower central inhibitory side effects than diphenidol HCl and scopolamine HBr, and is used clinically^[1-3]. (\pm)DMCPG, which has one chiral center and two enantiomers [R(-) and S(+)]DMCPG] was the active dominant N-demethyl metabolite of CPG. We believe that this is an important way of looking for active compounds from the

metabolites to discover new medicines. We synthesized (\pm)DMCPG and its two enantiomers (Figure 1). To avoid adverse effects and to optimize the therapeutic value of enantiomeric drugs, it is necessary to establish the effectiveness of isomers of the chiral drug, and to detect the presence of the enantiomer with lower therapeutic activity and undesirable adverse effects. For this purpose, we investigated the binding characteristics of these new chiral compounds by using a radioligand receptor-binding assay with muscarinic receptors from rat brain, and compared its pharmacological effects on muscarinic receptors by means of *in vitro* and *in vivo* assays.

Figure 1. Chemical structures of (\pm)DMCPG and its optical isomers.

Materials and methods

Animals The experiments were carried out in accordance with the Guide for the Care and Use of Laboratory Animals, from the National Research Council (1996), under the approved protocols. Animals used in the present study were as follows: Kunming species mice weighing 18–22 g [grade II, certificate No scxk (Army) 2002-001], provided by our animal center; male and female Wistar rats weighing 180–220 g [grade II, certificate No scxk (Jing) 2002-0003], and male guinea pigs weighing 200–300 g [grade II, certificate No scxk (Jing)

2002-0003] purchased from Weitonglihua Co (Beijing, China).

Compounds ^3H -quinuclidinyl benzilate (^3H]QNB; 43.3 Ci/mmol) was purchased from Amersham (Uppsala, Sweden; TRK604). (\pm)DMCPG and its isomers were synthesized at our institute. The (\pm)DMCPG comprised equal proportions of R(–) and S(+)-DMCPG. Atropine, pentobarbital, oxotremorine and carbachol were purchased from Sigma (St Louis, MO, USA).

Binding assays on rat cerebral cortex homogenate Male or female Wistar rats were killed by decapitation. The cerebral cortex was immediately removed and processed as described by Yamamura and Snyder^[4]. The protein concentration was determined by using the method of Lowry *et al*^[5]. The samples of homogenate (each containing 50 mg of protein) were incubated for 30 min at 37 °C in 0.5 mL of assay buffer containing 6 nmol/L ^3H]QNB and various concentrations of drugs. In saturation binding assays, the homogenate was incubated as indicated above, in the presence of ^3H]QNB (0.25–20 nmol/L). Non-specific binding was defined as binding in presence of atropine (1 $\mu\text{mol/L}$). Each sample was filtered through GF/C glass fibers with vacuum. The filters were rinsed 3 times with 3 mL cold buffer, and placed in scintillation vials containing 3 mL of scintillation fluid. Radioactivity trapped on the filters was determined by liquid scintillation spectrometry at approximately 40%–50% efficiency.

Carbachol-induced contraction Male guinea pigs were killed by cervical dislocation. The organs required were set up rapidly under 1 g of tension in 20 mL organ baths containing physiological salt solution (PSS), which was kept at 37 °C and aerated with 5% CO_2 and 95% O_2 . Two-centimeter-long portions of terminal ileum were taken at about 5 cm from the ileum–cecum junction and mounted in PSS at 37 °C. The composition of PSS was as follows (mmol/L): NaCl 118, NaHCO_3 23.8, KCl 4.7, $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ 1.18, KH_2PO_4 1.18, CaCl_2 2.52, glucose 11.7. Tension changes were recorded isotonicly. Tissues were equilibrated for 90 min before the experiments were conducted.

The carbachol-induced ileum contraction was obtained by incubation with carbachol (10^{-5} mol/L) until the concentration had reached a plateau. Then, the ileum strips were washed several times with PSS until the tension of the strips relaxed to the baseline level. Following washing, the strips were incubated with different concentrations of R(–), S(+), or (\pm)DMCPG for 10–15 min. After incubation, the maximum contraction induced by carbachol (10^{-5} mol/L) was observed again in the presence of increased concentrations of different antagonists. The IC_{50} values for the carbachol-induced contractions in the presence of the antagonists were ob-

tained to assess the pharmacological potency of (±)DMCPG and its optical isomers.

Effect on sub-threshold hypnotic dose of sodium pentobarbital induced-sleep Four dosage groups were used for each drug and each group consisted of 10 mice of each sex. Mice were pretreated with (±)DMCPG and its optical isomers intraperitoneally (ip), then after 15 min, a sub-threshold hypnotic dose of sodium pentobarbital (30 mg/kg) was given ip. The loss of righting reflex was used as a measure of the central inhibitory effect of drugs. The ED₅₀ values of these three drugs were estimated to compare the central inhibitory effect of the indicated agents.

Inhibition of oxotremorine-induced salivation Kunming mice were assigned randomly into 4 groups for each drug. Each group consisted of 10 mice of each sex. (±)DMCPG and its optical isomers were administered ip 15 min prior to oxotremorine (3 mg/kg) being injected subcutaneously (sc). ED₅₀ values were calculated to evaluate the anti-secretive potencies of the compounds used.

Data analysis and statistics

Binding assays The IC₅₀ values were obtained from at least three separate experiments performed in triplicate with 6-8 concentrations of drugs. Data were analyzed by curvilinear regression using the program ORIGIN 6.0. The inhibition constants (K_i) were calculated using the Cheng-Prusoff equation^[6], $K_i = IC_{50} / (1 + L / K_d)$, where L and K_d are the concentration and the equilibrium dissociation constant of [³H]QNB, respectively.

Functional assays In the carbachol-induced contraction experiments, the maximum contractile response (E_{max}) was obtained from the maximum stress, and the IC₅₀ value was calculated from a semi-logarithmic plot of the percentage of the maximum response versus drug concentration. Data were computer analyzed by curvilinear regression using the program ORIGIN 6.0. Statistical analyses for comparisons among groups were performed using analysis of variance (ANOVA). P<0.05 was considered statistically significant. To evaluate the effect of (±)DMCPG and its optical isomers on anti-salivation induced by oxotremorine and sleeping induced by a sub-threshold hypnotic dose of sodium pentobarbital, ED₅₀±95% CL (confidence limit) values were calculated and compared by weighted probit analysis. Data are shown as mean±SD.

Results

Competitive binding of (±)DMCPG and its optical isomers to rat central muscarinic acetylcholine receptors The K_d value for [³H]QNB binding to receptors was 6.66±0.95

nmol/L. The B_{max} was 760±92 fmol/mg. The competitive binding potency of R(-)DMCPG for [³H]QNB corresponded to a K_i value of 763.75±7.31 nmol/L (n=4). An average Hill coefficient (n_H) was 1.17±0.15. The affinity of R(-)DMCPG at central muscarinic acetylcholine receptors was higher than that of (±)DMCPG (K_i=3180±263 nmol/L, n_H=0.42) and S(+)-DMCPG (K_i=1699±260 nmol/L, n_H=1.26). The isomer with R(-) configuration was more potent than the isomer with S(+) configuration and (±)DMCPG. The competition profiles of R(-)DMCPG and S(+)-DMCPG to rat cortex muscarinic receptors were steep and adequately described by a one-site model, n_H>1, which exhibited positive cooperative effects at muscarinic receptors. However, for (±)DMCPG, n_H<1, which exhibited negative cooperative effects at muscarinic receptors, which is not consistent with a one-site binding model (Figure 2).

Figure 2. Effects of (±)DMCPG and its optical isomers on the binding of [³H]QNB to rat central muscarinic acetylcholine receptors [●, R(-)DMCPG; ▲, S(+)-DMCPG; ■, (±)DMCPG]. Rat cerebral cortex homogenate was incubated with 6 nmol/L [³H]QNB for 30 min at 37 °C in the absence and presence of increasing concentrations of different drugs. Data are the means of four independent experiments performed in duplicate.

Effect of (±) DMCPG and its optical isomers on carbachol-induced contraction Carbachol (10⁻⁵ nmol/L) caused contractions in guinea pig ileum. The E_{max} values for the carbachol-induced contractions were 2.90±0.17 g (n=30). (±)DMCPG and its optical isomers (10⁻⁹–10⁻⁴ mol/L) significantly suppressed the carbachol-induced contractions (P<0.05; Figure 3). The IC₅₀ values of (±) DMCPG, R(-) DMCPG and S(+)-DMCPG were 7.78×10⁻⁹, 1.88×10⁻⁷, and 1.03×10⁻⁷ mol/L, respectively. The results revealed that (±)DMCPG was more potent in the anti-contraction of smooth

Figure 3. Concentration-response curves for (\pm)DMCPG and its optical isomers (10^{-9} – 10^{-5} mol/L) on the maximum contractile response induced by carbachol (10^{-5} mol/L) in guinea pig ileum (\bullet , R(-)DMCPG; \blacktriangle , S(+)-DMCPG; \blacksquare , (\pm)DMCPG). For each experiment, contractile responses are expressed as percentages of the maximum contractile response in the absence of any antagonist. Each point represents the mean \pm SD of the results from 6–8 separate experiments. If not shown, SD bars fall within the boundaries of the symbol.

muscle induced by carbachol than the other two configurations ($P < 0.05$).

Potentiation of the effect of a sub-threshold hypnotic dose of sodium pentobarbital Pentobarbital (ip, 30 mg/kg) alone did not cause sleep in mice ($n=50$). However, after pretreatment with R(-)DMCPG (1.68–4.89 mg/kg) and S(+)-DMCPG (10–29.15 mg/kg) at 15 min intervals, sedation effects induced by a sub-threshold hypnotic dose of sodium pentobarbital were enhanced in a dose-dependent manner (Table 1). The ED_{50} values $\pm 95\%$ confidence limits of R(-) and S(+)-DMCPG were 2.53 ± 0.37 and 18.65 ± 4.03 mg/kg. Of the 10 mice pre-administered with (\pm)DMCPG at the highest dose (29.15 mg/kg), only 2 mice lost their righting reflex, which indicates that (\pm)DMCPG has a weak central depressant action. The order of central inhibition effects was R(-)DMCPG > S(+)-DMCPG > (\pm)DMCPG.

Inhibition of oxotremorine-induced salivation Oxotremorine (sc, 3 mg/kg) induced obvious salivation in mice ($n=50$), whereas (\pm)DMCPG and its optical isomers produced anti-salivation effects in a dose-dependent manner when mice were pretreated with these compounds. The $ED_{50} \pm 95\%$ CL values for (\pm)DMCPG and the R(-), S (+) configurations were 2.88 ± 0.35 , 0.44 ± 0.03 , and 5.05 ± 0.33 mg/kg, respectively, which indicates that the order of potency for inhibiting glandular secretion is R(-)DMCPG > (\pm)DMCPG > S(+)-DMCPG (Table 2).

Table 1. Effect of (\pm)DMCPG and its optical isomers on sleep induced by sub-threshold hypnotic doses of sodium pentobarbital. For each experiment, the rate of loss in righting reflex is expressed as the proportion of mice that lost their righting reflex per 10 mice. $n=10$. Mean \pm SD.

Discussion

(\pm)DMCPG is a derivative of its parent compound CPG, and there is one chiral carbonic atom in the molecular struc-

ture of (\pm)DMCPG, causing the R(-) and S(+) enantiomers. In this study, we compared the pharmacological activities of these enantiomers, to further investigate the relationships between anti-muscarinic activity and muscarinic receptors. Interestingly, for muscarinic acetylcholinic receptors, (\pm)DMCPG and its optical isomers did not have the same potency trends in the tests.

In the present investigation, the pharmacological activities of (\pm)DMCPG and its isomers were subjected to comparative radiobinding and functional assays. In the competitive binding assay, R(-)DMCPG was 4- and 2-fold more potent than its racemate and the S(+) configuration in inhibiting the binding of [3 H]QNB. These results demonstrate that there was receptor stereo selective action between the muscarinic receptor and R(-)DMCPG. In this case of receptor binding, R(-)DMCPG is the eutomer. The R(-) and S(+) configurations showed positive cooperation ($n_H > 1$) but (\pm)DMCPG had a negatively cooperative ($n_H = 0.42$) relationship with the muscarinic receptor. Low Hill numbers are most often attributed to recognition by the antagonist of more than one receptor site or receptor conformation, or to an interaction of the antagonist with a second binding site on the receptor molecule causing a negative cooperative effect for the first site^[7-9]. There is a second ligand-binding site on muscarinic receptors. A wide array of compounds is capable of modulating the binding of classical ligands to all five muscarinic subtypes^[10-12]. Allosteric modulation of muscarinic receptors has been much investigated^[13,14]. Proška and Tušek (1994) proposed that the binding site for modulators such as alcuronium, gallamine, and related compounds is located near the binding site for classical ligands, but more superficially^[15]. Our results imply that (\pm)DMCPG may act at the second binding site with an allosteric mechanism to muscarinic receptors. (\pm)DMCPG is composed of the R(-) and S(+) configurations, and R(-) and S(+)DMCPG showed marked central inhibitory effects, but (\pm)DMCPG had only a weak effect, even at a higher dose. Inversely, the ability of (\pm)DMCPG to inhibit the contraction of guinea pig ileum induced by carbachol was approximately 10 and 100 times more potent than that of R(-) and S(+)DMCPG. (\pm)DMCPG was the lowest one bound to the muscarinic receptor, and we can also deduce that the enantiomers must interact with each other to affect its binding characteristics and bioactivities. The allosteric mechanism of these chiral drugs needs to be further explored in subsequent experiments. However, our experiments showed that pharmacological differences exist between the optical isomers. The R(-) configuration was more potent at binding receptors and inhibiting glandular secretion, but had moderate effects on the con-

traction of smooth muscle. The pharmacological differences may be due to the distribution of different subtypes in different tissues. Muscarinic acetylcholine receptors (mAChR) include five subtypes of receptors (M_1 - M_5). The selective action on the salivary gland of R(-)DMCPG may be related to its subtype-selective effects. Individual members of the mAChR are expressed in a complex overlapping fashion in most tissues and cell types^[16]. The M_1 , M_2 , and M_4 subtypes of the mAChR are the predominant receptors in the central nervous system^[17]. The M_1 and M_3 subtypes are the major muscarinic acetylcholine receptors in the salivary glands and M_3 is thought to be more abundant^[18,19]. Guinea pig ileum smooth muscle is enriched with muscarinic receptors, the majority of which are of the M_2 subtype, and the remaining minority are of the M_3 subtype^[20,21]. In our experiments, we comparatively studied the anti-muscarinic pharmacological profiles of these compounds to see whether there is any correlation between pharmacological activity and muscarinic subtype selectivity. Fulfilling our expectations, of these three chiral drugs, (\pm)DMCPG had the greatest ability to inhibit smooth muscle contraction as a muscarinic receptor antagonist, whereas R(-)DMCPG had a moderate effect on smooth muscle contraction, but had the greatest anti-salivary effect and enhancement of sedation effects caused by sub-threshold hypnotic doses of sodium pentobarbital. S(+)DMCPG was less potent in all experimental models. Our results imply that there are subtype-selective mechanisms that correspond to the different pharmacological actions of the compounds. Therefore, further studies are necessary to resolve the underlying actions of (\pm)DMCPG and its enantiomers with respect to muscarinic subtype receptors.

In conclusion, the present work demonstrated that there are receptor stereo selective actions between muscarinic receptors and the R(-) configuration of DMCPG. R(-)DMCPG acted as a eutomer relative to its S(+) configuration in the racemate. These differences must be related to subtype selectivity and allosteric mechanisms.

Abstract

Aim: To explore whether overexpression of HSP20 in the myocardium could protect against ischemia/reperfusion injury in rats. **Methods:** Rat hearts were injected with vector, recombinant adenovirus encoding green fluorescent protein (Ad.GFP) or recombinant adenovirus encoding wild-type HSP20 (Ad.HSP20) in the left ventricle. Four days later, hearts were removed and expression of HSP20 was measured in the left ventricle. Subsets of animals in the vector-, Ad.GFP-, and Ad.HSP20-treated groups were subjected to 20-min ischemia and 120-min reperfusion. Myocardial injury was evaluated by infarct size and level of serum cardiac troponin T and creatine phosphokinase. Apoptosis of cardiomyocytes was determined by TUNEL staining. Cardiac function was evaluated by hemodynamic indexes. **Results:** Infarct size and serum cardiac troponin T and creatine phosphokinase levels were significantly reduced in Ad.HSP20-treated hearts compared with vector- and Ad.GFP-treated hearts. The ratio of TUNEL-positive cardiomyocytes to total number of cardiomyocytes in the Ad.HSP20 group was significantly reduced as compared with the vector and Ad.GFP groups. Left ventricular end systolic pressure, and maximal rate of pressure increase ($+dp/dt_{max}$) and decrease ($-dp/dt_{min}$) values were increased significantly, while left ventricular end diastolic pressure was decreased significantly in Ad.HSP20-treated hearts compared with vector- and Ad.GFP-treated hearts. **Conclusion:** These data indicate that the cardioprotective effects of HSP20 may contribute to the reduction of myocardial necrosis and apoptosis in ischemia/reperfusion injury in rats.

Introduction

Members of the small heat shock protein (sHSP) family, including HSP20, HSP25, HSP27, α B-crystallin, and myotonic dystrophy kinase binding protein, are expressed in muscle tissues and share a homologous sequence of approximately 80–100 amino acids at the C-terminus, known as the α crystallin domain^[1,2]. The past decade has witnessed the discovery of new mammalian sHSP, of which HSP20 is the best characterized. HSP20 was co-purified from skeletal muscle with α B-crystallin and HSP27 by affinity chromatography on a column of immobilized antibodies against α B-crystallin^[3]. Exposure of rat diaphragm tissue to heat stress *in vitro* results in the redistribution of HSP20, as well as α B-crystallin

and HSP27, from the cytosol into insoluble fractions, and enhanced dissociation of the aggregated form to the small form, which is characteristic of stress proteins^[4]. Stable overexpression of HSP20 in Chinese hamster ovary cells results in enhanced survival after heat shock, which is similar to results obtained with α B-crystallin^[5]. Chu *et al*^[6] were the first to identify the *de novo* phosphorylation of cardiac HSP20 in mouse cardiomyocytes after prolonged activation of the β -adrenergic signaling pathway. The adenovirus-mediated overexpression of HSP20 in adult rat cardiomyocytes increases cell contractility, which indicates that HSP20 is involved in the regulation of myocardial contractility^[6,7].

Heat shock proteins have been implicated in modulating the cellular response to many stressors, and as molecular

chaperones in suppressing the aggregation or assisting in the refolding of partially denatured proteins. They usually protect against ischemic/reperfusion (I/R) injury *in vitro*^[8-11] and *in vivo*^[12-14]. However, whether gene transfer of the HSP20 gene into the beating heart produces a myocardial protective effect has not been shown. In the present study, we transferred the HSP20 gene through a recombinant adenovirus encoding HSP20 into the myocardium, and showed that HSP20 protected against I/R injury, probably by reducing myocardial apoptosis and necrosis in rats.

Materials and methods

Animals and experimental protocols Male adult Sprague-Dawley rats (230 g–280 g) received a standard diet and free water. The treatment of the animals and experimental protocols adhered to the guidelines of the Health Sciences Center of Peking University (Beijing, China). The animals were allowed to readjust to the new housing environment for 1 week before the experiments.

Rats were assigned randomly to 4 groups. In the no-vector control group, the chest was opened and injected with saline. The I/R control group was also injected with saline. The third group received the recombinant adenovirus encoding wild-type HSP20 (Ad.HSP20), and the fourth group received the recombinant adenovirus encoding green fluorescent protein (Ad.GFP).

Construction of recombinant adenoviruses The recombinant Ad.HSP20 and Ad.GFP were prepared as described previously^[15]. Adenovirus was propagated in 293 cells and purified by 2 rounds of CsCl density ultracentrifugation (4 °C, 13 000×g for 105 min and 16 h, respectively). Viral stocks were then desalted through a PD-10 desalting column (Amersham Biosciences, Buckinghamshire, UK) into a Tris-buffered solution (10 mmol/L Tris, pH 8.0, 2 mmol/L MgCl₂ and 4% sucrose)^[16], plaque-titered, aliquoted, and stored at -80 °C with 4% sucrose until use.

***In vivo* intracoronary delivery of adenoviruses** The surgical procedures were carried out as described previously^[17]. Donor rats were anesthetized with sodium pentobarbital (50 mg/kg, ip). Further injections were given as needed throughout the surgical procedure. Animals were placed supine on a thermoregulated table (37 °C). The surgery was carried out under sterile conditions. The animals were intubated and ventilated on a positive-pressure ventilator. The tidal volume was set at 1.5 mL–2.5 mL, and the respiratory rate was adjusted to within the range of 80 cycles/min to 90 cycles/min to maintain normal arterial p_{aO_2} , p_{aCO_2} , and pH. The chest was entered through a left intercostal approach.

Before virus infusion, adenosine (0.15 mg), lidocaine (0.03 mg), and heparin (50 U) were administered via the jugular vein. With the use of a 26 gauge needle, 200 µL diluted replication-deficient adenovirus (2.2×10^{10} pfu) or 200 µL sterile saline were injected from the apex of the left ventricle into the left ventricular cavity while the aorta and pulmonary arteries were clamped just above the aorta root. The clamp was maintained for 15 s when the heart pumped against a closed system. After injection, the exposed heart was monitored for 5 min for resumption of normal sinus rhythm. Hemodynamic indices were measured and electrocardiography was carried out throughout the experimental period.

Myocardial infarction protocol Four days after the injection of saline or virus, the animals were re-anesthetized and ventilated artificially with room air. The thorax was reopened and the heart were exposed to identify the left anterior descending coronary artery (LAD). A 7-0 silk suture was passed around the LAD with an atraumatic needle just 4 mm inferior to the left auricle, and the artery was occluded by snaring with a vinyl tube through which the ligature had been passed. The coronary artery was occluded by pulling the snare tight and securing it with a hemostat. Ischemia was confirmed by myocardial blanching and electrocardiography evidence of injury. After 20-min ischemia, the ligature was released and the heart was reperfused for 2 h. Reperfusion was identified by an obvious ST segment change.

Measurement of infarction At the end of the infarction protocol, the ligature around the LAD was retightened and 0.1 mL of 10% Evans blue dye was injected as a bolus into the left ventricle (LV) cavity with a 26-gauge needle positioned in the apex of the heart. When the eyes turned blue, the animals were euthanized immediately, the heart was excised and rinsed in water to remove excess dye, the atria and right ventricular free wall were removed, and the remaining LV was frozen. The LV was then cut from apex to base into 4–6 transverse slices of 2 mm thick. Each slice was weighed and then incubated in 4% triphenyltetrazolium chloride solution (TTC) in isotonic pH 7.4 phosphate buffer at 37 °C for 30 min. The slices were subsequently fixed in 10% formalin solution for 24 h. Viable tissue (red-stained by the TTC) was distinguished easily from the infarcted regions (pale or unstained by the TTC) and the risk area (unstained by Evans blue). The total slice area, the infarcted area, and the risk area of each slice were determined by computer-assisted planimetry (Leica Qwin image analysis software; Leica, Cambridge, UK). During planimetry, the operator was blinded as to the type of animal. The ratios of risk area to total slice area, infarct area to total slice area, and infarct area to risk

area were calculated and multiplied by the weight of the slice to determine risk and infarct weight per slice. Infarct size was expressed as a proportion of LV mass or risk area mass.

Hemodynamic studies Hemodynamic measurements were taken at 0 min, 10 min and 20 min ischemia and 30 min, 60 min and 120 min reperfusion. A 1.5 F micronanometer-tipped catheter was advanced into the LV through the right carotid artery. The heart rate, blood pressure, left ventricular end diastolic pressure (LVEDP), left ventricular end systolic pressure (LVESP) and maximal rates of pressure increase ($+dp/dt_{max}$) and decrease ($-dp/dt_{max}$) were recorded on a polygraph (NEC San-ei Instruments, Japan).

Measurement of serum cardiac troponin T (cTnT) and creatine phosphokinase (CK) levels At the end of the myocardial I/R experiment, a 1-mL blood sample was obtained from the carotid cannula, stored at 4 °C for 30 min, and centrifuged at $3000\times g$ for 10 min. The serum was stored at -40 °C prior to analysis. The concentration of serum cTnT was determined by the short-turn-around-time (STAT) assay (Roche Diagnostics, Basel, Switzerland), with use of the Roche Elecsys 2010 immunoassay analyzer (Roche Diagnostics). The serum was also analyzed spectrophotometrically for CK activity (Roche Diagnostics).

Western blot analysis Three hearts from each of the experimental groups were used separately for measurement of HSP20 by Western blot analysis. After 4 d of injection of saline or virus, the hearts were removed quickly, and the LV was separated and frozen in liquid nitrogen. The frozen LV tissue was homogenized in protein extraction buffer containing 20 mmol/L Tris-HCl, pH7.4, 1% Trion X-100, 150 mmol/L NaCl, 1 mmol/L ethylenediaminetetraacetic acid, 2.5 mmol/L sodium pyrophosphate, 1 mmol/L NaF, 1 mmol/L Na_3VO_4 and 0.1 mmol/L phenylmethylsulfonyl fluoride. Aliquots were resolved on sodium dodecyl sulphate-polyacrylamide gel electrophoresis. Proteins were transferred to polyvinylidene difluoride membranes (Schleicher & Schuell, Keene, NH, USA) and incubated with primary polyclonal anti-HSP20 antibodies (1:1000) (presented by Prof Rui-ping XIAO, NIH, USA), which recognized HSP20, at 4 °C overnight. Bound antibodies were detected using a secondary antibody conjugated to horseradish peroxidase (Santa Cruz Biotechnology, Inc, CA, USA) and visualized by use of an enhanced chemiluminescence kit (SuperSignal® West Pico Trial Kit, Pierce Biotechnology, Inc, IL, USA) and exposed to X-ray film for the appropriate time.

Terminal dUTP nick-end labelling staining Hearts were isolated from each group after I/R for analysis using the terminal dUTP nick-end labeling (TUNEL) assay. Tissue samples were fixed in a 4% paraformaldehyde solution, par-

affin embedded, and cut transversely into 6- μ m sections. The assay was operated according to the manufacturer's instructions (DeadEnd™ Fluorometric TUNEL System; Promega, WI, USA). Stained samples were analyzed using a confocal microscope; at least 500 cells were counted in randomly selected views.

Statistical analysis Data were expressed as mean \pm SD. Differences were analyzed for significance by one-way repeated-measures ANOVA and further analyzed with the use of the Newman-Keuls test for multiple comparisons between treatment groups. The results were considered significant at $P<0.05$.

Results

Expression of HSP20 Intraventricular injection of Ad.HSP20 *in vivo* resulted in increased HSP20 expression in the LV as compared with vector and Ad.GFP treatments (Figure 1A). The hearts treated with Ad.GFP showed only low-level of HSP20 expression, which indicates that treatment with viral vectors has no significant effect on HSP20 expression in the rat myocardium. LV treated with Ad.HSP20 showed homogenous expression of GFP, whereas those treated with vector showed no background fluorescence (Figure 1B).

Myocardial infarction Ad.HSP20-treated hearts showed a significant reduction in infarct size (39.2% \pm 4.3% risk area) compared with vector- and Ad.GFP-treated hearts (56.3% \pm 2.9% and 54.9% \pm 8.1%, respectively; $P<0.01$; Figure 2A). Infarct size did not differ between vector- and Ad.GFP-treated hearts ($P>0.05$). A similar result was observed when infarct size was expressed as a proportion of LV (Figure 2B). Both results suggest that the reduced infarct size observed in Ad.HSP20-injected hearts is entirely due to the overexpression of HSP20. However, the risk areas (% of LV) were not significantly different among the groups (ie 53.2% \pm 6.5%, 57.9% \pm 7.3%, and 56.4% \pm 7.5% in the vector-, Ad.GFP-, and Ad.HSP20-treated groups, respectively; $P>0.05$; Figure 2C).

HSP20 gene delivery reduced serum cTnT and CK levels Ad.HSP20-treated hearts showed a significant reduction in cTnT release (2.2 μ g/L \pm 1.7 μ g/L) compared with vector- and Ad.GFP-treated hearts (12.9 μ g/L \pm 3.2 μ g/L, and 11.8 μ g/L \pm 3.1 μ g/L, respectively; $P<0.01$; Figure 3A). Similar results were observed for CK release (Figure 3B).

HSP20 gene delivery attenuated apoptosis in the acute ischemia/reperfusion rat model Figure 4A shows representative apoptotic cardiomyocytes identified by TUNEL staining in the I/R-injured region. The ratio of TUNEL-positive

Figure 1. Expression of adenovirus-mediated gene delivery 4 d after intracoronary gene delivery. (A) Western blot showing expression of HSP20 proteins and β -actin after intracoronary delivery of vector, recombinant adenovirus encoding wild-type HSP20 (Ad.HSP20) or recombinant adenovirus encoding green fluorescent protein (Ad.GFP). (B) Representative image of high efficiency of GFP expression in hearts compared with vector after injection of Ad.HSP20.

cardiomyocytes to total number of cardiomyocytes in the Ad.HSP20 group was significantly reduced as compared with the vector and Ad.GFP groups ($15.4\% \pm 3.2\%$ vs $25.7\% \pm 4.5\%$ and $27.6\% \pm 2.2\%$, $P < 0.01$; Figure 4B).

HSP20 gene delivery improved cardiac function *in vivo* LVEDP, LVESP, $+dp/dt_{\max}$ and $-dp/dt_{\max}$ values are shown in Figure 5. All parameters were comparable among the 3 groups before and during ischemia and during reperfusion. All parameters, except LVEDP, declined in value after ischemia. LVEDP in HSP20-treated rats was significantly decreased after 60-min reperfusion compared with that in vector- and Ad.GFP-treated rats ($P < 0.05$, Figure 5A). LVESP, $+dp/dt_{\max}$, and $-dp/dt_{\max}$ values in HSP20-treated rats

Mean \pm SD. $^{\circ}P < 0.01$ vs Ad.GFP. (D) Typical reperfusion injury was observed in all groups by high-power microscopy ($\times 40$).

were significantly increased after 60-min reperfusion compared with those in vector- and Ad.GFP-treated rats ($P < 0.05$, Figure 5B, 5C, 5D).

Figure 3. (A) Alterations in the serum levels of cardiac troponin T (cTnT). (B) Alterations in the serum levels of creatine phosphokinase (CK). $n=6$. Mean \pm SD. ^c $P<0.01$ vs Ad.GFP.

Discussion

Gene therapy has emerged as a genuine alternative therapy in coronary artery disease, including ischemic heart disease. One of the commonly used intramyocardial gene transfer methods is direct intramyocardial injection. There have been a few promising trials involving the use of direct intramyocardial injection in this area^[18,19]. However, the technical problems with this method are that only a small volume of the myocardium is accessible for transfection and the distribution of transgenes in the myocardium is not homogeneous. To overcome these problems, we used an *in vivo* intracoronary gene delivery method that modified the approach of Hajjar *et al*^[17] to transduce the HSP20 gene into the ventricular muscle with the use of recombinant adenoviral vectors. The adenoviral vectors are delivered into the myocardium via the coronary circulation. Using this delivery method, we sought to elucidate a direct cause and effect relationship between HSP20 and cardioprotective effects in the intact rat heart.

The present study demonstrates, for the first time, that gene transfer of Ad.HSP20 into the LV muscle causes robust expression of HSP20 as compared with vector or Ad.GFP transfer. Ad.GFP-treated LV showed no significant increase in HSP20 expression compared with vector-treated LV. These

Figure 4. Terminal dUTP nick-end labelling staining showed *in vivo* cardiomyocyte apoptosis after 20-min ischemia and 120-min reperfusion. (A) Cardiomyocytes are depicted by red fluorescence from propidium iodide. Yellow fluorescence showed TUNEL-positive nuclei. (B) Proportion of positive TUNEL-stained nuclei in tissue sections from the no-vector control group or rat hearts exposed to ischemia/reperfusion under different treatments. $n=3-4$. Mean \pm SD. ^c $P<0.01$ vs Ad.GFP.

results suggest that the increased expression in the Ad.HSP20-treated hearts is not due to virus-related stress.

Infarct size was reduced significantly in the I/R hearts injected with Ad.HSP20. We also examined serum cTnT and CK levels independently. cTnT originating exclusively from the myocardium clearly differs from skeletal muscle troponin T. As a result of its high tissue specificity, cTnT is a cardio-specific, highly sensitive marker for myocardial damage^[20]. Our results showed that the cTnT level in Ad.HSP20-treated

Figure 5. Cardiac function *in vivo*. Left ventricular end diastolic pressure (LVEDP) (A), left ventricular end systolic pressure (LVESP) (B), maximal rate of pressure increase ($+dp/dt_{max}$) (C), and decrease ($-dp/dt_{min}$) (D) were measured in the left ventricle at different time points in vector-, Ad.HSP20-, or Ad.GFP-treated hearts. $n=6-8$. Mean \pm SD. ^b $P<0.05$ vs Ad.GFP.

hearts was reduced significantly as compared with that in vector- and Ad.GFP-treated hearts. Similar results were shown with CK. TUNEL staining showed that apoptosis of cardiomyocytes was reduced in Ad.HSP20-treated hearts.

The decrease of LVEDP and increase of LVESP, $+dp/dt_{max}$ and $-dp/dt_{min}$ in HSP20-treated hearts may be explained by HSP20 being an actin-associated protein. It is biochemically associated with α B-crystallin and localized to distinct transverse bands in a pattern similar to α B-crystallin and sarcomeric actin^[21,22]. Phosphorylated HSP20 increases the contractility rate of cardiac myocytes, which indicates that HSP20 is involved in the regulation of myocardial contractility^[6,7].

Heat shock proteins are a family of endogenous protective proteins. Various HSP have protective effects against stress injury. HSP70 prevents cell death by inhibiting apoptosis via associating with apoptosis protease activating factor-1 (Apaf-1) and blocking the assembly of a functional apoptosome^[23]. Combined and individual mitochondrial HSP60 and HSP10 expression in cardiomyocytes protects mitochondrial function and decreases apoptotic cell death induced by simulated I/R accompanied by decreased mitochondrial cytochrome c release and caspase-3 activity^[11]. HSP60 interacts with Bax and Bak to regulate apoptosis^[24]. Overexpression of α B-crystallin in transgenic mice hearts provides resistance to I/R injury by negatively regulating myocyte and non-myocyte apoptosis^[25]. HSP27 binds to cytochrome c released from the mitochondria into the cytosol and prevents cytochrome c-mediated interaction of Apaf-1 with procaspase-9^[26]. These results highlight the notion that the protective effects of HSP are closely related to mitochondrial function. Thus, HSP are anti-apoptotic proteins in cardiomyocytes.

Myocardial ischemia is followed frequently by reperfusion. Reperfusion and the resultant re-oxygenation lead to the generation of oxygen radicals that can cause reperfusion injury. Our results *in vivo* are consistent with those of Fan *et al*^[15], who showed that HSP20 and its phosphorylation at Ser16 might provide protective effects against β -agonist-induced apoptosis *in vitro*.

Death of cardiomyocytes due to I/R injury is caused by 2 distinct mechanisms, necrosis, and apoptosis, which contribute independently to myocardial infarction^[25,27]. The infarct area represents cell death, including necrotic cell death and apoptotic cell death. cTnT and CK are indicators of myocardial necrosis, whereas TUNEL staining can reveal apoptosis. Thus, our results suggest that the protective effect of HSP20 is attributed to a reduction of necrosis and apoptosis in cardiomyocytes. In addition, our recent data shows that lactate dehydrogenase release and caspase-3

activity in H9c2 cells infected with Ad.HSP20 are also decreased. Therefore, the cardioprotective effect of HSP20 *in vivo* might be mediated mainly by inhibiting both cardiomyocyte necrosis and apoptosis.

In conclusion, our results show that overexpression of HSP20 protects against I/R injury *in vivo*, not only by inhibiting cardiomyocyte necrosis and apoptosis but also by increasing myocardial contractility. Our data suggest that HSP20 is a potential therapeutic protein for ischemic diseases and additional experiments should be carried out.

Welcome Contributions to JZUS-B (www.zju.edu.cn/jzus)

Introducing a New One——Journal of Zhejiang University SCIENCE B (Biomedicine and Biotechnology), ISSN 1673-1581, Monthly

JZUS-B is indexed & abstracted by the famous database MEDLINE, and will also be accepted by PubMed Central (PMC) which is a new core full text-online database of MEDLINE in Life Science Periodicals and today, is among 189 Biology and Science journals accepted by PMC. JZUS-B will be the only one from China.

JZUS-B has linked its website (<http://www.zju.edu.cn/jzus>) with MEDLINE (<http://www.ncbi.nlm.nih.gov/PubMed>), CrossRef: <http://www.crossref.org> (doi:10.1631/jzus.xxxx.Bxxxx), etc. Therefore, your latest research would be rapidly spread on-line and read by researchers in biology and medicine area in the world.

JZUS-B has an International Editorial Board, International Peer Review System, International Author-Pool and International network, all of which are highly appraised by MEDLINE, Ei and SCI, etc.

JZUS-B now has contributions from universities & Chinese Academy of Sciences of the China mainland and Hong Kong, Macao and Taiwan, from over 20 countries, such as USA, Canada, Japan, Germany, New Zealand, U.K., Netherlands, Italy, Austria, Australia, Singapore, Korea, India, Pakistan, Iran, Malaysia, Thailand, Russia, Ukraine etc.

Welcome Your Contributions to JZUS-B

JZUS-B warmly and sincerely welcome scientists all over the world to contribute to JZUS-B in the form of Review, Article and Science Letters focused on biomedicine and biotechnology areas. Especially, Science Letters (3-4 pages) would be published as soon as about 30 days (Note: detailed research articles can still be published in the professional journals in the future after Science Letters are published by JZUS-B).

Contributions requests

(1) Electronic manuscript should be sent to jzus@zju.edu.cn only. If you have any question, please feel free to visit our website: <http://www.zju.edu.cn/jzus>, and hit “For Authors”.

(2) English abstract should include Objective, Method, Result and Conclusion.

(3) Tables and figures could be used to prove your research result.

(4) Full text of the Science Letters should be in 3-4 pages. The length of articles and reviews are not limited.

(5) Please visit our website (<http://www.zju.edu.cn/jzus/pformat.htm>) to see paper format.

Introduction

Apoptosis is essential for normal development and aging in multicellular organisms, and abnormal regulation of apoptosis can result in multiple human diseases. Mitochondria release apoptogenic proteins such as cytochrome C and apoptosis-inducing factor (AIF) into the cytosol, which are involved in the signaling pathway of caspases and induce cell apoptosis^[1–3]. One major pathway of the release of the apoptogenic factors to the cytosol is via the rupture of the outer mitochondrial membrane due to mitochondrial permeability transition (MPT) pore opening^[3]. It is suggested that MPT pores play a potent role in cell aging^[4,5], and opening

Abstract

Aim: To investigate methods for identifying specific cyclophilin D (CypD) inhibitors derived from quinoxaline, thus developing possible lead compounds to inhibit mitochondrial permeability transition (MPT) pore opening. **Methods:** Kinetic analysis of the CypD/inhibitor interaction was quantitatively performed by using surface plasmon resonance (SPR) and fluorescence titration (FT) techniques. IC₅₀ values of these inhibitors were determined by PPIase inhibition activity assays. **Results:** All the equilibrium dissociation constants (K_D) of the seven compounds binding to CypD were below 10 μmol/L. The IC₅₀ values were all consistent with the SPR and FT results. Compounds GW2, 5, 6, and 7 had high inhibition activities against Ca²⁺-dependent rat liver mitochondrial swelling and Ca²⁺ uptake/release. Compound GW5 had binding selectivity for CypD over CypA. **Conclusion:** The agreement between the measured IC₅₀ values and the results of SPR and FT suggests that these methods are appropriate and powerful methods for identifying CypD inhibitors. The compounds we screened using these methods (GW1–7) are reasonable CypD inhibitors. Its potent ability to inhibit mitochondrial swelling and the binding selectivity of GW5 indicates that GW5 could potentially be used for inhibiting MPT pore opening.

of the MPT pores may cause changes in mitochondrial shape and function, such as the massive swelling of mitochondria, rupture of the outer membrane and release of inter-membrane components that induce apoptosis. It has been reported that the agents that inhibit MPT may have therapeutic potential for the treatment of human diseases such as ischemia-reperfusion injury in peripheral organs, trauma and neurodegenerative diseases^[5–7].

Recent studies have shown that the MPT pore is composed of three major proteins: the voltage-dependent anion channel (VDAC) in the outer membrane that forms a large H₂O-filled pore with a diameter of 2.5–3.0 nm, the adenine nucleotide translocator (ANT) that mediates the ADP-ATP

exchange in the inner membrane, and cyclophilin D (CypD)^[8]. CypD belongs to the family of highly homologous peptidyl prolyl *cis-trans* isomerases (PPIases) that are thought to be important for protein folding, and can bind to the immunosuppressor cyclosporin A (CSA)^[9,10]. It is known that CypD is a mitochondrial-targeted PPIase, even though its specific physiological role is largely obscure^[11,12]. CypD has been confirmed to play a decisive role in MPT pore regulation, and PPIase activity of CypD might be a necessary step in MPT pore opening^[8,13]. A model was recently proposed concerning the mechanism of permeability transition-related cytochrome c release, whereby the Ca²⁺ requirement for the induction of the MPT pore opening might be due to the Ca²⁺-dependent interaction between CypD and ANT^[14–16]. It has been reported that CypD inhibitor CSA and its analogues may block MPT pore opening^[17,18], which thereby makes discovering the CypD inhibitor an appealing project. However, to our knowledge, investigating the small molecular CypD-specific inhibitor for allowing brain penetration is still a

challenge.

In this paper, we report 7 novel quinoxaline derivatives (Scheme 1 and Figure 1) that inhibit the PPIase activity of CypD. By using surface plasmon resonance (SPR) and fluorescence titration techniques, the kinetics of the CypD-inhibitor interaction was investigated. The compounds' inhibition effects against rat liver Ca²⁺-dependent mitochondrial swelling and Ca²⁺ uptake/release were also determined. The binding selectivity of CypD over CypA for the tested compounds was analyzed, and explained based on the molecular docking technique. We hope that this research will provide a useful approach for the discovery of cyclophilin D inhibitors, and thus help to develop promising compounds using CypD as a drug target for the inhibition of MPT pore opening.

Materials and methods

All solvents and reagents were purchased commercially and were used without further purification. ¹H nuclear mag-

Figure 1. Chemical structures of GW1–7. GW1: R=ethoxy; GW2: R=diethylamino; GW3: R=3-((R)-ethoxycarbonyl) piperidino; GW4: R=3-((S)-ethoxycarbonyl) piperidino; GW5: R=pyrrolidin-1-yl; GW6: R=morpholino; GW7: R=*N,N*-diisopropylamino.

netic resonance (NMR) spectra (400 MHz) were recorded on a Varian (Palo Alto, California, USA) Mercury-400 spectrometer. Plasmid extraction was performed using the GenElute Plasmid Miniprep Kit (Sigma-Aldrich, St Louis, Missouri, USA).

The compound 6-amino-2,3-di(furan-2-yl)quinoxaline was synthesized according to the patented method^[19]. (*R*)-ethyl nipecotate and (*S*)-ethyl nipecotate were prepared according to a previously published method^[20].

General preparation procedure of compounds GW1–7

The chemical structures of the seven tested compounds are shown in Figure 1, and the general synthetic procedure is shown in Scheme 1. Briefly, the compounds were prepared from 2,4-dinitroaniline in five steps.

2,3-di(furan-2-yl)-6-ethoxycarbonylamino quinoxaline (GW1) To a solution of 6-amino-2,3-di(furan-2-yl)quinoxaline (83.1 mg, 0.30 mmol) and triethylamine (100 μ L, 0.72 mmol) in dichloromethane (10 mL) we added triphosgene (30 mg, 0.10 mmol) while stirring. The mixture was stirred at room temperature for 1 h, then ethanol (100 μ L, 1.7 mmol) was added. After another 1 h of stirring, the solvent was evaporated in a vacuum to give the crude product, which was further purified by flash column chromatography on a silica gel using petro-ether/ethyl acetate (3:1) as the eluent. The obtained compound GW1 (45.2 mg, 43% yield) was a yellowish amorphous solid. ¹H NMR (CDCl₃, 400 MHz). δ : 8.10 (d, 1H, *J*=2.4 Hz), 8.05 (d, 1H, *J*=9.1 Hz), 7.87 (dd, 1H, *J*=2.2 Hz, 9.1 Hz), 7.60 (m, 2H), 7.17 (s, 1H), 6.62 (m, 2H), 5.54 (m, 2H), 4.28 (q, 2H, *J*=7.0 Hz), 1.32 (t, 3H, *J*=7.0 Hz); IR (KBr): 3419, 3246, 2982, 2928, 1732, 1622, 1572, 1539, 1495, 1261, 1226 per cm; High-resolution mass spectra (electron impact) calculated value [HRMS(EI) Calcd] for C₁₉H₁₅N₃O₄ 349.1063; Found 349.1068.

2,3-di(furan-2-yl)-6-*N*-(*N*',*N*'-diethylcarbamoyl)amino quinoxaline (GW2) GW2 was synthesized by using a method similar to that described for the preparation of GW1, except that diethylamine was used instead of ethanol. GW2 is a brown amorphous solid (63.0 mg, 56% yield). ¹H NMR (CDCl₃, 400 MHz). δ : 8.03 (d, 2H, *J*=1.8 Hz), 7.96 (d, 1H, *J*=1.0 Hz), 7.59 (dd, 2H, *J*=0.7 Hz, 1.0 Hz), 6.78 (s, 1H), 6.61 (ddd, 2H, *J*=0.7 Hz, 3.5 Hz, 12.2 Hz), 6.54 (m, 2H), 3.42 (q, 4H, *J*=7.2 Hz), 1.25 (t, 6H, *J*=7.2 Hz); IR (KBr): 3440, 3114, 2972, 2929, 1649, 1524, 1491, 1429, 1265 per cm; HRMS (EI) Calcd for C₂₁H₂₀N₄O₃ 376.1535; Found 376.1528.

2,3-di(furan-2-yl)-6-((*R*)-3-ethoxycarbonyl-piperidino) carbonylamino quinoxaline (GW3) GW3 was prepared by using a method similar to that described for the preparation of GW1, except that (*R*)-ethyl nipecotate was used instead of ethanol. GW3 is a yellow amorphous solid (66.4 mg, 48% yield). ¹H NMR (CDCl₃, 400 MHz). δ : 8.13 (s, 1H), 8.02 (m,

1H), 7.95 (m, 2H), 7.59 (m, 2H), 6.59 (m, 2H), 6.53 (m, 2H), 4.22 (m, 2H), 3.99 (m, 2H), 3.48 (dd, 1H, *J*=3.3, 14.2 Hz), 3.10 (m, 1H), 2.70 (m, 1H), 2.20 (m, 1H), 1.45–1.95 (m, 3H), 1.29 (t, 3H, *J*=6.1 Hz); IR (KBr): 3404, 2937, 2860, 1728, 1649, 1570, 1527, 1473, 1431, 1256 cm⁻¹; HRMS(EI) Calcd for C₂₅H₂₄N₄O₅ 460.1747; Found 460.1725. [α]_D²⁰ = -52° (c=0.83, CH₃OH).

2,3-di(furan-2-yl)-6-((*S*)-3-ethoxycarbonyl-piperidino) carbonylamino quinoxaline (GW4) GW4 was prepared by using a method similar to that described for GW1 except that (*S*)-ethyl nipecotate was used instead of ethanol. GW4 was a yellow amorphous solid (68.7 mg, 50% yield). ¹H NMR (CDCl₃, 400 MHz). δ : 8.13 (s, 1H), 8.02 (m, 1H), 7.95 (m, 2H), 7.59 (m, 2H), 6.59 (m, 2H), 6.53 (m, 2H), 4.22 (m, 2H), 3.99 (m, 2H), 3.48 (dd, 1H, *J*=3.3, 14.2 Hz), 3.10 (m, 1H), 2.70 (m, 1H), 2.20 (m, 1H), 1.45–1.95 (m, 3H), 1.29 (t, 3H, *J*=6.1 Hz); IR (KBr): 3404, 2937, 2860, 1728, 1649, 1570, 1529, 1475, 1431, 1254 cm⁻¹; HRMS(EI) Calcd for C₂₅H₂₄N₄O₅ 460.1747; Found 460.1738. [α]_D²⁰ = +55° (c=1.78, CH₃OH).

2,3-di(furan-2-yl)-6-(pyrrolidin-1-yl)carbonylamino quinoxaline (GW5) GW5 was prepared by using a method similar to that described for the preparation of GW1 except that pyrrolidine was used instead of ethanol. GW5 is a brown amorphous solid (106.9 mg, 95% yield). ¹H NMR (CDCl₃, 400 MHz). δ : 8.18 (dd, 1H, *J*=2.3, 9.2 Hz), 8.02 (m, 2H), 7.60 (m, 2H), 6.68 (s, 1H), 6.65 (d, 1H, *J*=3.4 Hz), 6.60 (dd, 1H, *J*=0.7, 3.4 Hz), 6.55 (m, 2H), 3.53 (t, 4H, *J*=6.6 Hz), 2.00 (t, 4H, *J*=6.6 Hz); IR (KBr): 3404, 2970, 2877, 1672, 1568, 1525, 1502, 1429, 1382, 1340, 1203 per cm; HRMS(EI) Calcd for C₂₁H₁₈N₄O₃ 374.1379; Found 374.1360.

2,3-di(furan-2-yl)-6-morpholinocarbonylamino quinoxaline (GW6) GW6 was prepared by using a method similar to that described for the preparation of GW1 except that morpholine was used instead of ethanol. GW6 was a yellow amorphous solid (101.4 mg, 87% yield). ¹H NMR (CDCl₃, 400 MHz). δ : 7.96–8.06 (m, 3H), 7.60 (m, 2H), 6.99 (s, 1H), 6.66 (dd, 1H, *J*=0.8, 3.5 Hz), 6.63 (dd, 1H, *J*=0.8, 3.5 Hz), 6.56 (m, 2H), 3.77 (t, 2H, *J*=4.9 Hz), 3.56 (t, 2H, *J*=4.9 Hz), 1.80 (b, 4H); IR (KBr): 3423, 2920, 2852, 1653, 1529, 1475, 1429, 1333, 1254 per cm; HRMS(EI) Calcd for C₂₁H₁₈N₄O₄ 390.1328; Found 390.1309.

2,3-di(furan-2-yl)-6-*N*-(*N*',*N*'-diisopropylcarbamoyl) amino quinoxaline (GW7) GW7 was prepared by using a method similar to that described for the preparation of GW1 except that diisopropylamine was used instead of ethanol. GW7 is a brown amorphous solid (43.9 mg, 36% yield). ¹H NMR (CDCl₃, 400 MHz). δ : 7.99–8.06 (m, 2H), 7.90 (d, 1H, *J*=2.3 Hz), 7.57 (m, 2H), 6.76 (s, 1H), 6.59 (m, 2H), 6.51 (m, 2H), 3.99 (m, 2H), 1.32 (d, 12H, *J*=6.9 Hz); IR (KBr): 3427, 2968, 2928, 1647, 1566, 1520, 1495, 1433, 1375, 1205 per cm; HRMS

(EI) Calcd for $C_{23}H_{24}N_4O_3$ 404.1848; Found 404.1857.

Preparation of His-tagged human CypA protein All cloning techniques including polymerase chain reaction (PCR), restriction, ligation, *E. coli* transformation, and plasmid DNA preparation were carried out according to standard methods^[21]. The His-tagged CypA protein was expressed and purified from the plasmid pQE30-CypA according to the published procedure^[22].

Preparation of rat CypD protein The plasmid pcDNA3.1(+)/Zeo-CypD was kindly provided by Dr James D LECHLEITER (University of Texas Health Science Center, U3SA). By using the forward primer 5'-ATAGAATTCATGCT-AGCTCTGCGCTGCG-3' (containing an *EcoRI* site) and the reverse primer 5'-ATATCTCGAGGCTCAACTGGCCACAGTC-3' (containing an *XhoI* site), the PCR product was subcloned into the vector pGEX-4T-1 between the *EcoRI* and *XhoI* sites to obtain the expression plasmid pGEX-4T-1-CypD. Sequencing was carried out to confirm the insertion.

E. coli strains were prepared in Luria-Bertani medium containing 100 mg/mL ampicillin. BL21 (DE3) bacteria transformed with pGEX-4T-1-CypD were grown until the OD₆₀₀ reached 0.8, and isopropylthio- β -D-galactoside (IPTG) was added to a final concentration of 0.2 mmol/L to induce GST-CypD expression at 25 °C overnight.

Bacteria were harvested and lysed by sonication in a sonication buffer [1×phosphate-buffered saline (PBS), 1 mmol/L phenylmethylsulfonyl fluoride (PMSF), pH 7.3, 1 mmol/L ethylenediamine tetraacetic acid (EDTA), 1% Triton X-100]. The bacterial lysate was centrifuged and the supernatant was collected. GST-CypD protein was purified by using a glutathione Sepharose 4B column (Amersham Biosciences, Uppsala, Sweden), and the purified CypD protein was obtained by the on-column cleavage of GST-CypD using thrombin according to the instructions given by the manufacturers of the glutathione Sepharose 4B column (Amersham Biosciences). The purity of the obtained CypD protein was verified by sodium dodecyl sulfate-polyacrylamide gel electrophoresis as a single band.

Surface plasmon resonance technology-based Biacore 3000 analyses The interactions between compounds GW1-7 and CypD (A) were performed using the dual flow cell Biacore 3000 instrument (Biacore AB, Uppsala, Sweden). All the experiments were carried out using HBS-EP (10 mmol/L *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid [HEPES], 150 mmol/L NaCl, 3.4 mmol/L EDTA and 0.005% surfactant P20 at pH 7.4) as a running buffer at a constant flow rate of 20 μ L/min at 25 °C. The protein was immobilized directly and covalently on the hydrophilic carboxymethylated dextran matrix of the CM5 sensor chip (BIAcore) by using

the standard primary amine coupling reaction. The protein to be bound to the sensor chip was diluted in 10 mmol/L sodium acetate buffer (pH 6.5) to a concentration of 17 μ mol/L. The concentrations of the compounds dissolved in the running buffer varied from 1.18 to 10 μ mol/L. All the data analyses were carried out using BIAevaluation software, and the sensorgrams were processed by automatic correction for nonspecific bulk refractive index effects. The kinetic analyses of the ligand binding to the protein were performed based on the 1:1 Langmuir binding fit model according to the procedures described in the software manual.

Fluorescence titration assay Fluorescence measurements were performed on a Hitachi (Tokyo, Japan) F-2500 fluorescence spectrophotometer equipped with a thermal controller. The change in the intrinsic tryptophan fluorescence when the compound bound to the protein (CypA or CypD) was monitored using a procedure similar to that described in the literature^[23,24]. The experiments were carried out at 25 °C in PBS (pH 7.3) with the protein concentration set at 13 μ mol/L and the compound concentrations varied from 0 to 40 μ mol/L. The compounds were prepared in dimethylsulfoxide as a stock solution of 10 mmol/L. The fluorescent absorption was recorded with excitation at 280 nm and emission at 340 nm.

PPIase inhibition activity assay The PPIase activity assay for the proteins CypA and CypD was performed based on a published method^[25] with some modifications. The substrate *N*-succinyl-Ala-Ala-Pro-Phe-p-nitroanilide (Suc-AAPF-pNA, S-7388) and α -chymotrypsin (C-7762) were purchased from Sigma (St Louis, Missouri, USA). Suc-AAPF-pNA was dissolved in tetrahydrofuran containing 400 mmol/L of LiCl, and the stock solution concentration was 10 mmol/L. α -chymotrypsin was dissolved in 1 mmol/L HCl containing 2 mmol/L $CaCl_2$, and the stock solution concentration was 80 mmol/L. The assay buffer (173 μ L of 50 mmol/L HEPES, 100 mmol/L NaCl; pH 8.0 at 0 °C; final concentration 43 mmol/L HEPES, 86 mmol/L NaCl), 15 μ L of de-ionized water and CypD (2 μ L of a 2700 nmol/L stock solution) and the compounds (final concentration ranging from 100 nmol/L to 50 μ mol/L) were pre-equilibrated for 3 h on ice. Immediately before the assay was started, 7.5 μ L of chymotrypsin solution was added. Absorbance readings at 390 nm were recorded when 2.5 μ L of the peptide substrate was added into the 1 cm path length cuvette and the solution was mixed rapidly. The data were collected on a Hitachi U2010 spectrophotometer.

Rat liver mitochondrial swelling and Ca^{2+} uptake/release inhibition assays The mitochondrial swelling and Ca^{2+} uptake/release inhibition assays were carried out according to published methods^[26]. The mitochondria were isolated

by differential centrifugation from the livers of adult Wistar rats (180–200 g) after overnight starvation treatment. The rat livers were excised and washed with 0.25 mol/L sucrose. The fat and connective tissue were removed, and the livers were homogenized (1/10, w/v) using buffer A (250 mmol/L mannitol, 0.5 mmol/L EDTA, 5 mmol/L HEPES, 0.1% bovine serum albumin; pH 7.4) on ice. The homogenate was centrifuged at 1000×g for 10 min in a Biofuge Stratos centrifuge (Hereus Company, Hanau, Germany). The sediment was discarded and the supernatant was centrifuged at 1000×g for 10 min twice. The collected supernatant was then further centrifuged at 10 000×g for 15 min. The pellet (mitochondrial fraction) was resuspended in the test buffer (250 mmol/L mannitol, 70 mmol/L sucrose, 5 mmol/L HEPES; pH 7.4). The total mitochondrial protein was determined by using the Lowry assay using bovine serum albumin as a standard. Rat mitochondria were added to the test buffer to yield a final concentration of 0.5 mg protein per mL^[27]. The tested compounds (100 μmol/L) were mixed with mitochondria for 1 h before CaCl₂ (200 μmol/L) was added. Mitochondrial swelling was determined by monitoring absorbance at 540 nm using a Hitachi U2010 spectrophotometer and the mitochondrial Ca²⁺ uptake/release assay was monitored using a Hitachi F-2500 fluorescence spectrophotometer as described previously^[26].

Molecular modeling and docking The CypD sequence from *Rattus norvegicus* was retrieved from GenBank (GenBank protein ID U68544; <http://www.ncbi.nlm.nih.gov>). The CLUSTAL W program was used to carry out sequence alignment between the sequences of CypD from *Rattus norvegicus* and human CypA^[28]. The sequence similarity identity between CypD and CypA was 63%, and positives were 81%, making the Protein Data Bank (PDB) of human CypA an ideal template for CypD 3-D model building. The 3-D model of the TrpRS was generated based on PDB templates 1AK4^[29], 1AWT^[30], and 1NMK^[31] retrieved from the Protein Data Bank by using the MODELLER program^[32] encoded in Insight II^[33]. MODELLER uses a spatial restraint method to build up 3-D protein models. The structure of each template protein was used to derive spatial restraints expressed as probability density functions for each of the restrained features of the models. The structure with the lowest violation score and lowest energy score was chosen as the candidate. Refinements of the routine in the Homology module of Insight II were used to adjust the positions of the side chains. Finally, the structural models were optimized using Amber force field^[34] with the following parameters: a distance-dependent dielectric constant of 4.0, nonbonded cut-off 10 Å, and Kollman-all-atom charges^[34].

The structures were first minimized by steepest descent, then by conjugating the gradient method to the energy gradient root-mean-square <0.05 kcal·(mol·Å)⁻¹. Several structural analysis software packages were used to check the structure quality. The Prostat module of Insight II was used to analyze the bonds, angles and torsions. The Profile-3D program^[35] was used for checking the structure and sequence compatibility. The 3-D structures of the compounds GW1–7 were constructed from scratch by Sybyl 6.8^[36], and optimized to energy convergence with the Tripos force field and MMFF94 charges.

The major residues possibly comprising the binding site of CypD were identified by sequence alignment with human CypA, and the SiteID program encoded in Sybyl 6.8^[36]. The surface structure of the binding pocket was constructed by using the MOLCAD module of Sybyl 6.8.

The DOCK suite of programs is designed to find possible orientations of a ligand in a “receptor” site^[37]. The orientation of a ligand is evaluated with a shape-scoring function and/or a function approximating the ligand-receptor binding energy. The shape-scoring function is an empirical function resembling the van der Waals’ attractive energy. The ligand-receptor binding energy is taken to be approximately the sum of the van der Waals’ and electrostatic interaction energies. After the initial orientation and scoring evaluation, a grid-based rigid body minimization is carried out for the ligand to locate the nearest local energy minimum within the receptor binding site. The position and conformation of each docked molecule were optimized using the single anchor search and torsion minimization method of DOCK 4.0. Thirty conformations per ligand building a cycle and 50 maximum anchor orientations were used in the anchor-first docking algorithm. All docked configurations were energy minimized using 100 maximum iterations and one minimization cycle.

Results and Discussion

Synthesis of the compounds Generally, the compounds GW1–7 were synthesized as outlined in Scheme 1.

Kinetic analysis of CypD (A) binding to GW1–7 by surface plasmon resonance In order to perform kinetic analyses of the binding of GW1–7 to CypD and CypA, the Biacore 3000 instrument (based on surface plasmon resonance [SPR] technology) was used. As a typical example, the Biacore sensorgrams for the binding of GW2 to the immobilized CypD are shown in Figure 2. The 1:1 Langmuir binding fit model was used for determining the equilibrium dissociation constant (K_D), and the association (k_{on}) and dissociation (k_{off}) rate constants by using Equations (1) and (2).

$$\frac{dR}{dt} = k_{\text{on}} \times C \times (R_{\text{max}} - R) - k_{\text{off}} \times R \quad (1)$$

where R represents the response unit, C is the concentration of the analyte, and

$$K_{\text{D}} = k_{\text{off}}/k_{\text{on}} \quad (2)$$

The obtained results were evaluated by χ^2 analysis. All the kinetic parameters are listed in Table 1.

The Biacore results show that all the 7 tested compounds exhibited strong binding affinities with CypD, with K_{D} values approximately 3–6 $\mu\text{mol/L}$. Due to the high structural homology of CypD and CypA, the tested compounds had high binding affinities with CypA, as indicated in Table 1. However, compound GW5 exhibited higher binding specificity with CypD than with CypA. This was further verified by the intrinsic fluorescence titration analysis and cyclophilin PPIase activity inhibition assay as shown in Tables 2 and 3. Structurally, the R group of the compound (Scheme 1) might play an important role in the ligand binding selectivity for CypD over CypA.

In addition, the K_{D} values obtained from the Biacore assay agreed with the apparent equilibrium dissociation constants (K_{D}) from the intrinsic fluorescence titration analysis

Figure 2. Sensorgrams of the binding of GW2 to CypD measured by the Biacore assay. Representative sensorgrams obtained from the injection of GW2 at concentrations of 1.18, 1.68, 2.40, 3.43, 4.90, 7.00, and 10.00 $\mu\text{mol/L}$ over CypD immobilized on the CM5 chip.

and the IC_{50} values in the cyclophilin PPIase activity inhibition determination as shown in Tables 2 and 3. In agreement with Huber *et al*^[38], we suggest that Biacore is a powerful and useful method for screening cyclophilin inhibitors.

Table 1. Kinetic parameters of GW1–7 binding to CypD and CypA (in parentheses) as analyzed using Biacore 3000.

Compound	R_{max}	$k_{\text{on}}/\text{mol}\cdot\text{L}^{-1}\cdot\text{s}^{-1}$	$k_{\text{off}}/\text{s}^{-1}$	$K_{\text{D}}/\mu\text{mol}\cdot\text{L}^{-1}$	χ^2

Intrinsic fluorescence titration analysis of compounds

binding to CypD(A) Because both of the binding sites of CypD and CypA have a tryptophan residue (Trp 124 for CypD and Trp 121 for CypA), we investigated the binding affinities of the tested compounds for CypD and CypA by using an intrinsic fluorescence titration technique^[23]. During the assay, a 1:1 ratio of CypD(A) to binding compound was used based on published information about CypA/CSA interactions^[39,40] and the results of our molecular docking analyses. The apparent equilibrium dissociation constant (K_D') used for evaluating CypD(A) binding affinity to the tested compound was calculated according to the method in the literature^[23]. We assumed that a 50% occupancy of CypD (or CypA) is set at a fractional fluorescence change of 0.5 ($FC_{0.5}$), and at this point the concentration of the bound ligand is equal to that of the bound protein, which is half of the total concentration of protein. Accordingly, K_D' is equal to the total ligand concentration minus the concentration of the bound protein at $FC_{0.5}$ ^[23].

Figure 3 shows the typical tryptophan fluorescence quenching of CypD induced by titration of the tested compounds with an increase in their concentration. Since none of the compounds showed any intrinsic fluorescence absorption, their possible effects on the experiments could be discounted (data not shown). The K_D' values of GW1–7 are summarized in Table 2. Obviously, the binding selectivity of GW5 for CypD over CypA could also be determined, and the K_D' values are very comparable to the K_D values determined by the Biacore assay.

Figure 3. Tryptophan fluorescence quenching by compounds binding to CypD. CypD (13 mmol/L) was incubated with increasing amounts of GW1–7, respectively. ▲, GW1, 0–30 $\mu\text{mol/L}$; ▼, GW2, 0–30 $\mu\text{mol/L}$; ■, GW3, 0–40 $\mu\text{mol/L}$; ●, GW4, 0–40 $\mu\text{mol/L}$. The data for GW5–7 are not shown here for clarity. The resulting fluorescence change is plotted as a fraction of the maximal change.

CypD (A) PPIase activity inhibition assay Both CypD and CypA belong to the PPIase family, and classic spectrophotometric methods^[41] can be used to determine the PPIase inhibition activity of GW1–7 against CypD and CypA. During the assay, the rate constants for the *cis-trans* interconversion were evaluated by fitting the data to the integrated first-order rate equation by nonlinear least-square analysis^[25,41].

As a typical example, Figure 4 shows the CypD PPIase inhibition results with increases in the concentrations of the

Figure 4. CypD PPIase activity inhibition assay for GW1–7. PPIase (26 nmol/L) was pre-incubated with the tested compound at a number of concentrations, and the PPIase activity change was plotted as a fraction of the maximal change. ▲, GW1 (1.0, 1.25, 2.5, 5.0, 7.5, 10.0, 12.5, 25.0, 50.0 $\mu\text{mol/L}$); ▼, GW2 (1.0, 2.5, 3.75, 5.0, 7.5, 10.0, 12.5, 25.0, 50.0 $\mu\text{mol/L}$); ■, GW3 (0.1, 0.5, 1.0, 1.25, 2.5, 3.75, 5.0, 7.5, 10.0, 25.0 $\mu\text{mol/L}$); ●, GW4 (0.1, 0.5, 1.0, 1.25, 2.5, 3.75, 5.0, 7.5, 10.0, 25.0 $\mu\text{mol/L}$); ►, GW5 (0.1, 0.5, 1.0, 2.5, 5, 7.5, 10.0, 25.0, 50.0 $\mu\text{mol/L}$); ◆, GW6 (0.1, 0.5, 1.0, 2.5, 5, 7.5, 10.0, 25.0, 50.0 $\mu\text{mol/L}$); ◄, GW7 (0.1, 0.5, 1.0, 2.5, 5, 7.5, 10.0, 25.0, 50.0 $\mu\text{mol/L}$).

compounds, and Table 3 shows the IC_{50} values of GW1–7 against CypD and CypA. The fact that the IC_{50} values accord well with the Biacore and fluorescence titration results (Tables 1, 2) confirms the reliability of these three detection approaches.

Rat Ca^{2+} -dependent mitochondrial swelling and Ca^{2+} uptake/release inhibition assays In general, MPT pores are open when mitochondria encounter abnormally high concentrations of exogenous Ca^{2+} ions. These pores allow solutes of <1500 Da in size across the inner mitochondrial membrane, leading to mitochondrial swelling. Such swelling can be detected by time scans of absorbance at 540 nm (A_{540}) and the extent of swelling is proportional to $A_{540}^{[26]}$.

Fluo-5N fluorescence is quite low without binding to Ca^{2+} in controls, because the high mitochondrial membrane potential prevents the release of endogenous mitochondrial Ca^{2+} . When exogenous Ca^{2+} was added, Fluo-5N fluorescence increased immediately and decreased rapidly as Ca^{2+} ions were taken up into the mitochondria. Subsequently, the accumulation of cations in the mitochondria led to mitochondrial swelling and depolarization. Ca^{2+} ions were then released from mitochondria as a consequence of the onset of MPT, as indicated by an increase in Fluo-5N fluorescence. Ca^{2+} release was completely blocked by 1 $\mu\text{mol/L}$ CSA. Fluo-5N fluorescence also revealed that compounds GW1–7 inhibited the uptake/release of exogenously added Ca^{2+} to a

Figure 5. Ca^{2+} -dependent mitochondrial swelling and Fluo-5N fluorescence after induction of MPT with CaCl_2 . Mitochondria (0.5 mg/mL) were mixed with CSA (1 $\mu\text{mol/L}$) (as a control) or the compounds GW1–7 (100 $\mu\text{mol/L}$ for each). The symbols (+) and (–) represent the solution with or without 200 $\mu\text{mol/L}$ of CaCl_2 , respectively. Absorbance changes at 540 nm (A) and Fluo-5N fluorescence excited at 485 nm (B) were monitored soon after CaCl_2 (200 $\mu\text{mol/L}$) was added, as described in the text.

certain extent.

Figure 5A shows the results of the rat mitochondrial swelling inhibition assay for GW1–7 (100 $\mu\text{mol/L}$) with CSA (1 $\mu\text{mol/L}$) as a control. Figure 5B gives the results of the mitochondrial Ca^{2+} uptake/release inhibition assay for GW1–7 (100 $\mu\text{mol/L}$). The results show that the inhibition abilities of compounds GW1–7 against Ca^{2+} uptake/release are in good agreement with their inhibition abilities against mitochondrial swelling. We found that compounds GW2, 5, 6, and 7 had a strong ability, whereas GW1, 3, and 4 did not have any inhibition activity, which could be because of the R group. Compared with GW2, 5, 6, and 7, the tails of GW1, 3, and 4 were ethoxycarbonyl, which might prevent them from transferring into mitochondria through the membranes or cause the loss of inhibition ability for other (unclear) reasons. The behavior of CypD in mitochondria is much more complicated

than that of the purified CypD protein, so the different R groups might cause different results. CSA had the highest inhibition activity, and the relative general inhibition abilities of the other compounds were: GW5>GW7>GW6>GW2. Such a sequence seems to be consistent with the CypD PPIase inhibition ability of the compounds (Table 3). This result thus confirms the fact that CypD inhibitors may possess possible inhibition activity against Ca^{2+} -dependent MPT pore opening.

Molecular docking analyses To gain further insight into the CypD(A)/inhibitor interaction model at the atomic level, docking analysis based on molecular modeling was carried out without the published rat CypD crystal data. Our rat CypD model tallies very well with the human CypD crystal [PDB ID: 2bit] structure shown in Figure 6A. The weighted root mean square distance is 0.6040 and the identity score is 95.7%. Because of the similar structures of the compounds, they share the same precursor, with some overlapping structural elements in common (Figure 6B). Similar to CypA, the binding pocket of CypD is also fairly large and shallow, and is composed of residues Arg58, Ile60, Phe63, Met64, Glu66, Gly75, Thr76, Gly77, Ala104, Asn105, Ala106, Gln114, Phe116, Thr122, Trp124, Leu125, Lys128, and His129. GW1–7 and CSA bind to the same binding site of CypD. Unlike the case of full occupation by CSA, GW1–7 occupied only part of the binding pocket and might swing in the pocket. Helekar and Patrick even demonstrated that Arg55 of CypA was a key determinant against PPIase activity^[42]. Compounds GW1–7 showed their hydrophobic contact with Arg58 of CypD (Arg55 of CypA). Therefore, the PPIase activity of CypD could be inhibited by hydrophobic interactions with the inhibitors. In addition, GW1–7 formed stacking interactions with Trp124 of CypD (Trp121 of CypA) and the only tryptophan residues of CypD and CypA that contribute to the change in fluorescence intensity (data not shown).

Conclusion In this work, we reported on 7 small quinoxaline derivatives as novel CypD inhibitors. *In vitro* assays indicated that compounds GW2, 5, 6, and 7 inhibit Ca^{2+} -dependent rat liver mitochondrial swelling and Ca^{2+} uptake/release. By using SPR and fluorescence titration techniques, kinetic analysis of CypD/inhibitor interactions were quantitatively performed. The measured IC_{50} values for the tested compounds are all in good agreement with the SPR and fluorescence titration results, which suggests that these are powerful methods for identifying CypD inhibitors^[38]. Further studies indicated that GW5 has binding selectivity for CypD over CypA.

In summary, in this present work we used an appropriate and powerful approach for identifying CypD inhibitors, and

Figure 6. Overlapping of the rat CypD model/human CypD crystal data (A) and GW1–7 in the binding pocket of rat CypD (B).

developed a small compound that shows specific ligand-binding ability for CypD, which could be used in the inhibition of MPT pore opening.

Important Announcement: the Online Manuscript Submission and Review System was Launched!

Acta Pharmacologica Sinica is happy to announce that the online manuscript submission and review system, ScholarOne Manuscript Central (<http://mc.manuscriptcentral.com/aphs>), was launched on May 25, 2005.

As the leading web-based peer-review system, Manuscript Central is a complete, database-driven software for the online submission and review of full-text manuscripts and graphics. The system provides fully electronic workflow and will speed up the time from submission to decision.

We strongly recommend authors to submit manuscript via this system, which enables us to handle your manuscript quickly and efficiently. Please read the User Guide before submitting your manuscript online. For more detailed submission instruction, please consult the Manuscript Central Online User Guide (<http://mcv3help.manuscriptcentral.com/tutorials/>). You may also contact the Editorial Office who will be pleased to help you.

Abstract

Aim: To study the effects of propyl gallate on the interaction of tumor necrosis factor- α (TNF- α) with its soluble receptor, sTNFR-I. **Methods:** Interactions between TNF- α and sTNFR-I were analyzed using an IAsys biosensor. sTNFR-I was immobilized on the carboxymethyl dextran (CMD) surface of the IAsys biosensor cuvettes, and TNF- α preincubated with different concentrations of propyl gallate was added to the cuvettes. The resonant angle shift caused by the binding between TNF- α and sTNFR-I was then recorded. **Results:** sTNFR-I was immobilized on the CMD surface at a density of 2.76 ng/mm². TNF- α then bound the immobilized sTNFR-I specifically, and propyl gallate was able to enhance the binding between TNF- α and sTNFR-I in a dose-dependent manner. **Conclusion:** The binding between TNF- α and sTNFR-I is one of the targets that propyl gallate can act on *in vivo*. The IAsys biosensor offers a new clue as to the study on the mechanisms of action of propyl gallate.

Introduction

Propyl gallate (PG) is a well-known synthetic antioxidant on the US Food and Drug Administration list (Figure 1). It is a derivative of gallic acid, which is one of the active ingredients of *Paeoniae Radix*, a commonly used traditional Chinese medicine (TCM). Besides its antioxidant activity, PG has many pharmacological effects such as free radical elimination^[1,2], inhibiting platelet aggregation^[3,4], anti-inflammatory effects^[5] and anti-tumor activities^[6]. It is used widely to nourish blood, activate circulation, alleviate pain, regulate menstruation and treat liver disease and cancer. However, until now the research on PG has been focused on its curative effects at the holistic level. There are no detailed studies on the mechanism and dynamics of action at the molecular level, which limits the further clinical use of PG.

Tumor necrosis factor- α (TNF- α) is produced mainly by activated macrophages and monocytes. Mature TNF- α molecules are released as 17 kDa monomers, under physiological conditions, and the monomers associate non-covalently to form a homotrimer that is biologically active^[7,8]. TNF- α is one of the most pleiotropic cytokines; besides its antitumor

activity *in vitro* and *in vivo*, it plays an important role in many physiological and pathophysiological responses, such as inflammatory reactions, thrombosis, cardiac failure, infection, immune regulation, antiviral responses and endotoxic shock, as well as in the pathogenesis of certain autoimmune diseases^[9–13].

The biological activities of TNF- α are mediated by binding to 2 distinct membrane TNF receptors (TNFR), TNFR-I (p55, ~55 kDa) and TNFR-II (p75, ~75 kDa). Although both TNFR-I and TNFR-II bind TNF- α with high affinity, it has been generally believed that most of the cellular TNF responses are dominated by TNFR-I. Membrane TNFR (mTNFR) can be cleaved proteolytically to release soluble forms of the receptors (sTNFR). Though sTNFR lacks an intracellular domain, it binds free TNF- α with high affinity, competing with mTNFR^[14,15].

Though their physiological roles are not fully understood, sTNFR might regulate the function of TNF *in vivo* through 2 different mechanisms: (i) by eliminating mTNFR and thereby reducing cellular reactivity to TNF, sTNFR may protect the cell from TNF pathological injury; and (ii) whereas sTNFR inhibits the activity of TNF by binding and neutralizing the cytokines at high concentrations, it may also enhance TNF

Figure 1. Chemical structure of propyl gallate, M_r 213.

activity at low concentrations by stabilizing TNF trimer molecules and prolonging their availability for binding mTNFR, thereby acting as an immunoregulator^[16,17].

Because sTNFR is present constitutively in serum derived from receptor shedding after cellular activation by stimuli such as TNF- α production^[18], sTNFR serum level is considered a reliable indicator of TNF- α system activation^[19]. Moreover, TNF- α and sTNFR are considered to be key disease molecules and therapeutic targets^[9,20]. Because the pharmacological functions of PG and the biological activity of TNF- α are probably correlative, the TNF- α -mTNFR-sTNFR system may be a potential target of PG *in vivo*. In order to find out if this is the case, in the present paper, an affinity biosensor, the cuvette-based IAsys biosensor, was used to study the effects of PG on the interaction of TNF- α with sTNFR-I.

Materials and methods

Chemicals *N*-hydroxysuccinimide (NHS), 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC), ethanolamine and PG were purchased from Sigma-Aldrich (St Louis, MO, USA). TNF- α and sTNFR-I were purchased from PeproTech EC (London, UK). Carboxymethyl dextran (CMD) dual-well cuvettes were purchased from Labsystems Affinity Sensors (Cambridge, UK). Phosphate-buffered saline Tween-20 (PBST, pH 7.4) was composed of 10 mmol/L $\text{Na}_2\text{HPO}_4/\text{NaH}_2\text{PO}_4$, 138 mmol/L NaCl, 2.7 mmol/L KCl and 0.05% Tween-20. All solutions were made by using deionized water. All reagents were of analytical grade and were used without further purification.

Apparatus All analyses were carried out using an IAsys Plus optical biosensor (Labsystems Affinity Sensors, Cambridge, UK), which is based on resonant mirror technology. This instrument employs a dual-well stirred cuvette (pre-derivatized with CMD) and monitors the interaction between a pair of biomolecules inside the reaction cuvette^[21–23]. One of the biomolecules, the ligand, is immobilized to the sensing surface of the cuvette. Its binding partner,

the ligate, is then injected into the cuvette. Changes in refractive index and thickness on the sensing surface occur upon binding (association) of ligate to the immobilized ligand. The IAsys biosensor detects these changes continuously, producing a plot of responses that are measured in arc seconds^[24–27]. Following each interaction, the surface of the cuvette is regenerated to remove bound ligate, and another ligate can then be introduced to the sensing surface. The IAsys biosensor has been applied to many kinds of studies on molecular recognition, affinity, kinetics, solute concentrations and multi-molecular interactions. It is especially useful for capturing measurements quickly and in real time, and can eliminate the need for radiolabels or other chemical tags. Compared to traditional methods, numerous additional steps are saved.

sTNFR-I immobilization To examine the binding of TNF- α to sTNFR-I, the receptor protein was immobilized onto the cuvette surface through its residual amine groups via amide with CMD. The IAsys instrument parameters were set at 100% for stirring, and 0.3 s for the sampling interval. The running buffer was PBST. Data acquisition then began and baseline data was gathered for several minutes. The surface of the cuvette was activated with 40 μL of a 1:1 (v/v) EDC/NHS mixture (0.4 mol/L EDC and 0.1 mol/L NHS) for 7 min. The function of EDC/NHS is to activate and promote the formation of covalent linkages by forming the *N*-hydroxysuccinimide ester. The carboxyl on the CMD bound NHS under the action of EDC and created active ester intermediates that bound the primary amines of sTNFR-I to make the amide bonds. Thus, sTNFR-I can be covalently immobilized on the CMD. The cuvette was subsequently washed with PBST and 10 mmol/L acetate (pH 5.5). After gathering baseline data in the acetate buffer, 10 μL diluted sTNFR-I was added to the cuvette to begin the electrostatic uptake of protein and covalent coupling. After a sufficient reaction time, 15 min or so, unreacted NHS esters were blocked by 40 μL 1 mol/L ethanolamine (pH 8.5) and the baseline was stabilized by washing with PBST.

At the same time, another cuvette channel was used as the blank control, without anchoring of sTNFR-I. The acetate buffer was injected instead of the sTNFR-I solution.

Binding detection The sTNFR-I modified and unmodified cuvettes were both rinsed 3 times with 40 μL PBST, and 10 μL TNF- α (0.01 mg/mL) was then added into each of the cuvettes to equilibrate for 15 min, before they were washed with PBST. The resonant angle response was recorded. The chip surface was then regenerated by adding 10 mmol/L HCl, until the response signal returned to baseline to proceed with another binding cycle. To evaluate the affinity binding

of TNF- α and sTNFR-I, a wide range of TNF- α concentrations (from 0.625 $\mu\text{g/mL}$ to 20 $\mu\text{g/mL}$) were used.

Effects of PG on binding of TNF- α and sTNFR-I After 3 times of washes with 40 μL PBST, 10 μL TNF- α (0.01 mg/mL), preincubated with different concentrations of PG, was added into the sTNFR-I-modified cuvette. Binding between TNF- α and sTNFR-I was detected as described above.

Results

sTNFR-I immobilization on the surface of cuvettes As described in the "sTNFR-I immobilization" section, the sTNFR-I molecules were immobilized onto the surface of the IAsys cuvette by the ester exchange reaction of NHS to COOH groups on CMD. Figure 2 shows the response sensorgram of the IAsys biosensor to EDC/NHS activation as well as to the consequent sTNFR-I immobilization (solid line). Phase (1) is the initial baseline obtained when the surface of the cuvette was exposed to the PBST; phase (2) is the addition of EDC/NHS mixture to the sensor chip; phase (3) is the buffer washing to remove unreacted EDC/NHS mixture; phase (4) is the washing with acetate buffer; phase (5) is the addition of sTNFR-I; phase (6) is the dissociation course by washing with PBST; phase (7) is the blocking of non-coupled activated CMD sites with ethanolamine; phase (8) is the baseline stabilization. Arrow (9) is the resonant angle shift caused by the immobilization of sTNFR-I onto the cuvette surface. The broken line indicates the reference channel signal in order to follow non-specific binding on the biosen-

Figure 2. Sensorgram of EDC/NHS activation and soluble tumor necrosis factor receptor-I (sTNFR-I) immobilization. (1) Initial baseline obtained when the surface of the cuvette was exposed to the phosphate-buffered saline Tween-20 (PBST); (2) addition of the EDC/NHS mixture to the sensor chip (7 min reaction time); (3) PBST washing to remove unreacted EDC/NHS mixture; (4) acetate buffer re-equilibration; (5) addition of sTNFR-I; (6) PBST washing to allow dissociation; (7) blocking of non-coupled activated carboxymethyl dextran sites with ethanolamine; and (8) baseline stabilization. Arrow (9) is the resonant angle shift caused by the sTNFR-I immobilization.

sor surface.

The amount of immobilized sTNFR-I was calculated by subtracting the baseline level after phase (4) from that after phase (8), described in Figure 2 as arrow (9), which is approximately 450.61 arc seconds. The sensitivity of the CMD cuvette is 163 arc seconds/ng per mm^2 . Thus the density of immobilized sTNFR-I is 2.76 ng/mm^2 . Dual-well IAsys cuvettes have a sensor area of 4 mm^2 , so the total amount of sTNFR-I immobilized was 11.04 ng.

Detection of interaction between sTNFR-I and TNF- α Figure 3 shows the comparison of TNF- α binding to the sTNFR-I modified cuvette surface (solid line) and the unmodified surface (broken line). The results showed that there was no specific binding on the unmodified cuvette surface except for non-specific absorption, which was easily washed away. This indicates that TNF- α bound sTNFR-I on the cuvette surface specifically.

Figure 3. Sensorgram of the interaction between soluble tumor necrosis factor receptor-I (sTNFR-I) and tumor necrosis factor- α (TNF- α) on the cuvette surface. (1) phosphate-buffered saline Tween-20 (PBST) re-equilibration and baseline stabilization; (2) TNF- α addition with increase in irreversible response; (3) PBST washing to remove non-specific absorption.

The dissociation equilibrium constant (K_D) of binding of TNF- α and sTNFR-I were determined by using the FASTfit program, which is specifically designed for biomolecular interaction analysis using the IAsys biosensor. The K_D value was 5.05×10^{-7} mol/L, while the K_D of TNF- α /mTNFR-I binding has been reported as about 1×10^{-9} mol/L^[28]. It can be inferred that though sTNFR-I can bind TNF- α with high affinity, its binding ability is lower than mTNFR-I. The results indicate that sTNFR-I binding affinity for TNF- α is decreased, which is probably attributable to the denaturation that occurred when sTNFR-I was produced.

Effects of PG on the interaction between TNF- α with sTNFR-I Figure 4 shows the experimental results obtained at a PG concentration of 500 nmol/L. With the presence of PG, the initial velocity of TNF- α /sTNFR-I binding increased

Figure 4. Comparison between the binding reactions of tumor necrosis factor- α (TNF- α) (b) and TNF- α -propyl gallate mixture (a) on the soluble tumor necrosis factor receptor-I-modified surface.

and the time taken to approach equilibrium decreased, which indicated that PG was able to enhance the binding of TNF- α to sTNFR-I.

The concentration-dependent effects of PG on the binding of sTNFR-I and TNF- α were studied. The PG concentrations varied from 5 nmol/L to 500 nmol/L, and the results are summarized in Figure 5. The increase in amplitude of the initial velocity of TNF- α /sTNFR-I binding, as well as the decrease in amplitude of the time taken to approach equilibrium, both increased as PG concentration increased, which indicated that PG enhanced TNF- α /sTNFR-I binding in a dose-dependent manner.

Figure 5. Binding reactions on a CMD surface of immobilized sTNFR-I and TNF- α with 500 nmol/L PG (a), 50 nmol/L PG (b), 5 nmol/L PG (c) and without sTNFR-I (d).

Discussion

Recent researches showed that the pathogenesis of the traditional Chinese medicine syndromes is the result of perturbation of cytokine networks, and the mechanism of TCM

is to regulate and correct the perturbation of cytokine networks. It has been observed for many years that Chinese prescriptions can regulate the gene expression level of cytokines or their receptors. But for the initial step of the cytokine action, the binding to the corresponding receptor, there is few reports mainly due to the lack of appropriate methods. In the present study, an affinity biosensor, the IAsys biosensor, was used to explore the interaction of the cytokine and its receptor. The involvement of TNF- α in the pathogenesis of various diseases makes it an obvious and attractive therapeutic target. The effects of PG on the interaction between TNF- α and sTNFR-I were examined by using the IAsys biosensor in an *in vitro* assay. The experimental results showed that PG enhanced TNF- α /sTNFR-I binding in a dose-dependent manner. Though the mechanisms of PG are not clear and the roles of TNF- α and sTNFR-I are debated, it can be concluded that the binding between TNF- α and sTNFR-I is another target that PG can act on *in vivo*. Researches showed that serum level of sTNFR-I are often increased in a variety of conditions which are characterized by an antecedent increase in TNF- α , such as sepsis, inflammatory responses, autoimmune diseases, human immuno-deficiency virus infection, transplant rejection and malignant tumor^[29-32], which indicated that sTNFR-I production seems to neutralize and reduce the toxicity associated with the elevated serum TNF- α level. PG can enhance the cellular protection of sTNFR-I through increasing neutralization to TNF- α , which is in agreement with the experimental and clinical results reported^[33]. Thus it may sound theoretically that PG is helpful for therapy or assistant therapy in TNF- α corresponding diseases, which may leads to the new therapeutic application of PG. These are the first results obtained using affinity biosensors for studying the interactions of these molecules. This finding offers a new clue to the study of the mechanism of action of PG. The IAsys biosensor could be used widely as a reliable tool for similar studies. With respect to most of the other available methodologies to study biomolecular interactions, there are many advantages of this new method, such as real time measurement, high sensitivity, high selectivity and high veracity, as well as being easy to handle and eliminating the need for labeled compounds. It has tremendous application prospects in studies on the mechanisms of TCM *in vitro*. It will be more compellent when data on bioactivity, such as from cell experiments, were acquired to support the results from those from biosensor technology. Further studies in this area are in progress.

Abstract

Aim: To evaluate the phylogenetic relationships among related species of *Lycium* samples. **Methods:** Random amplified polymorphic DNA (RAPD) fingerprinting and lab-on-a-chip electrophoresis techniques were used to analyze the characteristics of *Lycium* species. Seven species and 3 varieties of *Lycium* were studied. Based on RAPD fingerprint data obtained from 11 primers, we proposed a new index, called dispersivity, using entropy theory and projection methods to depict the diversity of the DNA fingerprints. **Results:** Using the proposed dispersivity, primers were sorted and the dendrograms of the 7 species and 3 varieties of *Lycium* were constructed synthetically by merging primer information. **Conclusion:** Phylogenetic relationships among *Lycium* samples were constructed synthetically based on RAPD fingerprint data generated from 11 primers.

Introduction

Traditional Chinese medicine (TCM) has been used for thousands of years in China. It represents the collective wisdom of the Chinese people to utilize nature for survival^[1]. With the advantages of multi-target effects, low toxicity and the current appeal for more 'natural' remedies, TCM has become widely used as an alternative to treat various complex and chronic diseases. Authentication of Chinese medicinal materials is an old but important issue. With the unprecedented development of modern biological methods, identification of species relationships using traditional anatomical and physiochemical methods is being supplemented by DNA fingerprinting techniques, such as random amplified polymorphic DNA (RAPD) analysis.

The fruit of *Lycium* species, especially *Lycium barbarum*, has been used in TCM to improve eyesight, protect liver and kidney, and to replenish vital essence. The fruit of the *Lycium* species are all red in color with very similar physical appearance and anatomical structure. Chemical analysis methods, such as high-performance liquid chromatography, have been used for different species of *Lycium*, but have failed to dif-

ferentiate the *Lycium* species.

Recently, a Fourier-transform infrared spectroscopy method was used to identify 7 species and 3 varieties of *Lycium*^[2]. The method provides a novel approach for the identification and differentiation of plants used in TCM. Such a technique can serve as a rapid, simple, reliable and non-destructive analytical method for differentiating *Lycium* species. Alternatively, with the development of modern biotechnology, a polymerase chain reaction (PCR)-based method using random primers (10-mers), known as RAPD^[3,4], has become another method for the study of TCM^[5,6]. RAPD analysis is simple and effective. It has many advantages, such as it only requires a minute quantity of DNA; no prior sequence data are needed, many primers can be used; and the method is relatively simple. However, RAPD suffers the drawback of low reproducibility, which has severely hampered the popularity of this method. Usually, PCR products are analyzed by agarose gel electrophoresis followed by densitometric analysis of the DNA banding pattern. In the present study, the lab-on-a-chip (Agilent 2100 Bioanalyzer DNA 7500 assays, Agilent Technologies, Palo Alto,

California, USA) was used to analyze the PCR products of *Lycium* samples, including 7 species and 3 varieties. After preprocessing using the Agilent 2100 Bioanalyzer, including baseline adjustment and alignment, data were exported as XML files, which were imported into the Matlab software. All further analyses were performed using Matlab. We will clarify these analyses in detail in the following sections.

Materials and methods

Sample preparation Twelve *Lycium* samples were used in this study. Dried fruits of *Lycium* were rinsed with 70% ethanol and distilled water for surface sterilization. They were then ground in liquid nitrogen with a mortar and pestle. Information for the samples is summarized in Table 1. Samples of *Lycium barbarum*, LB and LBB, were treated as positive controls in the RAPD analysis. The remaining 10 samples, which represent 7 species and 3 varieties, were used in our data analysis.

Table 1. List of *Lycium* species analyzed in this study.

Scientific name	Abbreviation	Chinese name

Genomic DNA extraction The cetyl triethylammonium bromide (CTAB) extraction method, a modified protocol of Draper and Scott^[7], was used for the extraction of DNA. *Lycium* powder was mixed with 600 μ L of 1 \times CTAB extraction buffer [50 mmol/L Tris-HCl (pH 8.0), 0.7 mol/L NaCl, 10 mmol/L ethylenediaminetetraacetic acid (EDTA), 1% CTAB], which was preheated at 60 °C. The mixture was then incubated for 30 min with occasional shaking. After cooling to room temperature, the mixture was extracted with an equal volume of chloroform/isoamyl alcohol (24:1, v/v). After centrifugation at 13 000 \times g for 15 min at room temperature, the superna-

tant was collected and a 0.1 mol/L volume of 10% CTAB solution (10% CTAB, 0.7 mol/L NaCl) and an equal volume of chloroform/isoamyl alcohol were added for another extraction. After centrifugation at 13 000 \times g for 15 min at room temperature, the supernatant was collected and extracted with an equal volume of CTAB precipitation buffer [50 mmol/L Tris-HCl (pH 8.0), 10 mmol/L EDTA, 1% CTAB]. It was then allowed to stand at room temperature for at least 1 h, before being centrifuged again at 13 000 \times g for 15 min at room temperature. The pellet was resuspended in 400 μ L of 1 mol/L NaCl, which was pre-heated at 60 °C. For further purification, it was extracted again with an equal volume of chloroform/isoamyl alcohol. After centrifugation at 13 000 \times g for 15 min at room temperature, the supernatant was collected and 800 μ L of cold absolute ethanol was added. The solution was allowed to stand at -20 °C overnight for precipitation of DNA. To recover the DNA, the suspension was centrifuged at 13 000 \times g for 20 min at 4 °C. The pellet was collected and washed twice with 75% ethanol. After that, the pellet was air-dried and resuspended in 30 μ L distilled water.

Estimation of DNA concentration and purity The concentration and purity of DNA was checked by UV spectroscopy at wavelengths 230 nm, 260 nm, and 280 nm. The quality of DNA (5 μ L) was also checked by electrophoresis on a 1% agarose gel in 1 \times TBE (Total Binding Energy) buffer.

RAPD and optimization of PCR conditions The RAPD reactions were carried out as described by Nadeau *et al*^[8] in a 25 μ L reaction mixture containing DNA (10 ng–100 ng), 0.1 mmol/L dNTP, 25 pmol primer, 1 \times Taq buffer [20 mmol/L (NH₄)₂SO₄, 75 mmol/L Tris-HCl (pH 8.8), 0.01% Tween-20, 2.5 mmol/L MgCl₂, 0.001% gelatin (w/v)] and 0.5 U Taq DNA polymerase. The tubes were placed in the thermocycler (PTC-100™, MJ Research Inc Waltham, Massachusetts, USA) and subjected to the following profiles: denaturation for 5 min at 94 °C, then 45 cycles at 94 °C for 1 min, 35 °C for 1 min, 72 °C for 2 min, final extension at 72 °C for 5 min. In order to optimize the RAPD conditions, the PCR conditions were varied using 100-fold, 500-fold, 1000-fold and 5000-fold dilutions of genomic DNA, 2 mmol/L or 2.5 mmol/L MgCl₂, 1 U or 1.25 U Taq polymerase in the presence or absence of the final extension step. The PCR products were monitored by 1.5% agarose gel electrophoresis and the DNA fragments were visualized by staining with ethidium bromide. The amplification products (1 μ L) were also analyzed with the lab-on-a-chip system, the Agilent 2100 Bioanalyzer, using the DNA 7500 assays kit according to the manufacturer's instructions.

Results

Preprocessing of raw data Raw lab-on-a-chip DNA fingerprints can be treated as multi-dimensional vectors or functional curves. Because they are usually observed and stored discretely, in the present study, the vector form was adopted to represent the DNA fingerprint. We let $(t_i, x_i), i=1, \dots, T$ denote the discrete observations for a DNA fingerprint, where x_i is the fluorescence intensity measured at migration time t_i and T is the number of migration time points. Customarily, fluorescence intensity is referred while omitting migration time in representing DNA fingerprint, namely, (x_1, \dots, x_T) repre-

sents a fingerprint, where a is the transpose of a vector for a .

A complete preprocessing for raw fingerprint data includes baseline adjustment, alignment, linear interpolation match and normalization issues. In order to eliminate the background and peak drift effect for DNA fingerprints, we used the up-to-date Agilent 2100 Bioanalyzer^[9] software to adjust baseline and handle alignment based on the ladder, lower marker and upper marker. Figure 1 shows the alignment process.

After baseline adjustment and alignment, we exported the data into an XML format, which could be opened by Microsoft Excel. The XML files were then imported by the

Figure 1. RAPD fingerprints of 10 *Lycium* samples (1–10), two control samples (11, 12) and ladder sample (L) obtained from primer opam2 performed by Agilent 2001 Expert software. (A) Fingerprints without alignment; (B) aligned fingerprints.

software Matlab, which was our main tool for further analysis. It was easy to detect the lower marker and upper marker that define the informative region for each fingerprint. Therefore, we could concentrate on the observations between the lower and upper markers. However, fingerprint data after baseline adjustment and alignment was shown with relative migration time, which was different from the unaligned data, that is, fingerprint data with the same length of interval between the lower marker and upper marker but with different number of migration time points. Here linear interpolation was used to match all of the fingerprints such that they had the same number of migration time points between the lower marker and upper marker. This method is called linear interpolation match (LIM). Our main purpose for using LIM was to render the fingerprints directly comparable. Another reason was to make the data format suitable for our statistical analysis. Details about the LIM method are described using *Lycium* samples as follows.

After exporting *Lycium* sample data from Agilent 2100 Expert software, the total 110 fingerprints produced by 11 primers and the corresponding number of migration time points were denoted by $x_i(k)$ and $n_{k,p}$, $k=1, \dots, 11$; $i=1, \dots, 10$. Because these fingerprints shared the common interval between the lower marker and the upper marker, we first chose the minimum number $\{n_{k,j}\}$, denoted as m , and then made the migration time points the same for all of the other fingerprints in the following way. We uniformly partitioned $m-1$ cells on interval $[0,1]$. Similarly, for any fingerprint that had s migration time points, we uniformly partitioned $s-1$ cells on interval $[0,1]$. The total migration time points corresponded to $0, 1/(s-1), 2/(s-1), \dots, 1$. For any $i/(s-1)$, $0 < i < s-1$, we found j such that $i/(s-1)$ located on an exclusive interval $[j/(m-1), (j+1)/(m-1)]$. Linear interpolation of the fluorescence intensity value at corresponding retention time $j/(m-1)$ and $(j+1)/(m-1)$ was changed to the i -th fluorescence intensity value for the newly matched fingerprint. Following the above rule, all of the fingerprints were matched with the same number of migration time points. After performing LIM, the common peaks of both ends, which were parts of the lower and upper markers, were removed as these peaks were of no concern. For simplicity, the number of migration time points of these fingerprints was still noted as T .

Because the outcomes of most statistical methods are strongly influenced by the scale and range of the fingerprint data, it was necessary to normalize all of the fingerprint data before analysis. To accomplish this goal, the sample mean and variance of the fingerprint $x=(x_1, \dots, x_T)'$ were calculated as follows:

$$m(x) = \frac{1}{T} \sum_{i=1}^T x_i \quad (1)$$

$$s^2(x) = \frac{1}{T} \sum_{i=1}^T (x_i - m(x))^2 \quad (2)$$

All of the fingerprints were normalized by subtracting the sample mean and then dividing by the standard deviation, namely the following form:

$$x \leftarrow \frac{x - m(x)}{s(x)} \quad (3)$$

The effect of this normalization is shown in Figure 2. From then on, fingerprint i referred to the registered fingerprint after normalization.

Figure 2. Normalization effect on fingerprints. (A) Fingerprint before normalization; (B) fingerprint after normalization.

Primer sorting by the revealed fingerprint diversity DNA fingerprinting performed by RAPD using different primers may have had different detected diversities. The diversity of fingerprints obtained from a primer, what we call

dispersivity, can be regarded as an index to indicate whether this primer is effective or not. As an example, for our tested DNA fingerprints of *Lycium* samples representing 7 species and 3 varieties, all DNA fingerprint data were denoted by:

$$X=(X^{(1)}, \dots, X^{(11)}),$$

where $X^{(k)}=(X_1^{(k)}, \dots, X_{10}^{(k)})$, $k=1, \dots, 11$, k denotes k -th primer, and the total primer number 11, 10 denotes the total number of *Lycium* samples, namely, 7 species and 3 varieties. $X_i^{(k)}$ is a T -dimensional column vector that denotes the fingerprint of *Lycium* sample from species i obtained from primer k . T is the number of migration time points. Initially, the information about dispersivity revealed by primer k was contained in the data set $X^{(k)}$. Usually the more peaks in the data set $X^{(k)}$ obtained from primer k , the higher the dispersivity. However, that is not always true because the difference in peak location and the variation in peak height and peak shape among fingerprints obtained from primer k can also affect the corresponding dispersivity. It is necessary and important to integrate all of the factors in the evaluation of the dispersivity for each fingerprint set $X^{(k)}$.

In the present study, we used the concept of entropy, introduced by Shannon and Weaver^[10], to quantify the dispersivity revealed by primer k . For a discrete probability distribution p , the motivated definition of entropy by statistical mechanics is:

$$h(p) = -\sum_{i=1}^n p_i \times \ln(p_i) \tag{4}$$

were $\sum_{i=1}^n p_i = 1$. In the context of probability, $h(p)$ is regarded as a measure of the information carried by p , with high entropy corresponding to much uncertainty. This uncertainty score reflects the property of dispersivity. Intuitively, it manifests itself as the way we describe dispersivity.

The dispersivity revealed by primer k is defined as the following way:

Step 1. Compute the sample covariance matrix

$$S^{(k)} = (s(x_i^{(k)}, x_j^{(k)}))_{(10 \times 10)}, 1 \leq i, j \leq 10, \text{ where}$$

$$s(x_i^{(k)}, x_j^{(k)}) = \frac{1}{T} \sum_{t=1}^T (x_{it}^{(k)} - m(x_i^{(k)}))(x_{jt}^{(k)} - m(x_j^{(k)})) \tag{5}$$

Step 2. Calculate the eigenvalues of $S^{(k)}$ and note them as $\lambda^{(k)}=(\lambda_1^{(k)}, \dots, \lambda_{10}^{(k)})$

Step 3. Make the sum of eigenvalues equal to 1, namely,

$$\lambda_j^{(k)} \leftarrow \frac{\lambda_j^{(k)}}{\sum_{j=1}^{10} \lambda_j^{(k)}}, j = 1, \dots, 10$$

Step 4. Compute entropy of $\lambda^{(k)}$, namely,

$$h(\lambda^{(k)}) = -\sum_{j=1}^{10} \lambda_j^{(k)} \times \ln(\lambda_j^{(k)}).$$

$h(\lambda^{(k)})$ is defined as the dispersivity revealed by the primer k . The definition of dispersivity is very intuitive. In the first step, we used the covariance matrix $S^{(k)}$ to describe all of the variant information for the fingerprints obtained from primer k . The variant information was then extracted by computing the eigenvalues of $S^{(k)}$. These eigenvalues, $\lambda^{(k)}$, can be regarded as the information reconstructed from $X^{(k)}$ and can be interpreted by the principal component analysis (PCA). Sort $\lambda_1^k, \dots, \lambda_{10}^k$ as $\lambda_{(1)}^{(k)} \geq \dots \geq \lambda_{(10)}^{(k)}$, for the fixed primer k , the closer to 1 for

$$\lambda_{(1)}^k / \sum_{j=1}^{10} \lambda_{(j)}^k,$$

which can be considered as the contribution rate for the first principal component, the stronger for the first principal component to synthesize the information of $X^{(k)}$. For example, if fingerprints $l_1^{(k)}, \dots, l_{10}^{(k)}$ are very similar, it will result in the contribution rate for the first component being close to 1 and the sum of the remaining 9 being near to 0, which means that the first component can synthesize almost all of the information. This case is not expected, because it reflects little diversity for $X^{(k)}$. We desired that the contribution rates for all of the components were scattered, not concentrated, and allowed for the entropy, which has the property that the more dispersive it is for the probability distribution, the larger the corresponding entropy value. Finally, we defined the dispersivity revealed by primer k as

$$h(\lambda^{(k)}) = -\sum_{j=1}^{10} \lambda_j^{(k)} \times \ln(\lambda_j^{(k)})$$

Here all the $\lambda_j^{(k)}$ denote the contribution rates subject to the sum being equal to 1. From the definition of dispersivity, some eigenvalues may be equal to 0, which will result in no meaning due to the function. In such cases, we defined $0 \times \ln(0) = 0$, which is reasonable because $\lambda \times \ln(\lambda)$ will approach 0 if λ approaches 0 from the positive direction.

For our *Lycium* data, 11 primers were used to perform the analysis. A direct question is which primer is the best one as far as dispersivity is concerned? To some extent, the best primer would be able to differentiate the *Lycium* samples to the maximum degree. The dispersivity revealed by primer k was given by $h(\lambda^{(k)})$, simply noted as $D(X^{(k)})=h(\lambda^{(k)})$, where $\lambda^{(k)}$ is dependent on $X^{(k)}$. The best primer was chosen as the one that maximized the value of $D(X^{(k)})$. Memory the best primer and the corresponding dispersivity value as $S1$ and D_{S1} , respectively.

After choosing the primer $S1$, we then wanted to chose a second primer from the remaining 10, such that the fingerprints obtained from these 2 primers had the maximum

diversity. In order to do this, we had to define the dispersivity of the 2 primers. For a striking example, if fingerprints $X^{(i)}$ and $X^{(j)}$ obtained from primers i and j , respectively, were very similar, that would mean that primers i and j almost revealed the same dispersivity. Furthermore, if primer i revealed the maximum dispersivity and primer j revealed the second maximum dispersivity, then primer i would be picked as the best primer, while in most cases, primer j would not be selected as the primer that reveals the maximum diversity combined with primer i , because $X^{(i)}$ and $X^{(j)}$ have much mutual information. This indicated to us that we should remove overlapping information before choosing primers from the remaining 10. The method of space projection was utilized to solve the information overlap.

The dispersivity revealed by primers i and j , on condition that primer i was chosen, was defined as $D(X^{(i)}, (1-X^{(i)}(X^{(i)+})X^{(j)})$, where A^+ denotes the pseudoinverse of matrix A ^[11] and can be numerically calculated by Matlab. The computation of $D(A,B)$ was similar to $D(A)$ except for substituting A union B for A . For simplicity, we define $CP(X^{(i)}|X^j)=(1-X^{(i)}(X^{(i)+})X^j$. Matrix $CP(X^{(i)}|X^j)$ was orthogonal to the space expanded by $X^{(i)}$. That means that it contained extra information relative to $X^{(i)}$. The eigenvalues of covariance matrix for $X^{(i)}$ union

$CP(X^{(i)}|X^j)$ were the union of eigenvalues of covariance matrix for $X^{(i)}$ and $CP(X^{(i)}|X^j)$. For our *Lycium* data, on the condition that primer S1 was chosen, the second primer chosen was the one that corresponded to the maximum value of $D(X^{(S1)}, CP(X^{(S1)}|X^{(k)}))$, $k \in \{1,2, \dots, 11\} \setminus \{S1\}$, where A/B denotes the set that includes the elements belonging to A but not to B . Without loss of generality, the second primer chosen is recorded as S2, the corresponding dispersivity value is denoted by $D_{S1,S2}$.

We could then obtain the order of primers, denoted S1, ..., S11. The corresponding dispersivities for the primers were denoted $D_{S1}, \dots, D_{S1, \dots, S11}$. For illustrating our space projection method, in Figure 3, we plot the original fingerprint for primer S9, namely, $X(S9)$, extra information relative to primer S1, namely, $CP(X^{(S1)}|X^{S9})$, and extra information relative to primers S1, ..., S8, namely, $CP\{X^{(S1)}, CP(X^{(S1)}|X^{(S2)}), \dots, CP[X^{(S1)}, CP(X^{(S1)}|X^{(S2)}), \dots, CP(X^{(S1)}|X^{(S8)})]\}|X^{(S9)}$. Comparing the plots in Figure 3, the information provided by primer S9 gradually decreased as the mutual parts relative to primers chosen earlier S1, ..., S8 were removed one by one. This property can be interpreted by the projection theory and Figure 3 is an intuitive manifestation.

Construction of the dendrogram for *Lycium* samples From

Figure 3. Fingerprints obtained from primer S9 and extra information relative to the earlier-picked primers. (A) Original fingerprints for primer S9; (B) extra information relative to primer S1; (C) extra information relative to primers S1,S2; (D) extra information relative to primers S1,S2,S3; (E) extra information relative to primers S1, ..., S7; (F) extra information relative to primers S1, ..., S8.

Figure 4, the x coordinate denotes the primers according to the order in which they were chosen and the y coordinate denotes the corresponding dispersivity. For example, 2 denotes primers S1 and S2, and the corresponding y-value is $D_{S1,S2}$, which shows that the dispersivity increases as the newly chosen primer is added. Furthermore, the extent of the increase becomes smaller and smaller. That means that adding a primer can increase the amount of information available while the last primer chosen provides less information than the previous primer. Generally, the more primers chosen, the better the conclusion drawn, such as in distinguishing and constructing the dendrogram for our *Lycium* samples of 7 species and 3 varieties. However, because the last primers chosen provided relatively little information, it was not necessary to pick all 11 of the primers to construct the dendrogram. In the present study, we decided on the primer number that contained almost all of the information to distinguish and construct the dendrogram for *Lycium* samples using $\text{argmin}(D_{S1,\dots,Si})/(D_{S1,\dots,S11}) > 95\%$. For our *Lycium* samples, $(D_{S1,\dots,S11})' = (1.9476, 2.3398, 2.6624, 2.8600, 3.0690, 3.2071, 3.3133, 3.3998, 3.4380, 3.4611, 3.4772)'$. The number of primers to use can be obtained by simple computation according our proposed rule. Because, $(3.2072/7.3772) = 0.9223 < 0.95$, $(3.3133/3.4772) = 0.9529 > 0.95$, 7 primers, S1, ..., S7, were chosen for final analysis. We used the 95% rule to decide the number of primers. Generally, in most data analyses (such as PCA) it is possible to use other rules, for example, the 80% rule, to decide the number of principal components. However, we used the larger number 95% because our proposed dispersivity is a sensitive index. This means that the dispersivity changes only a small amount, while the fingerprint changes much. It is therefore better to widen the boundaries for choosing in case some important primers are lost.

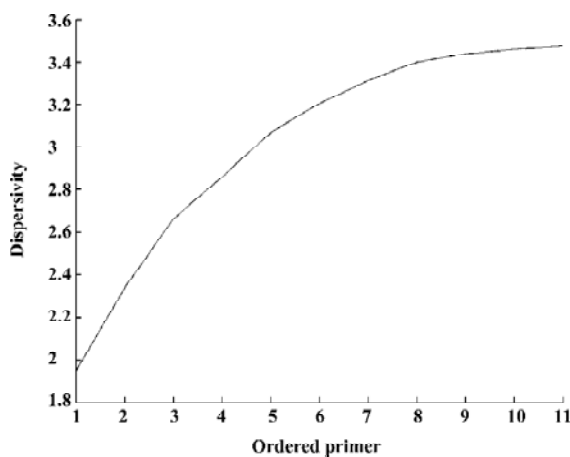

Figure 4. Plot of $\{(i, D_{S1,\dots,Si})\}$ for *Lycium* samples.

In the present study, we used the hierarchical cluster method to construct a dendrogram of *Lycium* species. Because each *Lycium* sample was analyzed using 7 primers, the primer information was merged by weighting. The weights were assigned by $\omega_1 = D_{S1}/D_{S1,\dots,S7}$, $\omega_k = (D_{S1,\dots,Sk} - D_{S1,\dots,S(k-1)})/D_{S1,\dots,S7}$, $k=2, \dots, 7$. Using the obtained weights of primers, the distance of each *Lycium* sample from species i and j was defined by:

$$d(x_i, x_j) = \sum_{k=1}^7 \omega_k d(x_i^{(k)}, x_j^{(k)}), \tag{6}$$

were

$$d(x_i^{(k)}, x_j^{(k)}) = 1 - \rho^2(x_i^{(k)}, x_j^{(k)}), \quad \rho(x_i^{(k)}, x_j^{(k)}) = \frac{s(x_i^{(k)}, x_j^{(k)})}{s(x_i^{(k)})s(x_j^{(k)})},$$

$s(x_i^{(k)}, x_j^{(k)})$ and $s(x_i^{(k)})$ are defined by (5) and (2). $\rho(x_i^{(k)}, x_j^{(k)})$ is the correlation coefficient between $x_i^{(k)}$ and $x_j^{(k)}$, which is often used to measure the similarity of fingerprint. In order to use distance matrices to construct the dendrogram, we transformed the data by $1 - \rho(x_i^{(k)}, x_j^{(k)})^2$.

Unweighted pair-group method using arithmetic average (UPGMA) linkage, which defines the cluster distance, is advocated for constructing a dendrogram. Details about the UPGMA clustering method can be found in Sokal and Michener^[12]. Using the above distance measure between fingerprints and the UPGMA cluster method, we visualized the cluster results using the dendrogram shown in Figure 5.

Figure 5. Dendrogram of 10 *Lycium* samples using the first 7 primers ordered.

For evaluating our procedure to decide the number of primers, we used primers S1, ..., S8 to construct the dendrogram as above, further more, we use the first ordered 9, 10, and 11 primers to construct dendrogram, respectively. All of these were similar to Figure 5. This indicated that the first 7 primers contained almost all of the information provided by

the total 11 primers. Furthermore, when using primers S1, ..., S6, the outcome shows little difference relative to Figure 5 (Figure 6). It manifests our picking procedure for primer number is so delicate.

Figure 6. Dendrogram of 10 *Lycium* samples using the first 6 primers ordered.

Discussion

Phylogenetic relationship construction based on RAPD fingerprint data generated from a number of primers was investigated in this study. We proposed an index called dispersivity using entropy theory to describe the diversity of RAPD fingerprints obtained by several primers. Generally, this index can be applied to other DNA fingerprint data, such as arbitrarily primed PCR and DNA amplification fingerprinting, and to chromatographic fingerprints, such as chromatogram, spectrum and mass spectrum. Based on this index, the order for choosing primers is obtained using the orthogonal projection method and entropy theory. Our proposed method provides the guidelines for primer picking in the consequent experiments. An on-line analysis program on RAPD primer selection is provided on the web site: <http://math.nenu.edu.cn/shiz/yinxiaolin.files/program.htm>, which

can be downloaded easily if required.

Abstract

Aim: To clone the pollen allergen genes in *Humulus scandens* (Lour) Merr (LüCao in Chinese) and short ragweed (*Ambrosia artemisiifolia* L) for recombinant allergen production and immunotherapy. **Methods:** The allergen genes were selectively amplified in the weed pollen cDNA pool by using a special PCR profile, with the primers designed by a modeling procedure. Following truncated gene cloning and confirmation of the pollen source, unknown 3'cDNA ends were identified by using the 3'-RACE method. The gene function conferred by the full-length coding region was evaluated by a homologue search in the GenBank database. Recombinant proteins expressed in *Escherichia coli* pET-44 RosettaBlue cells were subsequently characterized by N-terminal end sequencing, IgE binding, and cross-reactivity. **Results:** Three full-length cDNAs were obtained in each weed. Multiple alignment analysis revealed that the deduced amino acid sequences were 83% identical to each other and 56%–90% identical to panallergen profilins from other species. Five recombinant proteins were abundantly expressed in non-fusion forms and were confirmed by using the N-terminal end sequence identity. Sera from patients who were allergic to *A artemisiifolia* reacted not only with rAmb a 8(D03) derived from *A artemisiifolia*, but also with recombinant protein rHum s 1(LCM9) derived from *H scandens*, which confirmed the allergenicity and cross-reactivity of the recombinant proteins from the 2 sources. Comparison of the degenerate primers used for truncated gene cloning with the full-length cDNA demonstrated that alternative nucleotide degeneracy occurred. **Conclusion:** This study demonstrates a useful method for cloning homologous allergen genes across different species, particularly for little-studied species. The recombinant allergens obtained might be useful for the immunotherapeutic treatment of *H scandens* and/or *A artemisiifolia* pollen allergies.

Introduction

Accurate allergy diagnosis and efficient immunotherapy protocols are strongly dependent on the use of standardized extracts or well-characterized allergen mixtures^[1–3]. However, standardization of specific allergens from natural allergen extracts is a huge task^[4] and it is almost impossible to carry out standardization on a large scale for day-to-day clinical practice. Recombinant allergens that have similar

structures, functions and immunoreactivity to their native counterparts could be used to overcome this problem, given that they can be produced in large quantities, leading to more specific, effective and safer immunotherapy treatment^[5].

Currently, gene cloning for novel allergens is mainly based on the construction of a cDNA library, which is time-consuming and expensive^[6–9]. Other methods for isolating unknown allergens involve using the polymerase chain reaction (PCR) with either degenerate primers consisting of a

pool of primers containing most or all of the possible nucleotide sequences encoding a conserved amino acid motif^[10], or consensus primers consisting of a single primer containing the most common nucleotide at each codon position within the motif^[11]. Although these strategies have been successful in isolating closely related sequences, they have generally failed when sequences are more distantly related^[11]. Many programs and algorithms have been developed for sequence comparisons of multiple members of protein families^[12-15]. By using alignment techniques, the first amino acid sequence that emerges, that is, the sequence aligned uppermost in each large and dense cluster in the output tree produced, has provided the most information about amino acid diversity in the cluster. In the current study, we refer to these sequences as “core sequences”, and we designed the degenerate primers based on the core sequences and their cognates. Under special PCR conditions, we expected that the degenerate primers could match all associated sequences in the abovementioned cluster, and thus could be used for cloning new allergen gene members in a distantly related species. We will hereafter refer to these primers as “pan-degenerate primers”. We expected that the process involving the pan-degenerate primers would be more efficient and less expensive than the cDNA library technique, and would have a higher success rate than an ordinary PCR method.

Humulus scandens (Lour) Merr (Moraceae: Cannabaceae; Lücao in Chinese) is a weed that grows in most provinces of China. The plant blossoms in summer and bears a large quantity of pollen. Short ragweed (*Ambrosia artemisiifolia* L; Compositae) is one of the most invasive weeds in the world. It was introduced to China in 1930s, and is now distributed from the Yantze River to the 3 northeastern provinces of China. Nanning, Wuhan, Nanchang-Jiujiang and Shenyang-Tieling-Dandong are the 4 areas in which the weed is most pervasive in China. Pollen from *H scandens* and *A artemisiifolia* have become the main source of pollen allergens in this country. However, little is known of the actual allergens in the pollen of the weeds. In this study, we report on the cloning, expression and characterization of 6 pollen allergen genes from the 2 weeds. Following the non-fusion expression and purification of the 5 encoded proteins, 2 representative proteins of the 5, provisionally named rAmb a 8 (D03) and rHum s 1 (LCM9), were immunologically characterized in detail.

Materials and methods

Sample preparations Wild plants of *H scandens* and *A artemisiifolia* were harvested in Wuhan. Flowers were

bagged, and the pollen collected from each plant was mixed with other pollen collected from the same plant. All pollen collected was immediately submerged in liquid nitrogen until use. Twenty-five patients with *A artemisiifolia* pollen allergy and 10 patients with *H scandens* pollen allergy (as assessed by a positive skin prick test reaction to *A artemisiifolia* and a serum level of *A artemisiifolia*/*H scandens* specific IgE higher than 3.5 kU_A/L) and 13 healthy volunteers were recruited. Blood samples were taken from all participants in the Allergy Clinic, Shenyang North Hospital. All the samples were tested by using the UniCAP Specific IgE Fluoroenzymeimmunoassay (Pharmacia Diagnostics AB, Uppsala, Sweden). After centrifugation at 500×g, 4 °C, for 10 min, serum from each individual was collected and stored at -70 °C until use. The study was approved by the Ethics Committee of Shenyang North Hospital, Shenyang, China, and written informed consent was obtained from all participants.

Primer design The 478 pollen allergens and their related sequences were retrieved by keyword searches in the SWISS-PROT and TrEMBL websites (<http://www.expasy.org>) and were multiple-aligned online by using Clustal W software^[16]. For alignment, the default values were used to obtain the output tree in a phylogram pattern, with the absolute distances labeled. The uppermost allergen sequence in each large and dense cluster in the output tree was taken as the core sequence. There were several of these core sequences found in the output phylogenetic trees. Based on the core sequences, allergen sequences with high homology (with BLAST E values $\leq 10^{-10}$) were selected for further analysis to acquire conservative gene domains. Pan-degenerate primers, which we expected to be successful in all species, were thus designed according to cDNA sequences of the conservative domains chosen.

RT-PCR analysis Frozen pollen samples were ground in a mortar filled with liquid nitrogen, and the total RNA was extracted by using an RNeasy Maxi Kit (Qiagen Valencia, CA, USA) according to the manufacturer's instructions. After quality and concentration assessments, the RNA was either immediately used for RT-PCR analysis or stored at -80 °C until use.

After reverse transcription (2 µg total RNA per sample) was performed by using the ProtoScript First Strand cDNA Synthesis Kit (New England Biolabs, Beverly, MA, USA) according to the manufacturer's instructions, PCR was carried out by using 50 ng of the reverse transcription product in 25 µL of the reaction mixture containing 1.25 U HotstarTaq DNA polymerase (Qiagen), 1× PCR buffer (Qiagen), 0.2 mmol/L dNTP, and 0.4 µmol/L of each primer. Thermal cycling was

performed in a PTC-200 Peltier Thermal Cycler (MJ Research, Watertown, MA, USA) as follows: after an initial step at 95 °C for 15 min to activate the DNA polymerase, 9 touch-down cycles were carried out at 94 °C for 45 s, 68 °C for 30 s and 72 °C for 30 s, with the annealing temperature decreasing by 1 °C per cycle. This was followed by 26 gradient cycles at 94 °C (45 s)→55 °C→61 °C (30 s)→72 °C (30 s). After purification with a QIAquick PCR Purification Kit (Qiagen), the PCR products were cloned into the pGEM-T easy vector (Promega, Madison, WI, USA). The inserted plasmids were transformed into JM109 (Promega). Positive clones were confirmed first by colony PCR with the former PCR primers, and then by sequencing. DNA sequencing was carried out by the BioAsia Biotechnology Co (Shanghai, China) by using the dideoxy chain-terminating method.

Full-length cDNA synthesis and sequencing The clones derived from the degenerate primers did not cover the full-length coding region. Gene-specific primers were therefore synthesized (Table 1), and combined using the RACE process^[17] with RA3, a 3' reverse primer from the GeneRacer Kit (Invitrogen Corporation, Carlsbad, CA, USA). The PCR conditions were similar to those for RT-PCR, with a slight modification in the denaturing temperature and extension time. PCR products were also cloned into the pGEM-T easy vector, and positive clones were confirmed by colony PCR and sequencing. Full-length cDNAs, acquired by deduction of the truncated gene and its 3' end, were translated into amino acid sequences, with their isoelectric point and molecular weight calculated (<http://www.expasy.org>). cDNA and protein homologues, retrieved by using the BLAST program in the NCBI website (<http://www.ncbi.nlm.nih.gov/>), were

aligned by using the CLUSTAL W (1.82) program^[16]. Phylogenetic trees were subsequently generated using MEGA2 software^[18].

Northern blot Northern blots were performed according to the membrane manufacturer's instructions. Briefly, a total of 20 µg RNA was loaded on to a formaldehyde-containing gel. After running the gels at 40 V for 3 h, the RNA bands were electrically transferred onto Nytran SuPerCharge nylon transfer membrane (Schleicher & Schull BioScience, New Hampshire, USA). After UV cross-linking treatment, the membrane was stained with methylene blue [0.02% [w/v] methylene blue in 0.3 mol/L sodium acetate(pH 5.5)] to investigate the transferring efficiency. Following destaining, BrightStar Psoralen-Biotin (Ambion Inc, Autin, TX, USA)-labeled probe D03 was applied for hybridization in ULTRhyb hybridization buffer (Ambion Inc). The membrane was washed twice with a buffer containing 2× SSC (0.3 mol/L NaCl, 0.03 mol/L sodium citrate) and 0.1% sodium dodecylsulfate before the probes were detected by using the Phototope Star Detection Kit (New England Biolabs). Finally, the filter was exposed to Fuji Medical X-ray film at room temperature for 5–8min.

Protein expression and immunoblotting To enable non-fusion protein expression, the S-protein tag and His-tag were removed from the pET-44 vector and the allergen-coding regions were decorated by introducing restriction sites (5' *NdeI* and 3' *PstI*) by PCR using the corresponding primers (Table 1). Subsequent to double restriction digestion and purification, the PCR products were ligated with the pET-44 EK/LIC vector (Novagen, Madison, WI, USA). After transformation of the ligation products into NovaBlue Singles

Table 1. Sequences of primers used in this study. The underlined sequences denote the restriction sites of *NdeI* and *PstI*, respectively. Bracketed alternative nucleotides in primer Sg1P3 represent the degenerate loci.

cells (Novagen), positive clones and in-frame insertions were confirmed, initially by colony PCR with the primer SProt and 3' primers related to each clone, and then by sequencing with the S-Tag 18-mer primer or ColiDown primer (Novagen). Plasmid DNA was extracted with the QIAprep Miniprep Kit (Qiagen), and transformed into *E coli* RosettaBlue (DE3) cells (Novagen) for expression, following the manufacturer's instructions. Cells were grown in 1 L Luria-Bertani (LB)-medium until the OD₆₀₀ value reached 0.6. Target protein expression was induced by the addition of isopropyl-D-thiogalactopyranoside (IPTG) to 1 mmol/L for 4 h at 30 °C before harvest. Finally, the recombinant proteins were purified by affinity chromatography using poly-(L)-proline as the solid phase. The bacterium lysate was applied to the column, followed by washing with 1 mol/L urea and elution with 6 mol/L urea. The elution product was dialyzed stepwise against decreasing amounts of urea (6, 4, 2 mol/L, no urea) in phosphate-buffered saline (PBS; 1.8 mmol/L potassium phosphate, pH 7.4, 0.137 mol/L NaCl) and then dialyzed against double-distilled water, followed by freeze-drying.

Purified rAmb a 8(D03) and rHum s(LCM9) were selected as representatives for immunoblotting. Fifteen micrograms of protein were loaded onto the 15% SDS-PAGE gel, and were then electrically transferred to a polyvinylidene difluoride (PVDF) membrane (Amersco, Solon, OH, USA). Following blocking the membrane overnight with a 4% bovine serum albumin solution at 4 °C, allergic sera (diluted 1:7) were added to each membrane strip for 2 h before the addition of peroxidase conjugated goat anti-human IgE (Sigma-Aldrich, Saint Louis, MO, USA). The blotted band was finally visualized with a diaminobenzidine (DAB) chromogenic substrate solution (Amersco).

N-terminal end sequencing Sequencing of the N-terminal end of recombinant proteins was performed by using the Applied Biosystems Procise 491 Sequencer from Applied Biosystems, according to the manufacturer's instructions.

Results

Homology between different allergen genes The 478 pollen allergens obtained from the SWISS-PROT and TrEMBL websites were clustered into 8 large groups, which consisted of a number of subgroups. Further searching with the core sequences from each subgroup demonstrated that these core sequences matched a large quantity of closely related homologues. For instance, Q9XF40, the first core sequence in group 8, was an apple pollen allergen with extensive homology with other pollen allergens from different species (Figure 1), such as *Poa pratensis*, *Lolium perenne*,

Figure 1. The core subgroup cut off from the large group VIII clustered from 478 allergens obtained from SWISS-PROT. The conserved regions in Q9XF40, O81982 and Q9XF37 were used for pan-degenerate primer (Sg1P5/P3) design. Q9XF40 and O81982 were selected for their clustering priority, whereas Q9XF37 was selected for its amino acid length of 133 aa. All allergens shown were from SWISS-PROT. The numbers on the right-hand sides of each allergen denote absolute distance.

Dactylis glomerata, *Hordeum vulgare*, *Holcus lanatus* (e values $<2e^{-25}$). The conservative domains in the Q9XF40 cDNA sequence (1–20 bp, 343–369 bp) as resolved by multiple sequence alignment of Q9XF40 and its cognates were taken as the Sg1p5/Sg1p3 primer sequence (Table 1). Other degenerate primers were designed following the same principle.

Full-length cDNA generation By combining the gradient PCR with touchdown PCR, 3 gene fragments were obtained from each weed species, and were subsequently inserted into the pGEM-T vector. Sequence analysis showed that the inserts, 5 of 363 bp and 1 of 369 bp, were homologous to the known allergen gene profilin from different species with up to 90% (5 clones except for D03) and 79% (for D03) identity, but with ~30 bp truncated at the 3' ends, suggesting a further requirement of the RACE process for the full-length cDNA. After cloning of the amplificants from the specific PCR with primer pairs PC11/RA3, PM9/RA3, PD10/RA3 and PD03/RA3, a total of 29 positive RACE clones were detected. Subsequent sequencing reactions demonstrated that they all contained the initiation and stop codons, primer sequences and poly (A) tails, reflecting the mRNA source of the clones. Northern blotting with a clone D03 probe further confirmed that the cDNA cloned was derived from the pollen

mRNA (Figure 2). Bridging the 3' end and the corresponding fragment genes produced 6 novel full-length coding genes, among which LCS13, LCM20 and LCM9 were from *H scandens*, whereas A0418, D106 and D03 were from *A artemisiifolia*. They are all available in GenBank under accession Nos AY268422-AY268427.

Figure 2. Northern blot results of the total RNA extracted from the *A artemisiifolia* pollen at different times. Total RNA of 20 µg was electrophoresed, blotted onto Nytran SuPerCharge nylon transfer membranes (Schleicher & Schull BioScience) and stained with methylene blue to confirm the transferred RNA quality. After destaining, Psoralen-Biotin labeled probes for D03 were applied for hybridization.

Sequence analysis Sequence analysis revealed that there were several altered nucleotides in the cDNA sequences compared with the degenerate primers used in the fragment-gene cloning process (data not shown), which means that the degeneracy was effectively expanded. The predicted amino acid sequences of the 6 genes were acidic proteins (pI of approximately 5.0) with molecular weights of approximately 14 kDa. Multiple sequence alignment demonstrated that these 6 novel sequences shared a high homology, up to 83%. Moreover, cDNA and protein sequence searches with Blastn and Blastx programs in GenBank showed that the new genes were homologous to profilin genes from more than 10 plant families including Rosaceae, Euphorbiaceae, Phaseoleae, Liliaceae, Poaceae, Urticaceae, Apiaceae, Oleaceae, Solanaceae, Brassicaceae, and Compositae. Alignment of the cognates derived from this search produced a phylogenetic tree, which showed that the 6 novel genes cloned were clearly separated into 3 subgroups, but with high homology (Figure 3).

Of the 6 clones, A0418, D106 and LCM9, 3 closely related clones that encoded 131-amino acid residues, exhibited high homology with apple pollen allergen Q9XF41 (Mal d 4; GenBank accession number: AF129427). LCS13 and LCM20, 2 clones from *H scandens*, had only differences in the cDNA non-coding regions and therefore encoded the same protein, which had 80% and 85% identity with Q8L5D8 from date palm pollen and Q9XF40 from apple pollen, respectively. Clone D03 encoded 133 amino acid residues, and had an identity of 79% and 72% with O81982 (Hela 2)^[19] and CAD12862^[20], 2 profilin proteins from common sunflower and mugwort. Hel a 2 and D03, along with the timothy grass profilins O24282, P35079, O24650, were clustered into one

Figure 3. Phylogenetic relationship between the profilin cognates and the 6 novel allergens cloned in the current study as analyzed by using the Mega2 software with amino acid sequences. The amino acid sequences of the 6 new allergens (LCS13, LCM20, LCM9, A0418, D106, D03) are available from GenBank (accession numbers: AAP15198, AAP15199, AAP15200) and SWISS-PROT (accession numbers Q64LH2, Q64LH1, Q64LH0).

subgroup (Figure 3). Furthermore, D03 was quite different from the other 5 clones in 4 regions of its amino acid sequence, which represents an approximately 90% difference between D03 and other profilins (Figure 4).

Protein expression and purification, and immunoblotting

After detecting the correct reading frame of the target protein gene in the expression vector, the in-frame plasmids were then successfully transformed into *E coli* RosettaBlue (DE3) cells. Following induction and further incubation at 30 °C for 6 h, the recombinant non-fusion proteins were visualized using SDS-PAGE, and had an apparent molecular mass of ~14 kDa (Figure 5A). The N-terminal sequence of 10 amino acids of rAmb a 8(D03) confirmed that the recombinant protein was the same as that deduced from the cDNA sequence. The yield of purified protein was approximately 8 mg per L of cultured bacteria.

IgE antibodies from 6 of 8 sera (75%) from the *A artemisiifolia* allergic patients reacted with recombinant protein rAmb a 8(D03) in the immunoblot experiments. The bands occurred at approximately 14 kDa (Figure 5B). Other recombinant proteins were also very efficiently expressed and purified in non-fusion form (Figure 5C, 5D). As a representative from *H scandens*, the immunoblotting profile of rHum s 1(LCM9) is shown in Figure 5E. Interestingly, rHum s 1(LCM9) not only

Figure 4. ClustalX (1.8) alignment of the deduced amino acid sequences of the 6 clones obtained from the pollen of *H. scandens* and *A. artemisiifolia*. The amino acid residues shown represent the specific region in clone D03 that was markedly different from the profilin proteins of other species. The conservative domains in each clone are shown in bold, and the different amino acid residues are in gray.

Figure 5. Non-fusion expression, purification and immunological characterization of recombinant proteins. A: 15% SDS-PAGE analysis of the no-fusion expression profile of rAmb a 8 (D03). Lanes 1 and 2, purified target protein in non-reducing loading buffer; Lane M, broad range prestained SDS-PAGE standards (Bio-Rad, catalog No 161-0318), similar to Lane M in all other panels; Lanes 4 and 5, re-purified target protein in non-reducing loading buffer; Lane 6, re-purified target protein in reducing loading buffer; Lanes 7 and 8, cell lysate in loading buffer; Lanes 9 and 10, supernatant and sediment of the cell lysate. B: Western blot of rAmb a 8(D03). Fifteen micrograms of the purified rAmb a 8(D03) was loaded into each lane and blotted. Lanes 3–8, sera from patients with allergy to *A. artemisiifolia*; Lanes 1, 2 and 9, healthy control sera. C: Representative presentation of non-fusion protein expression of rHum s 1(LCS13) (Lane 1) and rHum s 1(LCM9) (Lane 2) (arrowhead). D: Recombinant proteins purified by affinity chromatography. Lanes 1–5 represent rAmb a 8(D03), rHum s 1(LCS13), rHum s 1(LCM9), rAmb a 8(D106) and rAmb a 8(A0418), respectively. E: Western blot of rHum s 1(LCM9), which was detected in sera from both patients with *H. scandens* allergies (lanes 1–5) and patients with *A. artemisiifolia* allergies (lanes 6–9).

reacted with the sera from 5 patients with *H. scandens* allergy, but also reacted with sera from patients with *A. artemisiifolia* allergy, which suggests that cross-reactivity occurred for rAmb a 8(D03) and rHum s 1(LCM9).

Discussion

In the past, most allergen genes have been cloned by cDNA library screening^[7-9], and hundreds of pollen allergen genes from more than 170 species are available in online databases, which can be sorted into several groups. This means that homologous genes exist in many related or unre-

lated species, which provided support for the current method. In this study, we designed pan-degenerate primers and succeeded in cloning pollen allergen cDNAs from different weeds, thus showing that there is a way to clone homologous genes from distantly related species or little-studied species. Furthermore, by using a combination of the gradient PCR process and touchdown steps, the genes with some divergence in their primer regions could be obtained in the weed genome; that is, the degeneracy of the primers was expanded. The method could therefore be used to clone the same allergens in other species or to clone other kinds of allergen genes.

It has been argued that allergenicity cannot be rationalized on the basis of either overall folding pattern or biological function, and thus any protein should be regarded as a potential allergen^[19]. According to alignment studies, the proteins coded by our new clones had more than 60% identity over the full-length peptide with the known allergens, suggesting that the proteins would be allergenic. Thus, D03 and LCM9, the most different variants of the 6 clones obtained, were expressed as recombinant proteins. Through efficient expression in a pET-44 system, ideal solubility of all the recombinant proteins was obtained, which facilitated protein purification through affinity chromatography, and would ensure efficiency in commercial production.

The molecular basis of cross-reactivity has been of primary concern in numerous publications^[19–21]. The relationship between sequence similarity, as obtained by pair-wise alignment, and structural or functional properties has been the goal of much research^[22–24]. Recent studies have confirmed a widely accepted rule-of-thumb that 30% or 35% identity over aligned regions suffices for structural or functional deduction^[25,26]. A remote homologue study^[27] demonstrated that allergens from diverse sources have a common structural motif, namely a groove located inside an α - β motif, which could potentially serve as a ligand-binding site, thus leading to the stimulation of the T cell helper type 2 (Th2) response and a subsequent bias towards the synthesis of IgE. This result expanded cross-reactivity to between microbes and higher plants. In the present study, the clones were different from each other in their cDNA or protein sequence, suggesting open pollination and/or large genetic variation in the weeds. This was also consistent with other studies on ragweed and timothy grass sequence polymorphism^[28,29]. However, multiple sequence analysis demonstrated that the newly cloned genes had up to 83% homology with each other and 60%–90% identity with previously described allergen profilins from latex, food, and pollens from various organisms, which can produce extensive cross-reactivity^[30,31]. This result demonstrated that proteins from *H scandens* and *A artemisiifolia* would have cross-reactivity. In a previous study we also inferred that the proteins coded by clone D106 would have cross-reactive properties for food- and/or pollen-sensitive allergic individuals^[32,33]. All of these results imply that the newly cloned genes would function the same way as pan-allergen profilins. Based on the issues described herein and the results obtained in the current study, we assume that cross-reactivity would occur so widely that atopic individuals would be surrounded by a dynamic network of allergens, and would be predisposed towards allergic diseases.

Abstract

Aim: To study effects of arachidonic acid (AA) and its metabolites on the hyposmotic membrane stretch-induced increase in calcium-activated potassium currents ($I_{K(Ca)}$) in gastric myocytes. **Methods:** Membrane currents were recorded by using a conventional whole cell patch-clamp technique in gastric myocytes isolated with collagenase. **Results:** Hyposmotic membrane stretch and AA increased both $I_{K(Ca)}$ and spontaneous transient outward currents significantly. Exogenous AA could potentiate the hyposmotic membrane stretch-induced increase in $I_{K(Ca)}$. The hyposmotic membrane stretch-induced increase in $I_{K(Ca)}$ was significantly suppressed by dimethyleicosadienoic acid (100 $\mu\text{mol/L}$ in pipette solution), an inhibitor of phospholipase A_2 . Nordihydroguaiaretic acid, a lipoxygenase inhibitor, significantly suppressed AA and hyposmotic membrane stretch-induced increases in $I_{K(Ca)}$. External calcium-free or gadolinium chloride, a blocker of stretch-activated channels, blocked the AA-induced increase in $I_{K(Ca)}$ significantly, but it was not blocked by nifedipine, an L-type calcium channel blocker. Ryanodine, a calcium-induced calcium release agonist, completely blocked the AA-induced increase in $I_{K(Ca)}$; however, heparin, a potent inhibitor of inositol triphosphate receptor, did not block the AA-induced increase in $I_{K(Ca)}$. **Conclusion:** Hyposmotic membrane stretch may activate phospholipase A_2 , which hydrolyzes membrane phospholipids to ultimately produce AA; AA as a second messenger mediates Ca^{2+} influx, which triggers Ca^{2+} -induced Ca^{2+} release and elicits activation of $I_{K(Ca)}$ in gastric antral circular myocytes of the guinea pig.

Introduction

Mechanical stretch is an important physiological stimulus in gut smooth muscles. It is well known that mechanical stretch induces myogenous contraction of gut smooth muscle, but the mechanism underlying this ionic channel process remains unknown. Mechanical stretch regulates the activities of ionic channels, which exist widely in the membranes of various cells and activate many signal transduction pathways. A hypothesis was proposed that membrane stretch induces alterations in the lipid bilayer, which transmits membrane tension to channel proteins or generates lipid-soluble second messengers, such as arachidonic acid (AA)

and other endogenous fatty acids, by membrane-bound phospholipases^[1,2]. Unsaturated fatty acids are major components of membrane lipids and they are mainly released by phospholipase A_2 (PLA₂) activation. AA in the cell membrane is esterified in phospholipids and can be released by PLA₂ in response to various extracellular stimuli^[3,4]. AA and other unsaturated fatty acids modulate the activities of various ion channels and enzymes through direct or indirect pathways. For example: AA potentiates hKir2.3 in part by decreasing inward rectification of the channel^[5]; AA induces membrane depolarization by inhibiting K_{ATP} currents in murine colonic smooth muscle cells^[6]; and AA increases choline acetyltransferase activity in spinal cord neurons, and

this effect is mediated by protein kinase C (PKC)^[7]. In addition, it was shown that AA induces endothelium-dependent hyperpolarization and relaxation of rabbit aorta through activation of apamin-sensitive K⁺ currents^[8]. Abundant evidence has revealed that AA is an important mediator in hyposmotic stress. It was observed that swelling induces AA release via the 85 kDa cell phospholipase A₂ (cPLA₂) in human neuroblastoma cells^[9], and that cell swelling activates PLA₂ in ehrlich ascites tumor cells^[10]. Tinel *et al*^[11] also reported that AA acts as a second messenger for hypotonic-induced calcium transients in rat inner medullary collecting duct (IMCD) cells.

The calcium-activated potassium current ($I_{K(Ca)}$) has been considered to play an important role in excitability and functional regulation in excitable cells. In our previous study, AA and other unsaturated fatty acids directly inhibited calcium currents^[12] and muscarinic currents^[13]. For both AA and hyposmotic membrane stretch-activated $I_{K(Ca)}$ ^[14,15], activation by hyposmotic membrane stretch is associated with calcium-induced calcium release (CICR)^[16], which is triggered by extracellular calcium influx through the stretch-activated channels (SAC) in gastric antral circular myocytes of the guinea pig. However, the roles of AA and other unsaturated fatty acids in the process of $I_{K(Ca)}$ activation by membrane stretch in gastric myocytes remains unclear. In the present study, we therefore investigated the effects of AA and its metabolites on hyposmotic membrane stretch-induced increases in $I_{K(Ca)}$ in gastric antral circular myocytes of guinea pig.

Materials and methods

Preparation of cells EWG/B guinea pigs (obtained from the Experimental Animal Department of Norman Bethune University, Changchun, China; Certificate No 10-6004) of either sex, weighing 250–350 g, were killed by lethal dose of pentobarbital sodium (50 mg/kg, iv). The antral part of the stomach was cut rapidly, and the mucosal layer was separated from the muscle layer. Circular muscle was dissected from the longitudinal layer using fine scissors, and cut into small segments (1 mm×4 mm). These segments were kept in a modified Kraft-Bruhe (K-B) medium at 4 °C for 15 min. The muscle segments were incubated at 36 °C in 4 mL of digestion medium [calcium-free physiological salt solution (Ca²⁺-free PSS)] containing 0.1% collagenase (II), 0.1% dithioerythritol, 0.15% trypsin inhibitor and 0.2% bovine serum albumin for 25–35 min. The softened muscle segments were then transferred into the modified K-B medium, and cells were dispersed individually by gentle agitation with a wide-pore fire-polished glass pipette. Isolated gastric myocytes

were kept in modified K-B medium at 4 °C until use.

Electrophysiological recording Isolated cells were transferred to a small chamber (0.1 mL) on the stage of an inverted microscope (IX-70 Olympus, Tokyo, Japan) for 10–15 min to settle down. The cells were superfused continuously with isosmotic PSS by gravity (0.9–1.0 mL/min). An 8-channel perfusion system (L/M-sps-8, List Electronics, Darmstadt, Germany) was used to change solution. Experiments were carried out at 20–25 °C and the whole-cell configuration of the patch-clamp technique was used. Patch-clamp pipettes were manufactured from borosilicate glass capillaries (GC 150T-7.5, Clark Electromedical Instruments, Kent, UK) using a 2-stage puller (PP-83, Narishige, Japan). The resistance of the patch pipette was 3–5 MΩ when filled with pipette solution. Liquid junction potentials were canceled before seal formation. Whole-cell currents were recorded with an EPC-10 patch-clamp amplifier (HEKA Instrument, Darmstadt, Germany) and command pulses were applied by using the Pentium IV-grade computer and pCLAMP software (Version 6.02; Axon Instruments, USA).

Drugs and solutions All drugs were purchased from Sigma (Sigma-Aldrich Corp St Louis, MO, USA). Tyrode's solution contained 147 mmol/L NaCl, 4 mmol/L KCl, 1.05 mmol/L MgCl₂·6H₂O, 2 mmol/L CaCl₂·2H₂O, 0.42 mmol/L NaH₂PO₄, 1.81 mmol/L Na₂HPO₄·2H₂O and 5.5 mmol/L glucose, and the pH was adjusted to 7.35 with NaOH. Ca²⁺-free solution contained 134.8 mmol/L NaCl, 4.5 mmol/L KCl, 10 mmol/L HEPES, 1 mmol/L MgCl₂ and 5 mmol/L glucose, and the pH was adjusted to 7.4 with TRIZMA BASE (Tris). The isosmotic solution (290 Osmmol/kg) contained 80 mmol/L NaCl, 4.5 mmol/L KCl, 1 mmol/L MgCl₂·6H₂O, 2 mmol/L CaCl₂·2H₂O, 5 mmol/L glucose, 10 mmol/L HEPES and 110 mmol/L sucrose, and the pH was adjusted to 7.4 with Tris. Hypoosmotic solution (200 Osmmol/kg) contained 30 mmol/L sucrose, with the other ingredients at the same concentrations as in the isosmotic solution. Modified K-B solution contained 50 mmol/L L-glutamate, 50 mmol/L KCl, 20 mmol/L taurine, 20 mmol/L KH₂PO₄, 3 mmol/L MgCl₂·6H₂O, 10 mmol/L glucose, 10 mmol/L HEPES, and 0.5 mmol/L egtazic acid, and the pH was adjusted to 7.4 with KOH. The pipette solution contained 110 mmol/L K-aspartic acid, 5 mmol/L Mg-ATP, 1 mmol/L MgCl₂·6H₂O, 20 mmol/L KCl, 0.1 mmol/L or 10 mmol/L egtazic acid, 2.5 mmol/L di-tris-creatine phosphate and 2.5 mmol/L disodium-creatine phosphate, and the pH was adjusted to 7.3 with KOH. AA, nordihydroguaiaretic acid (NDGA) and dimethyleicosadienoic acid (DEDA) were all prepared as aqueous stock solutions (1 mmol/L).

Data analysis Data were expressed as mean±SD. Statistical significance was evaluated using the Student's *t*-test.

Differences were considered to be statistically significant when $P < 0.05$.

Results

Effects of hyposmotic membrane stretch and AA on $I_{K(Ca)}$ and STOC Under whole-cell configuration, membrane potential was clamped at -60 mV, and $I_{K(Ca)}$ was elicited by a single-step command pulse from -60 mV to $+60$ mV for 400 ms at 15 s intervals. $I_{K(Ca)}$ started increasing at 139.3 ± 11.3 s after cells were exposed to hyposmotic solution (200 mOsm),

and at 165.0 ± 25.1 s after cells were exposed to $10 \mu\text{mol/L}$ AA (Figure 1A, 1B). There was no significant difference between the 2 latent periods. Hyposmotic membrane stretch and $10 \mu\text{mol/L}$ AA increased markedly in peak current of $I_{K(Ca)}$ to $168.3\% \pm 16.1\%$ and $158.5\% \pm 20.5\%$, respectively ($n=6$, Figure 1B.).

The calcium-activated potassium current is activated by intracellular Ca^{2+} and can be monitored by spontaneous transient outward currents (STOC)^[17]. We therefore observed STOC to investigate effects of hyposmotic membrane stretch and AA on $I_{K(Ca)}$. In whole cell configurations, the holding

potential was clamped at -20 mV, and STOC were elicited and enhanced by hyposmotic membrane stretch and 10 $\mu\text{mol/L}$ AA, respectively (Figure 1C).

Effects of exogenous AA on hyposmotic membrane stretch-induced increase in $I_{K(\text{Ca})}$ Under whole-cell configuration, membrane potential was clamped at -60 mV, and $I_{K(\text{Ca})}$ was elicited by a step voltage command pulse from -40 mV to +100 mV for 400 ms with a 20-mV increment at 10-s

intervals. Exogenous AA significantly increased $I_{K(\text{Ca})}$ elicited by the command step pulse when membrane potential was depolarized from -40 mV to +100 mV, and hyposmotic membrane stretch potentiated the AA-induced increase in $I_{K(\text{Ca})}$ when the membrane potential was depolarized from -40 mV to +100 mV (Figure 2A, 2B). Hyposmotic membrane stretch also increased $I_{K(\text{Ca})}$ elicited by the command step pulse when the membrane potential was depolarized from

Figure 2. The effect of exogenous arachidonic acid (AA) on the hyposmotic membrane stretch-induced increase in calcium-activated potassium currents ($I_{K(\text{Ca})}$). (C) Summary of the effects of exogenous AA on the hyposmotic membrane stretch-induced increase in $I_{K(\text{Ca})}$ and those of hyposmotic membrane stretch on the exogenous AA-induced increase in $I_{K(\text{Ca})}$ at +60 mV. (D) The effect of exogenous AA on the hyposmotic membrane stretch-induced increase in spontaneous transient outward currents. ^b $P < 0.05$, ^e $P < 0.01$ vs control. ^e $P < 0.05$, ^f $P < 0.01$ vs 10 $\mu\text{mol/L}$ AA. ^b $P < 0.05$, ⁱ $P < 0.01$ vs 202 mOsm.

-40 mV to +100 mV, and AA potentiated hyposmotic membrane stretch-induced increase in $I_{K(Ca)}$ when membrane potential was depolarized from -40 mV to +100 mV (Figure 2A, 2B). The peak current of $I_{K(Ca)}$ was increased to 184.2%±17.7% by hyposmotic membrane stretch and then the hyposmotic membrane stretch-induced increase in $I_{K(Ca)}$ was potentiated by 10 μmol/L AA, and the peak current increased to 281.3%±28.3% at +60 mV ($n=8$, Figure 2C). In another way, the peak current of $I_{K(Ca)}$ was increased to 171.8%±20.3% by 10 μmol/L AA, and the AA-induced increase in $I_{K(Ca)}$ was potentiated by hyposmotic membrane stretch, with the peak current increasing to 311.5%±44.4% at +60 mV ($n=8$; Figure 2C). However, there was no significant difference between the potentiated effects of AA on the hyposmotic membrane stretch-induced increase in $I_{K(Ca)}$ and hyposmotic membrane stretch on the AA-induced increase in $I_{K(Ca)}$ ($P>0.05$, Figure 2C). As with the protocol above, the effects of hyposmotic membrane stretch and AA on STOC were investigated.

Hyposmotic membrane stretch markedly increased STOC, and 10 μmol/L AA potentiated this effect ($n=2$, Figure 2D).

Effects of endogenous AA and its metabolites on hyposmotic membrane stretch-induced increase in $I_{K(Ca)}$ Intracellular free AA are metabolized by 3 enzymes: cyclooxygenase, lipoxygenase and epoxygenase. To determine the effects of endogenous AA and its metabolites on the hyposmotic membrane stretch-induced increase in $I_{K(Ca)}$, DEDA, a non-selective inhibitor of PLA₂, and NDGA, a lipoxygenase inhibitor, were used to inhibit the hydrolyzation of AA from membranes and to decrease the production of AA metabolites. DEDA (100 μmol/L in pipette) significantly suppressed the hyposmotic membrane stretch-induced increase in $I_{K(Ca)}$ (Figure 3A,3B), and the increased percentage was reduced from 164.3%±9.8% of the control to 113.4%±3.6% at +60 mV ($n=15$, Figure 3C). When cells were pretreated for 15 min with 10 μmol/L NDGA, AA (Figure 4A,4B) and hyposmotic stretch-induced increases in $I_{K(Ca)}$ could be significantly suppressed (Figure 5A,

Figure 3. The inhibitory effect of dimethyleicosadienoic acid (DEDA), an inhibitor of phospholipase A₂ (PLA₂), on calcium-activated potassium currents ($I_{K(Ca)}$) increased by hyposmotic membrane stretch. (A) Raw traces of the hyposmotic membrane stretch-induced increase in $I_{K(Ca)}$ in the presence of DEDA. (B) I/V relation curves of the hyposmotic membrane stretch-induced increase in $I_{K(Ca)}$ in the presence of DEDA and control. Peak values of the currents were normalized to the values at +100 mV under control conditions. (C) The inhibitory effect of DEDA on $I_{K(Ca)}$ increased by hyposmotic membrane stretch at +60 mV. ^b $P<0.05$, ^c $P<0.01$ vs control. ^e $P<0.05$ vs 200 mOsm.

Figure 4. The inhibitory effect of nordihydroguaiaretic acid (NDGA), a lipoxygenase inhibitor, on calcium-activated potassium currents ($I_{K(Ca)}$) increased by arachidonic acid (AA). (A) Raw traces of the AA-induced increase in $I_{K(Ca)}$ in the presence of NDGA. (B) I/V relation curves of the AA-induced increase in $I_{K(Ca)}$ in the presence of NDGA and control. The peak values of currents were normalized to the values at +100 mV under control conditions. (C) The inhibitory effect of NDGA on $I_{K(Ca)}$ increased by AA at +60 mV. ^b $P < 0.05$, ^c $P < 0.01$ vs control. ^ε $P < 0.05$ vs NDGA.

5B). The AA-induced increase in $I_{K(Ca)}$ was decreased from $145\% \pm 10\%$ to $110\% \pm 4\%$ by NDGA ($n=8$, Figure 4C). NDGA also suppressed the hypotonic membrane stretch-induced increase in $I_{K(Ca)}$ (Figure 5A,5B) and the increased percentage was reduced from $170\% \pm 10\%$ to $142\% \pm 3\%$ at +60 mV (Figure 5C). These results showed that endogenous AA and its metabolites were involved in the hypotonic membrane stretch-induced increase in $I_{K(Ca)}$.

Effect of calcium mobilization on AA-induced increase in $I_{K(Ca)}$ It is well known that $I_{K(Ca)}$ is activated by intracellular free calcium, while extracellular calcium is necessary for efficiently controlling calcium homeostasis. To determine whether the AA-induced increase in $I_{K(Ca)}$ was mediated by calcium influx, the effect of AA on $I_{K(Ca)}$ was observed following the removal of extracellular calcium and the addition of 10 μmol/L EGTA in bath solution. The AA-induced increase in $I_{K(Ca)}$ was completely blocked by the removal of extracellular calcium, and the changes in the percentage of $I_{K(Ca)}$ were $146.30\% \pm 10.4\%$ and $95.64\% \pm 11.7\%$ in the presence or absence of extracellular calcium, respectively ($n=6$,

Figure 6A). Our previous study indicated that hypotonic membrane stretch activated L-type calcium currents^[12] and calcium-activated potassium currents via extracellular calcium influx through SAC in gastric myocytes of guinea pig^[15,16]. We therefore examined the relationship between the AA-induced increase in $I_{K(Ca)}$ and L-type calcium channels or SAC. However, 5 mmol/L nifedipine, an L-type calcium channel blocker, did not block the AA-induced increase in $I_{K(Ca)}$, but gadolinium (Gd^{3+}), a blocker of SAC, completely suppressed the AA-induced increase in $I_{K(Ca)}$. The changes in the percentage of $I_{K(Ca)}$ were $146.3\% \pm 10.4\%$, $151.1\% \pm 14.4\%$ and $102.5\% \pm 2.2\%$ in the control, nifedipine and Gd^{3+} groups, respectively ($n=6$, Figure 6A).

Intracellular free calcium has 2 sources: extracellular calcium influx and intracellular calcium release from calcium stores. Intracellular calcium is released through 2 pathways, one is CICR and the other is inositol-triphosphate-induced calcium release (IICR). We therefore investigated the role of intracellular calcium release in the AA-induced increase in $I_{K(Ca)}$. Heparin (3 mg/mL), a potent inhibitor of IICR, could

(A) Raw traces of the hyposmotic membrane stretch-induced increase in $I_{K(Ca)}$ in the presence of NDGA. (B) I/V relation curves of the hyposmotic membrane stretch-induced increase in $I_{K(Ca)}$ in the presence of NDGA and control. The peak values of currents were normalized to the values at +100 mV under control conditions. (C) The inhibitory effect of NDGA on $I_{K(Ca)}$ increased by hyposmotic membrane stretch at +60 mV. ^b $P < 0.05$ vs control; ^e $P < 0.05$ vs NDGA; ^h $P < 0.05$ vs 200 mOsm.

Figure 6. The effect of calcium mobilization on $I_{K(Ca)}$ increased by arachidonic acid (AA) 10 μmol/L. (A) Summary of $I_{K(Ca)}$ increased by AA at +60 mV under conditions of no external Ca²⁺, administration of nifedipine (Ni) and gadolinium (Gd³⁺). (B) Effect of inositol triphosphate-induced calcium release on the AA-induced increase in spontaneous transient outward currents (STOC) and effect of calcium-induced calcium release on the AA-induced increase in STOC. ^b $P < 0.05$ vs control. ^e $P < 0.05$ vs Ni.

inhibit STOC significantly, but did not block the AA-induced increase in STOC (Figure 6B). Ryanodine (10 $\mu\text{mol/L}$), a specific CICR inhibitor, binds to CICR channels and locks them in a subconductance state, thereby functionally depleting calcium stores^[18]. In the present study, ryanodine increased STOC, and STOC were then almost abolished by ryanodine after approximately 8 min with caffeine, a CICR activator; AA could not then enhance them again (Figure 6B). These results indicated that CICR, but not IICR, was involved in the AA-induced increase in $I_{K(\text{Ca})}$.

Discussion

Our previous study demonstrated that $I_{K(\text{Ca})}$ was activated by hyposmotic membrane stretch and Ca^{2+} signaling played an important role in the process in gastric antral circular myocytes of guinea pig^[15,16]. Under hyposmotic conditions, extracellular calcium influx through SAC triggered CICR, and intracellular free calcium then activated $I_{K(\text{Ca})}$. However, it remains obscure how the membrane stretch is turned into the signal for Ca^{2+} entry from the extracellular space. We therefore investigated whether AA is involved in the hyposmotic membrane stretch-induced increase in $I_{K(\text{Ca})}$.

In the present study, both hyposmotic membrane stretch and AA significantly increased $I_{K(\text{Ca})}$ with a similar latent period. Moreover, exogenous AA potentiated the hyposmotic membrane stretch-induced increase in $I_{K(\text{Ca})}$ (Figure 1). The results indicated that there may be a similar mechanism for the $I_{K(\text{Ca})}$ activated by hyposmotic membrane stretch and AA. Activation of various signaling pathways may induce an increase in the production of AA, for example, phospholipase C, phospholipase D and PLA_2 . In mammalian tissues AA is mainly liberated directly from phospholipids by PLA_2 , which is a ubiquitous enzyme^[4]. We have observed that when cells are exposed to DEDA, a non-selective inhibitor of PLA_2 , the hyposmotic membrane stretch-induced increase in $I_{K(\text{Ca})}$ is significantly blocked by DEDA (Figure 3). The results suggest that hyposmotic membrane stretch activates PLA_2 , which hydrolyzes membrane phospholipids to produce AA, and AA as a second messenger mediates the hyposmotic membrane stretch-induced increase in $I_{K(\text{Ca})}$ in gastric myocytes of guinea pig. Many experiments also support our results. It was observed that hyposmotic cell swelling induced AA release from cell membranes in human neuroblastoma cells^[9] and Ehrlich ascites tumor cells^[10]. In rat inner medullary collecting duct cells, AA acted as a second messenger in hypotonicity-induced calcium transients^[11]. AA was also a second messenger in cultured rabbit principal cells^[19] and ciliary epithelial cells under hyposmotic condi-

tions^[20]. Meanwhile, many reports have described that AA is able to affect cell functions, via its metabolites, under hyposmotic conditions in several cell systems. Leucotrienes, for example, appeared to mediate the inositol efflux in glial cells^[21], and to activate chloride and potassium conductances as well as taurine transport in Ehrlich ascites cells^[22]. In the present study, we also examined the possibility that AA metabolites could be involved in activating potassium currents under hyposmotic conditions by using NDGA, a lipoxygenase inhibitor. NDGA significantly inhibited AA and the hyposmotic membrane stretch-induced increase in $I_{K(\text{Ca})}$ (Figure 4). These results suggest that AA metabolites generated by lipoxygenase mediate the hyposmotic membrane stretch-induced increase in $I_{K(\text{Ca})}$ in gastric myocytes.

In various cell types, AA was found to induce Ca^{2+} flux and to mobilize intracellular calcium to trigger different Ca^{2+} -dependent physiological functions in cells. For example, AA or its metabolites mobilized Ca^{2+} from intracellular stores, and intracellular Ca^{2+} then activated ion transport^[19]. In several cell types, for example, in rat IMCD cells^[11], human embryonic kidney (HEK293) cells^[23] and *Dictyostelium discoideum*^[24], AA released Ca^{2+} from the stores to trigger extracellular Ca^{2+} entry, and Ca^{2+} released from calcium stores was a prerequisite for extracellular Ca^{2+} entry. However, Murthy *et al*^[20] found that AA induces Ca^{2+} influx, which triggers CICR in longitudinal smooth muscle of the intestine. Our previous study also demonstrated that hyposmotic membrane stretch activates $I_{K(\text{Ca})}$ via CICR in gastric myocytes^[15]. In the present study, the roles of AA and its metabolites in the relationships among hyposmotic membrane stretch-induced increase in $I_{K(\text{Ca})}$, extracellular Ca^{2+} and intracellular calcium mobilization were investigated. Under extracellular calcium-free conditions, $I_{K(\text{Ca})}$ was not increased by AA or hyposmotic membrane stretch (Figure 6). It was elucidated that extracellular calcium is necessary for AA and the hyposmotic membrane stretch-induced increase in $I_{K(\text{Ca})}$, and some ionic channels participate in extracellular calcium influx. McCarty and O'Neil indicated that there are 2 alternative kinds of channel activated by hyposmotic swelling: voltage-activated Ca^{2+} channels and stretch-activated channels^[25]. We observed previously that hyposmotic membrane stretch increases L-type current in gastric myocytes of guinea pig^[12], and Yamamoto and Suzuki^[26] also observed that there are 2 kinds of SAC in gastric myocytes of guinea pig. In the present study we examined whether these 2 channels are associated with extracellular calcium influx. Nicardipine, an L-type calcium channel blocker, could not block the AA-induced increase in $I_{K(\text{Ca})}$. However, it was completely blocked by Gd^{3+} , which blocks not only SAC but also store-operated

Ca²⁺ channels (Figure 6). A similar effect of Gd³⁺ in blocking AA-induced Ca²⁺ entry has also been observed in other cell types, such as IMCD^[11] and HEK293 cells^[23].

Intracellular Ca²⁺ release from Ca²⁺ stores is the primary source of the increase in intracellular calcium. It was found that the entry of extracellular calcium via activating stretch-sensitive channels is amplified by calcium release from internal stores in toad gastric myocytes^[26]. Sutko and Airey^[27] suggested that ryanodine-sensitive calcium stores were positioned near the surface membrane in some smooth muscle cells, Ca²⁺ release from which was found to influence the activity of *I*_{K(Ca)}. Our previous study also indicated that hyposmotic membrane stretch activates *I*_{K(Ca)}^[15,16] and carbachol currents^[13], and the activations are associated with CICR, which is triggered by extracellular calcium influx^[15,28]. In the present study, heparin, a potent inhibitor of inositol triphosphate receptor, did not block the AA-induced increase in *I*_{K(Ca)}; however, ryanodine, a CICR agonist, completely blocked the AA-induced increase in *I*_{K(Ca)} (Figure 6B). The results suggest that AA mobilizes intracellular calcium via triggering CICR and activates *I*_{K(Ca)} in gastric antral circular myocytes of guinea pig. The potassium efflux through *I*_{K(Ca)} hyperpolarized the membrane potential of smooth muscle cells, thereby limiting depolarization-dependent calcium and promoting relaxation. CICR can thus participate in both the contraction and relaxation of smooth muscle cells. Therefore, AA may be involved in both the contraction via activating extracellular Ca²⁺ influx and relaxation via activating *I*_{K(Ca)} in gastric antral circular myocytes of the guinea pig.

In summary, hyposmotic membrane stretch may act on cell membranes to activate PLA₂ and then generate AA. AA may then act as a second messenger to mediate extracellular calcium entry and trigger CICR to activate *I*_{K(Ca)} in gastric myocytes of the guinea pig. AA and its metabolites may play an important role in regulating many cell functions under the hyposmotic conditions in gastric antral circular myocytes of the guinea pig.

Abstract

Aim: To investigate the anti-implantation effect of droloxifene and study the possible relationship between the anti-estrogenic activity of droloxifene and its anti-implantation effect. **Methods:** Pregnant rats were treated orally with droloxifene at 10:00 AM on d 2 at doses of 1.25–20 mg/kg to observe anti-implantation effects, and then doses of 14 mg/kg or 2.5 mg/kg were given at different time on d 2 to d 5 to determine the optimal administration time for anti-implantation effects. Pregnant rats were treated with a combination of droloxifene (2.5 mg/kg, ig) and E2 (0.5–8.0 µg/kg, sc) on the optimal administration time to observe the antagonistic effect of external estrogen on the anti-implantation effect of droloxifene. Serum estrogen and progesterone levels were measured by carrying out radioimmunoassays on d 1 to d 6 in droloxifene-treated and control rats to determine the surge time for nidatory estrogen and the effect of droloxifene on ovary function. **Results:** Droloxifene has anti-implantation effects in rats. The optimal oral administration time was at 22:00 PM on d 4, which was after the surge time for nidatory estrogen (on d 4 at 10:00 AM). This suggests that the anti-implantation effect of droloxifene is not attributable to antagonism of the surge in secretion of nidatory estrogen. External estrogen did not antagonize the anti-implantation effect of droloxifene. Droloxifene had no effect on the serum levels of estrogen and progesterone on d 5 or d 6 when administered on d 4 at 22:00 PM. **Conclusion:** Droloxifene has an anti-implantation effect in rats, and the effect appears to be not completely due to its anti-estrogenic activity.

Introduction

Droloxifene, a derivative of the triphenylethylene drug tamoxifen, is a novel selective estrogen receptor modulator (SERM)^[1]. Its higher affinity to the estrogen receptor, higher anti-estrogenic to estrogenic ratio, more effective inhibition of cell growth and division in estrogen receptor-positive cell lines, and lower toxicity give it theoretical advantages over tamoxifen in the treatment of human breast cancer^[2]. Droloxifene may also be a potentially useful agent for the treatment of postmenopausal osteoporosis because it can prevent estrogen deficiency-induced bone loss without causing uterine hypertrophy^[3]. Droloxifene may have an effect on bone and breast tissue because it induces apoptosis^[4].

The corpus luteum is an ovarian tissue that synthesizes and secretes progesterone, which plays a key role in the establishment and maintenance of pregnancy in mammals. Abnormal regression of the corpus luteum will disturb or even terminate both the implantation process and early pregnancy. Apoptosis is involved in the regression of the corpus luteum in many species^[5]. Therefore, better understanding the compounds that induce the apoptosis of luteal cells may contribute to the development of new anti-implantation agents. Our laboratory was the first to report that droloxifene induced the apoptosis of rat luteal cells *in vitro* and the pre-implantation luteal cells in pregnant rats^[6–8]. Moreover, droloxifene facilitates the apoptosis of luteal cells and short-

ens the period of pseudopregnancy in pseudopregnant rats^[9]. These results suggest that droloxifene induces the regression of the corpus luteum and has potential anti-implantation effects. Exact equilibrium of estrogen and progesterone is essential for implantation, and any disturbance in the effects of these hormones can cause infertility^[10]. As a novel selective estrogen receptor modulator with greater anti-estrogenic effects, droloxifene seems to interfere with the effect of estrogen and cause anti-implantation effects. However, the anti-implantation effect of droloxifene has not been evaluated and reported on. Therefore, in the present study, the anti-implantation effect of droloxifene was evaluated and the relationship between the anti-estrogenic activity of droloxifene and its anti-implantation effect was analyzed in rats.

Materials and methods

Drugs and reagents The droloxifene was synthesized by Prof Peng XIA (Department of Organic Chemistry, College of Pharmacy, Fudan University, Shanghai) and was suspended in 1% sodium carboxymethylcellulose (CMC). Estradiol (E_2) was purchased from the Shanghai 9th Pharmaceutical Factory (Shanghai, China) and was suspended in corn oil. Serum estrogen and progesterone radioimmunoassay (RIA) kits were obtained from DEPU Ltd (Tianjin, China).

Animals and treatment Sprague-Dawley rats (body weight: female, 220–250 g and male 300–350 g, SIPPR/BK Ltd Shanghai) were kept in a temperature-controlled (24–26 °C) and light-regulated (12 h light, 12 h dark) room, and were given *ad libitum* access to standard chow and water. The female animals were cohabited with male animals at a ratio of 2:1. The day that sperm were found in the vaginal smear was designated as d 1 of pregnancy.

Evaluation of anti-implantation efficacy Confirmed pregnant female rats were randomly assigned into different groups and were treated with droloxifene (ig), estradiol (E_2 , sc), or 1% CMC (as a control, ig). The doses and treatment times of the different experiments are shown in the results section. At autopsy on d 9, the number of animals with implantation sites in each group was recorded. The Bliss method was used to calculate the ED_{95} , ED_{90} , and ED_{50} of the anti-implantation effect of droloxifene.

Assay of the serum levels of estrogen and progesterone The pregnant rats were treated orally with 2.5 mg/kg droloxifene or 1% CMC at 22:00 PM on d 4. Blood samples of 0.5 mL were obtained from the tail veins of pregnant rats at 10:00 AM on d 1, d 2, d 3, d 4, d 5 and d 6, and at 22:00 PM on d 4. The serum levels of estrogen and progesterone were measured by RIA according to the manufacturer's inst-

ructions.

Statistical analysis Differences in pregnancy rates between the groups were tested by using the χ^2 test. Serum levels of estrogen and progesterone are expressed as mean \pm SD and Student's *t*-test was used to calculate significance.

Results

Optimal administration time for the anti-implantation effect of droloxifene Pregnant rats were treated orally with droloxifene with doses ranging from 1.25 to 20.0 mg/kg at 10:00 AM on d 2. Within the treatment time, droloxifene had an anti-implantation effect in rats (ED_{95} =17.62 mg/kg and ED_{50} =5.34 mg/kg; Table 1). To determine the optimal administration time for the anti-implantation effect of droloxifene, pregnant rats were treated orally with droloxifene at either a high dose (14 mg/kg) or a low dose (2.5 mg/kg) at 10:00 AM on d 2, d 3, d 4, or d 5, or at 22:00 PM on d 4. Although the differences in the anti-implantation rates in different groups were not significant for the 14 mg/kg groups, the anti-implantation rates of rats treated with droloxifene at 22:00 PM on d 4 were the highest in the two dose groups (Table 2). These results suggest that droloxifene has anti-implantation effects in rats, and that the optimal administration time is at 22:00 PM on d 4.

Table 1. Anti-implantation effects of droloxifene in rats treated in at 10:00 AM on d 2. *n*=10. Mean \pm SD. ^b*P*<0.05, ^c*P*<0.01 vs control.

ED_{95} , ED_{90} , and ED_{50} for the anti-implantation effect of droloxifene Pregnant rats were treated orally with droloxifene at various doses (10, 5.0, 2.5, 1.25, 0.62, 0.31, or 0.15 mg/kg) at 22:00 PM on d 4. The anti-implantation rates of the droloxifene groups (0.62–10 mg/kg) were higher than that observed in the control group (*P*<0.01; Table 3). There was a dose-dependent relationship between the anti-implantation rates and droloxifene doses from 0.15 mg/kg to 5.0 mg/kg. The values of ED_{95} , ED_{90} and ED_{50} were 3.70 mg/kg, 2.63

mg/kg and 0.79 mg/kg, respectively.

Antagonistic effect of external E₂ on the anti-implantation effect of droloxifene To investigate the antagonistic effect of external E₂ on the anti-implantation effect of droloxifene, the anti-implantation effect of external E₂ only was first evaluated. When rats were treated at 22:00 PM on d 4 with external E₂ at doses of 2.0 μg/kg or 8.0 μg/kg (sc), significant anti-implantation effects were observed (*P*<0.05), whereas at doses of 0.5 μg/kg or 1.0 μg/kg, there was no anti-implantation effect. For rats treated at 22:00 PM on d 4 with 2.5 mg/kg droloxifene alone or 2.5 mg/kg droloxifene com-

bined with various doses of E₂, there was no difference in implantation rates, although E₂ at higher doses (2.0 or 8.0 μg/kg) reduced the anti-implantation rates (Table 4).

Table 4. Antagonistic effects of E₂ on the anti-implantation effect of droloxifene (2.5 mg/kg) in rats. Effect of droloxifene on the serum level of estrogen during early pregnancy

Pregnant rats were treated orally with 2.5 mg/kg droloxifene or 1% CMC at 22:00 PM on d 4. The rate of implantation was 100% and 0% in the control and droloxifene groups, respectively. In the control group, the serum level of estrogen remained at low levels from d 1 to d 3, began to rise on d 3, reached the maximum at 10:00 AM on d 4, then declined sharply, such that the levels on d 5 and d 6 were similar to those on d 3. The serum estrogen levels in the droloxifene group between d 1 and d 6 were not significantly different from those in the control group (Figure 1). These results indicate that there was a surge of estrogen in the pregnant rats at 10:00 AM on d 4, and that treatment with droloxifene at 22:00 AM on d 4 had no effect on the level of estrogen; however, a significant anti-implantation effect was induced. Therefore, the anti-implantation effect of droloxifene in rats appears not to be due to antagonism of a surge in the secretion of nidatory estrogen.

Effect of droloxifene on serum levels of progesterone during early pregnancy in rats

Pregnant rats were treated orally with 2.5 mg/kg droloxifene or 1% CMC at 22:00 PM on d 4. The rates of implantation were 100% and 0% in the control and droloxifene groups, respectively. In the control

Figure 1. Nidatory estrogen surge and effect of droloxifene on serum levels of estrogen during early pregnancy in rats. $n=4$. Mean \pm SD.

groups, the serum levels of progesterone rose from 10:00 AM on d1 to 22:00 PM on d 4 and remained at high levels until d 6. In groups treated with droloxifene at 22:00 PM on d 4, the levels of progesterone were similar to that of controls (Figure 2). These results indicate that treatment with droloxifene at 22:00 PM on d 4 had no effect on the level of progesterone in early pregnancy.

Figure 2. Effect of droloxifene on the serum levels of progesterone during early pregnancy in rats. $n=4$. Mean \pm SD.

Discussion

It is well established that an exact equilibrium of estrogen and progesterone is indispensable for implantation in rats^[10]. A nidatory surge that occurs on d 4 is essential for the sensitization of the uterus to induce decidual cell reaction, the most specific function of the progestational endometrium^[11,12]. As a novel selective estrogen receptor modulator with considerable anti-estrogenic effects, droloxifene might disturb the hormonal effects and cause an anti-implantation effect. The present study found that droloxifene had anti-implantation effects in rats (Tables 1–3) and that 22:00 PM on d 4 was the optimal oral administration time. At this time there was a good dose-effect relationship between the anti-implantation rates and droloxifene doses from 0.31 mg/kg to 5.0 mg/kg. The ED₉₅, ED₉₀ and ED₅₀ of droloxifene were 3.70 mg/kg, 2.63 mg/kg, and 0.79 mg/kg, respectively.

We found that the serum levels of estrogen in pregnant

rats reached a peak at 10:00 AM on d 4, which indicates that the nidatory estrogen surge before implantation occurs at approximately this time. However, the optimal oral administration time of droloxifene for anti-implantation effects was at 22:00 PM on d 4, 12 h later than the nidatory estrogen surge. Therefore, we propose that the anti-implantation effect of droloxifene is not caused by its interfering with the nidatory estrogen surge via its anti-estrogenic effect. The effects of droloxifene are different from those of tamoxifen, a triphenylethyl compound, which antagonizes the nidatory estrogen surge^[13,14].

In order to further clarify the relationship between the anti-implantation effect and the anti-estrogenic activity of droloxifene, the antagonistic effect of external E₂ on the anti-implantation effect of droloxifene was observed in rats. At first, the anti-implantation effect of external estrogen (0.5–8.0 µg/kg, sc) was examined after administration at 22:00 PM on d 4. We found that E₂ at doses of 0.5–1.0 µg/kg produced no anti-implantation effect (Table 4), and had no antagonistic effect on the anti-implantation effect of droloxifene ($P > 0.05$; Table 4). When droloxifene was combined with E₂ at higher doses (4.0 or 8.0 µg/kg), the anti-implantation effect of droloxifene was reduced, but the difference was not significant according to the χ^2 test. Therefore, it seems that the anti-implantation effect of droloxifene may be not related to its anti-estrogenic activity, especially at physiological doses.

Because an exact equilibrium of estrogen and progesterone is essential for implantation, and any disturbance in the effects of these hormones can cause infertility, we investigated whether droloxifene inhibited implantation by affecting the serum levels of estrogen and progesterone. We found that droloxifene had no effect on the serum estrogen and progesterone levels in early pregnancy when treated at 22:00 PM on d 4. However, in our previous study, we found that apoptosis of luteal cells and decreases in serum progesterone levels were induced by treatment with droloxifene at a dose of 20 mg/kg on d 2 in pregnant rats^[8]. The differences between the two experiments can be explained by the different doses and administration times. In addition, the period of observation was too short in the present study.

In conclusion, droloxifene can inhibit implantation in rats and the optimal oral administration time is 22:00 PM on d 4. ED₉₀ was 2.63 mg/kg. The anti-implantation effect of droloxifene is not related to its antiestrogenic activity, or an antagonistic effect on the nidatory estrogen surge. The direct inhibition of endometrial receptivity to blastocyst signal (s) and the apoptosis of luteal cells might be involved in the anti-implantation mechanism of droloxifene. This characteristic may make droloxifene useful in developing new

contraceptives.

Abstract

Aim: To study the anticancer activity of sodium caffeate (SC). **Methods:** A nucleoside transport assay was used to analyze the inhibitory effects of SC on nucleoside rescue. The MTT assay was used to measure cell proliferation. Flow cytometry was used to measure the apoptosis of BEC-7402 induced by SC and the cell cycle distribution change. Western blotting analysis was employed to investigate Bcl-2, caspase and Bax expression. Intracellular Ca²⁺ and mitochondrial membrane potential were determined by flow cytometry. *In vivo* anti-tumor activity was measured using a tumor transplantation model in mice. **Results:** SC inhibited the nucleoside transport of BEL-7402 cells with an IC₅₀ of 1.02 mg/mL. SC inhibited tumor cell proliferation with an IC₅₀ between 100 µg/mL and 200 µg/mL. SC induced BEL-7402 cell apoptosis in a time- and dose-dependent manner, which was induced by arresting cells in S phase. The *in vivo* study showed that tumor growth was inhibited in a dose-dependent manner. Activated caspase-3 and Bax expression were up-regulated after treatment with SC, while Bcl-2 expression was down-regulated. Intracellular Ca²⁺ was increased while mitochondrial membrane potential was decreased by SC. **Conclusion:** SC is a new anticancer agent with promising potential.

Introduction

There have been an increasing number of anticancer phytochemicals identified in our daily diet. Some of the most promising and extensively investigated are those present in the cruciferous family of vegetables, alliums and tea. Phytochemicals should be considered as an inexpensive and readily applicable, acceptable and accessible approach to cancer control and management for general populations. This is particularly important considering the sluggish progress made in cancer treatment. It is still an urgent task to seek new anticancer drugs from natural resources in oncology pharmacology.

Cinnamic acid is one of the phytochemicals with potential chemopreventive effects in preventing carcinogenesis^[1,2]. Cinnamamide, a natural compound containing the cinnamic acid structure, is a new antitumor agent that acts on matrix metalloproteinase, which has been demonstrated by previous work in our laboratory^[3]. Caffeic acid (3,4-dihydroxy-

cinnamic acid) is a polyphenol that is found in coffee, fruits, vegetables, grains and many others plants^[4–7]. It is also particularly abundant in propolis beehives with 20%–25% content and has various pharmacological activities, such as antioxidant and antiviral effects^[8]. The anticancer effect of caffeic acid, however, has not been reported up to now. Because caffeic acid is prone to air oxidation and is only slightly soluble in water, its stable sodium salt (sodium caffeate, SC) was prepared in our laboratory and used in the present study. Here we report the antitumor effect of SC both *in vitro* and *in vivo*.

Materials and methods

Reagents RPMI-1640 medium was purchased from Gibco BRL (Gaithersburg, Maryland, USA). Fetal calf serum (FCS) was purchased from Hyclone (Logan, Utah, USA). MTT, nonidet P-40 (NP-40), phenylmethylsulfonyl fluoride (PMSF), aprotinin, ponceau S, Triton X-100, propidium

iodide, Fluo-3, rhodamine 123, RNase A, proteinase K, Hoechst 33342 and other reagents were purchased from Sigma (StLouis, Missouri, USA). [^3H]TdR was purchased from Chinese Atomic Energy Institutes (Beijing, China). Annexin V-FITC/PI apoptosis detection kit was purchased from BioVision company (Hannover, Germany). Mouse anti-Bcl-2 monoclonal antibody, mouse anti-caspase-3 monoclonal antibody and rabbit anti-bax polyclonal antibody were products of Calbiochem (San Diego, California, USA). Horseradish peroxidase-conjugated secondary anti-mouse antibody and anti-rabbit antibody were products of Santa Cruz Biotechnology, Inc (Santa Cruz, California, USA). Enhanced luminol reagent and oxidizing reagent were products of NEN Life Science Products (Boston, Massachusetts, USA). Dr Dan-qing SONG in Department of Chemistry, Institute of Medicinal Biotechnology (Beijing, China) synthesized the SC.

Cells and carcinoma Human oral cavity epidermis squamocellular carcinoma cell line (KB), human hepatocarcinoma cell line (BEL-7402) and human acute promyelocytic cell line (HL-60) were purchased from the Shanghai Institute of Cell Biology, Chinese Academy of Sciences (Shanghai, China), and were grown routinely in RPMI-1640 supplemented with 10% heat-inactivated FCS. The medium was supplemented with 100 U/mL penicillin, 100 $\mu\text{g}/\text{mL}$ streptomycin and 2 mmol/L glutamine, and the cells were incubated in a humidified atmosphere, with 5% CO_2 in air at 37 °C.

Mouse-transplanted hepatocarcinoma H22 and mouse colorectal cancer C26 cell lines were maintained by serial transplantation into mice in our laboratory. Kunming species mice were supplied by the Experimental Animal Center, Chinese Academy of Medical Sciences (Beijing, China).

Nucleoside transport assay^[9] Briefly, cells in the logarithmic growth phase were harvested. The cell suspension was prepared with RPMI-1640 medium at 5×10^6 in 0.9 mL in each test tube. Different concentrations of SC in 0.1 mL RPMI-1640 were added and the tube was kept in a water bath at 37 °C for 5 min. Phosphate-buffered solution (PBS) was used as a control. RPMI-1640 0.1 mL (containing 3.7×10^4 Bq of [^3H]TdR in medium free of serum) was added for 30 s and 5 mL ice-cold normal saline was added to terminate the reaction. The reaction was filtrated through a GF/B glass fiber filter (Whatman International, Maidstone, UK) under vacuum. The filters were washed with 0.2 mL of 1 mol/L NaOH and 0.5 mL ethanol, dried under vacuum and placed in scintillation vials containing 2 mL of dimethylbenzene with 0.4% PPO/0.01% POPOP. The cpm (counts per minute) were measured using an LS-9800 scintillometer (Beckman Instruments, Fullerton, California, USA).

MTT assay Briefly, cells in the logarithmic growth phase were harvested and seeded in 96-well plates (Costar, Cambridge, Massachusetts, USA) overnight. The test compound was added and cells were further incubated for 72 h. The viability of cells was determined using the MTT assay according to the method described by Carmichael *et al*^[10].

Long-term clonogenicity Cell survival was tested using a clonogenic assay, as described by Valduga *et al*^[11]. Briefly, cells in the logarithmic growth phase were harvested and 250 cells/mL of a single-cell suspension was prepared with medium. The cell suspension 200 μL was seeded in 96-well plates (50 cells/well) overnight, and the test compound was added. After 1 week of incubation at 37 °C in air with 5% CO_2 , colonies were counted.

Flow cytometry After appropriate treatment, cells were harvested by centrifugation and washed with PBS. The cells were fixed with ice-cold 75% ethanol for 18 h at 4 °C. The cell apoptosis was measured according to the protocol of Annexin V-FITC/PI apoptosis detection kit. Cell cycles change was measured by treatment of the fixed cell suspensions which were washed with PBS and stained with 80 μL of 50 $\mu\text{g}/\text{mL}$ propidium iodide and 50 $\mu\text{g}/\text{mL}$ RNase A for 30 min in the dark. Samples were run through an EPICS XL flow cytometer (Coulter, Miami, Florida, USA). Results are presented as the number of cells versus the amount of DNA as indicated by the intensity of fluorescence^[12]. The results on flow cytometry represented the average of 3 individual experiments.

Western blotting assay The cells were lysed in lysis buffer at 4 °C with sonication. The lysates were centrifuged at 15 000 $\times g$ for 15 min and the concentration of protein in each lysate was determined using Coomassie Brilliant Blue G-250. Loading buffer was added to each lysate, which was subsequently boiled for 3 min and then electrophoresed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis. Proteins were transferred to nitrocellulose and incubated with anti-Bcl-2, anti-caspase-3 or anti-Bax antibodies and then with peroxidase-conjugated secondary antibodies. Detection was carried out using an enhanced chemiluminescence agent^[13,14]. The results on Western blot analysis represented the average of 3 individual experiments.

Intracellular Ca^{2+} and mitochondrial membrane potential ($\Delta\psi$) Following appropriate treatment, cells were collected by centrifugation and incubated at 37 °C with Fluo-3 for 40 min and then with rhodamine 123 for 20 min. Cells were then washed 3 times with cold PBS, and the intracellular Ca^{2+} concentration and $\Delta\psi$ were measured by flow cytometry^[15-17].

Tumor transplantation and drug administration H22 as-

cites were diluted to 7.5×10^5 /mL suspension and 0.2 mL of the cell suspension was inoculated subcutaneously into the right axilla of each mouse of the Kunming species (weighing 20 ± 2 g). A C26 tumor-cell suspension was prepared by gently suspending tumor tissue in normal saline (1 g of tumor tissue with 3 mL of normal saline) in a cold water bath and inoculated as above. After 24 h of tumor cell inoculation, SC was administered intraperitoneally for 10 d. Normal saline was used as a control. On the d 11 the mice were killed, and body weight and tumor tissue were weighed.

Statistical analysis The data are the mean values of at least 3 experiments and are expressed as mean \pm SD. The Student's *t*-test was used to compare data. $P < 0.05$ was considered to be statistically significant.

Results

Inhibition of nucleoside transport by SC SC inhibited nucleoside transport in the hepatocarcinoma BEL-7402 cell line with an IC_{50} of 1.02 mg/mL. However, the inhibiting effect on nucleoside transport was not very strong.

Inhibition of proliferation and induction of apoptosis by SC SC inhibited tumor-cell proliferation with an IC_{50} of between 100 μ g/mL and 200 μ g/mL (Table 1). Inhibition of BEL-7402 cells proliferation by SC was dose-dependent and time-dependent (Figure 1).

Table 1. Inhibition of proliferation by sodium caffeate treatment for 72 h in different cell lines. $n=3$. Mean \pm SD.

Cell line	IC_{50} / μ g·mL ⁻¹
HL-60	135 \pm 19
KB	157 \pm 22
BEL-7402	192 \pm 28

Figure 1. Inhibition of proliferation by SC in BEL-7402 cells. $n=3$. Mean \pm SD.

Flow cytometry showed that SC induced BEL-7402 cell apoptosis in a time- and dose-dependent manner (Table 2). After 24 h of treatment with SC, the cell cycle changed. The percentages of cells in S phase increased markedly while percentages of cells in G₂/M phase decreased, which suggested the apoptosis was induced by arresting the cells in S phase (Table 3).

Table 2. SC-induced apoptosis (%) in BEL-7402 cells. $n=3$. Mean \pm SD.

Effect of SC on transplanted tumor growth H22 and C26 were inoculated subcutaneously into mice. After SC administration for 10 d, tumor growth was inhibited in a dose-dependent manner. No significant difference in body weight was found between the groups, suggesting that SC does not show toxicity *in vivo* (Table 5 and 6).

Table 5. Anti-tumor activity of sodium caffeate treatment for 10 d on Kunming mice with transplanted H22 cells. ^c*P*<0.01 vs control. *n*=10. Mean±SD. No mouse died during the experimental period.

Group	Dose /g· kg ⁻¹	Body weight change/g	Tumor weight/g	Inhibition/%
Control	0.00	+4.9	4.13±0.19	0
SC	0.15	+4.3	3.00±0.69	27.4 ^c

SC	2.0	+5.6	1.13±0.42	57.5 ^c

Effect of SC on expression of apoptosis-associated proteins The bands were scanned with light density. Activated caspase-3 and Bax expression were up-regulated after SC treatment, while Bcl-2 expression was down-regulated (Figure 2).

Figure 2. Caspase-3, Bax and Bcl-2 expression in BEL-7402 cells treated with sodium caffeate (SC). (A) Control; (B) 10 µg/mL SC; and (C) 25 µg/mL SC.

Effect of SC on intracellular Ca²⁺ and mitochondrial membrane potential After treatment with 10 µg/mL SC for 24 h, intracellular Ca²⁺ was increased 1.78-fold compared to the control. Δψ was decreased by 22.7% compared to the

control. The results showed that SC increased intracellular Ca²⁺ levels and decreased Δψ.

Discussion

Most anti-metabolites in tumor chemotherapy inhibit nucleoside *de novo* synthesis but can not block nucleoside rescue in cancer cells. It is therefore important to control nucleoside rescue by inhibiting nucleoside transport. Previous work found that dipyrindamole enhanced the anticancer effect of acivicin by inhibiting nucleoside transport^[9]. The present study demonstrated that SC was a new member of the nucleoside transport inhibitor family.

Caffeic acid is an active phytophenol that has been found to inhibit rat glutathione-S-transferase isoenzymes both *in vitro* and *in vivo*^[18]. A large number of population-based studies have found that consumption of wholegrains, vegetables and fruits abundant in caffeic acid reduces the risk of cancer^[19-21]. The aqueous extract of *Salvia miltiorrhiza*, a traditional Chinese herb containing caffeic acid was found to strongly inhibit the proliferation of human hepatoma HepG₂ cells. It was also observed that its crude extract caused apoptotic cell death^[22]. Salvianolic acid A, a caffeic acid trimer, showed synergistic effects in combination with other antitumor agents. Further, salvianolic acid A could increase the antitumor effects of 5-fluorouracil without increasing its toxicity in an animal study^[2]. However, no report has been published on the anticancer effects of caffeic acid either *in vitro* or *in vivo*. We are the first to report that the sodium salt of caffeic acid inhibits proliferation of cancer cells, with IC₅₀ between 100 µg/mL and 200 µg/mL. Further, we showed that it induced the apoptotic cell death and changed cell-cycle distribution by arresting cells in S phase. The *in vivo* study showed that SC inhibited the tumor growth of transplanted H22 and C26 cells in mice with an inhibition rate of 42%–54% when treated with 1 g/kg SC for 10 d.

Preliminary studies on the anticancer mechanism of SC demonstrated that after treatment with SC, Bcl-2 expression was down-regulated and mitochondrial membrane permeability was changed. The mitochondrial permeability transition pore was opened and the mitochondrial membrane potential was broken up. The mitochondrion was swelled and in α state of hyperosmosis before apoptosis was induced. Meanwhile cytochrome c was released, caspase-3 was activated in the presence of Apaf-1 and caspase-9, and apoptosis was induced^[23-27].

Abstract

Aim: To study the expression of proline-rich Akt-substrate PRAS40 in the cell survival pathway and tumor progression. **Methods:** The effects of three key kinase inhibitors on PRAS40 activity in the cell survival pathway, serum withdrawal, H₂O₂ and overexpression of Akt were tested. The expression of PRAS40, Akt, Raf and 14-3-3 in normal cells and cancer cell lines was determined by Western blot. **Results:** The PI3K inhibitors wortmannin and Ly294002, but not rapamycin, completely inhibited the phosphorylation of Akt and PRAS40. The phosphorylation level of Akt decreased after serum withdrawal and treatment with the MEK inhibitor Uo126, but increased after treatment with H₂O₂ at low concentration, whereas none of these treatments changed PRAS40 activity. 14-3-3 is a PRAS40 binding protein, and the expression of 14-3-3, like that of PRAS40, was higher in HeLa cells than in HEK293 cells; PRAS40 had a stronger phosphorylation activity in A549 and HeLa cancer cells than in HEK293 normal cells. In the breast cancer model (MCF10A/MCF7) and lung cancer model (BEAS/H1198/H1170) we also found the same result: PRAS40 was constitutively active in H1198/H1170 and MCF7 pre-malignant and malignant cancer cells, but weakly expressed in MCF10A and BEAS normal cell. We also discussed PRAS40 activity in other NSCLC cell lines. **Conclusion:** The PI3K-Akt survival pathway is the main pathway that PRAS40 is involved in; PRAS40 is a substrate for Akt, but can also be activated by an Akt-independent mechanisms. PRAS40 activation is an early event during breast and lung carcinogenesis.

Introduction

Chemoprevention is a logical and obvious strategy to help alleviate the effects of cancer^[1,2]. Much effort has been focused on the discovery and development of new chemopreventive agents, especially agents targeted at mechanisms known to be involved in the process of carcinogenesis^[3,4].

The PI3K-Akt signaling pathway regulates many normal cellular processes including cell proliferation, survival, growth and motility, which are critical for tumorigenesis. The role of the PI3K-Akt signaling pathway in oncogenesis has been extensively investigated and altered expression or mutation of many components of this pathway have been implicated in human cancer^[5]. Akt functions as a major down-

stream target of phosphatidylinositol-3-kinase (PI3K), carrying out functions including stimulation of glucose uptake and cell growth as well as inhibition of apoptosis^[6,7].

Kovacina *et al* used a combination of the 14-3-3 protein and anti-pAkt substrate antibodies to screen and isolate a substrate of Akt, the major 14-3-3 binding protein observed in cells after insulin treatment (a 40 kDa molecule)^[8]. This protein contains a consensus Akt phosphorylation site (Thr-246) but not other recognizable motif. It is highly proline-rich, with 15% of its amino acids being proline (versus 5% for a typical protein), and these proline-rich regions are potential SH3 and/or WW domain binding partners. The protein has therefore been named PRAS40, which stands for the "proline-rich Akt substrate of 40 kDa". Activation of induc-

ible Akt alone was sufficient to stimulate PRAS40 phosphorylation, and phosphorylation of this protein was reduced in cells lacking Akt1 and Akt2. Thus PRAS40 is a novel substrate of Akt, the phosphorylation of which leads to binding of this protein to 14-3-3^[8]. Saito *et al* demonstrated that the expression of PRAS40, PRAS40/Akt and PRAS40/14-3-3 increased in Nerve Growth Factor (NGF) treated mice but decreased with inhibition of PI3K and the NGF receptor after transient focal cerebral ischemia (tFCI)^[9].

However, the critical role of PRAS40 in the biological processes of cell proliferation and carcinogenesis remains unknown. The aim of our study was to examine the expression of PRAS40 in the cell survival signaling pathway, tumor progression and its relationship with Akt and 14-3-3. Information from this study will be helpful for further functional studies of PRAS40.

Materials and methods

Plasmids and expression The constitutively active Akt plasmid HA-Akt-ΔpH and kinase mutation Akt plasmid HA-Akt-Km were the gift of Prof Dr Haian FU (Emory university, USA). After transfection into human embryonic kidney cell HEK293, the supernatant was boiled for 5 min in sodium dodecylsulfate (SDS) sample buffer and resolved using SDS-polyacrylamide gel electrophoresis (SDS-PAGE, 12.5%). The proteins were transferred to polyvinylidene difluoride (PVDF) membranes (BIO-RAD, CA, USA). The primary antibodies were 1:2000 dilution of mouse monoclonal antibody against HA-Prob, Western blots were performed with horseradish peroxidase-conjugate anti-mouse IgG. Cross-reacting materials were visualized using ECL Detection Reagents (Amersham Biosciences, UK).

Source of antibody Rabbit polyclonal antibody against phosphorylated PRAS40(T246), and mouse monoclonal antibody against PRAS40 were purchased from BioSource International (Camarillo, CA, USA); Rabbit polyclonal antibodies against phosphorylated Akt (S473), Akt, phosphorylated-Raf (S338) and Raf were purchased from Cell Signaling Technology (Beverly, MA, USA); Rabbit polyclonal antibody against 14-3-3 (Pan-14-3-3), mouse monoclonal antibody against tubulin and HA-Prob, goat anti-mouse IgG-HRP and goat anti-rabbit IgG-HRP were purchased from Santa Cruz Biotechnology (CA, USA).

Reagents Ly294002/worthmannin (PI3K inhibitor) were purchased from Cell Signaling Technology; rapamycin (mTOR inhibitor) was purchased from Calbiochemistry (USA); hydrogen peroxide and U0126 (MEK inhibitor) were obtained from Sigma-Aldrich (St Louis, MO, USA).

Cell culture and DNA transfection HEK293, A549, HeLa

and other cancer cells were provided by the Winship Cancer Institute (Atlanta, GA, USA) and maintained in Dulbecco's modified Eagle's medium (DMEM) or RPMI1640 (GIBCO Invitrogen, CA, USA) with 10% heat inactivated fetal bovine serum (FBS) and 5% CO₂ at 37 °C. The confluent cells were separated and trypsinized with 0.05% trypsin-ethylenediamine tetraacetic acid (EDTA) to produce single cells. They were then seeded at 1×10⁵ per cm² and allowed to form subcultures. Cells were transfected with plasmids using the FuGENE6 reagent (Roche Applied Science, USA) according to the manufacturer's instructions.

Western blot After the cells were transfected, harvested and lysed by in 1% NP-40 lysis buffer [0.15 mol/L NaCl, 0.01 mol/L N-2-hydroxyethylpiperazine-N'-2-ethanesulfonic acid (HEPES), 1% NP-40, 5 mmol/L sodium pyrophosphate, 5 mmol/L sodium fluoride, 2 mmol/L sodium orthovanadate, 10 mg/L aprotinin, 10 mg/L leupeptin, 1 mmol/L phenylmethylsulfonyl fluoride (PMSF)] at 4 °C for 20 min, cell extracts were clarified by centrifugation, prepared in SDS sample buffer, boiled for 5 min, and resolved using SDS-PAGE (12.5%) for Western blot. The enzyme-linked immunoblotting procedures were performed essentially as described previously^[10]. Corresponding secondary antibodies were used against each primary antibody: horseradish peroxidase-conjugated goat anti-mouse IgG was used for monoclonal antibodies and horseradish peroxidase-conjugated goat anti-rabbit IgG was used for polyclonal antibodies. Cross-reacting materials were visualized using ECL detection reagents.

Saito *et al* suggested that PRAS40 might play a critical role in the neuronal cell survival pathways mediated by NGF after cerebral ischemia^[9]. In order to test which cell survival signal cascade PRAS40 is involved in, we used three key kinase inhibitors (Worthmannin/Ly294002, U0126, rapamycin) and cell death or apoptosis induction factors (serum withdrawal, H₂O₂) to treat normal cell line HEK293 and cancer cell line A549 and HeLa. The expression of PRAS40, Akt, Raf and 14-3-3 were analyzed by Western blot.

Results

PRAS40 was mainly involved in the PI3K-Akt survival pathway After treatment with the PI3K inhibitor Worthmannin (2 μmol/L) or Ly294002 (25 μmol/L) in HEK293 for 2 h, Worthmannin and Ly294002 almost completely blocked phospho-PRAS40 and phospho-Akt activity, compared with total expression of PRAS40 and Akt. However, inhibition of Akt phosphorylation was also induced by serum withdrawal. Overexpression of constitutively active Akt (Akt-ΔpH) promoted the expression of phospho-PRAS40 in HEK293, compared with negative control Kinase mutation Akt (Akt-Km)

(Figure 1). Therefore, the main pathway that PRAS40 is involved in is the PI3K-Akt pathway, and Akt is the upstream kinase of PRAS40.

Figure 1. Western blot analysis for endogenous expression of PRAS40, Akt and Raf activity in HEK2993, which were treated with different drugs or overexpression of Akt ($n=3$). Overexpression of constitutively active Akt (Akt-ΔpH) and kinase mutation Akt (Akt-Km). HEK2993 were treated with serum withdrawal for 24 h, 1 mmol/L H₂O₂ for 20 min, 2 μmol/L Worthmannin for 2h, 25 μmol/L Ly294002 for 2 h, or 25 μmol/L U0126 for 20 min. Tubulin analysis is shown as an internal control.

MEK-ERK pathway is not necessary for PRAS40 activity The Raf-dependent activity of the MEK-ERK pathway promotes cell survival by targeting various death pathways^[11]. To test whether MEK-ERK is involved in the regulation of PRAS40/Akt activity, we used the MEK antagonist U0126 to treat HEK2993, A549 and HeLa cell lines. Western blot analysis revealed that U0126 had no effect on PRAS40 activity (Figure 1, 2), which implies that PRAS40 does not contribute to the MEK-ERK pathway.

ROS induced phosphorylation of Raf/Akt activity but not PRAS40 at low concentration ASK1 is known to play an important role in the apoptotic response induced by ROS, in particular H₂O₂. Goldmann *et al* showed that phosphorylation of ASK1 at Ser-976 by H₂O₂ stimulation was dose-dependent, and that treatment with 1 mmol/L H₂O₂ for 30 min could completely dephosphorylate ASK1 at Ser-967^[12]. In our experiment, the increase in phospho-Akt and phospho-Raf expression was induced by treatment with 1 mmol/L H₂O₂ for 20 min in HEK2993 and A549, but there was no change on PRAS40 activity (Figure 1, 2).

Figure 2. Western blot analysis for PRAS40, Akt and Raf expression in the A549 cell line. A549 cells were treated with serum withdrawal, 1 mmol/L H₂O₂ for 20 min, 2 μmol/L worthmannin for 2 h, 25 μmol/L Ly294002 for 2 h, 25 μmol/L U0126 for 20 min, or untreated HEK2993 as a control, the cells were than lysed, followed by Western blot. Tubulin analysis is also shown as an internal control.

Akt was not the only upstream kinase of PRAS40 Akt phosphorylation could be blocked by worthmannin, U0126 and serum withdrawal in A549 and HEK2993 cells; however, only worthmannin and Ly294002 inhibited phospho-PRAS40 activity (Figure 1, 2), Therefore, Akt was not the only upstream kinase of PRAS40. PRAS40 could also be activated by an Akt-independent mechanism. Western blot analysis showed that the phospho-PRAS40 and phospho-Akt activity in A549 cancer cells were stronger than in HEK2993 normal cell line (Figure 2).

Expression of PRAS40 and 14-3-3 was higher in HeLa than in HEK2993 cells The 14-3-3 protein is an anchor protein for some Akt substrates, and it is also a PRAS40 binding protein. Therefore, we investigated the relationship between PRAS40 and 14-3-3 expression in normal and cancer cells. HEK2993 and HeLa cells were treated with serum withdrawal, H₂O₂, rapamycin (mTOR inhibitor), worthmannin and U0126. Western blot demonstrated that, except for worthmannin, these treatments produced no significant difference with regard to PRAS40 activity in HEK2993 and HeLa cells. We found that HEK2993 was more sensitive: treatment with worthmannin only decreased the phosphorylation of PRAS40 in HeLa cells, but completely blocked PRAS40 phosphorylation in HEK2993 cells. We also found that phospho-PRAS40 and 14-3-3 were expressed more strongly in HeLa cells than in HEK2993 cells, and the total expression of PRAS40

was almost the same in the two cell lines (Figure 3).

Figure 3. Western blot analysis for endogenous expression of PRAS40 and 14-3-3 in HEK293 and HeLa cell lines. Cells were treated with serum withdrawal for 24 h, 1 mmol/L H₂O₂ for 20 min, 2 μmol/L worthmannin for 2 h, 25 μmol/L Ly29004 for 2 h, or 25 μmol/L U0126 for 20 min, followed by Western blot.

We also noticed that there was a difference in sensitivity to worthmannin between normal cells and cancer cells (HEK293 and HeLa) and among cancer cells (A549 and HeLa).

PRAS40 phosphorylation activity was stronger in cancer cells than in normal cells In order to determine if PRAS40 activity is different in normal cells, different types and different development phases of cancer cells, we used Western blot analysis to determine the expression of phospho-PRAS40, PRSA40, Akt and Raf *in vitro*. Because Akt and Raf are the key control factors in the cell survival pathway

(PI3K-Akt pathway and Raf-MEK pathway), we used them to find a expression relationship between PRSA40, Akt and Raf.

For a breast cancer model, we used the MCF10A/MCF7 cell lines. MCF10A is a normal breast cell line and MCF7 is a breast carcinoma line. For a lung cancer model, we used the BEAS/H1190/H1170 cell lines. BEAS cells are Human bronchial epithelial cells, immortalized with the hybrid adenovirus/simian virus 40. H1198 and H1170 are both derived from BEAS cells; H1198 is pre-malignant, because 1) it is sensitive to serum in that it was growth inhibited and terminally differentiates into squamous cells similar to normal HBE and BEAS-2B cells; 2) *in vitro* invasiveness was detected after exposure of BEAS cells to either phorbol myristate acetate or cigarette smoke condensate (CSC). H1170 is defined as a malignant cell line because it exhibits several features that are typical of invasive adenocarcinomas, including increased expression of epidermal growth factor receptor (EGFR) and transforming growth factor-α (TGFα)^[13]. We also investigated other non-small cell lung cancer (NSCLC) cell lines: H460, H1299, H596, H157, H552, H1944, H1792. The details of each cancer cell lines are given in Table 1.

We found that the expression levels of phospho-PRAS40 were higher in pre-malignant and malignant cells than in normal cell lines (eg MCF10A); Later phase cancer cells, such as H1198/H1170, showed stronger PRAS40 activity than pre-cancer cell lines (eg BEAS) except H460, H1299, H1944, in which there were no p53 mutations. We also noticed that there was no difference in the total expression of PRAS40 and Akt, whereas the total expression of Raf was different in different types of cancer cell lines, for example, there was no expression in BEAS and H1944, and weak expression in H460

Table 1. Cancer cell lines.

and H157 (Figure 4).

Discussion

The PI3K-Akt pathway has been implicated in the development of multiple human cancers^[14,15]. PI3K has an active role in oncogenic transformation. Akt, an important and probably essential downstream component of PI3K-mediated oncogenic signaling^[16], provides a critical cell survival signal for tumor progression by phosphorylating a number of proteins involved in cell cycle regulation and proapoptotic factors^[17]. Because only a subset of the cellular processes regulated by the PI3K-Akt pathway, are involved in tumorigenesis, the choice of drug targets must take into account the adverse effects resulting from the inhibition of other PI3K-Akt-dependent cellular processes. For example, the effects of insulin on metabolism are mediated through the PI3K-Akt pathway, so inhibitors of PI3K or Akt are therefore likely to perturb glucose homeostasis. It would be desirable, therefore, to target components of branches further downstream in the PI3K-Akt pathway^[18].

Our data provided evidence that the proline-rich Akt-substrate PRAS40 showed higher expression levels in cancer cells (eg A549 and HeLa) than in normal cells (eg HEK293). In our breast cancer model (MCF10A/MCF7) and lung cancer model (BEAS/H1198/H1170) we also found the same

result: PRAS40 was constitutively active in pre-malignant and malignant cancer cells (H1198/H1170 and MCF7), but only weakly expressed in normal cells (MCF10A and BEAS). In the NSCLC cell line, we found some interesting results: a higher expression level of phospho-PRAS40 was found in lung cancer cells with p53 mutations (eg H596, H157, H522 and H1792) than in other lung cancer cells. PRAS40 activity in lung cancer cells with only Ras mutations was almost the same as in the MCF10A normal cells (eg H460, H1299 and H1944). The strongest activity of PRAS40 was in H157, which had both the p53 mutation and the Ras mutation. The p53 mutation could be related to PRAS40 activity, but further studies are needed to clarify this relationship. These results suggested that PRAS40 activation is an early event during breast and lung carcinogenesis, PRAS40 could be used as a early detection marker in carcinogenesis.

We tested the effect of key kinase inhibitors on PRAS40 activity: PI3K inhibitors Worthmannin or Ly294002, MEK inhibitor Uo126 and mTOR inhibitor rapamycin. Only the PI3K inhibitors inhibited or decreased PRAS40 activity, therefore the PI3K-Akt survival pathway is the main pathway that PRAS40 is involved in; The Raf-MEK pathway probably doesn't contribute to PRAS40 activity. Also, PRAS40 is the substrate of Akt, but it can be activated by an Akt-independent mechanism, for example, serum withdrawal decreases Akt activity, but has no effect on PRAS40.

Figure 4. Western blot analysis for PRAS40, Akt and Raf in the cytosolic fraction in different types and different development phases of cancer cell lines. Tubulin was used as an internal control for the cytosolic fraction. *n*=3. Mean±SD.

14-3-3 is also a PRAS40 binding protein. A striking feature of the 14-3-3 proteins is their ability to bind a multitude of functionally diverse signaling proteins. This plethora of interacting proteins allows 14-3-3 to play important roles in a wide range of vital regulatory processes, such as mitogenic signal transduction, apoptotic cell death and cell cycle control^[19]. Our data show that the expression level of 14-3-3, like that of PRAS40, is higher in the HeLa cell line than in HEK293, but exactly how 14-3-3 helps PRAS40 in the PI3K-Akt pathway is unknown and warrants further investigation.

To our knowledge, our results provide the first evidence that PRAS40 is constitutively active in pre-malignant and malignant breast and lung cancer cell lines, and that PRAS40 is mainly involved in the PI3K-Akt survival pathway. However, PRAS40 can also be activated by Akt-independent mechanisms. We suggest that PRAS40 could be chosen as an early detection marker in carcinogenesis, but it is also a protein that can be targeted by anti-tumor drugs, that is a “druggable” protein.

Abstract

Aim: To study the distribution of [¹³¹I]-labeled anti-CEA MoAbs and its therapeutic effect on the human colonic cancer model in nude mice. **Methods:** A nude mice model of human colonic cancer was established. [¹³¹I]-labeled anti-CEA MoAbs were injected intravenously into mice. The distribution of the MoAbs was then determined and the effect of RIT on human colonic cancer was observed. **Results:** The [¹³¹I]-labeled anti-CEA MoAbs had a specific distribution after injection. Tumor/non-tumor ratios for [¹³¹I]-labeled anti-CEA MoAbs were 10–20 times higher than [¹³¹I]-labeled IgG 96 h after injection. Thirty days after injection, significant inhibition of the volume and weight of tumor was observed in the treated mice compared with the control. The tumor growth inhibition rate of 3.1 mCi/kg CEA MoAbs group (LS180, LS174T, SW1116) was 47.8%–64.0%. This was 69.6%–78.6% in the 6.25 mCi/kg CEA MoAbs group, and 81.8%–86.2% in the 12.5 mCi/kg [¹³¹I]-labeled anti-CEA MoAbs group. The plasma CEA level was also lower in treated mice. **Conclusion:** The results indicate that [¹³¹I]-labeled anti-CEA MoAbs can be effective in RIT on colonic cancers.

Introduction

Human colonic carcinoma is one of the most common cancers. The 5-year survival rate of patients with chemotherapy is zero. More than half of the patients with this tumor experience metastasis or reoccurrence after treatment. The liver is the most common metastasis foci^[1]. Radiolabeled MoAbs offer the prospect of a localized, highly targeted radiation treatment for these cancers. The range of action for radionuclides is defined predominantly by the nature of the particle and energy of the emission. One of the earliest radioisotopes to be coupled to antibodies for therapeutic purposes was Iodine 131 (¹³¹I). Its high-energy α particles can penetrate approximately three tumor cells, so it can be effective even when only deposited near the tumor cells and has minor toxicology to normal cells^[2]. There are several antibodies for a variety of human tumors that have been used to localize human tumors in xenograft models as well as in patients. Several of these antigens have served as targets for testing whether MoAbs as conjugates with radionuclides can act as selective therapeutic agents. For

example, antibodies directed against CEA, α -fetoprotein, ferritin, melanoma, and epithelial-specific antibody have been radiolabeled with ¹³¹I and used in the treatment of human cancers^[3,4].

In histological classifications, colon cancers are over 90% adenocarcinoma. CEA can be observed in either the cancer cell surface or patients blood serum in this type of tumor^[5]. Until recently, three products have been approved worldwide for the treatment of tumors in patients: Bexxar, Zevalin and ChTNT. The antibody used in this experiment is a new product awaiting permission for clinical trial, provided by Beijing Second Pharmaceutical Co, Ltd (Beijing). We undertook this study to determine the antitumor effect of the [¹³¹I]-labeled anti-CEA MoAbs and its distribution in nude mice bearing xenografts.

Materials and methods

Mice Athymic nude female BABL/c nu/nu mice, 4–6 weeks old, were obtained from the Institute of Laboratory Animals, Chinese Medical Science Academy. Mice were kept under

SPF conditions and were fed with a diet of sterile mice chow and water. Animals were given 10% Lugol's (5% Iodine and 10% KI) water from 2 d before the start of the experiment beginning until the experiment was completed.

Cell lines Three colonic carcinoma derivative cell lines were used: LS180 (ATCC No: CL-187) with a cell surface CEA expression rate of 81%; LS174T (ATCC No: CL-188) with a cell surface CEA expression rate of 66%; SW1116 (ATCC No: CCL-233) with a cell surface CEA expression rate of 2654 ng/10⁶ cells^[6]. LS180 was grown in DMEM/F-12 (Hyclone) medium, LS174T and SW1116 in MEM (Invitrogen Technologies, Inc, Carlsbad) essential medium, supplemented with 10% FBS, 2 mmol/L *L*-glutamine, 100 U/mL penicillin and 100 U/mL streptomycin.

[¹³¹I]-labeled anti-CEA MoAbs [¹³¹I]-labeled anti-CEA humanized chimeric recombinant MoAbs ([¹³¹I]-labeled-rch24) were supplied by Beijing SaiKe Pharmaceutical. Radioactivity was 5 mCi/mg. Radiochemical purity was more than 98.5%.

Establishing colon tumors in nude mice The three tumor cells were harvested and suspended in sterile PBS at a concentration of 25×10⁶ cells/mL. Cell viability was determined by trypan blue dye exclusion. Cells (5×10⁶) in sterile PBS were inoculated subcutaneously into the flank of nude mice^[7]. Tumors became apparent in 8–10 d.

Radiolabeled antibody treatment of tumors Mice bearing tumors were randomly divided into groups outlined in Table 1. Mice were administered i.v. in the tail vein. Antibodies were given 2 times with the interval of 10 d. The positive chemotherapy drug (5-FU) was given 2 weeks, 6 times a week.

Radiolabeled antibody effect The tumor growth rate was determined by measuring the length (a) and width (b) (mm) of each tumor using a caliper. Tumor volume=a×b²/2. The relative tumor volume (RTV), RTV=V_t/V₀. V₀ is the tumor vol-

ume when the experiment started. V_t is the measured tumor volume at different experiment time. The relative tumor growth rate was calculated by % of T/C=T_{RTV} (treated group)/C_{RTV} (control group)×100%. The effective criterion is T/C (%) above or equal to 60%. Tumor growth inhibition rate was calculated by S%=(mean weight of treated group-mean weight of control group)/(mean weight of control group)×100%^[8].

To evaluate peripheral plasma CEA levels, mice in each group were bled from the eye using heparinized capillary tubes. The plasma CEA level was determined by ELISA (Hoffmann-La Roche Ltd).

Radiolabeled antibody biodistribution Two animals from each group were bled, killed, and dissected at 24 h, 48 h, or 96 h after treatment, respectively. Tissues and organs were immediately dissected, rinsed with saline, blotted dry, and placed in plastic tubes and weighed. The radioactivity of each sample of blood, liver, heart, lung, kidney, and tumor tissue was measured using a well-type gamma counter. From the data, [¹³¹I]-labeled anti-CEA MoAbs biodistributions (%ID/g) were calculated: %ID/g=(tissue or organ cpm)/(total injected cpm)/(tissue or organ weight).

Statistical analysis Differences among the groups were tested using a one-way ANOVA. Results are given as mean±SD unless indicated otherwise.

Results

Distribution studies Tables 2, 3 and 4 summarize the tumor/non-tumor ratios found with either [¹³¹I]-labeled anti-CEA MoAbs or [¹³¹I]-labeled-IgG in mice with tumors. The results confirmed the tumor-specific targeting and retention of [¹³¹I]-labeled anti-CEA MoAbs in tumor tissues in contrast to [¹³¹I]-labeled-IgG. While the percentage of injected dose per gram (%ID/g) in the normal tissues continued to

Table 1. Animal group and treatment.

	Group name	Drug and dosage
A	Model control	Saline
B	Low dosage "nude" anti-CEA MoAbs control	156.2 μg/kg

decrease over time for both [¹³¹I]-labeled anti-CEA MoAbs and [¹³¹I]-labeled-IgG, the percentage of [¹³¹I]-labeled anti-CEA MoAbs increased in the tumor between d 1 and 4. This caused the T/NT ratios continue to increase in this period. T/NT ratios for [¹³¹I]-labeled anti-CEA MoAbs were 2–2.5 times higher than [¹³¹I]-labeled-IgG on d 1 and continued to increase so that T/NT ratios were 10–20 times higher than [¹³¹I]-labeled-IgG by day 4.

Inhibition of tumor growth The biological effect of [¹³¹I]-labeled anti-CEA MoAbs in mice bearing three tumor types was assessed. The tumor growth curves are summarized in Figures 1, 2 and 3. The volume of both [¹³¹I]-labeled anti-CEA MoAbs groups was less than the control group. As the administrative dosage increased, the tumor volume increment rate became slow or was not obvious.

The relative tumor growth rate of three tumor types was

**Figure 1.** The effect of [¹³¹I]-labeled anti-CEA MoAbs on tumor growth curve of LS180. *n*=7. Mean±SD.**Figure 2.** The effect of [¹³¹I]-labeled anti-CEA MoAbs on tumor growth curve of LS174T. *n*=7. Mean±SD.

calculated. The growth of tumors were inhibited significantly at the dosage groups of 3.1 mCi/kg, 6.25 mCi/kg, and 12.5 mCi/kg in nude mice bearing LS180 or LS174T (T/C%<60%).

**Figure 3.** The effect of [¹³¹I]-labeled anti-CEA MoAbs on tumor growth curve of SW1116. *n*=7. Mean±SD.

For SW1116, only the 6.25 mCi/kg and 12.5 mCi/kg dosages were effective. With the increasing dosage, more obvious inhibition of the tumor growth was observed.

Tumor weight and tumor growth inhibition rate (TIR) were calculated. The data is shown in Table 5. The tumor weights of three dosage [¹³¹I]-labeled anti-CEA MoAbs groups were all less than that of the control. With the increase in dosage, the tumor growth inhibition rate was more obvious. The tumor growth inhibition rate of the 3.1 mCi/kg CEA MoAbs group (LS180, LS174T, SW1116) was 47.8%–64.0%. This was 69.6%–78.6% in the 6.25 mCi/kg CEA MoAbs group, and 81.8%–86.2% in the 12.5 mCi/kg [¹³¹I]-labeled anti-CEA MoAbs group.

Plasma CEA level The plasma CEA level is shown in Table 6. Three groups' CEA levels were lower than the control group. This shows a relationship between the CEA level

and dosage. Compared with the “nude” antibody and [¹³¹I]-labeled-IgG, [¹³¹I]-labeled anti-CEA MoAbs was more effective in lowering the CEA level.

Discussion

A new approach in radiation therapy for cancer involves the use of radiolabeled MoAbs raised against tumor-associated antigens^[9]. The approach adopted in this study was the use of [¹³¹I]-labeled anti-CEA MoAbs at different doses to produce tumor growth inhibition in groups of athymic nude mice bearing human colon adenocarcinoma xenografts. The two principal objectives of this study were to examine the biodistribution and antitumor activity of the [¹³¹I]-labeled anti-CEA MoAbs.

Our data show that [¹³¹I]-labeled anti-CEA MoAbs at different dosages can significantly inhibit the growth rate of tumors (LS180, LS174T, SW1116) in a dose-dependent manner. We are encouraged by the finding that the destruction of tumors was apparent in approximately 50% of tumors in the animals given 3.1 mCi/kg of radiolabeled rch24 antibody. This suggests that we may be able to use a low dosage to produce slight toxicity.

With one exception, most therapeutic studies with [¹³¹I]-labeled antibodies in experimental animals have failed to inhibit completely the growth of well-established tumors^[10-12]. However, Cheung *et al* were able to ablate 0.5–2.0 cm³ neuroblastoma xenografts in nude mice with a single injection of 1 mCi of [¹³¹I]-labeled 3F8 MoAbs^[13]. Whether these results are a result of a property of the antibody, radiosensitivity of the tumor or some other factor, is unclear, but all current experimental evidence indicates that radiolabeled antibodies can be effectively used to inhibit tumor growth.

In this report we examined the distribution of [¹³¹I]-labeled anti-CEA MoAbs. Targeting was observed 24 h after the drug was administered. It was more obvious 96 h after administration. The blood and liver have the main uptake and the kidney has a low uptake. Toxicity was measured by the change in bodyweight and by determination of the total peripheral white blood cells (WBC). There was no significant difference in the bodyweight and peripheral WBC counts between the treated groups and model control (data not shown).

Because [¹³¹I] is not as effective radionuclide as other isotopes, other radioconjugates are being pursued^[14,15]. One of the best candidates for convenient coupling to antibodies is Yttrium-90 [⁹⁰Y]. But there are difficulties in the application. These include high uptake in normal tissue,

especially the liver, and problems associated with obtaining high specific activity [^{90}Y]. In addition, [^{90}Y] are known to concentrate in the bone^[16]. This may cause severe problems. Each radionuclide antibody tumor system has advantages and disadvantages, but [^{131}I] label is the most promising method at present.

Overall, the results of the present study indicate that tumor growth inhibition using radiolabeled antibodies can be confirmed. Using selectively localizing antitumor antibodies conjugated with suitably cytotoxic radionuclides may provide a useful new approach to the treatment of disseminated cancers.

Abstract

Aim: To investigate the anticancer effects and the molecular mechanisms of deguelin on human U937 leukemia cells, and to explore the underlying mechanism regulating nucleoporin 98 (Nup98) and nucleoporin 88 (Nup88) *in vitro*. **Methods:** The effects of deguelin on the growth of U937 cells were studied by MTT assay. The effect of deguelin on the cell cycle of U937 cells was studied by using a propidium iodide method. The localization of the nuclear pore complex proteins Nup98 and Nup88 was investigated by using immunofluorescence and immunoelectron microscopy. The expression of Nup98 and Nup88 in U937 cells was investigated by using flow cytometry and Western blot. **Results:** The proliferation of U937 cells was inhibited in the deguelin-treated group, with a 24-h IC₅₀ value of 21.61 nmol/L and a 36-h IC₅₀ value of 17.07 nmol/L. U937 cells treated with deguelin had reduced percentages of cells in the G₀/G₁ phase, whereas cells accumulated in the S and G₂/M phases. Nup88 and Nup98 were found on both the nuclear and cytoplasmic sides of the U937 cells by using immunofluorescence and immunoelectron microscopy. The expression of Nup98 was upregulated and that of the Nup88 protein was downregulated in U937 cells treated with deguelin. **Conclusion:** Deguelin is able to inhibit the proliferation of U937 cells by regulating the cell cycle such that cells are arrested at the S and G₂/M phases, so that the proportion of cells in the G₀/G₁ phase decreases. The antitumor effects of deguelin are related to upregulating the expression of Nup98 and downregulating the expression of Nup88 protein in U937 cells.

Introduction

The nuclear pore complex (NPC) comprises a central eight-fold symmetrical ring and spoke assembly, cytoplasmic fibers, and a filamentous nuclear basket^[1]. Molecular trafficking between the nucleus and the cytoplasm of interphase cells occurs via the NPC, which are large molecular assemblies that are embedded in the double-membraned nuclear envelope (NE)^[2]. The NPC provide peripheral channels of approximately 9 nm in diameter, which allow the diffusion of ions and small molecules, and mediate the selective transport of nuclear proteins, RNA, and ribonucleoprotein (RNP) particles by energy-dependent mechanisms. Several inter-

actions between individual FG (Phe-Gly) repeat-containing nucleoporins and transport factors have been reported, leading to the idea that such interactions may play a pivotal role in the docking, translocation, and/or termination steps of the transport process^[3]. Recent research has shown that Nup98 can dynamically associate with the nuclear pore and shuttle between the NPC and intranuclear bodies, and additionally between the nucleus and the cytoplasm in a transcription-dependent manner. The most common oncogenic fusions involve a segment of the gene encoding the FG-repeat domain of Nup98, which, in turn, becomes linked to genes of the homeobox family of transcription factors^[4]. Nucleoporins are involved in several types of acute myeloid

leukemia and a few other hematological malignancies, as well as rare cases of other tumors. Overexpression of nucleoporin 88 (Nup88) is associated with malignant tumors, whereas in most other cases the role of the Nup proteins in tumorigenesis stems from chromosomal rearrangements that results in oncogenic fusion proteins^[5]. Nup98 and Nup88 play important roles in nucleocytoplasmic shuttling activity in carcinoma cells.

Several natural compounds, in particular plant products and dietary constituents, have been found to have chemopreventive activities both *in vitro* and *in vivo*^[6]. Deguelin has been isolated from several plant species, including *Mundulea sericea* (Leguminosae). Recent experiments have verified that deguelin can lead the cell cycle to block and induce apoptosis; however, the mechanism by which it acts is not yet completely clear^[7-9]. In our previous studies, we found that deguelin was able to inhibit the proliferation of Burkitt's lymphoma cell line Daudi cells by regulating the cell cycle such that cells were arrested at the G₀/G₁ phase, and apoptosis was induced. Moreover, deguelin has low toxicity in human peripheral blood mononuclear cells (PBMC), but selectively induces the apoptosis of Daudi cells. Deguelin has antitumor effects because it downregulates the expression of cyclin D1 and the pRb protein^[10]. In the present study, we chose human myeloid precursor cell line U937 cells as the target. This study was designed to explore the mechanism by which deguelin regulates Nup98 and Nup88 in U937 cells. We focused on changes in the expression of Nup98 and Nup88, and analyzed the underlying mechanism by which molecular trafficking between the nucleus and the cytoplasm is carried out.

Materials and methods

Drugs and reagents Deguelin was purchased from the Sigma (St Louis, MO, USA) and was initially dissolved in dimethylsulfoxide (Me₂SO), and stored at -20 °C, and was then thawed before use. 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl-2H-tetrazolium bromide (MTT) was purchased from Janssen Chimica Company (New Brunswick, NJ, USA). RPMI-1640 medium, propidium iodide (PI), Hoechst 33258, and Me₂SO were purchased from Sigma. Fetal calf serum (FCS), anti-Nup88 and anti-Nup98 antibodies were purchased from Santa Cruz (California, USA). Fluorescein isothiocyanate (FITC)-labeled secondary antibodies were purchased from Zhongshan Company (Beijing, China). Chemiluminescence (ECL) reagent kits were purchased from Pierce Biotechnology (Rockford, IL, USA). The U937 cell line was obtained from the China Center for Typical Culture Collection (Wuhan,

China). All cell groups were grown in an RPMI-1640 culture medium containing 10% FCS and 2 mmol/L *L*-glutamine at 37 °C in a 5% CO₂ incubator.

MTT assay The antiproliferative effect of deguelin against different group cells was determined by using the MTT dye uptake method as described previously^[11]. Briefly, the final concentrations of deguelin were 0, 5, 10, 20, 40, 80, and 160 nmol/L. Each concentration of deguelin was added to 6 wells, respectively. The plates were in the presence or absence of the indicated test samples for 0 h, 12 h, 24 h, 36 h, 48 h, 60 h, and 72 h. Thereafter, 20 μL MTT solution [5 mg/mL in phosphate-buffered saline (PBS)] was added to each well. After incubation for 4 h at 37 °C, the supernatant was removed and 150 μL Me₂SO was added. When the blue crystals were dissolved, the optical density (OD) was detected in a microplate reader at a wavelength of 570 nm using a 96-well multiscanner autoreader (Biotech Instruments μQuant, NY, USA). The following formula was used: cell proliferation inhibited (%) = [1 - (OD of the experimental samples / OD of the control)] × 100% (*n* = 6. Mean ± SD).

DNA content and cell cycle analysis Untreated and treated cells were collected, after being cultured in the presence or absence of deguelin for the indicated time, rinsed with PBS, and suspended in 75% ethanol at -20 °C overnight. Fixed cells were centrifuged at 1200×*g* and washed twice with PBS. For detecting DNA content, cells were incubated in the dark with 50 mg/L PI and 0.1% RNase A in 400 μL PBS at room temperature for 30 min. Stained cells were analyzed using FACSsort (Becton Dickinson, New Jersey, USA). The percentage of cells was determined using the CellQuest software program (Becton Dickinson, New Jersey, USA). Cells were grouped as follows: the control group; and those treated with deguelin at concentrations of 5, 10, 20, 40, and 80 nmol/L for 24 h, respectively (*n* = 3).

Immunofluorescence with confocal microscopy For the immunofluorescence experiments, cells were fixed in 4% paraformaldehyde for 10 min and permeabilized with 0.2% Triton X-100 on ice for 10 min. Samples were blocked with 3% bovine serum albumin plus 0.02% Triton X-100 in PBS for 30 min, incubated with anti-Nup88 (1:200) and anti-Nup98 (1:100) antibodies overnight at 4 °C, and washed 4 times with 1.5% bovine serum albumin plus 0.02% Triton X-100 in PBS. FITC-labeled secondary antibodies diluted in PBS were applied for 30 min, and cells were washed 3 times every 15 min. Hoechst 33258 (1 μg/mL) and PI (50 mg/L) were included in the penultimate wash step to visualize the DNA. Coverslips were mounted with 3-amino propyltriethoxy silane (APES). Images were captured using a FV500 confocal microscope (Olympus, Tokyo, Japan).

Nup98 and Nup88 protein analysis using flow cytometry Flow cytometry was performed to determine the expression of Nup98 and Nup88 in cells by using primary antibodies to the peptide-binding domain. A total of 1×10^6 cells were collected, washed with PBS, and anti-Nup88 antibody (1:50) and anti-Nup98 antibody (1:50) were added, then the mixture was kept at 4 °C overnight. Mouse IgG1 (1:50) antibody was the isotype control group. FITC-labeled secondary antibody diluted in PBS (1:100) was applied for 30 min at room temperature. Stained cells were analyzed by using FACSsort. A total of 10 000 cells were analyzed from each cell group. The percentage of cells was determined using the CellQuest software program. Cells were grouped as follows: the negative group; the blank group; those treated with 10 nmol/L deguelin for 24 h; those treated with 20 nmol/L deguelin for 24 h.

Immunoelectron microscopy U937 cells on coverslips were fixed in 4% paraformaldehyde and 0.2% glutaraldehyde and washed with 0.1 mol/L phosphate buffer (PB; pH 7.4), followed with PB containing 0.1% sodium borohydride to inactivate residual aldehyde groups. The cells were permeabilized with PB containing 0.05% Triton X-100 for 20 min at room temperature and washed with PB. The blocking solution was PBS (pH 7.4) containing 4% normal goat serum (NGS). After blocking, cells were incubated with affinity-purified goat anti-Nup98 antibody (1:100) and affinity-purified mouse anti-Nup88 antibody (1:100) in PBS containing 1% NGS at 4 °C overnight. After 6 washes with PBS, cells were incubated with a biotinylated respondent secondary antibody (1:200) in PBS and 1% NGS. Immunoreactivity was visualized by incubation with 0.05% diamino-benzidine (DAB; Sigma) and 0.003% hydrogen peroxide in 0.05 mol/L Tris (pH 7) for 2 min. Cells were washed, postfixed with 2.5% glutaraldehyde in PB, washed again, fixed with 0.5% osmium tetroxide for 15 min, dehydrated, and embedded in Leica ultracut UCT (Wetzlar, Germany) for sectioning. Sections were observed on an electron microscope (Tecnai F12; FEI, Eindhoven, the Netherlands).

Western blot analysis Lysates were prepared from 1×10^7 cells by dissolving cell pellets in 100 μ L of lysis buffer [20 mmol/L Na_2PO_4 (pH 7.4), 150 mmol/L NaCl, 1% Triton X-100, 1% aprotinin, 1 mmol/L phenylmethylsulfonyl fluoride, 10 g/L leupeptin, 100 mmol/L NaF, and 2 mmol/L Na_3VO_4]. Lysates were centrifuged at $18\,000 \times g$ for 15 min and the supernatant was collected. Protein content was determined using a Bio-Rad protein assay (Bio-Rad laboratories, Hercules, CA, USA). Sodium dodecylsulfate-polyacrylamide gel electrophoresis (SDS-PAGE) sample buffer [10 mmol/L Tris-HCl (pH 6.8) 2% SDS, 10% glycerol, 0.2 mol/L 1,4-Dithiothreitol,

(DTT)] was added to the lysates. Lysates were heated to 100 °C for 5 min, and 100 μ g of protein was loaded into each well of a 10% SDS-PAGE gel. Resolved proteins were electrophoretically transferred to nitrocellulose and blocked with 5% non-fat milk. After incubation with the Nup88 antibody (at a 1:2500 dilution) and the Nup98 antibody (dilution 1:1000) at 4 °C overnight, the blots were washed 3 times with TBS/Tween [TBST; 25 mmol/L Tris-HCl (pH 8.0), 125 mmol/L NaCl, 0.1% Tween 20], and exposed to horseradish peroxidase (HRP)-conjugated corresponding secondary antibodies for 1 h, and finally detected by using ECL. Quantification of the bands was carried out using the Quantity One densitometric analysis software (Bio-Rad).

Statistical analysis All data are expressed as mean \pm SD, and analyzed using SPSS 10.0 for Windows 98. Linear *t*-test were used for statistical analyses, and $P < 0.05$ was considered to be statistically significant.

Results

Effects of deguelin on proliferation of U937 cells U937 cells treated with different concentrations of deguelin (0, 5, 10, 20, 40, 80, or 160 nmol/L) for 0 h, 12 h, 24 h, 36 h, 48 h, 60 h, and 72 h, respectively, resulted in the inhibition of cell proliferation in a dose- and time-dependent manner. The *OD* value of the deguelin-treated group was significantly lower than that of the untreated group (Figure 1). The IC_{50} value for 24 h for the U937 cells was 21.61 nmol/L, whereas the IC_{50} value for 36 h was 17.07 nmol/L.

Effects of deguelin on the cell cycle of human leukemia U937 cells Figure 2 illustrates the changes in DNA content

Figure 1. Antiproliferation effect of deguelin on U937 cells. U937 cells were treated with various concentrations of deguelin as indicated for 0, 12, 24, 36, 48, 60, or 72 h. Growth inhibition was determined using an MTT assay and is shown as an inhibitory rate. $n=6$. Mean \pm SD.

distribution in cells treated with 0, 5, 10, 20, 40, or 80 nmol/L deguelin for 24 h. As the treatment dose increased, the percentage of cells in S phase and G₂/M phase increased, whereas the number in the G₁/G₀ phase decreased accordingly. After treatment with 0, 5, 10, 20, 40, or 80 nmol/L deguelin for 24 h, the proportion of cells in the G₁/G₀ phase were 73.01%, 71.15%, 68.42%, 53.83%, 43.99%, and 22.82%, respectively; the proportion decreased in a dose-dependent manner. The proportion of S phase cells were 17.18%, 16.30%, 18.09%, 27.56%, 31.21%, and 46.85%, respectively; the proportion increased in a dose-dependent manner. The proportion in the G₂/M phase was 9.75%, 12.31%, 13.99%, 18.99%, 24.83%, and 27.79%, respectively. These results show that deguelin arrested the U937 cells at the S phase and the G₂/M phase, and decreased the number of cells in the G₁/G₀ phase *in vitro*.

Effects of deguelin on Nup98 and Nup88 in U937 cells

In this study, FITC-labeled secondary antibodies marked

Nup98 and Nup88 with green fluorescence, and Hoechst 33258 and PI labeled the DNA of U937 cells with blue and red fluorescence, respectively. In Figure 3, part Ad is merged parts Ab and Ac, and part Bd is merged parts Bb and Bc using confocal microscopy. We found that Nup98 had low fluorescence intensity, with an *OD* value of 50.23 in U937 cells, and the fluorescence was located both within the nucleoplasm and nucleus in intensely fluorescent dots. After treatment with 20 nmol/L deguelin for 24 h, Nup98 had greater fluorescence intensity, with an *OD* value of 252.28, and its distribution was mainly within the nucleus. In U937 cells, Nup88 had high fluorescence intensity, with an *OD* value of 215.16. After treatment with 20 nmol/L deguelin for 24 h, Nup88 had lower fluorescence intensity, with an *OD* value of 63.24. Compared with the control group, expression of Nup98 and Nup88 after treatment with 20 nmol/L deguelin for 24 h was significantly different ($P < 0.05$). When these

	Concentration/nmol·L ⁻¹					
	Control	5	10	20	40	80
G ₀ /G ₁ (%)	73.01	71.15	68.42	53.83	43.99	22.82
S (%)	17.18	16.30	18.09	27.56	31.21	46.85
G ₂ /M (%)	9.75	12.31	13.99	18.99	24.83	27.79

Figure 2. Distribution of cells in phases of the cell cycle caused by deguelin. Data were obtained using FACSsort (Becton Dickinson). A is the control; B, C, D, E, F are cells treated with 5, 10, 20, 40, or 80 nmol/L deguelin for 24 h, respectively ($n=3$).

Figure 3. Deguelin regulates the expression of Nup98 and Nup88 proteins in U937 cells. Images were obtained using an FV500 confocal microscope. In part A, a, b, c, and d correspond to the expression of Nup98 in control U937 cells, treatment with 20 nmol/L deguelin for 24 h, DNA staining with Hoechst 33258, and merged parts Ac and Ad, respectively. In part B, a, b, c, and d correspond to the expression of Nup88 in control U937 cells, treatment with 20 nmol/L deguelin for 24 h, DNA staining with PI, and merged parts Bc and Bd, respectively. Scale bars=20 μ m.

data are considered together, we conclude that Nup98 and Nup88 are regulated by deguelin, but the mechanism by which this occurs is not completely clear.

Nup98 and Nup88 protein analysis in U937 cells We used flow cytometry to measure the expression of Nup98 and Nup88 in untreated U937 cells, and in U937 cells treated with deguelin. In untreated cells, the average fluorescence intensity of Nup98 in the blank controls was 23.55. In cells treated with 10 nmol/L and 20 nmol/L deguelin for 24 h, the average fluorescence intensity of Nup98 was 189.58 and 249.32, respectively. The average fluorescence intensity of Nup88 in the blank controls was 53.92. When cells were treated with 10 nmol/L and 20 nmol/L deguelin for 24 h, the average fluorescence intensity of Nup88 was 11.12 and 10.03, respectively (Figure 4; $n=3$).

Location of Nup98 and Nup88 in U937 cells To visualize the subcellular location of Nup98 and Nup88, untreated and treated U937 cells were detected by using immunoelectron microscopy. In Figure 5, the nuclear pore proteins are indicated by arrowheads and are mainly located within the nuclear membrane. The density of the nuclear pore protein is based on DAB staining. In Figure 5, the electronic density of Nup98 in untreated cells is lower than that in deguelin-treated U937 cells. The electronic density of Nup88 in untreated cells was higher than that in deguelin-treated U937 cells.

Expression of Nup98 and Nup88 in U937 cells Our results reveal that deguelin can induce antiproliferation and apoptosis in U937 cells. However, it is unclear how U937 induces these effects. U937 cells treated with 10 nmol/L and 20 nmol/L of deguelin for 24 h were lysed and resolved using 10% SDS-PAGE, and then Western blot analysis was carried out using anti-Nup98 and anti-Nup88. Figure 6 shows the marked change in Nup98 and Nup88 expression following deguelin treatment. Deguelin is related to upregulating the expression of Nup98 and downregulating the expression of the Nup88 protein. This indicates that Nup98 and Nup88 are related to the deguelin-mediated nucleocytoplasm shuttling activity, which is related to cell proliferation and apoptosis.

Discussion

Deguelin, a natural plant extract, is commonly used as an insecticide in Africa, South America and China. Deguelin belongs to a class of compounds called rotenoids, which have chemopreventive activity^[6]. In fact, deguelin has already been shown to prevent skin and breast tumors in experimental models^[7]. It has chemopreventive activity, and acts by inhibiting NADH:ubiquinone oxidoreductase activity, and by regulating the cell cycle and inducing apoptosis^[7]. Chun *et al* found that deguelin inhibited the growth of and promoted apoptosis of premalignant and malignant cells^[8].

Figure 4. Deguelin regulates the expression of Nup98 and Nup88 protein in U937 cells. Data were obtained using FACSsort (Becton Dickinson). A and E are the negative controls (1); B and F are the Nup98 blank control and the Nup88 blank control (2); C and G are cells treated with 10 nmol/L deguelin for 24 h (3); D, H are cells treated with 20 nmol/L deguelin for 24 h (4). $n=3$. Mean \pm SD. ^b $P<0.05$ vs blank control.

In contrast, the compound had little effect on normal HBE cells. The drug's antineoplastic effects and specificity appeared to be due to its ability to inhibit phosphatidylinositol 3-kinase (PI3K)/Akt-mediated signaling pathways^[9,10]. Bortol *et al* found that deguelin enhanced the sensitivity of U937 leukemia cells and acute myeloid leukaemia (AML) blasts to chemotherapeutic drugs with an activated PI3K/Akt network^[10]. In the present experiment we found that deguelin suppressed the proliferation of U937 cells, and that deguelin may have potential as an anti-tumor medicine. After treatment with different doses of deguelin, U937 cells accumulated in the S and G₂/M phases, whereas the number of cells in the G₀/G₁ phase decreased in a dose-dependent manner. We also found that deguelin upregulated the expression of Nup98 and downregulated the expression of Nup88 in U937 cells. This suggests that changes in the ratio of Nup98 and Nup88 might contribute to the apoptosis-promoting activity of deguelin in these cells. The changes effected in nucleoporin in U937

cells by deguelin offer new possibilities for exploring the underlying anti-tumor mechanism of deguelin.

The various events of nuclear division, cytoplasmic division, cell growth, and cell maturation are repeated in each generation of cells^[12]. The periods of time and the sequence of events from one cell division to the next are collectively referred to as the cell cycle. Severe defects in chromosomes block progression through the cell cycle, and can lead to cell suicide or apoptosis^[13]. Deguelin plays an important pharmacological role by acting on different stages of the cell cycle in tumor cells. In this study, U937 cells were arrested mainly in the S and G₂/M phases by deguelin, whereas the proportion of cells in the G₀/G₁ phase gradually declined. After treatment with different doses of deguelin for 24 h, cells in the G₀/G₁ phase were earliest influenced, and the proportion of cells in this phase decreased gradually in a dose-dependent manner. At the same time, the proportion of cells in the S phase increased gradually, with treatment

Figure 5. Regulation of Nup98 and Nup88 in U937 cells by deguelin. Images were obtained by immunoelectron microscopy. Nuclear pore proteins are indicated by arrowheads and are mainly located within the nuclear membrane. A and B show the localization of Nup98 in the untreated and deguelin-treated U937 cells. C and D show the localization of Nup88 in the untreated and deguelin-treated U937 cells. B and C show images with higher electronic density than A and D. In all panels, orientation is with cytoplasm up, nucleus down. Bars=800 nm.

Figure 6. Effect of deguelin regulating the expression of Nup98 and Nup88 in U937 cells. Cells were treated with different concentrations of deguelin for 24 h, and Nup98 and Nup88 expression was evaluated by using Western blot analysis. 1, 2, and 3 are the control, 10 nmol/L deguelin and 20 nmol/L deguelin, respectively. $n=3$. Mean \pm SD. ^b $P<0.05$ compared with the control.

with 80 nmol/L deguelin resulting in the highest value. The proportion of cells in the G₂/M phase increased in a dose-dependent manner. These data show that deguelin usually regulates the G₁/S and G₂/M checkpoints in U937 cells. Cell cycle checkpoint controls at the G₁ to S transition and the G₂ to M transition prevent the cell cycle from progressing when DNA is damaged^[14]. That deguelin regulates the cell cycle checkpoints has been verified in other tumor cells. Chun *et al* found that after treatment with deguelin, the proportion of premalignant cells in the G₀/G₁ phase increased and the proportion of malignant HBE cells in the G₂/M phase increased from 9.6% to 40.2%^[8]. Bortul *et al* found that deguelin (10 nmol/L) induced S phase arrest by interfering with the progression to G₂/M^[10]. In our previous studies^[11], we found that deguelin was able to inhibit the proliferation of Daudi cells by regulating the cell cycle that arrests cells at the G₀/G₁ phase, and had no effect on the G₂/M phase. The mechanism by which deguelin causes these different cell cycle changes is not yet completely clear, but it is mainly related to the sensitivity of tumor cells to deguelin.

Transport between the nucleus and the cytoplasm occurs through NPC embedded in the nuclear envelope.

Nucleoporins are involved in several types of acute myeloid leukemia and a few other hematological malignancies, as well as rare cases of other tumors^[15]. An expanding subgroup of chromosomal translocation-generated oncoproteins in human acute myeloid leukemias (AML) involve the FG repeat-containing NPC proteins Nup98 and CAN/Nup214^[16]. The *Nup98* gene is found at the breakpoints of two distinct chromosomal rearrangements: t(7;11)(p15;p15) and inv(11)(p15;q22), which link Nup98 to the class I homeotic transcription factor HOXA9 and the putative RNA helicase DDX10, respectively. The most common oncogenic fusions involve a segment of the gene encoding the FG-repeat domain of Nup98, which, in turn, becomes linked to genes of the homeobox family of transcription factors. The Nup98-derived FG-repeat segments of the resulting oncogene interact with the transcriptional coactivators CBP (CREB binding protein) and P300, thereby leading to increased gene transcription^[17]. FG-repeat segments of two other nucleoporins, Nup153 and CAN/Nup214, can substitute for the Nup98 segment in the oncogenic fusion protein. When Nup98 is disrupted, it selectively impairs discrete protein import pathways, which supports the idea that transport of distinct import complexes through the NPC is mediated by specific subsets of nucleoporins. Because Nup98 plays a role in RNA export, its mobility suggests that Nup98 might associate with RNA close to its transcription site and then further accompany the processed RNA through the NPC into the cytoplasm^[18]. Using confocal microscopy, we found that Nup98 was present on both sides of the NPC in U937 cells, and was localized inside the nucleus. When cells were treated with 10 nmol/L and 20 nmol/L deguelin for 24 h, the average fluorescence intensity of Nup98 was 189.58 and 249.32. Deguelin can regulate the expression of Nup98, and this shows that deguelin participates in Nup98 leading nucleocytoplasmic traffic.

Nup88 is a NCP protein; the *Nup88* gene is localized at 17p13 and the Nup88 protein is involved in nuclear–cytoplasmic transport and cell growth^[19]. Overexpression of Nup88 has been found in human tumors of the stomach, colon, liver, pancreas, breast, lung, ovary, uterus, prostate and kidney^[20]. The Nup88 protein is also overexpressed in malignant tumor tissue relative to normal surrounding tissue. Recent studies have found that the Nup88 protein is enhanced in most metastatic melanomas relative to their corresponding primary tumors^[21]. Both RNA transcription and protein expression levels are higher in malignant tumor cell lines compared with non-transformed cells. The Nup88 protein is strongly expressed in the invasive margins of both primary and metastatic breast, endometrial and colorectal

carcinomas^[22]. Overexpression of Nup88 in malignant tumors is probably due to the enhanced nucleocytoplasmic transport required to meet the increased demand for proteins in the tumor cells. Nup88 is considered to be a tumor growth factor, and is a positive regulator in the cell cycle. For this reason, we devised the present study on Nup88 expression in U937 cells and studied the regulative effects of deguelin on Nup88. Our data support the idea that Nup88 might be involved in the tumor progression of U937 cells, and these findings show that deguelin participates in Nup88 leading nucleocytoplasmic traffic.

In summary, our results show that deguelin can inhibit U937 cell proliferation in a dose- and time-dependent manner, with an IC₅₀ value for 24 h of 21.61 nmol/L and an IC₅₀ value for 36 h of 17.07 nmol/L. Deguelin usually regulates the G₁/S and G₂/M checkpoints. In addition, deguelin causes upregulation of the expression of Nup98, and downregulation of the Nup88 protein in U937 cells. The reasons for this effect, and the mechanisms for this regulation of Nup98 and Nup88, and whether these mechanisms are linked to inhibited cell proliferation, are unknown, but our findings suggest that Nup98 and Nup88 may be involved in nucleocytoplasmic shuttling in carcinoma cells.

Introduction

Human immunodeficiency virus (HIV) infection is now a major public health problem for both developing and developed countries as it has dramatically increased the global burden of disease^[1–5]. Many efforts have been made on research and discovery of anti-HIV drugs; however, it still remains difficult to develop more effective, affordable, and less toxic anti-HIV drugs for the increasing number of HIV-infected patients^[6].

In recent years, more and more researchers have fixed

Abstract

Aim: To study the pharmacokinetics of sifuvirtide, a novel anti-human immunodeficiency virus (HIV) peptide, in monkeys and to compare the inhibitory concentrations of sifuvirtide and enfuvirtide on HIV-1-infected-cell fusion. **Methods:** Monkeys received 1.2 mg/kg iv or sc of sifuvirtide. An on-line solid-phase extraction procedure combined with liquid chromatography tandem mass spectrometry (SPE-LC/MS/MS) was established and applied to determine the concentration of sifuvirtide in monkey plasma. A four-¹²⁷I iodinated peptide was used as an internal standard. Fifty percent inhibitory concentration (IC₅₀) of sifuvirtide on cell fusion was determined by co-cultivation assay. **Results:** The assay was validated with good precision and accuracy. The calibration curve for sifuvirtide in plasma was linear over a range of 4.88–5000 µg/L, with correlation coefficients above 0.9923. After iv or sc administration, the observed peak concentrations of sifuvirtide were 10 626±2 886 µg/L and 528±191 µg/L, and the terminal elimination half-lives ($T_{1/2}$) were 6.3±0.9 h and 5.5±1.0 h, respectively. After sc, T_{max} was 0.25–2 h, and the absolute bioavailability was 49%±13%. Sifuvirtide inhibited the syncytium formation between HIV-1 chronically infected cells and uninfected cells with an IC₅₀ of 0.33 µg/L. **Conclusion:** An on-line SPE-LC/MS/MS approach was established for peptide pharmacokinetic studies. Sifuvirtide was rapidly absorbed subcutaneously into the blood circulation. The $T_{1/2}$ of sifuvirtide was remarkably longer than that of its analog, enfuvirtide, reported in healthy monkeys and it conferred a long-term plasma concentration level which was higher than its IC₅₀ *in vitro*.

their eyes on preventing the entry of HIV into a host cell at the step of gp41-mediated viral and cellular membrane fusion, which was denoted as fusion inhibitors^[7]. The Food and Drug Administration of the United States announced, in 2003, the accelerated approval of enfuvirtide, the first fusion inhibitor, for use in combination with other anti-HIV medications to treat advanced HIV-1 infection in adults and children aged 6 years and older^[8]. Enfuvirtide is administered twice daily by subcutaneous injection into the abdomen, the upper arm, or the anterior thigh for clinical therapeutics^[9].

Sifuvirtide is a linear 36-amino acid peptide with an amino

acid sequence of Acetyl-SWETWEREIEENYTRQIYRILEE-SQEQQDRNERDLLE. It is a novel antiviral peptide that has been classified as a fusion inhibitor. The profiles of absorption, distribution, metabolism and excretion of sifuvirtide have been characterized in rats and monkeys by using radioactive ^{125}I -sifuvirtide combined with radioactivity detection of samples derived from trichloroacetic acid precipitation or size-exclusion chromatography. For the requirement of clinical pharmacokinetic (PK) study, we have developed an advanced and validated on-line solid-phase extraction procedure combined with liquid chromatography tandem mass spectrometry (SPE-LC/MS/MS) approach for determination of non-labeled sifuvirtide in monkey plasma^[10].

In the present study, an *in vitro* fusion inhibitory experiment was used to determine the 50% inhibitory concentration (IC_{50}) of sifuvirtide. According to the results of 50 times lower IC_{50} value than enfuvirtide and the pharmacological experiments in monkeys, a relatively low clinical dosage was set at about 10 mg per adult, per day (while that of enfuvirtide was 180 mg^[9]). The PK profiles and bioavailability of sifuvirtide following single sc or iv dosage of 1.2 mg/kg in rhesus monkeys were investigated. The preliminary results indicated that sifuvirtide made a difference in antiviral activity *in vitro* and PK behaviors *in vivo* compared with enfuvirtide.

Materials and methods

Drugs and reagents The sifuvirtide standard was provided by FusoGen Pharmaceuticals (Tianjin, China). Enfuvirtide was obtained from Hoffmann-La Roche (Nutley, NJ, USA). RPMI-1640 complete culture medium containing 10% heat-inactivated newborn calf serum (NCS), *L*-glutamine 2 mmol/L, 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) 10 mmol/L, 2-mercaptoethanol 50 $\mu\text{mol/L}$, benzylpenicillin 100 kIU, and streptomycin sulfate 100 mg/mL were purchased from Gibco BRL (Gaithersburg, Maryland, USA). C8166 and HIV-1_{IIIB} chronically infected H9 cell lines (HIV-1_{IIIB}/H9) were kindly donated by the Medical Research Council of United Kingdom (AIDS Reagent Project) (London, UK). Drug-free monkey plasma was collected from 6 healthy rhesus monkeys of both sexes. Acetonitrile (ACN) and other solvents were of HPLC-grade and purchased from Fisher Scientific (Pittsburgh, PA, USA). A protease inhibitor cocktail tablet, Complete Mini (Roche Diagnostics, Mannheim, Germany), without ethylene diamine tetraacetic acid, was used to prevent peptide degradation in biological matrixes. Formic acid (FA), trifluoroacetic acid (TFA) and sodium iodine were obtained from Aldrich Chemical Co (Milwaukee, WI, USA). Highly purified water was produced

by a Millipore Simplicity 185 Unit (Millipore, Bedford, MA, USA). Mobile phase A (MP_A) was 0.1% (v/v) FA in water. Mobile phase B (MP_B) was 0.1% (v/v) FA in ACN.

Synthesis of the internal standard In this study, a novel strategy, non-radioactive iodination of peptides, was used to acquire an internal standard (IS) for the quantitative assay. Reaction of iodination was carried out mainly as described previously^[11]. To acquire the highest productivity of peptide iodide, the molar ratio of iodine-127 to peptide standard was at least 20:1. The reaction was carried out at room temperature for 10 min. The reaction mixture was then desalted and purified by a RP-HPLC method utilizing a Vydac analytical C18 column (5 μm , 300 \AA , 4.6 mm \times 150 mm; Vydac, Hesperia, CA, USA) with a gradient of MP_B increasing from 25% to 75% in 20 min, coupled with fraction collection equipment (Pharmacia, Uppsala, Sweden). The purified product was stored at 4 $^\circ\text{C}$ and identified using LC/MS/MS to be the goal peptide (purity >97%) with the 4- ^{127}I modifications ($^{127}\text{I}_4$ -sifuvirtide) on tyrosine (Y) residues [SWETWEREIEENY(I)₂TRQIY(I)₂RILEESQEQQDRNERDLLE].

Cell fusion assay The inhibition of sifuvirtide on cell-to-cell transmission of HIV-1 was determined by co-cultivation of uninfected normal cells and HIV-1_{IIIB} chronically infected cells, as described previously^[12]. Briefly, 3×10^4 C8166 cells were mixed with 1×10^4 HIV-1_{IIIB} chronically infected H9 cells in 96-well plates in the presence or absence of sifuvirtide at various concentrations. Enfuvirtide was used as the control. After co-culture for 24 h at 37 $^\circ\text{C}$ in 5% CO_2 , the number of syncytia was counted using an inverted microscope. The percentage inhibition of cell fusion was calculated by dividing the number of syncytial cells in compound-treated cultures by those in untreated cultures. The IC_{50} was determined from a dose-response curve.

On-line sample preparation The on-line extraction column was prepared using an empty stainless steel column (size of 50 mm length \times 2.1 mm ID, 2 μm frit; GEA Co, Beijing, China) packed with reversed-phase materials. The packing materials used for SPE were obtained from Agilent (Zorbax C18; spherical; average particle size 50 μm ; pore size 80 \AA ; Agilent; Waldbronn, Germany). Aliquots of calibrators or unknown samples (100 μL) were introduced onto the extraction column for on-line preparation and LC/MS/MS analysis. The plasma samples were diluted 5 times on-line, based on the design of an on-line splitter, between the sample loop and bypassing branch at a ratio of approximately 1:4. The whole process, including sample loading, extraction, separation and analysis, was carried out based on the column-switching program. Programmed events corresponding to valve switching were set up using the ChemStation (version

9.02) for Agilent 1100 series HPLC system and Xcalibur™ (version 1.4) for LTQ-MS system.

LC/MS/MS system The separation and detection section, the LC/MS/MS system used for the assay, was made up of the Agilent 1100 series HPLC system (including an on-line degasser), a 100-vial autosampler, a temperature control compartment equipped with a 6-port/2-position switching valve, and a binary solvent delivery pump, coupled to a novel linear ion trap mass spectrometer, LTQ-MS (ThermoFinnigan, San Jose, CA, USA), equipped with a new atmospheric pressure ionization interface, Ion MAX™. MS/MS detection was operated in electrospray ionization positive ion mode. The representative parameters of MS were as shown below. The spray voltage was 4.5 kV and the temperature of the heated capillary was set at 200 °C. The flow rates of sheath gas, auxiliary gas and sweep gas were set (in arbitrary units/min) to 20, 5, and 4, respectively. Other parameters were optimized automatically by infusing the analyte in water: ACN:formic acid (49.9:50:0.1, v:v) at a flow rate of 200 µL/min. Quantitation was carried out using selected reaction monitoring (SRM) of the transitions m/z 946.5→ m/z 871.8 for sifuvirtide and m/z 1047.2→ m/z 972.3 for the IS ($^{127}\text{I}_4$ -sifuvirtide).

Preparation of stock solutions and calibration standard samples Stock solutions of sifuvirtide were prepared at concentrations of 1.0 g/L in a $\text{MP}_A:\text{MP}_B$ (90:10, v/v) solvent system. The drug-free monkey blood was deactivated by spiking with protease inhibitor cocktail tablets (2 tablets/5 mL whole blood). All blood samples collected from monkey sources were transferred immediately into tubes coated with calculated heparin and an inhibitor mixture of protease and peptidase on the tube surface. After incubation on ice for 30 min, they were centrifuged at $1000\times g$ for 10 min. The supernatant of each was then harvested and stored at -80 °C until analysis. The deactivated drug-free plasma from monkey sources was used as the standard dilution for the calibration samples. Each calibration curve consisted of blank samples, zero samples (plasma sample processed with IS), and 6 non-zero samples, ranging from 4.88 µg/L to 5000 µg/L. Before the assay, the frozen samples were thawed at ambient temperature, vortex-mixed and centrifuged at $1000\times g$ for 5 min. For each of the calibrators or unknown samples, 100 µL aliquots of supernatant were added to vials containing 10 µL $^{127}\text{I}_4$ -sifuvirtide working solution (5 mg/L) and 10 µL 2.5% ammonia solution ($\text{NH}_3\cdot\text{H}_2\text{O}$, w/v). The vials were vortex-mixed for 30 s, placed immediately in the autosampler tray and kept at room temperature for assay.

Method validation The calibration curve and the concentration of unknown sample were acquired using LCQuan

software (version 2.0) from Thermo Finnigan. A weighting of $1/x^2$ (where x is the concentration of a given standard) was used for curve fit. The intra-day and inter-day accuracy and precision of the method presented here was investigated by analyzing plasma samples at the whole calibration concentration levels. The regression equation for the calibration curve was used to back-calculate the measured concentration for each standard, and the results were compared to the theoretical concentration to calculate the accuracy, expressed as a percentage of the theoretical value, for each standard measured.

Animal experiments Three rhesus monkeys (2 and 1, body weight of 4.1 ± 0.4 kg) were provided by the Animal Center of the Academy of Military Medical Sciences, with certificate number 97083. The monkeys were fasted overnight prior to dosing and given free access to food and water 48 h post dosage. A dosing solution (1.0 g/L) was formulated in saline. Sifuvirtide was administered iv to monkeys at 1.2 mg/kg via a side femoral venous catheter. Blood samples (0.5 mL) were collected from a femoral venous catheter on the opposite side at 0 min, 1 min, 5 min, 15 min, 30 min, 1 h, 2 h, 4 h, 6 h, 8 h, 12 h, 24 h, and 48 h after dosing. After a 7-d washout period, the monkeys were administered the same dosage and blood samples were harvested at 0 min, 10 min, 15 min, 30 min, 1 h, 2 h, 4 h, 5 h, 6 h, 8 h, 10 h, 12 h, 24 h, 36 h, and 48 h following dosing. All samples were harvested and treated in the same way as calibrators. A 200 µL aliquot from each time point was used for the assay. The plasma samples from 1 min, 5 min, and 15 min after iv were diluted 5 times because their concentrations were suspected to be higher than detectable levels. The curve according to plasma sifuvirtide concentration versus time after dosing was obtained using Origin software (Version 5.0; Microcal, Northampton, MA, USA).

Estimation of pharmacokinetic parameters Pharmacokinetic modeling and estimation of PK parameters were carried out using Excel XP software (Microsoft, Redmond, WA, USA). C_{max} and T_{max} were observed values. Other PK parameters, including area under the concentration-time curve (AUC), apparent plasma terminal elimination $T_{1/2}$, mean residence time (MRT), volume of distribution (V_d) and systematic clearance (CL), were calculated according to a previous description of the non-compartmental approach^[13]. In addition, the absolute bioavailability (F_{abs} , %) was calculated by the following equation: $[(\text{subcutaneous AUC}_{0-t}/\text{intravenous AUC}_{0-t})\times 100\%]$.

Results

Effects of sifuvirtide on HIV-1 entry Sifuvirtide inhib-

ited syncytium formation between HIV-1_{IIIB}/H9 cells and C8166 cells with an IC₅₀ value of 0.33 µg/L. The IC₅₀ of sifuvirtide was approximately 50-fold lower than that of enfuvirtide (16.8 µg/L). The results suggested that sifuvirtide was more effective than enfuvirtide in blocking HIV-1 entry into cells.

Mass spectrometry detection of sifuvirtide and ¹²⁷I₄-sifuvirtide The mass spectrum obtained by infusing 10 mg/L solution of sifuvirtide and ¹²⁷I₄-sifuvirtide in water:ACN (50:50, v/v) at a flow rate of 5 µL/min is shown in Figure 1A. A series of multiply charged ions, [M+5H]⁵⁺ at *m/z* 946.5, [M+4H]⁴⁺ at *m/z* 1182.9 and [M+3H]³⁺ at *m/z* 1576.6 for sifuvirtide, and [M+5H]⁵⁺ at *m/z* 1047.2, [M+4H]⁴⁺ at *m/z* 1308.7 and [M+3H]³⁺ at *m/z* 1744.6 for ¹²⁷I₄-sifuvirtide, were observed in positive ion mode. Deconvoluted mass obtained automatically utilizing the Bioworks software (Ver 3.1 SR1, Thermo-Electron, San Jose, CA, USA) showed a difference of 503.3 u (theoretical value was 503.6 u) between sifuvirtide and ¹²⁷I₄-sifuvirtide, which demonstrated that a complete iodination had been performed and reached the goal product. The most abundant ions of sifuvirtide and ¹²⁷I₄-sifuvirtide, [M+5H]⁵⁺ at *m/z* 946.5 and *m/z* 1047.2, respectively, were selected as parent ions for a collision-induced dissociation

experiment. The most intensive product ions for sifuvirtide and IS were observed at *m/z*=871.87 (b33⁵⁺) and *m/z*=972.6 (b33⁵⁺), respectively, both with optimized normalized collision energy of 28%^[10].

Method validation Under the established SPE-LC/MS/MS conditions, the typical retention times for sifuvirtide and IS were 7.68 min and 7.91 min, respectively, without interference from endogenous plasma components. The limit of detection was 1.22 µg/L, which represented 122 pg on-column injected analyte (approximately 26 fmol in drug-free monkey plasma, absolute recovery was seen as 100%), with a signal to noise (S/N) ratio above 10. The typical chromatograms of sifuvirtide in monkey plasma are illustrated in Figure 2. Calibration curves exhibited excellent linearity over a range of 4.88 µg/L to 5000 µg/L, and the typical regression equation for sifuvirtide was $y=0.01736-0.003759x$, with a r^2 of 0.9929. The intra-assay and inter-assay precision and accuracy values of the method were assessed using spiked plasma samples at whole calibration concentration levels for sifuvirtide, shown in Table 1. The mean accuracy of back-calculated concentrations of the standards compared with theoretical ones ranged from -5.36% to 4.61%. The inter-batch CV ranged from 2.9% to 8.8%, and the intra-batch CV

did not exceed 10.5%. The stability of sifuvirtide in solution and in plasma samples was also evaluated^[10]. The areas ratios of SRM chromatography spectra of sifuvirtide versus IS were investigated in stock solution kept in 4 °C for approximately 15 d and in plasma samples left at 15 °C over-

night (12 h–14 h). No real change in the area ratio of sifuvirtide to IS was observed.

Pharmacokinetics of sifuvirtide in rhesus monkeys The individual concentration–time profiles of sifuvirtide after iv or sc administration are shown in Figure 3. Plasma concen-

tration versus time data was analyzed and the PK parameters are shown in Table 2. After administration of sifuvirtide at doses of 1.2 mg/kg, the observed peak concentration was $10\ 626\pm 2886\ \mu\text{g}/\text{L}$ for iv at 1 min, and $528\pm 191\ \mu\text{g}/\text{L}$ for sc at 0.25 h–2 h, respectively. The terminal elimination plasma half-lives ($T_{1/2}$) after iv or sc were $6.3\pm 0.9\ \text{h}$ and $5.5\pm 1.0\ \text{h}$, respectively. Following sc administration, sifuvirtide was absorbed and distributed rapidly, and meanwhile was eliminated quickly in plasma. The bioavailability after sc injection was $49\%\pm 13\%$. In the present study, a remarkable inter-individual variability of the PK parameters, such as AUC, C_{max} , T_{max} , and F_{abs} , of sifuvirtide was observed in both iv and sc administration groups.

Discussion

In the present study, the advanced on-line SPE-LC/MS/MS system was validated as being reliable, reproducible, and highly sensitive for the quantitative determination of sifuvirtide in monkey plasma. The programmable column-switching technique was the core of this fully automatic system. Based on the design of on-line splitting injection

mode (OSIM), this novel on-line SPE system showed a powerful performance and capability for sample preparation of more than 300 raw plasma samples. The addition of pH adjusting solvent is very important for increasing the extraction efficiency of sifuvirtide. Coupled with LTQ-MS, a novel quadrupole ion trap mass spectrometer, a satisfactory sensi-

tive and good calibration curves yielding a wide linearity range over 3 orders of magnitude with correlation coefficients higher than 0.9923 were obtained.

Due to the lack of effective vaccines for the prevention of HIV infection, development of potent and affordable anti-HIV drugs is an international priority. As the first fusion inhibitor, enfuvirtide has been considered to have the disadvantages of short elimination half-life (2.5 h–3.5 h in the monkey via sc route^[14]), which is administered twice at a high cost. A lower IC₅₀ value of sifuvirtide for cell-to-cell transmission inhibition of HIV-1 *in vitro* was determined at around 0.33 µg/L, which is lower than that of enfuvirtide (16.8 µg/L). Therefore, a relatively lower dosage of sifuvirtide is recommended for future clinical treatments. In addition, the PK parameters of sifuvirtide after sc or iv dosing at 1.2 mg/kg weight in rhesus monkeys were below those of enfuvirtide (0.8 mg/kg in cynomolgus monkey^[14]). Although the average observed concentration of sifuvirtide at 10 min after dosing was lower than that of enfuvirtide, the plasma concentration profiles of sifuvirtide after iv or sc were sustained at a relatively higher ratio to the *in vitro* IC₅₀, even at 36 h after dosing. The terminal half-life of sifuvirtide was estimated as 5.5 h–7.2 h after iv and 4.6 h–6.6 h after sc administration, which is longer than that of enfuvirtide. A lower average AUC_{0-∞} and higher mean V_d and CL (normalized by animal weight) was found for sifuvirtide compared with enfuvirtide, which indicated that sifuvirtide was widely distributed to tissues or organs via circulation of blood and showed the benefit of antiviral action *in vivo*. These results were in accordance with those derived from tissue distribution experiments by radioactive determination (data not shown). The comparative MRT and F_{abs} (%) of two peptides were estimated in monkeys by the non-compartmental approach. All of these results derived from inhibitory activity *in vitro* and PK characteristics provide an important reference for future clinical studies.

Abstract

α_1 -Adrenergic receptors (AR) play an important role in the regulation of physiological responses mediated by norepinephrine and epinephrine, particularly in the cardiovascular system. The three cloned α_1 -AR subtypes (α_{1A} , α_{1B} , and α_{1D}) are G protein-coupled receptors that signal through the $G_{q/11}$ signaling pathway, each showing distinct pharmacological properties and tissue distributions. However, due to the lack of highly subtype-selective drugs, the functional roles of individual subtypes are still not clear. Development of new subtype-specific drugs will greatly facilitate the identification of the functions of each subtype. Conopeptide ρ -TIA has been found to be a new α_{1B} -AR selective antagonist with different modes of inhibition at α_1 -AR subtypes. In addition, recent studies using genetically engineered mice have shed some light on α_1 -AR functions *in vivo*, especially in the cardiovascular system and brain. Several proteins have been shown to interact directly with particular α_1 -AR, and may be important in regulating receptor function. Receptor heterodimerization has been shown to be important for cell surface expression, signaling and internalization. These new observations are likely to help elucidate the functional roles of individual α_1 -AR subtypes.

Introduction

α_1 -Adrenergic receptors (AR) are members of the G protein-coupled receptor (GPCR) superfamily that mediate physiological responses to norepinephrine (NE) and epinephrine (EPI). Pharmacological analysis and molecular cloning have shown that this receptor family has three subtypes (α_{1A} , α_{1B} , α_{1D}), which have different pharmacological properties and amino acid sequences^[1]. Four C-terminal splice variants of the α_{1A} -AR have been found^[2,3]. Stimulation of all three subtypes results in activation of the $G_{q/11}$ signaling pathway, involving activation of phospholipase C, generation of the second messengers inositol (1,4,5) triphosphate and diacylglycerol, and mobilization of intracellular calcium. Because of their clinical importance, research on α_1 -AR has been very active for many years. Several recent reviews have summarized this research from different perspectives^[4–9]. In this review, we mainly focus on recent developments in subtype-selective drugs, genetically engineered mouse models, interacting proteins, receptor dimerization, and factors controlling receptor cell surface expression.

 α_1 -AR subtype selective drugs

Although all three α_1 -AR subtypes activate the same $G_{q/11}$ protein signaling pathway, their different tissue distributions suggest that they play distinct functional roles. For example, the α_{1A} -AR subtype has been considered to be the dominant receptor subtype controlling benign prostatic hypertrophy, and is an important therapeutic target for treatment of this disease^[10]. Therefore, identifying the specific functions of individual α_1 -AR subtypes is of considerable therapeutic interest. Unfortunately, this has proved difficult because of difficulties in identifying highly subtype-selective drugs. Despite extensive efforts to address this difficulty, only a few subtype-selective compounds have been characterized^[11,12]. WB 4101^[13], (+)-niguldipine^[14], and 5-methylurapidil^[15] have been used extensively as α_{1A} -AR selective antagonists, and BMY7378^[16] is widely used to characterize α_{1D} -AR. However, there has been little progress in identifying α_{1B} -AR selective antagonists. Chlorethyclonidine was originally characterized as an α_{1B} -AR selective site-directed alkylating agent^[17]; however, it has limited selectivity in alkylating the cloned

subtypes, and is no longer widely used. Recently, a conopeptide isolated from a sea snail, known as ρ -TIA, was identified as a non-competitive α_{1B} -AR antagonist^[18,19] that may serve as an allosteric modulator, but acts as a competitive inhibitor at the other two subtypes^[20,21]. This suggests that ρ -TIA may interact with a novel antagonist binding site specific to the α_{1B} -AR and serve as a template for development of highly selective α_{1B} -AR drugs.

Genetically engineered mouse models

Since attempts to elucidate the function of individual receptor subtypes has been limited by a lack of agonists, antagonists, and antibodies with adequate subtype selectivity, recent studies using genetically engineered mice have shed some light on the contributions of each subtype to physiological responses to NE and EPI. In general, α_1 -AR knockout mice do not show overt physical abnormalities (Table 1). Studies in knockout mice lacking a single α_1 -AR subtype have shown that all three subtypes seem to be involved in the regulation of blood pressure. Consistent with previous pharmacological characterization *in vitro*, studies in α_{1D} -AR knockout mice have shown that the α_{1D} -AR subtype plays a dominant role in aortic contraction^[22]. Not only do genetically engineered mouse models help clear up some of the confusing cardiovascular effects mediated by individual subtypes, they also provide clues as to the functional roles of each subtype in the central nervous system, where these receptors are expressed in high concentrations, but their functions have been difficult to determine. The involvement of α_{1B} -AR in the regulation of locomotion has been suggested by pharmacological manipulation^[23]. Interestingly, knockout mice lacking α_{1B} -AR also showed decreased locomotor hyperactivity in response to psychostimulants and opiates, suggesting that targeting the α_{1B} -AR might be a useful therapeutic strategy in the treatment of drug abuse^[24]. In addition to the altered phenotypes being examined in the knockout or transgenic models, the underlying molecular mechanisms have been investigated using oligonucleotide microarrays. Alteration in the expression of NMDA receptors, GABA_A receptors, and apoptotic and calcium regulatory genes shown in transgenic murine brains may provide a potential molecular basis for neurodegeneration induced by overexpressed constitutively active α_{1B} -AR^[25]. Despite the new insights provided by the genetically engineered studies, some discrepancies have been noticed from different studies, such as the contribution of α_{1B} -AR in the aortic contractile response^[26,27]. In addition, some of the altered phenotypes observed in the α_{1B} -AR knockout model may result from compensatory effects of other receptor subtypes^[28]. Further

investigation using classic pharmacological approaches with highly subtype-selective drugs would be useful to facilitate future interpretations of those data.

Receptor interacting proteins

Recent studies have revealed that GPCR can interact with various cellular proteins in addition to the cognate G proteins, thereby expanding the receptor signaling network and establishing the distinct functional roles of closely-related receptor subtypes within the same family^[29,30]. Those interacting proteins include cytoplasmic and membrane proteins that may play regulatory roles in receptor pharmacology, trafficking and signaling^[31]. Although all three α_1 -AR subtypes couple to G_{q/11} signaling pathways, previous studies have shown that the three subtypes can activate distinct downstream signaling components in the G_{q/11} signaling pathway or couple to different signaling pathways^[1]. Because of their relatively long C-termini, which have the least sequence homology among the three subtypes, most attention has been focused on finding binding partners interacting with this region. In addition, the sequence diversity in the third intracellular loop (I3 loop) is also attractive due to its importance in coupling to G_{q/11}. In a similar manner, it has been shown that the three β -AR subtypes differentially associate with a variety of proteins other than G proteins^[32]. However, only a handful of interacting proteins have been identified for α_1 -AR subtypes (Table 2). A few of these interactions have been shown to have functional consequences, but most of them require further evaluation. For example, gC1qR and the mu2 subunit of the AP2 clathrin adaptor complex are involved in α_{1B} -AR trafficking or internalization. Although transglutaminase II (Gh) is the first non-G_{q/11} binding partner found to specifically associate with the α_{1B} - and α_{1D} -AR^[33,34], the α_1 -AR signaling pathways seem to remain intact in Gh knockout mice^[35]. Nevertheless, the search for novel binding partners should be considered as an alternative approach to study the molecular differences among the three α_1 -AR subtypes.

Receptor dimerization

Unlike the conventional view that GPCR are monomers, a growing body of evidence indicates that GPCR are able to form dimers or oligomers that are required for their pharmacology, function and/or cell surface expression. This concept has gained great appreciation for the class III GPCR subfamily, including the GABA_B receptors^[36,37] and taste receptors^[38]. However, the significance of class I GPCR dimerization has been under debate, due to difficulties in identify-

Table 1. Characteristics of α_1 -AR knockout or overexpression models.

	No alteration	Altered phenotype	Reference
Knockout			
α_{1A}	Cardiac output and renal function	Decreased basal blood pressure; reduced blood pressure response to α_1 agonist (PE)	[55]
α_{1B}	Basal blood pressure	Reduced blood pressure and aorta contractile responses to α_1 agonists (NE, PE)	[26]
	General physical mobility (motor activity)	Impaired modulation of memory consolidation and fear-motivated exploratory activity	[56]
		Increased exploratory response to novelty	[57]
		Attenuated hypertrophic growth after vascular injury	[58]
	Blood glucose, insulin and free fatty acid levels in the fed state	Elevated leptin concentration in the fed state; impaired glucose homeostasis and free fatty acid levels in the fasted state; increased parasympathetic activity	[59]
	Basal dopaminergic activity and basal locomotor behavior	Reduced locomotor responses induced by psychostimulants and opiates	[24]
α_{1D}	Cardiac function	Decreased basal blood pressure; decreased aorta contractile response to α_1 agonists (NE, PE)	[22]
	Renal function	Attenuated increase in blood pressure in salt-induced hypertension	[60]
	Mechanical and chemical nociception	Impaired thermal nociception	[61]
	Basal locomotor activity	Better motor coordination; impaired working memory or attention	[62]
	Hypertrophic growth after vascular injury		[58]
α_{1A}/α_{1B}	Heart sizes for female mice; basal blood pressure	Smaller heart sizes for male mice; decreased heart rate	[63]
		Increased myocardial contraction; decreased responsiveness to β -AR stimulation	[64]
Overexpression			
α_{1A}	Basal blood pressure	Enhanced cardiac contractility	[65]
α_{1B}	Basal blood pressure	Cardiac hypertrophy	[66]
		Granulovascular neurodegeneration; locomotor impairment and seizure	[67]
		Myocardial hypertrophy and hypertension	[68]
	Basal cardiac parameters (heart rate, blood pressure)	Decreased inotropic response to PE	[69]

NE, norepinephrine; PE, phenylephrine.

ing unique functional responses or pharmacological properties. Our group has shown that the three α_1 -AR subtypes can form homodimers and subtype-specific heterodimers with other AR^[39,40], which has been confirmed by data from other groups^[41,42]. Because truncation of either the amino or the carboxyl terminus of the receptor does not affect receptor dimerization^[40], the transmembrane domains or associated loops have been proposed to be involved in this interaction. Because the pharmacological analyses of the three cloned α_1 -AR subtypes in heterologous expression systems have not yet recapitulated all the receptor sub-

types previously defined by pharmacological criteria in tissues, such as the α_{1L} -AR^[43], the newly found receptor dimers have been hypothesized to perform atypical α_1 -AR pharmacology, which has been seen in the opioid receptor family^[44]. Although the homo- or heterodimers formed by α_{1A} -AR C-terminal splice variants have failed to show any novel pharmacology when studied with existing selective drugs^[45], it is still hard to conclude that the dimerization does not have effects on receptor pharmacology, because the available drugs are limited and the particular receptor dimers may yet be identified. On the other hand, the α_1 -AR sub-

Table 2. Receptor interacting proteins other than G_{q/11} with potential functional roles.

Subtypes	Interacting proteins	Interacting domains	Roles	Reference
α_{1A}	Regulator of G protein signaling 2 (RGS2)	I3 loop	Signaling	[70]
	Bone morphogenetic protein-1 (BMP-1)	C-terminus	Unknown	[71]

	Filamin C	C-terminus	Unknown	[73]

type-specific dimerization has been found to be important for receptor trafficking and signaling (summarized in the next section).

α_{1D} -AR cell surface expression

Theoretically, all three α_1 -AR subtypes should be present at the cell surface to be recognized by their highly hydrophilic natural ligands that are unlikely to cross cell membranes. However, when expressed in recombinant systems, the α_{1D} -AR subtype has been noted to show almost exclusively intracellular expression^[46,47], which makes them difficult to characterize. We recently reported that cell surface expression of the α_{1D} -AR could be specifically rescued by coexpression with the α_{1B} -AR but not the α_{1A} -AR^[48]. The coexpressed receptors seem to form a new receptor entity, and then modulate signaling and internalization of each receptor subtype in the complex. Recently, the β_2 -AR was also reported to be able to translocate α_{1D} -AR^[49]. Besides receptor dimerization, removal of the long amino-terminus of the α_{1D} -AR has also been shown to facilitate translocation of intracellular receptors to the cell surface^[50]. Subsequent studies using receptor N-terminal chimeras showed that this N-terminal domain might convey a retention signal to prevent receptor cell surface expression^[51]. Moreover, the density of α_{1D} -AR cell surface expression was shown to increase upon sequential truncation^[52].

Future directions

In the past few years, our knowledge of the functional

roles of the α_1 -AR family has been dramatically expanded using many different approaches. These findings generate several interesting directions that may be worth pursuing.

1 Further development of highly subtype-selective drugs, especially non-competitive antagonists: most of the specific α_1 -AR drugs available are competitive antagonists with moderate subtype-selectivity, which also target other cell surface proteins. Since the three α_1 -AR subtypes have relatively high homologies among the transmembrane domains that are believed to form the ligand binding pocket, designing new subtype-selective drugs that compete for this site has not been easy. However, development of noncompetitive drugs may be a good strategy because those drugs normally recognize a different site with less homology. This strategy has been successfully applied in designing highly subtype-selective drugs for other GPCR^[53].

2 Investigate the physiological relevance of receptor oligomers: the success of this direction requires the advance of two other research fields, characterization of subtype-specific antibodies and development of new α_1 -AR drugs. Although receptor dimerization and protein-protein interactions have been identified in recombinant systems, and their importance in advancing our knowledge of the α_1 -AR family has been recognized, their physiological relevance *in vivo* cannot be confirmed and exploited without subtype-specific antibodies. On the other hand, new subtype-selective drugs may recognize the discrete pharmacology of receptor dimers, therefore expanding the existing cloned α_1 -AR family and providing new therapeutic targets.

3 Characterize subtype-specific interacting proteins: the

growing list of GPCR interacting proteins has elucidated the molecular mechanisms of the differences among subtypes, which could lead to the development of drugs specifically targeting to such interactions. Because previous evidence suggests that the three α_1 -AR subtypes might couple to different signaling pathways, it is likely that more interacting proteins would be identified through the approaches that have been successfully used, such as yeast two-hybrid screenings and pull-down assays with fusion proteins.

4 Study the functional role of α_1 -AR in the central nervous system^[5]. In fact, almost all typical and atypical antipsychotics are α_1 -AR antagonists, although they show little, if any, subtype selectivity^[54]. In addition, tricyclic antidepressants are also α_1 -AR antagonists, and it is possible that this property may contribute to their therapeutic efficacy. We believe that studies focusing on those directions would further improve our understanding of the functional roles of each α_1 -AR subtype.

Over the past few years, the research team of Professor Ding-feng SU has reported an impressive quantity of experimental data about the relationships between blood pressure variability (BPV) and end-organ damage, a topic of obvious clinical interest. This research work has been summarized in a paper that appeared in the August issue of the renowned journal *Trends in Pharmacological Sciences*^[1]. The studies by Su *et al* provide convincing evidence that BPV is an independent cardiovascular risk factor that should be considered as such and, therefore, might become an important target for therapeutic interventions. Besides these exciting perspectives in the prevention and treatment of cardiovascular diseases, the work by Su *et al* raises a series of physiological questions.

In most, if not all, studies by Su *et al*, BPV is expressed as the standard deviation of beat-to-beat blood pressure data^[2,3]. The standard deviation provides an index of overall BPV that incorporates all kinds of blood pressure (BP) variations, from those resulting from the respiratory cycle to the slow trends occurring over the whole recording period. However, when studied in the frequency domain, it becomes apparent that the bulk of BPV is concentrated at low frequencies (<0.15 Hz in rats)^[4]. In other words, the standard deviation of BP essentially corresponds to the low-frequency component of the BP spectra. In the low frequency band, BPV is mainly the result of opposing interactions between hemodynamic perturbations and the corrective feedback provided by the arterial baroreceptor reflex. Hemodynamic studies in conscious rats with neonatal chemical sympathectomy^[5], chronic sinoaortic baroreceptor denervation^[6], and acute neurohumoral blockade^[7] have revealed that one major source

of slow (or low frequency) hemodynamic perturbations is the myogenic response of vascular smooth muscle cells that promotes vasoconstriction in regional circulations when BP increases and vasodilatation when BP decreases (Figure 1)^[8].

Figure 1. Schematic diagram of opposing interactions between myogenic and baroreflex responses. The relative importance of these responses determines the net change in vascular resistance (VR) in regional vascular beds as well as in the systemic circulation.

Taking into consideration this fundamental underlying physiology of BPV, the soundest pharmacological approach to reducing BPV is twofold. First, it would be beneficial to enhance baroreflex function. Chronic treatment with a non-antihypertensive dose of ketanserin increases baroreflex sensitivity while reducing BPV in spontaneously hypertensive rats^[3]. This effect was observed for the cardiac component of the baroreceptor reflex. It is not known whether this also applies to the sympathetic component. The second

approach would be to attenuate myogenic responses of regional circulations (Figure 1). This can be achieved with dihydropyridine L-type calcium channel blockers. Su *et al* have demonstrated that nitrendipine can selectively reduce BPV^[2]. However, this strategy is more problematic than the first because although the reduction of BPV afforded by calcium channel blockers would be beneficial in terms of arterial stiffness and left ventricular workload, this would probably be achieved at the cost of a reduced protection of capillary vascular beds (eg in the brain and kidney)^[9]. Further investigations including regional hemodynamic measurements are required to clarify this issue. Finally, it should be noted that the research team of Professor Su will soon make available a rat strain with a spontaneous deficiency in baroreflex function^[10], which will undoubtedly facilitate the study of pharmacological modulation of BPV.

Abstract

Aim: Anticonvulsant tolerance and dependence are two obstacles that restrict the clinical use of benzodiazepines (BDZ). In order to explore the mechanism of these two adverse reactions, changes of neuropeptide Y (NPY) and its receptors in the hippocampus of rat models, in relation to flurazepam (FZP, a member of BDZ) tolerance and dependence, were investigated. **Methods:** The mRNA of preproNPY and its receptors (Y_1 , Y_2 , and Y_5) in the hippocampus were determined by competitive RT-PCR, and the distribution of NPY in the hippocampus was examined by immunohistochemistry. **Results:** A decrease of preproNPY mRNA in the hippocampus was found in tolerant and dependent rats. The level of preproNPY mRNA in the hippocampus was reversely correlated with the degree of tolerance and dependence, measured by the threshold of pentylenetetrazol-induced seizures. Immunohistochemistry indicated a decrease of NPY-immunoreactive material in neurons of the CA1, CA3, and dentate gyrus regions of both tolerant and dependent rats. The mRNA of NPY receptors Y_1 and Y_5 decreased in tolerant rats but did not change in dependent rats. The mRNA of NPY receptor Y_2 increased in tolerant rats but decreased in dependent rats. **Conclusion:** A decrease of NPY in the hippocampus might be involved in anticonvulsant tolerance and dependence following long-term treatment with FZP. Y_1 , Y_2 , and Y_5 mRNA were also altered in FZP tolerance and dependence.

Introduction

Benzodiazepines (BDZ) have been widely used as anxiolytics, sedatives, hypnotics and anticonvulsants. BDZ produce therapeutic effects through the major fast inhibitory neurotransmitter receptors, GABA_A receptors, in the central nervous system (CNS). BDZ positively modulate GABA_A receptors by increasing their affinity for GABA and thus reduce the excitability of the post-synaptic neurons.

However, long-term treatment with BDZ often leads to drug tolerance, which means the therapeutic efficacy of the drug decreases after a period of continuous administration. Another consequence of chronic administration of BDZ is the dependence manifested by the aggravation of primary symptoms and/or appearance of abstinence syndrome, which includes anxiety, discomfort, diarrhea, loss of bodyweight and salivating when the drug is withdrawn abruptly. Toler-

ance and dependence are frequently encountered in the clinical use of BDZ as an antiepileptic medicine. The usefulness of BDZ is therefore limited, although most have primarily satisfactory antiepileptic efficacies.

Many studies have focused on the mechanisms of tolerance and dependence. Changes of binding capacity, gene expression and metabolism in neural receptors, including GABA_A receptors^[1], glutamatergic receptors^[2] and peripheral BDZ receptors^[3], were studied in the presence of tolerance and/or dependence. Other factors, such as nitric oxide^[4], calcium-channel blockers^[5], protein kinases^[6] and bicarbonate radicals^[7] were also studied. However, the exact mechanism underlying the tolerance and dependence is still unknown.

Neuropeptide Y (NPY) is a polypeptide of 36 amino acid residues widely distributed in the nervous system. This neuropeptide regulates various functions such as food

uptake, blood pressure, circadian rhythm and anxiety. It induces the central and peripheral activities through at least six receptor subtypes called Y_1 – Y_6 that belong to the G-protein coupled receptor superfamily^[8].

After a period of BDZ treatment, the glutamatergic system was modified, which was thought to be one of the reasons underlying tolerance to BDZ. For example, an increase of 206% in *in vitro* glutamate release was found in the hippocampus of animals chronically treated with lorazepam^[2]. Based on the facts that the NPYergic system inhibited the release of glutamate from presynaptic membranes^[9] and that NPY was reduced in the CNS in alcohol dependence^[10], the changes of NPYergic system in rat models with BDZ tolerance and dependence attracted our attention.

In this study, rat models of anticonvulsant tolerance and dependence to flurazepam (FZP, a BDZ) were established and the changes of NPY and its receptors (Y_1 , Y_2 , and Y_3) in the hippocampus of these rat models were investigated.

Materials and methods

The establishment of rat models and the experiments on rats in this study were approved by the Ethics Committee of Animal Experiments of Peking University First Hospital.

Rat model of FZP tolerance The rat model of FZP tolerance used was produced by following the method developed by Rosenberg^[11]. Male Sprague-Dawley rats (initial weight 180–200 g) were housed in a climate-controlled room with free access to standard rat food. FZP dissolved in a 0.02% saccharin solution was given as drinking water for 1 week (FZP-tolerant group, $n=10$). The concentration of FZP was adjusted to provide a daily dose of up to 100 mg/kg for the first 3 d and 150 mg/kg for the next 4 d. All rats consumed an average concentration of more than 100 mg/kg FZP daily. Control rats ($n=10$) were handled identically, but received 0.02% saccharin solution without the drug. After one week of treatment, rats were given saccharin solution as drinking water. Withdrawal signs such as overt ataxia, anxiety and hyperactivity were not found with this treatment^[12].

Tolerance to FZP was evaluated 12 h after discontinuation of FZP intake. Because of the very rapid biotransformation of FZP and its metabolites in rats, and the corresponding plasma half-life ($T_{1/2}$) of less than 2 h, the residual drug should not interfere with the anticonvulsant test at this time^[13]. FZP dissolved in distilled water (100 mg/mL) was diluted to 20 mg/mL with normal saline for injection. This solution was injected intraperitoneally to deliver a dose of 20 mg/kg. After 30 min, 20 mg/mL pentylenetetrazol (PTZ, freshly prepared in normal saline) was infused at a con-

stant rate of 0.5 mL/min into a tail vein, and clonus of the front legs was monitored to determine the threshold of PTZ-induced seizures. The onset time of clonus was recorded, and the PTZ threshold (mg/kg) was then derived. Rats in the control group were tested along with those in the FZP-tolerant group using the same procedure. FZP tolerance was determined by the decrease of PTZ threshold as compared with that of the control group. After the PTZ threshold test, the brain was removed and stored at -70°C immediately.

Rat model of FZP dependence We integrated the methods reported by Rosenberg^[11] and Izzo *et al*^[14] to establish a rat model of FZP dependence. The animals used, drug dosage, method of drug intake and PTZ threshold test were from the method reported by Rosenberg^[11], but the days of drug administration and the dependence test were from the method reported by Izzo *et al*^[14]. To obtain a more stable blood concentration, male Sprague-Dawley rats were given FZP dissolved in 0.02% saccharin solution as drinking water instead of an oral gavage of diazepam three times daily^[14]. For rats in the FZP-dependent group ($n=10$), FZP was given at increasing doses for 14 d: d 1–3, 100 mg·kg⁻¹·d⁻¹; d 4–7, 150 mg·kg⁻¹·d⁻¹; d 8–10, 200 mg·kg⁻¹·d⁻¹; and d 11–14, 250 mg·kg⁻¹·d⁻¹. Control rats ($n=10$) were handled identically, but received 0.02% saccharin solution without the drug as drinking water. The emergence of dependence was determined by the susceptibility to PTZ-induced seizures 96 h after termination of the 14-day FZP administration. PTZ (20 mg/mL) was infused at a constant rate of 0.5 mL/min into a tail vein and the infusion was discontinued at the first sign of tonic-clonic seizures. The PTZ threshold (mg/kg) was derived from the amount of PTZ used to induce tonic-clonic seizures. Rats in the control group were treated identically. FZP dependence was determined by the decrease of the PTZ threshold as compared with that of the control group. After the PTZ threshold test, the brain was removed and stored at -70°C immediately.

PTZ-induced seizures themselves may also cause changes in the brain. To minimize these interferences, we killed rats immediately after the PTZ threshold test and compared the changes in the hippocampus with those from the respective control rats.

Reagents FZP was purchased from DaZhong Pharmaceutical (Shanghai, China).

Rats were from the Animal Department of Peking University Health Sciences Center. PTZ and anti-NPY antibody were from Sigma-Aldrich (Saint Louis, MO, USA). RNase-free DNase I was obtained from Promega (Madison, WI, USA), Trizol reagent and M-MuLV reverse transcriptase were from Gibco (Rockville, MD, USA). The sequences of oligonucle-

otide primers for the amplification of preproNPY (386 bp), Y₁ (426 bp), Y₂ (393 bp), and Y₅ (391 bp) cDNA are: NPY-F, 5'-TATCCCTGCTCGTGTGTTTG-3'; NPY-R, 5'-AACGACAA-CAAGGAAATGG-3'; Y₁-F, 5'-ACTCTCACAGGCTGTC-TTAC-3'; Y₁-R, 5'-ATAGTCTCGTAGTCGTCGTC-3'; Y₂-F, 5'-AGCCTTCCACCCTGCTAAT-3'; Y₂-R, 5'-GTGAATGGCA-TCCAACCTCT-3'; Y₅-F, 5'-CACCTAGCCGTTCCAGAA-AA-3'; Y₅-R, 5'-GGGCTCTCAAGTCTGCTTTG-3'.

Measurement of preproNPY and NPY receptor cDNA in hippocampus by competitive RT-PCR Animals were decapitated immediately after the PTZ threshold test. The hippocampus was quickly removed and stored at -70 °C until use. Brain tissue was homogenized in Trizol reagent in a pre-cooled mortar following manufacturer's protocol^[15]. Total RNA samples were treated with RNase-free DNase I to eliminate genomic DNA contamination before reverse transcription. Total RNA of 3 µg was reversely transcribed into cDNA using oligo d (T)₁₅ as the primer and M-MuLV reverse transcriptase.

The internal competitive standards for the measurement of preproNPY, Y₁, Y₂, and Y₅ cDNA were made using PCR. These DNA fragments had the same sequences as their respective PCR products, except that approximately 80 bp at the downstream site of the forward primers were deleted. Quantitative PCR was performed in a 0.2 mL tube containing brain cDNA 1 µL, internal competitive standard 1 µL, 5 µmol/L each primer mixture 1 µL, 2.5 mmol/L each dNTP mixture 1 µL, 1.5 mmol/L MgCl₂, 10×PCR buffer 2.5 µL, and 1.25 unit *Taq* DNA polymerase, in a total volume of 25 µL. PCR was run at 94 °C 30 s, 62 °C 30 s, and 72 °C 40 s (93 °C 1 min, 65 °C 2 min and 72 °C 2 min for the amplification of Y₁ cDNA) for 35 cycles. PCR products were separated in a 1.5% agarose gel and stained using ethidium bromide. The ratio of the optical density of the two DNA bands under UV light was measured by a gel image analysis system. A standard curve of the ratio was drawn using the same conditions as described above, except that brain cDNA was changed to a serial dilution of the purified PCR product. The relative amount of the cDNA in a sample was then obtained from the standard curve.

Immunohistochemistry of NPY in hippocampus After anesthesia, rats were perfused through the left ventricle with 0.9% sodium chloride followed by 4% paraformaldehyde in phosphate buffer solution for approximately 30 min. The removed brain was sequentially soaked in 4% paraformaldehyde in phosphate buffer solution for 24 h and 30% sucrose at 4 °C for 72 h. Frozen sections of 8-mm thickness in a coronal plane were used for immunohistochemistry. One brain section from the treated rat and one from the respective control rat were placed on one slide and processed

together. After treatment with 0.3% H₂O₂ to block the endogenous peroxidase, sections were incubated with 1:50 polyclonal anti-NPY antibody overnight at 4 °C. The secondary antibody was biotinylated anti-rabbit IgG antibody (Vector, Burlingame, CA, USA). Signals were visualized by horseradish peroxidase conjugated avidin and diaminobenzidine. The relative density of NPY-immunoreactive material in neurons in the pyramidal cell layer of CA1, CA3 region and granular cell layer of the dentate gyrus region was measured in a defined area by a densitometer.

Statistical analysis Data were expressed as mean±SD. Paired *t*-tests were used to evaluate the significance of intergroup differences. *P*<0.05 was considered as significant.

Results

Rat models of FZP tolerance and dependence

FZP-tolerant model The rat model of FZP tolerance was evaluated by studying the FZP anticonvulsant efficacy after discontinuing the 7-d FZP treatment for 12 h when the brain FZP should have been metabolized^[13]. Anticonvulsive efficacy of a single dose of 20 mg/kg FZP was measured by studying the threshold of PTZ-induced seizures after 30 min. In comparison with the control group, the average PTZ threshold decreased by more than 3 times in the FZP-tolerant group, indicating the successful establishment of an FZP-tolerant model in rats (Table 1).

FZP-dependent model In contrast to the evaluation of FZP tolerance, FZP dependence was estimated by studying the PTZ threshold after discontinuing the 14-d FZP treatment for 96 h when maximum withdrawal signs were expected to occur^[14]. As shown in Table 1, the average PTZ threshold in the FZP-dependent model was lower than that in its control group by more than 2 times, indicating that the FZP-dependent model is acceptable for further study (Table 1).

Changes of preproNPY cDNA in hippocampus of FZP-tolerant and-dependent rats In the hippocampus, preproNPY

Table 1. Extent of FZP tolerance and dependence evaluated by the threshold of PTZ-induced seizures. *n*=10. ^b*P*<0.05 vs the respective control groups.

Group	Threshold of PTZ-induced seizures/mg·kg ⁻¹
FZP-tolerant	22.47±10.24 ^b
Control	71.74±23.68
FZP-dependent	5.69±1.77 ^b
Control	15.91±2.45

cDNA was dramatically reduced both in FZP-tolerant and -dependent groups, as compared with that of the respective control groups (Table 2, Figure 1).

Table 2. Relative amount of preproNPY, Y₁, Y₂, and Y₅ cDNA in hippocampus of rats with anticonvulsant tolerance and dependence to FZP. *n*=8. Mean±SD. ^b*P*<0.05 vs those of the respective control groups.

Group	PreproNPY	Y ₁	Y ₂	Y ₅
FZP-tolerant	0.09±0.01 ^b	0.99±0.13 ^b	16.32±6.26 ^b	0.64±0.16 ^b
Control	5.37±1.06	3.67±1.10	3.11±1.13	3.75±1.33

Control	5.16±1.70	3.61±1.79	3.33±1.37	3.51±0.86

NPY-immunoreactive cells were found in many brain regions, with the hippocampus showing the most remarkable changes in FZP tolerant and dependent rats. In the hippocampus of control animals, NPY-immunoreactive cells were mostly located in CA1, CA3, and dentate gyrus regions. NPY-immunoreactive cells were large multipolar or fusiform neurons, and NPY positive material was found in their cytoplasm and processes (Figure 2A, 2B). In the hippocampus from FZP-tolerant and FZP-dependent rats, NPY-immunoreactive material in the cytoplasm and processes was significantly reduced as compared with that in the same regions of the respective control rats (Figure 2C, 2D, Table 3).

Figure 1. Representative electrophoresis profiles of competitive PCR for the quantification of preproNPY, Y₁, Y₂, and Y₅ cDNA in the hippocampus of FZP-tolerant model (A) and FZP-dependent model (B). The density ratio of the upper/lower bands in a lane is positively proportional to the amount of the cDNA in the hippocampus. Lane T, samples from FZP-treated rats; lane C, samples from control rats.

Changes of NPY receptor cDNA in hippocampus of FZP-tolerant and -dependent rats Y₁ and Y₅ cDNA were decreased in the tolerant group as compared with those of the respective control group. However, no quantitative changes of these two cDNA were found in the FZP-dependent group. In contrast, Y₂ cDNA was increased significantly in the FZP-tolerant group, but was decreased in the FZP-dependent

Figure 2. NPY-immunoreactive cells in pyramidal cell layers of CA1 region detected by immunohistochemistry (counterstained by hematoxylin ×400). (A), A sample from a control rat for FZP-tolerant group and (B), a sample from a control rat for FZP-dependent group show plenty of NPY-immunoreactive material (brown-red colour) in the cytoplasm of most neurons as well as neurofibers in white matter. (C), A sample from an FZP-tolerant rat and (D), a sample from an FZP-dependent rat show reduced NPY-immunoreactive material in the neuronal cytoplasm and neurofibers.

Table 3. Relative density of NPY-immunoreactive material in neurons of the hippocampus (area of 0.05 mm²). *n*=6. ^b*P*<0.05 vs control groups.

Group	CA1	CA3	Dentate gyrus

Control	209.47±11.18	221.84±14.05	218.58±13.94
FZP-dependent	75.33±9.86 ^b	71.65±7.25 ^b	72.97±6.34 ^b
Control	202.51±10.09	214.59±13.28	227.76±11.62

group, as compared with that of the respective controls (Table 2, Figure 1).

Correlations between the threshold of PTZ-induced seizures and the levels of preproNPY, Y₁, Y₂, and Y₅ cDNA in hippocampus of FZP-tolerant and -dependent rats The correlations were examined to show whether changes of NPY and its receptors in the hippocampus were related to the pathogenesis of FZP tolerance and dependence. The PTZ threshold was positively correlated with the level of preproNPY cDNA in the hippocampus both in FZP-tolerant and -dependent groups (Figure 3A, 3B). In other words, the

lower the expression of NPY in the hippocampus, the higher degree of tolerance and dependence the rat showed. The PTZ threshold was negatively correlated with the level of hippocampal Y₂ cDNA in the FZP-tolerant group and was positively correlated with the level of hippocampal Y₂ cDNA in the FZP-dependent group (Figure 3C, 3D). No correlation between the PTZ threshold and the changes of Y₁ and Y₅ cDNA were found (data not shown).

Discussion

Pharmacologically, BDZ produce their sedative, anxiolytic and antiepileptic activities through a modulation action on GABA_A receptors. However, tolerance to BDZ and dependence on BDZ are the two major adverse reactions in clinical practice. Neuronal hyperexcitability may be the common basis for the tolerance and dependence, although they may have different manifestations.

Hippocampus is implicated in the generation and modulation of seizure activities, and plays a central role in controlling excitability of the CNS^[16]. In the present study, the hippocampus was separated to investigate the changes of NPY and its receptors (Y₁, Y₂, and Y₅) in rat models with

Figure 3. Correlations between the PTZ threshold and the level of hippocampal preproNPY cDNA: (A), in the FZP-tolerant group ($r=0.9855$, $P<0.01$) and (B), in the FZP-dependent group ($r=0.9295$, $P<0.01$). Correlation between the PTZ threshold and the level of hippocampal Y₂ cDNA: (C), in FZP-tolerant group ($r=-0.8986$, $P<0.01$) and (D), in FZP-dependent group ($r=0.9414$, $P<0.01$).

anticonvulsant tolerance and dependence to FZP.

We found that preproNPY cDNA in the hippocampus was significantly decreased in both the FZP-tolerant and FZP-dependent groups. Immunohistochemistry also showed the reduction of NPY-immunoreactive material in the neuronal cytoplasm and neurofibers of CA1, CA3, and dentate gyrus regions. Y_1 and Y_5 receptor cDNA were decreased in the tolerant group but were not changed in the dependent group. Y_2 receptor cDNA was increased in the tolerant group but was decreased in the dependent group.

To date, only one paper has been published on the relationship between the NPYergic system and drug tolerance and/or dependence^[17]: contingent tolerance to carbamazepine after repeatedly giving the drug may be associated with the down-regulation of NPY. However, no data about the changes of the NPYergic system following long-term treatment of BDZ have been found in the published literature.

The level of preproNPY cDNA in the hippocampus reversely relating to the degree of tolerance and dependence may suggest that the changes of preproNPY cDNA are involved in the pathogenesis of FZP tolerance and dependence. NPY, one of the most abundant and widely distributed neuropeptides in the central and peripheral nervous systems, acts as an endogenous modulator to reduce seizure activities. In the hippocampus, the inhibition of epileptiform discharges after NPY treatment was attributed to the decrease of glutamate released from the presynaptic nerve terminals through blocking of the G-protein dependent calcium channel^[18]. Therefore, the decrease of cellular NPY we found may result in neuronal hyperexcitability that is the fundamental pathological state of BDZ tolerance and dependence.

Six subtypes of NPY receptors, Y_1 – Y_6 , have been identified. Their pharmacological characteristics are very similar, although the identity of amino acid sequences is as low as 30% among these receptor subtypes^[19]. Of the six receptor subtypes, Y_1 , Y_2 , and Y_5 are the major functional receptors and are expressed abundantly. In rodents, changes in the Y_1 receptor and its mRNA in the CNS can be induced by various stimuli, suggesting the multiple functions of the Y_1 receptor^[20]. The Y_2 receptor demonstrates a predominant role in modulation of seizure activity^[21]. The Y_5 receptor may also be involved in the modulation of anticonvulsant activity in rodents^[22,23]. Theoretically, drug tolerance and dependence are caused by the imbalance of excitation over inhibition in the brain, and NPY receptors would decrease in association with the decrease of NPY. The different changes to NPY receptors between the FZP-tolerant and FZP-dependent group and the increase of Y_2 in FZP-tolerant rats in this study can not be satisfactorily explained because of the in-

sufficient and conflicting data regarding Y_1 , Y_2 , and Y_5 receptors in the regulation of neuronal excitability at the present time. More experiments should be performed on the distribution and ligand binding capacity of the three subtype receptors in FZP tolerance and dependence.

Our preliminary results suggest that the decrease of NPY in the hippocampus plays an important role in the generation of anticonvulsant tolerance and dependence following long-term FZP treatment. The NPYergic system may be a new target for the comprehension of these adverse effects of BDZ.

Abstract

Aim: To investigate whether histidine can enhance the anticonvulsant efficacy of carbamazepine (CBZ) and simultaneously improve the spatial memory impairment induced by transauricular kindled seizures in Sprague-Dawley rats. **Methods:** Chronic transauricular kindling was induced by repeated application of initially subconvulsive electrical stimulation through ear-clip electrodes once every 24 h until the occurrence of 3 consecutive clonic-tonic seizures. An 8-arm radial maze (4 arms baited) was used to measure spatial memory, and histamine and γ -aminobutyric acid levels were measured by high performance liquid chromatography (HPLC). **Results:** Chronic transauricular kindling produced a significant impairment of spatial memory and a marked decrease in histamine content in the hypothalamus, the brainstem, and the hippocampus. Injection of histidine (1000 mg/kg or 1500 mg/kg, ip) significantly inhibited transauricular kindled seizures. Injection of histidine at lower doses (200 mg/kg or 500 mg/kg, ip) had no appreciable anticonvulsant effect when administered alone, whereas it significantly potentiated the protective effects of CBZ against kindled seizures. CBZ had no ameliorative effect on memory deficit, but, in contrast, histidine (200 mg/kg or 500 mg/kg, ip) alone or co-administered with CBZ significantly ameliorated the memory deficits induced by the seizures. **Conclusion:** Chronic transauricular kindling is a very useful animal model for evaluating memory deficits associated with epilepsy, and histidine has both a potentiate effect on the anticonvulsant efficacy of CBZ and an ameliorative effect on the spatial memory deficits induced in this model. Histidine at a specific dosage range might serve as a beneficial adjuvant for the clinical treatment of epilepsy, especially when accompanied by impaired spatial memory.

Introduction

Epilepsy is frequently accompanied by impairments in various cognitive functions. More than 45% of epileptics have psychological or social problems with behavioral manifestations and are completely or partly disabled^[1]. Although the causes of cognitive impairment in patients with epilepsy have not yet been completely elucidated, 3 factors are proposed: the underlying etiology of the epilepsy, the effects of seizures themselves, and the side-effects of antiepileptic drugs (AEDs) at therapeutic doses^[2]. There is a need for drugs or adjuvants that can simultaneously sup-

press seizures and ameliorate the concomitant cognitive impairment.

Brain histamine levels might play an important role in the regulation of seizure susceptibility. Injection of histidine ip, a precursor of histamine, and metoprine, a histamine N-methyltransferase inhibitor, or icv injection of histamine, inhibited seizures induced by pentylenetetrazol, maximal electroshock (MES) or amygdaloid kindling in mice or rats^[3-6], whereas α -fluoromethylhistidine, a selective and irreversible histidine decarboxylase inhibitor, increases the duration of clonic convulsions induced by MES in mice^[3] and causes severe seizure development in pentylenetetrazol-induced

kindling^[7]. In contrast, the involvement of histamine in learning and memory processes has also been well documented. Histamine significantly ameliorates memory deficits induced by aging, dorsal hippocampal lesions, scopolamine and MK-801, as determined in rats using passive and active avoidance tasks and the 8-arm radial maze^[8–12]. It is proposed that histamine and histaminergic compounds might be useful adjuncts for conventional AEDs, with dual advantages: one for enhancement of the anticonvulsant efficacy of AEDs, and the other for improvement of the memory deficits occurring with epilepsy.

The objectives of the present study were to further clarify whether histidine can both enhance the anticonvulsant efficacy of AEDs and ameliorate the spatial memory impairment induced by seizures. The chronic transauricular kindling procedure was used in rats as a new animal model of epilepsy, and an 8-arm (4 arms baited) radial maze paradigm was used to evaluate spatial memory and differentiate between short-term and long-term memory.

Materials and methods

Animals All experiments were carried out in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals. Male Sprague-Dawley rats (220–270 g, Grade II, Certificate No. 22-9601018, Experimental Animal Center, Zhejiang University) were maintained in an air-conditioned room at 22–26 °C and 40%–70% humidity, and housed in individual cages with a 12-h light-dark cycle (lights on from 8:00 to 20:00). Animals were given free access to water and kept at 80%–85% of their free feeding body weight throughout the radial-arm maze experiments. Experiments were carried out each day between 10:00 and 17:00.

Radial-arm maze training The apparatus used is described in our previous reports^[9,10,13]. The rats were familiarized with the radial maze once per day for 2 d prior to training. Food pellets (45 mg each, Bio-Serv) were scattered over the entire maze surface, and 3 or 4 rats were simultaneously placed in the maze and allowed to explore and take food freely for 10 min. After adaptation, all rats were trained with 1 trial per day. In each trial, only 4 arms (3, 5, 6, and 8) were baited, and the sequence was never changed throughout the experiment. One rat was placed on the center platform that was closed off by a door. After 15 s, the door was opened and the rat was allowed to make an arm choice to obtain food pellets until all 4 pellets had been eaten or 5 min had elapsed. The number of entries into unbaited arms was regarded as the total error (TE). The number of entries into never-baited arm was taken as reference memory error (RME),

whereas re-entry into arms where the pellet had already been eaten was considered as a working memory error (WME). Rats continued training until reaching a criterion of less than 1 error per trial for 5 consecutive trials. Memory retrieval was tested in the same maze.

Chronic transauricular kindling After successful training in the radial maze, each rat in the experimental group was given 1 subconvulsive electrical stimulation daily via ear-clip electrodes (40 mA, 0.2 s, Hugo Saches type 221) until fully kindled. Animals in the sham group had the electrodes applied, but no current was delivered. Each rat was placed separately under a glass funnel, and the appearance of clonic-tonic seizures was recorded. When rats exhibited clonic-tonic seizures after each of 3 consecutive stimulations, they were regarded as fully kindled and used for the drug study. The endpoint of efficacy was taken as the inhibition of tonic hindlimb extension (HLE). The number of animals showing complete abolition of tonic HLE was expressed as percent protection.

Measurements of brain histamine and γ -aminobutyric acid (GABA) content

Sample preparation Rats were sacrificed by decapitation. The brain was quickly removed, placed on an ice-cold stainless steel plate, and dissected into the cortex, hippocampus, brainstem and hypothalamus according to the methods of Glowinski and Iversen^[14]. The brain tissues were stored at -80 °C until assayed. The tissue was homogenized in 3% perchloric acid containing 5 mmol/L disodium EDTA and 5-hydro-*N*⁰-methyltryptamine in a Polytron homogenizer (Kinematica) at the maximum setting for 20 s in an ice bath. The homogenate was centrifuged at 15 000×*g* at 4 °C for 20 min. Then, the supernatant was removed and filtered with a 0.22 μ m polyvinylidene difluoride membrane.

Chromatographic conditions Tissue samples were analyzed by high performance liquid chromatography (HPLC) combined with electrochemical detection using a technique developed in our laboratory for the simultaneous and sensitive analysis of histamine and GABA. The system consisted of a model 582 pump, a model 540 autosampler and a 4-channel CoulArray electrochemical detector. The HPLC was controlled and the data acquired and analyzed using CoulArray software. All of the above equipment was obtained from ESA. After reacting with the derivate *o*-phthalaldehyde, analytes were separated on a 3 μ m, 3 mm×50 mm Capcell Pak MG C18 column from Shiseido. A 2-component gradient elution system was used, with component A of the mobile phase being 100 mmol/L Na₂HPO₄, 13% acetonitrile, and 22% methanol, pH 6.8, and component B being similar to A except with 5.6% acetonitrile and 9.4% methanol. The gradient elu-

tion profile was as follows: 0–3.5 min, isocratic 100% B; 3.5–20 min, linear ramp to 0% B; 20–22 min, isocratic 0% B; 22–23 min, linear ramp to 100% B; 23–30 min, isocratic 100% B. Flow rate was set to 0.75 mL/min. The first cell was set at +250 mV, whereas the second cell was set at +350 mV. All standards were obtained from Sigma. The retention times of GABA and histamine were 15.16 min and 18.36 min, respectively.

Drugs Histidine monohydrochloride and carbamazepine (CBZ) were obtained from Sigma. Histidine was dissolved in saline, and CBZ was suspended in a 1% solution of Tween 80. All drugs were injected ip in a volume of 1 mL/kg of body weight. Histidine was injected 1 h before and CBZ was injected 0.5 h before transauricular electrical stimulation or before the radial maze test. Drugs were given once a week. The same animals were used repeatedly, and they experienced all doses of each drug given in ascending order.

Statistical analysis Results were expressed as mean±standard error of the mean and analyzed by one-way analysis of variance followed by Dunnett's *t*-test. For percentage incidence, the χ^2 -test with Fisher's exact test was used. All statistical analyses were carried out using SPSS 11.5 for Windows. *P*<0.05 was considered as statistically significant.

Results

Effects of histidine and CBZ on transauricular kindled seizures in rats Both histidine and CBZ inhibited transauricular kindled seizures in a dose-dependent manner, as reflected by the increase in percentage protection against tonic HLE. Histidine at doses of 200 mg/kg and 500 mg/kg slightly inhibited tonic HLE, but had no significant effect, whereas at doses of 1000 mg/kg and 1500 mg/kg, it significantly inhibited tonic HLE (*P*<0.05). CBZ at doses of 1 mg/kg and 2 mg/kg showed a tendency to inhibit tonic HLE, but no significant effect was observed, whereas at doses of 5 mg/kg and 10 mg/kg, it provided significant protection against tonic HLE (*P*<0.01). In addition, histidine at a low dose of 200 mg/kg showed a tendency to potentiate the anticonvulsant effects of 1 mg/kg CBZ and it significantly potentiated the anticonvulsant effects of 2 mg/kg CBZ (*P*<0.05). At a dose of 500 mg/kg histidine significantly potentiated the anticonvulsant effects of CBZ (1 mg/kg or 2 mg/kg) (*P*<0.05 and *P*<0.01, respectively) (Figure 1).

Effects of histidine and CBZ on radial maze performance in rats with spatial memory deficits induced by chronic transauricular kindled seizures The chronic transauricular kindling resulted in a significant increase in the number of TE, WME, and RME in the spatial memory retrieval process (*P*<0.01). Histidine at doses of 200 mg/kg and 500 mg/kg

Figure 1. Effects of histidine and carbamazepine (CBZ) on transauricular kindled seizures in rats. Histidine was injected ip at 1 h and CBZ 0.5 h before chronic transauricular electrical stimulation. *n*=14–18 rats. Mean±SEM. ^b*P*<0.05, ^c*P*<0.01 vs saline group. ^e*P*<0.05 vs CBZ (1 mg/kg) group. ^b*P*<0.05, ^h*P*<0.01 vs CBZ (2 mg/kg) group. HLE: hindlimb extension.

significantly decreased the number of TE and WME (*P*<0.05), but not the number of RME. However, histidine at doses of 1000 mg/kg and 1500 mg/kg had no ameliorative effect on the spatial memory deficits induced by transauricular kindled seizures. In contrast, CBZ (2, 5, 10, and 20 mg/kg) had no effect on memory impairment. The co-administration of CBZ also did not influence the improvement of spatial memory deficits induced by 500 mg/kg histidine (Table 1).

Effects of histidine and CBZ on brain histamine content Compared with control rats, chronic transauricular kindling produced a significant decrease in the histamine content of the hypothalamus (41.8%), hippocampus (43.6%), and brainstem (57.3%) (*P*<0.05). Histidine (500 mg/kg, ip) significantly increased the histamine content of the hypothalamus (157.9%) (*P*<0.05) and slightly increased that of the cortex (114.7%), hippocampus (112.7%) and brainstem (122.7%). CBZ (2 mg/kg) had no effect on the increased histamine content induced by histidine treatment (Table 2).

Effect of histidine and CBZ on brain GABA content Neither treatment with histidine (500 mg/kg) or CBZ (2 mg/kg) alone, nor co-administration of the 2 drugs had any effect on brain GABA levels (Table 3).

Discussion

In the present study, we provide evidence for the first time that chronic transauricular kindling can induce not only generalized tonic-clonic seizures but also spatial memory deficits in rats. So far, few animal models are suitable for studying the memory deficits associated with epilepsy, espe-

cially for the form with generalized tonic-clonic seizures^[15]. MES is a representative animal model of generalized tonic-clonic seizures^[16]; however, it has no appreciable effect on cognitive behaviors, such as in passive avoidance learning^[17,18]. This might be because MES is a model of acute

seizures (reactive or provoked), rather than a model of epilepsy^[19]. In the present study, we developed a chronic transauricular kindling model that was relatively simple and required neither expensive equipment nor highly skilled personnel. We found that chronic transauricular kindled

seizures produced spatial memory deficits, which remained in a steady state for approximately 3 weeks after fully kindled (data not shown). Therefore, it is likely that the chronic transauricular kindling model is a very useful animal model for evaluating memory deficits associated with epilepsy, and in drug screening for both anticonvulsant and memory-improving actions.

In the present study, high doses of histidine (1000 mg/kg and 1500 mg/kg), a precursor of histamine, significantly inhibited chronic transauricular kindled seizures, but had no ameliorative effect on the spatial memory deficits induced by these seizures in rats. However, at doses of 200 mg/kg and 500 mg/kg, although it had no appreciable anticonvulsant effect, histidine significantly ameliorated spatial memory deficits. Therefore, it is proposed that at a lower dose, histidine combined with CBZ can simultaneously enhance the anticonvulsant effects and ameliorate spatial memory impairment in rats. Interestingly, we found that the lower doses of histidine significantly potentiated the protective effects of CBZ against transauricular kindled seizures and the cognitive improvement was not affected by co-administration of CBZ. Therefore, our results indicate that histidine, at a specific dosage range, potentiates both the anticonvulsant efficacy of CBZ and ameliorates the spatial memory deficits induced by chronic transauricular kindled seizures in rats. This indicates that histidine might serve as a beneficial adjuvant for the clinical treatment of epilepsy.

In addition, we found that chronic transauricular kindling resulted in a marked decrease of histamine content in the hypothalamus (41.8%), hippocampus (43.6%) and brainstem (57.3%). Consistent with our findings, decreased histamine content of the amygdala and hypothalamus has been reported to follow amygdaloid kindling^[20]. The observed decrease in histamine levels following chronic transauricular kindled seizures further supports the concept of histamine as an endogenous anticonvulsant^[21]. However, in contrast to our data, Vohora *et al* reported that acute MES significantly increased histamine concentration in the brainstem^[22]. We have no data to explain this difference, which might be a result of different mechanisms underlying the seizures (acute vs chronic). Therefore, our results might at least partly elucidate why acute MES has no appreciable effect on cognitive behavior, whereas chronic transauricular kindling induces significant spatial memory deficits in rats^[17,18].

It remains unclear why and how histidine potentiates the anticonvulsant effect of CBZ. A possible pharmacokinetic interaction is unlikely, because the plasma levels of CBZ remain unchanged in the presence of histidine^[17]. Furthermore, we found the GABA levels in the brain after treatment

with histidine and/or CBZ were not significantly different from the values in the control group, which suggests that the enhancement of the anticonvulsant effect of CBZ at the doses used is independent of GABA levels. However, treatment with histidine (200 mg/kg or 500 mg/kg) significantly increased brain histamine content in the hypothalamus. The significant increase of brain histamine content induced by injection of histidine might at least partly contribute to the observed enhanced anticonvulsant efficacy of CBZ.

It is interesting that the effects of histidine on performance in the radial maze showed a bell-shaped inhibition. These results are in accordance with the reports by Sakai *et al*^[23] and Ghi *et al*^[24], who found dose-dependent biphasic effects of histamine on locomotor activity. Alvarez *et al* also reported that treatment with a lower dose of histamine (45 nmol) in the hippocampus improved memory retrieval in contrast to the effect of a higher dose (90 mg/kg)^[25]. These findings suggest that the biphasic effects of histamine in the brain might be mediated through different mechanisms, and the memory improvement induced by histidine only occurs within a specific lower range of dosage.

We were further interested to find that histidine significantly decreased both the number of TE and WME, but not the number of RME induced by transauricular kindled seizures in rats. Our data suggests that histidine can only ameliorate the short-term memory deficit induced by the kindled seizures. Similar findings show that histidine, at doses that cause a significant increase of brain histamine content, improves the working memory deficit induced by 8-OH-DPAT and 7-chlorokynurenic acid in rats^[26,27]. Our previous work also shows that the H₃-antagonist clobenpropit facilitates deficits of working memory induced by intrahippocampal application of MK-801, and we demonstrate that the effects on working memory are a result of an increase in endogenous histamine, whereas the effects on reference memory are most likely a result of neurotransmitters other than histamine^[28]. From the above evidence, it is likely that different mechanisms underlie working memory and reference memory, and brain histamine mainly participates in the former. Because short-term memory complaints are frequent in patients with epilepsy^[29], the improvement in working memory induced by co-treatment with CBZ and histidine appears potentially useful.

In conclusion, we found that chronic transauricular kindling in rats was a very useful animal model for evaluating memory deficits associated with epilepsy. Histidine at relatively low doses significantly enhanced the anticonvulsant efficacy of CBZ against the kindled seizures and also had a significant ameliorative effect on the spatial memory impair-

ment induced by these seizures. It is proposed that histidine, at a specific range of dosages, might serve as a beneficial adjuvant for the clinical treatment of epilepsy, especially when it is accompanied by impairment of spatial memory.

Abstract

Aim: To test the synergistic effects of atenolol and amlodipine on lowering blood pressure (BP) and reducing blood pressure variability (BPV) in 2-kidney, one-clip (2K1C) renovascular hypertensive rats. **Methods:** Forty-eight 2K1C renovascular hypertensive rats were randomly divided into 6 groups. They were respectively given 0.8% carboxymethylcellulose sodium (control), atenolol (10.0 mg/kg), amlodipine (1.0 mg/kg), and combined atenolol and amlodipine (low dose: 5.0+0.5 mg/kg; intermediate dose: 10.0+1.0 mg/kg; high dose: 20.0+2.0 mg/kg). The drugs were given via a catheter in a gastric fistula. BP was recorded for 25 h from 1 h before drug administration to 24 h after administration. **Results:** Compared with BP before medication, all 3 doses of combined atenolol and amlodipine significantly decreased the BP at 24 h after administration, except for the low dose on diastolic BP. Compared with the control group, all 3 doses of combined atenolol and amlodipine significantly reduced the average BP levels for the 24 h period after administration; furthermore, the high and intermediate doses also significantly decreased the BPV levels for the same period. The *q* values calculated by probability sum analysis for systolic and diastolic BP for the 24 h period after administration were 2.29 and 1.45, respectively, and for systolic and diastolic BPV for the same period they were 1.41 and 1.60, respectively. **Conclusion:** There is significant synergism between atenolol and amlodipine in lowering and stabilizing BP in 2K1C renovascular hypertensive rats.

Introduction

Blood pressure (BP) is not constant, and can vary spontaneously. This variation is defined as blood pressure variability (BPV). BPV is increased in hypertensive humans and animals^[1-3]. Furthermore, BPV is positively related to the severity of organ damage in hypertensive humans and rats^[4-6]. In other words, increased BPV can produce organ damage. Therefore, it has been proposed that antihypertensive drugs with a BP-stabilizing effect would act to protect organs in the treatment of hypertension. We have demonstrated that long-term treatment with ketanserin, candesartan, nitrendipine, a combination of nitrendipine and atenolol, and a hydrochlorothiazide mixture not only decrease BP, but also decrease BPV, and have obvious effects on organ protec-

tion in spontaneously hypertensive rats as well. Importantly, organ protection was attributed to the decrease in BPV^[7-10].

Clinically, combination therapy against hypertension using 2 or more drugs from different classes can produce better drug efficacy^[11]. Furthermore, the use of such synergistic therapy is also recommended for the initial treatment of hypertension^[12]. Both β -blockers and dihydropyridine calcium antagonists are widely used in the treatment of hypertension. Atenolol and amlodipine are examples of long-acting drugs from these 2 classes. We hypothesized that these 2 drugs combined would produce a synergistic effect in the treatment of hypertension. Therefore, this study was designed to investigate the synergistic effects of atenolol and amlodipine on both lowering and stabilizing BP in 2K1C renovascular hypertensive rats (RVHR).

Materials and methods

Drugs and drug administration Amlodipine (Nanjing Pharmaceutical Co, Nanjing, China), atenolol (Shanghai Second Pharmaceutical Co, Shanghai, China) and a combination of these 2 drugs were dissolved in 0.8% carboxymethylcellulose sodium (CMC). The doses used were as follows: atenolol 10.0 mg/kg, amlodipine 1.0 mg/kg and 5.0+0.5 mg/kg, 10.0+1.0 mg/kg, and 20.0+2.0 mg/kg combinations of the 2 drugs. Five groups of rats received antihypertensive drugs and one group of rats received 0.8% CMC as control. Drugs were administered by a catheter in a gastric fistula implanted 3 days before treatment.

Animals and RVHR preparation Male Sprague–Dawley rats (160–180 g), purchased from the Sino-British SIPPR/BK Lab Animal Ltd (Shanghai, China), were anesthetized with a combination of ketamine (40 mg/kg) and diazepam (6 mg/kg). The right renal artery of each animal was isolated through a flank incision as described previously^[13], and a silver clip (0.2 mm internal gap) was placed on the renal artery. Five weeks after placement of the clip, the systolic blood pressure (SBP) of rats was measured by using the tail-cuff method (CB10; Alcott Biotech Co, Shanghai, China). In total, 48 RVHR whose SBP was greater than 160 mmHg were used in this study. Rats were kept in a controlled temperature (23 °C–25 °C) and lighting (light 08:00–20:00, dark 20:00–08:00) environment, and had free access to food and tap water. All the animals used in this work received humane care in compliance with institutional animal care guidelines.

BP and BPV measurement SBP, diastolic blood pressure (DBP) and heart period (HP) were continuously recorded using a previously described technique^[10]. Briefly, rats were anesthetized by injection (ip) with a combination of ketamine (40 mg/kg) and diazepam (6 mg/kg). A floating polyethylene catheter was inserted into the lower abdominal aorta via the left femoral artery for BP measurement, and another catheter was placed into the stomach via a mid-abdominal incision for drug administration. The catheters were exteriorized through the interscapular skin. After a 2-d recovery period, the animals were placed for BP recording in individual cylindrical cages containing food and water. The aortic catheter was connected to a BP transducer via a rotating swivel that allowed the animals to move freely in the cage. After approximately 14-h habituation, at 9:00 o'clock the BP signal was begun to be digitized by a microcomputer. One hour later, at 10:00 o'clock the drug was given via the catheter in the gastric fistula. SBP, DBP, and HP values were recorded beat-to-beat for 25 h, up to 10:00 o'clock on the second day. The mean values of these parameters during a designated

period were calculated and served as SBP, DBP and HP values. The standard deviation of all values obtained over 24 h was denoted as the quantitative parameter of variability; that is, SBP variability (SBPV), DBP variability (DBPV), and HP variability (HPV) for each rat.

Probability sum test To determine whether the drugs were acting synergistically, we used the probability sum test. This test comes from classic probability analysis and is useful for evaluating the synergistic interactions between 2 drugs (*q* test)^[10,14,15].

In the present work, we used the following criteria. Compared with the mean values from control rats, treated rats with a decrease in BP (SBP or DBP) >20 mmHg were defined as responders and rats with a decrease in BP ≤20 mmHg were defined as non-responders. For BPV (SBPV or DBPV), the criterion was 2 mmHg. The formula used is as follows: $q = P_{A+B} / (P_A + P_B - P_A \times P_B)$. Here, A and B indicate drug A and drug B; *P* (probability) is the percentage of responders in each group. P_{A+B} is the real percentage of responders and $(P_A + P_B - P_A \times P_B)$ is the expected response rate. $P_A + P_B$ is the sum of the probabilities when drug A and drug B are used alone. $P_A \times P_B$ is the probability of rats responding to both drugs when they were used alone. When $q < 0.85$, the combination is antagonistic, when $q > 1.15$, the combination is synergistic, and when q is between 0.85 and 1.15, the combination is additive.

Statistical analysis Data were expressed as mean ± SEM. Comparisons between values obtained in the same group before and after drug administration were made using the paired *t*-test. Comparisons among groups were carried out using ANOVA followed by Duncan's test. $P < 0.05$ was considered statistically significant.

Results

Effects of atenolol and amlodipine on BP and HP at 24 h after treatment The effects of atenolol and amlodipine alone and in combination on BP and HP at 24 h after administration in 2K1C RVHR are shown in Table 1. The mean values of these variables 1 h before administration serve as the control values and are defined as "before"; the mean values at 24 h after administration are defined as "after". We found that SBP was significantly decreased in all 3 groups treated with both atenolol and amlodipine when compared with "before". A significantly lower DBP was also found in 2 groups of rats treated with both atenolol and amlodipine (10.0+1.0 mg/kg and 20.0+2.0 mg/kg) when compared with "before". Relative to "before", the mean HP value at 24 h after administration was higher only in rats treated with atenolol (10.0

SBP, systolic blood pressure; DBP, diastolic blood pressure; Before, the mean value of 1-h blood pressure and HP before administration; After, the mean blood pressure and HP value at 24 h after administration.

mg/kg) alone. Of the 3 groups treated with both atenolol and amlodipine, we found that both the intermediate and the high doses reduced SBP at 24 h after administration more effectively than the low dose.

Effects of atenolol and amlodipine on BP and HP for the 24-h period after administration We found that the average SBP in control rats during the 24 h after administration was 171.0±3.5 mmHg. The average SBP over this time was significantly lower in all 5 groups treated with either atenolol, or amlodipine, or both when compared with the control group (Figure 1). The minimal decrease (-13.0 mmHg) was found in rats treated with amlodipine alone and the maximal decrease (-39.0 mmHg) was found in rats treated with both atenolol and amlodipine at a high dose (20.0±2.0 mg/kg). Compared with control, the decrease in average DBP in the experimental groups during the 24 h after administration was also significant but not so profound. The mean value of HP during this time was only increased in the group treated with atenolol (10.0 mg/kg) alone. Of the 3 groups treated with both atenolol and amlodipine, both the intermediate and the high doses reduced SBP more obviously than the low dose (Figure 1).

Effects of atenolol and amlodipine on BPV and HPV for the 24-h period after administration Compared with the control group (13.00±0.53 mmHg for SBPV and 9.40±0.64 mmHg for DBPV), a significant decrease in BPV was found in groups treated with both atenolol and amlodipine at an intermediate (8.80±0.85 mmHg for SBPV and 7.60±0.53 mmHg for DBPV) and high dose (8.50±0.71 mmHg for SBPV and 7.30±0.53 mmHg for DBPV) (Figure 2).

Synergistic interaction of atenolol and amlodipine on BP and BPV for the 24-h period after administration Based on the results presented in Figure 1, the effectiveness of the

decrease in BP was calculated for rats individually. Rats with a decrease in BP >20 mmHg (relative to controls) were defined as responders and those with a decrease in BP ≤20 mmHg as non-responders. The results of probability testing are presented in Table 2. We arrived at *q* values of 2.29 for SBP and 1.45 for DBP for the combination of both atenolol and amlodipine (10.0+1.0 mg/kg). Compared with the mean values for control rats, rats with a decrease in SBPV or DBPV >2 mmHg were defined as responders. According to this criterion, the *q* values were 1.41 for SBPV and 1.60 for DBPV for the combination of both atenolol and amlodipine (10.0+1.0 mg/kg).

Table 2. Results of probability sum tests for the combination of atenolol (Ate; 10.0 mg/kg) and amlodipine (Aml; 1.0 mg/kg) on blood pressure and blood pressure variability for the 24-h period after administration in 2K1C renovascular hypertensive rats. *n*=8.

SBP P, percentage of responders for systolic blood pressure; DBP P, percentage of responders for diastolic blood pressure; SBPV P, percentage of responders for systolic blood pressure variability; DBPV P, percentage of responders for diastolic blood pressure variability. $q = P_{Ate+Aml} / (P_{Ate} + P_{Aml} - P_{Ate} \times P_{Aml})$. If *q* < 0.85, the combination is antagonistic, if *q* > 1.15, the combination is synergistic, if *q* is between 0.85 and 1.15, the combination is additive.

Figure 1. Effects of atenolol (Ate) and amlodipine (Aml) alone and in combination on blood pressure and heart period (HP) in 2K1C renovascular hypertensive rats for the 24-h period after administration. SBP, DBP, and HP are the mean values of systolic blood pressure, diastolic blood pressure, and heart period, respectively, and were calculated from each beat during the 24-h test period. The numbers shown after the compounds are dosages (mg/kg). $n=8$ rats. Mean \pm SEM. ^b $P<0.05$, ^c $P<0.01$ vs control. ^f $P<0.01$ vs Ate+Aml (5+0.5 mg/kg).

Discussion

The purpose of using fixed-dose combinations of 2 different kinds of antihypertensive drugs in the treatment of hypertension is to obtain increased BP control and to enhance compliance by using a single tablet that is taken once or twice daily^[16]. Furthermore, by combining 2 different agents at lower doses, the clinical and metabolic side effects that would be produced by either drug at higher doses can be minimized^[17]. Therefore, fixed-dose combinations of antihypertensive drugs could potentially increase BP control, simplify dosage regimens, improve compliance, decrease

Figure 2. Effects of atenolol (Ate) and amlodipine (Aml) alone and in combination on blood pressure variability and heart period variability (HPV) in 2K1C renovascular hypertensive rats for the 24-h period after administration. SBPV, DBPV, and HPV are the standard deviations of systolic blood pressure, diastolic blood pressure, and heart period, respectively, and were calculated from each beat during the 24-h test period. dose-dependent side effects, and reduce costs as the first-line treatment for hypertension^[18]. These advantages make combination antihypertensive therapy the recommended initial treatment, particularly in patients with end-organ damage (EOD) or more severe initial hypertension^[19,20]. However, high BP is not a unique factor determining hypertensive EOD. Parati *et al* found that for patients with similar hypertension levels for the 24 h after treatment, those whose BPV

levels were lower had less severe organ damage than those with higher BPV levels^[4]. Our previous study found that in 60-week-old spontaneously hypertensive rats, the severity of organ damage was positively related to BP ($r=0.31-0.32$, $n=50$, $P<0.05$) and BPV levels ($r=0.63-0.65$, $n=50$, $P<0.01$), and BPV was positively related to the extent of organ damage, so BPV might be a new determinant of EOD^[6,21,22].

Therefore, it seems very important to emphasize the role of BPV in antihypertensive therapy. However, it is not clear how BPV can be controlled in the treatment of hypertension. We have previously proposed 2 ways to reduce BPV in antihypertensive therapy^[6]: (1) find antihypertensive drugs that decrease BPV even at a dose that does not affect BP, for example ketanserin; and (2) treat patients with long-acting antihypertensive drugs, for example candesartan or amlodipine. In the present work, we investigated a third way to control BPV in the treatment of hypertension, that is, combination therapy.

Both β -blockers and dihydropyridine calcium antagonists are widely used in antihypertensive therapy. The combination of a β -blocker and a dihydropyridine calcium antagonist is a logical choice^[23], and is effective for treating hypertensive patients with chronic renal insufficiency and left ventricular hypertrophy^[24]. Theoretically, calcium antagonists are vasodilators and tend to increase plasma renin, therefore combining them with β -blockers is a good idea^[25]. A combination of these compounds can also neutralize the side effects of both, for example the initial heart rate increases induced by dihydropyridine calcium antagonists, and the rise in peripheral resistance elicited by some β -blockers^[26].

In terms of the synergistic effects of atenolol (10.0 mg/kg) and amlodipine (1.0 mg/kg) on BP reduction, the findings of the present work are: (1) the combination of atenolol and amlodipine significantly decreases BP 24 h after administration, whereas neither drug alone had an obvious influence; (2) both atenolol or amlodipine alone reduced the average BP for the 24 h period after administration by less than 15 mmHg, but in combination they decreased SBP by up to 35 mmHg and DBP by approximately 25 mmHg. The q values for SBP and DBP for the 24 h period after administration were 2.29 and 1.45, respectively, which are higher than 1.15, the threshold value for synergistic effects. Concerning the synergism of combined atenolol and amlodipine on the reduction in BPV for the 24 h period after administration, we found that BPV was not influenced by treatment with atenolol or amlodipine alone, but was markedly reduced when they were used in combination. The q values for SBPV and DBPV for the 24 h period after administration were 1.41 and 1.60, respectively. These findings demonstrate that the combina-

tion of atenolol and amlodipine has a significant synergistic effect on lowering BP and stabilizing BPV in RVHR.

Our previous studies have demonstrated that long-term (4 months) treatment with a hydrochlorothiazide mixture, which consisted of 5 drugs at low doses, markedly reduced BP and BPV in spontaneously hypertensive rats^[9]. Long-term (3 months) treatment with atenolol and nitrendipine had a significant protective effect on organs in spontaneously hypertensive rats^[8].

We conclude that atenolol and amlodipine in combination have a synergistic effect in lowering and stabilizing BP in RVHR. Combination therapy is likely to be the optimal way to control BP and reduce BPV in the treatment of hypertension.

Abstract

Aim: To elucidate the involvement of the endothelin (ET) pathway in the pathogenesis of monocrotaline (MCT)-induced pulmonary arterial hypertension (PAH) and the therapeutic effect of CPU 86017 (*p*-chlorobenzyltetrahydroberberine chloride) in rats. **Methods:** Rats were injected with a single dose (60 mg/kg, sc) of MCT and given CPU 86017 (20, 40, and 80 mg·kg⁻¹·d⁻¹, *po*) or saline for 28 d. The hemodynamics, mRNA expression, and vascular activity were evaluated. **Results:** Right ventricular systolic pressure and central venous pressures were elevated markedly in the PAH model and decreased by CPU 86017. In the PAH group, the endothelin-1 (ET-1) in serum and lungs was dramatically increased by 54% (79.9 pg/mL, *P*<0.01) and 93% (166.2 pg/mL, *P*<0.01), and mRNA levels of preproET-1, eNOS, and iNOS also increased dramatically compared with control. Compared with PAH group, CPU 86017 decreased the content of ET-1 to the normal level in lung tissue, but was less effective in serum. The level of NO was significantly increased in CPU 86017 at 80 and 40 mg·kg⁻¹·d⁻¹ groups in tissue, whereas the difference in serum was not significant. A significant reduction in MDA production and an increase in the SOD activity in the serum and lungs was observed in all three CPU 86017 groups. CPU 86017 80 mg·kg⁻¹·d⁻¹ *po* increased the activity of cNOS by 33% (*P*<0.01). The up-regulation of eNOS and iNOS mRNA levels induced by MCT was significantly reversed in 3 CPU 86017 groups, and preproET-1 mRNA abundance was also reduced notably in CPU 86017 80 mg·kg⁻¹·d⁻¹ group vs the PAH group. The KCl-induced vasoconstrictions in the calcium-free medium decreased markedly in PAH group but recovered partially after CPU 86017 intervention. The constrictions in the presence of Ca²⁺ was not improved by CPU 86017. The phenylephrine-induced vasoconstrictions in the calcium-free medium decreased markedly in PAH group but not recovered after CPU 86017 intervention. The constrictions in the presence of Ca²⁺ completely returned to the normal after CPU 86017 intervention. **Conclusion:** CPU 86017 suppressed MCT-induced PAH mainly through an indirect suppression of the ET-1 system, which was involved in the pathogenesis of the disease.

Introduction

Pulmonary arterial hypertension (PAH) is a common disease induced by many etiological factors. Pulmonary vascular remodeling by monocrotaline (MCT) affects both vas-

cular smooth muscle and vascular wall connective tissue at the molecular level^[1]. Endothelium plays an important role in controlling vascular tone as well as vascular remodeling by releasing endothelium-derived relaxing factors [EDRF, nitric oxide (NO)] and contracting factors mainly endothelin-1

(ET-1)^[2]. ET-1 is a potent endothelium-derived vasoconstrictor peptide, which possesses mitogenic effects to proliferate the vascular smooth muscle cells (VSMC) in the development of PAH^[3]. NO, which is released from the endothelium, attenuates proliferation of VSMC^[4] and is opposed functionally to ET-1^[5].

Monocrotaline (MCT), a pyrrole alkaloid, causes substantial and sustained inflammatory damage to the pulmonary arterial system and, therefore, causes PAH in rats^[5]. CPU 86017, *p*-chlorobenzyltetrahydroberberine (Figure 1), a new compound derived from berberine, possesses a calcium channel blocking effect^[6], combined with an antioxidative effect^[7]. CPU 86017 ameliorates the progression of chronic congestive heart failure in relation to suppression of the ET-1 system^[8]. Therefore, it is hypothesized that CPU 86017 might relieve the pulmonary hypertension, with an indirect effect on the overactive ET pathway underlying the pulmonary hypertension induced by MCT. We intend to explore the pathogenesis of PAH induced by MCT in relation to an activated ET pathway, and its downstream events (iNOS and ROS activity) in response to the medication of CPU 86017.

Figure 1. The chemical structure of CPU 86017.

Materials and methods

Experimental protocol Sixty-five male Sprague-Dawley rats (weighing 250 g-300 g, from the Experimental Animal Center of Nanjing Medical University) were randomized into 5 groups ($n=13$). Animals (apart from the normal group) were injected with a single dose 60 mg/kg, sc) of MCT (Promega). *p*-Chloro-benzyl-tetrahydro-berberine chloride (CPU 86017) was first synthesized by the New Drug Center of China Pharmaceutical University and provided by Shandong Xinhua Pharmaceutical Industry Co. The 5 groups were the normal group (Ctl), PAH untreated group (PAH), and the 3 treatment groups (CPU 86017 20, 40, and 80 mg·kg⁻¹·d⁻¹, *po*, daily for 28 d from the day of MCT, sc). CPU 86017 was suspended freshly in 0.5% CMC-Na of 0.4%, 0.8%, and 1.6% (20, 40, and 80 mg·kg⁻¹·d⁻¹, sc). The normal and PAH groups were given an equal volume of CMC-Na.

The investigation was performed in accordance with the Guide for the Care and Use of Laboratory Animals in Jiangsu Province.

Hemodynamic analysis and heart weight index After 4 weeks of MCT medication and interventions with CPU 86017, rats were killed with urethane (1.5 mg/kg, ip). RVSP (right ventricular systolic pressure), CVP (central venous pressure), and blood pressure were measured using 2 catheters separately, as described previously^[9]. Animals were then exsanguinated, and the hearts and lungs were dissected and weighed. The right ventricular remodeling was assessed by measuring the RVWI (right ventricle weight index): the RV weight to body weight ratio (RVW/BW, mg/g) and the RV-to-left ventricular (LV) plus septal (S) weight ratio [RVW/(LVW+SW), mg/g]. The improvement after drug intervention was calculated as follows: improvement % = (PAH-Treated)/(PAH-Normal)×100%.

ET-1, NO, NOS, superoxide dismutase (SOD), and malondialdehyde (MDA) assays Blood samples were col-

lected in chilled vials containing 30 mL EDTA2Na and 20 mL Aprotinin. ET-1, NOS activity, SOD, and MDA in serum and lung tissue were measured using radioimmunoassay or the kits supplied by Nanjing Jiancheng Biotechnological Co, following the practice described previously^[9].

Assessment of pulmonary artery remodeling Transverse sections of lungs, 4 μm in thickness, were cut at the right middle zones and stained with hematoxylin-eosin, then the wall thickness of small pulmonary arteries (diameter<150 μm) was analyzed using a colorful picture analysis system (Quantment 500), as described in a previous report^[9]. The thickness (μm) and WT (wall thickness ratio) percentage value were determined as the average data of 10 fields per slice and the WT was calculated as below: WT%=(diameter_{ext}-diameter_{int})/diameter_{ext}×100.

mRNA expressions of preproET-1, iNOS, and eNOS in lung tissue Lung tissue was homogenized in TRIZOL, and then extracted with hydroxybenzene-chloroform. Reverse transcription-polymerase chain reaction (RT-PCR) was performed in 25 μL final volume under the following conditions: initial denaturalization at 94 °C for 5 min, denaturalization at 94 °C for 40 s, annealing for 40 s at 64 °C for preproET-1, at 58 °C for eNOS, at 58 °C for iNOS, and at 60 °C for β-actin, all extension at 72 °C for 1 min. The circular numbers of β-actin, preproET-1, eNOS, and iNOS were 25, 28, 26 and 28, respectively. The sequences of primers are shown in Table 1 and the procedures were the same as described previously^[9]. The PCR products were electrophoresed and determined semi-quantitatively.

Functional assessment of isolated pulmonary arterial rings The pulmonary arteries were carefully isolated and cleaned of outer connective tissue in cold K-H solution saturated with 100% oxygen. The rings from each pulmonary artery (approximately 3 mm in length) were mounted vertically between 2 hooks in organ chamber myographs, which

were filled with K-H solution and kept at 37 °C. Isometric tension was measured with force transducers (MPA-V). Constrictions of the isolated pulmonary arterial rings by KCl 100 mmol/L or phenylephrine 1 μmol/L were performed in calcium free KH solution and after adding up to 2.5 mmol/L Ca²⁺ in the presence of either KCl or phenylephrine, separately^[10-12].

Statistical analysis Data are presented as mean±SEM. For statistical evaluation one-way analysis of variance was used, following Dennett's test. The Student Newman Keuls test was performed when the variance was equal, and the Games-Howell test was performed when variance was not equal. Pearson correlation analysis was also carried out on some indices. A value of P<0.05 was considered statistically significant.

Results

Hemodynamic changes The RVSP and CVP in MCT PAH group were elevated markedly by 79% (P<0.01) and 2400% (P<0.01) compared with normal, respectively. CPU 86017 20, 40, and 80 mg·kg⁻¹·d⁻¹ po decreased the RVSP by -18.5%, -37.2%, and -15.1%, compared to the PAH (P<0.01), respectively, and the reduction in CVP was by -66.7%, -73.3%, and -80.0%, respectively (P<0.01, Table 2).

Regression in RVWI The RVWI in the control group was increased by 50.0 % in RVW/BW and 53.3 % in RVW/(RVW+SW) (P<0.01), respectively. Reduction in RVW/BW by CPU 86017 20, 40, and 80 mg·kg⁻¹·d⁻¹, po was -30.5%, -33.3%, and -25.9%, respectively, compared to the untreated group and in RVW/(RVW+SW) was -28.2%, -30.4%, and -28.2% (P<0.01), respectively. The remodeling of the right ventricle was regressed remarkably in each intervention group (Table 3).

Regression in the vasculature of the pulmonary arteriole In PAH group, the thickness (μm) and the relative value of

WT% (wall thickness percentage) of small pulmonary arteries (<150 μm in diameter) were increased by 106.0% and 80.7% ($P < 0.01$) compared with the control group. In CPU 86017 80, 40, and 20 mg·kg⁻¹·d⁻¹ groups, thickness (μm) and the relative value of WT percentage of small pulmonary arteries decreased significantly compared with the untreated group (Table 4, Figure 2).

WT, wall thickness (%) of the total area of the vascular transactions.

NO, ET-1, cNOS, SOD, and MDA in serum and lung tissue In the PAH group, the ET-1 in the serum and lungs was dramatically increased by 53.9% ($P < 0.01$) and 93.7% ($P < 0.01$), respectively. CPU 86017 decreased the content of ET-1 to the normal level in lung tissue, but was less effective in serum. The NO content was increased by 60.0% ($P < 0.01$) in serum, but decreased by -52.5% ($P < 0.01$) in pulmonary tissue, compared to that of the normal group. The level of NO was significantly increased in CPU 86017 80 and 40 mg·kg⁻¹·d⁻¹ groups in tissue, whereas the difference was not significant in serum. Activity of cNOS in tissue decreased by -38.5%

Figure 2. Morphological analysis of the wall thickness of pulmonary arteriole transactions in monocrotaline-induced pulmonary artery hypertension (PAH) in rats. ($P < 0.01$) in the PAH group compared to the normal. The activity of cNOS was increased by 33.0% ($P < 0.01$) in CPU 86017 80 mg·kg⁻¹·d⁻¹ *po* group compared to the PAH (Table 5, 6). The MDA was significantly increased in both the serum and lungs, whereas the activity of SOD decreased markedly. A significant reduction in MDA production was observed in all three CPU 86017 groups, which was associated with an increase in the SOD activity in the serum and lungs.

PreproET-1, iNOS, and eNOS mRNA expression

Twenty-eight days after MCT injection, the mRNA expression of preproET-1, eNOS, and iNOS in the PAH group was upregulated by approximately 4, 6.5, and 2.7 times, respectively, against the normal lung tissue. The upregulation of eNOS and iNOS mRNA levels was significantly reversed in three CPU 86017 groups, and preproET-1 mRNA abundance was also reduced notably in CPU 86017 80 mg·kg⁻¹·d⁻¹ group versus the PAH group (Figure 3).

Isolated pulmonary artery activity Two sorts of pulmonary vascular activities were assessed using high KCl and

Discussion

CPU 86017 is derived from chemical modification of the moiety of berberine and possesses a blocking effect on the K⁺ and Ca²⁺ channels^[13], together with an improvement in the water solubility and availability in pharmacokinetics. The chemical reformation leads to a reinforcement of calcium antagonism, providing a potential beneficial use in the treatment of cardiovascular disorders^[12].

The chronic inflammation of the lung tissue by MCT contributes to an insult to vascular endothelium and myocardium, consequently resulting in a substantial increase in ET-1 release, which promotes the pathological progression of PAH. The voltage-dependent calcium channels are coupled to ET_A receptors by G proteins; therefore, an enhancement of the calcium influx is anticipated to follow an excess ET-1 release, as we found in the PAH. The activation of the L-type Ca²⁺ channels caused by an excess ET-1 in the myocardium and vasculature is an important etiological factor resulting in maladjustment and remodeling changes in the pulmonary vessels and the right ventricle.

The ET-1 closely linked with the ROS system is an important pathway involved in cardiovascular derangement^[14]. One of the up-stream events in the pathway to the tissue ET-1 is

the mRNA of preproET-1, which is also elevated significantly. An excess of ET-1 binding to the ET_A receptors stimulates the protein kinase C (PKC), mitogen-activated protein kinase (MAPK) pathway, finally leading to an abnormality of phenotype of genes encoding the preproET-1, iNOS, and eNOS, matrix formation, as well as to pulmonary VSMC proliferation^[15-17].

A low level of NO and elevated ET-1 in the pulmonary tissue is a result of endothelial damage and dysfunction by MCT. MCT selectively damages pulmonary endothelium, reducing NO production and secretion. The vascular NO is biosynthesized and released in a constant manner, which is necessary to maintain the normal vascular vasodilatation response. The bioavailability of NO (ie basal release) is compromised significantly, resulting in impaired vascular activity in the PAH group. An abnormally low NO exerts a suppressive effect on the proliferation of smooth muscle cells, because of an excess of ET-1, which mediates an activation of MAPK pathway. An increased serum NO in the PAH group is a result of activated activity of the iNOS resulting from the stimulation of chronic inflammation by MCT, which accelerates both pulmonary artery hypertension and portal hypertension^[18].

The ROS play an important role in remodeling of the small pulmonary artery, as they proliferate smooth muscle cells by activating the phosphorylation of ERK/MAPK. The ET-1 stimulates the downstream events in the pathway; that is, activation of iNOS and ROS. It is likely that a circulated activation mechanism takes place between the upstream and the downstream to exacerbate an activation of the ET pathway involved in the pathological process. An increment of ROS causes an increase in the abundance of mRNA of prepro-ET-1, eNOS, and iNOS, attributable to the enhancement of the transcription process in the nucleus^[19,20]. This is easily reversed by suppression of the ET-ROS pathway after treatment with CPU 86017.

An intervention to interrupt the targets located at either the upstream or the downstream of the ET pathway is capable of relieving the disturbance in the PAH by MCT. The insult to the pulmonary endothelium and the later developed myocardial insufficiency of the right ventricle are the main factors contributing to excess ET-1 and the over-stimulation of the ET pathway. The overactivated ET pathway can be reversed indirectly by the calcium antagonism and antioxidative effects of CPU 86017. Actually an attenuation of the activated ET pathway by CPU 86017 in the MCT PAH in rats can not be ascribed to a direct blocking action on ET receptors, but ascribed to a calcium antagonism relieving an injury of the pulmonary endothelium and the myocardium and rebal-

ancing an interruption of the ROS formation. A reduced formation of the ET-1 and an indirect blockade of endothelin receptors to alleviate its downstream events are achieved using CPU 86017 chronic medication.

Plasma ET-1 was less responsive than the pulmonary origin ET-1 to CPU 86017 treatment. The ET can be sourced from the two: physiological and pathological conditions, such as the ET in the affected lung is totally from the insult from MCT. In the blood stream the majority of ET is released from the organ under normal conditions such as the central nervous system, the kidney, endometrium, and normal tissue^[21], but ET from the affected lung contributes to a small portion of plasma ET-1. So only a heavy inhibition of the release from the pathological lung by the high dose of CPU 86017 could provide a reduction in the serial total ET, but not the middle and small doses. In contrast, paracrine and autocrine ET-1 is effective in the local region. The pulmonary origin of ET-1 was the main pathological factor and responded well to the CPU 86017 treatment.

We found that eNOS mRNA expression was significantly increased in MCT-induced PAH, and was up to 6.5 times higher than that in normal group, whereas both NOS activity and NO content decreased in the same way as reported by Resta *et al*^[22]. Such a contradiction might be contributed to damage to endothelium by MCT with which the eNOS can not be converted into a normally active form. The maladjustment resulted from phosphorylation of threonine^[23], which causes defective activity of the eNOS, contributing to PAH progression^[24].

In conclusion, an activated ET-ROS pathway damages the endothelium system which results in consequent pulmonary vasculature derangement in PAH by MCT in rats. By suppressing the ET pathway, CPU 86017 relieves MCT PAH.

Introduction

Elevated plasma homocysteine (Hcy) concentration is an independent risk factor for cardiovascular disease^[1,2]. Although the exact mechanism by which hyperhomocysteinemia (HHcy) induces cardiovascular disease is still uncertain, recent evidence suggests that HHcy may induce the process of atherogenesis by initiating inflammation. Hcy may affect inflammatory cells, such as mononuclear leukocytes, monocytes, and T cells, as well as multiple cytokines, to alter the inflammatory status of endothelial cells, smooth muscle cells (SMC) and intimal macrophages during the formation of lesions^[3,4]. Hcy induces the expression and secretion of monocyte chemoattractant protein -1 (MCP-1) and interleukin-8 (IL-8) in human aortic endothelial cells, SMC lines, and monocyte cells^[5-8]. Furthermore, we have shown that Hcy not only promotes the secretion of MCP-1 and IL-8 but also enhances their gene expression in primary cultured human monocytes^[7]. Holven *et al*^[9] also reported that

Abstract

Aim: To investigate the changes in plasma level of the chemokine RANTES (regulated upon activation, normal T cells expressed and secreted) and the responsiveness of lipopolysaccharide (LPS)-induced RANTES secretion from monocytes in patients with hyperhomocysteinemia (HHcy). **Methods:** The plasma levels of homocysteine (Hcy), folate, and RANTES were measured in 38 control patients with normal Hcy levels and 40 patients with HHcy and the mRNA synthesis of RANTES in isolated human monocytes was determined by RNase protection assays. **Results:** The plasma level of RANTES was elevated in HHcy patients compared with controls (median 5.3 vs 3.5 ng/mL, $P < 0.01$). LPS-induced RANTES production from monocytes of HHcy patients was also increased significantly. In addition, Hcy directly increased the mRNA level of RANTES in isolated normal human monocytes in a time- and dose-dependent manner. **Conclusion:** Upregulated RANTES from monocytes in HHcy patients may be involved in the atherogenesis of HHcy-induced atherosclerosis.

the plasma level of the chemokine epithelial neutrophil-activating peptide-78 (ENA-78) and growth-regulated oncogene (GRO α) was elevated in patients with HHcy. This evidence suggests a role of pro-inflammatory chemokines in HHcy-initiated atherogenesis.

RANTES (regulated upon activation, normal T cells expressed and secreted) is a CC chemokine, normally derived by T lymphocytes. It is also produced by mono/macrophages. It plays an important role in the inflammatory process. It has been found to play an important role in autoimmune disorders such as asthma or systemic lupus erythematosus and is nearly as potent a chemoattractant for monocytes as MCP-1^[10,11]. To date, no evidence exists on the relation between HHcy and RANTES. In the present study, we determined the plasma level of RANTES and the responsiveness of monocytes to low-dose lipopolysaccharide (LPS)-induced RANTES secretion in patients with HHcy and elucidated the direct effect of Hcy on RANTES mRNA level in human monocytes.

Materials and methods

Subjects Two groups of subjects were studied: 40 patients with HHcy (plasma Hcy level more than 15 $\mu\text{mol/L}$) and 38 control patients with normal blood Hcy level (NHcy). All subjects had no infectious diseases, malignancies or immunologic or hematological diseases; were not being treated with anti-inflammatory drugs other than low-dose aspirin; did not use any vitamins including folic acid during the study period; had no depressed cardiac function (ejection fraction <40%); were younger than 75 years; had no renal failure; and had not had acute myocardial infarction in the previous 3 months.

Venous blood samples were obtained from fasting subjects to assay the chemokines from plasma and isolated monocytes stimulated by low-dose LPS. All subjects gave their written, informed consent. This study was approved by the Ethics Committee of the Health Science Center, Peking University.

Measurement of RANTES The supernatant of cultured monocytes and plasma stored at $-70\text{ }^{\circ}\text{C}$ were used to measure the chemokines. The concentration of RANTES was determined by ELISA according to the manufacturer's protocols (R&D Systems, Minneapolis, MN, USA).

Measurement of plasma level of Hcy and folate A plasmid-encoding human placental AdoHcy hydrolase (pPROK-1) kindly provided by the University of Kansas (USA) was overexpressed in *E coli* JM109 cells transformed with pPROK-1 and purified as described in a previous study^[12]. Total Hcy level in plasma was determined with the use of an assay based on the conversion of Hcy to *S*-adenosyl-homocysteine (SAH) in the presence of adenosine and SAH hydrolase as described from our previous study^[8]. Briefly, plasma samples from fasting subjects were collected. Protein-bound circulating Hcy was reduced to free Hcy with the use of dithioerythritol as a reductant. The free Hcy was then converted to SAH by using SAH hydrolase and excess adenosine. Samples were quantified by HPLC. The range of measurement was 1–100 $\mu\text{mol/L}$, with a sensitivity of less than 0.5 $\mu\text{mol/L}$. The within-assay and between-assay coefficients of variation were 3.5% and 4.9%, respectively.

Plasma folate was measured by radioisotope dilution assay with use of a kit from Nanjing Jiangcheng Bioengineering Institute (Nanjing, China).

Responsiveness of human monocytes to LPS Blood of HHcy and NHcy patients was drawn into heparinized syringes. The whole blood was separated into peripheral blood mononuclear cells and neutrophils by use of the density gradient from Nycoprep 1.077 (Life Technologies, Grand Island, NY, USA). Monocytes were then isolated from the

peripheral blood mononuclear cells by their adherence to a serum-coated culture flask for 2 h. Adherent cells were then detached and resuspended in RPMI-1640 medium containing 5% autologous plasma. Freshly isolated monocytes (5×10^5) were incubated at $37\text{ }^{\circ}\text{C}$ and treated with or without LPS (final concentration 0.01–0.1 $\mu\text{g/mL}$) for 24 h. The cell-free supernatant was harvested and stored at $-70\text{ }^{\circ}\text{C}$ for chemokine analysis. Cellular viability was determined with Trypan blue exclusion. Only cell preparations with 95% viability or greater were used.

RNase protection assays Total RNA was isolated from healthy human monocytes with Trizol Reagent (Life Technologies). Assays involved use of a nuclease protection assay kit (Riboquant, Pharmingen, San Diego, CA, USA) as used in our previous published report^[7]. In summary, the isolated RNA (2 mg) was hybridized with ^{32}P end-labeled RANTES oligonucleotide probes overnight at $30\text{ }^{\circ}\text{C}$, followed by nuclease digestion. A GAPDH and L-32 rRNA oligonucleotide probe was used as an internal control. After digestion, the protected fragments were resolved on a denatured 12% polyacrylamide gel containing 8 mol/L urea, then transferred to filter paper, which was later exposed to X-ray film. The bands corresponding to RANTES, L-32 or GAPDH mRNA were analyzed by use of a gel documentation system (Cold-Spring Electro Doc and Analyst Edas 290, New York, USA).

Statistical analysis Because chemokine and Hcy values do not follow a normal distribution in patients, comparisons between groups involved the use of the Mann-Whitney test. Values are expressed as median, 25th and 75th percentile, and 10th and 90th percentile. Patients' age, body-mass index and plasma level of cholesterol, triglycerides and creatinine were analyzed with use of the Student's *t*-test and expressed as mean \pm SD. Proportions were analyzed by use of the Chi-squared test. $P < 0.05$ (two-tailed) was considered statistically significant.

Results

Clinical characteristics of the study participants The NHcy control and HHcy groups did not differ significantly with respect to age, sex, and body-mass index. The prevalence of smoking, coronary artery disease, hypertension and diabetes, as well as base-line demographic characteristics and laboratory values, were also similar in the two groups (Table 1).

Plasma level of Hcy, folate, and RANTES The Hcy level was significantly higher in HHcy subjects than that in NHcy controls, while the folate level was lower in HHcy subjects than that in NHcy controls. In the HHcy group, the plasma

The diagnosis of diseases is guided by definitions from the World Health Organization or authorized textbooks. Especially, the diagnosis of coronary artery disease (CAD) determined by coronary angiography; at least 50% stenosis in at least 1 main coronary vessel. The continuous variables were compared by Student's *t*-test. Proportions were compared by chi-squared test. HDL, high density lipoprotein; LDL, low density lipoprotein.

level of RANTES was significantly elevated (median 5.3 ng/mL) compared with NHcy controls (3.5 ng/mL) (Table 2).

Chemokine secretion from isolated monocytes in response to LPS To test whether monocytes isolated from patients with HHcy exhibited enhanced inflammatory response of RANTES production, monocytes were incubated with low-dose LPS (0.01 μg/mL) for 24 h. As shown in Figure 1, RANTES production was not significantly increased in HHcy patients without LPS stimulation, but LPS treatment (0.01 μg/mL) significantly increased the level of RANTES secretion of monocytes from HHcy patients compared with that of NHcy controls. Thus, monocytes from patients with HHcy may show an enhanced RANTES secretion response in a pro-inflammatory condition.

Effect of Hcy on RANTES mRNA expression To determine whether Hcy modulates the expression of RANTES mRNA, total RNA was isolated from normal human monocytes treated with Hcy at various times and at different concentrations. As shown in Figure 2, RNase protection

Cells were incubated with LPS (0.01 μg/mL) for 24 h, and the production of RANTES from monocytes was assessed by ELISA. Data are presented as median and ranges (Kruskal-Wallis one-way ANOVA test). *n*=38 in NHcy control group. *n*=40 in HHcy group. Mean±SD.

assays revealed that the expression of RANTES mRNA was significantly enhanced after Hcy treatment. Cultured monocytes incubated with Hcy (10–1000 μmol/L) for 8 h showed significantly increased RANTES expression as compared with untreated cells (Figure 2A), beginning as low as Hcy 10 μmol/L. The increased level of RANTES mRNA after incubation with Hcy 100 μmol/L peaked at 4–8 h after incubation (Figure 2B).

Discussion

The results from the present study demonstrated that the plasma RANTES level was elevated in HHcy individuals and RANTES secretion from monocytes was increased. We also provided evidence that Hcy directly induced RANTES mRNA synthesis from isolated human monocytes.

Atherosclerosis is a chronic inflammatory disease char-

Figure 2. Effect of Hcy on RANTES mRNA expression. A, Representative autoradiogram of RNase protection assay for RANTES, L-32, and GAPDH mRNA in cultured human monocytes treated with Hcy 10–1000 $\mu\text{mol/L}$ for 8 h. B, Representative autoradiogram of RNase protection assay for RANTES, L-32, and GAPDH mRNA in human monocytes treated with Hcy 100 $\mu\text{mol/L}$ for the indicated times. Data are representative of at least three independent experiments (the monocytes were isolated from different subjects).

acterized by the recruitment of monocytes and lymphocytes to the artery wall. Increasing evidence supports the involvement of inflammation in the early phases of atherosclerosis. Recruitment of leukocytes within the vascular wall is an essential process in the development of this common disease, which is mainly regulated by adhesion to molecules and chemokines^[3,4]. In the classic inflammatory response, adhesion is followed by transmigration of the leukocytes through the endothelial layer into the intima. This process is also mediated by chemotactic factors.

A number of studies have determined the important role of chemokines such as MCP-1 and IL-8 in the initial stages of atherosclerotic plaque formation^[5,6]. RANTES, a CC chemokine, has been found to play an important role in autoimmune injury to several tissues. RANTES is generated by circulatory lymphocytes and some kinds of tissue cell monocytes. RANTES is nearly as potent a chemoattractant for monocytes as MCP-1. RANTES induces leukocyte transendothelial migration, implicated in the initial stages of the inflammatory part of the atherosclerotic process^[13]. Furthermore, evidence implies the important role RANTES plays in atherosclerosis. Simeoni *et al*^[14] reported that a mutant RANTES genotype was associated with the increased coronary heart disease death rate, independent of conventional risk factors. A causal role for RANTES in atherosclerosis was also shown by a protective effect of the blockage of RANTES receptors with the CC chemokine antagonist Met-RANTES in an ApoE-deficient hypercholesterolemic mouse model^[15]. These data suggest that the alteration of the level of the chemokine RANTES may affect the progress

of atherosclerosis through the inflammatory pathway.

Hyperhomocysteinemia is found in 30% of patients with premature atherosclerosis of carotid and peripheral arteries. Elevated plasma Hcy levels have been implicated as an independent risk factor for coronary heart disease^[16,17]. Therefore, intensive studies have focused on whether HHcy is the cause or merely a marker for cardiovascular disease. Hcy significantly enhances MCP-1 and IL-8 levels in healthy human monocytes, which can increase leukocyte chemotaxis^[7]. However, compared with studies of MCP-1 and IL-8, little study has focused on RANTES secretion in HHcy. Economou *et al*^[17] reported the negative association of circulating Hcy and RANTES in prepubescent lean children. Until now, no direct evidence of the relation between HHcy and RANTES in human monocytes exists.

In the present study, we found that both the plasma level of RANTES and low-dose LPS-induced RANTES production in isolated monocytes from patients with HHcy were significantly elevated. Hcy not only increased the RANTES level in HHcy patients but also increased RANTES gene expression in primary human monocytes. Thus, our results support our hypothesis that HHcy may play an important role in the pathogenesis of atherosclerosis through a mechanism involving an increase in RANTES secretion in human monocytes.

Our recent published data show that folate acid treatment in HHcy patients can reverse the hyper-responsiveness of MCP-1 and IL-8 secretion from monocytes^[8]. On the basis of the current results, further study should focus on whether the intervention of HHcy influences monocyte-derived RANTES secretion and also the exact mechanism underlying the Hcy-upregulated RANTES production.

Important Announcement: the Online Manuscript Submission and Review System was Launched!

Acta Pharmacologica Sinica is happy to announce that the online manuscript submission and review system, ScholarOne Manuscript Central (<http://mc.manuscriptcentral.com/aphs>), was launched on May 25, 2005.

As the leading web-based peer-review system, Manuscript Central is a complete, database-driven software for the online submission and review of full-text manuscripts and graphics. The system provides fully electronic workflow and will speed up the time from submission to decision.

We strongly recommend authors to submit manuscript via this system, which enables us to handle your manuscript quickly and efficiently. Please read the User Guide before submitting your manuscript online. For more detailed submission instruction, please consult the Manuscript Central Online User Guide (<http://mcv3help.manuscriptcentral.com/tutorials/>). You may also contact the Editorial Office who will be pleased to help you.

Abstract

Aim: To use membrane-interaction quantitative structure-activity relationship analysis (MI-QSAR) to develop predictive models of partitioning of organic compounds in gastrointestinal cells. **Methods:** A training set of 22 structurally diverse compounds, whose apparent permeability across cellular membranes of Madin-Darby canine kidney (MDCK) cells were measured, were used to construct MI-QSAR models. Molecular dynamic simulations were used to determine the explicit interaction of each test compound (solute) with a dimyristoyl-phosphatidyl-choline monolayer membrane model. An additional set of intramolecular solute descriptors were computed and considered in the trial pool of descriptors for building MI-QSAR models. The QSAR models were optimized using multidimensional linear regression fitting and the stepwise method. A test set of 8 compounds were evaluated using the MI-QSAR models as part of a validation process. **Results:** MI-QSAR models of the gastrointestinal absorption process were constructed. The descriptors found in the best MI-QSAR models are as follows: 1) $ClogP$ (the logarithm of the 1-octanol/water partition coefficient); 2) E_{HOMO} (the highest occupied molecular orbital energy); 3) E_s (stretch energy); 4) PM_Y (the principal moment of inertia Y , the inertia along the y axis in the rectangular coordinates); 5) C_t (total connectivity); and 6) E_{nb} (the energy of interactions between all of the non-bonded atoms). The most important descriptor in the models is $ClogP$. **Conclusion:** Permeability is not only determined by the properties of drug molecules, but is also very much influenced by the molecule-membrane interaction process.

Introduction

A majority of drugs used today are taken orally, so the drugs must traverse several semipermeable cell membranes before reaching the systemic circulation^[1]. These membranes are biological barriers that selectively inhibit the passage of drug molecules and are composed primarily of a bimolecular lipid matrix, containing mostly cholesterol and phospholipids. The lipids provide stability to the membrane and determine its permeability characteristics. Drugs can cross a biological barrier by passive diffusion, facilitate passive diffusion, active transport, and pinocytosis, but passive diffusion is the most common method^[1]. In the small intestine, in which the major part of oral drug absorption occurs, the barrier to drug absorption is a membrane comprising intestinal columnar

epithelial cells. For any novel drug that is developed, it is necessary to examine how it is absorbed in the small intestine. In the absorption process, transport across a cell membrane depends on the concentration gradient of the solute. Most drug molecules are transported across a membrane by simple diffusion from a region of high concentration (eg gastrointestinal fluids) to one of low concentration (eg blood)^[2]. Because drug molecules are rapidly removed by the systemic circulation and distributed into a large volume of body fluids and tissues, drug concentration in the blood is initially low compared with that at the administration site, producing a large gradient. The diffusion rate is directly proportional to the gradient, but also depends on the molecule's lipid solubility, degree of ionization, and the size and the area of the absorptive surface^[3]; that is, the diffusion rate depends

on the characteristics and area of the intestinal membrane and the drug's properties, as well as the drug concentration gradient on both sides of the membrane.

Given the limitations of biomembranes, artificial membranes are usually used instead of biomembranes to study the absorption of drugs in the intestine. *In vitro* studies show that artificial membranes have some properties that are similar to those of biomembranes *in vivo*; that is, artificial membranes can be good mimics of biomembranes^[3-5]. The Caco-2 cell monolayer is commonly used as an artificial membrane. When cultured on semipermeable membranes, Caco-2 cells, which are derived from a human colon adenocarcinoma, differentiate into a highly functionalized epithelial barrier with remarkable morphological and biochemical similarity to small intestinal columnar epithelium. The P_{app} values obtained from Caco-2 transport studies have been proven to correlate with those of human intestinal absorption, and the Caco-2 monolayer model has been proven to be extremely useful as a tool for mechanistic studies of drug absorption^[3]. However, although the Caco-2 model is well characterized and has been proven to be useful, assays using the system are not perfect. The system requires a 3-week growth period and regular maintenance feeding, so it remains a relatively low throughput method. Irvine and co-workers tried another system using Madin-Darby canine kidney (MDCK) cells and found that it was possibly a useful tool for testing rapid membrane permeability^[3]. MDCK cells are commonly used for studying cell growth regulation, metabolism, and transport mechanisms in distal renal epithelia. They can also differentiate into columnar epithelia and form tight junctions when cultured on semipermeable membranes. Irvine and co-workers studied a large number of compounds using both MDCK and Caco-2 assays to evaluate the suitability of MDCK cells as a possible tool for assessing membrane permeability and found that they were well suited. Others have also pointed out that MDCK cells are good candidates for modeling simple epithelia^[6].

Based on the study carried out by Irvine and coworkers, we built membrane-interaction quantitative structure-activity relationship analysis (MI-QSAR) models to predict drug permeability through MDCK cells. The QSAR approach involves statistical analysis of various molecular descriptors for a series of biologically active molecules. The result of a QSAR study provides useful clues regarding the type of substituents that should be tested to improve the activity further. QSAR can play a vital role in lead exploitation. One successful example is the transformation of nalidixic acid with the help of QSAR into an important family of drugs: the quinolone carboxylates^[7]. Since the method was established

in the 1960s, QSAR equations have been used to describe the biological activities of thousands of different drugs and drug candidates^[8,9]. Some new approaches have been used in QSAR since its initial development, for example, principal component analysis (PCA), partial least squares (PLS), artificial neural network (ANN)^[10]. MI-QSAR is an advanced form of QSAR, in which membrane-interaction properties are added to the descriptor pool. MI-QSAR models predicting drug permeability through Caco-2 cells have been built by Kulkarni and co-workers^[11]. In the present study, we built MDCK cell models for MI-QSAR analysis.

Materials and methods

MDCK cell permeation coefficients The dependent variable used in MI-QSAR analysis is the MDCK cell permeability coefficient, P_{app} . Irvine and co-workers performed permeability experiments on a data set of 55 structurally and chemically diverse drugs ranging in molecular weight from 130 to 470 and varying in net charge at pH 7.4^[3]. MDCK cells were obtained from the American Type Culture Collection (ATCC; Rockville, MD, USA). MDCK cells were maintained in minimal essential medium containing 10% fetal bovine serum and fresh *L*-glutamine 2 mmol/L. Culture inserts were preincubated with culture medium at 37 °C for 1 h and then seeded with 6.64×10^5 cells per cm^2 . MDCK monolayers were washed and fed with fresh medium 1 h post-seeding and again 24 h post-seeding. After 3 d of culturing, MDCK monolayers could be used to test the permeability of compounds. All compounds were tested in 6 replicate monolayers. Monolayers were incubated with donor and acceptor solutions for 60 min at 37 °C, 95% humidity, with 30 r/min reciprocal shaking^[3,12]. The permeability coefficient was calculated according to the following equation^[3]:

$$P_{app} = \left(\frac{dQ}{dt} \right) \times \frac{1}{C_0} \times \frac{1}{A} \quad (1)$$

In this equation dQ/dt is the permeability rate, C_0 is the initial concentration in the donor compartment, and A is the surface area of the filter.

Table 1 contains the P_{app} values for 22 structurally diverse drugs used as a training set of compounds and 8 drug compounds as a test set. The 22 training set compounds and 8 test compounds were selected according to the criterion that members of the test set were to be representative of all members of the training set in terms of the range of P_{app} values, molecular weights, and structural and chemical diversities, to achieve a composite representative subset. Table 1 also contains a composite summary of the human

percentage absorption values of many of the drugs in the table. These data were obtained from published values. Compared with the P_{app} value and the human percentage absorption value, it is obvious that the P_{app} values are indicative of *in vivo* drug uptake. Figure 1 shows the structures of these thirty molecules.

Building solute molecules and a dimyristoyl-phosphatidyl-choline (DMPC) monolayer All the solute molecules of the training set and test set were built using HyperChem software^[13]. A single DMPC molecule was built using HyperChem from the published crystal structure data^[14]. The

DMPC molecule was selected as the model phospholipid in this study. The structure of the DMPC molecule is shown in Figure 2. An assembly of 25 DMPC molecules, $5 \times 5 \times 1$ in x , y , and z directions, respectively, was used as the model membrane monolayer. The size of the monolayer simulation system was selected based on the work done by van der Ploeg and Berendsen^[15]. These workers built 2 decanoate bilayers, with $2 \times 8 \times 2$ and $2 \times 16 \times 2$ phospholipid molecules, respectively, and performed a molecular dynamic simulation for each of them. It was found that the estimated order parameters for these 2 model bilayers agreed with one another, which suggests that the smaller assembly is adequate for modeling short-range properties. Other researchers have obtained similar geometric and energetic equilibrium property values with regard to the size of the simulation system that permits a minimum effective size (phospholipids) of the monolayer to be defined^[16].

To prevent unfavorable van der Waals' interactions between solute molecules and the membrane DMPC molecules, the single DMPC molecule in the center of the monolayer, which was located at position $x, y=3,3$ of the 5×5 DMPC monolayer model, was taken out^[11], creating a space for the test solute molecules to insert into. Each of the test solute molecules of the permeation data set was inserted at 3 different positions or depths in the DMPC monolayer, with the most polar group of the solute facing toward the head group region of the monolayer. Three corresponding MDS (molecular dynamic simulation) models were generated for each solute molecule with regard to the trial positions of the solute molecules in the monolayer. The 3 trial positions were as follows^[4,5,17]: solute molecule in the head group region, solute molecule between the head group region and the aliphatic chains, and solute molecule in the tail region of the aliphatic chains.

The energetically favorable geometry of the solute molecule in the monolayer was sought after using each of these trial positions. The 3 different positions of AZT, one of the training set solute molecules, are shown in Figure 3A to illustrate this modeling procedure. The most energetically favorable geometry of this solute molecule in the model DMPC monolayer is shown in Figure 3B.

Molecular dynamic simulations MDS were carried out using the Discover module in Material Studio^[18] with compass force field and NVT ensemble (an ensemble in which the dynamics are modified to allow the system to exchange heat with the environment at a controlled temperature). The selection of the simulation temperature was based on the phase transition temperature for DMPC, which was 297 K^[11]. A simulation temperature of 311 K was selected because it is

Figure 1. Structures of training set compounds and test set compounds.

Figure 2. Chemical structure of a DMPC molecule.

body temperature, and it is also above the DMPC phase transition temperature. Temperature was held constant in the MDS by coupling the system to an external fixed temperature bath. The trajectory step size was 0.001 ps over a total simulation time of 10 ps for each solute of the training set and test set. After 10 ps of simulation, molecule-membrane interactions arrived at an energetically stable phase (Figure 4). Two-dimensional periodic boundary conditions were used ($a=32 \text{ \AA}$, $b=32 \text{ \AA}$, $c=80 \text{ \AA}$, and $\gamma=96.0^\circ$) for the

Figure 3. (A) “Side” view of an AZT molecule inserted at 3 different positions in the DMPC model monolayer, prior to the start of each simulation; (B) “Side” view of the most energetically favorable geometry of AZT in the DMPC model monolayer.

Figure 4. Total potential energy vs trajectory step number for acyclovir embedded in the model DMPC monolayer.

DMPC molecules of the monolayer model, but not the test solute molecule. Only a single solute molecule was explicitly considered in each MDS. The angle γ is the angle that an extended DMPC molecule makes with the “planar surface” of the monolayer. Each of the solute molecules was placed at each of the 3 different positions in the monolayer, as described earlier, with the most polar portion of the solute “facing” toward the head group region. A snapshot of molecule AZT and the membrane around it was taken after MDS, as shown in Figure 3b.

Calculation of descriptors Both intramolecular physi-

cochemical properties and features of the solute molecules and intermolecular solute-membrane interaction properties were calculated. These properties and features will both be referred to as descriptors from this point forward because they constitute the trial pool of independent variables used to build the QSAR models. The descriptors used in the MI-QSAR analysis can also be divided into the following 3 kinds: 1) solute aqueous dissolution and solvation descriptors; 2) solute-membrane interaction descriptors; and 3) general intramolecular solute descriptors. Table 2 and Table 3 reporting the trial pool of descriptors used in the MDCK cell permeation MI-QSAR modeling use both classifications of the descriptors.

The general intramolecular solute descriptors included as part of the trial descriptor pool are defined in Table 2. The term “general” is used because solute descriptors in this class may be useful in describing different aspects of the bioavailability (in this case the MDCK cell permeation process) of a solute. There are other intermolecular properties computed using intramolecular computational methods, which are not included in Table 2, for example $ClogP$ (the logarithm of 1-octanol/water partition coefficient), MP (melting point), T_c (critical temperture), Sol (water solubility). All of these descriptors are intermolecular properties. They

Table 2. General intramolecular solute descriptors used in the MI-QSAR descriptor pool.

Descriptors	Explanation of descriptors
HOMO	Highest occupied molecular orbital energy
LUMO	Lowest occupied molecular orbital energy
D_p	Dipole moment
V_m	Molecular volume
SA	Molecular surface area
MW	Molecular weight
MR	Molecular refractivity
$PM(x,y,z)$	Principal moment of inertia along the x,y,z axis in the rectangular coordinate
HF	Heat of formation (Δh_f) for the structure at 298.15 K and 1 atm
H	The logarithm of Henry’s law constant
G	Standard Gibbs free energy
Ovality	The ratio of the molecular surface area to the minimum surface area, which is the surface area of a sphere having a volume equal to the solvent-excluded volume of the molecule
E_b	Sum of the angle bending terms of the force-field equation
E_c	Sum of the electrostatic energy representing the pairwise interaction of charged atoms
E_v	Sum of pairwise van der Waals’ interaction energy terms for atoms separated by more than 3 chemical bonds
E_s	Stretch energy, the energy contribution associated with the deformation of a bond from its equilibrium bond length
E_{sb}	Sum of the stretch-bend coupling terms of the force-field equation
E_t	Sum of the dihedral bond rotational energy term of the force-field equation
E14	Sum of pairwise van der Waals’ interaction energy terms for atoms separated by exactly 3 chemical bonds
NRE	Repulsion energy
C_t	A kind of index defined according to the number of atoms and bonds and how they connect together

are classified as solvation and dissolution intermolecular descriptors and are reported in Table 3b. In Table 3a, there are solute-membrane interaction descriptors extracted directly from the MDS trajectories. These intermolecular descriptors were calculated using the most stable (lowest total potential energy) solute-membrane geometry from the 3 positions sampled for each of the solutes. For example, Figure 3b shows the lowest potential energy state of AZT in the membrane monolayer, which was used to estimate the solute-membrane interaction descriptors. Other solute-membrane interaction descriptors used in the QSAR descriptor trial set were determined using data from the MDS trajectories.

Construction and testing of MI-QSAR models Independent and useful descriptors can be extracted from all descriptors calculated earlier. The methods in common use are forward regression, backward regression and stepwise regression. Stepwise regression is the method used most frequently. The resulting regression equation from the stepwise regression method is not the best, rather it is an optimized result. SPSS was used to obtain the regression equation; it selected proper variables according to the partial sum of squares of regression in every step. The partial sum of squares for regression means that the sum of squares for regression increased or decreased after one variable was

added to or deducted from the present regression equation. A parameter, F , is defined to check whether to introduce a variable or reject it when partial sum of squares for regression is of some value.

The stepwise regression method was used in this study, which was the combination of forward regression and backward regression methods. The single worst variable was picked out after each new variable was added. Two threshold constants, F_{entry} and F_{removal} ($F_{\text{entry}} < F_{\text{removal}}$), were given before the regression. If the F value of one variable, which had the largest partial sum of squares for regression of all the variables not included in the regression equation, was larger than or equal to F_{entry} , the variable could be introduced into the equation. Conversely, if the F value of one variable, which had the smallest partial sum of squares for regression among all the variables included in the regression equation, was less than or equal to F_{removal} , the variable should be removed from the regression equation. These steps were carried out alternately until there was no variable to be introduced into the regression equation and none to be removed from it. The adjustment of the threshold values F_{entry} and F_{removal} could affect the result of the selection of variables. If the prepared variables were few, it was appropriate to increase F_{entry} in order to introduce variables to the regression

Table 3. Intermolecular interaction descriptors in the trial MI-QSAR descriptor pool.

Part a	
Membrane-solute descriptors	Description of the membrane-solute descriptors
Potential	The energy of a particle or system of particles derived from position, or condition, rather than motion
Electrostatic	The energy created by the interaction of charges between the molecule and the membrane
E_{nb}	The energy of interactions between non-bonded atoms
Angle	Valence angle bending
Bond	Bond stretching
Torsion	Dihedral angle torsion
Out-of-plane	Part of nearly all force fields for a covalent system
Part b	
Dissolution and solvation-solute descriptors	Description of the dissolution and solvation-solute descriptors
ClogP	The logarithm of 1-octanol/water partition coefficient
MP	The melting point for the structure at 1 atm
Tc	The temperature above which the gaseous form of the structure cannot be liquefied, no matter what pressure is applied
Sol	Solubility of the structure in water at 25 °C

Note: Part a includes the membrane-solute interaction descriptors and Part b lists the intermolecular dissolution and solvation descriptors of the solute.

equation as much as possible. If the prepared variables were too many, F_{removal} could be decreased to cut down the number of variables introduced into the regression equation.

SPSS was used to carry out the regressions and construct the models^[19].

Results and Discussion

The best MI-QSAR models for MDCK cell permeability were realized by considering the combination of general intramolecular solute, intermolecular dissolution/solvation solute, and intermolecular membrane-solute descriptors presented as a function of the number of terms, that is, descriptors, included in a given MI-QSAR model:

$$P_{\text{app}} = 115.657 + 319.687 \text{Clog}P$$

$$n=22 \quad R^2=0.646 \quad S=0.396 \quad (2)$$

$$P_{\text{app}} = 3113.84 + 374.691 \text{Clog}P + 338.881 E_{\text{HOMO}}$$

$$n=22 \quad R^2=0.719 \quad S=0.362 \quad (3)$$

$$P_{\text{app}} = 3115.743 + 399.894 \text{Clog}P + 374.586 E_{\text{HOMO}} + 35.07 E_s$$

$$n=22 \quad R^2=0.764 \quad S=0.341 \quad (4)$$

$$P_{\text{app}} = 3453.482 + 409.333 \text{Clog}P + 391.596 E_{\text{HOMO}} + 48.403 E_s - 0.0971 \text{PM}_Y$$

$$n=22 \quad R^2=0.813 \quad S=0.312 \quad (5)$$

$$P_{\text{app}} = 3609.933 + 387.817 \text{Clog}P + 356.922 E_{\text{HOMO}} + 32.256 E_s - 0.163 \text{PM}_Y - 16594 C_1$$

$$n=22 \quad R^2=0.866 \quad S=0.272 \quad (6)$$

$$P_{\text{app}} = 1029.094 + 398.972 \text{Clog}P + 459.781 E_{\text{HOMO}} + 24.048 E_s - 0.174 \text{PM}_Y - 18164.4 C_1 + 2.594 E_{\text{nb}}$$

$$n=22 \quad R^2=0.896 \quad S=0.248 \quad (7)$$

where n is the number of compounds, R^2 is the coefficient of determination, and S is the standard error of the estimate (and its value could be different if the unit of the variables changed). The descriptors found in the best MI-QSAR models are as follows: 1) $\text{Clog}P$ is the logarithm of the 1-octanol/water partition coefficient; 2) E_{HOMO} is the highest occupied molecular orbital energy; 3) E_s is stretch energy, the energy contribution associated with the deformation of a bond from its equilibrium bond length; 4) PM_Y is principal moment of inertia Y , the inertia along the y axis in the rectangular coordinates; 5) C_1 is total connectivity, which is a kind of index defined according to the number of atoms and bonds and their connecting sequence (C_1 is a structural parameter; molecules with different structures have different connectivity indices according to a given definition); and 6) E_{nb} is the energy of interactions between all of the non-bonded atoms.

The values of the 6 descriptors found in the 1–6 term MI-QSAR models for each compound in the training set and test set are given in Table 4.

The observed and predicted (using the 3–6 term MI-QSAR models) MDCK cell permeation coefficients of the training and test set compounds are listed in Table 5 and plotted in Figure 5. Corticosterone, ondansetron, phenytoin, progesterone, propranolol hydrochloride, and testosterone are observed to permeate better than predicted by each of the MI-QSAR models, whereas acetylsalicylic acid, bupropion hydrochloride, methylprednisolone, and nadolol have a lower permeation coefficient than the one predicted by any of the models. Nevertheless, none of the compounds in either the training or test sets are outliers for the 3–6 term MI-QSAR models. Figure 6 contains plots of R^2 and S for the training set. R^2 increases with increasing numbers of descriptor terms, whereas the value of S decreases when the number of descriptor terms increases.

Figure 5. Observed versus predicted MDCK cell permeability coefficients for all the compounds of the training and test sets in the corresponding MI-QSAR model.

Figure 6. Diagnostic plot of the MI-QSAR. R^2 is the correlation coefficient and S is standard error of the estimate in the regression progress.

Analyzing Equations 2–7, it appears that $\text{Clog}P$ in the 1-term model accounts for much of the variance of P_{app} across the training set. Both principal moment of inertia Y and total

connectivity have a negative effect on the permeation coefficient. In 1-term to 5-term models, the descriptors are all intramolecular descriptors, but in the 6-term model, one membrane-solute interaction descriptor, E_{nb} , is added in.

Eight compounds from the parent MDCK cell permeation coefficient data were selected to construct a test set to validate the MI-QSAR models. The molecules of the test set were selected so as to span the entire range of MDCK cell permeability for the composite training set. At the bottom of Table 5 are the observed and predicted P_{app} values for this test set. Figure 5 plots the test set as the last 8 compounds. There are no outliers, but antipyrine and guanabenz, compounds 1 and 3 of the test set, are predicted to have lower permeability coefficients than observed. Conversely,

dexamethasone, hydrocortisone, propylthiouracil and AZT have higher predicted P_{app} values in all the models than the observed value.

The most important descriptor in the models is ClogP. ClogP is the computed logarithm of the 1-octanol/water partition coefficient, and it has been ubiquitously used as a quantitative measure of hydrophobicity/lipophilicity since the 1960s^[20,21]. A high ClogP value of a molecule implies that the molecule dissolves easily in hydrophobic materials and dissolves poorly in water. In the MI-QSAR models we built, ClogP had a positive effect on P_{app} , which implies that chemicals with high lipophilicity have better permeability through membranes than hydrophilic structures. It is easy to see why this is the case, because biomembranes are mainly composed

of double phospholipid layers, so small hydrophobic molecules can pass through the layer with little obstruction. Commonly, lipophilic drugs permeate the small intestinal columnar epithelium quicker and easier than hydrophilic drugs.

In Equation 3, another descriptor, E_{HOMO} appears, which represents HOMO energy. HOMO energy is the energy of the highest occupied molecular orbit, which is the opposite of LUMO energy, the energy of the lowest unoccupied molecular orbit^[22]. The greater E_{HOMO} is, the greater the electron-donating capability; conversely, the smaller E_{LUMO} is, the smaller the resistance to accept electrons. Compounds that present larger values of E_{HOMO} are more electron donor and the compounds that present smaller values of E_{LUMO} are

more electron acceptor. These variables are interpreted as measures of molecular reactivity and stability. As E_{HOMO} increases (relative to other molecules), the molecule is less stable and more reactive. For E_{LUMO} , the situation is the opposite. HOMO energy is relevant because Equation 3 measures the electron-donating character of the drug molecules. P_{app} has a positive relationship with HOMO energy, which means that drug molecules with higher electron-donating capacities can permeate membranes better.

As seen in the literature, energy is often discussed in many research programs. There is another energy descriptor, stretch energy, which influences P_{app} as E_{HOMO} does in our models. Stretch energy is the energy contribution associated with the deformation of a bond from its equilibrium bond

length. It is a kind of vibration energy, which is composed of bend energy and stretch energy. From Models 3–6, we can see that stretch energy is positively correlated with the value of P_{app} . Increasingly positive stretch energy values correspond to increasing P_{app} . Drug molecules with higher stretch energies metamorphose better and can permeate membranes more easily.

PM_y is the principal moment of inertia along the y axis. It gives information about how the product of force and distance influence the value of P_{app} . P_{app} decreases as the value of PM_y increases. The coefficients of PM_y in Models 4–6 are very small when contrasted with the coefficients of other variables. This indicates that a change in PM_y value has comparatively little effect on the value of P_{app} and the permeability of the drug molecules.

Compared with the descriptors discussed earlier, connectivity is an element that rarely appeared in QSAR models constructed by other researchers. Connectivity is a parameter defined according to the conformation of a molecule, and presumes that there is some functional relationship between molecule properties and connectivity. One standard definition of connectivity is as follows^[23,24]:

Figure 7 is the structure of isopentanol without hydrogens. The figures are the bond numbers of each carbon connected with other carbons.

Figure 7. Structure of isopentanol without hydrogens.

$$Connectivity = \frac{1}{\sqrt{1 \times 3 \times 2 \times 1 \times 1}} \quad [24]$$

From the foregoing equation, we can see that connectivity reflects the connection and ramification conditions of the molecules. Connectivity is the quantitative description of the molecular structure. Molecules with different structures have different connectivity values. The connectivity method has been widely used in structure-activity analyses. In the models we constructed, connectivity is included in Model 5 and Model 6 and it has a negative effect on the P_{app} value. The larger the connectivity value, the more complicated the structure will be, and there will be more branch chains. Therefore an increase in connectivity will decrease the permeability of a molecule.

E_{nb} is the energy of interactions between non-bonded atoms. It includes van der Waals' energy, electrostatic energy and hydrogen bond terms in some older forcefields, as the following equation describes^[25],

$$E_{non-bond} = E_{vdW} + E_{coulomb} + E_{hbond} \quad (8)$$

The non-bond energy terms in Equations 6 and 7 suggest that permeability increases with increasing binding of the solute to the phospholipid regions of the membranes.

Kulkarni and coworkers carried out MI-QSAR analysis using the permeability coefficients of some drug molecules tested by Caco-2 cells. Thirty molecules were included in their training set, and significant MI-QSAR models were built. Twenty-three intramolecular descriptors, and 11 membrane-solute interaction descriptors were calculated. In our study, we calculated more than 70 descriptors for every drug molecule in the training set, including electronic, steric, and thermodynamic properties. MI-QSAR models were built based on the analysis of these descriptors. In addition, the present study confirmed the conclusion of Irvine and coworkers, that MDCK cells are suitable for studying drug permeability through biomembranes.

Abstract

Aim: To investigate the protective effects of berberine on ethanol-induced gastric ulcer in mice. **Methods:** Gastric ulcers were induced by oral ingestion of ethanol. Nitric oxide (NO) content was measured, and mRNA expression of endothelial nitric oxide synthase (eNOS) and inducible nitric oxide synthase (iNOS) were analyzed by reverse transcription-polymerase chain reaction (RT-PCR). **Results:** The ulcer index (UI) at 1 h, 2 h, 3 h and 6 h after oral administration of ethanol was 23.8±1.4, 23.3±2.2, 22.3±1.2 and 20.8±1.1, respectively. The UI in the berberine-treated groups (5 mg/kg and 50 mg/kg) was less than the control group. The content of NO in the control group was 73.3±7.3 µL/L, 94.0±9.2 µL/L, 109.6±6.4 µL/L and 138.2±10.2 µL/L in gastric juice and 5.8±1.1 µmol/g protein, 8.3±1.1 µmol/g protein, 9.8±1.1 µmol/g protein and 11.9±1.2 µmol/g protein in gastric tissue at 1 h, 2 h, 3 h and 6 h, respectively, after the oral administration of ethanol. The content of NO in the berberine-treated groups (5 mg/kg and 50 mg/kg) was higher than the control group at 1 h after the oral administration of ethanol ($P<0.05$), and was lower at 6 h ($P<0.05$). Analysis by RT-PCR showed that expression of eNOS was inhibited but iNOS expression was enhanced by ethanol. However, the expression of eNOS could be enhanced and iNOS expression could be inhibited by berberine ($P<0.01$). **Conclusion:** Berberine could significantly protect gastric mucosa from damage by ethanol. This effect may be related to the increased expression of eNOS mRNA and inhibited expression of iNOS mRNA.

Introduction

Berberine, also known as huangliansu, is an isoquinoline alkaloid derived from the Chinese herb Huanglian, Huangbai and other plants. It has multiple pharmacological actions, such as antibacterial activity and anti-inflammatory effects, and is used in the treatment of diarrhea and other digestive disorders^[1]. Berberine has been found to protect the gastric mucosa and inhibit gastric ulcers^[2], but the pharmacological mechanisms for the protective effect of berberine are not clear. Accumulating evidence from both animal and human studies indicates that nitric oxide (NO) plays a key role in normal wound repair. The beneficial effects of NO on wound repair may be attributed to its functional influences on angiogenesis and inflammation^[3]. A recent study demon-

strated that NO generated from endothelial nitric oxide synthase (eNOS) played an important role in gastric ulcer formation and gastric healing^[4]. However, NO generated from inducible nitric oxide synthase (iNOS) participates in ulcer formation through the production of peroxide free radicals and their cytotoxic action^[5]. At the same time, it was reported that berberine could induce the thoracic aorta of rats to release endothelial NO^[6], and 13-methylberberine and 13-ethylberberine reduced the production of NO and the expression of iNOS protein in a concentration-dependent manner in lipopolysaccharide (LPS)-stimulated macrophages^[7]. We therefore inferred that it was possible for berberine to protect the gastric mucosa and accelerate the healing of peptic ulcers through the NO pathway. In the present study, we

attempted to investigate whether the protective effect of berberine on gastric mucosa was related to NO and nitric oxide synthase (NOS).

Materials and methods

Drugs and reagents Berberine was supplied by Prof Jialin WANG (Department of Pharmacology, Tongji Medical College, Huazhong University of Science and Technology, Wuhan, China). The NO kit was supplied by Nanjing Jian Cheng Bioengineering Company (Nanjing, China).

Animals The present study was carried out using 72 Kunming mice (Certificate No SYXK 2004-0028) weighing 18 g–22 g from the Experimental Animal Center of Tongji Medical College. Both sexes were used. They were kept in separate cages at room temperature and deprived of food 24 h before oral administration of ethanol but were allowed free access to water.

Induction of gastric ulcer Gastric ulcers were produced by oral administration of ethanol 24 h after starvation. Each of the mice was given 0.1 mL ethanol (100%, anhydrous alcohol).

Drugs treatments and measurement of ulcer size Animals were divided into 3 groups of 24 mice each. Group I received saline at a dose of 0.1 mL/kg (ip) and served as the control group. Group II received berberine at a dose of 5 mg/kg (ip) while group III received berberine at a dose of 50 mg/kg (ip).

Drugs were given 30 min before the oral administration of ethanol. The mice were killed by cervical dislocation 1 h, 2 h, 3 h and 6 h after oral administration of ethanol, and the gastric juice was sucked from the stomach before the stomach was removed. It was then opened along the greater curvature and the mucosa of the glandular portion of the stomach was rinsed gently with saline. Macroscopic damage was assessed and the number of ulcers, ulcer severity and ulcer index (UI) were recorded. Because each mouse had many lesions or ulcers and most gastric mucosal lesions were punctate or linear, each ulcer was graded according to severity using a scale of 1–4, as follows: 1, punctate ulcer; 2, linear ulcer of length ≤ 2 mm; 3, linear ulcer of length 2 mm–4 mm; and 4, linear ulcer of length ≥ 4 mm. The UI was calculated by summing the total number of ulcers, as described previously^[8,9]. The gastric tissues were stored at -70 °C until biochemical analysis.

Measurement of nitric oxide The content of nitric oxide in the gastric juice and gastric tissue was measured through the method of nitric acid reductase, and the operational processes were carried out strictly in accordance with the NO kit instructions.

Reverse-transcription polymerase chain reaction for the

detection of eNOS and iNOS mRNA The stomachs were removed from the saline-treated (0.1 mL/kg) and berberine-treated (50 mg/kg) groups both before and after ulcer induction (1 h, 3 h and 6 h) for the determination of eNOS and iNOS mRNA expression by reverse transcription-polymerase chain reaction (RT-PCR) using specific primers. Total RNA was isolated from gastric tissues using Trizol reagent (Gibco BRL, Gathersburg, MD, USA). First-strand cDNA was synthesized from 5 μ g of total cellular RNA using oligo-(dt)₂₀ primers with the thermoscript RT-PCR system (Gibco BRL). PCR cycles were carried out for amplification of eNOS, iNOS and β -actin cDNA using a thermal cycler (Perkin-Elmer Corporation 850 Lincoln Centre Drive, Foster City, California, USA) and oligonucleotides (Boya, Shanghai, China). The primers for eNOS were 5'-TTCCGGCTGCCACCTGATCCTAA-3' (sense) and 5'-AACATA TGT CCT TGC TCA AGG CA-3' (antisense)^[10]. The β -actin primer sequences for iNOS were 5'-CGG GCA TTG CTC CCT TCC GAAAT-3' (sense) and 5'-CTT CAT GAT AAC GTT TCT GGC TCT-3' (antisense)^[11]. The oligonucleotide primer sequences for β -actin were 5'-TCACCCACACTG TGC CCA TCT ACG A-3' (sense) and 5'-GGATGC CACAGG ATT CCA TAC CCA-3' (antisense). The number of PCR cycles was adjusted carefully to avoid saturation of the amplification system. In the RT step, the cellular mRNAs were reverse-transcribed into a "library" of cDNAs. This cDNA library was then used for the analysis of various genes in the PCR step. Briefly, total RNA (2.5 μ g) from each of the tissues was reverse transcribed into single-stranded cDNA in a 20- μ L reaction mixture containing: 4 μ L 5' buffer, 20 IU ribonuclease inhibitor, 10 mmol/L dNTP, 0.5 μ g oligo-(dt)₂₀ primer, 20 IU RNasin and 200 IU M-MLV reverse transcriptase. After incubation for 1 h at 42 °C, the RT mixture was incubated at 70 °C for 10 min to inactivate the reverse transcriptase. PCR was then carried out using 5 μ L cDNA in a final reaction volume of 50 μ L. The assay mix contained 50 mmol/L KCl, 10 mmol/L Tris-HCl (pH 8.3), 1.5 mmol/L MgCl₂, 0.2 mmol/L dNTP, 1 mmol/L of the respective primers and 1.5 IU of *Taq* DNA polymerase. The PCR cycling program was set for 1 cycle of pre-denaturation at 94 °C for 1 min, and then 35 cycles at 94 °C for 30 s, 55 °C for 30 s, 72 °C for 1 min, followed by 1 cycle at 72 °C for 5 min. PCR products were visualized by UV illumination after electrophoresis on a 2% agarose gel containing 0.5 μ L ethidium bromide. The location of a predicted product was confirmed using a 100 bp DNA ladder (Gibco BRL) as a standard size marker. The gel photographs were scanned with a computerized densitometer (SYNGENE, London, Britain). The signals for eNOS and iNOS mRNA were standardized against

the β -actin signal for each sample and the results are expressed as eNOS and iNOS mRNA/ β -actin mRNA ratio.

Statistical analysis All of the data were expressed as mean \pm SD and the analysis was carried out using the *t*-test. Values of $P < 0.05$ were considered statistically significant.

Results

Effects of berberine on ethanol-induced gastric lesions

The UI of ethanol-induced gastric lesions are shown in Figures 1 and 2. In the control group, the UI at 1 h, 2 h, 3 h and 6 h after oral administration of ethanol averaged 23.8 ± 1.4 , 23.3 ± 2.2 , 22.3 ± 1.2 and 20.8 ± 1.1 , respectively. The UI in the berberine-treated groups (5 mg/kg and 50 mg/kg) were less than the control group and this effect was time-dependent

Figure 2. The ulcer index (UI) of ethanol-induced gastric lesions in the different treatment groups. $n=6$. Mean \pm SD. ^b $P < 0.05$, ^c $P < 0.01$ vs NS group.

Figure 1. The appearance of gastric mucosa in mice 1 h, 2 h, 3 h and 6 h after being given 0.1 mL ethanol. After oral administration of ethanol, the gastric mucosa had many lesions, which were punctate or linear. Ulcer severity was graded using a score of 1 to 4. 1, punctate ulcer (white arrow); 2, linear ulcer of length =2 mm (yellow arrow); 3, linear ulcer of length 2–4 mm (blue arrow); and 4, linear ulcer of length =4 mm (black arrow).

NO, nitric oxide; NS, normal saline.

($P < 0.05$ and $P < 0.01$, respectively).

Change in nitric oxide content with the time The content of NO in gastric tissue and gastric juice is shown in Table 1. In the control group, the content of NO in gastric juice at 1 h, 2 h, 3 h and 6 h after oral administration of ethanol was $73.3 \pm 7.3 \mu\text{L/L}$, $94.0 \pm 9.2 \mu\text{L/L}$, $109.6 \pm 6.4 \mu\text{L/L}$ and $138.2 \pm 10.2 \mu\text{L/L}$, respectively, while the NO content in gastric tissue averaged $5.8 \pm 1.1 \mu\text{mol/g}$ protein, $8.3 \pm 1.1 \mu\text{mol/g}$ protein, $9.8 \pm 1.1 \mu\text{mol/g}$ protein and $11.9 \pm 1.2 \mu\text{mol/g}$ protein, respectively. However, in both gastric tissue and gastric juice the content of NO in the berberine-treated groups (5 mg/kg and 50 mg/kg) was higher than that in the control group at 1 h after oral administration of ethanol ($P < 0.05$, $P < 0.01$), but lower at 6 h after oral administration of ethanol ($P < 0.05$, $P < 0.01$).

Expression of eNOS and iNOS mRNA Expression of iNOS and eNOS mRNA is shown in Figures 3 and 4. In the base statement the mRNA of eNOS could be expressed while that of iNOS could almost not be expressed. In the control group the expression of eNOS was inhibited and iNOS was enhanced by ethanol, while in the berberine-treated groups the expression of eNOS could be enhanced and iNOS could be inhibited.

Figure 3. Determination of endothelial nitric oxide synthase (eNOS) and inducible nitric oxide synthase (iNOS) mRNA by reverse transcription-polymerase chain reaction in mouse gastric mucosa treated with saline before ulcer induction (lane 1), 1 h (lane 2), 3 h (lane 3) and 6 h after ulcer induction (lane 4), treated with berberine (50 mg/kg) before ulcer induction (lane 5), and 1 h (lane 6), 3 h (lane 7) and 6 h after ulcer induction (lane 8). M=100 bp ladder molecular weight DNA marker.

Figure 4. Determination of endothelial nitric oxide synthase (eNOS) and inducible nitric oxide synthase (iNOS) mRNA expression by the ratio of eNOS and iNOS mRNA over β -actin mRNA, as in experiment presented in Figure 2. $n=6$. Mean \pm SD. $^{\circ}P < 0.01$ vs saline-treated group. $^fP < 0.01$ vs before ulcer induction.

Discussion

Nitric oxide plays an important role in the host defense and inflammatory response^[12,13]. It also plays an important role in the mechanism of gastric mucosal protection and injury induced by pressure, ethanol, stress and endotoxins^[14-17]. Endogenous NO has a dual action in the gastrointestinal tract: protective effects by constitutive nitric oxide synthase (cNOS)/NO and proulcerogenic effects by iNOS/NO^[8].

cNOS lies in gastric endotheliocytes in the gastric tissue, also called eNOS^[18]. NO derived from eNOS is a pivotal mediator to accelerate gastric ulcer healing; it maintains the integrity of the gastric epithelium, regulates gastric mucosal blood flow, and stimulates gastric mucus secretion and synthesis^[19]. On the other hand, NO stimulates the release of vasoactive intestinal peptide (VIP) in gastric tissue and increases the concentration of cGMP^[20]. NO/cGMP plays a central role in producing relaxation of mouse gastric fundus smooth muscle, and cGMP protects gastric parietal cells from ethanol-induced cytotoxicity, implicating a basolateral Cl⁻ channel in the plasma membrane or that pepsinogen secretion stimulated by a Ca²⁺-mediated agonist is modulated by a NO/cGMP pathway^[8]. The results of the present study have shown that the content of NO in tissue from the berberine-treated group was higher than control group at 1 h after oral administration of ethanol, and further study has shown that expression of eNOS is higher. Therefore, we might conclude

that berberine can increase NO production through improving eNOS mRNA expression. The effect of berberine on NO formation in the vascular system was also demonstrated^[6,21].

High expression of iNOS was found in ulcer tissue of the control group at 3 h and 6 h after ulcer induction. A similar phenomenon was also found by Peng *et al*^[22]. Large amounts of NO synthesized from the inducible isoform have been implicated in tissue injury in the gut during inflammatory reactions^[23]. Guo *et al*^[24] also reported that high expression and activity of iNOS were found to coincide with severe inflammation in ulcer tissue. It is known that induction of high-output iNOS usually occurs in an oxidative environment, and thus high levels of NO have the opportunity to react with superoxide anion (O₂⁻) leading to peroxynitrite (ONOO⁻) formation and cell toxicity, protein tyrosine nitration, hydroxyl radical production and tissue damage^[24,25]. The results of the present study have shown that iNOS is under low-expression conditions at all times in the berberine-treated groups, as the content of NO had no peak and it was kept at a relatively steady level. This demonstrated that berberine might decrease NO production through inhibition of iNOS expression in the gastric ulcer tissue, prevent the abundant release of NO that aggravates gastric mucosal injury and, ultimately, improve the healing of ulcers. The study of Lee *et al*^[7] also showed that 13-methylberberine and 13-ethylberberine both inhibited iNOS expression in LPS-stimulated macrophages. In conclusion, the protective effect of berberine results in an increase in eNOS mRNA expression, which inhibits the iNOS mRNA expression process.

Abstract

Aim: To study the potential chemopreventive effect of dimethyl dicarboxylate biphenyl (DDB), an anti-hepatitis drug, on hepatocarcinogenesis *in vitro*. **Methods:** The anti-carcinogenesis effect of DDB was assessed on a two-stage chemical oncogenesis model induced by 3-methylcholanthrene and 12-*O*-tetradecanoyl phorbol 13-acetate (TPA) with WB-F344 rat liver epithelial cells (WB-F344 cells) *in vitro*. A soft-agar colony formation assay was used to determine the tumorigenic potential of the transformed WB-F344 cells. The gap junctional intercellular communication (GJIC) was detected using the scrape loading/dye transfer technique. **Results:** DDB at 1 $\mu\text{mol/L}$, 2 $\mu\text{mol/L}$, and 4 $\mu\text{mol/L}$ significantly prevented the malignant transformation of WB-F344 cells induced by 3-methylcholanthrene and TPA. The average number of transformed foci decreased dramatically by 10.0%, 37.2%, and 47.4%, respectively. In soft agar, a remarkable decrease in colony numbers was observed in transformed cells treated with 2 $\mu\text{mol/L}$ and 4 $\mu\text{mol/L}$ DDB. DDB at 1 $\mu\text{mol/L}$, 2 $\mu\text{mol/L}$, and 4 $\mu\text{mol/L}$ inhibited the downregulation of GJIC induced by TPA in a dose-dependent manner. The GJIC recovered to 25.6%, 34.6%, and 44.9%, respectively, of the control WB-F344 cells by DDB. **Conclusion:** DDB has a potential chemopreventive effect on hepatocarcinogenesis induced by carcinogens *in vitro*.

Introduction

Human hepatocellular carcinoma (HCC) is one of the most frequent malignant cancers. The carcinogenesis of HCC is a multifactorial event. Chronic hepatitis B virus (HBV) and hepatitis C virus (HCV) infections are the most frequent causes of HCC^[1]. Approximately 80% of human HCC are attributable to HBV infection^[2]. Chronic HBV carriers are 100–400 times more likely to develop HCC than non-carriers^[3]. HCV is the second most common cause of HCC after HBV^[4]. Currently, HCC represents more than 4% of all cancer cases worldwide and causes at least 315 000 deaths every year^[5]. Although early HCC can be cured by surgical resection, many HCC are asymptomatic, so most HCC patients are not diagnosed in time.

An effective approach to cancer control is chemo-

prevention. It is known that the therapy of both chronic HBV and HCV generally involves a long-term course. An anti-hepatitis drug with an inhibiting or a suppressing effect on the development of hepatocarcinogenesis, besides its improvement of abnormal liver function, would be of great clinical value.

Dimethyl dicarboxylate biphenyl (DDB) is a synthetic analogue of Schizandrin C, which was isolated from *Fructus Schizandrae chinensis*^[6]. Since 1983, DDB has been widely used to treat hepatitis B patients in China and is exported to Korea, Egypt, Vietnam, Indonesia, Pakistan, and Burma for the treatment of HBV and HCV. The results of the clinical application indicated that DDB markedly improved impaired liver functions, such as the elevated serum transaminase, bilirubin, α -fetal protein, and symptoms of the patients. Pharmacologically, DDB has a protective action against

experimental liver injury in mice and rats^[7,8,9]. DDB also had anticancer activity and differentiation-inducing effect on cancer cells^[10]. In the present paper, the chemoprevention effect of DDB on hepatocellular carcinogenesis *in vitro* is studied.

Materials and methods

Chemicals DDB with 99% purity was provided by the Beijing Union Pharmaceutical Plant. As DDB is not water-soluble, it was dissolved in dimethyl sulfoxide (Me₂SO) for *in vitro* use. 3-Methylcholanthrene (3MC), 12-*O*-tetradecanoyl phorbol 13-acetate (TPA), MTT, and Lucifer yellow CH were obtained from Sigma Chemical Company. Other chemicals were of analytical grade and purchased from Beijing Chemical Company.

Cell culture WB-F344 cells were grown in DMEM (GIBCO) media containing 10% newborn calf serum, 100 kU/L penicillin, and 100 mg/L streptomycin in a 37 °C humidified incubator containing 5% CO₂ and 95% air, and passaged using 0.25% trypsin plus 0.02% EDTA treatment. The culture medium was changed every other day.

MTT assay Cytotoxicity was determined by MTT assay according to the method of Mosmann^[11]. WB-F344 cells (3×10³ cells per well) were plated on 96-well plates, and 24 h later various concentrations of DDB were added (0.5 μmol/L–100 μmol/L). The cells were incubated at 37 °C in a CO₂ incubator for 72 h. The culture supernatant was sucked out and MTT 0.5 g/L stock solution was added to each well. After 4 h of incubation, Me₂SO was added. The optical density of each well was determined by a microplate reader at a wavelength of 570 nm. The values of absorbance were expressed as relative viable cell number.

***In vitro* transformation of WB-F344 cells** WB-F344 cells were seeded on 25-cm² tissue culture flasks containing the complete medium at a density of 4×10³ cells per flask. The medium was replaced with the complete medium containing 3MC (2 mg/L) or 0.1% Me₂SO 24 h after seeding, and the

cells were incubated for another 72 h. After the removal of the medium, the cells were washed twice with sterile phosphate-buffered saline (PBS) and incubated in fresh medium for 4 d. The cells were then incubated with medium containing 100 μg/L TPA. The TPA-containing medium was changed every 2–3 d for 14 d. After sucking out the TPA-containing medium, the cells were washed twice with sterile PBS and then incubated in fresh medium containing 10% newborn calf serum. The fresh medium was changed every 2 d until d 30. DDB was added to the medium from 24 h after cell seeding until the end of the experiment. At d 30, three of these flasks from each group were stained with Wright-Giemsa, and scored for transformed colonies. The remainders were used for soft-agar assay.

Soft-agar colony formation assay Cells derived from each group were seeded separately. Agar (0.6%) in the complete medium was kept at 44 °C and poured into 6-well plates (2 mL per well) as to form the lower layer. After the agar medium had set, 1×10⁴ cells per well in 2 mL of 0.3% agar (44 °C) were layered onto the gelled agar as the form of the upper layer. The cells were incubated in a humidified atmosphere of 95% air and 5% CO₂ at 37 °C. On d 9 and d 18, 1 mL of 0.3% agar in the complete medium was added. After 28 d, colonies of more than 20 cells were counted under contra-phase microscope.

Cell-cell communication assay The scrape loading/dye transfer (SL/DT) technique was used to detect GJIC according to the method of E1-Fouly *et al*^[12]. WB-F344 cells were pretreated with various concentrations of DDB for 1 h at 24 h prior to the addition of TPA (100 μg/L) for 1 h. The other cells were pretreated with 4 μmol/L DDB for 24 h, 48 h, and 72 h before treatment with TPA. Following incubation, the cells were washed twice with PBS. Then Lucifer yellow CH (a fluorescent dye permeating gap-junctional channels) was added and several scrapes were made with a surgical steel-bladed scalpel at low light intensities. These scrapes were performed to ensure that the scrape traversed a large group of confluent cells. After 3 min incubation, the cells were washed with PBS again. Dye migration was observed and photographed with an inverted fluorescent microscope (Olympus, Japan) at ×200 magnification. The number of dyed cells represents the ability of cells to communicate via GJIC. GJIC data are reported as a percentage of the corresponding mean control value. The data are obtained from 3 views per plate, pooled 4 separate plates for each point.

Statistical analysis Results are expressed as mean±SD. To compare mean values between 2 groups, the Student's *t*-test was used. *P*<0.05 was considered statistically significant.

Results

Cytotoxicity of DDB to WB-F344 cells To select the appropriate doses of DDB for the present study, the cytotoxicity of DDB to WB-F344 cells was assessed using the MTT assay. No significant cytotoxic effect on the cells was observed when the concentrations of DDB were below 4 $\mu\text{mol/L}$ (Table 1). Therefore, 1 $\mu\text{mol/L}$, 2 $\mu\text{mol/L}$, and 4 $\mu\text{mol/L}$ of DDB were used in the subsequent experiments.

Table 1. Cytotoxicity of dimethyl dicarboxylate biphenyl (DDB) to WB-F344 rat liver epithelial cells. $n=9$. Mean \pm SD. ^b $P<0.05$ vs control group.

Group	Dose/ $\mu\text{mol}\cdot\text{L}^{-1}$	Survival rate/%
Control	0	100.0 \pm 0.0
DDB	0.5	97.9 \pm 13.6
	1	105.1 \pm 9.3
	2	104.9 \pm 12.4
	4	90.2 \pm 4.7
	5	79.4 \pm 6.9 ^b
	10	78.4 \pm 17.6 ^b
	50	79.2 \pm 5.1 ^b
	100	61.8 \pm 5.4 ^b

Effect of DDB on two-stage transformation of WB-F344 cells A two-stage (initiation and promotion) chemical induction oncogenesis model with WB-F344 cells was established. The WB-F344 cells became transformed after 3-MC (2 mg/L) initiation for 72 h and then TPA (100 $\mu\text{g/L}$) promotion for 14 d. The transformed cells were grown in a disorganized multilayer instead of in a monolayer (Figure 1). DDB at con-

centrations of 1 $\mu\text{mol/L}$, 2 $\mu\text{mol/L}$, and 4 $\mu\text{mol/L}$ markedly inhibited transformation of WB-F344 cells in a dose-dependent manner. The average number of transformed foci decreased dramatically by 10.0%, 37.2%, and 47.4%, respectively, after DDB treatment (Table 2).

Table 2. The inhibitory effect of dimethyl dicarboxylate biphenyl (DDB) on transformed foci in WB-F344 rat liver epithelial cells undergoing initiation with 3-methylcholanthrene (3-MC) followed by promotion with 12-*O*-tetradecanoyl phorbol 13-acetate (TPA). $n=3$. Mean \pm SD. ^b $P<0.05$, ^c $P<0.01$ vs the model group. Transformed foci/flask: colonies containing >100 cells were scored positive.

Group	3-MC+TPA	Transformed foci/plate	Inhibitory rate/%
Control	-	4.5 \pm 1.3	-
Model	+	53.8 \pm 8.2	-
DDB 1 $\mu\text{mol/L}$	+	48.4 \pm 13.4 ^b	10.0
2 $\mu\text{mol/L}$	+	33.8 \pm 5.1 ^c	37.2
4 $\mu\text{mol/L}$	+	28.3 \pm 3.3 ^c	47.4

Effect of DDB on colony of transformed WB-F344 cells in soft agar To evaluate the tumorigenic potential of the treated WB-F344 cells, the efficiency of their soft-agar colony formation was determined. As shown in Table 3, no colony formed in soft agar in untreated WB-F344 cells, whereas the cells initiated with 3-MC and promoted with TPA developed the transformed phenotype of colony formation in soft agar. A remarkable increase in colony numbers was observed. The cells treated with 2 $\mu\text{mol/L}$ and 4 $\mu\text{mol/L}$ DDB also developed the transformed phenotype of colony formation, but the colony numbers significantly decreased compared with

the model group.

Effect of DDB on GJIC The GJIC of normal WB-F344 cells was well-characterized and did not decrease during the experimental incubation period (Figure 2Aa). After exposing the cells to TPA (100 μ g/L) for 1 h, over 85% inhibition of GJIC was detected. The Lucifer yellow CH only stayed at the incision sites or artificially damaged cells (Figure 2Ab).

When the cells were pretreated with DDB 1 μ mol/L, 2 μ mol/L, and 4 μ mol/L, respectively, for 24 h, a dose-dependent inhibition of TPA-induced downregulation of GJIC was observed. The GJIC recovered to 25.6%, 34.6%, and 44.9% of the control group, respectively (Figure 2B). The time-dependent inhibitory effect of 4 μ mol/L DDB on TPA-induced downregulation of GJIC is shown in Figure 3. By the addition of 4 μ mol/L DDB for 24 h, 48 h, and 72 h, TPA-induced downregulation of GJIC was markedly reversed in a time-dependent manner.

Discussion

WB-F344 cells have often been used in the study of hepatocarcinogenesis^[13]. In the present study, we found that the anti-hepatitis drug DDB at non-toxic doses markedly prevented the transformation of WB-F344 cells induced by 3-MC and TPA *in vitro*, which expressed as significant decrease of the number of transformed foci and the malignant degree of transformed cells.

It is well known that carcinogenesis is a multistage and multimechanism process, involving the irreversible alteration of a stem cell (the initiation phase), followed by the clonal

proliferation of the initiated stem cell (the promotion phase), from which the acquisition of the invasive and metastasis phenotypes are generated (the progression phase). Intervention to prevent cancer can occur at each step. For chemoprevention of carcinogenesis, the development of anti-tumor promoting agent has been regarded as the most effective pathway.

Intercellular communication is necessary in multicellular organisms to maintain tissue homeostasis and to control cell growth and differentiation. Gap junction channels play an important role in intercellular communication by providing a direct pathway for the movement of molecular information, including ions, polarized and non-polarized molecules up to a molecular mass of 1 kDa between adjacent cells^[14,15]. Much evidence has been documented to support the hypothesis that the downregulation of GJIC is a cellular event underlying the tumor promotion process, and that any treatment to prevent downregulation of GJIC is important in prevention of tumor promotion^[16,17]. Many tumor promoters have been shown to inhibit gap junctional communication

in vitro^[18,19]. TPA is a well-known classical inhibitor of cell communication in most cells, including the WB-F344 cell^[20]. In the present study, the underlying mechanisms of DDB against hepatocarcinogenesis were investigated during the promotional phase using TPA to inhibit GJIC. The WB-F344 cells are known to have high GJIC. The treatment with TPA significantly inhibited GJIC, as was determined using the SL/DT assay. The counteracting effect of DDB on GJIC inhibition caused by TPA suggests that DDB has a significant action in maintaining GJIC function, and that it might be beneficial in preventing tumor promotion.

In summary, the results of the present study suggest that DDB can prevent the malignant transforming of WB-F344 cells induced by 3-MC and TPA *in vitro*. The restoration of GJIC in the promotion phase should contribute, at least in part, to the anti-hepatocarcinogenic property of DDB. We conducted other experiments and found that DDB significantly inhibited liver carcinogenesis induced by DEN/PB in mice; the data from these experiments will be published in another paper soon. Both *in vitro* and *in vivo* experiments

demonstrated that DDB had a chemopreventive effect on hepatocarcinogenesis. It is worthy to pay attention to whether DDB potentially prevents liver carcinogenesis in patients with chronic viral hepatitis.

Abstract

Aim: To study the effect of selective interleukin-1 β -converting enzyme (ICE, caspase-1) inhibitor on ischemic acute renal failure (ARF). **Methods:** Mouse models of ischemic ARF were treated with the specific ICE inhibitor AC-YVAD-CMK. A renal function assay and renal morphological studies were employed to estimate the renal protective effect of AC-YVAD-CMK. The survival rate of mouse models was also analyzed by a time series test. Furthermore, renal ICE activity, mature interleukin-18 (IL-18) protein expression and interferon- γ (IFN- γ) mRNA expression were also detected by fluorescent enzyme-linked immunosorbent assay (ELISA), ELISA, and semi-quantitative reverse transcription-polymerase chain reaction, respectively. **Results:** The levels of blood urea nitrogen (BUN) and serum creatinine (Scr) increased remarkably in the model controls compared with the sham-operated groups ($P < 0.01$). Typical renal tubular necrosis was found in the model controls. Renal ICE activity, mature IL-18 protein expression, and IFN- γ mRNA expression were also increased significantly in the model controls compared with the sham-operated groups. The levels of BUN and Scr in the AC-YVAD-CMK therapy group were decreased significantly compared with the untreated model controls ($P < 0.01$). Renal tubulointerstitial lesion was also attenuated significantly ($P < 0.05$). AC-YVAD-CMK therapy alleviated the clinical features of ARF, and increased the survival rate ($P < 0.01$). Furthermore, AC-YVAD-CMK therapy also decreased ICE activity, mature IL-18 protein expression, and IFN- γ mRNA expression in renal tissue ($P < 0.05$). **Conclusion:** The selective ICE inhibitor AC-YVAD-CMK can effectively protect the kidney from acute ischemic lesions. This protective effect is associated with decreased renal ICE activity and suppressed IL-18 maturation and IFN- γ mRNA transcription.

Introduction

Acute renal failure (ARF) is a clinical syndrome with high morbidity and mortality. The incidence of ischemic ARF has been rising rapidly, especially with the rapid development of various difficult surgical operations and kidney transplantation^[1,2]. Unfortunately, up to now, there was no really effective medicine available to treat this disease.

Several recent studies have reported that, aside from tubular injury directly caused by renal abnormal hemodynamic states, the recruitment and activation of numerous inflammatory cells after ischemia, and immune inflammatory re-

sponses mediated by the expression and secretion of inflammatory cytokines are the main causes of ischemic acute renal injury^[3–5]. Among the various cytokines produced during renal ischemia, interleukin-18 (IL-18), interleukin-1 β (IL-1 β) and interferon-gamma (IFN- γ), a group of proinflammatory cytokines with closely related function, play an important role in the inflammatory reaction and renal tubulointerstitial impairment^[6–9]. Other studies have reported that applying antibodies or soluble receptors to block the roles of these cytokines can alleviate ischemic ARF^[10,11]. It has been demonstrated that both IL-1 β and IL-18 are members of the IL-1 family, which can be activated by interleukin-1 β -

converting enzyme (ICE) via cleaved precursor peptide, and furthermore, that IL-18 is the strongest inducing factor of IFN- γ ^[12,13]. We therefore postulated that it would be more effective to protect the kidney from acute ischemic injury by regulating the whole cytokine network, including IL-1 β , IL-18, and IFN- γ , with selective ICE inhibitors, instead of only blocking any one of the cytokines using antibodies or soluble receptors. More significantly, several kinds of ICE inhibitors with simple structure and low antigenicity have been synthesized by chemical methods. The inhibitors are superior to cytokine antibodies and soluble receptors, which are difficult to produce, expensive, hypersensitive and require injection.

The present study aimed at exploring the role of selective ICE inhibitors in preventing the kidney from ischemic ARF by the combined inhibition of IL-1 β , IL-18, and IFN- γ in mouse models of ischemic ARF.

Materials and methods

Materials All reagents were obtained from Sigma (St Louis, MO, USA), unless otherwise indicated.

Ischemic ARF model induction Male Kunming mice (SPF grade, Experimental Animal Center of Guangdong Medical College, Zhanjiang, China) weighing 22.1 \pm 1.3 g (20 g–25 g) were used. After being anesthetized with an injection of 0.3% sodium pentobarbital (5 mL/kg–10 mL/kg, ip), an abdominal mid-line incision was made and the renal pedicles were clamped bilaterally for 45 min with non-traumatic microaneurysm clamps. Restoration of blood flow was confirmed when the kidneys returned to their original color after the clamps were removed. Afterward, the abdomen was closed and the mice were allowed to recover. The mice were observed for 2 h after the operation was finished. A model was considered to be developed successfully if the animal's behavior returned to normal. Those that failed to return to normal behavior after operation or those in which any 1 of the kidneys failed to return to normal color after the clamps were removed were regarded as unsuccessful models and were removed from the experiment. The sham-operated group consisted of the same surgical procedure except that clamps were not applied.

Experimental groups Animals were kept in a clean environment at 24 °C–29 °C with free access to standard food and water after model induction. The study was composed of 3 parts as follows. **Experiment I:** Thirty-nine mice were distributed randomly into the sham-operated group, the model control group or the therapy group. After post-operative elimination, these groups contained 13, 13, and 11 mice,

respectively. The therapy group was administered AC-YVAD-CMK (6.25 mg/kg, ip; Calbiochem, Darmstadt, Germany), which was dissolved in 2% Me₂SO saline, at 2 h, 8 h, and 16 h after surgery. The other 2 groups received the vehicle; an equal volume of 2% Me₂SO saline at the same times as the therapy group. All of the mice were killed at 24 h after surgery. **Experiment II:** Forty-five mice were enrolled in this part of the experiment and were also distributed randomly into 3 groups as in Experiment I. Each group contained 13 mice after model construction and elimination. The mice underwent similar procedures as those in Experiment I, except that either AC-YVAD-CMK or the vehicle were administered to the mice at 2 h, 8 h, 14 h, 20 h, 28 h, and 36 h, and the mice were killed at 48 h after surgery. **Experiment III:** Thirty-nine mice were distributed randomly into the 3 groups as in Experiment I and Experiment II, and each group contained 12 mice. AC-YVAD-CMK or the vehicle was administered in the same way as in Experiment II, but the animals were not killed. Their clinical features were observed and recorded twice per day for 14 d after surgery.

Sample collection and pretreatment Blood samples were obtained via orbital cavity after removing eyeballs. The blood samples were then centrifuged to separate the serum. The kidneys were collected, each of which was divided into 4 equal sections. One section was fixed in 10% neutral formalin solution while the others were frozen immediately in liquid nitrogen and preserved at -72 °C until use.

Blood biochemical parameters assay The levels of blood urea nitrogen (BUN) and serum creatinine (Scr) were measured using an automatic biochemical analyzer (Beckman Instruments, Fullerton, CA, USA).

Renal histological examination The 4% paraformaldehyde-fixed and paraffin-embedded kidney samples were sectioned at 3 μ m and stained with hematoxylin-eosin (HE) and periodic acid-Schiff (PAS) using standard methods. Histological examinations were carried out in a single blinded fashion. Histological changes due to acute renal tubulointerstitial injury were quantitated using the method of Paller *et al*^[14]. Five fields (\times 200) were reviewed for each slide. The scores included: diffuse tubular epithelial cell flattening and tubular lumen dilatation (1 point), lesion of brush border (1 point), loss of brush border (2 points), cell membrane bleb formation (1 point), cytoplasmic vacuolization (1 point), interstitial edema (1 point), necrotic cells in tubular lumen but no cast formation (1 point), and casts or cell pieces formation (2 points). Higher scores represented more severe damage.

Renal ICE activity assay Renal ICE activity was measured using a ICE fluorescent assay kit (Calbiochem),

according to the manufacture's protocols. Briefly, 1 mL of tissue lysis buffer (containing 1× phosphate-buffered saline, 1% Nonidet P-40, 0.5% sodium deoxycholate, 0.1% sodium dodecylsulfate, 10 µg/mL phenylmethylsulfonyl fluoride and 10 µg/mL Aprotinin) was added to approximately 100 mg renal tissue. The renal tissues were then homogenized artificially and incubated on ice for 1 h. The tissue lysate was then centrifuged at 4 °C at 12 000×g for 5 min. The supernatant was collected in a separate microfuge tube and stored immediately at -72 °C until use. The protein concentration of each tissue lysate was measured by spectrophotometry after being dyed with Coomassie brilliant blue G250. Supernatants were adjusted to a final protein concentration of 150 µg/µL–200 µg/µL. The enzymatic activity was measured as follows: 50 µL of 2×ICE assay buffer, 5 µL of substrate (1 mmol/L YVAD-AFC) and 50 µL protein solution were added to a 96-well polyvinyl plate. The reaction system, kept in darkness, was incubated at 37 °C for 90 min. The absorbance of each well was then read by a DA620 fluorescence microplate reader (Bio-Tek, Winooski, Vermont, USA) at an excitation wavelength of 380 nm and an emission wavelength of 460 nm. Tissue lysis buffer was replaced with tissue lysate as a negative control. A ICE standard curve was determined for the experiment at the same time. ICE activity was expressed as units per mg protein.

Assay for expression of mature renal IL-18 protein The level of mature IL-18 protein expressed in renal tissue was measured using a mouse IL-18 enzyme-linked immunosorbent assay kit (MBL, Nagoga, Japan), which was only specific for mature IL-18. Renal tissue total protein was extracted as described above. The assay procedures strictly followed the manufacturer's instructions. Every sample was measured by double parallel wells, and was remeasured when the intra-error was over 10%.

Assay for renal IFN-γ mRNA expression Approximately 100 mg of frozen kidney sample was homogenized in a muller by adding liquid nitrogen to crisp the tissue. Total RNA was extracted from kidney tissue using TRIzol reagent (Invitrogen, Carlsbad, CA, USA). cDNA was synthesized with the SuperScript™ First-Strand Synthesis System (Invitrogen) according to the manufacturer's protocol. The primers used for the IFN-γ polymerase chain reaction (PCR) were as follows: 5'-AGG AACTGG CAAAAG GATGGTG-3' (sense), and 5'-GTG CTG GCA GAA TTA TTC TTA TTG-3' (anti-sense), and the product was 353 bp. The primers used for the glyceraldehyde-3-phosphate dehydrogenase (GAPDH) PCR were as follows: 5'-AAC GAC CCC TTC ATT GAC-3' (sense), and 5'-TCC ACG ACA TAC TCA GCAC-3' (anti-sense), and the product was 191 bp. Primers were syn-

thesized and purified by Shanghai Biological Engineering (Shanghai, China). The PCR-amplified system included 1.2 µL of 25 mmol/L MgCl₂, 0.4 µL of 10 mmol/L dNTP mix, 0.8 µL of 5 µmol/L sense and anti-sense primers, 2 U of *Taq* DNA polymerase, 1 µL of cDNA and sterile purified water to 20 µL. The IFN-γ PCR was carried out in a thermal cycler (Eppendorf, New York city, New York, USA) at 95 °C for 60 s, 58 °C for 60 s, and 72 °C for 60 s. The GAPDH PCR was carried out at 94 °C for 60 s, 58 °C for 60 s, and 72 °C for 60 s. IFN-γ was amplified for 35 cycles and GAPDH for 28 cycles. Equal volumes of each PCR product were loaded into gels and electrophoresis was carried out. The ethidium bromide-stained gels were analyzed semiquantitatively using a gel imaging system (UVP, Cambridge, UK). The quantity of IFN-γ expression in every renal tissue was the integral absorbency of the IFN-γ amplification band divided into GAPDH amplification band.

Statistical analysis SPSS version 11.0 software was used to obtain data statistics. Measurement data were expressed as mean±SD. One-way ANOVA was used for statistical analysis among multiple groups. Kaplan-Meier was used for statistical analysis of survival rates among multiple groups.

Results

Effect of AC-YVAD-CMK on renal function in ischemic ARF mice The levels of Scr and BUN in model controls were increased significantly compared with sham-operated groups both in experiment I and experiment II. The levels of Scr decreased significantly but that of BUN did not decrease significantly in the AC-YVAD-CMK therapy group compared with the vehicle-treated group in experiment I; the levels of both Scr and BUN decreased significantly in the therapy group in experiment II (Table 1).

Effect of AC-YVAD-CMK on renal tubulointerstitial injury in ischemic ARF mice Kidneys from sham-operated groups were normal in form and rubicund color while those from model control groups were swollen with pale cortex and congested medulla. These anatomical changes were also observed but were significantly less in kidneys from AC-YVAD-CMK therapy groups. Renal tissues from sham-operated groups had a basically normal microcosmic structure except for focal vacuolation of tubular epithelial cells (TECs). Renal tissues from model control groups showed severe damage in microcosmic structure, including extensive TECs vacuolation, scattered TECs brush border flattening, shrinkage and loss as well as focal TECs nucleus nakedness and necrosis. Dilated lumens and cast formation were also found in parts of the tubules. Interstitial inflammatory cell

Table 1. Effect of AC-YVAD-CMK on renal function in an ischemic acute renal failure model. Mean±SD. ^b*P*<0.05, ^c*P*<0.01 vs sham-operated group. ^e*P*<0.05, ^f*P*<0.01 vs model control group.

infiltration was also found, especially with neutrophil cells. Renal tissue damage was relieved significantly in AC-YVAD-CMK therapy groups. The main histological changes included extensive TECs vacuolation, focal TECs nucleus nakedness and very rare TECs necrosis. The basement membranes were basically integrated; casts were seldom. Inflammatory infiltration in interstitial areas was slight. The mean histological score for the kidney tissue of model control groups was significantly higher than that of the sham-operated groups, both in experiment I and experiment II. The mean score for the AC-YVAD-CMK therapy groups was much lower than that for the vehicle-treated groups, again in both experiment I and experiment II (Figure 1, Table 2).

Effect of AC-YVAD-CMK on survival rate in ischemic ARF mice In Experiment III, Sham-operated groups had no apparent abnormal appearance, activity or ingestion during the whole observation period, and all of them had survived at the end of observation. Model controls were cachexia in different extents, with reduced activity and ingestion. Anasarca and dyspnea occurred gradually. The survival rate was 83.3% on d 7, 58.3% on d 10, and only 8.3% on d 14. However, the clinical features were relatively improved in the AC-YVAD-CMK therapy group during the period of observation compared with model controls. The survival rate was 100.0% on d 7, 91.6% on d 10, and 25.0% on d 14.

Table 2. Effect of AC-YVAD-CMK on renal tubulointerstitial injuries in an ischemic acute renal failure model. Mean±SD. ^b*P*<0.05, ^c*P*<0.01 vs sham-operated group. ^e*P*<0.05 vs model control group.

All together, the 2-week accumulated survival rate in the AC-YVAD-CMK therapy group was higher than that of the vehicle-treated group by survival analysis for time (*P*<0.01, Figure 2).

Effect of AC-YVAD-CMK on renal ICE activity in ischemia ARF mice ICE activity in renal tissue from model controls was 347.0±97.5 U/mg protein in experiment I and 536.1±43.0 U/mg protein in experiment II, both much higher than that for the sham-operated groups, which was 239.5±56.5 U/mg protein in experiment I and 237.2±27.4 U/mg protein in experiment II. The ICE activity for the therapy group was 314.0±56.0 U/mg protein in experiment I and 412.2±

Discussion

The present study developed a successful ischemic ARF model according to the dynamic changes of the kidneys color during operation and the changes in renal function and morphological structure after operation. However, we also found that renal function parameters, especially the level of Scr, and renal histological scores in experiment I were higher than those in experiment II in the sham-operated group. This phenomenon may be caused by muscle lesion during peritoneotomy and incomplete recovery from stress after anesthesia and surgical operation. The difference might also result from the variation between experiments at different times.

Based on a successful mouse model of ischemic ARF, we first studied the renal protective effects of AC-YVAD-CMK dynamically using a renal function assay and renal morphological study at different times. The results showed that renal function and morphological impairment were significantly improved in the ischemic ARF mouse model after being treated with specific ICE inhibitor. The findings demonstrate that a specific ICE inhibitor can exert remarkable renal-protective effects against acute ischemic lesion.

However, the ultimate objective of ischemic ARF therapy is to increase patient survival from the disease. In the past decade, different kinds of medicines, such as prostaglandins, "renal-dose" dopamine and atrial natriuretic factor, have been tried to treat patients with ischemic ARF and these animal models. Although some of these agents have improved renal function, urine output and even renal histological impairment in patients and animal models, few studies have demonstrated that these medicines can reduce the mortality of the disease^[15-18]. In the present study, we found that applying this specific ICE inhibitor in the initial term of the disease remarkably increased the survival rate in this animal model. If it were applied continually for a longer period of time, the model's survival rate might be further improved. Thus, we

speculate that this medicine might be superior in some way to traditional medicines with regard to protection against ischemic ARF.

Caspases are a group of protein-cleaving enzymes, and play an important role in cell apoptosis and inflammatory responses. ICE, also known as interleukin-1 β -converting enzyme, is a member of the inflammatory group in the caspase family. It is a key initiative factor and an important inducer of inflammatory chain responses secondary to an organ's ischemic impairment^[19]. Kaushal *et al*^[20] reported that expression of the ICE gene and protein were up-regulated in an ischemic ARF rat model. In the present study, ICE activity was also increased in renal tissue of an ischemic ARF mouse model. All of the evidence above strongly revealed that gene transcription, protein synthesis and enzyme activation of ICE were up-regulated during the progression of ischemic ARF. Melnikov *et al*^[11] reported that renal tubular impairment and renal interstitial inflammatory infiltration were much slighter in ICE gene knock-out mice than in wild-type mice after renal ischemia reperfusion. The present study also found that ICE inhibitor alleviated the impairment of renal tissue and down-regulated the activity of renal ICE. We conclude that excessive ICE activity prompts the development of ischemic ARF, and selectively inhibiting sham-operated groups ICE activity can exert renal-protective effects on the disease. ICE activity was not suppressed to normal levels by the dose of inhibitor used in the present study. We presume that a better protective effect would be achieved if a larger dose were administered.

Precursors of IL-18 and IL-1 β are the main substrates of ICE^[12,13], and many reports have proved these 2 cytokines can prompt acute ischemic organ impairment^[21-23]. Recent reports seem to emphasize the role of IL-18. Mice with ischemic ARF have increased renal mature IL-18 expression, and IL-18 antiserum can significantly improve the state of the illness^[11,22]. It was reported recently by Parikh *et al*^[7] that urinary IL-18 level was increased almost 50-fold in patients with ARF, and the urinary IL-18 level in patients transplanted with corpse kidney was 10-fold that in patients transplanted with living kidney. These studies prove that IL-18 plays an important role in prompting renal impairment during acute ischemia. Does ICE mediate the acute renal impairment through prompting activation of IL-18 and IL-1 β ? In the present study we detected the expression of mature IL-18 in renal tissue. The results showed that expression of activated IL-18 increased remarkably in model controls and decreased significantly after the models were treated with ICE inhibitor, which demonstrates that the excessive activation of IL-18 resulting from ICE hyperactivity is one of the

main mechanisms causing renal tissue impairment. We infer that IL-1 β was also over-activated by ICE in this model. Specific ICE inhibitor indirectly inhibits activation of IL-18 and IL-1 β through inhibiting the activity of ICE, and thereby protects against acute ischemic ARF.

Because IL-18 is the strongest IFN- γ inducer^[13], we then detected the expression of the IFN- γ gene in renal tissue. We found that renal IFN- γ mRNA expression was up-regulated significantly in model controls, and decreased after the mice were treated with specific ICE inhibitor. The results again demonstrate that IFN- γ plays an important role in ischemic ARF, and ICE inhibitor suppresses the expression of IFN- γ mRNA through inhibiting activation of IL-18, thus further protecting against ischemic ARF.

In summary, the present study demonstrates that specific ICE inhibitors are promising agents in the treatment of ischemic ARF. It exerts renal-protective effects by inhibiting strong ICE activity, thereby regulating the activation of IL-18 and IL-1 β , and further regulating abnormal expression of IFN- γ .

Abstract

Aim: To study the immunosuppressive activity of SM735 {[3-(12- β -artemisininoxy)] phenoxy succinic acid}, a synthetic artemisinin derivative with nonsteroidal anti-inflammatory drug structure, with the aim of finding potential immunosuppressive agents. **Methods:** Concanavalin A (ConA), lipopolysaccharide (LPS), and mixed lymphocyte reaction (MLR), were used to induce the proliferation of splenocytes, and [³H]-thymidine incorporation was used to evaluate the proliferation of splenocytes. Cytokine production was promoted with ConA, LPS, or PMA plus ionomycin, and was detected with the enzyme-linked immunosorbent assay. Dinitrofluorobenzene (DNFB) and sheep red blood cells (SRBC) were used to induce delayed-type hypersensitivity and quantitative hemolysis of SRBC (QHS) mouse models, as criteria for the evaluation of *in vivo* immune activity. **Results:** SM735 strongly inhibited the proliferation of splenocytes induced by ConA, LPS, or MLR, with IC₅₀ values of 0.33 μ mol/L, 0.27 μ mol/L, and 0.51 μ mol/L, respectively. When compared with a CC₅₀ value of 53.1 μ mol/L, SM735 had a favorable safety range. SM735 dose-dependently inhibited proinflammatory cytokine production [including interleukins (IL)-12, interferon (IFN)- γ and IL-6] induced by LPS or PMA plus ionomycin. Upon ConA stimulation, SM735 suppressed IFN- γ in a dose-dependent manner, but did not affect IL-2 secretion. SM735 also strongly suppressed both T-cell-mediated delayed-type hypersensitivity (DTH) and B-cell-mediated QHS reactions. **Conclusion:** SM735 had strong immunosuppressive activity *in vitro* and *in vivo*, suggesting a potential role for SM735 as an immunosuppressive agent, and established the groundwork for further research on SM735.

Introduction

Artemisinin is extracted from the herb *Artemisia annua* L, and various forms of the drug are used as anti-malarial agents^[1,2]. Artemisinin is a potent anti-malarial agent with low toxicity, and its derivatives have improved efficacy in malaria treatment relative to artemisinin itself. In addition to anti-malarial effects, anti-lymphocytic effects have also been reported for artemisinin derivatives^[3,4]. Since the 1980s, the immunosuppressive actions of artemisinin and its deriva-

tives have been studied in China. Artemisinin derivatives have also been tested for the treatment of dermatoses such as photoallergic skin diseases and systemic lupus erythematosus, and promising results have been reported^[5-7].

Researchers have demonstrated that the anti-malarial activity of artemisinin and its derivatives is associated with their endoperoxides^[8,9]. When catalyzed by the ferrous ion in heme, cleavage of peroxy bonds produces free radicals and thus causes damage to malarial DNA and proteins. However, the underlying mechanism of the anti-lymphocytic

action of artemisinin and its derivatives is poorly understood.

Despite their anti-lymphocytic mechanisms being poorly understood, we hypothesized that artemisinin derivatives might be promising immunosuppressive agents, because some clinical studies have shown that they are effective in the treatment of immune dysfunction diseases. When considering an optimal molecular structure (higher efficacy and lower toxicity) for artemisinin derivatives for use as immunosuppressants, we noticed that nonsteroidal anti-inflammatory drugs (NSAIDs) remained the first-line therapy for most people with arthritis and other inflammatory diseases. Compared with other anti-inflammatory or immunosuppressive drugs such as steroids and cyclosporine, the molecular structures of NSAIDs are relatively simple and easy to synthesize. In addition, NSAIDs have few side effects, and a low level of toxicity, which are clinically desirable features. Given the relevance of the structure of NSAIDs to their immunosuppressive activity, we became interested in combining artemisinin and NSAIDs to develop a new class of immunosuppressive agents. Therefore, we synthesized and studied more than 100 different artemisinin derivatives. As a result of this screening program and subsequent medicinal chemistry studies, we obtained some derivatives that have significant immunosuppressive activity. Previous studies indicated that SM735 [3-(12- β -artemisininoxy)]phenoxy succinic acid, $C_{25}H_{32}O_9 \cdot 1/2H_2O$, MW: 485.5, Figure 1) is a representative compound, with markedly lower toxicity and higher immunosuppressive activity than artemisinin^[10]. Here, we further investigate its immunological characteristics both *in vitro* and *in vivo*.

Figure 1. Chemical structure of 3-(12- β -artemisininoxy) phenoxy succinic acid (SM735).

The discovery of cyclosporine (cyclosporin A; CsA) and its successful utilization in organ transplantation was a milestone in clinical transplantation. CsA has produced a new era in transplantation in terms of both efficiency and quality of life for patients. In addition, research into the mecha-

nisms by which CsA acts has been rewarding in that we now have a better understanding of the mechanisms leading to T lymphocyte activation^[11,12]. Recently, Noori *et al* reported that the immunosuppressive activity of artemisinin was even greater than that of CsA, as indicated by both *in vivo* and *in vitro* studies^[13]. Therefore, in the present study, we demonstrate that SM735 has strong immunosuppressive effects *in vitro* and *in vivo*, and explore its possible mechanism of action.

Materials and methods

Reagents Concanavalin A, lipopolysaccharide (*Escherichia coli* 055:B5), ionomycin, phorbol 12-myristate 13-acetate (PMA), 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyl-tetrazolium bromide (MTT), and 3,3',5,5'-tetramethylbenzidine were purchased from Sigma (St Louis, MO, USA). Mitomycin-C was purchased from Kyowa Hakko (Tokyo, Japan). RPMI-1640 and fetal bovine serum (FBS) was purchased from Gibco (Life Technology, NY, USA). 1-Fluoro-2,4-dinitrobenzene (DNFB) was purchased from Merck (Hong Kong, China). Mouse enzyme-linked immunosorbent assay (ELISA) kits of interleukin (IL)-2, IL-12p40, interferon (IFN)- γ and IL-6 were purchased from Pharmingen (San Diego, CA, USA).

Cyclosporine (Sandimmun) was purchased from Novartis Pharma AG, Switzerland. Cyclophosphamide was purchased from Hualian Pharma (Shanghai, China). SM735 [3-(12- β -artemisininoxy)phenoxy succinic acid] was synthesized by us. Before use, SM735 was dissolved in pure dimethyl sulfoxide (Me_2SO ; 100 g/L) as a stock solution, and stored at 4 °C. The stock solution was diluted to the needed concentrations with RPMI-1640 supplemented with 10% FBS. The final concentration of Me_2SO in the culture medium was less than 0.01%, which had no influence on the assays^[10,14]. For *in vivo* experiments, both SM735 and the reference drugs were dissolved in 0.5% Tween-80, 0.33% Me_2SO in saline.

Animals and housing conditions Inbred 7–9-week-old BALB/c, C57BL/6 mice were obtained from the Shanghai Experimental Animal Center of the Chinese Academy of Sciences (Certificate No 99-003). The mice were housed in specific pathogen-free conditions with a room temperature of 24 ± 2 °C, a 12-h light/dark cycle, and provided with sterile food and water *ad libitum*. All mice were allowed to acclimatize in our facility for 1 week before any experiments were started. All experiments were carried out according to the National Institutes of Health Guide for the Care and Use of Laboratory Animals, and were approved by the Bioethics Committee of the Shanghai Institute of Materia Medica.

Preparation of splenocytes Splenocytes were prepared

aseptically from inbred 7–9-week-old BALB/c, C57BL/6 mice, and cultured in RPMI-1640 supplemented with 10% endotoxin-free, heat-inactivated FBS, 100 kU/L penicillin, 100 mg/L streptomycin, 10 mmol/L *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES), and 50 μ mol/L 2-mercaptoethanol (2-ME).

Lymphocyte proliferation and cytotoxicity assay

Lymphocyte proliferation was carried out as described elsewhere^[15]. Briefly, 7–8-week-old male BALB/c mice were killed and splenocytes were prepared aseptically to a single-cell suspension. Splenic lymphocytes were stimulated with ConA (5 mg/L) or lipopolysaccharide (LPS 10 mg/L), plus the required concentrations of drugs. The cell cultures were then incubated for 48 h at 37 °C in a humidified 5% CO₂ incubator. Cells were pulsed with 0.5 μ Ci/well [³H]-thymidine 8 h prior to the end of the culture. After 48 h, cells were harvested onto a glass fiber filter using a HARVESTER96® (TOMTEC, USA) 96-well cell harvester and incorporated radioactivity was counted with a Beta Scintillation counter (1450 MicroBeta Trilux, PerkinElmer Life Sciences, Boston, MA, USA).

Cytotoxicity was assessed by using the MTT assay. Briefly, 15 μ L of 5 g/L MTT was pulsed 4 h prior to the end of the culture (in a total volume of 160 μ L), and then 80 μ L solvent [10% sodium dodecylsulfate (SDS), 50% *N,N*-dimethyl formamide, pH 7.2] was added to dissolve the precipitate. The solution was incubated for another 7 h and *OD*_{570 nm} was read by using a microplate reader (Bio-Rad, Model 550, Tokyo, Japan).

Mixed lymphocyte reaction proliferation assay The mixed lymphocyte reaction (MLR) was carried out as previously described, with some modifications^[16]. Briefly, spleen cells from 7–9-week-old BALB/c mice were prepared in a 1×10^{10} cells/L suspension, which was inactivated for 2 h with 50 mg/L of mitomycin C. Cells were washed and co-cultured with freshly prepared splenocytes from C57/BL6 mice (the ratio of stimulator to responder was 1.0) in a final concentration of 1.5×10^9 cells/L for 96 h. The desired concentrations of each compound were added in cultures for immunological activity assays. [³H]Thymidine (0.5 μ Ci/well) was pulsed 24 h prior to the end of the culture and then cells were harvested onto a glass fiber filter for measurement of incorporated radioactivity.

Cytokine production and analysis Splenocytes (5×10^6) were prepared from 7–9-week-old BALB/c mice, added to 1 mL of RPMI-1640 media, and then were incubated with 5 mg/L of ConA, 10 mg/L of LPS, or 10 μ g/L of PMA plus 1 μ mol/L of ionomycin, for 24 h of culture in 48-well microculture plates. The supernatants were harvested and stored

at –80 °C before the assay was carried out. Cytokine levels in supernatants were measured by ELISA, according to the manufacturer's instructions (Pharmingen, San Diego, CA, USA). 3,3',5,5'-Tetramethylbenzidine was used to develop the color reaction. The absorbance was read at 450 nm by a microplate reader (Bio-Rad, model 550, Tokyo, Japan). Cytokine concentrations were calculated based on a standard curve created using standard murine cytokines.

DNFB-induced delayed-type hypersensitivity response Female BALB/c mice were randomized into 6 groups and sensitized with 20 μ L of 0.5% DNFB dissolved in acetone-olive oil (4:1) on each hind foot on d 0 and d 1. Me₂SO vehicle, CsA and SM735 were administered to each group (*n*=10) by intraperitoneal injection on 4 consecutive days (d 7–d 10). On d 9 mice were challenged with 10 μ L of 0.2% DNFB on both sides of the right ear, using the method described by Phanuphak *et al*, with some modifications^[17]. The extent of ear swelling was expressed as the difference between the weight of punches taken from the left and right ears by using an 8-mm punch 48 h after the second challenge.

Quantitative hemolysis of sheep red blood cells Female BALB/c mice were immunized by ip injection with 0.2 mL of 16.7% sheep red blood cells (SRBC) on d 0. Me₂SO vehicle, 25 mg/kg of cyclophosphamide and SM735 were administered to each group (*n*=6) by ip injection on 4 consecutive days (d 1–d 4). On d 5, mice were killed, and mixed suspensions of 2×10^9 spleen cells/L were made. A total of 1 mL of cell suspension was incubated with 1 mL of 0.5% SRBC and 1 mL of 1:10 dilution of guinea pig complement for 0.5 h at 37 °C. The suspension was then centrifuged (3 min at 3000 \times g) and the extent of hemolysis in the supernatant was determined at 520 nm, according to the method used by Simpson and Gozzo with some modifications^[18].

Statistical analysis Three independent experiments were performed with similar results. We counted the 50% cytotoxic concentration (CC₅₀) and the 50% inhibitory concentration (IC₅₀) values using the Origin software package (Microcal Software). Student's *t*-test and one-way analysis of variance (ANOVA) with Newman-Keuls multiple comparisons on post-tests were used to analyze data and compare groups. *P*<0.05 was considered significant.

Results

Cytotoxicity of SM735 for murine splenocytes To determine the safe dose range of SM735, we first examined the cytotoxic effect of the compound. As Figure 2A shows, in a 48-h culture, SM735 had a typical S-shaped concentration-toxicity relationship for murine splenocytes. SM735 at

Figure 2. (A) Cytotoxicity of SM735 was tested in BALB/c mice splenocytes using the MTT assay on a 48-h culture, with a CC₅₀ value of 53.1±7.8 µmol/L. (B) SM735 inhibited ConA-induced splenocyte proliferation in a 48-h culture, with an IC₅₀ value of 0.33±0.06 µmol/L. (C) SM735 inhibited LPS-induced splenocyte proliferation in a 48-h culture, with an IC₅₀ value of 0.27±0.02 µmol/L. (D) SM735 suppressed the mixed lymphocyte reaction, with an IC₅₀ value of 0.86±0.18 µmol/L. Mitomycin C-inactivated splenocytes from BALB/c mice were co-cultured with splenocytes from C57BL/6 mice for 96 h in the presence of SM735. Three independent experiments were performed with similar results. Mean±SEM. The data were fitted with sigmoidal functions and the IC₅₀ values were counted by using the Origin software package. Correlation indices: (A) R²=0.960; (B) R²=0.993; (C) R²=0.997; (D) R²=0.984.

a dose of 25 µmol/L showed no cytotoxicity (inhibitive rate <10%, P>0.05). The 50% cytotoxic concentration (CC₅₀) value of SM735 was 53.1±7.8 µmol/L for a 48-h culture.

SM735 inhibits mitogen-induced murine splenocyte proliferation

Concentration-dependent suppression of murine splenocyte proliferation in response to ConA and LPS was observed when SM735 was added to cell cultures. Figure 2B, 2C shows that proliferation induced by ConA or LPS was significantly inhibited by SM735 exposure. Both concentration-dependencies fitted typical S-shaped curves. Comparisons with a vehicle control showed that this effect was statistically significant (P<0.05) when concentrations of SM735 were above 0.04 µmol/L in response to ConA and above 0.02 µmol/L in response to LPS. In response to ConA, the IC₅₀ value of SM735 inhibition of lymphocyte proliferation was 0.33±0.06 µmol/L, and in response to LPS, the IC₅₀ value was 0.27±0.02 µmol/L.

SM735 inhibits splenocyte proliferation in MLR

Mitomycin C-inactivated splenocytes from BALB/c mice (H-2^d) were applied as allogeneic stimuli to proliferating splenocytes of C57BL/6 mice (H-2^b). As shown in Figure 2D, SM735 strongly suppressed T cell proliferation in MLR in a dose-dependent manner, with an IC₅₀ value of 0.86±0.18 µmol/L for a 96-h co-culture. When concentrations of SM735 were above 0.08 µmol/L, comparisons with the vehicle control showed that this effect was statistically significant (P<0.05). The IC₅₀ values were comparable to those when ConA-stimulated T cell proliferation was suppressed.

Effects of SM735 on cytokine production

We used ConA alone, LPS alone, or PMA plus ionomycin as stimuli to promote cytokine secretion in mouse splenocytes. Then the effects of SM735 on the production of proinflammatory cytokine IL-6, and Th1-type cytokines IL-2, IL-12, and IFN-γ, were examined. The results are summarized in Table 1. The production of IL-12, IFN-γ, and IL-6 was significantly decreased in a concentration-dependent manner when the splenocyte cultures were exposed to SM735, upon stimulation with LPS or PMA plus ionomycin. We also detected a strong inhibitive effect of SM735 on IFN-γ production induced by ConA. Unexpectedly but interestingly, we did not observe a significant effect of SM735 on IL-2 production.

SM735 suppresses DNFB-induced delayed-type hypersensitivity reaction

Figure 3 illustrates the dose-dependent inhibitory effect of SM735 on DNFB-induced DTH ear swelling. When SM735 was administered for 4 consecutive days, at doses of 7.5, 15, and 30 mg/kg, SM735 significantly suppressed ear swelling by 19.6%, 35.5%, and 55.4%, respectively. The inhibition was comparable to that of CsA, which exerted 55.2% suppression at a dose of 50 mg/kg.

SM735 suppresses anti-SRBC specific immunoglobulin production

Quantitative hemolysis of SRBC (QHS) is a model of primary antibody production in response to anti-

Figure 3. BALB/c mice were initially sensitized with DNFB on d 0 and d 1, and then challenged with DNFB on d 9. Vehicle, CsA or SM735 was administered on d 7–d 10. Ear punches were taken 48 h post challenge, and ear swelling was calculated as the difference between the weights of the punches taken from the left ear (DNFB treated) and the right ear (untreated). $n=10$. Mean \pm SD. ^b $P<0.05$, ^c $P<0.01$ vs vehicle group. Three independent experiments were performed with similar results.

genic stimulation. Because CsA specifically blocks T cell activation by suppressing IL-2 production, with little effect on B cells, we chose cyclophosphamide (CTX) as a reference drug in the present study^[19]. As Figure 4 shows, administration of 15 and 30 mg/kg SM735 for 4 consecutive days significantly suppressed QHS in a dose-dependent manner. The inhibitive rates were 15.3% ($P<0.05$) and 25.4% ($P<0.01$), respectively, slightly less potent than the 31.8% inhibition effected by CTX ($P<0.01$).

Figure 4. BALB/c mice were immunized with SRBC for testing immunoglobulin secretion. Vehicle, 25 mg/kg CTX and SM735 were administered to each group for 4 consecutive days. Supernatant hemolysis at 520 nm was read to assess the immunoglobulin-secreting activity of B cells. $n=6$. Mean \pm SD. ^b $P<0.05$, ^c $P<0.01$ vs vehicle group.

Discussion

Patients who receive organ grafts are principally treated with immunosuppressive agents. In addition, there are a number of other autoimmune chronic inflammatory disorders that might be able to be treated with immunosuppressive drugs. In the 1970s and 1980s, the discovery and clinical use of CsA and tacrolimus (FK506) enabled the successful transplantation of major organs in human patients. However, it seems now that neither are able to be tolerated in the long term^[20,21]. These drugs cause systemic immunosuppression that greatly increases the risks of tumors arising and lethal fungal infections occurring. Therefore, new immunosuppressants are required that possess better therapeutic effects or can be combined with currently used drugs to reduce long-term tolerance and side effects.

Previous studies have indicated that artemisinin possesses anti-lymphocytic activities. There are numerous reports of clinical cases in which autoimmune diseases have been treated with artemisinin and artesunate; therapeutic

effects were achieved in these cases, thus encouraging us to study artemisinin and its derivatives. To improve the efficacy of the drug, we optimized artemisinin by linking it with various NSAID structures. Here, we report that a newly synthesized artemisinin derivative, SM735, possesses potent immunosuppressive activity both *in vitro* and *in vivo*.

Lymphocyte proliferation is a crucial event in the activation cascade of both cellular and humoral immune responses. Treatment with SM735 can dose-dependently reduce both the T and B cell proliferation promoted by mitogens. Because it has a relatively high CC_{50} value, SM735 has a favorably large safety range.

A mixed lymphocyte reaction is induced by allogeneic stimuli, and T lymphocytes are the main responders, indicating an immune response very similar to that which occurs in post-transplantation graft-versus-host diseases^[22,23]. MLR is often used clinically for tissue typing to identify the compatibility of donor organs and recipients. Furthermore, the suppression of MLR by immunosuppressants also helps improve the success of transplantation^[24,25]. Here we show that SM735 also potently inhibited MLR, with an IC_{50} value comparable to that for the inhibition of T cell proliferation. At concentrations above 10 $\mu\text{mol/L}$, SM735 almost completely abrogated MLR. This suggests that SM735 would probably act as an immunosuppressant in physiological conditions.

Cytokines are important modulators and effectors in the immune system. In particular, multiple proinflammatory cytokines have been proved to be closely associated with many autoimmune diseases. It is critical to silence proinflammatory cytokines to maintain successful immunosuppression^[26–28]. In the present study, we used mitogen ConA, bacterial LPS, and PMA plus ionomycin, which agitated the whole cell population by activating protein kinase C, to promote cytokine production in splenocytes. The results showed that SM735 significantly inhibited IL-12, IFN- γ and IL-6 production with LPS or PMA plus ionomycin stimulation. When using ConA as a stimulant, we also observed a dose-dependent inhibition of IFN- γ production. Unexpectedly, the IL-2 level was not obviously altered. Although the two cornerstone immunosuppressants, CsA and FK506, are putatively regarded as IL-2 inhibitors, it seems that SM735 acts totally differently, on some event(s) downstream of IL-2-mediated naive T cell activation. IL-2 is widely considered to be a key cytokine in T-cell-dependent immune responses. However, the main non-redundant activity of this cytokine centers on the regulation of T cell tolerance, and recent studies have indicated that a failure in the production of CD4⁺CD25⁺ regulatory T cells is the underlying cause of autoimmunity in the

absence of IL-2^[29]. Thus, the fact that SM735 does not inhibit IL-2 indicates that further research is necessary on the induction of long-term immune tolerance by SM735.

To examine the immunoregulatory effects of SM735 *in vivo*, we used a mouse DTH model and the QHS model. Ear swelling in DTH is primarily the result of antigen-specific CD4⁺ T cell activation^[30]. Administration of SM735 for 4 consecutive days significantly suppressed ear swelling, indicating that SM735 is capable of inhibiting the T-cell-dependent immune response *in vivo*. In our experiments, the effect of SM735 was comparable to that of cyclosporine at a curative dose. The QHS model reflects the antibody-producing capacity of plasma cells in response to SRBC^[18,19]. The suppressive effect of SM735 in QHS indicated that it also suppressed antibody-secreting B cells *in vivo*.

In conclusion, our results demonstrate that SM735, a newly synthesized artemisinin derivative, has strong immunosuppressive effects *in vitro* and *in vivo*. Because artemisinin and its derivatives potentially have low toxicity and few side effects^[4,31], our study suggests the possibility of developing SM735 and other artemisinin derivatives as novel safe immunosuppressants, probably with a different mechanism from that of CsA or FK506. However, further studies are necessary to elucidate the details of the mechanism.

Abstract

Aim: To investigate the effects of CpG-oligodeoxynucleotide (CpG-ODN) on the formation of macrophage foam cells and related gene expression. **Methods:** A gene expression profile was examined by microarray techniques, and mRNA expression was detected by reverse transcriptase polymerase chain reaction (RT-PCR). The cholesterol and cholesteryl ester contents of cells were determined by high performance liquid chromatography. **Results:** CD36, LPL, and Fcγ2b, which were related to lipid metabolism and the formation of macrophage foam cells, were upregulated after CpG-ODN stimulation. The mRNA expression related to the formation of foam cells was confirmed by semiquantitative RT-PCR. Moreover, histochemical analysis confirmed that lipid deposits inside cells increased after CpG-ODN treatment. However, using flow cytometry, we found that CpG-ODN had no effect on the expression of membrane receptors. **Conclusion:** CpG-ODN up-regulated the expression of genes in macrophage foam cell formation.

Introduction

CpG-oligodeoxynucleotides (CpG-ODN), the synthetic oligodeoxynucleotides containing unmethylated CpG dinucleotides in specific sequence contexts, are novel immune enhancers for systemic and mucosal immunization^[1]. Animal studies suggest that CpG-ODN could be used as vaccine adjuvants, or anti-allergenic, chemotherapeutic, or immunoprotective agents^[2–5]. Although the immunological effects of CpG-ODN have been widely studied^[6–9], including the mechanism by which CpG-ODN binds to the cell surface and the way in which its immunostimulatory activity is modulated by extracellular pH^[10], its biological activities are not comprehensively understood. To improve our knowledge of the biological activities of CpG-ODN, we used a DNA microarray to profile the gene expression in an immune cell line after CpG-ODN treatment, and found that some genes related to the formation of macrophage foam cells were upregulated. We therefore reasoned that CpG-ODN might affect the lipid metabolism and the formation of foam cells. Foam cells are characteristic pathological cells in atherosclerotic lesion. An excess lipid loading in macrophages results in the formation of foam cells, and this is a key process in the early stages of atherosclerotic lesions^[11]. Therefore, it is

very important to investigate how CpG-ODN affects the formation of foam cells. In the present study, we investigated the effects of CpG-ODN on the gene expression of the related receptors or enzymes involved in atherosclerosis, and further confirmed the results by using semiquantitative RT-PCR. Furthermore, by histochemical and high performance liquid chromatography (HPLC) analysis, we demonstrated that CpG-ODN could affect the formation of foam cells.

Materials and methods

CpG-ODN ODN-1826 (5'-TCCATGACGTTTCCTGACGTT-3') and ODN-2006 (5'-TCGTCGTTTTGT CGTTTTGTCGTT-3') were synthesized by Sangon Biotechnology Co in Shanghai, China.

Cell culture The mouse macrophage line RAW264.7 and the human monocyte line U937 were obtained from the Cell Bank in the Shanghai Institutes of Biochemistry and Cell Biology, Chinese Academy of Sciences, and were cultured in RPMI-1640 medium (Gibco/BRL, Rockville, USA), supplemented with 10% fetal bovine serum, 2 mmol/L glutamine, and 50 mg/mL gentamycin in 5% CO₂ at 37 °C. The culture medium was changed every 48 h.

Analysis of gene expression profile of immune cells by

using a cDNA microarray The MGEC-80s microarray obtained from Biostar Genechip (Shanghai) was used. RAW264.7 cells were stimulated with ODN-1826 6 $\mu\text{mol/L}$ for 6 h, and total RNA was isolated from cultured cells using TRIzol reagent (Gibco). mRNA was purified using the Oligotex mRNA midi Kit (Qiagen, Germany). The fluorescent cDNA probes were synthesized from total RNA by reverse transcription and then purified, referring to the protocol of Schena *et al* and Shalon D *et al*^[12,13]. The probes from the control were labeled with Cy3-dUTP; those from the stimulated cells by ODN-1826 were labeled with Cy5-dUTP. The probes were mixed and precipitated with ethanol, and resolved in 20 μL hybridization solution [$5\times\text{SSC}+0.4\%$ sodium dodecylsulfate (SDS)+50% formamide+5 \times Denhardt's solution]. Chips were prehybridized with the hybridization solution+3 μL denatured salmon sperm DNA at 42 $^{\circ}\text{C}$ for 6 h. After denaturing at 95 $^{\circ}\text{C}$ for 5 min, the probe mixture was added to the prehybridized chip and covered with glass. Hybridization was performed at 60 $^{\circ}\text{C}$ for 16 h. After hybridization of a sample to the microarray, the sample was removed, and arrays were washed in solutions of $2\times\text{SSC}+0.2\%$ SDS, 0.1% SSC + 0.2% SDS, and 0.1 $\times\text{SSC}$ at 60 $^{\circ}\text{C}$, respectively, for 10 min each, then dried at room temperature. Arrays were scanned with a laser scanner (ScanArray4000, General Scanning Inc, Watertown, Massachusetts) at 2 wavelengths. The acquired images were processed using a modification of GenePix Pro 3.0 software. The intensity of each spot at the 2 wavelengths represented the quantity of Cy3-dUTP and Cy5-dUTP, respectively. Each ratio of Cy3 to Cy5 was computed. The overall intensity was normalized by a coefficient according to the ratios of the 40 housekeeping genes that were also located.

Semiquantitative RT-PCR Total RNA of the U937 cells was extracted, purified using the Tissue/Cell Total RNA Isolation Kit (Watson, Shanghai), and quantified spectrophotometrically. A total of 200 ng RNA was reverse transcribed to cDNA in a volume of 20 μL using oligo(dT) prim-

ers and a commercially available kit (Reverse Transcription System, Promega, USA) according to the manufacturer's instructions. For transcription, the RNA was denatured at 70 $^{\circ}\text{C}$ and then transcribed for 1 h at 42 $^{\circ}\text{C}$. After inactivation of the avian myeloblastosis virus (AMV), (1 min at 99 $^{\circ}\text{C}$), the transcript was cooled down to 4 $^{\circ}\text{C}$. Four microliters of the reaction mixture was subjected to a final PCR reaction in a total volume of 20 μL , containing 0.5 μL of *Taq* polymerase (Takara Biotechnology, Dalian, China), 2 μL of $10\times\text{PCR Buffer}$ (Mg^{2+} Plus, Takara, Dalian), 2 μL dNTP mix (2.5 mmol/L), 0.5 μL of each of the 5' and 3' primers, and 10.5 μL of H_2O . All gene-specific PCR primers were designed based on the DNA sequences in GenBank (National Center for Biotechnology Information, Bethesda, MD, USA). The sequence of the primers and the annealing temperatures are shown in Table 1. The amplification was carried out over 35 cycles of the following: denaturation, 1 min at 94 $^{\circ}\text{C}$; annealing, 30 s, at temperature see Table 1; elongation, 1 min at 72 $^{\circ}\text{C}$. PCR products were separated by agarose gel electrophoresis. β -actin was used as a control. The intensities of the gene-specific PCR products were quantified from scanned images using the AlphaEase FC software (Alpha).

Preparation of ox-LDL Low-density lipoprotein (LDL) ($d=1.019$ to 1.063 kg/L; Sigma) was sterilized by filtration through 0.45 μm Millipore membranes, and stored at 4 $^{\circ}\text{C}$ as described previously^[14]. After edetic acid was removed by dialysis, LDL were oxidized by incubation in CuSO_4 10 $\mu\text{mol/L}$ at 37 $^{\circ}\text{C}$ for 12 h, and then dialyzed in phosphate buffered saline (PBS) containing edetic acid 0.1 mmol/L at 4 $^{\circ}\text{C}$ for 24 h.

In vitro induction of foam cell formation Confluent U937 cells were pretreated in serum-free RPMI-1640 for 24 h and then incubated with ox-LDL 80 mg/L for 48 h. The foam cell model was thus established. In the experiments, U937 cells were cultured with ODN-2006 6 $\mu\text{mol/L}$ and ox-LDL 80 mg/L for 48 h, which were added to the medium simultaneously. The control group was the U937 cells without ODN-2006 treatment. The morphological form of the foam cells was

Table 1. Primers used for RT-PCR.

LPL, lipoprotein lipase.

analyzed by histochemical methods.

Histochemical analysis of foam cells The foam cells were collected and fixed with 4% paraformaldehyde for 12 h on the slides as described previously^[15]. The slides were rinsed in water and placed in fresh 0.3% oil red O (Amresco, Solon, USA) solution for 20 min. The slides were rinsed in 50% isopropyl alcohol and examined.

Lipid extraction Lipids were extracted by using the method of Hara and Radin^[16] with modifications. The cells were collected from the culture flasks into 0.9% NaCl (2 mL per 75 cm² flask) and homogenized on ice by sonication for 10 s with a Sonifier 450 sonicator (Branson Ultrasonics, Danbury, USA) set to maximum power. The protein concentration of the cell lysate was determined by the method of Lowry *et al*^[17]. To a volume of cell suspension known to contain 1 mg of protein was added 100 µg of cholesteryl heptadecanoate in chloroform as an internal standard. An equal volume of freshly prepared cold (-20 °C) KOH in ethanol (150 g/L) was then added and the cell lysate was repeatedly vortexed until clear with 6% trichloroacetic acid. An equal volume of 4:1 hexane-isopropanol (v/v) was added and the mixture was vortexed for 5 min followed by centrifugation at 800×g and 15 °C for a further 5 min. The extraction procedure was repeated twice (a total of three extraction procedures). The combined organic phase was transferred to clean tapered glass tubes and thoroughly dried in a vacuum freeze dryer at 65 °C. The tubes were allowed to cool to room temperature, 100 µL of the mixture of isopropyl alcohol-*n*-heptane-acetonitrile at 35:12:52 (v:v:v) was added, and the sample was solubilized by placing it in an ultrasound water bath for 5 min at room temperature. After centrifugation at 800×g for 5 min, 20 µL of the sample was introduced into the HPLC device.

Determination of cholesterol and cholesteryl ester content of U937 cells by HPLC The cholesterol and cholesteryl ester content of cells were analyzed by HPLC as described previously^[18]. HPLC was performed using a Waters device

(Milford, USA) equipped with a model 1525 binary pump, a model 717 plus autosampler, a model 2487 dual λ absorbance detector, and a 4.6 mm×100 mm Gen-Pak FAX column (Waters). Waters' Breeze software was used to control the HPLC system. Cholesterol and cholesteryl esters were eluted isocratically at a flow rate of 0.5 mL/min and at a temperature of 4 °C using an eluent consisting of isopropanol-*n*-heptane-acetonitrile at the ratio of 35:12:52 (v:v:v) and detected by ultraviolet absorption at 206 nm.

Statistics Every experiment was repeated at least 3 times. All values are expressed as mean±SD. Differences were considered statistically significant when *P*<0.05 as determined by the paired *t*-test.

Results

Gene expression profile in immune cells By using the cDNA microarray, 119 genes related to cell cycle, immune modulation, and signal transduction were found to be differentially expressed, of which 3 genes related to the formation of macrophage foam cells had increased expression after ODN-1826 6 µmol/L stimulation (Table 2).

Table 2. Genes upregulated in RAW264.7 cells after ODN-1826 6 µmol/L stimulation.

Confirmation of foam cell-related gene expression by RT-PCR According to the 3 genes in Table 2, we designed primers and performed semiquantitative RT-PCR. The expression of these genes in the ODN-2006 treated group was markedly increased, compared with the control group (Figure 1).

Figure 1. Confirmation of foam cell-related gene expression in U937 cell line by RT-PCR. M: DL2000 marker; 1: Control; 2: ODN-2006 6 µmol/L. (A) CD36; (B) LPL; (C) Fcγ2b

Effect of CpG-ODN on lipid deposition in cells Lipid drops inside the foam cells were stained with oil red O, and some of the red pellets were found in the plasma of the U937 cells after being incubated with ox-LDL, indicating that the foam cell model was formed. After ODN-2006 6 $\mu\text{mol/L}$ was added to the medium, lipid deposition in U937 foam cells was enhanced (Figure 2).

Effect of CpG-ODN on cholesterol and cholesteryl ester in foam cells After incubation with ODN-2006 6 $\mu\text{mol/L}$ and ox-LDL 80 mg/L for 48 h, the level of cholesteryl ester in foam cells increased markedly compared with the controls (Figure 3). This suggests that CpG-ODN can also increase lipid accumulation (based on the assay of the concentrations of cholesteryl ester and the ratio of cholesteryl ester to total cholesterol; Table 3). Cholesterol concentration has a strong linear relationship with its peak area within 0.05–1.0 mg/L (r^2 in each case was >0.998).

Discussion

Previous reports have suggested that CpG-ODN is mainly involved in immunomodulation^[19,20]. Nevertheless, in the study presented here, we investigated immune cells treated with CpG-ODN using cDNA microarray technology and, surprisingly, found that the expression of 3 genes (CD36 [NM_007643], LPL [NM_008509], and Fc γ 2b [NM_010187]) increased markedly. These results were further confirmed by semiquantitative RT-PCR. CD36, LPL, and Fc γ 2b are thought to be closely related to lipid metabolism and the formation of macrophage foam cells, therefore CpG-ODN is able to modulate gene expression in foam cells, and increase lipid accumulation in foam cells. Our findings suggest that CpG-ODN has a novel biological activity.

Atherosclerosis, and the resulting coronary heart disease and cerebral stroke, is the most common cause of death

Figure 2. Effect of ODN-2006 on lipid deposition in U937 cells. Lipid drops (red pellets in the plasma of the cells) were stained by oil red O ($\times 400$). in industrialized nations. Mammalian cells have evolved complex feedback mechanisms to ensure a sufficient supply of cholesterol and to prevent its excessive accumulation. During the process of atherosclerosis, these homeostatic mechanisms fail in macrophages. Uncontrolled cholesterol deposition is promoted by scavenger functions of the macrophages and the adaptive mechanisms elicited are not sufficient to process the lipid load. Consequently, a lipid-laden “foam cell” is formed. The active stages of atherosclerotic lesions are characterized by the extensive infiltration of blood-derived monocyte/macrophages through the endothelium into the arterial intima. The monocytes migrate into the arterial intima where they internalize ox-LDL through scavenger receptors and become macrophage-derived foam cells results in the formation of fatty streaks, which are believed to represent the earliest type of atherosclerotic plaque. CpG-ODN can upregulate the related gene expression in foam cells, which implies that CpG-ODN might function as a facilitative atherosclerotic factor. This suggests that the clinical application of CpG-ODN might be risky in cases of atherosclerosis.

Macrophage-derived foam cells in atherosclerotic lesions are generally thought to play a major role in the pathology of the disease. The uptake of ox-LDL by macrophages is a key event implicated in the initiation and development of athero-

sclerotic lesions. Two macrophage surface receptors, CD36 (a class B scavenger receptor) and the macrophage scavenger receptor (a class A scavenger receptor), have been identified as the major receptors that bind and internalize ox-LDL. CD36 is an 88 kDa transmembrane glycoprotein that is expressed on monocytes, platelets, and microvascular endothelium. The expression of CD36 in monocytes/macrophages in tissue culture is dependent both on their differentiation state and exposure to soluble mediators (cytokines and growth factors). Modified lipoproteins such as LDL immune complexes can also enter the macrophage through the Fcγ receptor, which is a classic inhibitory receptor that is widely expressed on B cells, macrophages, neutrophils, and mast cells. Once LDL immune complexes combine with the Fcγ receptor, it may enhance LDL oxidation and expression of the scavenger receptor^[21]. Lipoprotein lipase (LPL) is the enzyme primarily responsible for the hydrolysis of core triglycerides in circulating chylomicrons and very low density lipoproteins (VLDL) to generate cholesterol-enriched remnants^[22]. LPL is synthesized by many cell types, including vascular smooth muscle cells (VSMC) and macrophages, and associates with the vascular endothelium. Increased LPL activity in the arterial wall correlates with increased areas of lipid deposition and increased atherosclerotic lesion forma-

tion^[23]. The activity of LPL in promoting atherosclerosis may depend on its dual role as an enzyme and as a bridging protein that increases the binding of lipoproteins to the cell surface^[22].

Our data suggest that CpG-ODN upregulates the expression of CD36, Fcγ2b, and LPL in foam cells, which indicates that CpG-ODN might have some influence on the formation of foam cells and related gene expression.

Abstract

Aim: To elucidate inhibition of protein kinase C α (PKC α) activity by staurosporine on apoptosis of oral cancer cell line tongue squamous cell carcinoma (TSCCa) cells and to clarify the role of survivin and caspase-3 in mediating apoptosis.

Methods: TSCCa cell viability was measured by MTT assay after 100 nmol/L staurosporine treatment. Apoptotic cells were identified by using phase contrast microscopy, acridine orange/ethidium bromide staining, and flow cytometry. Level of PKC α and its subcellular location were investigated using Western blot analysis. Expression of survivin and caspase-3 were evaluated using immunocytochemistry.

Results: Staurosporine significantly inhibited the cell viability of TSCCa cells in a dose- and time-dependent manner. Marked cell accumulation in G₂/M phase was observed after 100 nmol/L staurosporine exposure for 6 h and 12 h. In addition, the percentage of apoptosis increased in a time-dependent manner, from 2.9% in control cultures to approximately 27.4% at 100 nmol/L staurosporine treatment for 24 h. Staurosporine displayed difference in inhibitory efficacy between cytosolic and membrane-derived PKC α . The content of PKC α in membrane versus cytosol decreased quickly, from 0.45 in ethanol-treated control cultures to 0.18 after staurosporine exposure for 24 h ($P < 0.01$). After treatment with staurosporine, a time-dependent reduction of survivin and an activation of caspase-3 were observed in TSCCa cells. **Conclusion:** Staurosporine inhibited cell viability and promoted apoptosis in TSCCa cells. Inhibition of PKC α activity might be a potential mechanism for staurosporine to induce apoptosis in this cell line. The cleavage of survivin and activation of caspase-3 signaling pathway might contribute to PKC α inhibition-induced apoptosis.

Introduction

Cell proliferation, differentiation and apoptosis are central features of tissue homeostasis, and inhibition of apoptosis might be involved in the pathogenesis of cancer by prolonging cell life and sustaining growth of malignant tissues^[1,2]. Protein kinase C (PKC) is a family of phospholipid-dependent serine/threonine kinases and participates in many cellular responses, including cell apoptosis, which can be inhibited by staurosporine^[3–5]. The family contains at least 12 isoforms, and specific roles in cell cycle progression and in apoptosis have been hypothesized for the different

PKC isoenzymes. Of these PKC isoforms, PKC α is distributed in almost all tissues and is involved in various signal transductions. Considerable evidence suggests that PKC α plays an important role in the apoptosis of some tumor cells and that the inhibition of PKC α might induce apoptosis^[5,6]. In contrast, one recent study reported that elevated expression of PKC α might promote the apoptosis of gastric cancer cells^[7]. However, little is known about the protein level and subcellular distribution of PKC α in the apoptosis of oral cancer cells. Elucidating the patterns of PKC α action will lead to a better understanding of the molecular mechanism of the PKC α signal pathway involved in the apoptosis of

oral cancer cells.

The activation of caspases, particularly caspase-3, appears to be a central part in most apoptotic pathways and most types of cells^[8,9]. Caspases have been shown to be cleaved and possibly activated by PKCs suggesting that they act downstream of PKCs as effectors in the apoptotic machinery^[6]. Survivin, a recently characterized inhibitor of apoptosis protein (IAP), is abundantly expressed in oral squamous cell carcinoma (OSCC), but undetectable in normal oral tissues^[10,11], suggesting a potential role in oral carcinogenesis. However, no direct molecular interaction has been described so far between PKC α , survivin and caspase-3 in mediating apoptosis of oral cancer cells.

In the present study, we investigated the functional and molecular interactions among PKC α , survivin and caspase-3 in apoptosis induced by staurosporine with the aim of further highlighting their relevance in OSCC biology.

Materials and methods

Reagents Fetal bovine serum (FBS) and Dulbecco's modified Eagle's medium (DMEM) were obtained from Gibco Laboratories (Gibco/BRL, Grand Island, NY). MTT, acridine orange (AO), ethidium bromide (EB), propidium iodide (PI) and staurosporine were obtained from Sigma Biotechnologies (Sigma-Aldrich, Inc, Saint Louis, Missouri, USA). Staurosporine was dissolved in ethanol to make a stock solution of 1 mmol/L and diluted to their final concentrations in the culture medium. The final concentration of ethanol never exceeded 0.01%, a concentration at which there is no discernible effect on tongue squamous cell carcinoma (TSCCa) cells in comparison with the control. Primary antibodies including mouse monoclonal antibodies to PKC α (H-7, sc-8393), β -actin (C-2, sc-8432), caspase-3 (E-8, sc-7272) and rabbit polyclonal antibody against survivin (FL-142, sc-1081) were obtained from Santa Cruz Biotechnology (Santa Cruz, California, USA). An enhanced chemiluminescent detection system (ECL kit) from Amersham international Plc (Amersham Biosciences, Buckinghamshire, UK) was used for Western blot analysis. All other reagents were analytical reagents.

Cell culture TSCCa cell line was established by Dr Hui-xi JIN from a patient with OSCC of the tongue^[12]. TSCCa cells were cultured in DMEM, supplemented with 10% heat-inactivated FBS, 100 kU/L penicillin, and 0.1 g/L streptomycin. The cells were maintained at 37 °C in a humidified atmosphere of 5% CO₂. TSCCa cells were cultured and treated with either 0.01% ethanol (vehicle) or 1–100 nmol/L staurosporine. The treated cells were examined by phase contrast microscope (Nikon Instech Co Ltd, Kanagawa, Japan) for

evidence of morphological changes induced by staurosporine treatment.

MTT assay Cell viability and activity were detected using MTT dye assay, in which the dye was converted into formazan granules in the presence of reactive oxygen. TSCCa cells were plated at a density of 5×10^3 cells per well on a 96-well plate. At 24 h after seeding, staurosporine (1–100 nmol/L) was added to the culture medium. At 6 h, 12 h, and 24 h after drug treatment, MTT was added to each well at a concentration of 500 mg/L and incubated for 4 h at 37 °C. After that, media were aspirated and cells were solubilized in 400 μ L Me₂SO. Cells were incubated for 10 min at 37 °C with gentle shaking. Absorbance was measured at 540 nm using a computerized microplate analyzer.

AO/EB staining To assess apoptosis, cells were stained with AO/EB. In brief, after TSCCa cells were treated with 100 nmol/L staurosporine for 24 h, nonadherent cells in the medium and trypsinized adherent cells were centrifuged at $200 \times g$ for 10 min at 4 °C and all but 50 μ L media was removed. The pellet was resuspended with 2 μ L for each 0.1 g/L AO and EB. Cells were immediately viewed using a fluorescence microscope (Leica Microsystems AG, Wetzlar, Germany). Morphology was defined according to descriptions from Kern and Kehrer for general apoptotic characteristics^[13].

Flow cytometry For flow cytometric assessment of apoptosis and cell cycle phases, TSCCa cells were fixed with ice-cold 75% ethanol following 100 nmol/L staurosporine treatment for 6 h, 12 h or 24 h, and washed twice with phosphate-buffered saline (PBS). Cells were incubated at 37 °C for 30 min in PBS containing 1 g/L RNase, then stained with 100 mg/L PI. Cellular DNA content was measured by Beckman Coulter Epics Altra II cytometer (Beckman Coulter, California, USA).

PKC α subcellular fractionation and Western blot analysis TSCCa cells treated with 100 nmol/L staurosporine for 12 h and 24 h were washed twice with PBS and were then scraped from the culture vessels and collected. Harvested cells were suspended in 0.5 mL of hypotonic buffer [10 mmol/L *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES, pH 7.4), 1.5 mmol/L MgCl₂, 10 mmol/L KCl, 0.2 mmol/L phenylmethylsulfonyl fluoride (PMSF), 0.5 mmol/L DTT] and homogenized with a Dounce homogenizer at 4 °C. Unlysed cells, nuclei and cell debris were pelleted by centrifugation at $1000 \times g$ at 4 °C for 5 min. The supernatant was centrifuged at $100\,000 \times g$ at 4 °C for 1 h. The $100\,000 \times g$ supernatant was designated as a cytosol fraction. The $100\,000 \times g$ pellet was suspended in hypotonic buffer containing 1% Triton X-100 and centrifuged at $10\,000 \times g$ for 10 min, and the resulting supernatant is referred to as the membrane fraction. Protein

samples were mixed with an equal volume of 2×sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) sample buffer, boiled for 5 min, and then separated using 10% SDS-PAGE gels with 20 µg of protein loaded per lane. After electrophoresis, proteins were transferred to PVDF membranes by semi-dry electrophoretic transfer. The membranes were blocked in 5% dry milk (1 h), rinsed and then incubated with primary antibody of PKCα (1:1000 dilution) overnight at 4 °C. The primary antibody was removed, membranes were washed 4 times, and 0.1 mg/L peroxidase-labeled goat secondary antibody was added for 1 h. Bands were then visualized by ECL kit and exposed to X-ray film. Percentage of membrane or cytosol band was calculated by a Bio-Rad (Richmond, CA) model GS-670 Imaging Densitometer.

Immunocytochemistry TSCCa cells were seeded on 8-chambered glass slides and treated with 100 nmol/L staurosporine for 12 h and 24 h as described above. Cells were fixed for 10 min in 100% methanol at room temperature. Then, cells were washed with PBS, treated with 3% hydrogen peroxide to block endogenous peroxidase activity and incubated with normal serum. After a 2-h incubation with primary antibodies, cells were washed 3 times with PBS and incubated with biotin-labeled anti-mouse or anti-rabbit immunoglobulin G for 20 min. After washing 3 times with PBS, cells were stained using the UltraSensitive streptavidin-peroxidase detection system (Maixin Biotechnology, Fuzhou, China). Positive reaction was seen as brown staining. One hundred cells were counted to determine the intensities of protein expression of caspase-3 and survivin by using HPLAS-2000 analysis software (Qianping Biotechnology, Wuhan, China).

Statistical analysis Data were expressed as mean±SD. Statistical significance was assessed with one-way ANOVA followed by Duncan’s multiple-range test. $P < 0.05$ was considered statistically significant.

Results

Effect of staurosporine on cell viability in TSCCa cells

In the present study, the effect of staurosporine on TSCCa cell viability was evaluated using a MTT assay. Staurosporine exerted a marked dose- and time-dependent inhibitory effect on the viability of TSCCa cells. The effect was observed at 12 h after treatment, and increased with time, so that after 24 h with 100 nmol/L staurosporine cell viability was reduced to only 24% of the control (Figure 1).

Morphological changes in TSCCa cells induced by staurosporine To address the ability of staurosporine to

Figure 1. Effect of staurosporine on cell viability of tongue squamous cell carcinoma cells by colorimetric methylthiazol tetrazolium (MTT) assay. $n=4$. Mean±SD. ^a $P > 0.05$, ^b $P < 0.05$, ^c $P < 0.01$ vs control. (○) control; (●) staurosporine 1 nmol/L; (×) staurosporine 10 nmol/L; (□) staurosporine 100 nmol/L.

induce cell death, we first investigated the effect of staurosporine on cell morphological changes using a phase contrast microscope. Numerous TSCCa cells exhibited a flat appearance in the absence of staurosporine (Figure 2A). After incubation with 100 nmol/L staurosporine, TSCCa cells presented remarkable morphological changes. TSCCa displayed a long spindle shape 6 h after stimulation (Figure 2B). Then the number of TSCCa cells decreased, with an increased, large amount of intracellular vesicles (Figure 2C). After 24 h of staurosporine stimulation, we observed that treatment resulted in cells exhibiting evidence of apoptosis, including cell detachment, loss of cell processes and membrane shrinkage, as evidenced by curling up of cells (Figure 2D).

Morphological changes of TSCCa cells were also investigated by AO/EB staining using fluorescence microscopy. Live cells stain only with AO, which shows up green inside the cell. Apoptotic cells induce fragmentation of the yellow organelle. Necrotic cells stain with EB, and are detected by their red color. The images in Figure 3 show that with a dose of 100 nmol/L staurosporine treatment for 24 h, there were increasing amounts of swollen and distorted cells coupled with organelle disintegration and a rise in necrotic cells.

DNA content analysis of TSCCa cells treated with staurosporine

To determine the effects of staurosporine on cell cycle progression and apoptosis, TSCCa cells were stained with PI and subjected to flow cytometric analysis. A representative cell cycle profile of control cells is shown in Figure 4A. Treatment with 100 nmol/L staurosporine for various periods of time resulted in changed DNA content profiles. Staurosporine treatment for 6 h and 12 h caused an

Figure 2. Morphological changes of TSCCa cells caused by 100 nmol/L staurosporine incubation and photographed with a phase-contrast microscope. (A) control ; (B) staurosporine exposure for 6 h; (C) staurosporine exposure for 12 h; (D) staurosporine exposure for 24 h. $\times 200$.

Figure 3. Fluorescence micrographs of TSCCa cells stained with acridine orange/ethidium bromide treated with or without 100 nmol/L staurosporine. (A) control TSCCa cells; (B) staurosporine exposure for 24 h. $\times 400$.

accumulation of the cells in G_2/M phase of approximately 26.6% and 34.0%, respectively; and that of the control was approximately 9.9% (Table 1). This indicates that the appearance of a G_2/M arrest of staurosporine in TSCCa cells is time-dependent. With the time prolonged, the G_2/M arrest caused by staurosporine released and cells returned to G_0/G_1 phase and S phase. After 24 h of staurosporine treatment, the percentage of cells in G_2/M decreased to 19.8%;

Table 1. Effect of staurosporine on cell cycle distribution and apoptosis of tongue squamous cell carcinoma cells. $n=3$. Mean \pm SD. ^a $P>0.05$, ^c $P<0.01$ vs control.

Groups	Cell cycle/%			Apoptosis/ %
	G_0/G_1	S	G_2/M	
Control	58.9 \pm 1.0	31.2 \pm 2.1	9.9 \pm 1.2	2.9 \pm 0.3
Staurosporine 6 h	58.4 \pm 1.9 ^a	15.0 \pm 0.4 ^c	26.6 \pm 1.8 ^c	7.3 \pm 0.4 ^c
Staurosporine 12 h	56.0 \pm 0.7 ^a	9.9 \pm 0.4 ^c	34.0 \pm 1.0 ^c	10.6 \pm 1.5 ^c
Staurosporine 24 h	59.5 \pm 1.0 ^a	20.7 \pm 0.1 ^c	19.8 \pm 0.9 ^c	27.4 \pm 0.7 ^c

however, this was still higher than that of the control (Figure 4).

The percentage of cells or cell fragments with DNA content less than 2N (hypodiploid or apoptotic shift) increased in a time-dependent manner, from 2.9% in control cultures to approximately 27.4% at 100 nmol/L staurosporine exposure for 24 h (Table 1, Figure 4).

Changes in PKC α content and subcellular distribution in TSCCa cells Because the translocation of PKC α from cytosol to the membrane is a hallmark of PKC α activation, Western blot experiments were performed to detect the protein level of PKC α in cytosol and membrane of TSCCa cells treated with 100 nmol/L staurosporine for different periods of time. We found that PKC α is expressed in both cytosol and membrane in ethanol-treated control TSCCa cells. After treatment with staurosporine for various periods of time, PKC α content in cytosol and membrane decreased in a time-dependent manner (Figure 5). In addition, the percentage of PKC α content in membrane versus cytosol decreased quickly in staurosporine treated cells, from 0.45 in ethanol-treated control cultures to 0.18 at staurosporine exposure for 24 h (Table 2).

Effect of staurosporine on the activation of caspase-3 and the protein level of survivin To further characterize the mechanisms that control apoptosis in TSCCa cells, protein levels of caspase-3 and survivin in TSCCa cells treated with 100 nmol/L staurosporine for 12 h and 24 h was measured by immunocytochemical staining. In untreated TSCCa cells, there was a faint brown cytoplasmic staining for caspase-3 (Figure 6Aa). After incubation with staurosporine for 12 h and 24 h, cytoplasmic caspase-3 staining was substantially

Figure 5. Subcellular localization of protein kinase C α in tongue squamous cell carcinoma cells treated with or without 100 nmol/L staurosporine examined by Western blot. Cell lysates were fractionated into cytosol and membrane fractions, and 20 μ g of protein was loaded in each lane. An antibody against β -actin was used as a loading control. Lane 1, control; Lane 2, staurosporine exposure for 12 h; Lane 3, staurosporine exposure for 24 h.

increased in a time-dependent manner (Figure 6B). TSCCa cells with fusiform shape, numerous intracellular vesicles and shrinking cells showed deep brown cytoplasmic granules of caspase-3 staining (Figure 6Ab).

Furthermore, a strong cytoplasmic staining of survivin was observed in control cells, especially in nuclear division cells (Figure 6Ac). After incubation with staurosporine for 24 h, survivin expression was diminished (Figure 6Ad, 6B).

Discussion

The molecular mechanisms associated with apoptosis have been widely explored, but are not yet precisely understood^[14]. Staurosporine has been shown to induce apoptosis in a wide variety of cell types, such as rat cardiomyocytes, human dermal papilla fibroblasts and luteinized granulosa cells. Therefore, staurosporine-induced apoptosis has been recognized as a useful model for investigating the mechanism of apoptosis in mammalian cells^[15]. To assess whether staurosporine induces apoptosis in oral cancer cells, 3 specific methods were used in the present study to evaluate apoptosis. The presented data demonstrate that apoptotic changes induced by staurosporine were confirmed by morphological changes observed under phase contrast microscopy, AO/EB staining and flow cytometric analyses of cellular DNA content. A significant proportion of cells at G₂/M

phase were also observed after 6 h treatment with staurosporine, and appeared at peak after 12 h of treatment. With the time prolonged, the G₂/M arrest caused by staurosporine released and cells returned to G₀/G₁ phase and S phase after 24 h of treatment, whereas a significant proportion of cells appeared at sub-G₀/G₁ apoptotic peak. Another report showed that staurosporine induced apoptosis in Chang liver cells by a mitochondria-caspase-dependent pathway, which can be suppressed by z-VAD-fmk, a general inhibitor of caspases; whereas the arrest of cells in G₂/M phase of cell cycle was not modified by z-VAD-fmk, suggesting that apoptosis and G₂/M arrest caused by staurosporine might be controlled in different independent pathways^[16]. Although cells with typical apoptotic morphology were observed after the treatment, we cannot exclude the possibility that some necrosis occurred with the high staurosporine dose. However, our findings were consistent with other reports showing that staurosporine at 100 nmol/L concentration can trigger apoptosis regardless of the cell cycle status^[15].

To explore more precisely the mechanisms of staurosporine-induced TSCCa cells apoptosis, we investigated whether the PKC α signal pathway was involved, as it has been shown that perturbation of PKC α activity can induce or repress apoptosis^[5–7]. We determined, using Western blot analysis, that cultured TSCCa cells expressed PKC α both in cytosol and membrane under 10% serum concentration.

When TSCCa cells were treated with staurosporine, content of PKC α in cytosol and membrane decreased dramatically, especially in membrane. One important factor in determining specific functions of PKC isoforms is their intracellular localization. PKC isoforms show different patterns of subcellular localization, which can vary for the various isoforms according to tissue and cell type. PKC α typically reside in the cytosol in an inactive state. After cell stimulation, they are often translocated to other compartments. Our results suggest that inhibition of PKC α translocated from cytosol to membrane might mediate staurosporine-induced TSCCa cells apoptosis. It is not clear, however, how the complex isoform-specific subcellular distribution and stimulus-induced redistribution can be achieved. As staurosporine was a wide inhibitor of PKC, we could not exclude the possibility that other PKC isoenzymes could also mediate staurosporine-induced TSCCa cells' apoptosis.

Caspase-3 has been reported to play a key role in apoptosis^[8,9]. Caspase-3 normally exists in the cytosolic fraction of cells as an inactive precursor, activating proteolytically when cells are signaled to undergo apoptosis. Multiple apoptotic signals, including serum withdrawal and treatment with a variety of pharmacological agents, activate caspase-3. The role of caspase-3 in apoptosis of oral cancer cells has not yet been reported. Lewis *et al* report that PKC inhibition induces DNA fragmentation in the colon cancer cell line, COLO 205 cells, which is blocked by cysteine protease inhibition but not mediated through caspase-3^[17]. However, we have examined the caspase-3 content changes in TSCCa cells after staurosporine exposure for various periods of time, and have shown that staurosporine activates caspase-3 in a time-dependent manner. These results suggest that caspase-3 was activated by staurosporine in TSCCa cells, and might mediate staurosporine-induced TSCCa cells apoptosis.

Survivin is associated with the microtubules of the mitotic spindle. Disruption of the survivin-microtubule interaction leads to loss of survivin function and increased proapoptotic caspase-3 activity^[18]. In the present study, the majority of ethanol-treated control TSCCa cells overexpressed survivin, but this was not enough to protect TSCCa cells from staurosporine-induced apoptosis. Furthermore, a dose-related decrease of survivin content in TSCCa cells was associated with the induction of apoptosis by staurosporine; these results suggest that survivin in TSCCa cells could not protect TSCCa cells from the lethal effects of staurosporine.

In conclusion, the present study demonstrates that staurosporine induces apoptosis in TSCCa cells. Our results document, for the first time, the potential roles of the

inhibition of PKC α in TSCCa cells' apoptosis. This property of PKC α appears to be linked to the cleavage of survivin and activation of caspase-3. Previous studies have reported that PKC activation could cause stimulation of the transcription factor NF- κ B, which in turn induced expression of the IAP^[19-22]. As discussed in the present study, the IAPs are known to block caspase-3 activity and apoptosis. Therefore, it is possible that PKC α inhibition-mediated staurosporine causes reduction of survivin and results in the activation of the caspase-3 signaling pathway. Further study is needed to understand the role of other caspases in staurosporine-induced TSCCa cells apoptosis, which might be a potential target in the treatment of oral cancer diseases.

Abstract

Aim: To investigate the antitumor activity and safety of a novel recombinant mutant human tumor necrosis factor-related apoptosis-inducing ligand (rmh TRAIL). **Methods:** Antitumor activity of rmh TRAIL was evaluated by using several tumor cell lines by MTT assay *in vitro*, and by using a mouse xenograft model *in vivo*. rmh TRAIL-induced apoptosis in tumor cells was detected by cell death enzyme-linked immunosorbent assay (ELISA), TdT-mediated dUTP nick-end labeling (TUNEL) assay and flow cytometry. The safety of rmh TRAIL was also evaluated in several normal human cell lines. **Results:** At the concentration of 0.32–1 000 ng/mL, rmh TRAIL remarkably inhibited the proliferation of 5 tumor cell lines from lung, colon, and breast cancer compared with wild type (wt TRAIL) *in vitro*, whereas at the concentration of 1 ng/mL–10 µg/mL, rmh TRAIL showed no or mild cytotoxicity in the normal cell lines. rmh TRAIL (3, 15 mg/kg, ip, once daily for 10 d) exerted a significant inhibition on the growth of xenograft tumor NCI-H460 in nude mice compared with the saline group ($P < 0.01$), and was more potent than wt TRAIL, a positive control. The apoptosis of NCI-H460 cells was markedly induced in a concentration-dependent and time-dependent manner after rmh TRAIL treatment. The percentage of apoptotic cells induced by rmh TRAIL in NCI-H460 cells was significantly higher than that by wt TRAIL. **Conclusion:** rmh TRAIL provided potent antitumor activity *in vivo* and *in vitro*, whereas most normal human cells were resistant to rmh TRAIL. The results suggested that rmh TRAIL might be a useful anticancer agent in future.

Introduction

Apoptosis, or programmed cell death, is a regulated process that is essential to metazoan development and tissue homeostasis^[1]. Instructive apoptosis plays a physiological role in deletion of activated lymphocytes at the end of an immune response and in elimination of virus-infected cells and oncogenically transformed cells. Deregulation of programmed cell death leads to several human diseases, including cancer, neurodegenerative disorders, and acquired immunodeficiency syndrome^[2]. Since the 1980s, biotherapy has become an important modality for treating cancer^[3]. Biotherapy is achieved by inducing apoptosis of tumor cells, which is the ultimate objective of tumor therapy. The mem-

bers of the tumor necrosis factor (TNF) family became the focus of biotherapy of cancer^[4]. Despite the potential of TNF and Fas ligand (FasL; also called CD95L) to induce apoptosis in many types of tumor cells, severe toxic side-effects preclude both of these ligand from use in systemic anticancer therapy^[5,6]. TNF infusion causes a lethal inflammatory response that resembles septic shock mediated by activation of the proinflammatory transcription factor NF-kappaB in vascular endothelial cells and macrophages. Infusion of agonistic anti-Fas antibody causes lethal liver damage as a result of the induction of Fas-dependent apoptosis in hepatocytes. Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL, also called Apo2 ligand) is a newly discovered TNF superfamily member initially cloned

from human heart and lymphocyte cDNA libraries because of its sequence homology to TNF and FasL^[7,8]. The TRAIL mRNA is constructively expressed at significant levels in many tissues in humans (eg lung, liver, spleen, kidney, thymus, prostate, ovary, intestine, periphero-lymphoid nodes, heart, placenta, and skeletal muscle). Recent studies have shown that TRAIL could induce apoptosis in numerous transformed cell lines of different lineage, but showed nontoxicity systemically unlike TNF and FasL, ionizing radiation and chemotherapy^[9-11]. The combination of TRAIL and ionizing radiation or chemotherapy appears to have an enhancing effect on cancer therapy, and consequently reduces the dose and side-effects of chemotherapeutics^[12-16]. Therefore, TRAIL is considered to be the most promising among antitumor agents at present.

TRAIL is expressed as a type II transmembrane protein, as are other members TNF and FasL^[8], and its extracellular region forms a soluble molecule upon cleavage^[17]. There are several forms of recombinant TRAIL: soluble TRAIL fusion protein (termed LZ-TRAIL) in which the extracellular region of the ligand (amino acids 95-281) is linked to an exogenous, modified leucine zipper that drives trimerization^[11]; soluble TRAIL containing just the extracellular region (amino acids 114-281); polyhistidine-tagged soluble form (his-TRAIL, amino acids 114-281)^[8,18]; glutathione *S*-transferase-TRAIL (GST-TRAIL, amino acids 95-281); and flag epitope-tagged form (amino acids 95-281)^[8,18]. However, these other forms have deficiencies in solubility, antitumor activity and security. Therefore, Beijing Sunbio Biotech developed recombinant mutant human TRAIL (rmh TRAIL). The aim of the present work was to evaluate the antitumor activity of rmh TRAIL *in vitro* and *in vivo*, and to explore its antitumor mechanism.

Materials and methods

Expression and purification of protein *Escherichia coli* BL21 (DE3) strain was used for the expression of rmh TRAIL. After transformed the plasmid of rmh TRAIL [with a circular permuted extracellular sequence of native human Apo2L/TRAIL (amino acid 121-281)], which was built by Beijing Sunbio Biotech, into the expression vector, expression was induced by isopropyl- β -*D*-thiogalactopyranoside (IPTG) at 37 °C for 4 h. Optimized IPTG concentration was 1 mmol/L for the protein. Bacteria were harvested and resuspended in phosphate-buffered saline (PBS, containing 137 mmol/L NaCl, 2.7 mmol/L KCl, 4.3 mmol/L Na₂HPO₄, 1.4 mmol/L KH₂PO₄, pH 7.3), sonicated on an ice bath, and centrifuged before further analysis. Purification of rmh TRAIL was performed with Ni²⁺-loaded chelating (Amersham Pharmacia Biotech,

Piscataway, USA) and purified protein was subjected to de-salting with S-200 (Amersham Pharmacia Biotech). rmh TRAIL molecular weight is 19 kDa, and purity is >98%.

Reagents The wild type TRAIL (wt TRAIL) (amino acids 114-281) used in our experiments was produced by Beijing Sunbio Biotech, or purchased from Merck (Whitehouse Station, USA) (used only *in vitro*). An Annexin V-FITC apoptosis detection kit was obtained from Oncogene (Cambridge, USA). *In situ* cell death detection kit (peroxidase, POD) and cell death detection enzyme-linked immunosorbent assay (ELISA)^{PLUS} kit were from Roche (Nutley, USA). DAB kit was purchased from Beijing Zhongshan Golden Bridge Biotech. MTT was from Sigma (St Louis, USA). DTT and proteinase K was from Merck. All the reagents, including dimethyl sulfoxide (Me₂SO) (Tianjin Fuchen Chemicals Reagent Factory), ethanol, methanol, saturated phenol, paraformaldehyde (Beijing Chemical Reagents Company) were of analytical grade.

Animals BALB/c nude mice (female), 6-8 weeks old, weighing 23-27 g, were supplied by National Institute for the control of Pharmaceutical and Biological Products. Animals were kept at room temperature of 18-22 °C, with a relative humidity of 70%.

Cell culture Tumor cell lines: NCI-H460 human non-small cell lung cancer cells and COLO205 human colon cancer cells were obtained from American Type Culture Collection (ATCC); QG-56 human lung squamous cells were obtained from the cell bank of the Chinese Academy of Sciences; MDA-MB-231 and MCF-7 human breast cancer cells were obtained from the Institute of Materia Medica, Chinese Academy of Medical Sciences and Peking Union Medical College.

Normal cell lines: EC-304 human blood vessel endothelial cells were purchased from Nanjing KeyGen Biotech. Human embryonic lung fibroblasts (HELFL) were obtained from the Institute of Materia Medica, Chinese Academy of Medical Sciences and Peking Union Medical College. HL-7702 normal human hepatocytes were obtained from the cell bank of the Chinese Academy of Sciences. CCC-HEH-1 human primary embryo myocardium-derived cells, CCC-HEL-1 human primary embryo liver-derived cells, CCC-HBE-2 human primary embryo trachea-derived cells, MRC-5 human embryonic lung fibroblasts, CCC-ESF-1 human primary embryo skin fibroblast cells, and HK-2 human primary nephritic tubular epithelium cells, were all obtained from cell center of the Chinese Academy of Medical Sciences and Peking Union Medical College.

NCI-H460, COLO205, QG-56, EC-304, HELFL and HL-7702 were cultured in RPMI-1640 medium (GIBCO, Carlsbad, USA) supplemented with 10% fetal bovine serum (FBS) (Lanzhou

National HyClone Bio-engineering, Lanzhou, China). MCF-7 and MRC-5 were cultured in Minimum Essential Medium (MEM, GIBCO) supplemented with 10% FBS. MDA-MB-231 cells were cultured in Leibovitz's L-15 medium (GIBCO) supplemented with 15% FBS. CCC-HEH-1, CCC-HEL-1, CCC-HBE-2, and CCC-ESF-1 were cultured in Dulbecco's Modified Eagle's Medium (DMEM) medium (GIBCO) supplemented with 20% FBS. Insulin 0.2 IU/mL and hydrocortisone 1 µg/mL were added to CCC-HBE-2 cells. HK-2 cells were cultured in DF-12 medium (GIBCO) supplemented with 10% FBS.

Cell growth inhibition assay The cytotoxicity of the rmh TRAIL and wt TRAIL was determined using a colorimetric MTT assay. Cells in the logarithmic growth phase were dispersed to prepare a suspension of cell density of 6×10^4 – 20×10^4 mL⁻¹. Then cell suspension was seeded in a 96-well plate in total volume of 100 µL per well and incubated in a 5% CO₂ atmosphere at 37 °C for 24 h. Then, the supernatant was removed and the cells were added with 100 µL of different concentrations of the drugs followed by incubation at 37 °C for another 24 or 72 h. For controls, cells were placed in medium only. After removal of the supernatant, the cells were treated with 5.0 g/L MTT for 4 h, the purple blue sediment was dissolved in 150 µL Me₂SO, and the absorbance at 490 nm was measured using a microplate reader (BIO-RAD, Hercules, USA, model 550). The survival rate of cell growth was calculated using the following formula:

Survival rate (%) = $A_{490}(\text{drug})/A_{490}(\text{control}) \times 100\%$. Triplicate wells were analyzed for each concentration.

The 50% inhibitory concentration (IC₅₀) is the concentration required for 50% inhibition, which is calculated from the linear equation, which was deduced by concentration versus survival rate regression curve. The experiments were performed in triplicates.

Mouse xenograft tumor model According to the protocol of transplantation tumor research^[19], NCI-H460 tumor tissues were chopped into 2 mm³, and then transplanted sc into the right flank of nude mice. The diameter of transplantation tumor was measured with a vernier caliper. When the tumor size grew to 280 mm³, the 32 tumor-grafted mice were randomly divided into 4 groups ($n=8$); that is, negative control group (treated with normal saline), positive control group (wt TRAIL, 15 mg/kg) and rmh TRAIL treated groups (3 and 15 mg/kg). All drugs or saline were injected ip once daily for 10 d followed by another 14 d observation.

The tumor volume (TV) was calculated using the following formula:

TV = $1/2 \times a \times b^2$ (in which a is the length and b is the width of tumor).

The evaluation index of anti-tumor activity was relative tumor weight inhibition ratio (%), which was calculated by the following formula:

Tumor weight inhibition ratio (%) = $(1 - T/C) \times 100\%$ (T: test group's or positive control group's mean tumor weight; C: negative control group's mean tumor weight).

The data were then subjected to a statistical analysis (*t*-test) for actual efficiency of the material tested.

Assessment of apoptosis Various methods, described below, were used to evaluate NCI-H460 apoptosis.

(a) DNA fragmentation detection by ELISA A cell death detection ELISA kit was used according to the manufacturer's instructions for DNA fragment detection^[20]. The DNA fragments are discrete multiples of a 180–200 bp subunit, which can be detected as a DNA ladder on agarose gel. The enrichment of mono- and oligonucleosomes in the cytoplasm of the apoptotic cells is a result of DNA degradation that occurs several hours before plasma membrane breakdown. The principle on which this test is based is the detection of mono- and oligonucleosomes in the cytoplasmic fractions of cell lysates by using biotinylated antihistone and peroxidase-coupled anti-DNA antibodies. The enrichment of mono- and oligonucleosomes released into the cytoplasm is calculated as the ratio of absorbance of sample cells to absorbance of control cells. The enrichment factor was used as a parameter of apoptosis and is shown on the Y axis as mean ± SD of triplicate experiments performed in triplicates. An enrichment factor of 1 represents spontaneous apoptosis. NCI-H460 were grown in 96-well plates and exposed to rmhTRAIL 10 ng/mL for 0.5 to 4 h or 0.0128 ng/mL to 40 ng/mL for 2 h.

(b) TdT-mediated dUTP nick-end labeling (TUNEL) assay After incubated with 15 ng/mL rmh TRAIL for 1, 2, and 4 h, NCI-H460 cells were smeared on slides, fixed by 4% paraformaldehyde in PBS (pH 7.2) for 30 min at room temperature, washed 3 times with PBS, and blocked by 0.3% H₂O₂. Then, cells were permeabilized on ice using 0.3% Triton X-100 in PBS for 2 min. Subsequent operations were referred to the manufacturer's instruction of *In situ* cell death detection kit and DAB kit. The samples were dehydrated by ethanol and cleared in dimethylbenzene, analyzed by microscopy and photos were taken using a Nikon 4 500 digital camera.

(c) Flow cytometry For apoptotic cell detection analysis, NCI-H460 cells were treated with rmh TRAIL or wt TRAIL (1, 10, and 100 ng/mL) for 12 h. All of the attached and the detached cells were harvested. Detection of the apoptotic cells was referred to the manufacturer's instruction of Annexin V-FITC apoptosis detection kit.

Results evaluation:

Non-apoptotic cells: Annexin V negative and PI negative;

Early apoptotic cells: Annexin V positive and PI negative;

Necrotic cells or late apoptotic cells: Annexin V positive and PI positive.

Statistical analysis Data were expressed as mean±SD.

Data of the representatives were analyzed for statistical significance using a *t*-test. $P < 0.05$ was considered statistically significant.

Results

Various tumor cell lines are sensitive to rmh TRAIL-induced death *in vitro*

To explore the antitumor activity of rmh TRAIL against a spectrum of cancer cell lines, we tested its effect *in vitro* on the inhibition of 5 different cell lines derived from cancers of the lung, colon, and breast (2 lung cancer cell lines, 2 breast cancer cell lines, and 1 colon cancer cell line) by MTT assay. rmh TRAIL exerted a cytotoxic effect on these cell lines and inhibited cell growth after cells being treated for 24 h or 72 h. Furthermore, the antitumor activity of rmh TRAIL was notably higher than that of wt TRAIL, and IC_{50} for rmh TRAIL against all cell lines were significantly lower than wt TRAIL (Table 1, $P < 0.01$). Treatment with rmh TRAIL at the dose of 200 ng/mL caused substantial cell death. The morphology of the cells treated by rmh TRAIL was characteristic of apoptotic cells: blebbing and shrinkage of cytoplasm (Figure 1).

Antitumor activity of rmh TRAIL in a mouse xenograft study

To determine whether the tumoricidal activity of rmh TRAIL observed *in vitro* could be demonstrated *in vivo*, BALB/c nude mice were transplanted sc with NCI-H460 tumor tissue, which showed intermediate sensitivity to rmh TRAIL *in vitro* (Table 1), and allowed tumors to establish. The tumors in the control group grew steadily in an exponential manner. wt TRAIL treatment gave a 25.7% reduction in mean tumor volume, which was lower than that of rmh TRAIL. In contrast, the rmh TRAIL treated groups showed a marked reduction in tumor size, especially during the treatment period (Figure 2, Table 2). The tumors in some

mice in the high-dose rmh TRAIL group became invisible during the treatment period and shortly after withdrawal. The suppressed tumors recommenced growing 5 d after withdrawal, but still more slowly than the control group. The inhibitory effect of rmh TRAIL on transplantation of tumor NCI-H460 was in a dose-dependent manner. Tumor suppression in 3 mg/kg rmh TRAIL-treated group was less than 15 mg/kg group, but greater than 15 mg/kg in the wt TRAIL-treated group (Figure 2, Table 2).

Figure 2. Inhibitory effects of rmh TRAIL and wt TRAIL on the volumes of xenograft tumor NCI-H460 in nude mice. *n*=8. Mean±SD. Control: normal saline group; recombinant mutant human (rmh) TRAIL-15: 15 mg/kg rmh TRAIL-treated group; rmh TRAIL-3: 3 mg/kg rmh TRAIL-treated group; wild type (wt) TRAIL-15: 15 mg/kg wt TRAIL-treated group. All drugs or saline was injected ip once daily for 10 d followed by 14-d observation.

Apoptosis induced by rmh TRAIL

a. rmh TRAIL-induced cell death of NCI-H460 cells

detected by ELISA rmh TRAIL 10 ng/mL was chosen for DNA fragmentation experiment by ELISA at different time points. This concentration of rmh TRAIL-induced apoptosis showed a time-dependent manner. At 2 and 4 h after treatment, rmh TRAIL induced a significant increase of cytoplasmic nucleosomes (Figure 3A). The result accords with agarose gel electrophoresis result (data not shown). More-over, we examined different concentrations (from 0.0128 ng/mL to 40 ng/mL) of rmh TRAIL-induced apoptosis for 2 h. The result showed a dose-dependent manner (Figure 3B).

b. TUNEL assay The pictures displayed in the Figure 4 were taken after incubation with rmh TRAIL 15 ng/mL for 1, 2, and 4 h. The nucleus condensation and segmentation were observed by microscope. Lots of apoptotic bodies were found in rmh TRAIL-treated cells but none in untreated cells.

c. Flow cytometry To confirm that the percentage of apoptosis induced by various concentration of rmh TRAIL in NCI-H460 cells, Annexin V and PI double staining and flow cytometry were performed. The percentages of apoptosis induced by rmh TRAIL and wt TRAIL (1 ng/mL, 10 ng/mL, 100 ng/mL) for 12 h were 8.11%, 32.80%, 59.68% and 4.96%, 7.08%, 14.11%, respectively (Figure 5).

Effect of rmh TRAIL on normal cell types To test whether rmh TRAIL initiates apoptosis in normal cells, 9 lines of normal cells, were exposed to rmh TRAIL (1 ng/mL–10 µg/mL) or wt TRAIL (1 ng/mL–10 µg/mL) for 24 h. No morphological evidence of apoptosis was observed as induced by rmh TRAIL (except for HL-7702); in addition, there was no decreased cell viability in staining of the cells by MTT (Figure 6), which indicated that rmh TRAIL was not cytotoxic toward these normal cell types. There was mild injury on HL-7702 hepatocytes elicited by both rmh TRAIL and wt TRAIL, and no cytotoxicity on CCC-HEL-1, human primary embryo liver-derived cells (Figure 6). The IC₅₀ of rmh TRAIL and wt

Figure 3. Quantification of nucleosomal DNA fragmentation. The cell death detection ELISA^{PLUS} was used to quantify DNA fragmentation in NCI-H460 cells undergoing apoptosis in the presence of recombinant mutant human (rmh) TRAIL; A) rmh TRAIL 10 ng/mL treated for different time (0.5, 1, 2 and 4 h); B) treatment with different concentrations of rmh TRAIL (0.0128 ng/mL–40 ng/mL) for 2 h. The rate of apoptosis is reflected by the enrichment factor of nucleosomes in the cytoplasm shown on the Y axis. An enrichment factor of 1 is equivalent to background apoptosis. Experiments were performed in triplicate and repeated 3 times. $n=3$. Mean \pm SD.

TRAIL on HL-7702 exceeded 10 μ g/mL.

Discussion

Although TNF and FasL have potent cytotoxic activity against many types of tumor cells, the application of these death ligands to cancer therapy has been restricted by their severe toxicity to normal tissues. The discovery of TRAIL as a death ligand, with its wide tissue-mRNA distribution and its unique receptor system, suggests that this ligand might be more suitable than TNF or FasL for systemic cancer therapy.

rmh TRAIL, developed by Beijing Sunbio Biotech, is a

mutant form of human native TRAIL, but the functional sequences are conservative. Native TRAIL is expressed as a type II transmembrane protein that can be cleaved proteolytically to form a soluble homotrimer^[7,8]. The therapeutic potential of a recombinant soluble version of human TRAIL that can be produced in *E coli* and purified as a 60-kDa homotrimer has been evaluated^[9,11]. An optimized antineoplastic agent can selectively induce apoptosis of cancer cells while sparing normal cells. Some scientists have opposed the safety of TRAIL on hepatocytes^[22,23]. To obtain a form of TRAIL that has higher antitumor activity and safety, Beijing Sunbio Biotech produced rmh TRAIL with a circularly permuted extracellular sequence of native human Apo2L/TRAIL. Our previous work revealed that rmh TRAIL had a high affinity for its death receptors and water-solubility (data not shown). This molecule forms more stable homotrimers. The pharmacokinetics research of rmh TRAIL indicates that the concentration in tumor tissue was higher than that in plasma. Furthermore, rmh TRAIL was more resistant to trypsin proteolysis *in vitro* than wt TRAIL (data not shown). All of the above suggests that rmh TRAIL could contribute to long-standing antitumor activity.

The present study first assesses the antitumor activity of rmh TRAIL *in vitro*. A spectrum of cancer cell lines exhibited sensitivity *in vitro* to rmh TRAIL. This finding is consistent with previous reports that native TRAIL is cytotoxic toward cell lines from cancers of the lung, colon, and breast^[9-11]. rmh TRAIL triggers more cell death *in vitro* than wt TRAIL. The study of NCI-H460 xenograft models indicates that rmh TRAIL can cause tumor regression or suppress tumor growth, and can initiate tumor cell apoptosis, which is consistent with its apoptosis-inducing activity *in vitro*. The antitumor activity of TRAIL after ip administration has been demonstrated in several mouse xenograft models of human cancers, including colorectal^[9], breast^[11], and glioma^[24]. rmh TRAIL caused a dose-dependent suppression of tumor growth, and 15 mg/kg rmh TRAIL resulted in a 86.7% reduction in mean tumor volume, whereas wt TRAIL only caused a 25.7% reduction using the same dose. Therefore, in the present study, the antitumor activity of rmh TRAIL is higher than that of wt TRAIL in the experiments both *in vivo* and *in vitro*. Compared with wt TRAIL, rmh TRAIL can achieve same antitumor activity under lower dosages.

Second, rmh TRAIL induced apoptosis in NCI-H460 was confirmed by cell death ELISA assay, TUNEL assay, and flow cytometry. Nucleus condensation, apoptotic body appearance, and DNA fragmentation are universal characteristics in the cells undergoing apoptosis. Furthermore, cell

Figure 5. The flow cytometry using Annexin-V/PI double staining was performed on NCI-H460 cells. Representative dot plots of recombinant mutant human (rmh) TRAIL 1, 10, 100 ng/mL (A–C) and wild type (wt) TRAIL 1, 10, 100 ng/mL (D–F) treated for 12 h. The numbers in brackets denote percentage of apoptotic cells. The upper right quadrant represents apoptotic or necrotic cells positive for both Annexin and PI. Data from 1×10^4 cell per sample were collected.

Figure 6. Effect of rmh TRAIL or wt TRAIL on proliferation in normal cell lines. Cells were incubated with serial dilutions of recombinant mutant human (rmh) TRAIL (1 ng/mL–10 μ g/mL) or wild type (wt) TRAIL (1 ng/mL–10 μ g/mL) for 24 h, and cell growth relative to medium controls was determined by MTT assay.

death ELISA assay and flow cytometry showed the quantity of apoptotic cells. From the evidence in the present study, it is elicited that rmh TRAIL could induce NCI-H460 apoptosis, that and it is time- and concentration-dependent.

Third, MTT assay was used to examine the cytotoxicity effect of rmh TRAIL on normal cells. Although rmh TRAIL was cytotoxic toward many tumor cell lines *in vitro*, rmh TRAIL showed no inhibition on normal cells tested in the experiment from endothelial, fibroblastic, myocardial, cutaneous, lung, renal, and tracheal origin, supporting the notion that rmh TRAIL dose did not increase cytotoxicity to generally nontransformed cells. The results are consistent with Ashkenazi *et al*^[9,10,25,26]. rmh TRAIL and wt TRAIL showed mild cytotoxicity to HL-7702 cells, which are separated from adult liver. The IC_{50} of rmh TRAIL exceeded 10 μ g/mL. The IC_{50} for non-small cell lung cancer and colonic cancer, the main clinical indications, are all 0.01 μ g/mL, which

is at least 1000 times lower than the IC_{50} for HL-7702. Furthermore, the pharmacokinetics research on nonhuman primates (cynomolgus monkeys) indicated that the maximal plasma concentration (C_{max}) of rmh TRAIL (iv, 5 mg/kg) was 25 μ g/mL (data not shown). The dose used in humans would be no more than 5 mg/kg. Therefore, the C_{max} will be no more than 25 μ g/mL, which is less than the IC_{50} of HL-7702. The results suggest that the clinical effective dose of rmh TRAIL might be safety for human.

In conclusion, rmh TRAIL provided potent antitumor activity *in vitro* and *in vivo*, although it did not exert obvious cytotoxicity on a wide variety of normal cells. Therefore, rmh TRAIL might prove to be a useful new agent in fighting cancer cells, leaving normal cells unharmed.

Abstract

Aim: To investigate the modulation of liver cytochrome P450 1A2 (CYP1A2) expression by giving flutamide to adult rats. **Methods:** Rats were given 50, 100, and 200 mg/kg *po* of flutamide for 2 weeks. Liver CYP1A2 mRNA was measured using reverse transcription-polymerase chain reaction. CYP1A2 protein was detected using immunoblotting. CYP1A2 activity was assayed using high performance liquid chromatography, with caffeine as the CYP1A2 substrate. **Results:** CYP1A2 mRNA levels after flutamide treatment at 100 mg/kg and 200 mg/kg were, respectively, 1.86 and 3.11-fold higher than those of the control. Correspondingly, CYP1A2 protein increased 1.78 and 2.89-fold and CYP1A2 activity increased approximately 1.65 and 2.83-fold, respectively, relative to controls. Flutamide treatment at 50 mg/kg had no significant effect on CYP1A2 mRNA, protein, or enzyme activity. **Conclusion:** Giving rats flutamide induced liver CYP1A2 expression in a dose-dependent manner.

Introduction

Flutamide, 3'-trifluoromethyl-4'-nitro-2-methylpropionyl-anilide, is a nonsteroidal antiandrogen^[1,2] devoid of other hormonal activity and is recognized worldwide as the most beneficial drug for the treatment of patients with advanced prostate cancer^[3–5] when used in combination with various luteinizing hormone-releasing factor agonists. This antiandrogen is also used in combination with oral contraceptives for the treatment of hirsutism^[6] and benign prostatic hyperplasia^[7,8].

However, flutamide therapy is associated with hepatitis in a few subjects. The incidence of liver toxicity (as defined by an increase in serum transaminase activity of fourfold greater than upper normal limits) was found to be 0.36% in 1091 consecutively treated prostate cancer patients^[9–11]. Flutamide-induced hepatitis was decreased using piperonyl butoxide [cytochrome P450 (CYP450) inhibitor] and increased using β -naphthoflavone (CYP450 1A inducer)^[12].

Previous results show that CYP1A2 is involved in flutamide bioactivation^[12,13]. CYP1A2 is a cytochrome P-450 enzyme constitutively expressed in the liver, which catalyzes the metabolism of many drugs, such as caffeine, phenacetin,

and propranolol^[14]. The enzyme also participates in the metabolic activation of chemical mutagens in cooked food such as 2-amino-3-methylimidazo[4,5-f]quinoline and 2-amino-3,8-dimethylimidazo[4,5-f]quinoxaline and 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine^[15]. Previous studies have reported flutamide bioactivation using the P450 enzyme system generated a nitro anion free radical after treatment^[16]. These radicals can bind covalently to proteins and lipids, or remove hydrogen atoms from polyunsaturated fatty acids in lipids, thereby initiating lipid peroxidation and liver cell injury^[17]. Therefore, CYP1A2 increase might be a risk factor for flutamide-associated hepatotoxicity or carcinogenicity. In the present study, we investigate the modulation of CYP1A2 expression in adult male rats given flutamide for 2 weeks.

Materials and methods

Chemicals Flutamide was provided by the Shanghai Hongqi Pharmaceuticals Factory. Trizol reagent was obtained from Life Technologies and reverse transcription-polymerase chain reaction kits were obtained from Sangon Biological Technique. Caffeine and its metabolite, and β -hydroxyethyl-

theophylline (HT) were obtained from Sigma Chemical Company. Rabbit anti-rat CYP1A2 monoclonal antibody was obtained from Santa Cruz Biotechnology (kindly provided by Dr XC MA).

Animals and treatment Adult male Sprague-Dawley rats weighing between 200 g and 250 g (Experimental Animal Center of Fudan University, grade II, certification No 01212) were housed at a temperature of 20 °C–25 °C under a 12 h light/dark cycle with 50% relative humidity in filtered and pathogen-free air. The animals were acclimatized for 1 week prior to use. For CYP1A2 induction studies, rats were divided into five groups of 10 animals each. The first group was given 0.5% carboxymethylcellulose sodium (CMC) as a control, and the second group of rats received 3-methylcholanthrene (3-MC, 30 mg/kg, ip, for 5 d) as a positive control for CYP1A2 induction. Flutamide and 3-MC were also suspended in 0.5% CMC. The rats were treated once daily, ig, for 14 consecutive days. All rats were killed on d 16. Livers were excised and immediately frozen on ice and stored at -80 °C for total RNA and liver microsomal preparation.

RNA extraction and cDNA synthesis Total RNA was obtained from frozen rat livers (0.5 g–1 g) using Trizol reagent. The RNA concentration was determined spectrophotometrically at 260 nm, and 5 µg of total RNA was taken for reverse transcription. Random primer (300 ng) was added and primer annealing was performed using incubation for 10 min at 65 °C and 10-min progressive cooling on ice. Deoxynucleotides (dNTP) (4 mmol/L each), 5 µL of 10×reaction buffer, 50 U of block ribonuclease inhibitor, and 200 U of SuperScript II RNase reverse transcriptase were added to a final volume of 50 µL, and samples were incubated at 42 °C for 30 min. The reaction was stopped by heating to 90 °C for 5 min. Control samples contained distilled water instead of RNA. The synthesized cDNA was stored at -20 °C until use.

Polymerase chain reaction Reverse transcription sample of 2.5 mL was added to the corresponding polymerase chain reaction mixture containing 0.5 µmol/L sense and antisense primer, 2 mmol/L MgCl₂, 10 mmol/L Tris-HCl (pH 9), 50 mmol/L KCl, 0.1% Triton X-100, and 80 µmol/L dNTP. After heating at 95 °C for 5 min and cooling to the primer-annealing temperature for 5 min (60 °C), 2 U of *Taq* DNA polymerase was added. The following primers were used: CYP1A2 forward (+127 to +147), 5'-GGACCCTGGGGCTTGCCCTTC-3'; reverse (+484 to +504), 5'-AGCCTCTTTGCTCACGTGCTC-3'; β-actin forward (+59 to +69), 5'-CCCAAGTCGCCTCC-GTCCCGC-3'; reverse (+894 to +914), 5'-CCCTCCAGGAGCCCCATGAGC-3'. The specificity of CYP1A2 primers was confirmed through alignment with the CYP subfamily DNAs. Amplification con-

ditions for all primer pairs were used as follows: 94 °C 30 s, 60 °C 30 s, and 72 °C 30 s for 30 cycles. β-actin segment was amplified separately and used as an external standard, because interaction of primer pairs caused a decrease in signal intensity. A total 12 µL of each preparation was subjected to agarose gel electrophoresis in the presence of ethidium bromide. The gel was photographed using Polaroid 665 film and the intensity of each band was quantified using the software provided with the ABI 7700 system. Each assay was performed in triplicate. Results were expressed as a ratio of the optical intensity of the CYP1A2 to that of the β-actin. This approach allows for the semiquantitation of the expression of the CYP1A2 gene.

Immunoblot analysis Liver microsomes were prepared as described by Kamataki and Kitagawa^[18]. The protein concentration was determined using Bradford's method^[19], using a protein assay with bovine serum albumin as a standard. Three micrograms of microsomal protein were resolved separately by electrophoresis on 10% SDS-polyacrylamide gel and then transferred onto a nitrocellulose membrane. The membrane was incubated with a rabbit anti-rat CYP1A2 monoclonal antibody, and further incubated with goat anti-rabbit secondary antibody conjugated with horseradish peroxidase, followed by detection with 3,3'-diaminobenzidine and hydrogen peroxide. The membrane was scanned with an image scanner, and the signal intensity was quantified using the software provided with the ABI 7700 system. In the present study, the levels of CYP1A2 proteins were in the linear range for densitometric readings.

CYP1A2 activity Caffeine was used as a probe for CYP1A2 activity and plasma caffeine (137X) and its metabolite (17X) were assayed using high performance liquid chromatography^[20]. After the last dose of flutamide and overnight fast, each rat received 20 mg/kg (ip) of caffeine. Blood samples (2 mL) were drawn after caffeine administration. Plasma was separated and frozen at -20 °C for later analysis. The mixtures of plasma containing 17X and 137X were extracted with chloroform/isopropanol (9:1). The residue remaining after evaporation was dissolved in 0.1 mL elution and 20 µL was injected into the chromatographic system. HT was chosen as an internal standard (IS). All components were separated isocratically on a reversed-phase column using 0.05% acetic acid:acetonitrile:methanol (82:8:10) as a mobile phase at a flow rate of 1 mL/min. Ultraviolet detection wavelength was 282 nm. The retention times for 17X, 137X, and IS were 4.50 min, 5.03 min, and 8.13 min, respectively. The CYP1A2 activity was expressed as a ratio of the concentration of 17X to that of 137X observed 6 h after giving caffeine.

Statistical analysis The statistical significance of the difference between the means of the two groups was assessed using the independent *t* test (SPSS software package, 1997). $P < 0.05$ was considered statistically significant.

Results

CYP1A2 mRNA levels The levels of *CYP1A2* mRNA were normalized using a comparison with β -actin, constitutively expressed in the rat liver. The increase in *CYP1A2* mRNA was expressed as a percentage of the control. After flutamide treatment (50 mg/kg) of rats for 14 d, liver *CYP1A2* mRNA levels were similar to control levels, but *CYP1A2* mRNA levels were increased 1.86 and 3.11-fold relative to controls in rats in flutamide 100 mg/kg and 200 mg/kg group, respectively. *CYP1A2* mRNA levels were increased 15.6-fold by 3-MC treatment (Figure 1).

Figure 1. Effects of flutamide on cytochrome P450 1A2 (CYP1A2) mRNA levels in rats. (A) Total RNA was extracted from liver tissues, CYP1A2 and β -actin mRNA levels were detected using reverse transcription-polymerase chain reaction. Each lane contains 1 μ g total of RNA from the liver of the control rats, flutamide and 3-MC treated rats. Lane 1 corresponds to the control liver, whereas lanes 2, 3, and 4 correspond to liver RNA from rats treated with flutamide at 50 mg/kg, 100 mg/kg, and 200 mg/kg, respectively. Lane 5 corresponds to liver RNA from the 3-MC treated rats. (B) Signal intensity was quantified by a bioimage analyzer ($n=10$). The signals were normalized using β -actin. The columns represent the induction (fold) of *CYP1A2* mRNA relative to the control.

CYP1A2 protein Similar results were obtained for the analysis of the P450 protein. After 50 mg/kg flutamide treatment, CYP1A2 protein in rat liver microsomes was simi-

lar to that in the control group. However, CYP1A2 protein levels increased 1.78 and 2.89-fold respectively, after 100 mg/kg and 200 mg/kg flutamide treatment as compared to those in controls. In contrast, 3-MC treatment increased the CYP1A2 protein content 13.8-fold (Figure 2).

Figure 2. Induction of cytochrome P450 1A2 (CYP1A2) protein in the rat liver after flutamide treatment. (A) Liver microsomes (3 g) were separated using SDS-polyacrylamide gel electrophoresis, blotted onto a nitrocellulose membrane, and then probed with antibodies against rat CYP1A2. Liver microsomes prepared from 3-MC-treated rats were used as positive control in these analyses (lane 5). Lanes 2, 3, 4 correspond to liver microsomes from rats treated with flutamide (50 mg/kg, 100 mg/kg, and 200 mg/kg), respectively. Lane 1 corresponds to liver microsomes from control rats. (B) Immunoblots were scanned with an image scanner and then analyzed using software provided with the ABI 7700 system ($n=10$). The columns represent the induction (fold) of CYP1A2 protein as compared to the control.

CYP1A2 enzyme activity Caffeine is hydroxylated to form paraxanthine (17X) using CYP1A2. Concentration ratio of caffeine metabolite paraxanthine to caffeine (17X/137X) was used to express the activity of CYP1A2. After giving caffeine for 6 h, CYP1A2 activity in rats treated with flutamide (50 mg/kg) was similar to that in the control group. In rats given 100 mg/kg and 200 mg/kg of flutamide, CYP1A2 enzyme activity increased 1.65 and 2.83-fold, respectively, as compared to that in the control group. 3-MC increased CYP1A2 activity 8.50-fold more than those in the control group (Figure 3).

Discussion

In the present study, *CYP1A2* mRNA, protein, and enzyme activity were induced by flutamide treatment in rats.

Figure 3. Increase of cytochrome P450 1A2 (CYP1A2)enzyme activity using flutamide treatment. (A) Chromatograms of caffeine (137X), its metabolite paraxanthine (17X) and β -hydroxyethyl-theophylline (HT) in serum sample, the retention time for 17X, HT, and 137X were 4.50 min, 5.03 min, and 8.13 min, respectively. (B) CYP1A2 activity (fold) in flutamide (50, 100, 200 mg/kg) and 3-MC treated-rats as compared to the controls, which is expressed as ratio of caffeine metabolite (paraxanthine) concentration to that of caffeine.

It is reasonable to speculate that flutamide is a CYP1A2 inducer in rats. This P450 induction is dose-dependent as it increases with increasing amounts of flutamide in the liver. The magnitude of CYP1A2 induction assessed using three different parameters, that is, mRNA, protein, and enzyme activity, was found to be comparable. The differences between the mRNA and protein induction and between protein and enzyme activity in rats were less than 2-fold; therefore, it is highly probable that the CYP1A2 induction occurs mainly at a pretranslational level, and we speculate that flutamide-mediated CYP1A2 induction is a result of increased rate of transcription.

CYP1A2 is one of the major constitutively expressed P-450 in the liver tissue. It catalyzes steroid hydroxylations, such as 17 β -estradiol 2-hydroxylation^[21,22]. Of considerable interest is the ability of P4501A2 to catalyze the *N*-hydroxylation of carcinogenic aryl amines and heterocyclic amines^[23-25]. The oxidized products can modify DNA, either directly or following conjugation with acryl or sulfate groups^[26,27]. The heterocyclic amines are of considerable interest in that they are found in charbroiled food and cigarette smoke. There is some epidemiological evidence that elevated levels of CYP1A2 can be a predisposing factor to colon cancer, although the risk is marginal unless high levels of *N*-acetyl-

transferase are present along with high charbroiled meat consumption.

Flutamide can be metabolized by CYP1A2 to form the reactive metabolites. Nitro radical and one-electron reduction products have toxic effects on the liver cells^[16]. Induction of CYP1A2 can increase the formation of toxic metabolites, and increase the incidence of liver toxicity. This might explain why flutamide had no significant liver toxicity after low doses (50 mg/kg), although it caused liver toxicity at higher doses (100 mg/kg and 200 mg/kg) in previous studies^[28]. Therefore, the induction of CYP1A2 might have a large influence on the therapeutic efficacy and liver toxicity associated with flutamide treatment. Induction of CYP1A2 using flutamide treatment and its possible effects on the metabolism of other drugs and the carcinogenesis of heterocyclic amines in human beings would be useful topics of further study.

Abstract

Aim: To investigate the alterations of placental P-glycoprotein (P-gp) and cytochrome P450 1A1 (*CYP1A1*) at different gestational days (GD), and to explore the possible significance of placental P-gp and *CYP1A1* in tobacco smoke-induced intrauterine growth retardation (IUGR) in rats. **Methods:** An IUGR model was produced by passive tobacco smoking from GD 7 to parturition (GD 21) and predicted using fetal development parameters. Placental structure and function were monitored by observing pathological alteration and antioxidative function, including the content of malondialdehyde and the activities of superoxide dismutase and catalase (CAT). The expressions of *CYP1A1* and P-gp (*mdr1a* and *mdr1b*) were detected using a reverse transcription polymerase chain reaction and immunohistochemistry. **Results:** Placental pathological changes occurred and the malondialdehyde content increased, whereas the activities of superoxide dismutase and CAT lowered, when compared to their controls. In the rat placenta of the tobacco group, the level of *CYP1A1* mRNA increased significantly; the level of *mdr1a* mRNA increased significantly at GD 21 but not at GD 14, whereas the level of *mdr1b* mRNA in different term remained stable; the expression of P-gp increased significantly only in full-term placenta. **Conclusion:** The expression of placental *CYP1A1* and P-gp increased in tobacco-induced IUGR. Overexpression of placental *CYP1A1* can attribute to the metabolism of tobacco and the generation of reactive metabolites, which can trigger IUGR. As a compulsory mechanism, upregulation of P-gp might decrease tobacco exposure to a developing fetus with IUGR.

Introduction

There is ample epidemiological evidence that individuals with intrauterine growth retardation (IUGR) carry an increased risk of prenatal morbidity and mortality^[1] and that those born with IUGR are at a much greater risk of a wide range of medical problems, such as mental handicaps and neurobehavioral disorders^[2,3]. There are various possible causes of pathologically induced IUGR, and it is reported that some xenobiotic exposure during pregnancy, including to tobacco and drugs, could be attributable to IUGR^[4,5]. Clinically, there is no generally accepted effective treatment at present and, therefore, the understanding of the mechanisms for control-

ling fetal growth and the causes for IUGR induced by xenobiotics is extremely important in the development of therapeutic options.

The placenta is the organ responsible for the transfer of nutrients and waste products between the fetal and maternal circulations, and plays a pivotal role in fetal growth^[6]. The placenta receives oxygen from the maternal circulation and is positioned in an oxygen gradient between the mother and fetus. The placenta provides a link between the circulations of 2 distinct individuals, but also acts as a barrier to protect the fetus from xenobiotics in the maternal blood. Animal studies, such as embryo transplant and cross breeding experiments, have shown that, unlike postnatal growth, the

growth of the fetus is controlled predominately by the uterine environment, and not by fetal or maternal genetic factors^[7]. Therefore, placental dysfunction can have an important effect on fetal intrauterine development and can lead to fetal diseases such as IUGR.

The placenta can perform xenobiotic transportation and biotransformation. The transfer of foreign chemicals across the placenta can be modified by metabolism in the placenta itself. The extent to which drugs cross the placenta is also modulated by the actions of placental phase I and II drug-metabolizing enzymes. Cytochrome P450 enzymes in particular have been well characterized in the placenta at the level of mRNA, protein, and enzyme activity^[8]. In some cases, however, the enzymes can activate exogenous compounds, making them toxic to the fetus^[6]. Cytochrome P450 1A1 (*CYP1A1*) exists mainly in extra-hepatic tissue, and can activate some xenobiotics with possible deleterious effects. The alteration in *CYP1A1* expression, for example, as a result of inducers/inhibitors or maternal diseases, could potentially adversely affect placental function and pregnancy outcome^[9]. Studies show that *CYP1A1* expresses in the placentas of women who are exposed to cigarettes^[6]. However, little is known about the possible changes of placental *CYP1A1* expression over the course of pregnancy and its roles in IUGR formation.

Some drugs are pumped across the placenta by various active transporters located on both the fetal and maternal side of the trophoblast layer, and instances of drug-induced birth defects have been in part blamed on the placenta's apparent 'leakiness' to maternal blood-borne agents^[8]. The impact of active transporters such as P-glycoprotein (P-gp) on the disposition of drugs has been demonstrated in some studies^[10-12]. P-gp, which is encoded by the *mdr* gene, is a membrane transport protein that functions as an efflux pump for various cytotoxic compounds and, therefore, reduces the intracellular concentrations of these compounds^[10]. Studies suggest that P-gp of the trophoblast cells is involved in the function of the blood-placental barrier and is necessary in reducing fetal drug exposure^[11,12], although little is known about the expression of placental P-gp in different gestational time and its significance to IUGR.

It is difficult to correlate toxic chemicals and their transportation and metabolism in the human placenta with IUGR. The rat placenta is morphologically and histologically similar to the human one; both of them are of the same hemochorial type. Therefore, a rat model of IUGR established by tobacco smoking is useful in providing us with information about the relationships among xenobiotics, placental transportations/metabolisms, and IUGR. To under-

stand the toxic mechanism of tobacco in IUGR formation, in the present study, the alterations of placental *CYP1A1* and P-gp expressions were investigated in IUGR rats, so as to explore the possible significance of placental *CYP1A1* and P-gp in tobacco-induced IUGR.

Materials and methods

Chemicals Thiobarbituric acid (TBA) and 5, 5'-dithio-2, 2'-dinitrobenzoic acid were obtained from Sigma. Trizol reagent was obtained from Molecular Research Center and One Step RNA PCR Kit was obtained from TaKaRa Biotechnology. Oligonucleotide primers were custom synthesized by Sangon Biological Engineering Technology. Rabbit anti-rat *mdr1* and streptavidin-peroxidase (SP) reagent were obtained from BOSTER Biotechnology. All other chemicals and reagents were of analytical grade.

Animals Specific pathogen free (SPF) Wistar rats with the weights of 190±18 g (female)/280±23 g (male) were obtained from the Experimental Center of Medical Scientific Academy of Hubei (China, No 2003-0005). Virgin female and male rats were left undisturbed for 5 d and then subjected to experimental conditions. Overnight, every 2 females was mated up with 1 male rat and the occurrence date of a vaginal plug was considered as gestational d 0 (GD 0). Pregnant rats were then housed 1 per cage in an environment of constant temperature (21±2 °C) and relative humidity (50%±10%) with a 12 h L:D cycle. *Ad libitum* access to a standard diet and water was permitted. The study protocol was in accordance with the guidelines for animal research and was approved by the Ethical and Research Committee of Wuhan University.

Tobacco smoke exposure On GD 7, pregnant rats were allocated to either a control group or a tobacco group. A rat IUGR model was processed, with modification, according to the procedure of Younoszai and Li^[13,14]. From GD 7 till parturition (GD 21), at 8:00, 11:00, 14:00, and 17:00, four pregnant rats from the tobacco group were subjected to cigarette smoke in a chamber measuring 40 cm×28 cm×18.5 cm for 15 min, with the gross smoke concentration set at 9 g·m⁻³. The tar and nicotine yields of commercial cigarettes were 15 and 1.1 mg per cigarette, respectively. The control group was sham-treated; that is, a group of 4 pregnant rats were in the same chamber without cigarette smoke for 15 min. The pregnant rats were weighed at GD 0, GD 7, GD 14, and GD 21. Animals were killed at 8:00 on GD 14 and GD 21, corresponding to mid and late gestational time^[15]. Each fetoplacental unit was removed quickly from the uterus and placenta specimens were excised, rinsed with cold saline, immediately fro-

zen in liquid nitrogen and stored at -80°C until used. Placenta weight and fetal development parameters (fetal body and organ weights, and fetal body and tail lengths) were recorded.

Placental pathomorphological observations and immunohistochemistry Fresh placentas were put into 4% paraformaldehyde in phosphate buffered saline (PBS) for 24 h. The fixed placental samples were processed using standard histological techniques and stained with hematoxylin and eosin. The slides were observed using light microscopy (Axiostar PLUS).

Routine immunohistochemistry SP method was carried out. The paraffin slides were deparaffinized with xylene and rehydrated in a graded series of ethanol. To quench endogenous peroxidase activity 0.3% H₂O₂ was added for 10 min, and preimmune goat serum was used to block non-specific binding sites. Sections were then incubated at 37 °C for 20 min with a rabbit polyclonal anti-*mdr1* antibody diluted in PBS (1:100). The slides were then incubated at 37°C for 15 min with an anti-rabbit secondary antibody and visualized with a DAB chromotogen system. PBS substituted for anti-*mdr1* antibody for negative staining control. The slides were observed under light microscopy (Axiostar PLUS) and the average gray level was measured using Photo Imaging System (HMIAS-2000). The quantitative stereology was performed in triplicates with 5 fields in each slide.

Tissue biochemical analysis Placentas at GD 21 were homogenized with saline to be 10% (w/v) homogenates. After the homogenates were centrifuged at 200×g for 10 min, the supernatants were centrifuged at 9 000×g for 20 min and, finally, collected and stored at -30 °C for the further assays. Placental protein concentrations were determined using the Lowry method^[16], with the bovine serum albumin (BSA) as standard. The extent of lipid peroxidation was detected by measuring malondialdehyde (MDA) content using TBA according to a modified procedure described by Ondrejickova *et al*^[17]. The activities of superoxide dismutase (SOD) and catalase (CAT) were measured as described above^[18, 19].

Preparation of placental total RNA Total RNA was isolated from the frozen placentas according Trizol reagent

instructions. The protocol involved disruption of cells, denaturation of nucleoprotein complexes, inactivation of endogenous ribonuclease (RNase) activity and, finally, removal of proteins and degradation of residual DNA by nuclease digestion. The concentration and purity of RNA were determined using a spectrophotometer (UV-1601, Shimadzu) and adjusted to 1 µg/µL. Total RNA was stored in DEPC-H₂O at -80 °C until used.

Semiquantitative reverse transcriptase-polymerase chain reaction The cDNA synthesis and polymerase chain reaction (PCR) amplification were produced in 1 step using Promega’s reverse transcriptase-polymerase chain reaction (RT-PCR) System. Different primers and PCR products are shown in Table 1. The final concentrations of reagents in the RT-PCR reaction system were as follows: 1×One Step RNA PCR buffer, 5 mmol/L MgCl₂, 1 mmol/L of each dNTP, 0.8 U/µL RNase inhibitor, 0.1 U/µL avian myeloblastosis virus (AMV) RTase XL, 0.1 U/µL AMV-optimized *Taq*, 0.4 µmol/L of each primer, and 0.02 U/µL placenta RNA in each 50 µL reaction volume. For quantitative analysis of mRNA expression, the housekeeping gene cyclophilin, an internal loading control^[22], was used to amplify together with the specific target gene in 1 tube. RT-PCR reactions were carried out in a thermal cycler: 50 °C for 30 min for reverse transcription, then 94 °C, 2 min for RT inactivation; finally 72 °C, 5 min for a terminal elongation step following the amplification cycles. PCR cycling conditions were as follows: 94 °C, 30 s; 62 °C, 45 s; 72 °C, 30 s, 45 cycles for *CYP1A1*. 94 °C, 30 s; 54 °C, 60 s; 72 °C, 30 s, 30 cycles for *mdr1a*. 94 °C, 30 s; 56 °C, 20 s; 72 °C, 30 s, 25 cycles for *mdr1b*. DEPC-H₂O substituted for placental RNA for negative control. An aliquot (4 µL) of the RT-PCR reactions was separated on a 1.5% agarose gel containing ethidium bromide, visualized under UV light, photographed, and analyzed by densitometry using Photo Documentation and Imaging System (Bio-ID). The expression level of target gene mRNA was shown as the ratio of the intensities of the target-specific band and the CYC band individually.

Statistical analysis The experimental results were expressed as mean±SD. Statistical Packages for Social Sci-

ences (SPSS) was used for data analysis. Analysis of variance (ANOVA) was used for comparison of means of several groups and χ -square analysis was performed to test for differences in proportions of categorical variables between 2 groups. The level of significance was set at $P < 0.05$.

Results

Maternal body weights The change in pregnant rat body weight is a useful, indirect indicator of physical development. During the period of GD 7 to GD 21, there was a significant decline in the body weight and percentage weight gain after tobacco exposure (Figure 1).

Figure 1. Effects of prenatal tobacco exposure on the percentage of maternal body weight gain. $n=8$. Mean \pm SD. ^b $P < 0.05$ vs control group at gestational d 14 (GD 14). ^e $P < 0.05$ vs control group at GD 21.

Neonatal body weights and physical development indexes

Body weight was an important index for diagnosing IUGR (IUGR was diagnosed by the standard that the mean body weight in the treated group was less 2 standard deviations than that in the control group)^[23]. The offspring in the

tobacco group showed a lower average body weight (3.20 g) than the control group (4.30 g) at GD 21, indicating fetal IUGR. The ratio of IUGR increased to 44.74% (34/76) in the tobacco group, whereas it was only 5.06% (4/79) in the control group. In addition, the body and tail lengths, and liver and brain weights of the tobacco group significantly lagged behind those of control group at GD 21, with a suppression of 14.2%, 8.9%, 22.9%, and 10.5%, respectively ($P < 0.01$) (Table 2).

Table 2. Effects of prenatal tobacco exposure on the body weights and physical development indexes of rats' offspring on gestational d 21. $n=8$. Mean \pm SD. ^c $P < 0.01$ vs control group. IUGR, intrauterine growth retardation.

Indexes	Control	Tobacco
Body weight/g	4.30 \pm 0.68	3.20 \pm 0.85 ^c
Ratio of IUGR	5.06% (4/79)	44.74% (34/76) ^c
Body length/cm	3.87 \pm 0.26	3.32 \pm 0.32 ^c
Tail length/cm	1.35 \pm 0.15	1.23 \pm 0.13 ^c
Liver weight/mg	0.35 \pm 0.07	0.27 \pm 0.08 ^c
Brain weight/mg	0.19 \pm 0.02	0.17 \pm 0.02 ^c

Placental pathomorphology The rat placenta is composed of 3 distinct zones: labyrinth, basal, and maternal deciduas; where the labyrinth zone represents the main area of maternal-fetal exchange. According to our results, compared to those in the control group (Figure 2A), the obvious changes occurred in the labyrinth and basal deciduas of the full-term placenta in IUGR rats, such as through interstitial and endovascular hemorrhage in the labyrinth zone, and trophoblast cells necrosis in the basal zone (Figure 2B). Full-term placental weight (0.39 \pm 0.08 g) of tobacco-induced IUGR

Figure 2. Effects of prenatal tobacco exposure on placental pathomorphological changes at gestational d 21. A: control group; B: tobacco exposure group. Black arrowheads indicate between labyrinth and basal zone. Hemorrhage in labyrinth zone and necrosis in basal zone are represented by H and N, respectively. $\times 200$.

rats decreased by more than that of the normal placentas (0.49±0.06 g).

Placental antioxidative system In the tobacco exposure group, placental MDA content was significantly increased by 50.0% ($P<0.05$), and the activities of SOD and CAT were notably decreased by 58.2% and 30.6% ($P<0.05$, $P<0.01$), respectively (Table 3).

Table 3. Effects of prenatal tobacco exposure on full-term placental antioxidative function in rats. $n=8$. Mean±SD. ^b $P<0.05$, ^c $P<0.01$ vs control group.

Groups	Malondialdehyde /mmol·mg ⁻¹ protein	Superoxide dismutase /U·mg ⁻¹ protein	Catalase /k·mg ⁻¹ protein
Control	30±6	3.9±1.2	0.62±0.16
Tobacco	60±14 ^c	1.6±0.5 ^c	0.43±0.07 ^b

Placental *CYP1A1* mRNA expression No PCR product for *CYP1A1* mRNA was detected in normal placentas. However, expression was detected in the placentas of the tobacco exposure group; furthermore, the level at GD 21 was approximately 1.39-fold higher than that at GD 14, with a faint band (Figure 3).

Placental P-gp and *mdr1* mRNA expression Immunohistochemical analysis with anti-*mdr* specific antibody showed strong positive staining in placenta trophoblasts

Figure 3. Effects of prenatal tobacco exposure on expression of placental *CYP1A1* mRNA at different times by the quantitative reverse transcriptase-polymerase chain reaction using cyclophilin as internal control ($n=4$ per treatment). Discussion

The placenta, which is derived from both fetal and maternal tissues, is considered the first fetal organ to be exposed to exogenous substances and plays an important role in fetal intrauterine development. In the present study, gestational tobacco smoking resulted in significantly delayed fetal growth, as indicated by the fetal development parameters, especially fetal body weight. Meanwhile, placental weight decreased and obvious pathomorphological changes were observed. Our result showed that the content of MDA was higher and the activities of SOD and CAT were lower in IUGR placentas, suggesting a decreased ability of placental antioxidative defense. Therefore, these results suggest that prenatal tobacco exposure has a specific and deleterious

Figure 6. effect on the placenta that secondarily limits fetal growth.

The placenta is now viewed as a metabolic barrier rather than a physical barrier^[24]. The placenta can perform biotransformation that occurs in the liver. Numerous foreign compounds reach the placenta through the maternal circulation and placental tissue is capable of oxidizing several of them. In present study, the expression of *CYP1A1* mRNA was detected in the placentas of the tobacco group, but not in the normal placentas; furthermore, the expression of *CYP1A1* mRNA was higher in full-term placentas than that in mid-term placentas. These results demonstrate that an increase of *CYP1A1* with environmental tobacco exposure is obvious and that a time-response relationship exists during tobacco consumption. There are many well-known *CYP1A1* inducers in tobacco, and smoking is one important source of exposure to them. Increased *CYP1A1* level might explain the toxic mechanism because polyarylhydrocarbons can be bioactivated by *CYP1A1* and can generate reactive metabolites^[25]. Wu *et al* found that placental and fetal tissues were capable of metabolizing benzo(a)pyrene [B(a)P], albeit to a lower extent, and that *CYP1A1* was involved in metabolism of inhaled B(a)P^[26]. In addition, *CYP1A1* can result in free radical formation and lipid peroxidation, and then affect uterine redox environment and fetal growth. Oxidative stress has been increasingly postulated as a major contributor to

dysfunction in IUGR^[27], and our data indicates a decreased ability of placental antioxidative defense. The present finding of significant upregulation of placental *CYP1A1* mRNA subsequent to prenatal tobacco exposure supports a hypothesis that an elevated placental *CYP1A1* level can be a trigger for IUGR.

In P-gp, generally, *mdr1a* appeared to be the pharmacologically most relevant isotype. Schinkel *et al* also indicated that *mdr1a* was the critical placental P-gp in mice^[28]. In a study by Lin, *Mdr1b* was highly induced in the secretary epithelium endometrium of the uterus in mice during pregnancy and might protect steroid secreting cells from potentially damage^[29]. In the present study, we analyzed P-gp expression in the rat placenta during its maturation, using the methods of immunohistochemistry. Intensive immunoreactivity for P-gp was found in the developing labyrinth zone of normal placentas. Furthermore, tobacco smoking induced P-gp expression of the trophoblast cells only in full-term placentas. We examined the changes of *mdr1* levels in different stages, using the RT-PCR method. We found different P-gp members displayed distinct inductive patterns. Our PCR data indicates that the expression of *mdr1a* gene tends to increase from GD 14 to GD 21 in the normal placenta, which correlates well with the results of Novotna *et al*^[30]. During tobacco smoke exposure, a significant increase in the amount of *mdr1a* mRNA has been observed at GD 21, although it remained steady at GD 14. The level of *mdr1b* almost remained steady at GD 14 and GD 21 between control and tobacco groups. These results suggest that tobacco smoke induced P-gp, especially *mdr1a*. The different expressional patterns of *mdr1a* and *mdr1b* genes show that they were not co-regulated during pregnancy and signified that the expression of both genes probably underlied different regulation pathways, which is supported by the recent data of Lee^[31,32]. P-gp was able to extrude a wide variety of structurally and chemically unrelated compounds out of cells^[33]. Researches have selected B(a)P as a potential P-gp substrate^[34]. Therefore, we suspect that the higher expression of P-gp in rat IUGR placenta might be caused by the pumping out of part of the tobacco toxins, to decrease toxicity and, thus, to protect the fetus from potentially harmful xenobiotics during tobacco exposure, which might be a compulsory mechanism of IUGR. However, we cannot exclude the possibility that there exist some P-gp inducers in tobacco. Further experiments are needed to examine this possibility.

In summary, the present study has discussed the abnormal alterations of placental morphology and function in tobacco-induced IUGR. The expression of placental *CYP1A1* and P-gp increased in tobacco-induced IUGR. Overexpres-

sion of placental *CYP1A1* can contribute to the metabolism of tobacco and can generate reactive metabolites, which can be a trigger for IUGR. However, upregulation of P-gp might pump out part of the tobacco toxins, as a compulsory mechanism of IUGR, to decrease tobacco exposure to the developing fetus.

Abstract

Aim: To develop and optimize a sustained release multivesicular liposome (MVL) formulation of interferon (IFN) α -2b. **Methods:** IFN α -2b MVL were prepared using a typical double-emulsion procedure. The sustained release effects of IFN α -2b MVL were investigated by monitoring the blood IFN α -2b concentration using an enzyme-linked immunosorbent assay test after subcutaneous administration to healthy mice. **Results:** IFN α -2b was successfully encapsulated in MVL with high efficiency, and the integrity of encapsulated protein was maintained. After subcutaneous injection, the MVL slowly released IFN α -2b into systemic circulation in a sustained manner. The estimated serum half-life of IFN α -2b was approximately 30 h. In addition, varying the size of the MVL preparations could further modify the *in vivo* release profile. **Conclusion:** IFN α -2b MVL may be a useful sustained release formulation in the clinical treatment of viral diseases.

Introduction

Interferon (IFN) α -2b is an important cytokine and has been used widely as a therapeutic agent to treat patients with viral and oncological diseases. It is an essential component of the treatment of chronic hepatitis B infection^[1]. However, in the recommended dosing regimen, the protein needs to be administered every other day for 3 months, which brings about much inconvenience to the patients. The $t_{1/2}$ of IFN α -2b, when administered subcutaneously, is only about 4 h^[2]. The protein was shown to be cleared quickly, therefore frequent repeated administrations are necessary.

Much effort has been devoted to the development of IFN α -2b-based products with persistent effects. One approach, covalent attachment of polyethylene glycol (PEG) to the protein surface (PEGylation), has been the most successful. Several PEGylated IFN α products are already on the market. The half-life of the PEGylated protein is 40 h, thus it only needs to be administered once a week for similar therapeutic effects^[3]. However, the chemical conjugation process of PEGylation is rather complex and the PEGylated

products are usually mixtures with different PEG conjugation sites. In addition, a few studies have suggested that the chemical modifications can sometimes affect the structure as well as the bioactivity of the protein^[4].

An alternative approach is to develop sustained-release depot formulations of IFN α -2b. Liposome formulations of IFN γ have been developed and have been reported to have prolonged release profiles of up to 160 h. Even so, using conventional liposome formulations, the drug loading capacity and encapsulation efficiency are still rather low and variable^[5].

Multivesicular liposomes (MVL), on the other hand, have a different structure and possess some distinctive properties. They usually contain a larger internal space, which would allow more drug to be loaded. Their larger size would also deter rapid clearance by tissue macrophages so that they may act as drug depots to enable sustained release of drugs^[6]. The MVL formulation of the anticancer drug cytarabine (DepocytTM) has been developed successfully and is now being used widely for the treatment of leukemia^[7].

We took a similar approach in the present study and evalu-

ated the MVL formulation of IFN α -2b and its biopharmaceutical properties. Some of the parameters that affected the MVL *in vivo* pharmacokinetic behaviors were further investigated. Our data suggest that MVL formulation of IFN α -2b can be developed with satisfactory sustained release properties *in vivo*, which may have useful clinical applications.

Materials and methods

Materials 1,2-dioleoyl-sn-glycero-3-phosphocholine (DOPC), cholesterol, triolein and 1,2-dipalmitoyl-sn-3-phosphoglycerol (DPPG) were all purchased from Sigma (St Louis, MO, USA). *L*-lysine was purchased from Sangon Biological Engineering Technology and Service Co (Shanghai, China). IFN α -2b (recombinant human interferon α -2b) was kindly provided by Pan Asia Bio (Shanghai, China), and all other reagents were of analytical grade and purchased from Shanghai Chemical Reagent Co (Shanghai, China).

Multivesicular liposome preparation The MVL formulations of IFN α -2b were prepared based on the typical double-emulsion procedure developed by Kim *et al*^[8-12]. Briefly, 1 mL chloroform containing the lipids (molar ratio DOPC:cholesterol:DPPG: triolein, 7:11:1:1; two other molar ratios were also used: 7:11:1:4 and 7:11:1: 8) was emulsified at 10 000 r/min for 10 min with 1 mL aqueous solution containing IFN α -2b in phosphate-buffered solution (PBS) and various sucrose concentrations to produce a water-in-oil emulsion. This water-in-oil emulsion was subsequently emulsified with 4 mL of an aqueous solution containing 4% glucose (*w/v*) and 20 mmol/L lysine at 2500 r/min for 10 s, and then poured into another 4 mL of the same aqueous solution. Chloroform was removed by flushing nitrogen over the surface of the double emulsion at 37 °C for approximately 15 min. The resultant MVL were pelleted at 600 \times g and washed twice with PBS to remove unencapsulated IFN α -2b. The IFN α -2b concentration in MVL was determined by HPLC quantification and adjusted accordingly.

For preparing MVL samples with narrower size distributions, the procedures were further modified. For large-sized MVL, a smaller emulsification force (1000 r/min) was applied during the second emulsification and the chloroform was removed slowly (over 30 min). The large MVL were purified and harvested by centrifugation at 100 \times g and only the pellet was collected. For small-sized MVL, the second emulsification step was carried out at 10 000 r/min. Chloroform was removed over approximately 15 min. The resultant MVL were then centrifuged twice at 100 \times g for 10 min, and the precipitants were discarded. Small-sized MVL were then harvested

in the pellet after centrifugation at 600 \times g for 10 min. The size distributions were quite reproducible because of the purification-by-centrifugation step. The IFN α -2b concentration was determined by HPLC quantification and adjusted accordingly.

Multivesicular liposome size measurements The MVL suspensions were diluted in saline. The particle size distribution was measured using a CIS100 particle size analyzer (Ankersmid, the Netherlands).

Encapsulation efficiency determination IFN α -2b encapsulation efficiency was determined by measuring the amount of encapsulated protein as compared to the total amount added^[13]. Briefly, the MVL were pelleted by centrifugation at 600 \times g for 10 min. The pellet was then treated with extraction solution (0.2% Triton X-100, 28% ethanol, 71.2% water, *v/v*) and quantified using the HPLC assay described below.

IFN α -2b characterization IFN α -2b was characterized using reverse phase (RP)-HPLC, sodium dodecyl sulphate-polyacrylamide gel electrophoresis (SDS-PAGE) and enzyme-linked immunosorbent assays (ELISA). RP-HPLC was carried out on a Agilent 1100 liquid chromatography system at 45 °C using a linear gradient of 45%–70% solvent B [CH_3CN , 0.1% Trifluoroacetic Acid (TFA)] over 11 min, and then a sharp linear gradient of 70%–100% solvent B over 9 min at a flow rate of 1.0 mL/min. Solvent A was water (0.1% TFA). IFN α -2b was detected by UV absorbance at 280 nm. The standard curve showed a linear correlation within the range of 2.0 $\mu\text{g/mL}$ –100 $\mu\text{g/mL}$. The intra-day and inter-day assay precisions were determined to be less than 3% and 2%, respectively. SDS-PAGE analyses of encapsulated IFN α -2b were carried out using 12% acrylamide gels under reducing conditions and stained with silver stain. ELISA were carried out using the human interferon α ELISA Kit (sandwich method) from PBL Biomedical Laboratories (Piscataway, NJ, USA). The protein control and the MVL samples were both treated with extraction solution (0.2% Triton X-100, 28% ethanol, 71.2% water) for 30 min and then applied to the ELISA plate. IFN α -2b concentrations were determined according to the standard curve supplied with the kit.

In vitro drug release study Aliquots of IFN α -2b MVL (500 μL) were pipetted into a 50 mL beaker containing 25 mL of saline solution. The beaker was incubated at 37 °C under constant rotation at 12 r/min. Three samples were collected at each time point (0 h, 24 h, 48 h, 72 h, 96 h, 120 h, 144 h, and 168 h) and were centrifuged at 600 \times g for 10 min. The protein concentrations in the pellets were determined using the RP-HPLC assay^[14].

In vivo pharmacokinetic studies Free IFN α -2b and IFN α -2b MVL suspensions were injected subcutaneously

in a single dose in female SD rats. Three rats were included in each group. Blood samples (0.3 mL) were collected at specific time points (5 min, 30 min, 2 h, 8 h, 12 h, 24 h, 48 h, 72 h, 96 h, and 120 h after injection) and were placed aside for 30 min at room temperature. The supernatant (serum) was collected by centrifugation at 700×g for 10 min. IFN α-2b concentrations were determined using ELISA, which has a detection limit of 30 pg/mL. Any values lower than 30 pg/mL were considered undetectable.

Results

Interferon α-2b encapsulation in multivesicular liposomes Multivesicular liposomes containing IFN α-2b were prepared according to the standard double-emulsion method. The preparations were highly reproducible, usually yielding MVL with similar size distributions and encapsulation efficiencies. A representative light microscope image of the resultant MVL is shown in Figure 1A. The particle size distribution analysis is shown in Figure 1B. The MVL had a rather broad size distribution ranging from 2 μm to 50 μm in diameter. The median size was approximately 18 μm.

The encapsulated proteins were characterized using SDS-PAGE, ELISA, and HPLC. There was no chemical degradation in the peptide chain after the preparation. The structural integrity of the protein is considered crucial to its activity. We used an ELISA to partially characterize the 3-dimensional conformational change in the protein. Our data showed that the antibody binding affinity to the protein was only slightly reduced, indicating that there was a substantial amount of native structure remaining in the protein sample after preparation (Figure 2).

Interferon α-2b encapsulation efficiencies Several parameters were evaluated for their effects in optimizing IFN α-2b encapsulation efficiencies. Table 1 lists some of the representative scenarios. Using the standard lipid MVL formulation (48.3 mmol/L DOPC, 70.7 mmol/L cholesterol, 6.7 mmol/L DPPG and 6.7 mmol/L triolein), the encapsulation efficiency was approximately 30%. It can be further increased by adding more lipids. At a protein-to-lipid ratio of 0.031 (w/w), the encapsulation efficiency was more than 60%. In contrast to the reported development of MVL formulation of progenipointin, we did not find any evident correlation between the sucrose concentration in the first aqueous phase and IFN α-2b encapsulation efficiency^[15]. Furthermore, the encapsulation capacity only seemed to vary slightly with different triolein contents.

Interferon α-2b release from multivesicular liposomes *in vitro* The MVL were stable when stored in saline in small

into a large amount of saline (1:50 dilution) under well-mixed conditions, the encapsulated protein would gradually leak out (Figure 3). Approximately 90% of the content was shown to have been released after 7 d.

***In vivo* pharmacokinetic profiles** After subcutaneous injection of a dose of 2.5 mg/kg, free IFN α -2b proteins were cleared quickly within 1 d (the detection limit of the ELISA kit was at 30 pg/mL). The MVL sustained release formulations, however, would provide a continuous supply of IFN α -2b to the systemic circulation, which lasted more than 2 d. The detailed pharmacokinetic behavior was found to be related to the triolein content in the MVL formulation (Figure 4). Increases in triolein content resulted in longer release times.

Effect of multivesicular liposome size on *in vivo* protein release profiles To further optimize the sustained release profile of IFN α -2b MVL formulations, we specifically compared the *in vivo* release properties of MVL with different sizes. As the typical MVL preparation procedure yielded MVL with rather broad size distributions (Figure 1B), we modified some emulsification parameters and added a final

fractionation step to obtain MVL samples in much narrower size distributions. The lipid formulation remained the same.

Figure 4. Serum interferon (IFN) α -2b concentrations after subcutaneous injection of IFN α -2b multivesicular liposomes (MVL) prepared using various molar ratios of triolein to DOPC (0.139, 0.596 or 1.19). The dosage is 1.6 mg/kg. \square : Unencapsulated IFN α -2b; \bullet : triolein/DOPC=0.139; \circ : triolein/DOPC=0.596; \blacktriangledown : triolein/DOPC=1.19. Blood samples were collected at 8 h, 24 h, 48 h, 72 h, 96 h, 120 h after administration. $n=3$. Mean \pm SD.

Two different-sized populations were obtained and their size profiles are shown in Figure 5A. The large MVL had sizes of approximately 40 μ m–60 μ m diameter, and the small MVL were approximately 10 μ m–25 μ m in diameter. The samples were administered subcutaneously at a dose of 1.2 mg/kg and the IFN α -2b serum concentrations were determined and plotted in Figure 5B. It shows that small MVL released the encapsulated protein content over a longer time compared with large MVL.

Discussion

Multivesicular liposome formulations have been developed successfully for the prolonged release of cytarabine, morphine and other drugs^[16,17]. The long-lasting sustained release properties were most evident when the formulations were administered in a small confined space, such as the epidural. We showed here that MVL could also be used to achieve reasonable prolonged release properties after subcutaneous administration, and MVL IFN α -2b formulations may be developed for the treatment of viral infections requiring less frequent dosing. Our data indicate that MVL can maintain their structure in the subcutaneous interstitial space for a few days and slowly release the encapsulated proteins into the systemic circulation. There was considerable protein detected in the circulation for more than 5 d, and the serum half-life was estimated to be approximately 30 h.

The prolonged serum half-life that we achieved is actually comparable to what has been reported for the PEGylated

Figure 5. (A) Particle size distribution of 2 different preparations of interferon (IFN) α -2b multivesicular liposomes (MVL). (B) Serum IFN α -2b concentrations after subcutaneous injection of IFN α -2b MVL with different sizes. \circ : Free IFN α -2b; \bullet : IFN α -2b MVL with larger sizes (40 μ m–60 μ m); \square : IFN α -2b MVL with smaller sizes (10 μ m–25 μ m). The dosage was 800 μ g/kg. Blood samples were collected at 5 min, 30 min, 2 h, 8 h, 16 h, 24 h, 48 h, 72 h, 96 h, and 120 h after administration. $n=3$. Mean \pm SD.

IFN α -2b product currently in clinical use, even though their mechanisms for sustained serum concentration are quite different. PEGylated IFN α -2b requires chemical modification of the protein structure, which might affect its bioactivity. The PEGylated proteins are absorbed into the systemic circulation quickly after administration but remain there for a long time by avoiding various clearance mechanisms. In contrast, the proteins in MVL formulations are unmodified, which wait inside the subcutaneous MVL depot, slowly leak out, and enter the circulation. They should maintain their original structure, and most likely their full bioactivities. Their distribution and clearance mechanisms should also follow the same pathway as natural IFN α -2b. Therefore, compared to the PEGylated product, MVL formulations would have a more defined safety profile, established manufacture proce-

dures and drug efficacy, and side effects that are easier to evaluate. We therefore believe that MVL formulation may be an attractive candidate for the sustained delivery of IFN α -2b for the treatment of viral infections.

Another significant advantage of the MVL formulations is its high drug loading capacity. Compared with conventional liposomes, which often have limited encapsulation for hydrophilic proteins, the MVL offer a much larger internal space and therefore usually have higher encapsulation efficiencies. For IFN α -2b, the encapsulation efficiency was usually more than 30%. However, the double-emulsion preparation method has been shown to cause protein degradation and denaturation^[18]. Also, there might exist protein-liposomal bilayer interactions that may affect protein conformation and activity^[19,20]. We used three methods to test protein chemical and structural changes after encapsulation. Both the SDS-PAGE and HPLC analyses showed that the proteins were chemically intact. For protein conformational changes, some studies have used biophysical methods such as circular dichroism and fluorescence spectroscopy to detect the secondary structure or local amino acid environment changes^[19]. We adopted a biochemical approach using an ELISA to probe possible 3-dimensional conformational changes. The ELISA may have its limitations because it can only detect changes of structure near binding sites. However, antibody binding has been shown to be very sensitive to protein denaturing effects, and ELISA are commonly used in protein formulation studies to assay protein structure integrity^[21]. Our data showed that the antibody binding affinity for the protein after encapsulation was only slightly reduced, indicating that substantial native structure remained after preparation. Further studies are needed to confirm the detailed bioactivity of the encapsulated IFN α -2b.

We also tested several parameters that might affect the release profile of MVL. Triolein is used as a hydrophobic space filler at lipid membrane intersection points and can stabilize the junctions^[11]. The amount of triolein in the MVL formulation was suggested to be important for MVL morphology and stability^[11,22]. We showed that it had a significant impact on the *in vivo* release profiles of IFN α -2b (Figure 4). It is possible that when more triolein is present, the lipid walls are more stable and therefore the protein is released more slowly.

With a similar argument, we hypothesized that the size of the MVL would also be important for the drug release profile, because the inter-compartmental fusion and diffusion of the proteins in larger MVL would add another rate-limiting step and would eventually result in faster protein release into the environment. However, when we used the typical prepara-

tion procedure, the resultant MVL size distribution was rather broad, ranging from 2 μ m to 50 μ m (Figure 1). It is difficult to differentiate the release profile of different-sized MVL. Therefore, we developed a modified procedure to make MVL with much narrower size distributions (Figure 5). Based on our data, the protein release from MVL with smaller sizes (10 μ m–25 μ m) was indeed slower than that from larger MVL (40 μ m–60 μ m), which is an important observation. We therefore suggest that, in further development of control-released formulations, MVL sizes will need to be optimized and well controlled.

In summary, we have demonstrated that IFN α -2b MVL formulation can achieve high encapsulation efficiency, good stability and sustained release effects. The sustained release effect can be affected by the triolein content and particle sizes. Further optimization is needed in order to develop a clinically valuable sustained release formulation of IFN α -2b.

Abstract

Aim: To investigate the enhancing effects of chitosan with or without enhancers on nasal recombinant hirudin-2 (rHV2) delivery *in vitro* and *in vivo*, and to evaluate the ciliotoxicity of these formulations. **Methods:** The permeation-enhancing effect of various chitosan formulations was estimated by using the permeation coefficient of fluorescein isothiocyanate recombinant hirudin-2 (FITC-rHV2) across the excited rabbit nasal epithelium *in vitro*. The effect was further evaluated by measuring the blood concentration level after nasal absorption of FITC-rHV2 in rats. The mucosal ciliotoxicity of different formulations was evaluated with an *in situ* toad palate model. **Results:** Chitosan at a concentration of 0.5% with or without various enhancers significantly increased the permeability coefficient (P) and relative bioavailability (Fr) of FITC-rHV2 compared with the blank control. The addition of 1% sodium dodecylsulfate, 5% Brij35, 5% Tween 80, 1.5% menthol, 1% glycyrrhizic acid monoammonium salt (GAM) or 4% Azone into the 0.5% chitosan solution resulted in a further increase in absorption ($P < 0.05$) compared with 0.5% chitosan alone. But co-administration of chitosan with 5% hydroxyl-propyl-beta-cyclodextrin (HP- β -CD), 5% lecithin or 0.1% ethylenediamine tetraacetic acid (EDTA) was not more effective than using the 0.5% chitosan solution alone. Chitosan alone and with 5% HP- β -CD, 0.1% EDTA, 1% GAM or 5% Tween80 was relatively less ciliotoxic. **Conclusion:** Chitosan with or without some enhancers was able to effectively promote the nasal absorption of recombinant hirudin, while not resulting in severe mucosal ciliotoxicity. A chitosan formulation system would be a useful approach for the nasal delivery of recombinant hirudin.

Introduction

Hirudin, a 65–66 amino acid polypeptide (7 kDa), is one of the most potent inhibitors of thrombin and has proven to have outstanding anticoagulant and antithrombotic activities^[1]. Recombinant hirudin (rHV), which can now be produced through DNA techniques, has a similar anticoagulative effect to natural hirudin^[2]. Compared with other anticoagulants, including heparin, rHV possesses many advantages with respect to safety, antigenicity, and toxicity^[3]. Currently, rHV has been used for the prophylaxis and treatment of heparin-induced thrombocytopenia (HIT), venous and arterial thrombosis, and shunt thrombosis, and the treat-

ment of disseminated intravascular coagulation (DIC)^[4,5].

However, because of its susceptibility to protease degradation and low mucosal permeability, only parenteral injection (iv or sc) is available for the delivery of rHV. Frequent injections, especially when rHV is indicated by chronic symptoms (and during prophylactic usage) would cause considerable discomfort to patients. Therefore, considerable effort has been directed towards developing alternative administration routes other than injection. Although recombinant hirudin-1 (rHV1) and rHV2 can be absorbed in the gastrointestinal tracts of rats after duodenal and oral administration, the absorption was limited or it varied depending on the analytical methods used, which indicated

that the results were unreliable^[6,7]. As a convenient method of administration, nasal delivery has many benefits relative to oral administration, including the avoidance of the liver first-pass effect and a higher bioavailability. Additionally, for polypeptides, nasal delivery is one of a few non-parenteral administrative routes that have gained regulatory approval so far. Nasal delivery formats for polypeptide drugs such as calcitonin, insulin, desmopressin and growth hormone are already commercially available or in clinical trials. However, there is limited information about intranasal delivery of rHV.

The main barriers to the nasal administration of hydrophilic peptides are mucosal penetration and mucociliary clearance. Chitosan, a positively charged bioadhesive polysaccharide, has been found to be able to improve the nasal absorption of peptides and reduce the clearance of liquid formulations from the nasal cavity through its bioadhesive characteristics, while causing negligible damage to the nasal mucosal membrane^[8,9].

The present study was therefore intended to investigate the nasal administration of rHV using chitosan. To further improve the enhancing activity of chitosan, we studied the effects of chitosan with some enhancers on the permeation of rHV across excised rabbit nasal epithelium *in vitro* and the absorption of rHV by nasal delivery in rats. Furthermore, the mucosal cytotoxicity of different formulations was also evaluated by using an *in situ* toad palate model^[10]. In the present study, we chose rHV2 as the model drug. For the assays, the rHV2 was labeled with fluorescein isothiocyanate (FITC), which formed a stable covalent conjugate (FITC-rHV2) that could be assayed by fluorometry.

Materials and methods

Materials Recombinant hirudin-2 (rHV2, rHV-Lys47) was obtained from the College of Life Science (Peking University, Beijing, China), and chitosan (M_r 250 kDa, degree of deacetylation >85%) was from Yuhuan Ocean Biochemical Co (Zhejiang, China). FITC, Brij35, ethylenediamine tetraacetic acid (EDTA), lecithin and Sephadex G-25 were purchased from Sigma (St Louis, MO, USA), and sodium dodecylsulfate (SDS), hydroxyl-propyl-beta-cyclodextrin (HP- β -CD), menthol, 1-dodecylazacycloheptan-2-one (Azone) and Tween 80 were from Beijing Chemical Co (Beijing, China). Glycyrrhizic acid monoammonium salt (GAM) was the product of Xinjiang Tianshan Pharmaceutical Industry Co (Wulumuqi, Xinjiang, China). All other chemicals were in analytical grade.

Animals Male rats (Sprague-Dawley, weighing 280–300 g) and male rabbits (Japanese White, weighing 2.5–3.0

kg) were obtained from the Experimental Animal Center of Weitonglihua (Beijing, China); toads (weighing 30–40 g) were from the Experimental Animal Center of the Health Science Center of Peking University (Beijing, China).

The care and handling of animals was performed with the approval of the Institutional Authority for Laboratory Animal Care.

Preparation and purification of FITC-rHV2 The synthesis of FITC-labeled rHV2 was based on the reaction between the isothiocyanate group of FITC and the tyrosine in rHV2^[11]. FITC in 0.5 mol/L carbonate buffer (pH 9.5) was added into a 1/10 volume of rHV2 solution (20 g/L in 0.01 mol/L phosphate buffered saline [PBS]; pH 7.1); the molar rate of the two compounds was 3:1. After 4 h of reaction with magnetic mixture in the dark at 0–9 °C, FITC-labeled rHV2 was separated from unreacted FITC in a Sephadex G-25 column (2.0 cm ID×30 cm L) pre-washed with PBS (pH 7.4). A sample of approximately 1 mL was put on the top of the column and then washed with PBS as an elution solvent. The first yellow band was collected. After the collections were mixed, FITC-rHV2 was obtained by freeze-drying. All experiments were carried out under light exclusion conditions. The molecular weight of FITC-rHV2 was determined to be 7388.99 by mass spectrometry (data not shown). This result indicated that one rHV2 molecule had combined with one molecule of FITC. FITC-rHV2 and rHV2 were found to have similar activities when measured using the chromogenic thrombin substrate assay^[12].

Preparation of FITC-rHV2 formulations For the *in vitro* studies, FITC-rHV2 was dissolved in 0.5% chitosan (pH 5.0, w/v) at a concentration of 400 mg/L for transport. In the *in vivo* studies, FITC-rHV2 was dissolved in 0.5% chitosan solution at a concentration of 36 g/L for intranasal administration. When required, the enhancers were added into these formulations (menthol, Azone and lecithin were initially dissolved in propylene glycol). The concentration of FITC-rHV2 for transport control was 400 mg/L in Ringer's solution and for subcutaneous administration was 0.5 g/L in 0.9% NaCl. All the formulations were prepared on the day of the experiments.

FITC-rHV2 assay The concentration of FITC-rHV2 was determined in a fluorescence spectrofluorometer (650–60; Hitachi, Japan) at an excitation wavelength of 495 nm and an emission wavelength of 515 nm. A standard curve was prepared using FITC-rHV2 at concentrations between 4 μ g/L and 200 μ g/L. The FITC-rHV2 concentrations of the test samples were estimated using the standard curve.

Nasal epithelium preparation Rabbit nasal epithelium was prepared as described by previous reports^[13]. After

each rabbit was killed, its nasal septum was surgically removed with a scalpel immediately, and then the epithelium was carefully excised from the septum and stored in ice-cold Ringer's solution (pH 7.4; 125 mmol/L NaCl, 5 mmol/L KCl, 10 mmol/L NaHCO₃, 1.2 mmol/L NaH₂PO₄, 1.4 mmol/L CaCl₂ and 11 mmol/L *D*-glucose). The epithelium was used within 0.5 h of removal.

In vitro permeability experiments Prior to the experiment, Ringer's solution was added to both sides of the horizontal diffusion chamber with a 4 mL volume in each side, and the excised rabbit nasal epithelium was mounted in the diffusion chamber at 37 °C. After an equilibration period of approximately 0.5 h, the buffer was replaced with the FITC-rHV2 solution on the donor side (mucosal), and fresh buffer on the receiver side (serosal). A 200 µL aliquot of sample was taken from the receiver side at particular times (0, 0.5, 1, 1.5, 2, 3, 4 and 6 h), and at the same time an equal volume of Ringer's solution was added to the receiver side. The FITC-rHV2 concentration in the receiver side (*Cr*) was determined by FITC-rHV2 assay. All experiments were carried out under light exclusion conditions.

Calculation of the permeability coefficient The *Cr* values were plotted as a function of time (*t*) from 0 h to 6 h. The permeability coefficient (*P*) was calculated according to the following equation:

$$P = (dq/dt) / (C_0 A)$$

where dq/dt (µg/s) represents the permeability rate, C_0 (µg/mL) was the initial concentration in the donor chamber, and A (cm²) is the effective cross-sectional area available for diffusion (0.126 cm²). The transport enhancement ratios (ER) were calculated using the following equation:

$$ER = P_{\text{enh}} / P_{\text{ctrl}}$$

where P_{enh} and P_{ctrl} refer to the *P* values with added and no added enhancers, respectively. Student's *t*-test was used to determine statistical significance.

In vivo studies The *in vivo* studies were performed as previously described^[14]. The rats were fasted overnight before the study. Anesthesia was induced by intraperitoneal injection of 40 mg/kg sodium pentobarbital and maintained by additional 15 mg/kg doses as required. The rats were fixed on their backs on boards and were surgically prepared by cannulation of the trachea to enable breathing, cannulation of the carotid artery to facilitate blood sample collection, and ligation of the esophagus to prevent samples being swallowed. A 50 µL dose of the formulations was administered into the left nares via a flexible polyethylene tube attached to a microsyringe. In addition, 0.9% NaCl was administered as a control to ensure that there was no interference with FITC-rHV2. For the calculation of *Fr*, FITC-rHV2 solu-

tion (0.5 mg/kg) was subcutaneously administered by bolus injection. Blood samples (400 µL) were withdrawn from the carotid artery into the plastic microfuge tubes at particular times (0, 0.5, 1, 1.5, 2, 3, 4 and 6 h). The blood samples were anticoagulated with 3.8% (w/v) trisodium citrate solution at a ratio of 8.25:1.75 (v/v), and plasma was separated after centrifugation at 1 300×*g* for 5 min.

The fluorescence intensity in the plasma before and after trichloroacetic acid (TCA) precipitation was determined, and the intensity of the insoluble portion was used to calculate the intact FITC-rHV2 concentration^[15].

Data analysis The area under the FITC-rHV2 concentration time curves (AUC) was calculated by using the trapezoidal method. The relative bioavailability (*Fr*) was calculated by comparing the area under the curve obtained after intranasal administration with that obtained after subcutaneous injection. Statistical analysis was performed using Student's *t*-test. Differences were considered to be significant for values of $P < 0.05$.

Ciliotoxicity evaluation An *in situ* toad palate model^[10] was used. SDS (1%), Brij35 (5%), HP-β-CD (5%), Tween 80 (5%), EDTA (0.1%), and GAM (1%) were directly dissolved in a chitosan solution, and menthol (1.5%), Azone (4%), and lecithin (5%) were initially dissolved in propylene glycol and then in chitosan solution. The toads were fixed on their backs and their mouths were opened with pincers. The test formulations (0.5 mL) were applied to the upper palate of the toads for 30 min, and then the palates were rinsed twice with 0.9% NaCl. The palates were dissected out, and the mucocilia were examined with an optical microscope (Olympus, Japan). The duration of ciliary movement in different formulations was recorded and then the relative durations compared with 0.9% NaCl were calculated. Each group was duplicated 3 times and Student's *t*-test was used to determine statistical significance.

Results

The time versus the amount of FITC-rHV2 that had permeated across the excised rabbit nasal epithelium after application of the chitosan solution with or without enhancers to the mucosal side is shown in Figure 1. The corresponding permeability coefficients and the transport enhancement ratios (ER) are listed in Table 1. When chitosan or chitosan with various enhancers was added into the FITC-rHV2 formulation, the amount of FITC-rHV2 moving across the epithelium increased, and there were significant increases in the permeability coefficient. We found that the permeability coefficient of FITC-rHV2 in various chitosan formulations

was 1.7-fold to 33-fold higher than that without chitosan. In addition, there was a marked increase in the permeability coefficient of FITC-rHV2 in chitosan formulations with 1% SDS, 5% Brij35, 5% Tween 80, 1.5% menthol, 1% GAM or 4% Azone (*P*<0.05) compared with chitosan alone. No significant difference (*P*>0.05) in the permeability coefficient was observed between the chitosan formulations containing 5% HP-β-CD or 0.1% EDTA and chitosan alone, although there was a significant decrease in the permeability coefficient in the formulation containing 5% lecithin.

The mean plasma concentration of FITC-rHV2 versus

time after nasal administration to rats using various formulations is shown in Figure 2, and the Fr values are given in Table 2. When administered intranasally, in a formulation containing neither chitosan nor enhancer (as a control), FITC-rHV2 was only poorly absorbed, with an Fr value of 1.86% compared with subcutaneous injection (Figure 2, Table 2). The addition of chitosan at a concentration of 0.5% resulted in a significant improvement, with an Fr value of 8.26%, which is 4-fold that of the control. After enhancers were

added to the 0.5% chitosan solution, the Fr values of FITC-rHV2 changed markedly in some formulations. Compared with chitosan alone, the addition of 1% SDS, 5% Tween 80, 4% Azone, 1.5% menthol, 1% GAM or 5% Brij35 significantly increased the Fr of FITC-rHV2 ($P<0.05$), whereas the addition of 5% HP- β -CD, 5% lecithin or 0.1% EDTA did not increase Fr to any significant extent.

Regarding the permeability or absorption of FITC-rHV2 in chitosan formulations with or without enhancers, the results of the *in vitro* experiment (ER values) were in agreement with the *in vivo* results (Fr values), as shown in Figure 3 ($R^2=0.9059$).

Figure 3. Correlation of the absorption-enhancing effects between ER (*in vitro*) and Fr (*in vivo*) of different formulations.

The effects of chitosan with or without enhancers on the ciliary movement duration in toad palate are shown in Figure 4. Ciliary movements were significantly inhibited by co-administration of chitosan with 1% SDS, 5% Brij35, 4% Azone, 5% lecithin, 0.1% EDTA or 1.5% menthol compared with the 0.9% NaCl control, but not significantly inhibited by 0.5% chitosan alone or 0.5% chitosan with 5% HP- β -CD, 5% tween80 or 1% GAM. Based on these data, the rank order of the ciliotoxicity for different chitosan formulations based on the

relative ciliary movement durations was as follows: no enhancer<0.5% chitosan<+5% HP- β -CD<+1% GAM<+5% Tween80<+5% lecithin<+0.1% EDTA<+5% Brij35<+4% Azone<+1.5% menthol<+1% SDS.

Discussion

For a nasal solution formulation, 0.5%–1.0% chitosan and a molecular weight greater than 100 kDa are preferred^[16,17]. In the present study, we used 0.5% chitosan and found that at this concentration, the chitosan solution could significantly enhance the efflux as well as the nasal absorption of FITC-rHV2 both *in vitro* and *in vivo*. This result can be attributed to a combination of bioadhesion and a transient opening of the tight junctions in the cell membrane to allow hydrophilic macromolecules to pass through^[8,9].

SDS, Brij35, Tween 80 and Azone are all percutaneous enhancers^[18-20]. In our experiments, the addition of any of these agents into the chitosan solution significantly increased nasal absorption of FITC-rHV2 compared with chitosan alone. This result may be due to the fact that these compounds can all change the arrangement of the epithelial cell membrane phospholipids and increase the fluidity of the membrane lipid bilayers or interact with the membrane protein, therefore resulting in a transcellular pathway transport of FITC-rHV2. Chitosan was able to affect the paracellular pathway transport of FITC-rHV2 by its mucoadhesive properties and opening of the tight junction effect^[8,9]. The combined effect of the two agents consequently increased the absorption of FITC-rHV2 compared with chitosan alone.

When EDTA was added to the FITC-rHV2 solution containing chitosan, EDTA activated protein kinase C by depletion of extracellular calcium via chelation, resulting in an expansion of the paracellular route^[21], and chitosan interacted with the membrane protein, also causing the tight junctions

to open. The combination of these two effects could potentially result in a marked enhancement of FITC-rHV2 absorption. However, the negatively charged carboxyl groups of EDTA interact with the positively charged amino groups of chitosan, which may inhibit the enhancing action of both agents. Therefore, in the present study we did not observe any absorption enhancement of FITC-rHV2 with EDTA added to chitosan compared with chitosan alone.

There exists a controversial explanation for the enhancing mechanism of cyclodextrins; that is, that the enhancing effects include the disaggregation of protein aggregates (insulin), an interaction with lipids and divalent cations on the membrane surface, and a direct effect on the paracellular pathway by a transient effect on tight junctions^[22,23]. However, in most cases, cyclodextrin systems are used as a means of enhancing drug solubilisation^[24]. In our experiment, when HP- β -CD was co-administered with chitosan, we did not observe the reported synergistic effect for FITC-rHV2 absorption^[25]. The most likely reason is that FITC-rHV2 is not like insulin, which usually aggregates in hexamers in solution, and is more unstable in the presence of proteolytic enzymes in the nasal mucosa, so addition of HP- β -CD may lead to insulin deaggregation from hexamers to dimers and protect insulin from degradation by proteolytic enzymes in the nasal mucosa.

Phospholipids can bring about enhanced delivery of polar compounds administered nasally by inhibiting the apical membrane sodium channels and causing structural changes in tight junctions^[26]. However, in our experiment a significant decrease in FITC-rHV2 absorption was observed when lecithin was added to the chitosan solution. This was probably because lecithin is a negatively charged compound, whereas chitosan has positively charged amino groups, so the two oppositely charged molecules might interact and produce no increase in FITC-rHV2 absorption.

Menthol is a monocyclic terpene. The mechanism of its enhancing effect is mainly due to it forming a eutectic with the penetrating compound, thereby increasing its solubility, and also enhancing the fluidity of the local lipid bilayers^[27]. In the present study, the co-administration of menthol with chitosan markedly increased FITC-rHV2 absorption compared with chitosan solution alone, suggesting that the co-administration of the two agents cause the FITC-rHV2 molecule to more easily penetrate the cell membrane.

Sakai *et al* found that dipotassium glycyrrhizinate decreased intracellular calcium ion levels and did not induce any significant histomorphological changes in the actin filaments^[28]. In addition, dipotassium glycyrrhizinate enhanced the cellular permeability of sodium fluorescein and fluores-

cein isothiocyanate dextran by enhancing the activation of a protein kinase C via sodium deoxycholate (an enhancer)^[29]. Also, the combined use of the two enhancers had fewer toxic effects. In the present experiment we found that chitosan with GAM exerted an obvious enhancing effect on FITC-rHV2 absorption compared with chitosan alone, but it was not clear whether this effect was related to the mechanism described.

Because rat nasal epithelium covers an area that is too small to fit the device used in the *in vitro* experiment, we chose to use rabbit nasal epithelium instead. As shown in Figure 3, there is considerable correlation ($R^2=0.9059$) between ER and Fr, suggesting a relationship between the *in vitro* and *in vivo* studies. Therefore, in the present study, it appears that using nasal mucosa from different animal species in the *in vitro* and *in vivo* experiments did not influence the correlation between the absorption-enhancing effects of formulations *in vitro* and *in vivo*.

For most absorption enhancers, a direct relationship may exist between the absorption-promoting effect and local toxicity, hence it is important to evaluate the local toxic effect for a prospective novel enhancer system. An *in situ* toad palate model was used in the present study to evaluate the ciliotoxicity of different formulations. Although recording the duration of ciliary movement may be less objective and less accurate than the ciliary beating frequency method, using a microscope it is possible to directly examine the quantity of fallen cilia, as well as the integrity of the mucosa at the same time. This method is especially suitable for the initial screening of drugs or formulations. Among the tested enhancers, chitosan alone and chitosan with HP- β -CD, GAM or Tween 80 were least ciliotoxic.

In conclusion, chitosan is an effective enhancer for increasing the nasal absorption of FITC-rHV2, and co-administration of chitosan with other enhancers can improve absorption further. Some chitosan formulations were less ciliotoxic than others. The chitosan formulation system could be a useful approach for improving nasal absorption.

Abstract

The transcription factor antagonist inhibitor of differentiation 3 (Id3) has been implicated in many diverse developmental, physiological and pathophysiological processes. Its expression and function is subjected to many levels of complex regulation. This review summarizes the current understanding of these mechanisms and describes how they might be related to the diverse functions that have been attributed to the Id3 protein. Detailed understanding of these mechanisms should provide insights towards the development of therapeutic approaches to various diseases, including cancer and atherogenesis.

Introduction

Inhibitor of differentiation (Id) proteins are a family of transcriptional regulators that have been implicated in several developmental, physiological and pathological processes. Their name relates to their ability to inhibit the differentiation of a variety of cells by inhibiting the DNA binding activity of many transcription factors that regulate expression of cell-type specific genes. Id genes are widely expressed in the animal kingdom from humans to zebra fish^[1]. Four Id genes, Id1–Id4 have been found in humans and in rodents. A homologous Id-like gene, extramacrochaetae has been identified in drosophila^[2].

The Id proteins are small proteins of approximately 13 kDa–20 kDa. All 4 Id proteins contain a relatively conserved helix-loop-helix (HLH) structural motif in the middle of the protein, but are otherwise quite divergent in sequences. The 4 Id proteins constitute 1 subclass (Class V) of the large family of HLH transcriptional regulators. Unlike other HLH proteins that can bind to DNA as either homodimers or heterodimers, the Id proteins lack the basic amino acid domain needed for DNA binding. Instead, they are believed to function primarily by forming heterodimers with the “ubiqui-

tous” Class I HLH proteins known as E-proteins. This prevents the E-proteins from interacting with each other and with the cell-type specific Class II HLH proteins, inhibiting their binding to DNA and blocks their ability to modulate gene expression (Figure 1).

The first Id gene, Id1, was identified by virtue of the ability of its encoded protein to inhibit muscle differentiation and the activation of muscle-specific gene promoters^[3]. However, the Id proteins are now known to be important in other physiological systems and pathophysiological situations. In addition to the E-protein partners, Id proteins regulate other transcription factors such as ternary complex factor (TCF)/ETS^[4,5], Pax 5 and sterol regulatory element binding protein-1^[6]. Individual Id proteins might also interact selectively with proteins not recognized by other Id family members. For example, Id1 is the only Id protein shown to bind the proteasomal protein S5a^[7]. Similarly, only Id2 binds to the tumor suppressor retinoblastoma protein Rb and interferes with the ability of hypophosphorylated Rb to suppress cell proliferation when both are ectopically expressed (Figure 1)^[8].

Evidence to date indicates that the Id proteins are likely to carry out both common and distinct biological functions,

Figure 1. Inhibitor of differentiation (Id) proteins function by interacting with various protein partners. Binding of Id proteins to the class I basic-helix-loop-helix (bHLH) proteins (I) prevents them from forming homodimers or heterodimers with the class II bHLH proteins (II). This leads to the inhibition of gene expression (broken arrows). Alternatively, because some class I bHLH proteins repress transcription, sequestration of these repressor proteins could ameliorate their inhibitory effects. More recent data suggests that Id proteins also interact with and inhibit other transcription factors (OTF) such as ETS, SREBP-1 and Pax5. Individual members of the Id family proteins might interact selectively with specific proteins. For example, Id2 protein binds to the retinoblastoma protein (Rb) and prevents it from blocking cell cycle entry, thus stimulating cell proliferation. Id proteins also affect cell proliferation, as well as differentiation and other cell functions indirectly by modulating the expression of specific genes. Interaction with other proteins (p204, GSN5) accelerates Id3 degradation. Additional protein partners (X) could exist that might explain the many biological effects of the Id proteins.

depending in part on when and where the proteins are expressed. Consistent with this idea, mice engineered to be deficient in a single Id gene are viable, albeit with developmental defects in certain specific cell lineages depending on the particular gene that has been inactivated^[9–15]. For example, Id3-deficient mice have defects in both B cell^[14] and T cell^[15] maturation and develop salivary gland defects reminiscent of the autoimmune Sjogren's syndrome, but are otherwise generally normal^[16]. In contrast, mice with both copies of Id1 and Id3 genes inactivated die *in utero* (embryonic d 13.5) with severe vascular defects in the forebrain, aberrant neuronal differentiation^[17] and multiple cardiac abnormalities^[18]. In fact, mice with both copies of any 2 of the 3 Id genes (Id1–Id3) inactivated exhibit similar cardiac defect and are embryonic lethal. Mice with loss of 1–3 copies of the Id1/Id3 genes are viable but exhibit increasing degrees of resistance to tumor-induced angiogenesis^[17]. The

lethality of the double knockout mice and the dosage-dependent tumor angiogenesis phenotype clearly indicates that the Id genes mediate overlapping function in some developmental lineage. However, the developmental defects in specific cell lineages manifested in single knockouts suggest that Id genes are unable to compensate in some cells, perhaps because they are not co-expressed or, as in the case of Id2, because of specific dimerization with different protein partners such as Rb.

Many excellent and extensive reviews covering the Id family proteins have been published in recent years^[19–26]. Most of these reviews have dealt with the Id proteins as a group and concentrated primarily on the potential biological functions of the Id proteins. Relatively less attention has been devoted to reviewing the molecular mechanisms that regulate the expression and function of individual Id genes and proteins.

The present review will focus on the third member of the Id gene family, Id3, particularly on the mechanisms involved in its regulation. The Id3 gene was first identified as a serum-inducible immediate early gene in an established murine fibroblastic cell line^[27]. Subsequent studies have documented its involvement in various biological processes, including T and B cell development^[15,14], skeletal muscle differentiation^[28,29], vascular smooth muscle cell proliferation^[30,31], embryonic neurogenesis^[17], osteogenesis^[32] and tumor-induced angiogenesis^[17].

Expression and function of the protein is under many complex layers of regulation (Figure 2) and, therefore, could provide rich targets for therapeutic interventions.

Developmental and cell-type specific expression pattern of Id3

The most direct way to regulate the function of a particular protein is to control when and where the gene encoding the particular protein is expressed. Several studies have characterized the expression of Id3 at either the mRNA or the protein level. A wide range of techniques have been utilized, including Northern, *in situ* hybridization, reverse transcription with polymerase chain reaction, various genome expression profiling assays, Western immunoblots and immunocytochemical staining procedures.

Like other Id genes, the expression of Id3 is dynamically regulated during embryonic development. The general expression level is high at the early embryonic ages, but progressively declines as the embryo develops^[27,33]. Id3 is widely expressed throughout the embryo proper. Its expression is readily detectable within regions that are undergoing active

Figure 2. Multiple mechanisms regulating inhibitor of differentiation 3 (Id3) expression and function. A variety of stimuli and physiological states activate diverse signal transduction pathways (1) to regulate the expression and function of Id3 at multiple levels. For example, DNA methyltransferases (DNMT), histone acetyl transferases (HAT) and histone deacetylases (HDAC) might work together to control the silencing of the Id3 gene under certain conditions (2), whereas a variety of different transcription factors (TF) act in conjunction with each other to regulate transcription (3). The Id3 transcripts are also subjected to alternative splicing (4) that results in protein isoforms with distinct biological properties. Interaction of the Id3 transcript with additional factors likely affects its stability (5) and translation (6). The protein products undergo phosphorylation (7) and ubiquitination (8) mediated by specific kinases and ubiquitin ligases that modulate its function and stability. Finally, the subcellular localization and the ultimate biological effect of Id3 might be dependent on the availability, relative abundance and physiological significance of its various protein partners (9).

morphogenesis^[34], but can also be detected in some undifferentiated tissues^[33].

The expression pattern of Id3 during embryonic development overlaps with, but is not identical to that of, the other Id genes. At an early embryonic age, Id1 and Id3 are expressed in the tissues derived from the inner cell mass; Id2 is expressed in tissues derived from trophoblasts; but no Id4 expression is evident. In the primitive gut, Id1 and Id3 signals are expressed in the mesenchyme, whereas Id2 expression occurs within the epithelium^[34]. During early spinal cord development, expression of Id1 and Id2 are restricted to the roof plate, whereas Id3 is expressed both in the roof and the floor plate. At later stages, Id1 and Id3 expression is detected in the dividing neuroblasts, whereas Id2 and 4 are expressed in presumptive neurons undergoing maturation^[35]. Generally speaking, the pattern of Id3 expression most closely resembles that of Id1, but the coincidence is not absolute^[33].

Expression of Id3 in adult tissues is widely spread but not universal and the level of expression varies substantially among different tissues. Id3 is expressed in many cell types *in vivo* and in both primary cultures and established cell lines (Table 1). Depending on the cell and tissue type, the expression might be constitutive or detectable only after exposure to appropriate stimulus. The level of Id3 expression is generally high in proliferating, undifferentiated cells, but downregulated when cells undergo terminal differentiation^[28,29,36-39]. Expression of Id3 also tends to be higher in immortalized cell lines, consistent with the putative involvement of Id proteins in combating cellular senescence^[40,41] and maintaining the capacity for self-renewal in embryonic stem cells^[42].

Knowing what tissues and cell types express Id3 is, however, probably akin to just seeing the tip of the iceberg. The level of Id3 expression is not static, but varies dramati-

Table 1. Summary of the expression and regulation of Id3 in selected cell types.

Cell types	Comments	References
Cultured fibroblasts	Inducible by many agents as immediate early gene	[27]
Myogenic and osteogenic precursor cells	Downregulated with terminal differentiation	[93,47]
Preadipocytes	Downregulated following adipogenesis and no longer inducible by serum	[38]
Sertoli cells	Induced by serum but not follicle stimulatory hormone	[98]
Lymphoid and monoblastic cell lines	Downregulated in mature differentiated cells	[73,39,99,100]
Astrocytes	Upregulated in astrocytoma	[101,54]
Prostate epithelial cells	Detectable only following serum stimulation	[102]
Human dermal microvascular cells	Downregulated by treatment with statins	[103]
Ovarian surface epithelial cells	Downregulated in ovarian adenocarcinoma	[47,104]
Schwann cells	Downregulated during nerve maturation	[86]
Human keratinocytes	Protein localized to nucleus, downregulated with differentiation	[45]

cally with the growth and physiological state of the cells and is modulated in response to diverse extracellular stimuli. There are other layers of regulation superimposed upon the regulation at the expression level (Figure 2). Additional caveats should also be kept in mind when interpreting the results from the aforementioned studies. Results using immortalized cell lines need to be viewed with caution because the process of immortalization might involve alterations in Id3 expression not seen *in vivo*. Direct examinations of tissue sections *in vivo* or with primary cell cultures eliminate such concerns. However, the sensitivity of the assays used for detecting Id3 expression in various studies are not precisely known and might not always be comparable. The specificity of the antibodies used for immunodetection might not have always been adequately scrutinized. Therefore, care should be taken in making a firm conclusion as to whether Id3 is or is not expressed in a certain tissue or cell type. Nevertheless, because Id3 is expressed at many, but not all, cells indicates that its regulation is likely to involve both ubiquitous as well as cell-type specific regulatory mechanisms.

Altered patterns of Id3 expression in diseases and pathophysiological situations

Perturbation of Id3 expression has been correlated with a variety of disease states and pathological situations, including cancer, aging, atherosclerosis, muscle atrophy, and inflammation. Conversely, altered expression of Id3 has been detected during the regenerative process following tissue injury.

It is generally believed that members of the Id gene family behave like oncogenes. Overexpression of one or more Id genes has been detected in various cancers. The situation with Id3 is consistent in most part with this generalization^[43–45], but there are some exceptions. In certain neurological tumors, Id3 upregulation is observed not only in the tumors themselves but also in the vascular tissues surrounding the tumors^[44]. In contrast, expression is reduced in papillary thyroid carcinoma^[46] and ovarian carcinomas^[47], and either increased^[48] or absent^[49] in seminoma. The expression pattern is even more complex during the development of liver diseases and liver cancer. Id3 expression is low in normal liver, increases with the progression of liver diseases from chronic hepatitis to liver cirrhosis and is expressed at high levels in well-differentiated hepatocarcinomas, but not in the more advanced de-differentiated tumors^[50].

Variations in Id gene expression have also been correlated with aging in animals. Expression of Id1, Id2, and Id3

increases in hind limb muscles of aging rats^[51]. Because increased levels of Id proteins are associated with muscle disuse atrophy^[52], the upregulated Id expression in aging muscle might contribute to the loss of muscle mass that commonly accompanies aging. In contrast, Id3 expression appears to be reduced in the pituitary gland in aged rats^[53]. Taken together, the results suggest that some other aging-related physiological perturbations rather than aging per se might be responsible for the altered Id expression in different tissues.

Id3 expression level also changes in inflammatory and atherogenic processes. Id gene expression is upregulated in reactive astrocytes activated as part of the inflammatory process following spinal cord injury^[54]. Id3 expression is also altered in vascular smooth muscle cells (VSMC) during atherogenesis. It is expressed at low level in normal vessels of the carotid artery, but is increased within 3 d of balloon injury and remains high through 14 d postinjury^[30]. This is accompanied by the appearance of a novel differentially spliced Id3 transcript.

Changes in Id3 expression are not limited to pathological situations: increased Id3 expression has been implicated in tissue regeneration. In the African clawed frog, *Xenopus laevis*, which does not completely regenerate the missing limb following amputation, Id3 expression is upregulated transiently but returns to basal level when terminal differentiation of the limb stump tissues is initiated. In the Japanese newt, *Cynops pyrrhogaster*, which is capable of regenerating a complete limb, expression of Id3 persists until the stage of digit formation^[55]. The earlier downregulation of Id3 in the *Xenopus* might have contributed to premature differentiation and the aborted regeneration program. Similarly, Id3 upregulation might also contribute to the liver regeneration following partial hepatectomy in mice^[56].

The mechanisms accounting for the perturbation of expression of Id3 under different conditions are largely unknown. The presumption is that it involves changes in transcription, but the hypothesis is as yet unproven. No evidence has been found so far that would implicate either gene amplification or deletion in the altered pattern of Id3 expression found in different cancers; therefore, the change is probably epigenetic. There is some evidence that DNA methylation or histone acetylation might contribute to Id3 regulation but exactly how such processes affect Id3 expression is not known (see below). In most cases, the change in Id3 expression is likely to be either secondary to changes in the cell physiology and/or in response to environmental signals.

Stimulus and signaling pathways regulating Id3 expression

Id3 was originally identified as a serum-inducible gene in Balb/c3T3 fibroblasts and found to be induced in these cells, to a varying degree, by a variety of other agents^[27]. The Id3 transcript was induced rapidly and transiently, with peak accumulation occurring at about 1 h after stimulation. In this system, Id3 appears to behave as “immediate-early” or “primary response” genes, and can be induced in the absence of ongoing protein synthesis.

Id3 expression has been shown to be responsive to even more diverse stimuli in a variety of cell types (Table 2). Several conclusions can be drawn from this plethora of information. First, although the ability to regulate Id3 expression is wide spread, not all agents regulate Id3 expression in the same manner in all cell types. For example, the phorbol ester, phorbol 12-myristate 13-acetate (PMA), stimulates Id3 expression in thyrocytes^[46] but downregulates Id3 levels in the SH-SY5Y neuroblastoma cells^[57]. This suggests that the regulatory pathways might be different among

Table 2. Stimuli and signaling pathways implicated in Id3 regulation.

Stimuli	Cell types	Signaling pathways	Responses	References
Thyroid stimulating hormone	Dog thyrocytes	cAMP-dependent	Rapid increase	[46]
PMA, insulin	Dog thyrocytes	ND	Rapid increase	[46]
PMA	SH-SY5Y neuroblastoma	ND	Downregulation after 24 h	[57]
Insulin, methylisoxanthine, dexamethasone	3T3L1 preadipocytes	MEK-, PKC- and PI3K-independent	Rapid increase	[105]
TGF-β	B-lymphocyte progenitor	Smad	Transient increase, returned to basal within 24 h	[13]
TGF-β	Epithelial	ND	Biphasic, transient increase followed by long term suppression	[58,59]
BMP	Mesenchymal stem cells	ND	Transient increase, returned to basal within 3 d	[60]
BMP	Embryonic stem cells	ND	Increase	[42]
BMP	Epithelial	Smad 4	Sustained induction	[59]
TNF-β	Astrocytes, microglia	ND	Rapid and transient increase	[54]
B-cell receptor engagement	Mature B-cells	ND	Increase	[14]
PMA	Mature B-cells	ND	Biphasic, transient increase with a secondary peak	[61]
B-cell receptor engagement	WEHI-231 immature B-cells	ND	Persistent increase	[62]
T-cell receptor (TCR) ligation	T lymphocytes	RAS, ERK, Egr-1	Increase	[63]
Endostatin	Endothelial	ND	Increase	[106]
Estrogen	VSMC	ND	Decrease	[107]
Angiotensin II, Superoxide free radical	VSMC	ERK, p38MAPK, calcium	Rapid increase	[64]
Hydroxyl free radicals	VSMC	ND	Down increase	[69]

ND, not determined; PMA, phorbol 12-myristate 13-acetate; TGF-β, transforming growth factor-β; VSMC, vascular smooth muscle cells.

different cell types. Second, the temporal pattern of Id3 expression is very complex, and differs depending on the cell type and stimuli. In many cases, the induction is transient but biphasic, with an early peak of expression followed either by a later second peak or conversely by long-term suppression. In other cases, the change appears to be more persistent. For example, Id3 is induced transiently by transforming growth factor- β (TGF- β) in B-lymphocyte progenitors, but returns to basal level within 20 h^[13]; whereas in epithelial cells, the transient increase is followed by long-term suppression^[58,59]. Id3 is also transiently induced by bone morphogenetic proteins (BMP) in mesenchymal stem cells^[60], but a sustained induction is observed following BMP treatment of epithelial cells^[59]. Finally, and perhaps most importantly, the differences in the patterns of expression have immense biological significance. For example, insulin, which is an adipogenic agent, induces Id3 transiently in 3T3L1 preadipocytes, but adipogenic differentiation itself is accompanied by long-term downregulation of Id3 in 3T3F24A cells^[38]. Similarly, B cell receptor (BCR) engagement in mature B cells results in transient Id3 induction and stimulation of cell proliferation^[14]. PMA, which is also mitogenic, results in a biphasic response with a transient peak at 4 h and a secondary peak at 24 h, around the time when the stimulated cells are entering S^[61]. In contrast, a more persistent Id3 expression is induced by BCR engagement in immature B cells and results in the inhibition of cell proliferation^[62].

Because Id3 expression is regulated by many cytokines, hormones and other environmental signals, several different signal transduction pathways presumably contribute to its regulation. Pathways that have been implicated include the Ras, the ERK1/2 pathway following TCR engagement^[63], the Smad-dependent pathway in response to TGF- β and BMP^[59,13] and the p38, ERK and calcium-dependent pathways following superoxide free radical-induced oxidative stress^[64]. In the case of TGF- β , the biphasic response could reflect the differential actions of 2 classes of TGF- β receptors (Activin receptor-like kinase 1 and Activin receptor-like kinase 2) that are preferentially coupled to different Smad proteins^[65]. In most cases, the precise signaling pathway(s) responsible for regulating Id3 expression has not been completely defined. In addition, it has not been conclusively demonstrated that the change in transcript level reflects authentic transcriptional regulation.

Regulatory elements and transcription factors involved in Id3 promoter regulation

A systematic analysis of the Id3 promoter and the mecha-

nisms involved in its regulation has yet to be carried out. Yeh and Lim reported in 2000 the cloning and initial characterization of the promoter region of the mouse Id3 gene extending approximately 1 kb upstream of the transcription start site^[66] and found that a 180 bp proximal Id3 promoter fragment was sufficient for substantial transcriptional activity in the proliferating myogenic cell line C2C12^[66]. Recently, a 254 bp Id3 promoter fragment (-200/+54) has been shown also to be transcriptionally active and responsive to BCR engagement in the WEHI-231 immature lymphoid cells^[67]. Several putative transcription factor binding sites have been identified by computer-based analysis, but whether they are bona fide regulatory motifs has not been determined (Figure 3). Using *in vitro* DNase protection assay, we have identified 2–3 protected footprints within this region, at least 1 of which (site 1) seems to be responsible for much of the Id3 promoter activity seen in proliferating C2C12 cells^[67a]. Moreover, electrophoretic mobility shift assays detected proteins in the nuclear extracts of proliferating C2C12 cells that bind to the 180 bp Id3 promoter fragment^[66]. A mutation that eliminates the DNA binding to site 1 reduced the transcriptional activity of the Id3 promoter, indicating that the site is likely to be functional. Consistent with this idea, protein binding to the site declined substantially when incubated *in vitro* with nuclear extracts isolated from differentiated muscle cells that no longer express Id3^[68]. It is yet to be determined whether the site in the endogenous Id3 promoter is occupied by transcription factor *in vivo*.

Figure 3. Locations of putative transcription factor binding sites and footprints identified by computer analysis and DNase protection assay. The locations of putative transcription factor binding sites in the proximal 200 bp region of the mouse Id3 gene is determined by computer-based search of the TRASFAC database and indicated in the figure. Three regions (footprints) that are protected from DNase digestion following incubation with nuclear extracts of proliferating C2C12 cells are also indicated (numbered I-III) below the DNA fragment^[68].

The second DNase footprint (site 2) encompasses a previously identified early growth response factor 1 (egr-1) site that has been shown to bind recombinant egr-1 *in vitro*^[27]; whether the site binds egr-1 *in vivo* has not been established. Others have reported that the upregulation of Id3 upon TCR

engagement involves *egr-1*, but direct *egr-1* binding to the promoter has not been demonstrated and the *egr-1* binding site responsible for the upregulation of Id3 promoter activity has not been localized^[63]. We have found, however, that mutating the *egr-1* site in footprint 2 does not affect the promoter activity of the proximal promoter in proliferating C2C12 cell^[68]. Either other sites are involved in mediating *egr-1* dependent activation of the Id3 promoter or the mechanism of promoter regulation differs between the muscle and T-cell systems.

Several other transcription factors have been reported to either directly or indirectly regulate Id3 expression. The zinc finger transcription factor, gut-enriched kruppel-like factor (GKLF), downregulates the expression of Id3 in response to hydroxyl free radicals in VSMC, apparently by binding to a GKLF site in the Id3 promoter^[69]. Likewise, the transcriptional repressor, B lymphocyte induced maturation protein-1, also appears to act directly on the Id3 promoter region as demonstrated by the chromatin immunoprecipitation assay in mature B-lymphoblast cells^[70].

Exactly how the other transcription factors affect Id3 expression is not known. For example, ectopic expression of *myoD* in proliferating muscle cells upregulates Id3^[71], but it is not known whether this involves direct binding of *myoD* to the Id3 promoter. We did not find any E-box motif corresponding to *myoD* binding sites within the 1 kb region that we have analyzed, but interactions at more distal sites have not been ruled out. Other transcription factors, such as the homeodomain protein AT binding factor 1A (ATBF1A), the lymphocyte specific transcription coactivator BOB.1/OBF.1, and the forkhead transcription factor FOXM1B, have all been shown to either up or downregulate Id3 expression when overexpressed, but in no case has direct interaction between these factors and the Id3 promoter been established^[72,73,56]. Cells that are deficient in Smad4 fail to alter their Id3 level in response to either TGF- β or BMP, suggesting that the Smad proteins are involved in mediating the regulatory effect of these cytokines^[59,60]. However, direct binding of Smad on the Id3 promoter has not been demonstrated.

Several lines of evidence suggest that DNA methylation and histone acetylation might either directly or indirectly regulate Id3 expression. In some non-lymphoid hematopoietic cell lines, the lack of Id3 expression has been correlated with hypermethylation of DNA upstream of the Id3 transcription start site^[74]. Whether similar methylation events take place in other cases where Id3 expression is silenced is not known. Treatment with 5 azacytidine, an inhibitor of DNA methyl transferase, blocks the neuronal differentiation of PC12 cells induced by NGF and inhibits NGF-induced Id3

downregulation that occurs during differentiation^[36]. Conversely, Id3 expression is downregulated in lymphoblastic cells from patients with immunodeficiency, centromere instability and facial anomalies syndrome, a disease syndrome caused by a defective DNA methyltransferase (DNMT3B)^[75]. It is not yet known whether the methylation state of the Id3 promoter itself is directly affected in either case. Similarly, addition of histone deacetylase inhibitors to lung adenocarcinoma cells and the K562 hematopoietic cells upregulates Id3 expression, but whether this represents a direct effect on the histones associated with the Id3 promoter is not clear^[76-78].

Regulation of Id3 isoform expression by differential splicing

The Id3 gene is composed of three exons and two introns. The first exon includes the 5' untranslated region (UTR) and the coding region corresponding to the first 100 amino acid residues. The coding region is interrupted by a 105 bp intron at the +357 position of the mouse Id3 gene. The second exon contains the last 19 amino acid coding region and 26 bp of the 3' UTR of the mouse Id3 transcript. In the mouse gene, this is followed by a 506 bp second intron and the third exon coding for the rest of the UTR^[66]. Both the human and rat Id3 genes appear to be similarly organized, although the length and exact nucleotide sequence of the introns vary substantially among species.

It has been shown in both rats and human that an alternative transcript can be generated under certain conditions by the retention of the first intron^[79,31], resulting in the production of a novel Id3 protein isoform with an altered C-terminus. However, because of the divergent nucleotide sequences in the intron, the novel Id3 C-terminal peptides vary substantially in both length and sequences across species. In humans, the novel terminus is 60 amino acids in length; whereas in mice and rats it is only 29 amino acids long, with 7 out of the 29 amino acids differing between the two species. In contrast, the original protein isoform from the mouse and rat differs by only 1 amino acid substitution out of 119.

With such divergence in sequence among closely related species, one might have predicted that the novel isoforms (referred to as Id3L in humans and Id3a in rats) would have dubious biological significance. Contrary to this expectation, *in situ* hybridization and immunolocalization using isoform-specific antibody indicates that the novel variant is not produced in normal vasculature, but is dramatically upregulated during the later stages of vascular lesion formation, whereas

the original Id3 variant is upregulated earlier in the neoin-tima^[30]. Furthermore, the 2 Id3 protein variants appear to be functionally distinct. The human Id3L protein is a weaker inhibitor of the binding of E-proteins to DNA *in vitro* than the original shorter Id3 isoform^[31]. Overexpression of the original shorter rat Id3 protein in VSMC promotes proliferation and S-phase entry and inhibits transcription of the cyclin dependent kinase (cdk) inhibitor p21^{Cip1}, whereas overproduction of the novel Id3a does not inhibit p21 transcription, and causes a decrease in cell number, presumably by promoting apoptosis^[30].

What accounts for the unique biological functions of the novel Id3 isoform is perplexing, because the C-termini encoded by the non-spliced Id3 variants would be very different between humans and rats and differ substantially even between the more closely related rodent species. One possible explanation of this conundrum is that the altered C-termini might lead to a protein that acts essentially like a “dominant negative” mutant. In support of this possibility, we have shown that truncation of the Id3 C-terminal to a site roughly corresponding to the spliced junction resulted in a protein that was incapable of blocking E-protein binding, and the inhibition of E-box dependent transcription was compromised^[80]. Swapping the Id3 C-terminal with the corresponding region of the Id2 C-terminal likewise reduced the ability of the fusion protein to block E-protein activity. Why the C-terminus of the Id3 protein is so critical for its activity is presently unknown. Much remains to be learned about how the alternative splicing is regulated and when and where else the novel Id3 variant might be expressed. Because most of the earlier studies did not take into account the existence of the novel isoform, some of the expression data might need to be revisited.

Regulation of Id3 transcript and protein stability

Like many other immediate early genes, the Id3 transcript has a rather short half-life^[81]. Examination of the cDNA sequence revealed the presence of instability elements in the 3' UTR that bind to RNA-binding protein^[82,83]; sequence elements that regulate cytoplasmic polyadenylation are also present^[84]. These sequence motifs are likely to contribute to the regulation of the stability and/or translation of the Id3 transcripts, but detailed studies have yet to be reported.

The Id3 protein is also rather short lived, with a half-life of approximately 20 min when overexpressed in 293 cells. As with other short-lived proteins, Id3 appears to be degraded by proteasomes in an ubiquitination dependent manner^[85]. Treatment with proteasome inhibitors stabilizes Id3, allow-

ing it to accumulate. Cells with mutations in the E1 ubiquitin activating enzyme show increased Id3 stability. Co-expression of the bHLH protein E47 with Id3 significantly reduces the rate of degradation of Id3^[86]. In contrast, interaction with the interferon-inducible protein p204, which is upregulated during terminal muscle differentiation, enhances Id3 degradation^[87], suggesting that the stability of the Id3 protein might be affected by its dimerization partner.

Whether and how ubiquitination of Id3 is regulated by the cellular environment is not known. Id3 has been shown to interact physically with CSN5, a subunit of the COP9 signalsome complex that has been implicated in the regulation of the ubiquitination of a large number of cellular proteins. Inhibitors of the COP9-associated kinases increase the ubiquitination of Id3 and accelerate its degradation, whereas overexpression of another COP9 subunit CSN2 stabilizes the Id3 protein. Given these data, it has been speculated that CSN-mediated phosphorylation inhibits ubiquitination of Id3^[88].

Although the role of ubiquitination in Id3 degradation is now well-documented, we found that replacing all 4 lysine found in the mouse Id3 protein with arginine failed to stabilize the protein. This suggests that Id3 might be added to an increasing list of proteins like myoD^[89], Id2^[90], and p21^{Cip1}^[91], that gets ubiquitinated at the α -amino group of the N-terminal residue instead of an internal lysine residue.

How much the regulation at the level of protein stability contributes to the overall regulation of Id3 expression level is not presently known. In one study, experimental denervation to the muscle of young rats results in an increase in Id3 protein levels in both the soleus (900%) and gastrocnemius (80%) without apparently affecting the mRNA level^[51]. Similar regulation might occur under other conditions.

Regulation of protein localization and function

Although Id3 preferentially interacts with the class I HLH proteins (E proteins) and exhibits little or no affinity towards the class II bHLH proteins^[92], it also binds to other transcription factors such as TCF^[4] and the homeodomain protein Pax5^[6] through the HLH domain. Co-expression of E-proteins competes with Pax5 for binding to Id3. Other protein partners might also compete with each other for binding. The relative abundance of the various protein components could, therefore, affect the precise compositions of the protein complexes that are formed. This might in turn determine the biological effects of Id3 under conditions where Id3 level is limiting. In addition, because some E-protein isoforms can act as transcriptional inhibitors^[93], Id3 might even be expected to activate gene expression under certain circumstances.

Dimerization between Id3 and its target proteins might also affect its subcellular localization. When expressed alone in COS cells, Id3 is predominantly cytoplasmic/perinuclear. Co-expression with E-proteins causes it to accumulate in the nucleus^[94]. Whether other proteins or mechanisms might control the subcellular distribution of Id3 is presently unknown. Interestingly, the Id3 protein has been reported to be localized to specific subcellular locations in some cell types^[48,95], but the mechanism responsible remains unknown.

The Id3 protein contains several potential phosphorylation sites for various protein kinases^[96], including a conserved putative cdk2 site around Ser5 in the N-terminus, which is phosphorylated in a cell cycle-dependent manner (during late G1 to S). Id3 proteins with a mutation of Ser5 to Asp5 to mimic phosphorylation are better able to block the formation of heterodimers between E-protein and myoD but are less able to block E-protein homodimerization. Phosphorylation by cdk2 also interferes with the ability of Id3 to bind to TCF proteins^[5], suggesting that Ser5 phosphorylation might alter the dimerization specificity of Id3. In fibroblasts, the Id3 Asp5 mutant (mimicking phosphorylation) is unable to promote S-phase transition, whereas the non-phosphorylatable Ala5 mutant is more effective than the wild type^[61]. In contrast, in VSMC, the non-phosphorylatable Id3 Ala 5 mutant activates the cdk inhibitor p21^{cip1} promoter and is unable to promote an increase in cell number when over-expressed^[97]. Why the behavior is different between the two cell types is unknown.

Conclusions

It is clear from this brief review that the expression and function of the Id3 protein are regulated in a very complex manner. Much remains to be learned about how the Id3 gene is regulated transcriptionally. Almost nothing is known about how the alternative splicing event that generates a potentially dominant negative protein is controlled. Post-translational modifications might impact the stability, dimerization specificity and/or subcellular localization of the protein, which might then affect the function of the protein. In view of the many physiological and pathophysiological situations where Id protein function is involved or perturbed, understanding these issues will, no doubt, provide a fertile ground for the development of potential therapeutic interventions.

Abstract

Autophagy is a major cellular pathway for the degradation of long-lived proteins and cytoplasmic organelles in eukaryotic cells. A large number of intracellular/extracellular stimuli, including amino acid starvation and invasion of microorganisms, are able to induce the autophagic response in cells. The discovery of the *ATG* genes in yeast has greatly advanced our understanding of the molecular mechanisms participating in autophagy and the genes involved in regulating the autophagic pathway. Many yeast genes have mammalian homologs, suggesting that the basic machinery for autophagy has been evolutionarily conserved along the eukaryotic phylum. The regulation of autophagy is a very complex process. Many signaling pathways, including target of rapamycin (TOR) or mammalian target of rapamycin (mTOR), phosphatidylinositol 3-kinase-I (PI3K-I)/PKB, GTPases, calcium and protein synthesis all play important roles in regulating autophagy. The molecular mechanisms and regulation of autophagy are discussed in this review.

Introduction

Cell homeostasis is maintained by a precisely regulated balance between synthesis and degradation of cellular components. There are 2 powerful hydrolytic mechanisms in eukaryotic cells: the proteasome and the lysosome/vacuole. More than 90% of cellular proteins are long-lived. These proteins and some cytoplasmic organelles are believed to be degraded within a specific compartment, the lysosome/vacuole^[1]. There are at least 3 different pathways for lysosomal protein degradation: Cvt (cytosol to vacuole targeting pathway)^[2], Vid (vacuolar import and degradation pathway)^[3] and autophagy^[4]. Autophagy plays important roles in physiology and pathophysiology in all cell types. In addition to its role in protein and organelle degradation, autophagy may induce a type of programmed cell death that is different from apoptosis, namely type II programmed cell death^[5]. Recently it has been found that autophagy may be a transitory tactical response, and that it affects a range of normal developmental processes, such as sporulation in yeast and pupa formation in *Drosophila melanogaster*^[6,7]. Furthermore, autophagy may contribute to the extension of

lifespan induced by caloric restriction^[8]. Autophagy might also act as a means of defense against invasion by various bacteria and viruses. There is a potential link between autophagy and a number of diseases in humans. For example, cancer, cardiomyopathy and neurodegenerative disorders such as Alzheimer's, Parkinson's and Huntington's diseases, amyotrophic lateral sclerosis and prion diseases are all associated with increased autophagy activity^[9]. Consequently, study of the molecular basis of autophagy would result in a better understanding of the role of autophagy in cell death and ageing, and would also result in proposals for new therapeutic approaches for neurodegenerative diseases.

The morphology of autophagy was first characterized in studies of mammalian cells. With a few exceptions, however, the molecular components of autophagy were initially elucidated in yeast because of the convenience of gene analysis. Recent studies in various eukaryotic systems have revealed a conservation of the autophagic mechanism^[10]. In the past, the many terms used in the autophagy field have been highly confusing: Aut (autophagocytosis), Apg (autophagy), Vps (vacuolar protein-sorting) all have been used. Recently, the autophagy-related genes and the products of these genes were named *ATG* and *Atg*, respectively^[11].

Classification of autophagy

Autophagy is a ubiquitous physiological process that occurs in all eukaryotic cells. There are three primary forms of autophagy: macroautophagy, microautophagy and chaperone-mediated autophagy (CMA). Macroautophagy is the most prevalent form of autophagy. It comprises the following processes: initially, a “C” shape double-membrane structure appears in the cytoplasm, and then at both ends of this membrane a structure grows, and finally closes to form a vacuole. The bulk of the cytoplasm and some organelles are wrapped into the vacuole (autophagosome). Then the autophagosome targets the lysosome/vacuole, where its outer membrane fuses with the lysosomal membrane and the inter sac (autophagic body) enters the lysosome/vacuole. The autophagic body is degraded in the lysosome/vacuole so the carrying constituent components can be recycled^[12]. Microautophagy is a form with few features. In this pathway, the membrane of the lysosome/vacuole invaginates, and then finally pinches off to form an internal vacuolar vesicle that contains material derived from the cytoplasm, akin to the autophagic bodies formed in macroautophagy. The notable difference between macroautophagy and microautophagy is that in the latter the cytoplasm is directly up taken into the lysosome/vacuole^[13]. CMA differs from the other lysosomal degradation pathways in that vesicular traffic is not involved. Cytosolic proteins with particular peptide sequence motifs are recognized by a complex of molecular chaperones, then bind to a receptor in the lysosomal membrane, the lysosome-associated membrane protein (Lamp) type 2a. Proteins are delivered to lysosomes with the help of molecular chaperones and Lamp 2a^[14].

Autophagy is basically a non-selective process, in which bulk cytoplasm is randomly sequestered into the cytosolic autophagosome. However, in some cases it may select its target. For example, autophagy can selectively eliminate some organelles, such as injured or excrescent peroxisomes, endoplasmic reticulum (ER) and mitochondria^[15]. A recent report shows that in yeast, *Saccharomyces cerevisiae*, the cytosolic protein acetaldehyde dehydrogenase (Ald6) is delivered to the vacuole and degraded by means of specific autophagy^[16].

Molecular mechanisms of macroautophagy

Macroautophagy, a major form of autophagy, is relatively well characterized at present. Autophagy and the related processes are dynamic, and many molecules involved in the autophagic process have been identified. At least 25 specific yeast genes are exclusively involved in autophagy, and

there are more than 40 additional yeast genes required for autophagy, but they also play roles in other pathways^[11]. However, the physiological functions of many of these genes need to be further clarified.

Origin of the autophagosomal membrane There is still debate on the origin of autophagosomal membranes. Initially, the ribosome-free region of the rough ER and Golgi were proposed as the source of autophagosomal membranes^[17,18]. Now, it is generally accepted that the phagophore, a poorly characterized organelle, may be the major source of the autophagosomal membrane and related structures^[19].

Autophagosome formation

Two ubiquitin-like conjugation systems In yeast, autophagy almost completely shuts off under growing conditions, although every *ATG* gene is expressed. Molecular biological and biochemical analyses of these gene products uncovered the genetic and biophysical interactions among the Atg proteins. One of the most remarkable findings regarding the Atg proteins is the discovery of two ubiquitin-like conjugation systems, Atg12-Atg5 and Atg8-phosphatidylethanolamine (PE) (Figure 1). In fact, half of the *APG* genes essential for autophagy are involved in these conjugation systems, and these two conjugation systems are well conserved among eukaryotes. Furthermore, Atg12-Atg5 and Atg8 conjugation systems are somehow related to each other^[20–22]: if the former is defective, the latter can not target to the pre-autophagosomal structure (PAS); the levels of Atg8-PE also play an important role in the conjugation of Atg12-Atg5.

Figure 1. Two ubiquitin-like conjugation systems are involved in autophagosome formation.

Atg12-Atg5 conjugation system Atg12, a small hydrophilic protein of 186 amino acids with no apparent homology to ubiquitin, can covalently link to a unique target protein, Atg5^[23]. The mode of conjugation of Atg12 and Atg5 is quite similar to that of ubiquitination. Atg12 is first

activated in an ATP-dependent manner by Atg7 (it functions as an ubiquitin-activating enzyme, E1), leading to the formation of a thioester bond between the C-terminal glycine in Atg12 and a cysteine residue in Atg7^[24]. The C-terminal glycine in Atg12 is then transferred to the cysteine in Atg10 (it functions as a ubiquitin-conjugating enzyme, E2), forming a new thioester bond, and Atg7 is released^[25]. Finally, the C-terminal glycine in Atg12 forms an isopeptide bond with the ϵ -amino group of lysine 149 in Atg5, and Atg10 is in its free state again. The formation of the Atg12-Atg5 conjugate is indispensable to autophagosome formation. It seems that this ubiquitin-like system is a constitutive process, because the formation of the Atg12-Atg5 conjugate is not dependent upon starvation or other autophagy-inducing conditions^[26]. Atg12 and Atg5 form a conjugate immediately after their synthesis, and free forms of these are hardly detectable. The conjugation reaction between Atg5 and Atg12 is irreversible, and so far no protease has been found to deconjugate this conjugate. Atg16 also binds preferentially to the Atg12-Atg5 conjugate. Atg16 links with Atg12-Atg5 through self-oligomerization, and its C-terminal coiled-coil region may be responsible for this oligomerization. Therefore, Atg16 forms a 350 kDa multimeric complex with the Atg12-Atg5 conjugates. It should be pointed out that Atg16 only binds to Atg5, and not to Atg12^[27,28]. This new complex is necessary for the elongation of the isolation membranes (used for formation of the autophagosomal membrane). A small fraction of the Atg12-Atg5-Atg16 complex initially associates with a small crescent-shaped vesicle evenly. As the membrane elongates, Atg12-Atg5 shows asymmetric localization and most of these proteins associate with the convex surface of the isolation membrane. This complex will dissociate from the membrane upon completion of autophagosome formation; thus, it is not present in the mature autophagosome^[29]. The molecular basis of this transient association of Atg12-Atg5 conjugates with the autophagosome membrane is not yet known.

In mammalian cells, Atg5 and Atg12 are conjugated to each other in the same way as they are in yeast, but the complex interacts with Atg16L, forming an ~800 kDa structure instead of a 350 kDa complex in yeast^[27]. Atg16L is a 63 to 74 kDa protein, which has a binding region and coiled-coil region similar to that of Atg16. However, Atg16L has a long C-terminal extension containing 7 WD repeats, but the role of the WD repeats in autophagy has not yet been elucidated.

Atg8 conjugation system The second ubiquitin-like protein essential for autophagy is Atg8 (Aut7/Apg8). Atg8 is a 117-amino acid protein and is present in the early isolation membranes, autophagosomes and autophagic bodies^[30].

This feature makes Atg8 a good marker for studying membrane dynamics during autophagy. Cell fractionation studies have shown that Atg8 is mostly membrane-bound; approximately half of it is peripherally bound to the membrane and the other half behaves like an intrinsic membrane protein. Atg4, a novel cysteine protease, is responsible for processing Atg8 by cleaving a single Arg residue from it, consequently exposing Gly in the C-terminus of Atg8^[31]. Atg8 can be activated by Atg7 (E1) in an ATP-dependent manner and transferred to a conjugating E2 enzyme, Atg3^[32]. Atg7 is a unique enzyme that activates two different ubiquitin-like proteins, Atg12 and Atg8, and assigns them to their proper E2 enzymes, Atg10 and Atg3, respectively. Interestingly, in the final step, Atg8 does not form a conjugate with other proteins, but interacts with PE, an abundant membrane phospholipid^[32]. This lipidation reaction leads to a conformational change of Atg8 that is necessary for the membrane dynamics of autophagy^[33]. In addition, Atg8-PE is deconjugated by Atg4, which cleaves the lipid-protein linkage and provides a new source of cytoplasmic Atg8. The cycle of conjugation and deconjugation is important for the normal progression of autophagy.

Microtubule-associated protein 1 light chain 3 (LC3), the mammalian orthologue of Atg8, targets to the autophagosomal membranes in an Atg5-dependent manner and remains there even after Atg12-Atg5 dissociates. Thus LC3 is the only credible marker of the autophagosome in mammalian cells^[12]. In wild-type cells, LC3 is detected in 2 forms: LC3-I (18 kDa) and LC3-II (16 kDa)^[34]. Twenty-two amino acids in the C-terminus of the newly synthesized LC3 are cleaved immediately by the mammalian orthologue of the yeast cysteine proteinase Atg4, autophagin, to produce an active cytosolic form, LC3-I^[35]. Then with the catalysis of Atg7 and Atg3, LC3-I undergoes a series of ubiquitination-like reactions, and is modified to LC3-II. LC3-I is located in the cytoplasm, while LC3-II is a tightly membrane bound protein and is attached to PAS and autophagosomes. The relative amount of membrane-bound LC3-II reflects the abundance of autophagosomes, so the induction and inhibition of autophagy can be monitored through measuring total and free LC3-II levels by means of immunoassay^[34]. In addition, studies have shown that the Atg12 and LC3 systems have a functional relationship. In *ATG5*^{-/-} cells, LC3-II is not generated at all^[21]. As a result, LC3 cannot target the autophagosomal membranes. The recent generation of transgenic mice expressing green fluorescent protein (GFP) fused to LC3 provides a useful tool to investigate autophagy in various mammalian organs *in vivo*^[36].

In addition to LC3, at least another two mammalian

orthologs of yeast Atg8 have been identified^[37,38]: γ -aminobutyric acid type A receptor-associated protein (GABARAP) and Golgi-associated ATPase enhancer of 16 kDa (GATE-16). The 2 proteins also convert to membrane bound forms (form II), which are recovered in membrane fractions^[39]. These results suggest that all mammalian Atg8 homologues receive common modifications to associate with autophagosomal membranes, but the functions of these orthologs and their modified form II need to be further studied.

Two kinase complexes

Atg 1 protein kinase Atg1 is a serine/threonine protein kinase, which forms a protein complex with different regulatory proteins such as Atg13, Vac8, Atg17 and Cvt9. The complex controls the switch between Cvt and autophagy pathways (Figure 2). The composition of this complex is dynamic and it may vary depending on nutrient conditions^[40]. Under nutrient-rich conditions, Atg13 is hyperphosphorylated so that its association with Atg1 is blocked. On the other hand, under nutrient starvation conditions or after treatment with rapamycin, Atg13 becomes partially dephosphorylated. This dephosphorylation leads to an Atg1-Atg13 interaction and subsequent generation of autophagosomes instead of Cvt vesicles and, thus, activates autophagy. Vac8, the vacuolar inheritance protein that acts in the Cvt pathway is not essential for starvation-induced autophagy^[41]. Vac8 is also a phosphoprotein and may help to facilitate the phosphorylation of Atg13. Atg1 also interacts with 2 other proteins. One of these is Cvt9, which is only required for the Cvt pathway^[42]. Cvt9 is a large coiled-coil protein, and it interacts with itself, possibly through the coiled-coil domain. This could potentially crosslink the Atg1 complex into a higher-order structure required early in the sequestration process of autophagy. The other protein, Atg17, is only

required for the autophagic import and has been proposed to play a role in Atg1-Atg13 interactions^[43]. Recently, Atg17 has been found to interact with 2 Cvt pathway-specific components, Atg24/Cvt13/Snx4 and Atg20/Cvt20, proteins that contain PI3P-binding PX domains^[44,45]. But it remains a challenge to evaluate the meaning of interactions between the autophagic-specific Atg17 protein and Cvt pathway-specific Atg24 and Atg20 proteins. Genetic analysis suggests that the Atg1 complex functions at a rather late stage of autophagosome formation^[22]. The Atg1 complex may control membrane dynamics, rather than act as a signal transducer. The kinase activity of Atg1 is upregulated during induction of autophagy, thus the levels of kinase activity seem to be important for the regulation of autophagosome formation^[43]. A recent report has shown that Atg1 may only have a non-kinase structural role in autophagy induction, although the kinase activity of Atg1 is involved in autophagy; however, it plays more important roles in the Cvt pathway^[46].

Two putative human homologs of Atg1 have been identified^[47]: the UNC-51-like kinases ULK1 and ULK2. ULK1 has been shown by yeast two-hybrid screening to interact with GATE-16 and GABARAP, two homologs of the yeast autophagy protein Atg8.

Vps34/PI3K Early in 1982, it was found that 3-MA (3-methyladenine) inhibits the formation of autophagosomes^[48]. 3-MA is a PI3K inhibitor^[49]. Several studies have demonstrated that PI3K inhibitors interfere with the formation of autophagosomes in rat hepatocytes^[50]. Yeast is known to contain only one PI3K, Vps34^[51]. Vps34 function is regulated by the protein kinase activity of Vps15, with which it forms a stable, membrane-associated complex under normal conditions. This complex links the Vps34 kinase to cytoplasmic membranes. Vps34-Vps15 is present in 2 complexes, which are involved in a variety of membrane transport events (Figure 3)^[52]: complex I, which is composed of Vps34-Vps15, Atg6 and Atg14, controls autophagy, whereas complex II, which is composed of Vps34-Vps15, Atg6 and Vps38, is essential for sorting of carboxypeptidase Y (CPY) into the vacuole. Atg6 is a possible coiled-coil protein and is associated with the membrane through Vps15 and Vps34. Atg14 is a specific factor in the autophagy-specific PI3K complex. Complex I functions primarily, but not exclusively, at the PAS, whereas complex II functions at the endosome. The lipid kinase activity associated with Vps34 is thought to create lipid patches of PI3-P, the reaction product of class III PI3K, at specific trans-Golgi locations, and these patches then function in protein sorting into vesicles that travel from the Golgi to the endosome.

Figure 2. The Atg1 kinase complex includes components that are specific for the Cvt pathway or autophagy.

Figure 3. Two different PI3-kinase complexes participate in vacuolar protein targeting.

In mammalian cells, there are 3 classes of PI3K. Class I PI3K is an inhibitor of autophagy^[53]. Class II PI3K activity is thought to have no relevance to autophagy control. Class III PI3K, a functional orthologue of yeast Vps34, is an activator of autophagy and plays a crucial role at an early step of autophagosome formation in mammalian cells^[54], and it is required for increasing the size of the sequestering membrane, presumably through fusion events. PI3-P interacts with proteins containing FYVE or PX motifs, thus recruiting such proteins from the cytosol for autophagosome biogenesis^[55]. The activation of a population of PI3K located in a determined membrane domain may be responsible for autophagosome biogenesis. In addition, the presence of PI3-P in a specific membrane location may generate significant asymmetries and drive membrane curvature of PAS^[54]. Finally, PI3-P may be converted to higher-order polyphosphoinositides (PI), which are involved in diverse signaling functions. The mammalian cell orthologue of Vps15 is p150. It is associated with class III PI3K, and interacts with beclin-1, a functional orthologue of yeast Atg6 in mammalian cells^[56]. Beclin1, which is the first autophagy-related tumor suppressor gene reported so far, is required for both autophagy and Cvt pathways. The characterization of the tumor suppressor activity of beclin-1 could establish an important relationship between cancer and the autophagic pathway. Beclin-1 was originally isolated as a bcl-2-interacting protein that can downregulate bcl-2, but it is still unclear whether this interaction is instrumental in autophagy^[57].

Atg 9 complex Atg9 is an integral membrane protein, containing several potential transmembrane domains^[58]. A fraction of Atg9 is located in the PAS together with other autophagy proteins, but it is absent in the membranes of mature autophagosomes^[59,60]. If cells lack Atg9, neither the Cvt pathway nor autophagy can take place. However, Cvt

and autophagy can still accumulate protease-sensitive prApe1 (the precursor to aminopeptidase I), indicating that Atg9 has an effect prior to closure of the double-bilayer vesicle^[61]. A soluble protein, Atg2 physically interacts with Apg9, and this interaction is indispensable to autophagosome formation^[62]. The localization of Atg2 to the PAS requires the activity of several proteins, such as Atg1 and Atg9, but the kinase activity of Atg1 seems to be of questionable importance to this function. Atg18 is also indispensable to correct Atg2 localization, suggesting that there is a potential link between this protein and the Atg9 system^[63].

Mammalian orthologs of Atg2 and Atg9 are present in the genome sequence databases, but they have not been studied in detail.

PAS All the abovementioned Atg proteins have a function before or during the formation of autophagosomes. Thus, it is important to find out the distribution of these Atg proteins in cytoplasm. By using fluorescent protein fused with Atg proteins, it has been shown that Atg8 stains autophagosomes, autophagic bodies in the vacuoles, and also the intermediate isolation membrane. However, Atg5 shows a single bright dot structure next to the vacuole. This structure has been named the PAS, and Atg8 also co-localizes with it^[64,22]. In addition, no Golgi, ER or late-endosomal markers has been found in the PAS, suggesting that this is a novel structure that has not been described so far^[59]. However, little is known about the existence of a PAS-like structure in mammalian cells. Almost all Atg proteins are co-localized in the PAS, suggesting that it is an organizing center of the autophagosome. The autophagy-specific PI3K complex, PI3-P, may recruit different proteins such as Atg18, Atg20, Atg21, Atg24, and Atg27 to the PAS^[54,65,66]. The interaction between PI3-P and these proteins is a requisite for the re-recruitment of Atg proteins to the PAS. None of these proteins contains PX or FYVE motifs, so the domain of the lipidation has not been identified. Atg9 also has a strong effect on organization of the PAS, whereas defects in the Atg1 kinase complex show little effect on the PAS structure. Indeed, a recent study suggests that, in nutrient-rich conditions, the PAS does not form in the absence of prApe1, Atg19 or Atg11^[67].

Autophagosome fusion with the vacuole/lysosome In yeast, the fusion of autophagosomes with the vacuole requires several factors that are involved in other types of vesicular transport. Molecular genetic studies have indicated that the machinery required for homotypic vacuole fusion is also required for the fusion of autophagosomes with the vacuole. This machinery includes: the SNARE proteins Vam3, Vam7, Vti1, and Ykt6; the NSF, SNAP, and GDI

homologs Sec17, Sec18, and Sec19; the Rab protein Ypt7; members of the class C Vps/HOPS complex; and Ccz1 and Mon1^[68]. However, it remains to be determined whether different SNARE and/or other fusion components operate during autophagy. If the fusion process begins prior to completion of the double-membrane vesicle, the cargo will remain in the cytosol, so the timing of vesicle fusion with the lysosome/vacuole must be precisely regulated. Atg8-PE, which is located on the outer surface of the autophagosome, is removed prior to fusion as a result of a second cleavage by Atg4. Removal of Atg8-PE from autophagosomes can prevent premature fusion with lysosomes. Atg12-Atg5•Atg16 may have the same function. The expression of Atg8ΔR is a mutated form of Atg8 lacking the ultimate arginine residue, bypassing the need for the initial Atg4-dependent cleavage step. However, the mutation causes a loss of ability of Atg to carry out the second cleavage event that releases Atg8 from PE and results in a partial defect in autophagy^[31].

In mammalian cells, autophagosome fusion with lysosomes is a more complex process in which the autophagosome requires a series of maturation steps prior to its fusion with the lysosome. Similar to yeast, the activity of monomeric GTPases (Rab22, Rab24) and mammalian orthologs of SNARE protein family members and the NSF protein are needed for correct autophagosome maturation^[69,70]. Prior to their fusion with lysosomes, autophagosomes have to fuse with endosomes or endosome-derived vesicles. Overexpression of a mutant form of the regulator of endosome sorting, SKD1 ATPase, which is unable to hydrolyze ATP, hampers endosome function and causes a massive accumulation of nascent autophagosomes^[71]. Rab7, which is associated with autophagic vacuoles, is involved in maturation of autophagosomes. Overexpression of a Rab7 dominant negative mutant hampers fusion between autophagosomes and the late endosome/lysosomal compartment, leading to the accumulation of autophagosomes with a concomitant decrease in the degradation of long-lived proteins^[72]. In addition, the cytoskeletal elements are also involved in either autophagosome maturation or autophagosome-lysosome fusion. The microtubule is another important factor for this event, because treatment of cells with microtubule-destabilizing drugs blocks autophagosome maturation. For example, cells treated with cytochalasin D, an agent that disrupts actin filaments, display a significant reduction in autophagosome formation^[73], whereas the microtubule stabilization mediated by a new antitumor drug, taxol, increases the fusion of amphisomes with lysosomes^[74].

Degradation of autophagic body The main purpose of autophagy in yeast is to degrade cytoplasm and recycle the

resulting macromolecules for use in the synthesis of essential components during nutrient stress. Degradation of autophagy bodies requires a low pH, proteinase B (Prb1) and Atg15/Cvt17^[75,76]. Prb1 is a hydrolase that is involved in the activation of many other vacuolar zymogens, which indirectly affects the vesicle breakdown. Atg15/Cvt17 has sequence similarity to a family of lipases, and seems to function directly in vesicle breakdown. It is the only putative lipase that has been identified that has a role in the degradation of autophagic bodies^[76]. So far, we know that the expression of Atg15 is low in the vesicle, but the mechanism or site of action of Atg15 is unknown. Another protein, Atg22, has also been implicated in this last step. Atg22 is an integral membrane protein, and is needed only for the degradation of autophagic bodies^[77].

Molecular mechanisms of CMA

CMA is one of several lysosomal pathways of proteolysis. CMA is activated by physiological stressors such as prolonged starvation. During starvation, macroautophagy is activated first, but this process quickly declines and CMA is then activated. The mechanisms by which these 2 lysosomal protein degradation pathways interact, if any, are unknown. We now know that cytosolic proteins can be degraded by CMA in rat liver, kidney, heart, and other tissues. However, to date, there are no physiological phenomena similar to CMA found in yeast. Only the cytosolic proteins with exposed pentapeptide sequence motifs related to KFERQ can act as substrate proteins, and be recognized by a complex of molecular chaperones whose major constitutive form is the heat shock 70 kDa protein (hsc70)^[78]. The substrate protein and molecular chaperone complex bind to the lysosomal membrane and interact with lamp2a. The protein is unfolded by the molecular chaperone complex prior to importation into the lysosome. The protein is pulled into the lysosomal lumen with the help of lysosomal hsc70 (ly-hsc70)^[14,79]. The level of lamp2a can be a rate-limiting step in CMA. A lamp2 knockout mouse without any of the lamp2 isoforms showed a reduction in rate of protein degradation and an increase in accumulation of autophagic vacuoles in heart, skeletal muscle, and other tissues^[80]. The amount of lamp2a in the lysosomal membrane is regulated, in part, by changes in its degradation rate. For example, during starvation lamp2a levels increase due to a decrease in lamp2a degradation. The mechanisms of lamp2a degradation include an initial cleavage by the lysosomal protease cathepsin A. In fact, cathepsin A knockout mice had elevated levels of lamp2a in the lysosomal membrane and showed higher activity of CMA^[81]. A metalloprotease yet to be identified also

contributes to lamp2a degradation and works in cooperation with cathepsin A. A more rapid adjustment of lamp2a in the lysosomal membrane occurs through changing the proportions of lamp2a sequestered in the lysosomal matrix.

Regulation of autophagy

Autophagy is probably the main mechanism for degradation of long-lived proteins and cytoplasmic organelles. A great number of extracellular stimuli (starvation, hormone or therapeutic treatment) as well as intracellular stimuli (accumulation of misfolded proteins, invasion of microorganisms) are able to modulate the autophagic response. In yeast and mammalian cells, autophagy is a fundamental biological event that occurs under normal growth conditions. Thus, there must be an array of mechanisms by which extracellular and/or intracellular signals can be accepted and transmitted to the regulatory factors to promote or inhibit autophagy when it is needed.

TOR/mTOR There are a number of signaling complexes and pathways involved in the initiation and maturation of autophagy. The central player in these signaling pathways is TOR, the target of rapamycin. TOR is a serine/threonine kinase involved in most regulatory pathways that control the response to changes in nutrient conditions and energy metabolism. TOR acts as a good gate-keeper in autophagy and exerts an inhibitory effect on autophagy (Figure 4). TOR kinase may inhibit autophagy through two general mechanisms. First, TOR acts in a signal transduction cascade through various downstream effectors to control both translation and transcription^[82]. Second, TOR appears to directly or indirectly affect the Atg proteins, resulting in in-

terference with the formation of autophagosomes^[83]. In mammalian cells, there is a TOR orthologue, mTOR, which appears to modulate autophagy in a manner similar to that observed in yeast.

Protein phosphatase 2A (PP2A) In yeast, TOR phosphorylates the protein Tap42, causing its association with PP2A^[84]. This interaction significantly reduces the enzyme activity of PP2A. Inhibition of TOR by nutrient stress or rapamycin results in the dephosphorylation and dissociation of Tap42 from PP2A. PP2A may then dephosphorylate its targets, which eventually leads to a variety of antiproliferative responses and induction of autophagy. PP2A is a phosphatase that acts on several TOR substrates, including glutaminase (Gln3). Dephosphorylation of Gln3 by PP2A promotes its dissociation from urease 2 (Ure2) and its successive translocation into the nucleus, where it activates the transcription of several genes^[85,86]. Some of those genes are parts of the autophagy machinery such as Atg8 and Atg14^[87,88].

4E-BP1 mTOR has a serine/threonine kinase activity, and eukaryotic initiation factor 4E binding protein-1 (4E-BP1) is one of its substrates^[89]. 4E-BP1 is an inhibitor of translation and can be directly phosphorylated by mTOR. After phosphorylation, 4E-BP1 will dissociate from eukaryotic initiation factor 4E (eIF4E). Free eIF4E binds to the 5' terminal cap structure of RNAs and promotes the progress of translation.

p70S6 kinase p70S6 kinase (p70S6) is also a candidate of the substrates of mTOR, which can be called S6K for short. S6K is a protein kinase of ribosomal 40S subunit S6. Phosphorylation of S6 upregulates the translation of mRNAs containing 5' terminal oligopyrimidine tract (5' Top). The 5' Top mRNAs account for approximately 20% of all cell mRNAs and are foundations of protein biological synthesis. The major products of 5' Top mRNAs include ribosomal protein, elongation factor (EF1a, EF2), and polyA binding protein. When nutrition is sufficient, TOR is turned on and the activity of the enzyme S6K increases. Recently, it has been found that S6K is needed for the entire process of autophagy activation, and it must be activated first for maximal activation of autophagy^[90]. However, there is a contradictory phenomenon, in that TOR, an activator of S6K, is an inhibitor of autophagy. The possible explanation is that S6K needs to be active under starvation conditions in which its activator, TOR, is turned off. Perhaps, after TOR is switched off, any active S6K remains active for some time, ensuring maximal autophagy induction can be achieved, but other mechanisms might then gradually deactivate the p70S6 kinase, thereby preventing excessive autophagy, which

Figure 4. TOR/mTOR and PI3K-I/PKB signaling in the regulation of autophagy.

could be harmful.

Hormones The hormones glucagon and ecdysone in *Drosophila larvae* inhibit TOR by downregulating PI3K-I, resulting in an increase in autophagy. Conversely, the hormone insulin appears to have an inhibitory effect on the autophagic pathway^[91,92]. In response to food, insulin is produced; insulin binds a receptor on the surface of cells and triggers a signaling cascade. Insulin first activates its tyrosine kinase receptors, causing these receptors to phosphorylate themselves. P85 as a regulatory subunit of PI3K activates PI3K by association with these phosphorylated insulin receptors. The active PI3K transfers to the inner surface of the cell membrane and phosphorylates the lipid phosphatidylinositol, leading to the activation of protein kinase B (AKT/PKB) and other enzymes. This is followed by the activation of TOR. The latter then negatively regulates Atg proteins to prevent autophagy activation.

Amino acids Amino acids, which are the final products of autophagic protein degradation, act as negative feedback regulators for the process. In almost all cell types, especially in hepatocytes, a combination of leucine and a few other amino acids is very effective in inhibiting autophagy^[93-95]. It was discovered that the addition of amino acids (leucine in particular) in the absence of insulin or other growth factors resulted in a strong and fairly rapid stimulation of the phosphorylation of ribosomal protein S6K^[96,97]. Phosphorylation of 4E-BP1, similar to that of S6K, requires the presence of amino acids, and amino acids alone, but not insulin alone, stimulate phosphorylation of this protein in a rapamycin-sensitive manner^[98,99]. Furthermore, leucine activates glutamate dehydrogenase, which contributes to the ability of leucine to potentiate insulin production in β -cells^[100]. Amino acids and insulin act synergistically on both processes to inhibit autophagy^[96,97]. The amino acid/TOR signaling pathway can be confronted by the AMP-dependent protein kinase (AMPK). However, this effect can be blocked by rapamycin and two inhibitors of PI3K, wortmannin and LY294002^[101]. Recently, it has been found that amino acids can modulate activation of the kinase Raf-1. Raf-1 acts upstream of the mitogen-activated protein kinase (MAPK) and extracellular signal-regulated kinase (Erk1/2) cascades^[102]. However, the mechanism by which amino acids regulate the activation of Raf-1 remains to be elucidated.

ATP Autophagic sequestration is ATP-dependent, and the depletion of ATP inhibits autophagic sequestration^[103]. Because of adenylate kinase equilibrium in the cell, a fall in ATP is often associated with an increase in AMP. AMPK, which serves as a general integrator of metabolic responses to changes in energy availability, is activated in response to

elevations of the AMP/ATP ratio. Thus, autophagy can be suppressed by AMP through activation of AMPK. In addition, high levels of AMP can be reached under hypoxia and other conditions of energy depletion, which also suppress autophagy^[104,105]. Different studies suggest that in liver and muscle cells AMPK negatively modulates protein synthesis by impairing the mTOR-dependent signals to p70S6 kinase and 4E-BP1^[106], interfering with the occurrence of autophagy. Although AMPK is involved in the control of mTOR signaling, its role in autophagy needs to be clarified. However, Snf1, the yeast homologue of AMPK, has been identified as a positive regulator of autophagy^[107].

Atg proteins TOR signaling negatively regulates the association between Atg1 and Atg13. Under nutrient-rich conditions, active TOR causes hyperphosphorylation of Atg13, preventing or modulating its association with Atg1^[43]. It is not clear whether TOR directly phosphorylates Atg13. TOR inactivation by starvation or rapamycin treatment promotes the rapid dephosphorylation of Atg13, a process that seems to be independent of PP2A. Dephosphorylated Atg13 binds to Atg1. This association promotes autophosphorylation and activation of Atg1, leading to the induction of autophagy. The inhibition of TOR signaling also promotes the assembling of other regulatory proteins in the membrane of PAS due to increased Atg1 kinase activity. In other words, inactivation of TOR is necessary for the prolongation of pre-autophagosomal membranes and enhancement of the expression of autophagic specific genes such as Atg8.

PI3K-I/PKB The PI3K-I/PKB pathway is involved in the negative modulation of autophagy (Figure 4). If PI3K-I is activated, it will phosphorylate PI4P and PI(4,5)P₂ to produce PI(3,4)P₂ and PI(3,4,5)P₃^[108]. These lipids have a role in the PAS structure to recruit proteins necessary for the biogenesis of autophagosomes. These lipids bind to protein kinase B (Akt/PKB) and its activator phosphoinositide-dependent kinase-1 (PDK1) via its pleckstrin homology (PH) domains. Upon lipid binding, Akt/PKB is then activated^[108]. Furthermore, PDK1 phosphorylates other kinases, including p70S6 kinase, making them acquire kinase activity^[109]. Activation of this pathway by expression of a constitutive active form of PDK1 and PKB has an inhibitory effect on autophagy. The phosphatase PTEN, which selectively hydrolyzes PI(3,4,5)P₃, has a stimulatory effect on autophagy by relieving class I PI3K/PKB inhibition^[55]. Rapamycin can reverse most of the inhibition of autophagy because of activation of the class I PI3K pathway, which suggests that mTOR is a downstream target. The activation of PI3K/PKB has been shown to relieve the inhibitory effects of the tuberous sclerosis complex (TSC1/TSC2, hamartin/tuberin) on

mTOR/p70S6 kinase signaling^[110]. TSC2 has a GTPase-activating activity towards monomeric Rheb, which controls mTOR/p70S6 kinase signaling^[111], so TSC2 can promote the conversion of Rheb from the GTP-bound state (inhibitor of TOR) to the GDP-bound state (activator of TOR).

Beclin1/PI3K- III The beclin 1/PI3K-III complex is involved in the formation of autophagosomes and initiation of autophagy. 3-MA, wortmannin, and LY294002, three PI3K-III inhibitors, interfere with this pathway^[50]. Recently, it has been shown that in muscle cells, amino acids can negatively regulate autophagy by interference with the activity of class III PI3K^[55]. Further studies showed that all beclin forms a complex with PI3K, whereas ~50% of PI3K remains free from beclin. Indirect immunofluorescence microscopy demonstrated that the majority of beclin and PI3K localized to the trans-Golgi network (TGN). Some PI3K also distributed in the late endosome^[112]. This suggests that beclin and PI3K control autophagy by functioning in PI3-P sorting into vesicles that travel from the Golgi to the endosome as a complex at the TGN. In addition, an increase in the class III PI3K product, PI3-P, can also stimulate autophagy^[49]. Beclin-1, as an important element of mammalian autophagy, is consistently mono-allelically deleted in 40–75% of human sporadic breast, prostate and ovarian cancers. In *in vitro* cultured MCF-7 cells, overexpression of beclin-1 induces autophagy and is associated with inhibition of MCF-7 cell proliferation^[56]. The protein beclin-1 is able to shuttle between the nucleus and the cytoplasm^[113]. Its role in the nucleus is unknown, but nuclear beclin-1 does not control autophagy and does not inhibit tumorigenicity of breast carcinoma cells. Beclin-1 contains a leucine-rich nuclear export signal that is required for its autophagy and tumor suppressor functions^[113]. This nuclear export traffic is modulated by nuclear export protein chromosome region maintenance 1 (CRM1)^[113]. The CRM1-dependent nuclear export traffic plays an important role in the regulation of autophagy. However, when the traffic is inhibited by daunomycin B or a mutation of the nuclear export signal, beclin-1 exists almost exclusively in the nucleus. Thus, autophagy induction by starvation cannot be initiated and its anti-tumor effect is also blunted.

GTPases

Heterotrimeric G proteins and partners In the human colon cancer cell line HT-29, it was found that the trimeric $G_{\alpha\beta\gamma}$ ($\alpha_3\beta\gamma$) control the autophagic pathway at the sequestration step^[114]. The activity of autophagy was low when the $G_{\alpha\beta\gamma}$ protein was in the GTP-bound form, and it was stimulated when GDP was bound to the $G_{\alpha\beta\gamma}$ protein^[115]. The localization of the $G_{\alpha\beta\gamma}$ protein is also essential in controlling autophagy. It must first associate with the ER or Golgi in

order to control autophagy. The guanine nucleotide cycle of the $G_{\alpha\beta\gamma}$ protein is dependent upon the activity of the G alpha interacting protein (GAIP). GAIP belongs to the regulators of the G-protein signaling (RGS) family and is a GTPase-activating protein towards the $G_{\alpha\beta\gamma}$ protein. The phosphorylation of a conserved serine residue in the RGS domain of GAIP stimulates its GAP activity, and consequently the autophagic pathway^[116]. In addition, GAIP is a cytoplasmic substrate for the MAP kinase Erk1/2 and its phosphorylation is reduced in the presence of amino acids. The different domains of the activator of G-protein signaling 3 (AGS3) are all involved in the regulation of autophagy^[117]: its N-terminal part containing 7 tetratricopeptide regulatory (TPR) repeats can decrease the occurrence of autophagy; its C-terminal part containing G-protein regulatory (GPR or GoLoco) motifs can interact and stabilize the $G_{\alpha\beta\gamma}$ protein in its GDP-bound conformation. Recently, investigators showed that AGS3 had a stimulatory effect on autophagy in human colon cancer cells^[118], but this stimulatory effect could be counteracted by GoLoco motifs. The $G_{\alpha\beta\gamma}$ protein and its partners (GAIP and AGS3) act prior to the formation of the autophagosome. They may be involved in the control of membrane flux to the autophagic pathway. What is noticeable is that the $G_{\alpha\beta\gamma}$ protein and its partner proteins can control the balance between the flow of membranes in the exocytic pathway and the delivery of membrane constituents to the macroautophagic pathway.

Monomeric G proteins Rab proteins are monomeric GTPases necessary for vesicular transport in the exo/endocytic pathway, in which Rab22a is associated with early and late endosomes. However, Rab22aQ64L, a mutant with low GTPase activity of Rab22a co-localizes with the autophagic vacuoles^[69]. In addition, another monomeric GTPase, Rab24, existing preferentially in a GTP-bound state when expressed in cultured cells, is redistributed and co-localized with MAP1-LC3 during starvation. It has been shown that Rab24 has a role in autophagy. The GTP membrane-bound forms of Rab proteins are able to recruit cytosolic proteins, which target vesicles to appropriate sites on the acceptor membrane^[119]. Whether or not this function of Rab proteins is essential for membrane fusion, transport, and the maturation of autophagic vesicles is still to be investigated.

Calcium Autophagy is dependent on the presence of sequestered Ca^{2+} in some intracellular storage compartments that are sensitive to interference by a number of Ca^{2+} -perturbing agents^[120]. ER is the major reservoir for intracellular calcium, thus thapsigargin, which inhibits the ER calcium/ATPase promotes the release of intracellular calcium from ER and thereby lowers ER calcium levels leading to notable

inhibition of autophagy. This implies that depletion of sequestered, rather than of cytosolic, intracellular Ca^{2+} should be responsible for the common mechanism of autophagy inhibition. Inhibitors of Ca^{2+} -activated protein kinases (KN-62, H-7, W-7) had little or no effect on autophagy, indicating that the Ca^{2+} requirement of autophagy was not mediated by these kinases. Recent studies have shown that elements that modify the lysosomal calcium levels, such as phorbol myristate acetate, ionophore A23187, and phentolamine, may modulate the total volume of autophagic vacuoles^[121].

Protein synthesis pathway In rat hepatocytes, the phosphorylation of the ribosomal S6 protein, a p70S6 kinase substrate, is also related to the inhibition of autophagy. The degree of S6 phosphorylation determines the degree of occupancy of the endoplasmic reticulum by ribosomes, and thus determines the rate of autophagic sequestration and the rate of ER-linked protein synthesis^[97]. So it is possible that there is a relationship between the control of protein synthesis and of autophagy. Furthermore, the finding of the involvement of eukaryotic initiation factor-2 alpha (eIF2 α) kinases in autophagy strengthens this view. The eIF2 α kinases are members of a family of evolutionarily conserved serine/threonine kinases that regulate stress-induced translational arrest. Recently, it was demonstrated that two eIF2 α kinases (GCN2 and PKR) positively controlled autophagic sequestration in yeast and mammalian cells in response to nutrient deprivation by phosphorylating the translation factor eIF2 α ^[122]. However, a general inhibition of protein synthesis does not trigger autophagy. For example, when translation is inhibited by cycloheximide, autophagy is not induced, but the formation of smaller autophagosomes is observed. These results indicate that protein synthesis is required for the expansion of the preautophagosome vesicle^[123]. In addition, the *de novo* synthesis of proteins is also required after the sequestration step during the maturation of autophagosomes.

Other regulatory factors The regulation of autophagy is very complex. In addition to the above mentioned molecular mechanisms, microtubule-associated protein, integrin, and some other kinases such as tyrosine protein kinase II, naringin-sensitive protein kinase, death-associated related protein kinase-1 (DRP-1), death-associated protein kinase (DAPK) all have a role^[124]. However, the molecular mechanisms by which these regulatory factors contribute to the control of autophagy are still largely unknown and their downstream targets also remain to be identified.

Autophagy and diseases

Autophagy is an important gate-keeping mechanism for

the stabilization of cell homeostasis, which is required for eliminating discarded or damaged organelles and/or cytoplasmic components and remodeling cytoplasm. Autophagy has been studied for more than 40 years, but it is only in the last 10 years that the molecular basis of autophagy has been gradually understood through the utilization of yeast genes. The discovery of the *ATG* genes and the dissection of the signaling pathways involved in the regulation of autophagy have greatly increased our knowledge of the occurrence and development of this lysosomal degradation pathway. In yeast, many questions about the molecular mechanisms of autophagy have already been investigated, but there are a great number of tasks ahead, such as clarification of the putative links between the different signaling complexes and elucidation of the specific mechanisms mediating autophagosome biogenesis, transport, fusion and autophagic degradation. Although the molecular machinery of the autophagic pathway is well conserved during evolution in multicellular organisms, especially in mammals, this process is much more complex in mammals than it is in yeast. At present, many autophagic genes in mammals still remain unknown and their functions in autophagy also remain undiscovered. The creation and analysis of transgenic and knockout animal models will help to understand the evolutionarily-acquired complexity of autophagy-mediated processes in mammals. Some gene (*beclin-1*, *ATG5*, and *ATG7*) knockout mice have already been used in experiments to explore the functions of these genes and the relationships between autophagy and some diseases^[21,125,126]. For example, with a targeted *beclin-1* mutant mouse model, it has been shown that heterozygous disruption of *beclin-1* increases the frequency of spontaneous malignancies and accelerates the development of hepatitis B virus-induced premalignant lesions. In addition, it has also been demonstrated that *beclin-1* is a haplo-insufficient tumor-suppressor gene, and therefore it is possible that the genetic disruption of autophagy, either by mutations of downstream autophagy-execution genes or by mutations in upstream autophagy-regulatory signaling pathways, may be an important mechanism of oncogenesis^[126]. Thus, mutation of *beclin-1* or other autophagy genes might contribute to the pathogenesis of human cancers. A growing number of pathological conditions, including cancer and neurodegenerative disorders, are associated with autophagy, so it is very important to reveal the molecular relationships between autophagy and diverse diseases. In our laboratory, we found that autophagy may have dual functions in cultured tumor cells. On the one hand, it may delay the apoptotic process in one cell type; but on the other hand, it may promote cell

death in other cell types (Yan *et al*, unpublished observations). Autophagy plays important roles in the degradation of misfolded or aggregated proteins and, therefore, may play a role in certain neurodegenerative diseases that feature the misfolding and aggregation of disease proteins, such as Huntington's disease and Parkinson's disease. We have studied the degradation of mutant huntingtin by autophagy. We found that autophagy upregulated cathepsins and enhanced the clearance of huntingtin fragments, but mutant huntingtin was relatively resistant to degradation by cathepsin D^[127]. Over-stimulation of autophagy by mutant huntingtin resulted in mislocalization and dysfunction of mitochondria (Qin *et al*, unpublished observations). In our recent studies, we also found that an autophagic mechanism was involved in excitotoxicity. Activation of the NMDA (*N*-methyl-*D*-aspartate)- and KA (kainic acid)-type glutamate receptors stimulated autophagy and lysosomal enzymes. The apoptotic death of striatal neurons was blocked by 3-MA and a cathepsin B inhibitor, suggesting that the activation of autophagy probably contributes to excitotoxicity^[128]. These studies have opened a new field for investigating the pathogenic mechanisms in neurodegenerative diseases related to protein misfolding, aggregation and excitotoxicity.

Abstract

Recently, two different chemicals have been matched as ligands with the same G-protein-coupled receptor (GPCR). Double-pairing of OGR1 family GPCRs with proton and lysolipid raises several questions. First, whether both are the real ligands for the GPCRs. Second, whether modulation of a GPCR by two chemicals could be possible. Third, one of the chemicals is proton. Proton-sensing not only is a new action mode of GPCR activation, but also it could be generalized in other GPCRs. In this review, I'd like to summarize the issue and discuss questions with pharmacological criteria.

Introduction

G-protein-coupled receptor (GPCR) is the largest gene family of human genome. GPCR is glaringly obvious by the fact that more than 50% of drugs on the market are either agonists or antagonists on GPCRs^[1]. Positive or negative modulation of GPCRs with drugs has been successful tools to treat many diseases such as allergy, gastric ulcer, and hypertension. The common structural feature of all GPCRs is a seven-helical transmembrane region. GPCR activations are evoked by stimuli as diverse as light, Ca²⁺, odorants, amino acids, nucleotides, proteins, polypeptides, steroids, and fatty acid derivatives.

The completion of the human genome project has identified about 865 GPCR genes^[2]. Except sensory receptors, 367 GPCRs have been considered as receptors for endogenous ligands in the human genome^[3]. However, identification of novel members of GPCRs by genome sequencing faces orphan receptor problem, that is, ligands are not yet found^[1]. About 150 orphan GPCRs are waiting for discovery of their ligands^[4]. Pairing orphan GPCRs with their own ligands (endogenous or surrogate) would advance scientific knowledge and induces discovery of new drugs^[5–9]. However,

recent double-pairing of OGR1 subfamily GPCRs with two different chemicals, proton and lysolipid, raises several questions.

First, whether both chemicals are the real ligands for OGR1 subfamily. Second, whether modulation of a GPCR by two chemicals could be possible, because classic pharmacological concept is one ligand for one GPCR. Third, one of the chemicals is proton. Although it has been well established for ion channel receptors such as transient receptor potential/vanilloid receptor subtype-1 (TRPV1)^[10] and acid-sensing ion channels (ASICs)^[11], in GPCR area, not only proton-sensing is a new action mode of GPCR activation, but also it could be generalized in other GPCRs.

OGR1 subfamily and lysolipids

OGR1 subfamily is composed of four members (OGR1, GPR4, G2A, and TDAG8) and has previously been identified as receptors for lysolipids; sphingosylphosphorylcholine (SPC), lysophosphatidylcholine (LPC) and psychosine (galactosylsphingosine)^[12–14]. In 2000, Xu *et al* reported Ovarian cancer G-protein-coupled Receptor 1 (OGR1, GPR68) to be a high-affinity receptor for SPC ($K_d = 33$ nmol/L) and

SPC was shown to inhibit cell growth of OGR1-transfected HEK293 as well as various ovarian cancer cell lines^[12,15]. In 2001, Zhu *et al* reported GPR4 to be the second high affinity receptor for SPC and GPR4 was shown to be activated by structurally-related LPC^[13]. However, in contrast to OGR1, GPR4 activation stimulated cell growth and cell migration of GPR4-transfected Swiss3T3 cells^[13]. TDAG8 (T-cell death-associated gene 8, GPR65) was reported to be activated by psychosine and its activation was shown to result in multinuclear cell formation^[14]. G2A (G2 accumulation protein, GPR132), the last member of the subfamily, was characterized to cause cell cycle arrest in the G₂/M phase^[16]. LPC was initially reported as a ligand of G2A and T cell chemotaxis to LPC was shown to be mediated through G2A^[17].

Yan *et al* reported macrophage chemotaxis to LPC is dependent on G2A function and mutation of the conserved DRY motif of G2A results in loss of function^[18]. Wang *et al* demonstrated that murine G2A was spontaneously internalized and accumulated in endosomal compartments, whereas its surface expression was enhanced and stabilized by LPC treatment^[19]. Han *et al* reported G2A-mediated up-regulation of CXCR4 in human helper T cells^[20]. Murakami *et al* reported G2A-dependent actin stress fiber formation and its inhibition by LPC in G2A-NIH3T3 cells^[21]. Also LPC enhances dose-dependently intracellular cAMP accumulation and G2A-induced apoptosis in Hela cells^[22]. Ikeno *et al* reported that secretory phospholipase A₂ induce neurite outgrowth in PC12 cells through LPC generation and activation of G2A receptor^[23]. Lin and Ye reported that G2A displays a significant level of intrinsic signaling via Gα_q, Gα_s, and Gα₁₃ pathways^[22].

Lum *et al* showed that inflammatory stress increases GPR4 expression and LPC binding in human microvascular endothelial cells^[24]. Recently, Kim *et al* reported that GPR4 plays a critical role in SPC-induced angiogenesis and SPC transactivates VEGF receptor 2 in endothelial cells^[25].

Maghazachi *et al* reported that psychosine and glucosylsphingosine induce multinuclear cell formation and apoptosis in TDAG8-expressing natural killer cells^[26]. Malone *et al* reported that activation of TDAG8 by psychosine enhanced dexamethasone-induced apoptosis in a TDAG8-dependent manner in lymphomas^[27]. Tosa *et al* reported critical function of TDAG8 in glucocorticoid-induced thymocyte apoptosis^[28].

These ligand chemicals have similar lysolipid structures (Figure 1) and their significance in pathological conditions and pharmacological application has been discovered. Especially, G2A deficient mouse developed an autoimmune syndrome similar to systemic lupus erythematosus (SLE)^[29],

Figure 1. Structures of LPC and other lysolipids.

and therapeutic application of LPC for sepsis was proposed in relation with G2A receptor^[30].

Overexpression of G2A, GPR4, and TDAG8 in human cancers has been found to play a role in driving or maintaining tumor formation, however, transformation was achieved without addition of lysolipids^[31,32]. Bektas *et al* reported ligand-independent signaling of GPR4 and its inability to respond to SPC and LPC in several assay systems, that is, GTPγS binding, receptor internalization, and arrestin translocation^[33]. Additionally, the original paper that reported G2A-LPC pairing was recently retracted by authors, because they could not confirm the LPC-binding experiments^[34]. Constitutive activation of GPCR and lipid-independent responses raises a possibility, that is, another activator of GPCR is present in the culture medium or secreted from GPCR-transfected cells. Such a possibility has been suggested and supported with proton by five independent groups^[21,35-38].

OGR1 subfamily as proton-sensing GPCRs

Ludwig *et al* (2003) reported OGR1 and GPR4 to be proton-sensing receptors. At pH 7.8, OGR1 was inactive, but activated fully inositol phosphate (IP) formation at pH 6.8. Ludwig *et al* predicted several hydrogen-bond interactions occurring between unprotonated histidines by using a computational 3D model of OGR1. Under alkaline conditions these interactions could stabilize the receptor in an inactive state. Exposure to an acidic pH would destabilize the hydrogen bonds, switching the receptor to its active conformation. Indeed, mutation of several histidines (H17, H20, H84, H169, and H269) to phenylalanines reduced proton-sensing ability of OGR1 (Figure 2)^[35]. In the same paper, authors observed that a very similar activation of GPR4 by pH change, but GPR4 activates the Gs-adenylyl cyclase-cAMP pathway^[35].

Figure 2. Sequence alignment of OGR1 subfamily GPCRs. Histidine residues that have been reported to be involved in proton-sensing are bolded and underlined in OGR1 (H17, H20, H84, H169, and H269), TDAG8 (H10 and H14), and G2A (H174). Residues in GPR4 that are assumed to be critical for proton-sensing based on alignment with OGR1 are also marked. Suggested basic amino acids in G2A instead of histidines in OGR1 are underlined. A histidine in TMVI conserved in all four members of GPCRs is starred. Potential transmembrane regions are overscored; gaps are indicated by dashes.

However, they were not able to observe any effect of SPC and LPC, previously reported ligands, on OGR1 and GPR4. In 2004, Murakami *et al* reported that G2A functions as a proton-sensing GPCR^[21]. Transient transfection of G2A caused significant activation of the *zif268* promoter and IP accumulation at pH 7.6 and lowering extracellular pH aug-

mented the activation only in G2A-expressing PC12h cells^[21]. Site-directed mutation of His-174, which is predicted to be located at the extracellular part of the transmembrane helix IV (Figure 2), reduced partially G2A-dependent signaling at lower pH. They found that LPC and SPC did not cause IP formation at pH 7.6, but LPC inhibited IP formation at pH 6.8

in a dose-dependent manner, suggesting that LPC acts as an antagonist not an agonist. Wang *et al* reported that TDAG8 is also a proton-sensing GPCR stimulating cAMP accumulation^[36]. They found that psychosine and SPC are antagonistic on pH-dependent responses in the cells transfected with TDAG8. Psychosine-sensitive and pH-dependent cAMP accumulation was also observed in mouse thymocytes, where TDAG8 is endogenously expressed^[36]. Radu *et al* conducted experiments with all 4 members of OGR1 subfamily to test proton-sensibility and confirmed previous reports on OGR1, GPR4, and TDAG8^[38]. However, G2A was insensitive or less sensitive to extracellular pH change in their experimental conditions^[38]. They suggested that lack of many histidine residues, defined to be involved in pH-sensing of OGR1, could be a cause for insensitiveness of G2A to acidic pH (Figure 2)^[38]. Also they suggested that the constitutive activation of G2A in neutral pH might be resulted from maintaining active conformation of G2A via positively charged amino acids in human and mouse G2A instead of conserved histidines (Figure 2)^[38]. Ishii *et al* reported that TDAG8 is a proton-sensing GPCR, however, they were not able to observe any inhibitory effect of psychosine on pH-dependent TDAG8 activation^[37]. Therefore, a series of publications propose that extracellular proton could be an activator of the OGR1 subfamily of GPCRs. More than two independent groups reported proton-sensing properties of OGR1, GPR4, and TDAG8 (Table 1). In the case of G2A, constitutive activation at pH 7.4 has been observed in many transfected cells by many research groups, however, pH-dependent activation was supported only by one group^[21] and was not fully reproduced by another group^[38]. Dependence of pH sensing on the histidine residues on the extracellular domains of GPCRs has been tested on OGR1, TDAG8, and G2A^[21,35-37].

However, site-directed mutagenesis study of the histidines on GPR4 has not been experimentally reported.

In summary, there are four opinions in the published reports, that is agonism of lysolipid, antagonism of lysolipid, agonism of proton, and no confirmation of lysolipid action on OGR1 subfamily GPCRs. Table 1 shows list of publications supporting each opinion except negative observation or constitutive activation.

Two ligands for a GPCR, proton vs lysolipid

As for lysolipids as ligands, Ludwig *et al* could not confirm such activation of GPCRs with lysolipids^[35], and three research groups observed antagonistic effects of LPC, SPC and psychosine on the GPCRs in acidic conditions rather than agonism (Table 1)^[21,36-38]. In summary, lysolipids have been suggested as ligands for the OGR1 subfamily GPCRs, however, all four members of the GPCRs have also been proposed as proton-sensing GPCRs. OGR1 subfamily has been considered as a contentious GPCR subgroup, because pairing it with lysolipids has been controversial in the scientific society^[4,21,33,35,36]. Additionally, the original G2A paper was retracted^[34] and GPR4 paper would be retracted (Y XU, FASEB conference, 2005). However, there are growing numbers of reports supporting actions of lysolipids on OGR1 subfamily GPCRs (Table 1). As proposed by Kim *et al* it can be dependent on cell types. Kim *et al* recently confirmed pH-dependent cAMP production in GPR4-transfected HEK293 cells but not in GPR4-transfected HUVEC or HMEC-1 cells^[25]. Cell-type specific functions remind us RAMPS (receptor activity-modulating proteins) which are essential proteins for expression and function of GPCRs such as CGRP (calcitonin gene-related peptide) and adrenomedullin^[39]. If

Table 1. Summary of publications.

Name	Receptor		Agonist		Antagonist
	Expression	Lysolipid	Proton	Lysolipid	
OGR1 (GPR68)	Spleen, testis, small intestine, PBL, brain, heart, lung, placenta, kidney ^[53]	(SPC) ^[12]	(H ⁺) ^[35,36,38]	(Psy and SPC) ^[36]	
GPR4	Ubiquitous (ovary, liver, lung, kidney, lymph node, subthalamic nucleus) ^[13]	(LPC and SPC) ^[13] (LPC) ^[24] , (SPC) ^[25]	(H ⁺) ^[25,35,36,38]	(Psy and SPC) ^[36]	
TDAG8 (GPR65)	PBL, spleen, thymus, lymph nodes ^[14]	(Psy) ^[14,26,27]	(H ⁺) ^[36-38]	(Psy and SPC) ^[36]	
G2A (GPR132)	Spleen, thymus, T-lymphocytes, B-lymphocytes, monocytes, macrophages ^[16]	(LPC) ^[17,18,21,30]	(H ⁺) ^[21,38]	(LPC) ^[21,38]	

there are RAMP-like proteins specific for OGR1 subfamily, the complicated results may be solved. Wang *et al* recently observed spontaneous internalization of murine G2A and reported that LPC induces surface redistribution and stabilization of murine G2A^[19]. Such an action of LPC may support spontaneous activation of G2A and explain agonistic and antagonistic effects of LPC. If spontaneous activity of G2A was presumed as control level in neutral pH, LPC-induced action might be interpreted as agonism. However, if spontaneous activation or proton-activated effect was thought as agonism, LPC-induced action might be considered as antagonism. Further investigation on cell-type specificity and receptor distribution in the cells may clarify action mode of OGR1 subfamily GPCRs by both chemicals, proton and lysolipids.

Therefore, it is not easy to say which chemical is the real ligand, although both chemicals could be called as modulators of the GPCRs. Finding of antagonistic effects of lysolipids on the receptors at acidic conditions may advance our understanding and might reconcile the controversy in the future. If both chemicals could activate the same GPCRs in certain conditions, another issue might be two ligands for a GPCR. Dual actions may be a rare example in the GPCR area. However, considering that TRPV1 could be activated by capsaicin, proton, heat and lipids, two chemicals for a GPCR could not be a surprising action mode in biological sciences^[10]. Investigation of physiological roles and pathological implications of the GPCRs in the future may lighten importance of discovery of proton-sensing GPCRs, because acidosis is related with many diseases such as cancer^[40],

asthma^[41], atherosclerosis^[42], arthritis^[43], and osteopenia^[35,44].

Proton as an agonist

Another issue remains; could proton be a ligand? To be an agonist, it should bind to GPCR specifically and reversibly^[45]. Furthermore, it should dose-dependently activate GPCR. In five publications, proton has been shown to fulfill all the above criteria, except specificity^[21,35-38]. Basal activity of many other GPCRs has been observed in neutral pH without apparent presence of endogenous ligands as like δ -opioid receptor^[46,47]. Such basal activity of GPCR has further been confirmed by inverse agonists, which reduce the basal activity in a dose-dependent manner^[46,47]. Many GPCRs have histidine residues in extracellular loops and outer segments of GPCR helices. Thus, if change of extracellular pH could change basal activities of many GPCRs, although the magnitude of change varies, this means lack of specificity. If many GPCRs are activated or inactivated by change of pH without presence of any agonists, proton can not be an agonist, because it lacks specificity, even though OGR1 subfamily activation with proton was the greatest response among GPCRs activated with proton. Indeed, modulation of GPCRs by extracellular pH has been reported in P2Y₄ ATP receptor and calcium-sensing receptor^[48,49].

Four research groups have used the term “proton-sensing GPCR” for OGR1 subfamily, however, the term for proton, the counterpart, is omitted or the term “ligand” has been used for proton. However, it is inadequate, because of the above-mentioned reason, lack of specificity. GPCR modula-

Figure 3. Illustration of suggested modulators of OGR1 subfamily. Lysolipids have been suggested as agonists of OGR1 subfamily in neutral pH and as an agonist in acidic pH. Proton has been suggested as agonists of OGR1 subfamily. Two possibilities are also included. One is another chemical activating OGR1 subfamily in neutral pH. The other possibility is proton action on other GPCRs positively and/or negatively. The symbol (+) means activation of GPCR and (-) inactivation.

tor may be the good term for proton, because it changes activity of GPCRs, but it can not be an agonist. So far, the smallest particle ever reported to be a GPCR activator is photon. In this case, photon energy in light activates rhodopsin GPCR by isomerisation of 11-*cis*-retinal to *trans* conformation within the rhodopsin helices^[50,51]. Now, proton might become the second small molecule activating GPCRs. Although lysolipids as the ligand of OGR1 subfamily still remain controversial, proton as a ligand for the GPCRs also need to be considered with caution, because an endogenous ligand might be waiting to be discovered, suggesting possible presence of another chemical to activate OGR1 subfamily in neutral conditions (Figure 3). It may not be a surprise if there is another chemical activating OGR1 subfamily in neutral pH such as prostaglandins and capsaicin modulating TRPV1^[52].

In summary, proton activates OGR1 subfamily GPCRs and lysolipids modulate activity of OGR1 GPCRs positively or negatively. However, we need to consider other two possibilities. One is that modulation by proton could be generalized in other GPCRs even though the magnitude varies (Figure 3). Second, there could be another chemical activating OGR1 subfamily in neutral pH (Figure 3).

Abstract

Aim: To test the effect of orexin-A (hypocretin-1), a neuropeptide synthesized in the lateral hypothalamus and the perifornical area, on the glycinergic inputs and the GABAergic inputs of cardiac vagal neurons (CVN). **Methods:** The effects of orexin-A at three concentrations (20 nmol/L, 100 nmol/L, 500 nmol/L) on the glycinergic inputs and the GABAergic inputs were investigated by using retrograde fluorescent labeling of cardiac neurons (CVN) in the nucleus ambiguus (NA) and the voltage patch-clamp technique. **Results:** Orexin-A dose-dependently increased the frequency of both the glycinergic and the GABAergic spontaneous inhibitory postsynaptic currents (sIPSC). However, at a lower concentration (20 nmol/L) of orexin-A, although the frequency of the glycinergic sIPSC was significantly increased, the frequency of the GABAergic sIPSC was not significantly changed. **Conclusion:** The glycinergic inputs and the GABAergic inputs have different sensitivities to orexin-A, which suggests that the two kinds of inhibitory inputs might play different roles in the synaptic control of cardiac vagal functions.

Introduction

Orexin-A and orexin-B, also known as hypocretin-1 and hypocretin-2, are members of a new family of neuropeptides synthesized in the lateral hypothalamus and perifornical area neurons^[1,2]. Orexins have been shown to participate in many functions, including sleep-wakefulness, feeding, and neuroendocrine function^[3–5]. In addition, many studies have found that orexins also participate in the neural control of cardiovascular functions. And, although most studies have focused on the excitatory effect of orexins on cardiovascular sympathetic activity^[6–11], some evidence suggests that orexins might also have a role in the parasympathetic control of heart rate and cardiac functions.

Cardiac vagal nerves predominate over cardiac sympathetic nerves in the control of heart rate and cardiac functions, and their preganglionic fibers primarily originate from the cardiac vagal neurons (CVN) in the nucleus ambiguus (NA) and the dorsal motor nucleus of the vagus (DMNX)^[12–15]. CVN are intrinsically silent and their activity relies completely on their synaptic inputs^[15]. CVN receive excitatory gluta-

matergic and cholinergic inputs^[16,17], and inhibitory GABAergic and glycinergic inputs^[14,17,18]. Although previous studies have suggested that orexins are involved in the vagal control of heart rate and cardiac functions, the reported effects are largely contradictory. Microinjection of orexin-A into the NA of adult male rats elicited a dose-related decrease in heart rate^[19]. Microinjection of orexin-A into the nucleus tractus solitarius (NTS), where GABAergic neurons and glutamatergic neurons monosynaptically project to CVN^[14,16], elicited a decrease^[20] or increase^[21] in heart rate. In a very recent *in vitro* study using brainstem slices of newborn rats, orexin-A was found to inhibit CVN indirectly, via presynaptic enhancement of the action-potential-dependent GABAergic and glycinergic inputs, and via presynaptic attenuation of the action-potential-dependent glutamatergic inputs^[22].

The actual concentration of orexin-A in rat brainstem that acts to modulate the physiological synaptic control of CVN is not clear; however, the experimentally measured concentration of orexin-A in the cerebrospinal fluid is less than 1 nmol/L in rats^[23], and is even less in dogs and human

beings^[24,25]. Surprisingly, the concentration of orexin-A used in the *in vitro* study of Dergacheva *et al*^[22] was 1 $\mu\text{mol/L}$, and was as high as 1 $\mu\text{mol/L}$ in microinjection studies^[19–21]. It is possible that these previous studies have used overdoses of orexin-A, which might have resulted in a non-specific effect.

The response of each kind of synaptic input of CVN to orexin-A might be different at different concentrations. At the same concentration, the sensitivity of each kind of synaptic input to orexin-A might also be different. These possibilities make it necessary to reevaluate the effect of orexin-A on CVN at lower and more divided concentrations. The purpose of the present study is to reevaluate the effect of orexin-A on the glycinergic and GABAergic spontaneous inhibitory postsynaptic currents (sIPSC) at lower concentrations (20 nmol/L, 100 nmol/L, and 500 nmol/L). Using retrograde fluorescent labeling of CVN and the voltage patch-clamp technique, we have demonstrated that orexin-A dose-dependently increases the frequency of both the glycinergic and the GABAergic sIPSC. However, at a lower concentration (20 nmol/L) of orexin-A, although the frequency of the glycinergic sIPSC was significantly increased, the frequency of the GABAergic sIPSC was not significantly changed. These results suggest that the glycinergic inputs and the GABAergic inputs have different sensitivities to orexin-A, and suggest that the two kinds of inhibitory inputs might play different roles in the synaptic control of cardiac vagal functions.

Materials and methods

Retrograde fluorescent labeling of CVN The inhalation agent halothane (0.5 mL) was dripped into a glass box (5 cm \times 5 cm \times 5 cm) with a lid and a bottom cotton pad. Three to four-day-old Sprague-Dawley rats (Shanghai Institute for Family Planning) were put in the box for 30 s with the lid covered. This procedure anesthetized the rats but maintained their breathing in a relatively normal state. The rats were then buried in ice-filled bags to decrease the rats' body temperatures and slow their hearts. After autonomic breathing stopped (usually within 2 min) a right thoracotomy was carried out to expose the heart, and rhodamine (2% solution, 20–50 μL ; XRITC, Molecular Probes, Carlsbad, California, USA) was injected into the pericardial sac with a glass pipette (tip diameter 50 μm). The incision was sutured and the animals were heated with a thermo-pad to help recovery. After the surgery (about 5 min) the animals usually started autonomic breathing within 3 min and started free moving within another 5 min. The animals were allowed 1–2 d to

recover, and experiments were performed when animals were 4–6 d old. Rats at this age have been shown to have similar respiratory-related and reflex-related parasympathetic heart rate control as adult rats^[17,26]. Similar surgical procedures that selectively labeled CVN have been described previously by Mendelowitz and Kunze^[27], who proved that no brainstem neurons were labeled if rhodamine was injected into the chest cavity while the pericardial sac was kept intact, and if rhodamine was injected into the pericardial sac while the cardiac branch of the cardiac vagal nerve was sectioned. In addition, it has also been proved that intravenous injection of up to 10 mg of rhodamine failed to label any CVN^[27].

Slice preparation The animals were anesthetized deeply with halothane and decapitated at the supracollicular level. The hindbrain was exposed, isolated, and submerged in cold (4 $^{\circ}\text{C}$) artificial cerebral spinal fluid (ACSF) of the following composition (in mmol/L): NaCl (124), KCl (3.0), KH_2PO_4 (1.2), CaCl_2 (2.4), MgSO_4 (1.3), NaHCO_3 (26), *D*-glucose (10), sucrose (10), and constantly bubbled with gas (95% O_2 , 5% CO_2 ; pH 7.4). The cerebellum was removed and the brainstem was dissected using a dissection microscope. With the rostral end facing upwards and the ventral surface facing the razor, the brainstem was then secured in the slicing chamber of a vibratome (Leica VT 1000 S, Heerbrugg, Switzerland) filled with the same ACSF, and sequentially sectioned in variable thickness in the transverse plane. Once the NA and other landmarks^[17] emerged under the microscope, a single slice of 400 μm thickness was taken for experimentation. A medulla slice of this thickness from a 4–6-d-old rat actually includes the full range of the medulla, and such slices have been used in many studies (eg, respiratory rhythm studies) that require relatively intact *in vitro* neuronal networks. The slice was transferred into the recording chamber and submerged in the ACSF maintained at 22 $^{\circ}\text{C}$.

Electrophysiological recording Individual CVN in the NA were identified by the presence of the fluorescent tracer using an Olympus (Tokyo, Japan) upright microscope through a 40 \times water immersion objective. These identified CVN were then imaged with differential interference contrast (DIC) optics, and infrared illumination and infrared-sensitive video detection cameras to gain better spatial resolution and to visually guide and position the patch pipette onto the surface of the identified neuron. The pipette (2.0–5.0 Ω) was advanced until a high resistance seal was obtained ($>1\text{ G}\Omega$) between the pipette tip and the cell membrane of the identified neuron. The membrane under the pipette tip was then ruptured with a brief suction to obtain whole-cell patch-clamp configuration, and the cell was voltage-clamped at a holding potential of -80 mV. The pipette resistance and capacitance

was not compensated either before or after gaining intracellular access. To record GABAergic and glycinergic synaptic events, the patch pipettes were filled with a solution consisting of (in mmol/L): KCl (150), MgCl₂ (2), ethyleneglycol-bis(β-aminoethyl ether)-*N,N,N',N'*-tetraacetic acid (EGTA) (2), *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES) (10), Mg-ATP (2), at pH 7.35. With this pipette solution the Cl⁻ current induced by activation of the GABA (γ-aminobutyric acid) receptors and/or glycinergic receptors was recorded as an inward current. In some experiments a 2 ms, 5 mV, hyperpolarizing current was injected with a frequency of 0.25 Hz to calculate and monitor the membrane resistance change of CVN throughout the recording. All animal procedures complied with the institutional guidelines of Fudan University, and were in accordance with the National Administration Guidelines for Experimental Animals.

Drug application GABAergic synaptic currents were isolated by inclusion in a perfusate of strychnine (1 μmol/L), D-2-amino-5-phosphonovalerate (AP₅, 50 μmol/L), and 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX; 50 μmol/L) to block glycine, NMDA (*N*-methyl-*D*-aspartate), and non-NMDA receptors, respectively, and were confirmed by blockade of the synaptic currents by 1 μmol/L picrotoxin at the end of the experiment. Glycinergic synaptic currents were isolated by inclusion in a perfusate of picrotoxin (1 μmol/L), AP₅ (50 μmol/L), and CNQX (50 μmol/L) to block GABA, NMDA, and non-NMDA receptors, respectively, and were confirmed by blockade of the synaptic currents by 1 μmol/L strychnine at the end of the experiment. Orexin-A (20 nmol/L, 100 nmol/L, 500 nmol/L) was used to activate the orexin-A receptors. The duration of orexin-A application was 2 min and each slice was applied only once to avoid desensitization. All drugs were purchased from Sigma Aldrich (St Louis, MO, USA).

Data analysis Spontaneous GABAergic and glycinergic sIPSC were analyzed with MiniAnalysis (Synaptosoft, version 4.3.1, Decatur, GA, USA) with a minimal acceptable amplitude of 10 pA. Results are presented as mean±SEM, and are statistically compared by using the nonparametric Kolmogorov-Smirnov (K-S) test. Significant difference was set at $P < 0.05$.

Results

Responses of the glycinergic sIPSC to different doses of orexin-A Orexin-A significantly increased the frequency of the glycinergic sIPSC at all three concentrations tested. At a concentration of 20 nmol/L orexin-A increased the average frequency of the glycinergic sIPSC by 63%±4%, from

3.04±1.01 Hz to 4.97±0.91 Hz ($P < 0.01$, $n = 6$). This frequency increase was observed in all the 6 CVN tested. At a concentration of 100 nmol/L, orexin-A increased the average frequency of the glycinergic sIPSC by 167%±5%, from 3.60±0.90 Hz to 9.64±0.86 Hz ($P < 0.01$, $n = 8$). At a concentration of 500 nmol/L orexin-A caused a frequency increase by 149%±7%, from 3.55±1.21 Hz to 8.85±2.71 Hz ($P < 0.05$, $n = 8$), which was similar in degree to that produced by 100 nmol/L orexin-A. These results indicate that orexin-A dose-dependently increases the frequency of the glycinergic sIPSC, and a maximal effect can be achieved at 100 nmol/L. A typical CVN with an increased frequency of glycinergic sIPSC induced by orexin-A at 100 nmol/L is shown in Figure 1A, 1B, and the changes in average frequency caused by the three concentrations of orexin-A are shown in Figure 1C, 1D.

In most CVN and at all the three concentrations of orexin-A used, an increase in the amplitude of the glycinergic sIPSC was also observed. Because Dergacheva *et al* proved that this amplitude increase was presynaptically caused by summated action-potential-dependent release of glycine^[22], the amplitude data were not statistically analyzed and were not presented in this article. In addition, at no concentration of orexin-A used in this study was there any significant change in the membrane resistance, or visible change in the baseline currents of CVN. The average membrane resistance before and after 500 nmol/L orexin-A was 370.24±16.17 MΩ and 382.66±20.87 MΩ, respectively ($P > 0.05$, $n = 8$).

Responses of the GABAergic sIPSC to different doses of orexin-A Orexin-A significantly increased the frequency of the GABAergic sIPSC only at 100 nmol/L and 500 nmol/L. At a concentration of 20 nmol/L orexin-A changed the frequency of the GABAergic sIPSC from 3.40±0.75 Hz to 2.88±0.53 Hz ($P > 0.05$, $n = 6$). In none of these 6 CVN was obvious frequency change observed. At a concentration of 100 nmol/L orexin-A increased the frequency of the GABAergic sIPSC by 97%±11%, from 2.58±0.63 Hz to 5.07±1.22 Hz ($P < 0.05$, $n = 6$). At a concentration of 500 nmol/L orexin-A increased the frequency of the GABAergic sIPSC by 173%±14%, from 2.59±0.82 Hz to 7.08±0.86 Hz ($P < 0.01$, $n = 5$). These results indicate that although orexin-A also dose-dependently increased the frequency of the GABAergic sIPSC, a relatively higher concentration (>20 nmol/L) is needed to cause a significant change, and the maximal frequency increase could not be reached at a concentration of 100 nmol/L. A typical CVN with an increased frequency of the GABAergic sIPSC induced by orexin-A at 100 nmol/L is shown in Figure 2A, 2B, and the changes in average frequency caused by the three concentrations of orexin-A are illustrated in Figure 2C, 2D.

Orexin-A at concentrations of 100 nmol/L and 500 nmol/L

lyzed and are not presented in this article.

Discussion

There are two major findings in the present study. One is that the frequency increase of both the glycinergic and the GABAergic IPSC caused by orexin-A is dose-dependent. The

other is that orexin-A at a lower concentration (20 nmol/L) significantly enhances the glycinergic inputs but does not cause significant alteration in the GABAergic inputs.

Ever since the discovery of the GABAergic inputs and the glycinergic inputs in CVN, these two inhibitory inputs have shown identical roles in the regulation of CVN. The synaptic activities of both kinds of inputs are action-potential-dependent and are absent in the presence of tetrodotoxin (TTX)^[14,18]; both kinds of inputs are enhanced by endogenous acetylcholine and exogenous nicotine^[18], are inhibited by opioids, and are rhythmically augmented during inspiration^[17,28]. Little is known about whether and how these two inhibitory inputs play different roles in the synaptic control of CVN, except that dihydro- β -erythroidine, a nicotinic antagonist, prevents the inspiratory-related augmentation of the GABAergic, but not the glycinergic, inputs to CVN when focally applied at 3 mmol/L, a concentration under which dihydro- β -erythroidine specifically binds to the $\alpha 4\beta 2$ type of nicotinic receptors^[17]. The present study demonstrated that orexin-A at a lower concentration (20 nmol/L) significantly increased the frequency of the glycinergic sIPSC, but did not cause a significant frequency alteration in the GABAergic sIPSC. These results indicate that the glycinergic inputs and GABAergic inputs might have different roles in the orexinergic control of CVN. At lower concentrations (≤ 20 nmol/L) of orexin-A, glycinergic inputs might dominate, and at higher concentrations (≥ 20 nmol/L) of orexin-A, a synergistic action of both kinds of inputs might occur.

Although in the present study lower concentrations of orexin-A were used, the results were still quite consistent with those from the study of Dergacheva *et al*^[22]. The results of the present study as well as the results of Dergacheva *et al* indicate that the responses of the glycinergic inputs and the GABAergic inputs to different concentrations of orexin-A differ in degree, but do not differ in the direction of responses. The present study still cannot reveal why CVN are excited by microinjection of orexin-A into the NA *in vivo* and are inhibited *in vitro*. Further study is necessary.

The physiological roles of the glycinergic and the GABAergic inputs to CVN in cardiac vagal control are not fully understood. Currently, the only confirmed function of these two inputs to CVN is that they are involved in the generation of respiratory-related heart rate rhythm. During the inspiratory phase of the respiratory cycle, both the GABAergic and the glycinergic inputs are facilitated by acetylcholine to inhibit CVN and speed up the heart^[18,27]. These two inhibitory inputs to CVN have also long been postulated to be involved in the reflex parasympathetic control of

the heart. The serotonergic neurons in the brainstem or in the nodose ganglion have been reported to be activated during activation of the cardiovascular chemo- or baro-reflex^[29]. The activation of the serotonergic system, via inhibition of both the GABAergic and the glycinergic inputs to CVN, possibly excites CVN and mediates the reflex parasympathetic inhibition of the heart. The physiological significance of the modulation of the GABAergic and the glycinergic inputs to CVN by orexin-A is also not clear, and nothing is known about why the glycinergic neurons preceding CVN were more sensitive to orexin-A than the GABAergic neurons. Perhaps the receptors for orexin-A binding in these two kinds of neurons are different in density. Orexin-A is known to strengthen preying behavior and increases food uptake. Because the action of orexin-A on CVN is assumed to accelerate the heart, orexin-A might help mammals to adapt to their preying and eating behavior via speeding up the heart.

In conclusion, the present study demonstrated that orexin-A dose-dependently increased the frequency of both the glycinergic and the GABAergic sIPSC of CVN; the glycinergic neurons and the GABAergic neurons preceding CVN had different sensitivities to orexin-A, which might indicate that these two kinds of inhibitory neurons play different roles in the synaptic control of cardiac vagal functions.

Abstract

Aim: To investigate the role of histamine in memory deficits induced by MK-801 infusion into the ventral hippocampus in rats. **Methods:** An 8-arm radial maze (4 arms baited) was used to assess spatial memory. **Results:** Bilateral ventral intrahippocampal (ih) infusion of MK-801 (0.3 µg/site), an N-methyl-D-aspartate (NMDA) antagonist, impaired the retrieval process in both working memory and reference memory. Intrahippocampal injection of histamine (25 or 50 ng/site) or intraperitoneal (ip) injection of histidine (25, 50 or 100 mg/kg) markedly ameliorated the spatial memory deficits induced by MK-801. Both the histamine H₁ antagonist pyrilamine (0.5 or 1.0 µg/site, ih) and the H₂ antagonist cimetidine (2.5 µg/site, ih) abolished the ameliorating effect of histidine (100 mg/kg, ip) on reference memory deficits, but not that on working memory deficits induced by MK-801. **Conclusion:** The results indicate that histamine in the ventral hippocampus can ameliorate MK-801-induced spatial memory deficits, and that histamine's effect on reference memory is mediated by postsynaptic histamine H₁ and H₂ receptors.

Introduction

Recently, the differentiation of functions along the longitudinal axis of the hippocampus (dorsal–ventral in the rat and posterior–anterior in humans) has attracted interest^[1,2]. Anatomically, the hippocampus includes CA1, CA2, CA3, and dentate gyrus subfields, with the pattern of efferent and afferent connectivity changing between the dorsal and ventral hippocampus^[3]. Identification of distinct functional roles for the dorsal and ventral hippocampus may help to resolve differences among the various theoretical accounts of hippocampal involvement in learning behavior^[2].

Considerable evidence shows that the dorsal hippocampus plays an important role in spatial memory^[4–6]. Ablation of the dorsal hippocampus, in which between 20% and 37% of the total hippocampal volume is removed, results in profound impairment of spatial location of a submerged platform in the Morris water maze^[5]. Bannerman *et al* also found that performance in the water maze and elevated T maze was impaired by selective dorsal but not ventral hippocampal lesions^[4]. On the other hand, ventral hippocampal lesions

are considered to affect anxiety but not spatial learning^[7,8]. However, Ferbinteanu *et al* demonstrated that the ventral hippocampus might also be involved in acquisition of spatial memory in Long–Evans rats^[9]. So far, little is known about the functions performed by the ventral hippocampus in spatial memory.

Both histamine and its precursor histidine facilitate memory retrieval deficits induced by aging, dorsal hippocampal lesions and scopolamine, as determined by passive and active avoidance tasks and an 8-arm radial maze test for rats^[10–12]. α-Fluoromethylhistidine (FMH), a selective histidine decarboxylase (HDC) inhibitor, produces significant memory deficits in an active avoidance task and the 8-arm radial maze in rats^[13,14]. Furthermore, N-methyl-D-aspartate (NMDA) receptors play an important role in learning and memory^[15,16]. Bekkers^[15] and Vorobjev *et al*^[17] found that histamine could dramatically enhance NMDA receptor-mediated synaptic transmission and facilitate the induction of long-term potentiation in cultured hippocampal pyramidal cells. Our previous studies indicate that histamine in the

dorsal hippocampus ameliorates spatial working memory and reference memory deficits induced by MK-801, and the action is mediated by postsynaptic histamine H₁ receptors^[18,19]. However, whether histamine in the ventral hippocampus is involved in spatial memory deficits induced by MK-801 remains unclear.

Therefore, the objectives of this investigation were to use the radial maze task with 4-arms baited to further clarify the effects of the histaminergic system in the ventral hippocampus on the regulation of spatial memory in rats.

Materials and methods

Animals All experiments were carried out in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals. Male Sprague-Dawley rats (220–270 g, grade II, certificate No 22-9601018, Experimental Animal Center, Zhejiang University) were maintained in an air-conditioned room at 22–26 °C and 40%–70% humidity, and housed in individual cages with a 12-h light–dark cycle (lights on from 8:00 AM to 20:00 PM). Animals were given free access to water and kept at 80%–85% of their free-feeding body weight throughout the experiments. Experiments were carried out between 10:00 AM and 17:00 PM.

Surgical procedures The rats were anesthetized with sodium pentobarbital (35 mg/kg, ip), and fixed in a stereotaxic apparatus (Narishige, SR-5, Tokyo, Japan). Two guide cannulas made of stainless steel tubing (700 μm in outer diameter), were implanted bilaterally into the ventral hippocampus according to the following coordinates measured from the bregma: antero-posterior: -4.52 mm; medio-lateral: ±5.0 mm; dorso-ventral: 8.0 mm from the skull surface. The cannula was fixed to the skull with three screws and dental acrylic.

A stylet was inserted into the cannula to keep it patent prior to injections. At least 10 d were allowed for recovery from the surgery. After the behavioral tests, Evans blue (1 μL) was injected bilaterally into the ventral hippocampus and the rats were killed by decapitation. The accuracy of the injection site was carefully determined (Figure 1). Based on histological examination, data from nine rats with incorrect injections were excluded from the results.

Intracerebral microinfusion Rats were manually restrained and the stylets were carefully removed from the guide tubes. Infusion cannulae, connected via flexible polyetheretherketone tubing to 5 μL Hamilton microsyringes mounted on a microinfusion pump (KN-201, Natsume, Tokyo, Japan), were then inserted into the guide tubes. Drugs in 1 μL vehicle (0.9% saline) or 1 μL vehicle per side were infused into the ventral hippocampus at a rate of 1 μL/min. To allow absorption of the infusion bolus, infusion cannulae were left in the brain for 60 s after infusion before being replaced by the stylets.

Radial-arm maze training The apparatus used is described in our previous reports^[18,19]. The rats were familiarized with the radial maze once per day for 2 d prior to training. Food pellets (45 mg each, Bio-Serv, Frenchtown, NJ, USA) were scattered over the entire maze surface, and three or four rats were simultaneously placed in the maze and allowed to explore and take food freely for 10 min. After adaptation, all rats were trained with one trial per day. In each trial, only 4 arms (3, 5, 6, and 8) were baited, and the sequence was never changed throughout the experiment. The rat was placed on the center platform that was closed off by a door. After 15 s, the door was opened and the rat was allowed to make an arm choice to obtain food pellets until all 4 pellets had been eaten

Figure 1. Schematic of the locations of the tips of injection cannulae in rats (closed circles). The numbers beside each brain section show the antero-posterior distance (mm) from bregma.

or 5 min had elapsed. The number of entries into never-baited arms was regarded as reference memory error (RME), whereas re-entry into arms where the pellet had already been eaten was considered as working memory error (WME). Rats continued training until reaching a criterion of less than 1 error per trial for 5 consecutive trials. Once a rat reached criterion, training for that rat was reduced to 2 trials per week until all rats reached criterion (range 35–50 d). After each trial, the maze was wiped clean using paper towels that were dampened with 10% ethanol and rotated 180°.

Drugs During the drug test, (+) MK-801 hydrogen maleate (Sigma, St Louis, MO, USA), histamine dihydrochloride (Sigma), cimetidine dimaleate (Sigma), or pyrilamine dihydrochloride (Sigma) were dissolved in saline and injected bilaterally into the ventral hippocampus. Histidine monohydrochloride (Sigma) was dissolved in saline and injected ip. Studies for drug effects were carried out once a week, on Tuesday or Friday.

Statistics All results are expressed as mean±SEM. Statistical significance was assessed by one-factor analyses of variance (ANOVA) or the Kruskal-Wallis non-parametric ANOVA test (when the data were not normally distributed or the variances of the groups differed significantly), followed by Dunnett’s test or the Mann-Whitney *U* test as a *post hoc* analysis. The software SPSS 11.5 (SPSS, Chicago, IL, USA) was used. *P*<0.05 was considered statistically significant.

Results

Effect of MK-801 on memory retrieval as evaluated by 4-arm baited radial maze performance Non-parametric ANOVA (Kruskal-Wallis) showed that bilateral ih injection of MK-801 caused a significant impairment of working memory and reference memory {WME: $H[3]=13.873, P=0.003$;

Figure 2. Effect of bilateral intrahippocampal injection of MK-801 on spatial memory of rats in the 8-arm radial maze. MK-801 was injected 10 min before the maze test. Each value represents the mean±SEM from 15–18 rats. ^c*P*<0.01 vs Saline-treated group. WME: working memory errors; RME: reference memory errors.

RME: $H[3]=25.161, P<0.01$ }. MK-801 at a dose of 0.1 µg/site slightly increased the memory error, but this was not significant (Mann-Whitney *U* test; WME: *P*=0.335; RME: *P*=0.145). At a dose of 0.3 µg/site it significantly increased the number of both WME and RME (Mann-Whitney *U* test; *P*<0.01; Figure 2). However, at a dose of 0.5 µg/site MK-801 did not significantly impair spatial working or reference memory (Mann-Whitney *U* test; WME: *P*=0.338; RME: *P*=0.061).

Effects of histamine and histidine on MK-801-induced memory deficits Intrahippocampal injection of histamine antagonized the effects of MK-801 {WME: $H[3]=8.846, P=0.031$; RME: $H[3]=8.004, P=0.044$ }. At doses of 25 or 50 ng/site it significantly decreased the number of RME (Mann-Whitney *U* test; *P*<0.05; Figure 3), whereas histamine at a dose of 50 ng/site significantly decreased the number of WME (Mann-Whitney *U* test; *P*<0.05; Figure 3). Intraperitoneal injection of histidine produced an effect similar to histamine (WME: $H[3]=11.314, P=0.010$; RME: $H[3]=20.415, P<0.01$). At doses of 25, 50 or 100 mg/kg, histidine significantly inhibited MK-801-induced spatial reference memory

Figure 3. Effects of histamine on memory deficits induced in 8-arm radial maze performance by MK-801 injected into ventral hippocampus. MK-801 was injected ih 10 min before the maze test. Histamine was injected ih 15 min before the test. Each value represents the mean±SEM from 15–18 rats. ^b*P*<0.05 vs Saline-treated group. ^c*P*<0.05 vs MK-801+Saline-treated group. WME: working memory errors; RME: reference memory errors.

deficits (Mann-Whitney *U* test; $P < 0.01$; Figure 4). It significantly reversed the spatial working memory deficit induced by MK-801 only at the dose of 100 mg/kg (Mann-Whitney *U* test; $P < 0.01$; Figure 4).

Figure 4. Effects of histidine on memory deficits in 8-arm radial maze performance induced by MK-801 injected into ventral hippocampus. MK-801 was injected ih 10 min before the maze test. Histidine was injected ip 1 h before the test. Each value represents the mean±SEM from 15–18 rats. ^c $P < 0.01$ vs Saline-treated group. ^f $P < 0.01$ vs MK-801+Saline-treated group. WME: working memory errors; RME: reference memory errors.

Effects of pyrilamine and cimetidine on memory amelioration of histidine on MK-801-induced memory deficits

Intrahippocampal injection of pyrilamine, a representative central histamine H₁ antagonist, significantly antagonized the ameliorating action of histidine on RME ($H[3]=7.811$, $P=0.04$) at doses of 0.5 and 1.0 µg/site (Mann-Whitney *U* test; $P < 0.05$; Figure 5), but not on WME. In addition, cimetidine, a histamine H₂ antagonist, at the high dose of 2.5 µg/site, also significantly antagonized the ameliorating action of histidine on RME (Mann-Whitney *U* test; $P < 0.05$; Figure 5), but not on WME (Mann-Whitney *U* test; $P=0.974$).

Discussion

Previously, we observed that bilateral injection of MK-

Figure 5. Effects of bilateral intrahippocampal (ih) injection of pyrilamine and cimetidine on the amelioration by histidine (100 mg/kg, ip) of MK-801-induced memory deficits in rats. MK-801 was injected ih 10 min before the maze test. Pyrilamine and cimetidine were injected ih 5 min before MK-801 treatment. Histidine was injected ip 50 min before MK-801 treatment. Each value represents the mean±SEM from 15–18 rats. ^b $P < 0.05$ vs Saline-treated group. ^e $P < 0.05$ vs MK-801+Saline-treated group. ^h $P < 0.05$ vs MK-801+Histidine+Saline-treated group. WME: working memory errors; RME: reference memory errors.

801, an NMDA receptor antagonist, into the dorsal hippocampus impaired both working and reference memory^[18]. Our present results are consistent with previous studies as assessed by performance in the 8-arm (4-arm baited) radial maze. We found that blockade of NMDA receptors in the ventral hippocampus impaired the retrieval of spatial working and reference memory, which suggested that the ventral hippocampus might be involved in the spatial memory process in rats^[9,20], although a chemical lesion study demonstrated that the ventral hippocampus was less involved in spatial memory modulation^[5,7]. The different findings may arise from the different experimental procedures (eg using the Morris water maze, the T-maze, and the 8-arm maze). In addition, the lesion method is less specific than local delivery of compounds.

Intrahippocampal application of MK-801 (0.3 µg/site) did not lead to obvious changes in running time per choice (locomotor activity) or other behaviors, such as ataxia (data not shown), which usually occurs after systemic or intracerebroventricular (icv) treatment with MK-801^[16]. However, we found that MK-801 at a dose of 0.5 µg/site did not impair spatial memory. A few rats exhibited epileptic symptoms or even died when given a dose of 0.5 µg/site, phenomena resembling those following systemic or icv treatment with MK-801^[16]. Therefore, we used MK-801 (0.3 µg/site) to induce the spatial memory deficits in the following experiments.

Both histamine and histidine ameliorated the memory retrieval deficits induced by MK-801, including working memory and reference memory. Intraperitoneal injection of histidine significantly increased histamine levels in the cortex and hippocampus (data not shown). This was consistent with previous studies showing that ip or icv injection of histidine increased hippocampal histamine levels^[11,12]. Our results were consistent with previous findings in which MK-801 was delivered to the dorsal hippocampus^[18]. In addition, Chen *et al* reported that histidine at higher doses of 200, 500, and 1 000 mg/kg improved the impairment of radial maze performance induced by MK-801 (0.1 mg/kg)^[14]. Our results indicate that histidine at lower doses (25, 50 and 100 mg/kg) can ameliorate the impairment induced by MK-801. The difference can be attributed to the different injection routes, different species, and different learning models. But these present results at least suggest that ventral hippocampal histamine may participate in the amelioration of both short-term and long-term spatial memory deficits.

In the present study, the amelioration of reference memory elicited by histidine was completely reversed by pyrilamine, a central histamine H₁ antagonist. However, this result is different from those for the dorsal hippocampus in that pyrilamine infused into the ventral hippocampus produced no appreciable inhibition of the amelioration of working memory by histamine. This result suggests that the ameliorating effect of histidine on the working memory deficit induced by MK-801 is independent of histamine. Histamine can act directly on the NMDA receptor, as suggested by Bekkers^[15] and Vorobjev *et al*^[17]. Because the polyamine site of the NMDA receptor may be a binding site for histamine^[21], the facilitating effect of histidine on MK-801-induced working memory deficit may be attributed to histamine acting directly on this site. So far, we have no explanation of why histamine H₁ receptors in the dorsal and ventral hippocampus have different actions. We previously reported that the improvement of both working and reference memory induced by

dorsal hippocampal histamine were antagonized by pyrilamine^[18]. Our present data, at least in part, suggest that the histamine H₁ receptors in the dorsal and ventral hippocampus participate in different components of memory. Histamine H₁ receptors in the dorsal hippocampus are involved in both working and reference memory, but those in the ventral hippocampus are mainly related to reference memory.

Moreover, we were surprised to find that cimetidine, a histamine H₂ antagonist, also blocked histamine-induced amelioration of reference memory. So far, most reports show that histamine H₂ receptors are less involved in the learning and memory process^[18,19,21,22]. For example, the ameliorating effect of histamine on scopolamine-induced learning deficit is antagonized by pyrilamine but not by the selective histamine H₂ antagonists cimetidine and zolantidine^[10,11]. Intracerebroventricular injection of the histamine H₁ agonist, 2-thiazolylethylamine, but not the histamine H₂ agonist, 4-methylhistamine, reverses the working memory deficits induced by MK-801 as evaluated by the 8-arm baited radial maze in rats^[14]. However, Flood *et al* have recently reported that increased histamine H₁ and H₂ receptor activity in the septum facilitated memory retention, whereas decreased histamine receptor activity resulted in impaired memory processes as evaluated by T-maze behavior^[23]. Giovannini *et al* also provided evidence that bilateral post-training injection of the histamine H₂ agonist amthamine into the dorsal hippocampus improved memory consolidation^[24]. These findings combined with our present data suggest that the histamine H₂ receptor in certain brain regions may be involved in learning behavior. Further experiments are needed to elucidate the function of the histamine H₂ receptor.

In conclusion, histamine in the ventral hippocampus is involved in spatial memory, and histamine ameliorates the memory deficits of both working memory and reference memory induced by MK-801. The ameliorating action on reference memory is mediated by postsynaptic histamine H₁ and H₂ receptors, whereas the effect of histamine on working memory may be mediated by other neuronal pathways.

Abstract

Aim: To investigate the neuroprotective effect and mechanisms of scutellarin, a flavonoid extracted from *Erigeron breviscapus* Hand Mazz, against neuronal damage following cerebral ischemia/reperfusion. **Methods:** Rats were pretreated ig with scutellarin for 7 d and then subjected to cerebral ischemia/reperfusion (I/R) injury induced by a middle cerebral artery occlusion (MCAO). The infarct volume and neurological deficit were determined by TTC staining and Longa's score. The permeability of the blood-brain barrier was evaluated by measurement of the Evans blue (EB) content in the brain with a spectrophotometer. The total NOx content was determined. Nitric oxide synthase (NOS) isoforms (iNOS, eNOS, nNOS) and the key angiogenic molecules, vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF), were detected by Western blotting. **Results:** Scutellarin significantly reduced infarct volume ($P < 0.05$ or $P < 0.01$), ameliorated the neurological deficit and reduced the permeability of the blood-brain barrier (BBB) ($P < 0.05$). When rats were pretreated with scutellarin (50 or 75 mg/kg), upregulation of eNOS expression and downregulation of VEGF, bFGF, and iNOS expression was observed, whereas scutellarin had no effect on nNOS expression. **Conclusion:** Scutellarin has protective effects for cerebral injury through regulating the expression of NOS isoforms and angiogenic molecules.

Introduction

Cerebral ischemia is accompanied by a marked inflammatory process, which is initiated by higher levels of expression of cytokines, adhesion molecules, and other inflammatory mediators, including nitric oxide^[1,2]. Recent studies have demonstrated that nitric oxide (NO) and pro-inflammatory cytokines released by microglial cells, which act as resident macrophage-like cells in the brain, are partly responsible for neuronal cell death. NO levels are associated directly with the development of brain injury in strokes and other neuro-pathological disorders in humans^[3,4].

Following acute ischemic or hypoxic injury to the brain, over-entry of Ca²⁺ into cells causes the activation of nitric oxide synthase (NOS), which catalyzes an enzymatic reaction, leading to the synthesis of nitric oxide^[5–7]. Three kinds of distinct NOS isoforms have been identified, including neu-

ronal nNOS, endothelial eNOS, and an inducible isoform, iNOS, originally isolated from macrophages. nNOS and eNOS are constitutively expressed and calcium-dependent, whereas iNOS is expressed in response to various inflammatory stimuli, and its activity is independent of intracellular calcium concentrations. NO can be neuroprotective or neurotoxic during cerebral ischemia, depending on the NOS isoform involved. eNOS produces NO with beneficial effects (vasodilation, inhibition of platelet aggregation and polymorphonuclear neutrophil adhesion)^[7–9], whereas NO overproduction by nNOS or iNOS during ischemia is cytotoxic. Based on these findings, it thought that the NO-synthases could be attractive targets for treating cerebral ischemia-induced neuronal damage^[10,11].

Scutellarin, a flavonoid, is the major active ingredient extracted from *Erigeron breviscapus* Hand Mazz, a plant used in Chinese herbal medicine, which is a Ca²⁺-channel-block-

ing agent used for the clinical treatment of cerebrovascular disorders. Studies have demonstrated the protective effects of scutellarin on brain injury induced by cerebral ischemia/reperfusion (I/R) through interaction with a wide variety of targets because of its anti-oxidative and anti-inflammatory actions, and its ability to attenuate neuronal damage^[12,13]. It is presumed that these effects might be related to the effects of scutellarin on the NO synthases. Therefore, the objective of the present study was to elucidate the effects of scutellarin on the expression of the NOS isoforms (iNOS, eNOS, nNOS) in a model of cerebral I/R in rats. Moreover, the key angiogenic molecules, vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF), were also studied.

Materials and methods

Chemicals and drugs Scutellarin was supplied by Yuxi Pharmaceuticals (Kunming, China). The purity of this compound was more than 96% and it was dissolved in saline before use. 2,3,5-Triphenyltetrazolium chloride (TTC, No 20010201) was obtained from the Shanghai Chemical Agent Company. All other chemicals and solvents were of analytical grade.

Animal treatment and administration Male Sprague-Dawley rats (Grade II, Certificate No 19-050), weighing 230–280 g, were obtained from the Experimental Animal Center of Tongji Medical College. Rats were housed at a constant temperature of 22 °C under a 12 h light-dark cycle with free access to food and drinking water. Rats were divided into 5 groups. The sham-operated and vehicle-treated I/R groups were pretreated with 0.5 mL/kg ig saline for 7 d before ischemia, and the scutellarin-treated I/R groups were pretreated with 25, 50, 75 mg/kg ig scutellarin for 7 d before ischemia.

Cerebral I/R procedure Rats were anesthetized with chloral hydrate (300 mg/kg, ip). Brain I/R injury was induced by a middle cerebral artery occlusion (MCAO) as described previously^[14]. Briefly, the right common carotid artery, external carotid artery (ECA) and internal carotid artery (ICA) were isolated via a ventral midline incision. A 50 mm length of monofilament nylon suture (ϕ 0.22–0.24 mm), with its tip rounded by heating near a flame, was introduced into the ECA lumen and advanced into the ICA for a distance of 18–20 mm in order to block the origin of the MCA. The body temperature of the rats was maintained at 36.5–37.5 °C during the surgical procedure with an infra red heat lamp. Sham-operated animals were not exposed to I/R. After 2 h of ischemia, the nylon suture was withdrawn to establish reperfusion. After arousal from anesthesia, the rats were returned to the cages.

Behavioral testing and measurement of infarct area After 24 h reperfusion, the neurological deficit score of each rat

was obtained according to Longa's method^[14] by a single experimenter, who was blinded to the experimental treatment groups. The neurological findings were scored on a 5-point scale: no neurological deficit=0, failure to extend right paw fully =1, circling to right=2, falling to right=3, did not walk spontaneously and had depressed levels of consciousness=4. Then the rats were anesthetized with 10% chloral hydrate (350 mg/kg) ip and subsequently decapitated. The brains were removed for measurement of infarct volume by using the TTC staining method. Five thin sections were selected from the thick slices at 2 mm intervals (from the anterior 5 mm to the anterior 13 mm) to determine the infarct areas. The slices were immersed in 2% triphenyltetrazolium chloride in saline and incubated at 37 °C for 20 min, and then fixed with 10% formaldehyde (Sigma) neutral buffer solution (pH 7.4). At that time, the infarct tissue was unstained, whereas the normal part was stained red. Using a computerized image analysis system (NIH Image, Version 1.61), the infarct areas on each slice were summed and multiplied by slice thickness to give the infarct volume, and then expressed as the percentage of infarction per ipsilateral hemisphere.

Evaluation of permeability of blood-brain barrier The integrity of the blood-brain barrier (BBB) was investigated using Evans blue (EB) dye extravasation, according to the method of Matsuo *et al*^[15]. Briefly, after 6-h reperfusion, the rats were treated with EB dye (2% in saline, 3 mg/kg iv). After 45 min, the rats were anesthetized with 10% chloral hydrate (350 mg/kg ip) and then the rats' chests were subsequently opened. Physiological saline was perfused through the left ventricle until a colorless perfusion fluid was obtained from the right atrium. The cranial vault was opened, and the brain was removed, weighed (wet tissue) and placed in a 50% trichloroacetic acid solution. After homogenization and centrifugation, the supernatant (extracted dye) was diluted with ethanol (1:3) and its fluorescence was determined (excitation at 620 nm and emission at 680 nm) with a luminescence spectrometer (Hitachi, Tokyo, Japan). Calculations of the amount of EB dye in the tissue were based on a linear standard curve and were expressed per gram of tissue.

Determination of total NO_x content in brain tissue At the end of 2 h ischemia and 24 h reperfusion, the rats were decapitated and the ischemic hemispheres were removed for assay of the NO level in ischemic brain tissue. The levels of metabolic products (NO₂ and NO₃) *in vivo* were determined by using a chemiluminescent NO detector (Siever 280i) as described previously^[16].

Western blot analysis Western blot analysis was performed after 24 h reperfusion. The rats' brains were removed and the ischemic hemispheres were used for assay of the protein ex-

pression of iNOS, eNOS, nNOS, VEGF and bFGF. The hippocampus and the cortex were quickly isolated and rinsed in sterilized water on ice, and then stored at -80°C until use. Protein determination was performed according to the Lowry method. The obtained protein samples were subjected to 15% sodium dodecylsulfate-polyacrylamide gel electrophoresis, using 7.5%–15% polyacrylamide gel, and electrotransferred to polyvinylidene difluoride filter (PVDF) membranes. To reduce non-specific binding, the PVDF was blocked for 2 h at room temperature with 5% non-fat milk in phosphate-buffered saline (PBS). Then membranes were incubated overnight at 4°C with the primary antibodies for iNOS (anti-rabbit iNOS mouse monoclonal antibody, 1:200 dilution, Santa Cruz), eNOS (anti-human eNOS rabbit polyclonal antibody, 1:200 dilution, Affinity Bioreagents), nNOS (anti-human nNOS rabbit polyclonal antibody, 1:200 dilution, Sanying Biotechnology), VEGF (antihuman VEGF rabbit polyclonal antibody, 1:200 dilution, Santa Cruz) or bFGF (anti-human bFGF rabbit polyclonal antibody, 1:500 dilution, Santa Cruz), respectively. After incubation with the antibodies, the membranes were washed with PBS-Tween-20 (PBS-T: 10 mmol/L phosphate buffer, pH 7.4, 150 mmol/L NaCl, 0.05% Tween 20) for 30 min and incubated in the relevant horseradish peroxidase-conjugated secondary antibody (1:600 dilution) for 30 min. The membranes were washed again with PBS-T and immunoreactive protein bands were visualized using the enhanced chemiluminescence detection system.

Statistical analysis Data are expressed as mean \pm SD and analyzed by using Microsoft Excel 2002. Statistical analyses were performed by using Student's *t*-test. $P < 0.05$ was considered significant.

Results

Effects of scutellarin on the infarct area, neurological score and the permeability of the blood-brain barrier Scutellarin (50 or 75 mg/kg) significantly reduced the infarct area and ameliorated the neurological deficit ($P < 0.05$ or $P < 0.01$ vs vehicle-operated group) (Table 1). The EB content of brain tissue after I/R for sham-operated, vehicle-operated and scutellarin-operated groups (25, 50, or 75 mg/kg) was 3.83 ± 1.03 , 8.45 ± 1.67 , 7.45 ± 1.77 , 5.02 ± 1.12 , and 4.45 ± 1.05 , respectively (Figure 1). There was a significant increase in the permeability of the BBB in rats in the vehicle-treated group compared with the sham-treated group ($P < 0.01$). Scutellarin (50 or 75 mg/kg) obviously inhibited the increased EB content induced by cerebral I/R, and there was no obvious difference between the 2 doses.

Effects of scutellarin on total NO_x production After cerebral I/R, total NO_x production, as determined by NO_x content in the ischemic brain hemispheres, was markedly in-

Table 1. Effects of scutellarin on the cerebral infarct area and neurological score after 2 h ischemia and 24-h reperfusion (I/R) in rats. $n=6$. Mean \pm SD. ^b $P < 0.05$, ^c $P < 0.01$ vs vehicle-operated group (I/R+NS).

Groups	Dose/ mg·kg ⁻¹	Ratio of infarct area/%	Neurological score (on a 5-point scale)
Sham	0	–	–
Vehicle	0	31.26 ± 6.02	2.92 ± 1.27
I/R+scutellarin	25	25.63 ± 5.12	1.93 ± 0.84
	50	18.23 ± 3.63^b	1.32 ± 0.65^b
	75	9.24 ± 4.11^c	0.92 ± 0.64^c

Figure 1. Effects of scutellarin on the blood-brain barrier after 2-h ischemia and 6-h reperfusion. See legend of Table 1 for rat treatments. Scu25, 50, and 75 correspond to 25, 50, and 75 mg/kg scutellarin, respectively. Mean \pm SD. $n=6$. ^b $P < 0.05$, ^c $P < 0.01$ vs sham. ^e $P < 0.05$, ^f $P < 0.01$ vs vehicle (I/R+NS).

creased in the vehicle rats (4.87 ± 0.90) compared with the sham-treated rats (1.83 ± 0.34) ($P < 0.01$, Figure 2). Total NO_x production in rats pretreated with scutellarin at concentrations of 50 or 75 mg/kg (3.01 ± 0.68 , 2.31 ± 0.48), were significantly reduced compared with the vehicle-operated group ($P < 0.05$ or $P < 0.01$, respectively) (Figure 2).

After 24 h reperfusion, the expression levels of iNOS, eNOS and nNOS were detected in the hippocampus and in the cortex, with molecular masses of 130, 140, 160 kDa, respectively. In the vehicle-treated group, the expression levels of the 3 NO synthases in the hippocampus and in the cortex markedly increased after cerebral I/R ($P < 0.01$ or $P < 0.05$, Figure 3A, 3B, lane 2). Densitometric analysis showed that the protein levels of eNOS and iNOS in the scutellarin-treated (50 or 75 mg/kg) rats were $368.0 \pm 70.3\%$ and $278.0 \pm 56.6\%$ in the hippocampus (Figure 3A, lanes 3, 4), and $198.1 \pm 19.2\%$ and $148.3 \pm 17.6\%$ in the cortex

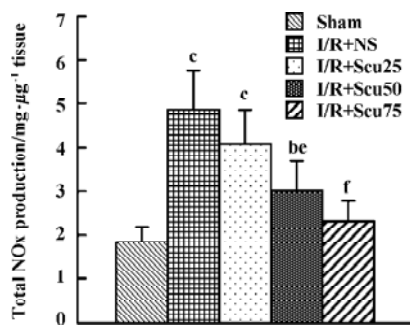

Figure 2. Effect of scutellarin on the total NOx production after 2 h ischemia and 24 h reperfusion. See legend of Table 1 for rat treatments. Scu25, 50, and 75 correspond to 25, 50, and 75 mg/kg scutellarin, respectively. $n=6$. Mean \pm SD. ^b $P<0.05$, ^c $P<0.01$ vs sham. ^e $P<0.05$, ^f $P<0.01$ vs vehicle (I/R+NS). Effects of scutellarin on expression of the 3 NOS isoforms (iNOS, eNOS, nNOS) and the angiogenic molecules (VEGF and bFGF).

(Figure 3B, lane 3, 4) for iNOS; and 469.0% \pm 40.5% and 523.0% \pm 67.3% in the hippocampus (Figure 3A, lanes 3, 4), and 188.3% \pm 31.2% and 234.2% \pm 37.8% in the cortex (Figure 3B, lanes 3, 4) for eNOS, respectively. The data indicate that scutellarin downregulated the expression of iNOS and simultaneously upregulated that of eNOS as compared with the vehicle-operated group ($P<0.05$ or $P<0.01$, respectively), whereas there was no difference in nNOS expression in the hippocampus or the cortex between the vehicle-treated and scutellarin-treated rats.

Immunoblot analysis showed single bands with molecular masses of approximately 39 and 18 kDa, which correspond to VEGF and bFGF in the hippocampus and in the cortex, respectively. The bands obtained from the vehicle-operated I/R rats (VEGF: 278.2% \pm 43.4% in the hippocampus and 256.7% \pm 36.8% in the cortex; bFGF: 432.2% \pm 50.4% in the hippocampus and 289.4% \pm 49.7% in the cortex) (Figure 3C, 3D, lane 2) were stronger than those from the sham group rats (VEGF: 111.9% \pm 24.2% in the hippocampus and 123.9% \pm 16.1% in the cortex; bFGF: 98.8% \pm 15.4% in the hippocampus and 98.8% \pm 10.9% in the cortex) (Figure 3C, 3D, lane 1, $P<0.01$). Scutellarin at doses of 50 or 75 mg/kg (Figure 3C, 3D, lanes 3, 4) significantly decreased the expression of VEGF and bFGF in the hippocampus and in the cortex, as compared with the vehicle-operated group ($P<0.05$ or $P<0.01$). When rats were pretreated with scutellarin at a concentration of 50 or 100 mg/kg, the VEGF protein levels in the hippocampus were 189.8% \pm 35.4% and 123.5% \pm 30.1%, whereas in the cortex they were 178.2% \pm 22.1% and 145.7% \pm 11.9%, respectively; bFGF protein levels in the hippocampus were 212.9% \pm 33.2% and 134.5% \pm 19.1%, while in the cortex they were 212.9% \pm 30.4% and 145.6% \pm 17.6%, respectively.

Discussion

In the present study, we demonstrated that scutellarin (at doses of 50 or 75 mg/kg) significantly reduced infarct volume, ameliorated the neurological deficit and reduced the permeability of the BBB after cerebral I/R. Therefore, the conclusions obtained from the above observations were that scutellarin has protective effects for the neuronal damage induced by cerebral I/R in rats.

Evidence has accumulated that NO produced both before and after cerebral ischemia may be an important factor in the pathogenesis of neuronal ischemic injury. NO is a signaling molecule that regulates many biological processes in the brain. The present paper also investigated the effects of scutellarin on the total NOx content in rat brain tissues after cerebral I/R. Our results showed that total NOx production, as determined by NOx content, in the ischemic brain hemispheres was markedly increased in cerebral I/R rats, which indicates that NO regulates the severity of cerebral ischemic injury. However, NOx content markedly decreased in brain tissues after treatment with scutellarin at doses of 50 or 75 mg/kg.

Numerous studies have been conducted regarding the differential roles of NOS isoforms and their temporal NO production in the pathogenesis of ischemic brain injury^[17-19]. eNOS-derived NO is thought to be beneficial for promoting collateral circulation and microvascular flow, whereas nNOS- and iNOS-derived NO is detrimental in the ischemic brain. NO is a nontoxic agent and acts as a second messenger in normal brain; however, in the presence of O₂⁻, NO reacts with O₂⁻ to form ONOO⁻ or nitrogen dioxide (NO₂⁻), causing injury to the mitochondrial electron transport system, resulting in neuronal damage. In addition, excess NO stimulates ADP ribosyltransferase and binds closely to iron-sulfur centers of enzymes, including enzymes involved in the mitochondrial electron transport chain and the tricarboxylic acid cycle (TCA), and DNA^[20-22]. In view of the detrimental and beneficial roles of NOS isoforms in ischemic brain injury, further investigations into the effect of scutellarin on the expression of NOS isoforms (iNOS, eNOS, nNOS) both in the hippocampus and in the cortex after cerebral I/R were also performed in the present study. We found that expression of the NO-synthases in the hippocampus and cortex all markedly increased after cerebral I/R in the vehicle-operated group, a similar finding to those of previously studies^[22-26]. Scutellarin at doses of 50 and 75 mg/kg downregulated iNOS expression and upregulated eNOS expression, which partly account for its protective effect on brain damage induced by cerebral I/R.

Increasing evidence has shown that some angiogenic molecules, including VEGF and bFGF, increase in concentration after cerebral I/R. VEGF is an angiogenesis and vascu-

Figure 3. Western blot analysis of the effect of scutellarin on the expressions of NO synthase isoforms and angiogenic molecules both in the hippocampus and in the cortex after 2 h ischemia and 24 h reperfusion in rats. lar permeability factor that undergoes transcriptional and post-transcriptional induction by hypoxia; it couples hypoxia to angiogenesis in diverse tissues, including the brain^[23-26]. VEGF may also play an important role in the vascular response to cerebral ischemia, because ischemia stimulates VEGF expression in the brain, which promotes the formation of new cerebral blood vessels^[27,28]. It is thought that eNOS is involved in mediating the angiogenic molecules (VEGF and bFGF). Both factors induced eNOS expression, so eNOS

may be a downstream messenger in their angiogenic action. In the present study we also investigated the expression of the angiogenic molecules VEGF and bFGF in the hippocampus and in the cortex. In agreement with the results of previous reports^[29,30], our data showed that the expression of VEGF and bFGF in the hippocampus and cortex were upregulated in the vehicle-operated group after cerebral I/R. Scutellarin downregulated the expression of VEGF and bFGF. Further study is needed to shed light on the mechanisms involved in

the effect of scutellarin on the expression of eNOS (upregulation) and VEGF (downregulation) in I/R brain tissue.

In conclusion, scutellarin alleviated hippocampal neuronal dysfunction after cerebral I/R. This alleviation was accompanied by the effects of the molecular features of NOS isoforms and angiogenic molecules. These findings suggest that scutellarin exerts neuroprotective effects on brain injury induced by cerebral I/R, which allows a better understanding regarding the potential clinical therapeutic use of scutellarin.

Abstract

Aim: Advanced glycation endproducts (AGE) have been implicated in the pathogenesis of diabetic complications, including diabetic cardiovascular dysfunction. 3-[2-(4-Bromo-phenyl)-1-methyl-2-oxo-ethyl]-4,5,6,7-tetrahydro-benzothiazol-3-ium bromide (C16), a novel AGE breaker, was investigated for its effects on the development of cardiovascular disease in diabetic rats. **Methods:** Rats that had streptozotocin-induced diabetes for 12 weeks were divided into groups receiving C16 or vehicle by gavage. **Results:** In hemodynamic studies of the left ventricle, C16 treatment (25 or 50 mg/kg) for 4 weeks resulted in a significant increase in left ventricular systolic pressure, $+dp/dt_{max}$, and $-dp/dt_{max}$ as compared with vehicle-treated diabetic rats. Furthermore, in hemodynamic studies of the cardiovascular system, C16 (12.5, 25, or 50 mg/kg) treatment for 4 weeks resulted in a dose-dependent and significant increase in cardiac output, a reduction of total peripheral resistance, and an increase in systemic arterial compliance when compared with vehicle-treated diabetic rats. Biochemical studies showed that C16 treatment also resulted in a significant decrease in immunoglobulin G-red blood cell surface crosslink content and an increase in collagen solubility. Morphological and immunohistochemical examinations indicated that C16 was able to prevent increases of the collagen type III/I ratio in the aorta and decrease the accumulation of AGE in the aorta. **Conclusion:** C16 has the ability to reduce AGE accumulation in tissues *in vivo*, and can restore diabetes-associated cardiovascular disorders in rats. This provides a potential therapeutic approach for cardiovascular disease associated with diabetes and aging in humans.

Introduction

Glucose and other reducing sugars react with proteins by a series of reactions to form a class of heterogeneous, nonenzymatic sugar-amino adducts that are called advanced glycation endproducts (AGE)^[1,2]. Numerous studies have indicated that the formation of AGE in long-lived connective tissue and matrix components is a causative factor in the development of diabetic complications and diseases associated with aging^[3-6]. In the cardiovascular system, the accumulation of AGE on structural tissue proteins is one of the main mechanisms underlying cardiovascular stiffness^[7,8]. Recently, a number of natural or synthetic compounds that

target AGE, including AGE inhibitors and breakers, have been discovered and are being further developed^[9-11]. Amino-guanidine (AG) was the first compound designed to inhibit AGE formation and cross-linking *in vitro* and *in vivo*, and is currently undergoing phase III clinical trials^[12,13]. ALT-711, a well-known AGE breaker, has also been reported to be effective in *in vitro* and animal studies, and is currently undergoing phase II clinical trials^[14-19]. Therefore, treatment targeting AGE is believed to be a potential effective therapeutic option for cardiovascular dysfunction^[10].

Based on the hypothesis that AGE crosslinks could be cleaved with N-phenacylthiazolium bromide^[20], the lead compound ALT-711, novel AGE breakers were synthesized in

our laboratory by using computer-aided drug design. Preliminary biological screening tests demonstrated that 3-[2-(4-bromo-phenyl)-1-methyl-2-oxo-ethyl]-4,5,6,7-tetrahydro-benzothiazol-3-ium bromide (C16; Figure 1) had the ability to break AGE crosslinks *in vitro*^[21]. C16 produced a concentration-dependent release of bovine serum albumin (BSA) from preformed AGE-modified BSA (AGE-BSA)-collagen complexes and C16 treatment decreased the red blood cell (RBC)-immunoglobulin G (IgG) crosslinks (unpublished data). Therefore, the aim of the present study was to investigate the effects of C16 on the cardiovascular system in experimental diabetic rats. Furthermore, the action site of C16 *in vivo* was explored by comparison with that of ALT-711.

Materials and methods

Reagents and compounds 3-[2-(4-Bromo-phenyl)-1-methyl-2-oxo-ethyl]-4,5,6,7-tetrahydro-benzothiazol-3-ium bromide (C16), whose structure (Figure 1) was identified by nuclear magnetic resonance spectroscopy-mass spectroscopy and elemental analysis, and ALT-711 were synthesized at the Beijing Institute of Pharmacology and Toxicology, as described previously^[21]. Streptozotocin (STZ) was purchased from Sigma. AGE antibody was kindly donated by the Beijing Institute of Radiation Medicine. All other chemicals and substances were of analytical grade unless stated otherwise.

Figure 1. Chemical structure of 3-[2-(4-bromo-phenyl)-1-methyl-2-oxo-ethyl]-4,5,6,7-tetrahydro-benzothiazol-3-ium bromide.

Animals Diabetes was induced in 9-10-week-old male Wistar rats by ip injection of 70 mg/kg of STZ after an overnight fast. Only animals that developed blood glucose levels >15 mmol/L were used. After 12 weeks of diabetes, the animals were used for studies. For the hemodynamic study of the left ventricle, diabetic rats were divided into 4 groups (8 rats in each group) to assess the exact hemodynamic changes in the left ventricle (LV) that were caused by the diabetic state. Rats were given either vehicle or 25 mg/kg per day of ALT-711, or 25 or 50 mg/kg per day of C16 (ig) for 4 weeks. In another hemodynamic study, 6 groups of diabetic rats ($n=8$) received either vehicle or 12.5 mg/kg per day of

ALT-711, or 12.5, 25 or 50 mg/kg per day of C16 (ig) for 4 weeks, or 50 mg/kg per day of C16 (ig) for 2 weeks to assess the possible reversal of diabetes-induced cardiovascular abnormalities. ALT-711 and C16 were dissolved in distilled water immediately before administration. An additional group of age-matched nondiabetic rats served as normal controls, and were observed in parallel for each study.

Hemodynamic study of the left ventricle Details regarding the surgical procedure and hemodynamic measurements have been described elsewhere^[22]. In summary, animals were anesthetized with 50 mg/kg of pentobarbital (ip). A fluid-filled catheter was introduced through the right carotid artery into the left ventricle. Tracings of LV pressure were digitized at a rate of 2000 samples/s with a commercially available analog-to-digital converter (MP150WS, BIOPAC Systems) and a personal computer using dedicated software (Acknowledge, Version 3, BIOPAC Systems). The digitized LV pressure recording was used to calculate the maximal rate of pressure rise ($+dp/dt_{max}$) and the maximal rate of pressure fall ($-dp/dt_{max}$).

Hemodynamic study of cardiovascular system After animals were anesthetized with 50 mg/kg of pentobarbital (ip), a midsternal thoracotomy was performed, and the ascending aorta was dissected free. The pressure transducer was advanced into the ascending aorta. An adapted Doppler probe was positioned around the vessel to measure phasic aortic blood flow. The system was allowed to stabilize for 10 min before aortic blood flow and pressure were digitized at a rate of 2000 samples/s with a commercially available analog-to-digital converter and a personal computer using dedicated software. All parameters were calculated on a beat-to-beat basis for 30 s and then averaged. In steady-state conditions, measurements were obtained of systolic and diastolic blood pressure (SBP, DBP), cardiac output (CO), and heart rate (HR). Total peripheral resistance (TPR) was determined as the quotient of mean arterial blood pressure and CO^[23]. Systemic arterial compliance (SAC) was calculated from the quotient of stroke volume and pulse pressure^[24].

RBC-IgG assay Detailed methods have been described elsewhere^[14]. Briefly, blood samples were collected, before hemodynamic studies of the left ventricle and RBC-IgG determinations were performed by using an anti-IgG enzyme-linked immunosorbent assay (ELISA) adapted for use with cellulose ester membrane-sealed 96-well microtiter plates (Multiscreen-HA, Millipore). Heparinized blood was washed 3 times with phosphate-buffered saline (PBS), then the packed RBC were diluted 1:250–1:500 in PBS. Membrane-containing wells were blocked with 0.3 mL Superblock (Pierce), then washed with 0.3 mL PBS/0.05% Tween, followed by 0.1 mL

PBS. RBC were gently vortexed and 50 μ L aliquots were pipetted into wells. Cells were then washed, and 50 μ L of a polyclonal rabbit anti-rat IgG (Sigma, diluted 1:25 000) was added. After incubation at room temperature for 2 h, the cells were washed 3 times with PBS, once with Tris-buffered saline, and 0.1 mL of p-nitrophenyl phosphate substrate was added (1 mg/mL in 0.1 mol/L diethanolamine buffer, pH 9.5). The plates were read in a microplate reader (Bio-Rad 550) at 410 nm. The content of RBC-IgG was expressed as OD_{410} .

Tail tendon collagen solubility assay The solubility of tail tendon collagen was measured by using a previously reported method with modifications^[25]. Briefly, after performing a hemodynamic study on the left ventricle, the rats' tails were removed and the tail tendon was removed by gentle pulling. The tendons were cleaned of debris and fat in 0.9% NaCl over ice. The tendons were rolled into a ball, patted dry on paper towels, then lyophilized. Following lyophilization, tail tendons were stored at -70°C in desiccated sealed containers until use. Collagen samples (2 mg) were weighed and digested with pepsin (5.0 μ g pepsin/mg collagen in 0.5 mol/L acetic acid) for 2 h at 4°C . After digestion, the samples were centrifuged at $40\,000\times g$ for 60 min at 4°C . The supernatant was collected and both the volume of the supernatant and pellet were determined. Aliquots (500 μ L) of the supernatant and all of the pellets were acid hydrolyzed and analyzed for their hydroxyproline content^[26], which was assumed to make up 14% of the collagen by weight. The recoverable collagen was defined as the sum of collagen in the supernatant and pellet after digestion and percentage solubility was defined as the amount of collagen in the supernatant fraction in relation to the total recoverable collagen.

Morphological study of arterial collagen distribution

After performing the hemodynamic study on the rats' cardiovascular systems, 2 to 3 cm segments from the rats' descending thoracic aortas were fixed in 10% formalin in saline, and embedded in paraffin for morphological and immunohis-

tochemical studies. Seven-micron sections of aorta were stained with picosirius red (Direct Red 80, Aldrich, in aqueous picric acid) for 4 h. The collagen type III/I ratio for the aortic media wall was measured by using polarizing light microscopy (Nikon, E600POL) according to previously published methods^[27,28].

Immunohistochemistry for AGE Four-micron sections of aorta were used for AGE staining. Briefly, the sections were rehydrated and treated with 3% H_2O_2 /methanol followed by incubation in blocking buffer (Superblock, Pierce) for 20 min at room temperature. The sections were then incubated with the anti-AGE antibody (diluted 1:100) for 2 h at room temperature, washed in PBS, and incubated with goat anti-rabbit IgG/horse radish peroxidase (Zymed). The staining was visualized by reaction with diaminobenzidine tetrahydrochloride (Sino-American Biotechnology).

Statistical analysis All results are expressed as mean \pm SD. Statistical analysis was performed by one-way ANOVA analysis with SPSS. $P<0.05$ was considered statistically significant.

Results

Hemodynamic study of the left ventricle Left ventricular systolic pressure (LVSP), $+dp/dt_{\text{max}}$, and $-dp/dt_{\text{max}}$ were decreased significantly ($P<0.01$ vs normal control) in the vehicle-treated diabetic group (Table 1). C16 treatment did not result in significant weight or fasting blood glucose levels changes ($P>0.05$ vs vehicle-treated diabetic rats). However, treatment with C16 (25 or 50 mg/kg) for 4 weeks resulted in a significant increase in all of these 3 parameters ($P<0.05$ or $P<0.01$, Table 1) as compared with vehicle-treated diabetic rats. There was no difference between C16-treated groups (25 or 50 mg/kg) or between the C16-treated groups and the ALT-711-treated group (25 mg/kg).

comparison with the normal controls, the body weights and HR of the vehicle-treated diabetic rats were lower ($P<0.01$ and $P<0.05$, respectively), whereas the TPR and TPR index were significantly higher ($P<0.01$). CO and SAC were significantly lower ($P<0.01$ vs normal control) in vehicle-treated diabetic rats. SBP, DBP, and HR were not significantly different in the 6 groups of diabetic rats (Table 2). Treatment with C16 for 4 weeks resulted in a dose-dependent significant increase in CO and the CO index ($P<0.05$ or $P<0.01$), a reduction in TPR and the TPR index ($P<0.05$ or $P<0.01$), and an increase in SAC ($P<0.05$ or $P<0.01$) as compared with the vehicle-treated rats. After 4 weeks of treatment, similar results were found in ALT-711-treated (12.5 mg/kg) rats. The effects of C16 on the cardiovascular system resembled those of ALT-711. Treatment with C16 (50 mg/kg) for 2 weeks produced values that were slightly different from those produced by the other treatment regimen. Although the difference did not reach statistical significance for the majority of the parameters, SAC was significantly increased ($P<0.01$ vs vehicle group).

RBC-IgG assay The RBC-IgG content of normal control rats was 0.21 ± 0.01 and the content of vehicle-treated diabetic rats was 0.61 ± 0.04 ($n=6$; $P<0.01$, Figure 2). Treatment

Figure 2. Effects of C16 on IgG crosslinked to the RBC surface in diabetic rats. $n=6$. Mean \pm SD. ^c $P<0.01$ vs normal control. ^f $P<0.01$ vs vehicle.

with C16 (25 or 50 mg/kg) resulted in a significant reduction of RBC-IgG content (0.51 ± 0.06 , 0.41 ± 0.06 ; $P<0.05$, $P<0.01$, respectively) in comparison with vehicle-treated diabetic rats. ALT-711 treatment (25 mg/kg) also significantly reduced RBC-IgG (0.48 ± 0.07 , $P<0.01$).

Collagen solubility assay In comparison with normal control animals, the tail tendon collagen solubility of the vehicle-treated animals tended to fall (from $63.9\%\pm 7.3\%$ to $37.7\%\pm 10.0\%$, $P<0.01$; Figure 3). Compared with vehicle-

treated animals, collagen solubility was increased significantly after treatment with C16 (25 mg/kg, $48.0\% \pm 9.0\%$; 50 mg/kg, $56.8\% \pm 7.4\%$; $P<0.05$, $P<0.01$, respectively). ALT-711 treatment resulted in a significant increase in collagen solubility ($57.7\% \pm 6.2\%$, $P<0.01$).

Morphological study of arterial collagen distribution

When stained with picrosirius red, different types of collagen in the aortic media wall could be distinguished by polarizing light microscopy, where type I collagen appeared yellow or yellow-red, and type III collagen appeared green (Figure 4). The collagen type III/I ratio of the aortic media wall tended to be greater in rats with diabetes (Figure 4B), but C16 (50 mg/kg) and ALT-711 (12.5 mg/kg) treatment could reverse this alteration (Figure 4C, 4D).

Immunohistochemistry for AGE In comparison with normal control animals, the amount of AGE accumulated in the

aortic media wall of the vehicle-treated animals was increased. But the amount of AGE was decreased by C16 (50 mg/kg) and ALT-711 (12.5 mg/kg) treatment (Figure 5).

Discussion

Nearly a century ago, glycation was first recognized in the food industry, and became known as the Maillard reaction: a process in which food proteins crosslink and become brown with age. In the 1980s, Brownlee *et al* first described the harmful consequences of AGE formation on the cardiovascular and renal systems in humans^[1,29] and diabetic rats^[13]. Recently, it has been thought more and more likely that AGE and AGE crosslinks are linked to the development of many age- and diabetes-related disorders through structural modifications as well as receptor-mediated pathways, which activate growth factors, induce a number of processes, and initiate inflammatory reactions^[30]. Therefore, targeting AGE, especially breaking established AGE crosslinks, was considered to be a novel and promising therapeutic candidate for reversing AGE-related pathologic conditions. In the present study, rats with STZ-induced diabetes of 16 weeks duration exhibited a marked increase in AGE and an abnormal distribution of collagen type in the aorta. However, significant decreases in hemodynamic parameters, such as LV dp/dt, CO, and SAC, were also observed. These results demonstrated that AGE-related changes in structure eventually increased the stiffness of the arterial tree and myocardium, which, in turn, resulted in functional changes. Immunohistochemical assays revealed that C16, a potential AGE breaker,

Figure 4. Picrosirius red staining for collagen distribution in descending thoracic aorta from normal control (A), vehicle-treated (B), C16-treated (C), and ALT-711-treated (D) rats. Type I collagen appears yellow or yellow-red, and type III collagen appears green. $\times 200$.

Figure 5. Immunohistochemical staining for AGE in descending thoracic aorta from normal control (A), vehicle-treated (B), C16-treated (C), and ALT-711-treated (D) rats. Positive staining is shown as brown. Sections are counterstained with hematoxylin. $\times 200$.

could prevent the increase of AGE accumulation in the aortic media wall of diabetic rats, and could reverse the increase in the collagen type III/I ratio (prior studies have generally shown an association between increased collagen type III and/or the III/I ratio and the accumulation of AGE crosslinks^[31,32]). Furthermore, both the diastolic function, as indicated by $-dp/dt_{max}$, and the contractile function of LV, as indicated by LVSP and $+dp/dt_{max}$, were restored significantly by C16. The significant improvements in the hemodynamic parameters could not be attributed to differences in blood pressure, which did not change significantly during treatment as compared with the vehicle-treated diabetic group. Therefore, the improvements reflect intrinsic modifications of the mechanical properties of the arterial wall. The increase in SAC and the decrease in TPR indicates that through treatment with C16 the stiffness of the aorta was reduced to levels comparable to those observed in normal control rats. Moreover, these effects seemed to be related to the duration of the treatment, with stronger effects after 4 weeks than 2 weeks, which indicates that the effects of C16 were exerted through the pathway of structural modification by slowly breaking the established AGE crosslinks. The different approaches used in the present study consistently show that C16, a novel AGE crosslink breaker, exerted beneficial cardiovascular actions and restored diabetes-associated cardiovascular dysfunction in experimental diabetic rats by reducing AGE, and that C16 has similar effects to ALT-711, the well-known AGE breaker.

The presence of AGE crosslinks is thought to contribute to increased insolubility and resistance of collagen to enzy-

matic and chemical digestion^[25], and IgG crosslinked to RBC as a structure of AGE crosslinks is formed earlier than other AGE crosslinks *in vivo*^[14]. Thus, the susceptibility of collagen to digestion by pepsin and the IgG-RBC crosslink content have previously been used to provide 2 indexes of protein crosslinking *in vivo*^[13,20,25]. In the present study, the considerably improved solubility of collagen and decreased content of IgG crosslinked to RBC after treatment with C16 demonstrated that C16 could reduce AGE crosslinks *in vivo*.

In summary, the novel compound C16 has the ability to break established AGE crosslinks and reduce AGE accumulation in tissues *in vivo*. Furthermore, C16 can restore diabetes-associated cardiovascular dysfunction in rats. This provides a potential therapeutic approach for diabetes- and aging-related cardiovascular disease.

Abstract

Aim: To develop an easy, fast, automated, and inexpensive method for constructing short-hairpin-RNA cassettes for RNAi studies. **Methods:** Using single oligonucleotides, a variety of DNA cassettes for RNAi vectors were constructed in only few minutes in an automated manner. The cassettes, targeting the eGFP, were cloned into plasmids driven by RNA polymerase III promoter H1. Then, the plasmids were transfected into HeLa cells that were later infected with a recombinant adenovirus encoding the eGFP gene. The level of eGFP fluorescence was evaluated by confocal imaging and flow cytometry. **Results:** The plasmids constructed with the DNA cassettes made by the one-oligonucleotide method inhibited eGFP with different potencies, ranging from 55% to 75%. **Conclusion:** By using the method reported here, it is possible to simultaneously construct hundreds of different DNA cassettes for RNAi experiments in an inexpensive, automated way. This method will facilitate functional genomics studies on mammalian cells.

Introduction

RNA interference (RNAi) is a powerful tool for inhibiting gene expression in a wide variety of organisms. When double-stranded RNA is introduced into cells, the ribonuclease III Dicer processes the double-stranded RNA into small fragments of about 21 nucleotides in length (termed siRNAs) that trigger the RNAi mechanism^[1–3]. Then, the siRNAs are incorporated into a protein complex, known as the RNA-induced silencing complex (RISC), which in turn unwinds the duplex siRNA in an ATP-dependent manner^[4]. After the unwinding, RISC uses the siRNA antisense strand as a guide to specifically cleave the complementary mRNA, which is further processed for degradation^[4–6].

There are different ways to induce mRNA degradation using RNAi. Several methods for preparing siRNA have been developed, such as chemical synthesis, *in vitro* transcription, siRNA expression vectors, and polymerase chain reaction (PCR) expression cassettes. For example, short hairpin RNAs (shRNAs) transcribed by RNA polymerase III

promoter-based vectors have been used as RNAi triggers in a variety of cell lines^[7,8]. These RNA polymerase III (RNA Pol) vectors have a variety of advantages over the siRNAs. First, they greatly reduce the cost of RNAi synthesis, making RNAi a viable tool for screening the function of large numbers of genes. Second, because hairpins are transcribed inside cells, it is possible to establish inducible systems for RNAi both *in vitro* and *in vivo*^[9–11]. Third, it is also possible to generate knock-down phenotypes to resemble knock-out animals without affecting the germline, as long as this strategy is combined with inducible systems^[12–14]. Therefore, it is relatively easy to establish cell cultures using retroviral or adenoviral vectors that stably express the hairpin for RNAi^[10,15–18].

Although there has been much progress in the RNAi field, it is not completely understood why some sequences are refractory to RNAi. Some groups have investigated this lack of activity, but at present, choosing the most effective siRNA sequence to knock down an mRNA is still a trial-and-error task. Thus, it is generally accepted that several se-

quences must be designed to achieve the highest RNAi efficiency, making the silencing experiments costly and slow. It would be advantageous to have a more efficient method for the production of a wide variety of sequences in a simple step, instead of using long DNA oligonucleotides or several PCR step-specific methods^[8,19–21].

Here we describe an inexpensive, easy to implement and automated method to produce DNA cassettes for RNAi experiments using a single oligonucleotide. With this method hundreds of DNA cassettes can be synthesized in a 1-step reaction. This method not only reduces the cost of testing sequences for RNAi experiments, but also accelerates the exploration of multiple-gene sequences.

Materials and methods

Construction of DNA cassettes and plasmid vectors To construct the plasmid vector pBB4H1, the human H1 promoter was PCR amplified from human genomic DNA using the following primers: forward 5'-CCATGGAATTCGAA-CGCTGACGT-3' and reverse 5'-GCAAGCTTTGGTCTCA-TAAGAATTATAAGATTCCC-3', which contain one *EcoRI* and one *HindIII* restriction site, respectively. The PCR product was subcloned in the pDRIVE vector (Qiagen, Valencia, CA) following the manufacturer's instructions. The pDRIVE-H1 vector was then digested with *EcoRI* and *HindIII* to obtain a DNA fragment of ~230 base pairs, which contained the H1 promoter. This fragment was then cloned into the *EcoRI* and *HindIII* site of the pBlueBac4 vector (Invitrogen, Carlsbad, CA) to obtain the pBB4H1 vector.

To generate the DNA cassettes the following chemically synthesized oligonucleotides were used: hpGFP1 5'-GC-AAGCTTCCCCAAAACCACTACCTGAGCACCCAGGGGCCCC-3', hpGFP2 5'-GCAAGCTTCCCCAAAAGGGCGA-GGAGCTGTTACCGGGGCCCC-3', hpGFP3 5'-GCAAGC-TTCCCCAAAACGGCCACCAAGTTCAGCGTGGGGCCCC-3', hpGFP4 5'-GCAAGCTTCCCCAAAAGGAGGACGGC-AACATCCTGGGGCCCC-3', hpTRPC4 5'-GCAAGCTT-CCCCAAAUUACUCGUCAACAGGCGGACGGGGCC-3'. Note that the sequence upstream of the 5 A's contained the *HindIII* restriction site (underlined), followed by 4 C's, and was included in the oligonucleotide design because it allows easy cloning of the DNA cassette and allows the RNA pol III to initiate in the first of the 5 A's, exactly 30 nucleotides after the TATA box. The sequence in italics corresponds to the *eGFP* mRNA.

To construct the DNA cassettes, 10 μ L of each oligonucleotide (~35 μ mol/L) were heated for 5 min to 94 °C. When the temperature reached 40 °C, 10 μ L of a reaction mix

was added [reaction mix: 2 mmol/L dNTPs; 5 U Klenow enzyme (Invitrogen); 2 μ L 10 \times reaction buffer 2 (Invitrogen); 10% Me₂SO; H₂O to 10 μ L]. All the reactions were performed identically using a thermo-cycler to precisely control the temperatures (Figure 1).

Figure 1. Temperature sequence used in the thermocycler reaction for the construction of DNA cassettes.

Then, the Klenow products were heated to 65 °C to inactivate the enzyme, digested with *HindIII* and cloned into the *HindIII* restriction site of the pBB4H1 vector previously dephosphorylated with alkaline phosphatase (Roche, Basel Switzerland). Only the correct cassettes would be ligated into the *HindIII* cohesive ends. We did not observe clones with tandem-repeated cassettes.

The sequences targeting the *eGFP* mRNA were chosen based on 2 criteria: (i) because they had fewer than 3 G or C repeats to prevent G-quartet formation; and (ii) because they were distributed along the *eGFP* mRNA.

Cell culture and transfection HeLa cells were grown in Dulbecco's modified Eagle's medium (DMEM) containing 10% fetal bovine serum and antibiotics, and were seeded every 3 d following standard procedures at 37 °C. The day before transfection, cells were grown without antibiotics in 12 well plates. Vectors containing the DNA cassette were transfected using lipofectamine 2000 (Invitrogen) at different concentrations following the manufacturer's instructions. The day after transfection, the cells were washed once with phosphate-buffered saline (PBS) and treated with 5 MOI of a recombinant adenovirus encoding the green fluorescent protein (eGFP) gene under the transcriptional control of the cytomegalovirus (CMV) promoter^[22]. Four hours later, the cells were washed with PBS and the media was replaced. Twenty-four hours later the fluorescence was evaluated using a FACScan flow cytometer (Becton & Dickinson, Franklin Lakes, NJ). To evaluate the fluorescence intensity, 10 000 events were counted in at least 3 independent experiments for each concentration.

Confocal microscopy The HeLa cells that were treated with the plasmids and adenovirus as described were washed with PBS, trypsinized and plated on sterile coverslips.

Twenty-four hours later, the cells were analyzed with a confocal microscope (Bio-Rad, Hercules, CA) using a 40× objective. The confocal images were analyzed using the Confocal Assistant freeware software.

Results

Construction of DNA cassettes For the construction of the DNA sequence that served as a template for shRNA transcription, we followed the principle of DNA amplification commonly used in PCR reactions (Figure 2A). That is, any given sequence that serves as a primer could be amplified at its 3' end with a proper DNA polymerase. In RNAi hairpins, the 2 strands that form the stem are fully complementary, so it is possible to use only a single oligonucleotide that is self-complementary within its 3' end (Figure 2B). After the self-complementary structure is formed, it is possible to further amplify the structure so that the oligonucleo-

tide becomes completely double-stranded DNA.

The self-complementary pairing must be strong enough to allow the DNA polymerase to initiate the reaction at the selected temperature. We chose the sequence 5'-GGGGCCCC-3' due to its high T_m (37 °C) and because its palindrome nature permits the self-complementary structure. Furthermore, this sequence allows amplification using the large (Klenow) fragment of the DNA polymerase, whose working temperature is 37 °C. Thus, because the 5'-GGGGCCCC-3' sequence is amplified and lies between the sense and antisense strand, it also functions as a loop for the shRNA (Figure 4).

Finally, most RNAi vectors contain an RNA pol III promoter such as U6 or H1, which is used to initiate the transcription of the shRNA. When the RNA pol III finds 5 consecutive T's, it terminates the transcription and removes the last three nucleotides on the 3' end^[17,20]. Therefore, we included 5 A's in the 5' end in the oligonucleotide; when the Klenow fragment synthesizes the antisense strand, it generated the 5 T's, which will be needed to terminate the transcription by RNA pol III inside the cell (Figure 2C). The expected shRNA structures that will form inside the cells are shown in Figure 4. All these structures were modeled using the Mfold server (see Materials and methods).

To determine if it was possible to construct the DNA cassette for shRNA vectors with this method, we designed and tested its ability to amplify different oligonucleotides. These oligonucleotides were prepared to target sequences from *eGFP* and a control oligonucleotide containing an *eGFP*-unrelated sequence. *eGFP* oligonucleotide sequences were selected to have low GC repeats to prevent G-quartet formation. Figure 3 illustrates the result of a typical filling-in reaction, showing that the Klenow fragment produced double-stranded DNA from single oligonucleotides. Therefore, the self-complementary 5'-GGGGCCCC-3' sequence is a good template for DNA amplification. Furthermore, all cassettes were constructed simultaneously in a single step reaction, so the 1-oligonucleotide method could be automated to perform a large number of reactions in a short period of time (see Materials and methods and Figure 1). We cloned the DNA cassettes in the vector under the transcriptional control of an RNA pol III (H1) promoter, and all cassettes were sequenced to confirm their integrity.

Efficacy of the 1-oligonucleotide method in RNAi experiments To test the ability of the DNA cassettes to trigger RNAi activity, HeLa cells were transfected with the plasmid vectors containing the cassettes targeting the mRNA from *eGFP* and a control construct. The day after transfection, cells were incubated with a recombinant adenovirus encoding the *eGFP*, and 24 h later the cell fluorescence was

Figure 2. Using the amplification principle (A), an oligonucleotide can be amplified if it is auto-hybridized by its 3' end (B). We selected the sequence 5'-GGGGCCCC-3' to form the secondary structure shown in (C), and we added it to the 21 nucleotide sequence. Also, to obtain the transcription termination, 5 A's are included in the oligonucleotide. After a filling-in reaction by the Klenow enzyme, a DNA cassette is formed. The optimum enzymatic temperature of the Klenow fragment is approximately 37 °C, which corresponds to the T_m value of the 5'-GGGGCCCC-3' sequence. To avoid enzyme denaturation, the Klenow fragment and dNTP mix is added until the temperature drops to 40 °C (see text, and Figure 1). Temperatures may be automated with a thermocycler.

Figure 3. Automation of the method. Using the same conditions as described in the text, a wide variety of DNA cassettes were generated simultaneously. A low melting point 4% agarose gel (*w/v*) is shown in the bottom half of the figure, with the filled shDNAs and control oligonucleotides (controls are on the left of the shDNA); the expected length of each filled DNA cassette is ~75 bp. The 21 nucleotide sequences correspond to the enhanced eGFP mRNA. The target positions of hairpin GFP1–4 (represented by black boxes) are shown on top: hpGFP1, nucleotides 595 to 616; hpGFP2 nucleotides 10 to 31; hpGFP3, nucleotides 69 to 90; hpGFP4, nucleotides 394 to 415; the length of the eGFP sequence is 718 bp. After the Klenow filling-in reaction, DNA cassettes were cloned into an RNA pol III vector for transfection.

evaluated. All the tested sequences silenced eGFP expression and, as expected, there was no gene silencing with the transfection of the unrelated construct (Figure 4). A dose-response experiment showed that the most effective plasmid concentration to achieve RNAi was 1–3.75 $\mu\text{g}/\text{mL}$. Of 4 tested DNA cassette sequences (termed hpGFP1 to 4), hpGFP 2, 3 and 4 inhibited eGFP expression/fluorescence by more than 70%. The less efficient cassette (hpGFP1) inhibited eGFP expression by 50% at 1 $\mu\text{g}/\text{mL}$ (Figure 5). The EC_{50} of each shRNA confirms this result; the less effective shRNA is hpGFP1, with an EC_{50} of approximately 0.5 $\mu\text{g}/\text{mL}$, whereas hpGFP 2–4 have EC_{50} values of approximately 0.05 $\mu\text{g}/\text{mL}$ (Figure 5). The finding that not all DNA cassette sequences had the same potency confirms the fact that a variety of sequences must be designed for the same target in order to find the most effective RNAi inducer. However, it was surprising that the hpGFP 1 sequence was the least effective of all tested sequences. This result was interesting because this sequence had been shown to be a strong inhibitor of eGFP expression in a previous study^[23]. The dose-response experiment with the unrelated cassette did not influence the eGFP fluorescence (data not shown). Together, these results suggest that diverse DNA cassettes must be produced by the 1-oligonucleotide method in order to identify the best

sequence for RNAi.

Discussion

In the present work we developed a novel, easy and efficient 1-oligonucleotide method to generate DNA cassettes for RNAi vectors. To test the capability of the method, we designed DNA cassettes to target the mRNA from eGFP. For this purpose a recombinant adenovirus encoding the eGFP gene was used to infect HeLa cells. Only cells infected with the virus and transfected with specific anti-GFP cassettes strongly inhibited eGFP fluorescence. The level of inhibition achieved with this method resembles the inhibition when RNAi is used to knock-down the expression of endogenous genes, because transfections usually reached 60%–75% of the cells, and the level of adenovirus infection almost reached 100%. The results obtained here suggest that eGFP expression was strongly reduced in the cells that were transfected with the DNA constructs, as illustrated in Figure 5. The fact that hpGFP1 was less efficient at knocking down eGFP expression suggests that a variety of RNA sequences are needed in order to find the most effective. Although this sequence has already been used by others^[23], it is reasonable that there could exist sequences that are even more effective; this method is an easy way to construct a large variety of DNA cassettes for 1 or more genes. Together, these results demonstrate that, although eGFP expression is under the transcriptional control of the strong CMV promoter in the adenoviral vector, it is still possible to induce gene silencing using the cassettes described here.

Previously reported methods to produce RNAi using DNA cassettes to generate shRNAs in mammalian cells require long oligonucleotides or several PCR reactions that are sequence and step specific^[17,20,21,24–28]. For example, in the method reported by Gou *et al*, at least three oligonucleotides (1 forward and 2 reverse) are used in 2 sequential PCR reactions to generate the DNA cassette^[21]. Once the 2 PCR reactions conclude, PCR products require further cleaning before transfection into cells. Another method previously reported is based on primer extension, and the DNA cassettes are cleaned and introduced in the cells directly^[26]. Although the latter method uses only 2 oligonucleotides to construct each DNA cassette, these oligonucleotides are fairly long (approximately 100 nucleotides), considerably increasing the cost of constructing multiple cassettes.

There are a number of effective methods that have been designed over the past few years to produce RNAi in mammalian cells^[29], but unfortunately none of these methods is easily automated because they require many step-specific reactions. Using the method described here, we simulta-

Figure 4. Inhibition of eGFP by plasmids that produce shRNAs. HeLa cells were transfected with 3.5 mg/mL of plasmid DNA. Confluent cells (~80%) were infected 24 h later with 5 MOI of a recombinant eGFP-adenovirus, and the next day the fluorescence was evaluated by confocal microscopy and flow cytometry. Left panels: Representative experiments measured by flow cytometry; the region marked M1 was considered to be the cell population expressing eGFP. Middle panels: Confocal images showing eGFP-positive cells, and the transmitted light shows the total number of cells in the field. Right panels: shRNA predicted structures. The shRNA structures were modeled based on the sequences that should be transcribed inside the cell after plasmid transfection. The shRNAs were modeled with the Mfold server: <http://www.bioinfo.rpi.edu/applications/mfold/>, and the conditions were 37 °C and 2 mmol/L Mg²⁺.

neously produced a large number of different DNA cassettes targeting different mRNAs (unpublished data). This is possible because the process can be automated to perform many

different reactions using the same temperature, time and reactant conditions using a thermocycler.

The advantages of the method described here over pre-

Figure 5. Quantification of eGFP fluorescence by flow cytometry. Data from all inhibition experiments were fitted to a dose-response equation (actual fit represented by the solid lines), showing that different cassettes have different RNAi potencies. Data were analyzed by using the GraphPad Prism 4.0 software. Data were obtained from at least three independent experiments and were mean \pm SEM.

viously reported methods are: (i) a single oligonucleotide is sufficient to generate a DNA cassette for shRNA production, significantly reducing the price of testing multiple sequences; (ii) oligonucleotides for cassette construction are easy to design: a 21–25 nucleotide sense target sequence is flanked by 5'-AAAAA- and -GGGGCCCC-3', thus the length of the oligonucleotide is considerably shorter; and (iii) the method is automated, allowing the construction of a wide variety of DNA cassettes in one step in a few minutes.

Recently it was shown that it is also possible to express synthetic miRNAs using RNA pol II promoters, which allows still more control over stem-loop RNA expression, because many RNA pol II promoters function in a inducible/tissue-specific fashion^[30]. We are currently constructing DNA cassettes by using the 1-oligonucleotide method for use with RNA pol II promoters (unpublished results). Because this type of polymerase does not terminate the transcription after 5 consecutive thymidines it is not necessary to include 5 adenines in the oligonucleotide, which further reduces the length and price of the DNA cassette.

In conclusion, we reported here a novel method for constructing large libraries of RNAi cassettes quickly and in a cost-effective manner, thus making the exploration of the function of a large number of genes an easier task and facilitating functional genomic studies.

Abstract

Aim: To study the enzymological characterization of a fibrinolytic enzyme (FII_a) from *Agkistrodon acutus* venom. **Methods:** The fibrinogenolytic effect and the influences of several protease inhibitors, chelating agents, and metal ions on fibrinogenolytic activity were visualized by sodium dodecyl sulfate-polyacrylamide gel electrophoresis. The metal content of FII_a was determined by atomic absorption spectroscopy. **Results:** After incubation with FII_a (0.25 g/L), A α -, B β - and γ -chains of fibrinogen disappeared within 5 min, 30 min, and 8 h, respectively. The molecular weights of major degradation products were 45 000 and 41 000, which were different from those bands produced by plasmin. The fibrinogenolytic activity of FII_a was strongly inhibited by ethylenediamine tetraacetic acid (EDTA), ethyleneglycol tetraacetic acid (EGTA), dithiothreitol and cysteine, but not by phenylmethyl-sulfonyl fluoride and soybean trypsin inhibitor. Zinc (3171 \pm 25 mg/kg), potassium (489 \pm 17 mg/kg) and calcium (319 \pm 13 mg/kg) were found in FII_a. Zn²⁺, Ca²⁺ and Mg²⁺ could recover the fibrinogenolytic activity of FII_a, which was inhibited by EDTA. Only Ca²⁺ could recover the fibrinogenolytic activity inhibited by EGTA. **Conclusion:** FII_a can degrade the A α -, B β - and γ -chains of fibrinogen. FII_a is a metalloproteinase, and Zn²⁺, Ca²⁺, and disulfide bonds are necessary for its fibrinogenolytic activity.

Introduction

Studies on snake venoms have been proceeding for a long time. It is known that fractions of snake venom exhibit a number of biological activities, such as fibrinogenolysis and/or fibrinolysis, and anti-platelet aggregation^[1]. Approximately 3 kinds of enzymes from snake venoms can degrade fibrinogen, these are thrombin-like enzyme (TLE)^[2], plasminogen activator^[3], and fibrinolytic enzyme. Among them, fibrinolytic enzymes can directly degrade not only fibrinogen but also fibrin *in vitro* and *in vivo*. Furthermore, they are not inhibited by proteinase inhibitors in human blood. With their potential use for treating thrombotic disease the fibrinolytic enzymes have been widely investigated. The fibrinolytic enzymes have been purified from the venoms of *Agkistrodon acutus*^[4], *A piscivorus piscivorus*^[5], *A contortrix*^[6], *A rhodostoma*^[7], *Bothrops jararaca*^[8], *Crotalus atrox*^[9], *Trimeresurus mucrosquamatus*^[10] and *Vipera lebetina*^[11].

More than 70 kinds of fibrinolytic enzymes have been isolated, and novel fibrinolytic enzymes continue to be reported.

The fibrinolytic enzyme from Taiwanese *Agkistrodon acutus* venom was first isolated by Ou-yang and Huang^[12]. In our previous work, another fibrinolytic enzyme called FII_a was purified from Anhui *Agkistrodon acutus* venom. FII_a can degrade fibrin and fibrinogen *in vitro*, and solubilize thrombus *in vivo*^[4,13]. However, the enzymological characteristics of FII_a have not been shown clearly. In the present investigation, we mainly investigate the influences of several protease inhibitors, chelating agents, and metal ions on the fibrinogenolytic activity of FII_a. The metal content was also determined.

Materials and methods

Snake venom Lyophilized *Agkistrodon acutus* venom

was collected from Qimen Snake Farm (Anhui, China).

Reagents DEAE-Sephadex A-50, Sephadex G-75, ethylenediamine tetracetic acid (EDTA), ethyleneglycol tetraacetic acid (EGTA), phenylmethylsulfonylfluoride (PMSF) and soybean trypsin inhibitor (SBTi) were purchased from GE Health Care (Little Chalfont, UK). Bovine fibrinogen and plasmin were from Sigma (St Louis, MO, USA). Molecular weight protein standards were from NEB (Beverly, MA, USA). All other chemicals and solvents were of analytical grade from commercial sources.

Purification of the enzyme FII_a, a fibrinolytic enzyme from *Agkistrodon acutus* venom, was prepared according to the method described by Liang *et al*^[4].

Fibrinogenolytic activity assay FII_a (1 g/L, 150 μL) was incubated with 450 μL of bovine fibrinogen (1 g/L) at 37 °C. Aliquots were taken at 5 min, 15 min, 30 min, 45 min, 1 h, 2 h and 8 h intervals, and 600 μL of a denaturing solution (10 mol/L urea, 4% sodium dodecylsulfate and 4% β-mercaptoethanol) was added and the mixture was incubated at 100 °C for 4 min. Each sample (20 μL) was analyzed by sodium dodecyl sulphate–polyacrylamide gel electrophoresis (SDS-PAGE) using a 4% spacer gel and a 12% separation gel^[14]. Human plasmin (50 U/L) was used as positive control.

Effect of inhibitors on fibrinogenolytic activity The effects of EDTA (5 mmol/L), EGTA (5 mmol/L), PMSF (5 mmol/L), SBTi (0.15 g/L), dithiothreitol (DTT; 5 mmol/L) and cysteine (5 mmol/L) on fibrinogenolytic activity were examined by incubation with FII_a (1 g/L) at 37 °C for 1 h. After adding bovine fibrinogen (1 g/L), the mixture was incubated for a further 1 h. Each sample (20 μL) was analyzed by SDS-PAGE.

Reactivation by metal ions on fibrinogenolytic activity FII_a (1 g/L, 150 μL) was incubated with EDTA (final concentration: 5 mmol/L) at 37 °C for 1 h. MgCl₂, CaCl₂ and ZnCl₂ (final concentrations: 5 mmol/L) were added to the incubation solution, and the mixture was incubated for a further 1 h. The fibrinogenolytic activity was examined by SDS-PAGE after a 1-h incubation with 450 μL of bovine fibrinogen (1 g/L). The same experiment was performed with EGTA (final concentration: 5 mmol/L) instead of EDTA.

Metal content assay Metal content was determined using an atomic absorption spectrophotometer. The absorbances of standard solutions were used to draw standard graphs. The metal content of FII_a was estimated by comparison with the standard curve^[14].

Results

FII_a degraded the Aα-chain preferentially, followed by the Bβ-chain of fibrinogen, but the γ-chain was the most unsusceptible to the enzyme. At a molar ration of 3:1 (fibrino-

gen: FII_a), the Aα-chain was totally degraded within 5 min, with relatively lower activity for the Bβ-chain, which disappeared within 30 min. The γ-chain was only degraded following a prolonged 8-h incubation with FII_a (Figure 1A). Concomitant with the digestion of fibrinogen, major fragments of *M_r* approximately 45 000 and 41 000 were observed.

Figure 1. Sodium dodecyl sulfate–polyacrylamide gel electrophoresis analysis of degraded fibrinogen (1 g/L, 450 μL) by (A) FII_a (1 g/L, 150 μL) and (B) plasmin (50 U/L) at 37 °C. (A) Lanes 1–8: FII_a+fibrinogen incubated for 5 min, 15 min, 30 min, 45 min, 1 h, 2 h, 4 h and 8 h. (B) Lanes 1–5: plasmin+fibrinogen incubated for 5 min, 15 min, 30 min, 45 min and 1 h. M, marker; F, fibrinogen.

When fibrinogen was incubated with human plasmin, the Aα- and Bβ-chains disappeared within 15 min, while the γ-chain disappeared within 1 h. The major digestion fragment observed was at *M_r* 45 000, of which the cleavage pattern was different from that of FII_a (Figure 1B).

The fibrinogenolytic activity of FII_a was inhibited by EDTA, EGTA, DTT and cysteine, but not by PMSF or SBTi (Table 1). The fibrinogen was still intact after incubation with FII_a pretreated with EDTA, EGTA, DTT, and cysteine (Figure 2). However, the fibrinogen was degraded after incubation with FII_a pretreated with PMSF and SBTi (Figure 2). Zn²⁺, Ca²⁺, and Mg²⁺, at concentrations of 5 mmol/L, could restore the fibrinogenolytic activity of EDTA-treated FII_a. Only Ca²⁺ could restore the fibrinogenolytic activity of EGTA-treated FII_a. Both 1 mmol/L and 5 mmol/L Ca²⁺ were effective (Figure 3).

Zn²⁺, K⁺ and Ca²⁺ were found in significant quantities, at 3171±25 mg/kg, 489±17 mg/kg and 319±13 mg/kg, respectively. The concentrations of Mg²⁺, Fe²⁺ and Cu²⁺ were only

Mg ²⁺	26±7
Fe ²⁺	26±2
Cu ²⁺	24±3

Discussion

FII_a is a α , β -fibrinogenase because it degraded both the A α -chain and the B β -chain of fibrinogen^[15]. The A α -chain of fibrinogen was very susceptible to FII_a, and it was completely degraded within 5 min. Cleavage of the γ -chain of fibrinogen was observed only with a prolonged incubation time. Thus far there have been few reports of fibrin(ogen)olytic snake venom enzymes that cleave of the γ -chain. No enzyme reported has shown cleavage specificity directed solely at the γ -chain^[16]. Because the γ -chain of fibrinogen was stable when was incubated with snake venom fibrin(ogen)olytic enzyme, we postulated that the degradation might occur at either an increased incubation time or at an increased concentration. In our previous study, the γ -chain was unaffected after a 2-h incubation. However, in the present study FII_a appeared to degrade the γ -chain after prolonged (8 h) incubation. The same phenomenon was noticed for cerastase F-4 (from *Cerastes cerastes* venom) and a fibrin(ogen)olytic enzyme from *V lebetina* venom, and they appeared to degrade the γ -chain following 48-h and 24-h incubations, respectively^[17,18]. Plasmin also cleavages the A α -, B β -, and γ -chains of fibrinogen, but the patterns are different from those observed when cleaved by FII_a. It is interesting that various fibrin(ogen)olytic enzymes seem to produce different degradation patterns for fibrinogen. For example, FII_a mainly yields fragments of 45 kDa and 41 kDa, while basilase produces fragments of 45 kDa, 36 kDa and 10 kDa, and atroxase gives fragments of 45 kDa and 38 kDa^[19]. The studies on some fibrin(ogen)olytic enzymes reveal that their cleavage preference is commonly directed to the amino-terminal side of hydrophobic amino acid residues. They display distinct and unique cleavage characteristics with fibrinogen.

The fibrin(ogen)olytic enzymes from snake venoms can be classified as metalloproteinases or serine proteinases. Chelating agents (EDTA, EGTA) completely inhibited FII_a, while serine protease inhibitors (PMSF, SBTi) were

ineffective, indicating that it belongs to the metalloproteinase group. This was supported by data from atomic absorption spectroscopy. For each mole of FII_a there was approximately 1 mole of Zn²⁺, 0.3 mole of K⁺ and 0.2 mole of Ca²⁺. Like many of the venom fibrinolytic enzymes, FII_a is a zinc metalloproteinase. Besides Zn²⁺, Ca²⁺ is another metal ion often found in venom with fibrinolytic enzymes. Metal analysis has indicated that the calcium content of atroxase (from western diamondback rattlesnake venom)^[9] and lebetase (from *V. lebetina* snake venom)^[20] is 0.3 mol/mol and 1 mol/mol, respectively. In adamalysin from *C. adamanteus*^[21] and atrolysin c(d) from *C. atrox*^[22] it was found that except Zinc-binding site, a calcium ion is bound near the carboxy-terminus of the enzyme. Thus far, only atroxase was reported to contain 1 mol/mol of K⁺, while FII_a contains 0.3 mol/mol of K⁺. The functions of calcium and potassium have not been elucidated, but they may play a role in retaining the stability of the protein.

Zn²⁺, Ca²⁺ and Mg²⁺ were effective in restoring the activity of EDTA-treated FII_a, while only Ca²⁺ could restore the activity of EGTA-treated FII_a. The mechanism for this is not clear. It is reported that snake venom metalloproteinases have Zn²⁺-dependent activities, but some are more active in the presence of Ca²⁺^[23,24]. This seems probably responsible in part for this phenomenon. The effect of Mg²⁺ on the activity of FII_a needs to be elucidated. FII_a is inhibited by DTT and cysteine, suggesting that disulfide bonds are necessary for holding the structure.

In conclusion, like many venom fibrin(ogen)olytic enzymes, FII_a is a metalloproteinase. Both Zn²⁺ and Ca²⁺ play important roles in the fibrinogenolytic activity of FII_a.

Abstract

Aim: The resurgence of severe acute respiratory syndrome (SARS) is still a threat because the causative agent remaining in animal reservoirs is not fully understood, and sporadic cases continue to be reported. Developing high titers of anti-SARS hyperimmune globulin to provide an alternative pathway for emergent future prevention and treatment of SARS. **Methods:** SARS coronavirus (CoV)F69 (AY313906) and Z2-Y3 (AY394989) were isolated and identified from 2 different Cantonese onset SARS patients. Immunogen was prepared from SARS-CoV F69 strain. Six health horses were immunized 4 times and serum was collected periodically to measure the profile of specific IgG and neutralizing antibodies using indirect enzyme-linked immunosorbent assay and a microneutralization test. Sera were collected in large amounts at the peak, where IgG was precipitated using ammonium sulphate and subsequently digested with pepsin. The product was then purified using anion-exchange chromatography to obtain F(ab')₂ fragments. **Results:** The specific IgG and neutralizing antibody titers peaked at approximately week 7 after the first immunization, with a maximum value of 1:14210. The sera collected at the peak were then purified. Fragment of approximately 15 g F(ab')₂ was obtained from 1 litre antiserum and the purity was above 90% with the titer of 1:5120, which could neutralize the other strain (SARS-CoV Z2-Y3) as well. **Conclusion:** This research provides a viable strategy for the prevention and treatment of SARS coronavirus infection with equine hyperimmune globulin, with the purpose of combating any resurgence of SARS.

Introduction

Severe acute respiratory syndrome (SARS) emerged in Southeast Asia in late 2002 and subsequently spread internationally. The causative agent was quickly identified as a previously unknown member of the Coronaviridae family^[1–3]. According to the World Health Organization, up to 2004 Apr 21, SARS coronavirus infected more than 8000 people in various countries worldwide and caused approximately 800 deaths^[4]. Although SARS infection of human beings has been contained through infection-control

measures, resurgence is still a threat because the causative agent remaining in animal reservoirs is not fully understood, and sporadic cases continue to be reported in Singapore^[5,6], Taiwan^[7] and mainland China^[8,9].

There are no specific vaccines and effective drugs currently available for SARS-CoV^[1,2,10,11]. Until an effective vaccine is developed, the best hope for the treatment of infection and the prevention and control of future outbreaks is the development of passive immunotherapy with SARS-CoV-specific antibodies^[11]. Immunoglobulin is an effective method used in protection against animal coronavirus: transmissible

gastroenteritis virus (TGEV)^[12,13], mouse hepatitis virus^[14], and bovine coronavirus^[15]. There is clinical evidence that serum from recovered patients is effective in infected individuals^[16,17]. These observations suggest that hyperimmune serum could be developed for the passive treatment of SARS. The use of equine antisera for emergent prevention and treatment of infectious diseases has been proven to be an effective and safe strategy, such as in rabies virus^[18,19]. Therefore, immunoprophylaxis and treatment of SARS coronavirus infection with equine hyperimmune globulin might be a viable strategy for controlling SARS.

Materials and methods

Virus strains Severe acute respiratory syndrome corona-virus Z2-Y3 (AY394989) and F69 (AY313906), isolated from the samples of 2 different Cantonese onset SARS patients in 2003, were sequenced and compared, showing certain differences (Table 1). Viral titres of SARS-CoV Z2-Y3 and F69 strains were determined to be $10^{6.5}$ 50% tissue-culture-infective doses (TCID₅₀)/mL and $10^{6.7}$ TCID₅₀/mL with the Reed-Muench method, respectively^[20–22].

Antigen preparation F69 strain was used as antigen for immunization. African green monkey kidney (Vero-E6) cells, infected with SARS CoV F69 strain, were cultivated in serum-free minimum essential medium (MEM) (GIBCO) and observed periodically for cytopathic effect (CPE). When 75%–100% cytopathy was reached, infected Vero-E6 cells

were frozen and thawed 3 times, which was subsequently centrifuged at 8000×g for 30 min, and then the cell debris was decanted. The supernatant was collected and stored at –70 °C until used. The viral supernatant was then centrifuged at 30 000×g for 3 h. The precipitate was diluted with phosphate buffered saline (PBS), which was used as antigen for immunization.

Animal immunization Six 4–9 year-old healthy horses were provided by the Quartermaster University of PLA. Immunization of horses was performed according to the State Food and Drug Administration (SFDA) standard operating procedures. On d 0 and d 10, all horses were injected with 1.0 mL antigen intramuscularly (SARS-CoV F69) with complete Freund's adjuvant (FCA, Sigma). On d 21 and d 28, horses were injected with the same antigen 2.5 mL im, with incomplete Freund's adjuvant (FIA, Sigma). Eight batches of sera were collected from trachelo veins on d 0, d 10, d 21, d 28, d 35, d 42, d 49, and d 55 after the first immunization, which were stored at –20 °C for the measurement of antibody titers.

Enzyme-linked immunosorbent assay (ELISA) Severe acute respiratory syndrome coronavirus specific IgG was measured using an indirect enzyme-linked immunosorbent assay (ELISA) and whole purified SARS-CoV F69 as antigen. In brief, polystyrene micro well plates were coated with antigen (100 μL/well containing 1.0 μg/mL virus protein) in carbonate-bicarbonate buffer (pH 9.6). The wells were washed 3 times with PBS and then blocked with 15% bovine serum in

PBS containing 0.05% Tween-20 (PBST) at 37 °C for 1 h. After 3 washes with PBST, serially twofold diluted serum samples (from 1:100 to a final 1:51200) were added to the plates and incubated at 37 °C for 1 h. Horseradish peroxidase (HRP)-conjugated goat anti-horse IgG (Sigma, USA) diluted 3000-fold in PBS was added, followed by 3 washes. Following incubation at 37 °C for 1 h, the plates were washed as above and the substrate tetramethylbenzidine (TMB) solution (Sigma) was added to the wells. After incubation at 37 °C for 15 min, the reaction was stopped by adding 2.0 mmol/L sulfuric acid, and the absorbance value at 450 nm (A₄₅₀) was measured with a microplate reader (Model 550, BioRad). IgG antibody titer was defined as the highest dilution of serum when the A₄₅₀ ratio (A₄₅₀ of negative serum) was greater than 2.0.

Microneutralization assay The neutralization assay was performed according to modified operating procedures of the Manual for the virological investigation of polio formulated by WHO/EPI/GEN/97.01. (<http://www.who.ch/programmes/gpv/gEnglish/avail/gpvcatalog/catlog.htm>). Each serum sample was serially diluted in twofold 1:10 dilution in MEM maintenance medium to a final dilution of 1:20 480 and incubated with an equal volume of 100 TCID₅₀/25 µL of purified F69 or Z2-Y3 strain for 3 h at 36 °C. The virus-antibody mix was then inoculated onto Vero-E6 cell (3×10⁵ cells/mL) monolayers in 96-well plates at 37 °C for approximately 6 d. Wells for normal cell control and virus control were added to 100 µL maintenance medium and unneutralized active virus dilution, respectively. The plates were incubated until CPE developed in all the virus controls but the cell control remained normal. Neutralizing antibody titer was the highest dilution of serum, which protected 50% of the cultures against 100TCID₅₀ of the challenge virus, when the virus control (no serum) showed complete CPE.

Purification of immunoglobulin Horse antiserum was thawed in 37 °C water bath, added to 45% saturated ammonium sulphate solution, then mixed gently at 22 °C for 30 min, centrifuged at 10 000×g, and the precipitation generated was collected and stored at 4 °C overnight. The ammonium sulphate precipitation was diluted using an equal volume of 0.9% NaCl solution and dialyzed to remove the salt. Then pH was adjusted to 3.5 with 0.36 mol/L HCl. Then horse serum was added to 2% pepsin (Sigma) solution and digested at 37 °C for 8 h, 24 h, 36 h, 48 h, 60 h, and 72 h, respectively. The reaction was stopped by adjusting the pH to 8.0 using 1.0 mol/L NaOH. Then the digested material was ultrafiltrated. Anion-exchange separations of ultrafiltrated material were further performed using diethylaminoethyl (DEAE) Sepharose Fast Flow (Pharmacia) Column, pre-equili-

brated with 200 mL of buffer A (50 mmol/L Tris-HCl, pH 8.0). The ultrafiltrated material was pumped down the column, while the A₂₈₀ nm of the eluted material was monitored, followed by pumping fresh buffer A until the A₂₈₀ nm returned to the baseline. All the unbound material, corresponding to the F(ab')₂ fragments was collected and stored at 4 °C. Bound contaminants can then be eluted to regenerate the column using a gradient of buffer B (containing 50 mmol/L Tris-HCl, pH 8.0, 1 mmol/L NaCl, pH 8.0). The product obtained using anion-exchange chromatography was ultrafiltrated, concentrated and added to 0.3 mol/L aminoacetic acid to obtain stock solution. According to the demanded standards of biological product, the product characteristics (eg, pH, the protein concentration and bacterial endotoxin content) were detected using serial procedures.

Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) Non-reducing SDS-PAGE gels, using the buffer system described by Laemmli (1970)^[23], were used to monitor the digestion process and to check for traces of undigested IgG and other unwanted materials.

Results

Identification of SARS coronavirus The virus (SARS-CoV F69) was electron microscopically visualized, and the characteristic coronavirus particle form was observed (Figure 1).

Figure 1. The virion form of severe acute respiratory syndrome coronavirus F69 isolate. 3×40 000.

Level of the specific IgG antibody Six health horses were immunized with purified SARS-CoV F69 strain. The titers of total anti-SARS-CoV IgG was measured using an indirect ELISA. The dynamic changes of specific anti-SARS-CoV IgG antibody titers are shown in Figure 2. On d 10, all sera distinctly showed positive reactions, with the range of specific IgG antibody titers from 1:160 to 1:980. Titers of specific IgG antibodies increased rapidly from week 4 and peaked at week 7 after the first immunization; the maximum value was

Figure 2. Changes of the specific anti-severe acute respiratory syndrome coronavirus IgG antibody titers. H, the immunized horse. The inoculation dates are on d 0, d 10, d 21, and d 28, respectively. The titers of serum specific IgG antibodies were shown on the highest dilution of serum at which the A450 ratio was greater than 2.0.

1:14210.

Titers of neutralizing antibodies The antiserum was measured using a micro-neutralization test. The kinetics of formation of neutralizing antibodies following immunization for horses were observed (Figure 3). The neutralizing antibodies were partially detectable on d 10 (from 1:10 to 1:60). After the third immunization, the neutralizing antibody titers of all the immunized horses increased rapidly on d 28. On d 48 after the first immunization, the neutralizing antibody titers of 4 of 6 equines reached the highest level. The other 2 continued increasing and reached the highest titer at 1:14240.

Figure 3. Kinetics of the specific anti-severe acute respiratory syndrome coronavirus neutralizing antibody titers. H, the immunized horse. The inoculation dates are on d 0, d 10, d 21, and d 28, respectively. Neutralizing antibody titers are shown on the highest dilution of serum, which protected 50% of the cultures against 100 50% tissue-culture-infective doses (TCID₅₀) of challenge virus.

Cross neutralization response Z2-Y3 strain was used in micro-neutralization test *in vitro* to measure the hyperimmune sera from the SARS-CoV F69 strain. The results indicate

Figure 4. Comparison of the trend of change in neutralizing antibody titers with that of the specific IgG antibody titers. Each titer value was denoted as the mean of the titers of IgG and neutralizing antibody detected.

that the horse antiserum induced by the inactivated SARS-CoV F69 strain is capable of neutralizing the SARS-CoV Z2-Y3 strain completely.

F(ab')₂ preparation Digestion with pepsin at different time points was assessed using SDS-PAGE (Figure 5). The results indicate that IgG could be digested completely at pH 3.5 within 48 h and unwanted protein bands (eg albumin and transferrin) could be eliminated as well. The reaction was stopped by adjusting the pH to 8.0 using 1.0 mol/L NaOH. The anion-exchange chromatography with a salt gradient was performed to further remove high molecular weight aggregates and pepsin. Digested antisera in buffer A are separated into 3 peaks (Figure 6). Material from peak I was then concentrated. Finally, approximately 15 g F(ab')₂ fragments were obtained from 1 litre antiserum with the purity

Figure 5. The digestion of equine antisera with pepsin, as assessed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) (10%) under non-reducing conditions. Digestion samples at various time points, with molecular weight markers: 97 kDa, 66 kDa, 45 kDa, 30 kDa, 20.1 kDa. F(ab')₂: approximately 100 kDa.

Figure 6. Removal of high molecular weight aggregate and pepsin using anion-exchange chromatography. diethylaminoethyl (DEAE) Sepharose Fast Flow ion-exchange separation of a diafiltered pepsin digested antisera. Peak I: F(ab')₂, Peak II: high molecular weight aggregate and Peak III: pepsin.

above 90%. The titer of neutralizing antibodies after purification was detected as 1:5120.

The product obtained above was dissolved in a suitable volume of 0.9% NaCl to adjust the protein concentration to 10 g/L. Then pH determined at 20 °C was 7.0. The bacterial endotoxin content was also detected at no more than 200 EU/mL. The terminal product according with the standard of SFDA [(2003) No.267], was stored at 4 °C.

Discussion

Severe acute respiratory syndrome has resulted in important challenges for the medical community. There are no available specific vaccines and effective drugs for use against SARS-CoV^[11]. Control depends on prompt detection and isolation of cases, good infection control in hospitals, and the tracing and quarantine of contacts^[24]. The widespread clinical successful application of immunoglobulins derived from heterogenous animals against rabies has a long history^[25]. The passive administration of neutralizing antibodies could be an effective strategy for emergency prophylaxis and the treatment of SARS^[26].

The results of our research indicate that healthy horses immunized with the SARS-CoV F69 strain can be induced to generate effective, specific and neutralizing antibodies. Analysis indicates that sequence difference existed among SARS-CoVs^[27]. The sequence of the SARS-CoV F69 strain is different from that of the SARS-CoV Z2-Y3 strain (Table 1). Immunoglobulin prepared from SARS-CoV F69 strain iso-

lated in April, 2003 could neutralize another SARS-CoV Z2-Y3 strain, which was isolated from SARS patient in February, 2003. This showed that SARS-CoV F69 and Z2-Y3 strain owned identical or similar neutralizing epitopes.

Heterogenous antisera used for treatment possibly result in anaphylactoid severe acute side-effects^[28]. To avoid the side-effects caused by horse antiserum, IgG against SARS-CoV was digested with pepsin and purified with anion-exchange separations to exclude the immunogenicity of Fc fragments and to retain the special activity of binding the antigen of F(ab')₂ fraction. The titers of neutralizing F(ab')₂ against SARS-CoV was detected at higher level (1:5120). And approximately 15 g F(ab')₂ fragments were obtained from 1 litre antiserum, with the purity above 90%.

Until we have an efficacious vaccine and have implemented effective epidemiologic infection control measures, and given the presence of effective anti-SARS-CoV agents, SARS is likely to remain a major health threat to the world. In this article, we provide an alternative pathway of prevention and treatment of SARS, with the purpose of combating any resurgence of SARS. The profile of the antibody titer was observed, while an effective, specific and neutralizing hyperimmunoglobulin was prepared. The results indicate that the kinetics of the induced specific IgG and neutralizing antibodies are similar (Figure 4). This data paves the way for the development of an inactivated SARS vaccine.

Abstract

Aim: To investigate the effects of the pleckstrin homology (PH) domain of phospholipase C δ_1 (PLC δ_1 PH) on inhibition of phospholipase C (PLC)-mediated hydrolysis of phosphatidylinositol 4,5-bisphosphate [PtdIns(4,5)P $_2$] by neomycin. **Methods:** A fusion construct of green fluorescent protein (GFP) and PLC δ_1 PH (PLC δ_1 PH-GFP), which is known to bind PtdIns(4,5)P $_2$ specifically, together with laser-scanning confocal microscopy, was used to trace PtdIns(4,5)P $_2$ translocation. **Results:** Stimulation of the type 1 muscarinic receptor and the bradykinin 2 receptor induced a reversible PLC δ_1 PH-GFP translocation from the membrane to the cytosol in COS-7 cells. PLC inhibitor U73122 blocked the translocation. Wortmannin, a known PtdIns kinase inhibitor, did not affect the translocation induced by ACh, but blocked recovery after translocation, indicating that PtdIns(4,5)P $_2$ hydrolysis occurs through receptor-mediated PLC activation. Neomycin, a commonly used phospholipase C blocker, failed to block the receptor-induced PLC δ_1 PH-GFP translocation, indicating that neomycin is unable to block PLC-mediated PtdIns(4,5)P $_2$ hydrolysis. However, in the absence of PLC δ_1 PH-GFP expression, neomycin abolished the receptor-induced hydrolysis of PtdIns(4,5)P $_2$ by PLC. **Conclusion:** Although PLC δ_1 PH and neomycin bind to PtdIns(4,5)P $_2$ in a similar way, they have distinct effects on receptor-mediated activation of PLC and PtdIns(4,5)P $_2$ hydrolysis.

Introduction

Phosphatidylinositol 4,5-bisphosphate [PtdIns(4,5)P $_2$], a minor phospholipid component of the plasma membrane, is a key regulator of several cellular processes, and has become the focus of research on intracellular signal transduction. PtdIns(4,5)P $_2$ is a precursor of important second messengers, such as the diffusible InsP $_3$, which regulates Ca²⁺ release from intracellular Ca²⁺ stores, and the protein kinase C activator, diacylglycerol^[1,2]. PtdIns(4,5)P $_2$ is also phosphorylated by class I PtdIns 3-kinases to form PtdIns(3,4,5)P $_3$, which controls membrane recruitment and the functions of several important signaling proteins^[3]. PtdIns(4,5)P $_2$ itself is a regulator of a great variety of target molecules, including ion channels^[4,5] and several proteins that regulate actin polymerization and the cytoskeleton^[6], providing a link between the plasma membrane and the cortical

cytoskeleton^[7]. PtdIns(4,5)P $_2$ has also been implicated in several forms of membrane remodeling events, including the fusion of secretory vesicles with the plasma membrane^[8], clathrin-mediated endocytosis^[9], and membrane recovery by endocytosis during neurotransmitter release^[10]. Such diverse functions rely upon interaction of the lipid with a large number of regulator molecules.

Pleckstrin homology (PH) domains have been described in a large number of signaling proteins, and they show remarkable specificity in recognizing various forms of inositides^[11]. The PH domain of phospholipase C δ_1 (PLC δ_1 PH) binds with high affinity and selectivity to PtdIns(4,5)P $_2$ ^[12]. Recently, a fusion construct of PLC δ_1 PH with enhanced green fluorescent protein (GFP) (PLC δ_1 PH-GFP) was developed as a probe to visualize PtdIns(4,5)P $_2$ in single cells because it binds to PtdIns(4,5)P $_2$ within the plasma and translocates to the cytoplasm after receptor stimulation. Subsequently,

when PtdIns(4,5)P₂ is resynthesized, fluorescence returns to the membrane^[13].

It has been demonstrated that neomycin, an aminoglycoside antibiotic with a large positive charge (about +4.5), binds with high affinity to PtdIns(4,5)P₂^[14]. Later studies also showed that neomycin bound to and neutralized the negative charge of PtdIns(4,5)P₂^[15].

Phospholipase C (PLC)-induced PtdIns(4,5)P₂ hydrolysis is an important cell signaling mechanism. Many membrane receptors couple to PLC, and thus regulate PtdIns(4,5)P₂ turnover and subsequent downstream cell signaling^[16]. A few PLC modulators have been developed and they play an important role in understanding the cell signaling process involving PLC and PtdIns(4,5)P₂. Neomycin has long been used as a blocker of PLC, although it actually binds to PtdIns(4,5)P₂ and presumably prevents PtdIns(4,5)P₂ from hydrolysis by PLC^[17]. Previous studies have demonstrated that both PLC_{δ1}PH and neomycin bind PtdIns(4,5)P₂ through an electrostatic interaction^[12,14]. This similar nature of interaction would indicate a similar consequence for PtdIns(4,5)P₂ hydrolysis by PLC. However, in the present study, we demonstrate that although both PLC_{δ1}PH and neomycin bind to PtdIns(4,5)P₂, only neomycin blocks PtdIns(4,5)P₂ hydrolysis by PLC activation.

Materials and methods

Reagents and plasmids Acetylcholine (ACh), bradykinin (BK), wortmannin, neomycin and Fluo 3-AM, the calcium indicators, were purchased from Sigma-Aldrich (St Louis, MO, USA). ACh, BK and neomycin were dissolved in distilled water. U73122 was purchased from Calbiochem (San Diego, CA, USA). U73122 and wortmannin were prepared as stock solutions in dimethylsulfoxide (Me₂SO), with a final concentration of Me₂SO of 0.1%. Fetal bovine serum (FBS) and Dulbecco's modified Eagle's medium (DMEM) were products of Hyclone (Logan, UT, USA). COS-7 was obtained from the Institute of Biochemistry and Cell Biology, Chinese Academy of Sciences. cDNA from the type 1 muscarinic (M₁) receptor (M₁R) and bradykinin 2 receptor (BK₂R), pEGFP-N1 (GFP) and the PLC_{δ1}PH construct with GFP (PLC_{δ1}PH-GFP) were gifts from Prof DE LOGOTHETIS (Mount Sinai Medical School, NY, USA). Red fluorescent protein (pDsRed-Express-C1, pDsRed) was purchased from Clontech (Mountain View, CA, USA). All other chemicals were of high performance liquid chromatography or analytical grade.

Cell culture and transfection COS-7 cells were seeded in 24-well plates on 12-mm glass coverslips, and cultured in 0.3 mL of DMEM supplemented with 10% (*v/v*) FBS, 100 µg/mL streptomycin, and 100 U/mL of penicillin at 5% CO₂

and 37 °C. When they were 60%–70% confluent, the cells were transiently transfected with DNA constructs for 8 h using calcium phosphate precipitate, with 1 µg of DNA and equal proportions for each kind of plasmid per well. Following transfection, cells were incubated in 10% FBS DMEM for 12–48 h. For fluorescence detection, cells were washed twice with a modified Krebs-Ringer buffer containing (in mmol/L): 120 NaCl, 4.7 KCl, 0.7 MgSO₄, 1.2 CaCl₂, 10 glucose, with 10 *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonic acid (HEPES) added (pH 7.4). The coverslips were placed into a flow-through chamber and mounted on an inverted microscope.

Confocal microscopy and image analysis For confocal imaging, a Leica (Wetzlar, Germany) DM-IRBE inverted microscope with a 20× objective (numerical aperture 0.7) and fitted with a TCS-SP2 scanhead was used. Excitation of PLC_{δ1}PH-GFP and Fluo 3-AM was achieved with a 488 nm argon ion laserline, and emissions were collected at 500–565 nm. pDsRed fluorescence was visualized with excitation at 543 nm and a 570–600 nm emission filter. For translocation studies, a series of confocal images were taken at 3–10 s intervals and stored on disk. Determination of the ratio of membrane to cytosolic fluorescence was carried out by assigning regions of interest for membrane and cytosol. TCS-SP2 confocal software (Leica) was used to analyze data off-line.

Measurement of intracellular Ca²⁺ ([Ca²⁺]_i) of single cells Cells were seeded onto sterile 12-mm borosilicate coverslips in 35-mm Petri dishes, and incubated with 5 mmol/L fluo 3-AM at 37 °C for 45 min. After loading, cells were washed twice and maintained in modified Krebs-Ringer buffer until assay. [Ca²⁺]_i changes were represented by relative fluorescence intensity calculated by using the equation $\Delta F/F_0$, where ΔF and F_0 are the change in fluorescence intensity before and after treatment, and the initial fluorescence intensity, respectively^[18,19].

Statistics Data were analyzed by using the Chi-square test. $P < 0.05$ was considered to be a statistically significant difference. All data shown are the mean value of at least 5 experiments and are expressed as mean ± SD.

Results

Activation of M₁R and BK₂R induced PtdIns(4,5)P₂ hydrolysis and a reversible translocation of PLC_{δ1}PH-GFP Both M₁R, and PLC_{δ1}PH-GFP or both BK₂ and PLC_{δ1}PH-GFP were expressed in COS-7 cells. To follow the localization of PLC_{δ1}PH-GFP within intact cells, we used GFP as a control. In unstimulated cells, expressed GFP was found to be cytosolic and also present in the nucleus (data not shown). PLC_{δ1}PH-GFP, on the other hand, accumulated strongly at

the plasma membrane and had a low and homogenous distribution in the cytosol (Figure 1A, 1B, left panel), consistent with the hypothesis that the large pool of PtdIns(4,5)P₂ exists in the plasma membrane^[13]. Next we examined the effects of ACh and BK, acting through their respective G protein-linked receptors, and subsequent activation of phospholipase C_β and hydrolysis of PtdIns(4,5)P₂, on the fluorescence distribution of the GFP and PLC_δ₁PH-GFP. COS-7 cells were transfected with the GFP or PLC₁PH-GFP together with the cDNA encoding the M₁R or BK₂R. After stimulation with either ACh (5 μmol/L) or BK (0.1 μmol/L), there was a decrease of PLC_δ₁PH-GFP fluorescence in the plasma membrane and a concomitant increase in cytosolic fluorescence (Figure 1A, 1B, Table 1). The kinetics of ACh- or BK-induced PLC_δ₁PH-GFP fluorescence translocation were characterized by a rapid onset, with translocation peaking at approximately 30–60 s and returning to baseline approximately 5–8 min after washout (Figure 1C). No significant change in fluorescence were seen in cells transfected with GFP only (data not

Table 1. Effects of ACh and its solvent on change in relative fluorescence ratios of PLC_δ₁PH-GFP. shown). To exclude the effects of the laser, we used modified Krebs-Ringer buffer solution as a solvent control of ACh. As shown in Table 1, there was no change in the relative fluorescence ratios (F_m/F_c) in the solvent control group during perfusion. To examine whether ACh- or BK-induced translocation of PLC $_{\delta_1}$ PH-GFP is due to the hydrolysis of PtdIns(4,5)P $_2$, we utilized 2 different PtdIns(4,5)P $_2$ resynthesis and hydrolysis blockers: wortmannin and U73122. Wortmannin is known to be able to block the PtdIns 3-kinase at low concentrations and block the PtdIns 4-kinase, so therefore block the formation of PtdIns(4,5)P $_2$ from phosphatidylinositol (PI), at high concentrations^[20]. As shown in Figure 2, in COS-7 cells expressing PLC $_{\delta_1}$ PH-GFP and the M $_1$ R, after the cell was pre-incubated with wortmannin (at 10 μ mol/L, a concentration known to block PtdIns 4-kinase) for 20 min, ACh induced a similar translocation of fluorescence from the plasma membrane to the cytosol, which lasted for more than 10 min after washout of ACh (Figure 2A). When the cells were pre-incubated with U73122 (10 μ mol/L), a relatively specific PLC inhibitor, for 5 min, ACh failed to induce transient translocation of the fluorescence signal (Figure 2B). These data strongly suggest that PLC $_{\delta_1}$ PH-GFP translocation induced by membrane receptor activation is indeed due to PtdIns(4,5)P $_2$ hydrolysis.

Expression of PLC $_{\delta_1}$ PH-GFP inhibited the effects of neomycin on PtdIns(4,5)P $_2$ hydrolysis Neomycin binds PtdIns(4,5)P $_2$ with high affinity and has often been used as an inhibitor of PLC. The blocking effect of neomycin on PLC is believed to be indirect, the result of neomycin binding to

PtdIns(4,5)P $_2$, the substrate of PLC^[15]. As we shown earlier, PLC $_{\delta_1}$ PH bound to PtdIns(4,5)P $_2$ but did not block receptor-mediated PLC activation, or PtdIns(4,5)P $_2$ hydrolysis. Because both PLC $_{\delta_1}$ PH and neomycin bind PtdIns(4,5)P $_2$ in a similar way (electrostatic interaction, see Introduction), we thought this difference between PLC $_{\delta_1}$ PH and neomycin was interesting, and worthy of further investigation. To determine whether the binding of PLC $_{\delta_1}$ PH-GFP to PtdIns(4,5)P $_2$ can disrupt the effects of neomycin on PtdIns(4,5)P $_2$ hydrolysis, COS-7 cells expressing PLC $_{\delta_1}$ PH-GFP and M $_1$ R were stimulated with ACh in the absence or presence of neomycin. Preincubation of the cells with neomycin (5 mmol/L) for 40 min failed to prevent the release of the fluorescence signal from the membrane to the cytosol upon the application of ACh (Figure 3). Thus in the presence of PLC $_{\delta_1}$ PH, neomycin could not block hydrolysis of PtdIns(4,5)P $_2$ induced by PLC.

Effects of neomycin on PLC activation in the absence of PLC $_{\delta_1}$ PH-GFP To further confirm that binding of PLC $_{\delta_1}$ PH-GFP to PtdIns(4,5)P $_2$ excludes the binding of neomycin to PtdIns(4,5)P $_2$, thus blocking neomycin's inhibitory effects on PLC, we used $[Ca^{2+}]_i$ as an indicator to reveal the effects of neomycin on PLC in the absence of PLC $_{\delta_1}$ PH-GFP. One of the downstream products of PtdIns(4,5)P $_2$ hydrolyzed by PLC is IP $_3$, which acts to release intracellular Ca $^{2+}$ ^[1,21]. Thus $[Ca^{2+}]_i$ would serve as a good indicator of PLC activation upon membrane receptor (M $_1$ R) stimulation. ACh induced a significant increase in $[Ca^{2+}]_i$ in COS-7 cells expressing the M $_1$ R alone and pretreated with modified Krebs-Ringer buffer

Figure 2. Effects of wortmannin and U73122 on translocation of PLC $_{\delta_1}$ PH-GFP. (A) Cells were preincubated with wortmannin (10 μ mol/L) for 20 min. ACh (5 μ mol/L) was applied for the indicated period of time. Shown in upper panels are confocal images from a representative cell taken at selected times after the application of ACh. The membrane:cytosol fluorescence ratios were determined (lower panels) as described earlier. $n=5$. Mean \pm SD. Bar=8 μ m. (B) Similar experiments were performed as shown in part A, except cells were incubated with 10 μ mol/L U73122 for 5 min before experiments were carried out.

solution for 40 min (Figure 4A, 4B); pDsRed was co-transfected with M₁R as a transfection tag (Figure 4A). However, when cells were pretreated with 5 mmol/L neomycin (40 min), no change was seen upon application of ACh (Figure 4A, 4B). Similar results were seen with BK as activator of PLC in cells expressing B₂R (data not shown). Thus, in the absence of PLC_{δ1}PH, neomycin was able to block activation of PLC.

To further confirm these findings, we next examined whether neomycin could also exert its inhibitory effects on [Ca²⁺]_i in the presence of PLC_{δ1}PH-GFP. In this section of the study, we imaged the whole-cell fluorescence intensity changes. GFP and Fluo 3-AM were excited and imaged at

the same wavelength. However, as shown in Figure 1C, the total GFP signal from one cell did not change during translocation, thus we were able to see an additional fluorescence signal from Fluo 3-AM (Ca²⁺) when Ca²⁺ was released from the store by IP₃. Figure 5 shows COS-7 cells transfected with PLC_{δ1}PH-GFP and the M₁R. Three types of cells, presumably representing different transfection results, can be identified. Cells designated a and b (Figure 5A) represent those cells that had been transfected with both PLC_{δ1}PH-GFP and the M₁R, giving a clear and dominant localization of the GFP signal on the cell membrane (Figure 5A), which translocated into the cytosol upon application of ACh (Figure

Figure 3. Neomycin failed to block PLC activation in the cells expressing PLC_{δ1}PH-GFP. Cells were preincubated with neomycin (5 mmol/L) for 40 min before the addition of ACh (5 μmol/L) for the indicated time. (A) Confocal images from a representative cell taken at selected times after the application of ACh. (B) The membrane:cytosol fluorescence ratios were determined as described earlier. n=5. Mean±SD. Bar=8 μm.

Figure 4. Neomycin blocked [Ca²⁺]_i increases upon M₁R activation in the cells not expressing PLC_{δ1}PH-GFP. [Ca²⁺]_i responses to ACh application were analyzed by confocal Ca²⁺ imaging using Fluo-3-AM and as indicated by ΔF/F₀, where ΔF and F₀ are the change in fluorescence intensity before and after treatment (ACh), and the initial fluorescence intensity, respectively. (A) Confocal images of a representative cell taken at selected times during the experiment. pDsRed was co-transfected with M₁R as a tag of transfection (Ab). The numbers indicate the elapsed time in seconds after ACh application. (B) ΔF/F₀ was plotted against time; a and b refer to the same cell measured at different wavelengths. n=5. Mean±SD. Bar=8 μm.

5A); cell c represents cells that had only been transfected with M_1R , with no visible localization of the $PLC_{\delta_1}PH-GFP$ signal on the cell membrane, and a clear rising in $[Ca^{2+}]_i$ signal seen upon application of ACh; cell d represents cells that had been transfected with $PLC_{\delta_1}PH-GFP$ but not the M_1R , so that the clear $PLC_{\delta_1}PH-GFP$ signal was not released from the membrane, and neither could an increase in $[Ca^{2+}]_i$ signal be seen upon application of ACh (Figure 5A). When these cells were pretreated with neomycin, only the response of cell c to ACh was blocked, whereas the responses of cells a and b were unaffected. These results strongly suggest that neomycin blocks PLC activation only in the absence of $PLC_{\delta_1}PH-GFP$.

Discussion

The main finding of the present study was that in the cells expressing $PLC_{\delta_1}PH-GFP$, neomycin could not exhibit its inhibitory effects on $PtdIns(4,5)P_2$ hydrolysis by PLC. There is increasing interest in understanding the actions of inositol phospholipids, especially $PtdIns(4,5)P_2$, in living cells^[21]. $PtdIns(4,5)P_2$ participates in many cellular functions, including exocytosis, cytoskeletal function and membrane transporter and ion channel functions^[4]. Many molecules have been found to be able to bind to phospholipids, and more specifically to $PtdIns(4,5)P_2$, which forms the basis of modulation by this lipid^[22]. The PH domain of PLC_{δ_1} is one of these molecules that are believed to selectively bind to

$PtdIns(4,5)P_2$ ^[12]. Recently, a fusion construct of $PLC_{\delta_1}PH$ with enhanced green fluorescent protein ($PLC_{\delta_1}PH-GFP$) was developed as a probe to visualize $PtdIns(4,5)P_2$ in single cells. This novel methodology allowed imaging and analysis of spatiotemporal changes in $PtdIns(4,5)P_2$ in single living cells, and has been used increasingly in efforts to understand the role $PtdIns(4,5)P_2$ plays in cell signaling, and protein function regulation^[13]. The central idea behind this methodology is that the GFP signal that has been linked to $PLC_{\delta_1}PH$ will faithfully follow the dynamic changes of $PtdIns(4,5)P_2$ during its metabolism, including during hydrolysis by PLC. However, because $PLC_{\delta_1}PH$ also binds to IP_3 , a downstream product of $PtdIns(4,5)P_2$ hydrolysis, with higher affinity, some have proposed that rather than being a faithful $PtdIns(4,5)P_2$ follower, $PLC_{\delta_1}PH-GFP$ molecules during $PtdIns(4,5)P_2$ hydrolysis are more likely to bind to newly produced IP_3 ^[18]. But van der Wal *et al* showed that physiological increases in IP_3 (10–100 $\mu\text{mol/L}$) on activation of PLC could not be solely responsible for the translocation of $PLC_{\delta_1}PH-GFP$ ^[23]. Our data presented in Figure 2 are in agreement with the results of van der Wal *et al*. In the cells expressing $PLC_{\delta_1}PH-GFP$ as well as the BK_2 or M_1 receptors, BK or ACh induced the reversible translocation of $PLC_{\delta_1}PH-GFP$ from the plasma membrane to the cytosol. Thus, although it bound to $PtdIns(4,5)P_2$, $PLC_{\delta_1}PH-GFP$ did not interfere with cleavage of $PtdIns(4,5)P_2$ by PLC. On the other hand, neomycin, a commonly used PLC blocker, is believed to block PLC cleavage of $PtdIns(4,5)P_2$ by preventing $PtdIns(4,5)P_2$ from

Figure 5. Presence or absence of $PLC_{\delta_1}PH-GFP$ determines the effect of neomycin on PLC activation. $[Ca^{2+}]_i$ responses to ACh application were analyzed as described in Figure 4 legend. (A) Confocal image from a representative cell taken at selected times in seconds after application of ACh. (B) $\Delta F/F_0$ was plotted against time. Bar=8 μm .

accessing PLC^[17]. It is interesting to note that whereas a smaller molecule such as neomycin would mask PtdIns(4,5)P₂ from PLC cleavage, a much bigger molecule such as PLC_{δ1}PH-GFP would allow the cleavage to happen. It is also interesting to consider that the expression of PLC_{δ1}PH-GFP blocked the action of neomycin (Figure 3), suggesting that PLC_{δ1}PH-GFP and neomycin bind to the same sites on PtdIns(4,5)P₂. Previous studies have demonstrated that both PLC_{δ1}PH-GFP and neomycin interact with PtdIns(4,5)P₂ in an electrostatic way^[12,14]. Thus the charged inositide head group of PtdIns(4,5)P₂ is the binding site for both PLC_{δ1}PH-GFP and neomycin^[24], yet binding of PLC_{δ1}PH-GFP or neomycin to PtdIns(4,5)P₂ has very different consequences for PLC hydrolysis of PtdIns(4,5)P₂. Although it is less likely, it needs to be noted that the GFP, rather than PLC_{δ1}PH, may block the binding of neomycin to PtdIns(4,5)P₂ through a spatial blocking effect. For many cellular proteins that have been known to interact with, and whose functions are regulated by, PtdIns(4,5)P₂, the molecular basis for the interaction remains to be elucidated. Less clear is the mechanism for PtdIns(4,5)P₂ hydrolysis by PLC. The present study provides interesting and stimulating information for further understanding protein-PtdIns(4,5)P₂ interactions and PtdIns(4,5)P₂ hydrolysis by PLC. We are currently investigating the mechanism underlying the different consequences of PtdIns(4,5)P₂ binding to PLC_{δ1}PH-GFP or neomycin with respect to its hydrolysis by PLC.

Abstract

Aim: To determine the effects of acetamide-45 on respiratory function, airway inflammation, and the activity of phosphodiesterase 4 (PDE4) in allergic rats. **Methods:** Rats were sensitized by a single intramuscular injection with ovalbumin (OVA) and were challenged with ovalbumin applied by using an aerosol repeatedly for 7 d after 2 weeks. Acetamide-45 at concentrations of 5, 10, or 30 mg/kg was then administered by intraperitoneal injection. Changes in dynamic lung compliance and lung resistance, the accumulation of inflammatory cells in bronchoalveolar lavage, PDE4 activity, and the concentration of interleukin-4 in rat lung tissue were determined. **Results:** Seven days of treatment with acetamide-45 prevented eosinophil accumulation in allergic rats. At doses of 5, 10, and 30 mg/kg, acetamide-45 decreased lung resistance to 0.20 ± 0.04 , 0.25 ± 0.07 , and 0.22 ± 0.05 cmH₂O·s⁻¹·mL⁻¹, respectively ($P < 0.05$ vs OVA), and it also increased dynamic lung compliance to 0.41 ± 0.07 , 0.39 ± 0.06 , and 0.42 ± 0.09 mL/cmH₂O ($P < 0.05$ vs OVA). After being treated with different doses of acetamide-45, the PDE4 activities in lung tissue were 281 ± 55 , 273 ± 57 , and 238 ± 36 nmol·g⁻¹·min⁻¹ ($P < 0.05$ vs OVA), and the concentrations of interleukin-4 in lung tissue were 6.22 ± 1.13 , 5.95 ± 1.20 , and 5.68 ± 2.20 µg/g protein ($P < 0.05$ vs OVA). **Conclusions:** Acetamide-45 was found to improve respiratory function and inhibit airway inflammation in this animal model, and the PDE4 activity of lung tissue was obviously inhibited. Acetamide-45 was an effective anti-inflammatory agent in respiratory inflammation, and the mechanism of its action might depend on inhibition of PDE4.

Introduction

Asthma is a chronic inflammatory disease of the airways, of which lung inflammation and bronchial hyperactivity (BHR) are two distinct characteristics^[1,2]. Eosinophils are considered to be the principal inflammatory leukocytes involved in the asthmatic reaction, due in part to the toxic granular proteins they secrete and the membrane products that induce airway epithelial pathology and mucus hypersecretion^[3,4]. 3',5'-Cyclic-nucleotide (cAMP) has important regulatory roles in the process of inflammation. Phosphodiesterase 4 (PDE4), which catalyzes the hydrolysis of cAMP to the corresponding nucleotide, 5'-monophosphate, appears to be an attractive target for anti-inflammatory drugs^[5,6].

Inhibition of PDE4 results in increased levels of cAMP, which leads to functional inhibition of inflammatory cells such as eosinophils and lymphocytes, and reduced release of inflammatory cytokines such as interleukin-4 (IL-4)^[7,8]. There has been significant interest in PDE4 inhibitors as potential therapeutic agents for asthma.

Because asthma has been the focus of much study effort, treatment of the disease has been improved by the implementation of management guidelines in recent years^[9]. Such treatments as corticosteroids, β₂-agonists, theophylline and leukotriene antagonists have been used as anti-inflammatory agents to control asthma^[10]. However, the possible dose-related adverse systemic effects produced by long-term treatment with these drugs are not acceptable in

clinical practice^[11,12]. Therefore, new anti-asthma agents are required.

A series of new *N*-(pyridin-4-yl)-(indol-3-yl) alkylamides (44-84) have been prepared in the search for novel anti-allergic drugs. Initial studies showed that acetamide-45 inhibited IL-4 and IL-5 biosynthesis and histamine release^[13]. We have also previously reported that acetamide-45 has an inhibitory effect on histamine- and methacholine-induced contractions of isolated guinea pig trachea, and that it can inhibit PDE4 activity^[14,15]. It was concluded that acetamide-45 was a new anti-allergic agent. However, little is known about its effects on eosinophil infiltration in airway and lung function in asthmatic rats. There have been no reports regarding the effect of acetamide-45 on PDE4 activity in the lungs in any animal model of asthma.

Therefore, in the present study, we examined the inhibitory effect of acetamide-45 on airway inflammation and lung function in a rat model of asthma, and indicated a possible mechanism by which the effect might be exerted.

Materials and methods

Animals Male Sprague-Dawley rats weighing 140–160 g were obtained from the Laboratory Animal Center of the Medical School of Zhejiang University (Certificate No 220010027, conferred by the Zhejiang Medical Laboratory Animal Administration Committee).

Chemicals Aminophylline, cAMP, and ovalbumin were purchased from Sigma (St Louis, MO, USA). Acetamide-45 was kindly provided by the Department of Organic Chemistry and Medical Chemistry, Faculty of Pharmacy (Nantes University, France). The rat IL-4-specific enzyme-linked immunosorbent assay (ELISA) kit was purchased from Jingmei BioTech Co (Shenzhen, China).

Sensitization and challenge procedure Rats were sensitized by a single intramuscular injection of 10 mg ovalbumin

(OVA) mixed with 100 mg aluminum hydroxide in 1 mL of saline. After 2 weeks, these animals were then challenged by exposure for 20 min to aerosolize 1% OVA in saline generated by a jet nebulizer once a day for 7 d. The drugs were administered by intraperitoneal injection before challenge. The doses of acetamide-45 were 5, 10, or 30 mg/kg, respectively, and the dose of aminophylline was 10 mg/kg per day for 7 d. At d 21, the animals were killed, and the lung tissues were immediately removed, frozen in liquid nitrogen, and then stored at -80 °C until analysis.

Measurement of lung function At 24 h after the last antigen challenge, rats were anesthetized with urethane (1 g/kg, ip). The trachea was cannulated and placed in a whole body plethysmograph for the measurement of lung resistance (R_L) and dynamic lung compliance (C_{dyn})^[16,17].

Cell counts in bronchoalveolar lavage Bronchoalveolar lavage (BAL) was performed by flushing the airways with 10 mL/kg saline containing 1% bovine serum albumin and 1000 kU/L heparin sodium through a tracheal cannula. The BAL fluid was pooled and immediately centrifuged at 500 ×g at 4 °C for 10 min. The supernatant was removed and the cells were resuspended in 1 mL saline containing 10% bovine serum albumin. Counts of the total number of leukocytes recovered in the BAL fluid were carried out using a Neubauer chamber, and differential cell analysis was carried out under a light microscope after Wright-Giemsa staining.

Determination of IL-4 in lung tissue At a ratio of 1 g to 10 mL, homogenized lung tissue was added to 50 mmol/L potassium phosphate buffer (pH 6.0) containing 0.05% Na₂S₂O₃ and 0.1% 3-[(3-cholamidopropyl) dimethylammonio]-1-propanesulfonate (CHARPS). The homogenates were centrifuged twice at 19 851 ×g, each for 30 min^[17]. IL-4 in the supernatants was quantified using a rat IL-4-specific ELISA kit.

PDE4 activity assay Frozen 25-mg pieces of lung tissue were homogenized and PDE4 activity was determined by high performance liquid chromatography (HPLC) as described elsewhere^[15,18].

Statistical analysis Data are expressed as mean ± SD. Statistical analysis was performed using one-way analysis of variance.

Results

Effects of acetamide-45 on inflammatory cells in the airways of allergic rats In our rat model of allergic asthma, ovalbumin sensitization and challenge caused an obvious increase in inflammatory cells in BAL. As shown in Figure 1, the total number of leukocytes and eosinophils in the OVA group was significantly greater than that in the normal group

($P < 0.05$), but the number of inflammatory cells was depressed when aminophylline (Ami) was administered ($P < 0.05$ vs OVA). Seven days of treatment with acetamide-45 (Ace) at 5, 10, or 30 mg/kg significantly decreased the number of inflammatory cells in BAL caused by sensitization and challenge ($P < 0.05$ vs OVA; Figure 1). There was no statistical difference between the Ace group and the Ami group ($P > 0.05$; Figure 1).

Figure 1. Effect of acetamide-45 on inflammatory cells in rat airway after ovalbumin challenge. Rats were sensitized and challenged with ovalbumin (OVA). Acetamide-45 at concentrations of 5 mg/kg (Ace5), 10 mg/kg (Ace10), or 30 mg/kg (Ace30), or aminothiophylline at a concentration of 10 mg/kg (Ami) were administered once a day for 7 d during challenge. $n=6$. Mean \pm SD. ^b $P < 0.05$ vs normal. ^e $P < 0.05$ vs OVA. ^{eg} $P > 0.05$ vs Ami.

Effects of acetamide-45 on R_L and C_{dyn} in allergic rats

After rats were given 7 aerosolized OVA challenges, a significant decrease in C_{dyn} was induced. However, through sensitization and challenge, R_L increased to a level that was significantly greater than that in the normal group. The administration of aminophylline decreased the R_L and increased the C_{dyn} of sensitized and challenged animals. At a dose of 5, 10, or 30 mg/kg, acetamide-45 improved both C_{dyn} and R_L (Figure 2).

Effect of acetamide-45 on IL-4 in lung tissue in allergic rats

As shown in Figure 3, IL-4 levels in the lungs of rats from the various groups were measured. Sensitization and challenge increased the concentration of IL-4 to a level significantly different from that of the normal group ($P < 0.05$). Seven days of treatment with acetamide-45 at concentrations of 5, 10, or 30 mg/kg, or with aminophylline at a concentration of 10 mg/kg, obviously reduced the increase in the concentration of IL-4 ($P < 0.05$).

Effect of acetamide-45 on PDE4 activity in lung tissue in allergic rats Sensitization and challenge increased the PDE4 activity of lung tissue to 503 ± 125 nmol \cdot g $^{-1}\cdot$ min $^{-1}$, which was greater than that of the normal group ($P < 0.05$). Acetamide-45 at concentrations of 5, 10, or 30 mg/kg inhibited the hy-

Figure 2. Effects of acetamide-45 on lung resistance (R_L , filled bars) and dynamic lung compliance (C_{dyn} , open bars) in allergic rats. Rats were sensitized and challenged with ovalbumin (OVA). Acetamide-45 at a concentration of 5 mg/kg (Ace5), 10 mg/kg (Ace10) or 30 mg/kg (Ace30), and aminothiophylline at a concentration of 10 mg/kg (Ami) were administered once a day for 7 d during challenge, and then lung function was measured. $n=6$. Mean \pm SD. ^b $P < 0.05$ vs normal. ^e $P < 0.05$ vs OVA. ^{eg} $P > 0.05$ vs Ami.

Figure 3. Effect of acetamide-45 on IL-4 concentration in lung tissue in allergic rats. Rats were sensitized and challenged with ovalbumin (OVA). Acetamide-45 at concentrations of 5 mg/kg (Ace5), 10 mg/kg (Ace10) or 30 mg/kg (Ace30), and aminothiophylline at a concentration of 10 mg/kg (Ami) were administered once a day for 7 d during challenge, and then the IL-4 concentrations of lung tissue were measured. $n=6$. Mean \pm SD. ^b $P < 0.05$ vs normal. ^e $P < 0.05$ vs OVA. ^{eg} $P > 0.05$ vs Ami.

drolysis of cAMP by the PDE4 extracted from lung tissue. The PDE4 activities of the lung tissue were 281 ± 55 , 273 ± 57 , and 238 ± 36 nmol \cdot g $^{-1}\cdot$ min $^{-1}$, respectively (for acetamide-45 at concentrations of 5, 10, or 30 mg/kg). As a non-selective inhibitor of PDE4, aminophylline suppressed PDE4 activity to 341 ± 44 nmol \cdot g $^{-1}\cdot$ min $^{-1}$ at a dose of 10 mg/kg, which was weaker than the activity produced by treatment with acetamide-45 at concentrations of 10 and 30 mg/kg ($P < 0.05$, Figure 4).

Discussion

Acetamide-45, *N*-(pyridin-4-yl)-[1-(4-fluorophenyl)indol-3-yl] acetamide, is a new anti-inflammatory drug that inhibits the release of cytokines and the activation of eosinophils^[12].

Figure 4. Effect of acetamide-45 on PDE4 activity in lung tissue in allergic rats. Acetamide-45 at concentrations of 5 mg/kg (Ace5), 10 mg/kg (Ace10), or 30 mg/kg (Ace30) and aminothiophylline at a concentration of 10 mg/kg (Ami) were administered once a day for 7 d during challenge, and then the PDE4 activity of lung tissues was measured. *n*=6. Mean±SD. ^b*P*<0.05 vs normal. ^e*P*<0.05 vs OVA. ^{eh}*P*<0.05 vs Ami.

It has also been reported that acetamide-45 inhibits the contraction of isolated guinea pig trachea induced by histamine and methacholine^[14]. However, the mechanism by which acetamide-45 acts remains unknown. The present study shows that acetamide-45 can suppress the accumulation of inflammatory cells in airways and improve the lung function of allergic rats. We also found that acetamide-45 could inhibit PDE4 activity and reduce the IL-4 level in the lung tissue of allergic rats. To our knowledge, this study represents the first investigation of the effect of acetamide-45 on lung function and PDE4 concentration in the lung in an animal model of asthma.

Asthma is a syndrome characterized by eosinophil infiltration and airway hyperresponsiveness, which occurs via a mechanism that is very complex. It is well known that eosinophils play a critical role in airway damage and dysfunction in asthma. We found that acetamide-45 had an inhibitory effect on eosinophil infiltration in the airways of allergic rats. Not only eosinophils but also other inflammatory cells were decreased in concentration, so that inflammation of the airway in allergic rats was inhibited by acetamide-45.

Inflammation of the airway leads to spasms of the bronchial smooth muscles, mucus hypersecretion, and airflow limitations, which result in pulmonary dysfunction in asthma. The data obtained by a whole body plethysmograph in this study indicate that acetamide-45 improves the lung function of allergic rats produced by sensitization and challenge. Its effectiveness has been demonstrated in two ways. First, the *C*_{dyn} of allergic rats increased obviously relative to normal rats at a dose of 5 mg/kg acetamide-45. Second, the *R*_L of allergic rats was reduced significantly by acetamide-45 in the same way. The improvement in lung function produced by acetamide-45 is similar to that produced by aminophylline.

The experiments presented here show that both acetamide-45 and aminophylline repress IL-4 production in allergic rats, but that there is no difference between the two agents. IL-4 is a key cytokine in the development of allergic inflammation. It is associated with the secretion of IgE by B lymphocytes and the expression of eotaxin and other inflammatory cytokines that contribute to inflammation and lung remodeling in asthma^[18,19]. A previous study shows that acetamide-45 inhibits IL-4 biosynthesis and release, which is identical to our result^[12]. This indicates that acetamide-45 can reduce the release of IL-4 and reduce its concentration in the lung, which results in the inhibition of airway inflammation.

Our study of PDE4 activity shows that acetamide-45 has an inhibitory effect on cAMP hydrolysis of PDE4 in the lung tissue of allergic rats. In a previous study, we demonstrated that acetamide-45 could inhibit the hydrolysis of cAMP by PDE4 extracted from transfected yeast, and that its inhibitory effect was stronger than that of theophylline^[15]. The present study also shows that at the same dose (10 mg/kg), the inhibitory effect of acetamide-45 is greater than that of aminophylline, which is a non-selective PDE inhibitor. PDE4 is specific for cAMP, and is predominantly expressed in inflammatory cells. It plays an important role in the regulation of cellular functions in inflammatory and immune cells, and inhibition of PDE4 may be one of the anti-inflammatory mechanisms of acetamide-45.

In conclusion, we have shown that acetamide-45 could improve the lung function of allergic rats produced by sensitization and challenge, and that production of eosinophils in those animals could also be repressed. Acetamide-45 had an inhibitory effect on PDE4 activity in the lung tissue of allergic rats, and the inhibition was stronger than that produced by aminophylline. The present research may provide an experimental basis for further study of this agent.

Abstract

Aim: To investigate the effect of cholecystokinin octapeptide (CCK-8) on the diacylglycerol-protein kinase C (DAG-PKC) signaling pathway in rat pulmonary interstitial macrophages (PIM) stimulated by lipopolysaccharide (LPS). **Methods:** The PIM from rat lung tissues were isolated using the collagenase digestion method combined with alveolar lavage and pulmonary vessel perfusion. DAG content and PKC activity were measured by radioenzymatic assay. The translocation of PKC ζ was determined by semi-quantitative immunoblot analysis. **Results:** CCK-8, at high concentrations (1×10^{-6} – 1×10^{-5} mol/L), decreased DAG content and inhibited PKC activity and PKC ζ translocation compared with that in rat resting PIM of a control group ($P < 0.01$). LPS increased DAG content, and promoted PKC activity and PKC ζ translocation ($P < 0.01$). CCK-8 decreased LPS-induced DAG content and inhibited LPS-induced PKC activity and PKC ζ translocation significantly at 1×10^{-8} – 1×10^{-5} mol/L ($P < 0.01$). This inhibitory effect of CCK-8 could be abrogated partly by proglumide (non-selective CCK receptor antagonist), CR-1409 (selective CCK-A receptor antagonist), and CR-2945 (selective CCK-B receptor antagonist) in a concentration-dependent manner ($P < 0.01$). **Conclusion:** CCK-8 was a negative modulator of the DAG-PKC signaling pathway in rat resting PIM, which is very important for maintaining body homeostasis. It significantly inhibited LPS-induced DAG content, PKC activity and PKC ζ translocation in a concentration-dependent manner. The CCK receptor, especially the CCK-A receptor, might play a major role in this process.

Introduction

Cholecystokinin (CCK) is a gut-brain peptide that exerts a variety of physiological actions in the gastrointestinal tract and central nervous system (CNS) through activating cell surface CCK receptors^[1]. CCK receptors have been pharmacologically classified into 2 subtypes, CCK-A receptors (CCK-AR) and CCK-B receptors (CCK-BR), according to their affinity for the peptide agonists CCK and gastrin^[2]. Our previous experiments demonstrated that CCK-8, as an intestinal neuropeptide, not only protected gastric mucosa against alcohol-induced injury, but also was a potent protective agent against acute lung injury caused by lipopolysaccharide (LPS)^[3,4]. It reduced pulmonary artery hypertension

(PAH) and lessened inflammatory lesions in lung tissues of endotoxin shock (ES) rats^[3,4]. Studies from our laboratory show that sulfated CCK-8 (sCCK-8) can inhibit LPS-induced TNF- α production *in vitro*, sCD14 release and mCD14 expression in rat pulmonary interstitial macrophages (PIM)^[5]. The production of proinflammatory cytokines, including TNF- α , IL-1 β , and IL-6 in ES rats, was also inhibited by sCCK-8 *in vivo*^[6,7]. The above data suggest that sCCK-8 has an anti-inflammatory effect, confirmed by a morphological observation that sCCK-8 clearly lessened the inflammatory lesions in the spleen and the liver tissues in endotoxin shock rats^[4]. However, the anti-inflammatory mechanisms and signaling pathways activated by CCK-8 remain unclear.

Several signaling pathways are involved in the activa-

tion of monocytes/macrophages induced by LPS, including the mitogen-activated protein kinase (MAPK) and the protein kinase C (PKC) pathway, and there is a lot of cross-talk between them. PKC, as an important message molecule, participates extensively in immune regulation and inflammatory signal transduction. In particular, PKC ζ plays a pivotal role in the complicated signaling networks induced by LPS^[8,9]. Several studies show that LPS-induced activation of the extracellular signal-regulated kinases (ERK) in alveolar macrophages is mediated by sequential activation of phosphatidylcholine-specific phospholipase C (PC-PLC), induction of cellular diacylglycerol (DAG) and ceramide, and activation of PKC ζ ^[10]. Previously we reported that CCK-AR and CCK-BR mRNA expressions were detected by reverse transcription-polymerase chain reaction. The presence of functional CCK receptors was confirmed by radioligand binding assay in rat PIM, and their expressions were upregulated by LPS^[11]. Increasing evidence supports the concept that the signal transduction cascades mediated by CCK receptors are cell specific. For example, CCK was found to activate cAMP and PKC regulated signaling pathways in pancreatic acinar cells, but CCK-8 induced a significant decrease in membrane and cytosol PKC activity in murine lymphocytes, neutrophils, and peritoneal macrophages, as well as an increase of intracellular cAMP levels^[12-14]. As PIM plays an important role in the inflammatory response to LPS in the lungs and little is known about the effect of CCK-8 on DAG-PKC signaling pathway in PIM, the present study was undertaken to investigate the effect of CCK-8 on DAG contents, PKC activities, and PKC ζ translocation in resting and LPS-stimulated rat PIM, and to explore the anti-inflammatory molecular mechanisms activated by CCK-8.

Materials and methods

Chemicals and reagents Collagenase IA, LPS (*Escherichia coli* 0111:B4), CCK-8s, proglumide, CR-1409, CR-2945, aprotinin, leupeptin, and DNaseI were obtained from Sigma Chemical Co. RPMI-1640 culture medium, phenylmethylsulfonyl-fluoride (PMSF), and nitrocellulose membranes were obtained from Gibco BRL. DAG biotrac assay reagents system (RPN 200) and Amprep Si minicolumns (RPN 1906) were obtained from Amersham Biosciences. SignaTECT® PKC assay system and Gel shift assay system were obtained from Promega. Diethylaminoethyl cellulose (DE52) was obtained from Whatman BioSystems. Affinity purified polyclonal nPKC ζ antibodies (C-20), peroxidase-conjugated goat anti-rabbit IgG, and Western blotting luminol reagent (sc-2048) were obtained from Santa Cruz Biotechnology. All other

reagents were of analytic pure grade.

Animals Adult healthy female Sprague-Dawley (SD) rats (180–220 g, Grade II, Certificate No 04057) were obtained from the Experimental Animal Center of Hebei Province (Shijiazhuang, China).

Cell culture and treatment PIM were isolated from perfused rat lungs with a collagenase digestion technique, modified as Wizemann *et al*^[15]. PIM were harvested with PBS containing 0.4 g/L edetic acid, pelleted by centrifugation (4 °C, 400×g, 10 min) and resuspended with serum-free medium. Cells were incubated with CCK-8 at different concentrations or stimulated with LPS (10 mg/L) in the absence or presence of CCK-8, proglumide, CR-1409, and CR-2945 for 1 h. At the end of incubation, PIM were centrifuged at 400×g for 60 s, and the pellets were measured for DAG contents, PKC activities, and translocation.

Measurement of intracellular DAG contents Total cell lipids were extracted using a modification of the method of Bligh and Dyer^[16]. Intracellular DAG contents were measured using the DAG assay reagents system from Amersham Biosciences. A radioenzymatic assay uses the diacylglycerol kinase and defined mixed micelle conditions to solubilize the DAG present and allow its quantitative conversion to [³²P]phosphatidic acid in the presence of [γ -³²P]ATP. Following the enzyme-catalyzed phosphorylation of DAG, the [³²P]phosphatidic acid reaction product was extracted and separated by Amprep chromatography. The radioactivity attributable to [³²P]phosphatidic acid was determined by liquid scintillation counting. The amount of DAG present in the sample was calculated from the amount of [³²P]phosphatidic acid produced and the specific activity of the ATP according to the standard curve was expressed as pmol per 2×10⁶ cells.

Preparation of cytosol and membrane fractions After treatment, the PIM were washed with 5 mL ice-cold PBS and centrifuged at 250×g for 60 s. The supernatant was discarded and the cells were suspended in iced 0.5 mL of extraction buffer [Tris-HCl 25 mmol/L (pH 7.4) containing edetic acid 0.5 mmol/L, egtazic acid 0.5 mmol/L, β -mercaptoethanol 10 mmol/L, leupeptin 1 mg/L, and aprotinin 1 mg/L] and sonicated on ice with 10-s bursts, each preceded by a 10-s pause. The homogenates were centrifuged at 100 000×g for 60 min at 4 °C and the supernatant was used for assay of PKC (cytosol fraction). The pellet (representing the membrane fraction) was suspended in 2 mL of iced extraction buffer containing 0.05% Triton X-100, shaken for 60 min at 4 °C and centrifuged at 100 000×g at 4 °C for 60 min. The supernatant was taken for assay of PKC (membrane fraction). Cytosol and membrane fractions were partially purified

using diethylaminoethyl (DEAE)-cellulose chromatography. The samples were passed over individual 1-mL columns pre-equilibrated with extraction buffer. Following washing the columns 1 time with 5 mL of extraction buffer, the fractions of PKC were eluted with 5 mL of extraction buffer containing NaCl 200 mmol/L, stored at 4 °C, and generally assayed within 24 h.

PKC activity assay PKC activity was analyzed by measuring the incorporation of ^{32}P from $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ (185 PBq/mol) into peptide Neurogranin ($_{28}\text{AAKIQAS}^*\text{-FRGHMA-RKK}_{43}$), a specific substrate of PKC. The standard assay mixture (25 μL) contained extraction buffer 5 μL , 5 μL PKC co-activation buffer (5 \times), 5 μL PKC substrate peptide 0.5 mmol/L, and 5 μL of ATP mixture containing ATP 0.5 mmol/L and $[\gamma\text{-}^{32}\text{P}]\text{ATP}$ 18.5 GBq (0.5 Ci). Control reaction used a control buffer instead of PKC substrate peptide. The reaction was terminated by adding ice-cold 7.5 mol/L guanidine hydrochloride 12.5 μL at 30 °C after 5 min. Each terminated reaction mixture (10 μL) was then spotted onto a SAM membrane. The membrane was rinsed with 2 mol/L NaCl and 2 mol/L NaCl in 1% phosphoric acid and deionized water, respectively. Aliquots of 5 μL in any 2 reactions were spotted onto SAM membrane. All membranes were dried at room temperature and put into liquid scintillator. Radioactivity was counted. All values represented the mean from 3 separate culture dishes, with an average difference between duplicates of $\leq 5\%$. Proteins were measured using Bradford's method by using bovine serum albumin as a standard.

Immunoblot analysis The effect of CCK-8 on distribution and on LPS-induced translocation of PKC ζ was determined using quantitative immunoblot analysis. Crude cytosolic and membranous fractions from PIM were prepared as described above, except that DE52 column chromatography was omitted. Protein concentrations of fraction were measured using Bradford's method using bovine serum albumin as standard. Aliquots of sample eluates were added to sample preparation buffer [Tris-HCl 0.05 mol/L, pH 6.8, 20% glycerol, 2% sodium dodecylsulfate (SDS), edetic acid 5 mmol/L, egtazic acid 5 mmol/L, β -mercaptoethanol 10 mmol/L, leupeptin 1 mg/L, aprotinin 1 mg/L, PMSF 0.5 mmol/L, and 0.1% bromphenol blue] and boiled for 5 min. The proteins were separated by SDS-polyacrylamide (10% acrylamide) gel electrophoresis and electrophoretically transferred to nitrocellulose membranes. The completeness of transfer was confirmed by staining the gel with Coomassie blue. The blots were incubated at room temperature for 2 h with PBS containing 5% nonfat dry milk and 0.05% Tween 20 (bovine serum albumin/Tris buffer saline) to block non-specific sites. The blots were washed with PBS, and incubated overnight

with affinity purified polyclonal nPKC ζ antibodies(1:200) at 4 °C. The blots were washed 3 times for 15 min each with PBS at room temperature and incubated at 37 °C for 1 h with peroxidase-conjugated goat anti-rabbit IgG antibody. The blots were finally washed 3 times for 15 min each with Tris buffer saline, incubated with enhanced chemiluminescence detection reagents for 3–5 min and exposed to X-ray films for up to 60 s. The density of the bands on the film was analyzed by Gel-Pro analyzer version 3.1 software (Media Cybernetics). The arbitrary unit ($D_{\text{area}}/D_{\text{density}}$) was used for expressing the relative level of PKC ζ of cytosolic and membranous fractions from PIM.

Statistical analysis Data were expressed as mean \pm SD and analyzed using analysis of variance and the least significant difference test using an SPSS statistical program. Statistical significance was accepted when $P < 0.05$. Half-maximal inhibition (IC_{50}) was calculated using the log-probit method.

Results

DAG content For resting PIM, CCK-8 did not affect DAG content at low concentrations (1×10^{-12} – 1×10^{-7} mol/L, $P > 0.05$), but decreased it at high concentrations (1×10^{-6} – 1×10^{-5} mol/L) compared with that of the control group ($P < 0.01$). Stimulation of PIM by LPS (10 mg/L) obviously increased DAG content ($P < 0.01$) (Figure 1). CCK-8 concentration-dependently inhibited the LPS-induced DAG content, and a significant inhibition was observed at high concentrations (1×10^{-8} – 1×10^{-5} mol/L, $P < 0.01$), but not at low concentrations (1×10^{-11} – 1×10^{-9} mol/L, $P > 0.05$) (Figure 1). The inhibitory effect of CCK-8 on DAG content induced by LPS was abrogated in part by proglumide, CR-1409, and CR-2945 in a concentration-dependent manner. Proglumide was so potent that it had an obvious effect on CCK-8-resultant inhibition of LPS-induced DAG content increase at low concentrations, and even resulted in a full reversal of it at high concentrations, and a similar effect was found for CR-1409, but not for CR-2945, with CR-2945 showing a weak effect only at high concentrations. The IC_{50} of proglumide, CR-1409, and CR-2945 were $(1.76 \pm 0.19) \times 10^{-6}$ mol/L, $(6.76 \pm 0.52) \times 10^{-5}$ mol/L, and $(5.45 \pm 0.42) \times 10^{-3}$ mol/L, respectively (Figure 2).

PKC activity and translocation Treating resting PIM with CCK-8, no changes of cytosolic and membrane-bound PKC activities were found at low concentrations (1×10^{-12} – 1×10^{-9} mol/L), but an increase of cytosolic PKC activities and a decrease of membrane-bound PKC activities were observed gradually with the increase of CCK-8 concentration, and significant differences presented at 1×10^{-6} – 1×10^{-5} mol/L

Figure 1. Effect of CCK-8 on DAG content in rat resting pulmonary interstitial macrophages (PIMs, A) and LPS-stimulated rat PIMs (B). PIMs were incubated with CCK-8 at different concentrations in the absence or presence of LPS for 1 h. DAG content was determined by radioenzymatic assay. *n*=3. Mean±SD. ^c*P*<0.01 vs control group. ^e*P*<0.05, ^f*P*<0.01 vs LPS group. C: control.

(*P*<0.01) (Figure 3). LPS decreased cytosolic PKC activity and increased membrane-bound PKC activity (*P*<0.01), indicating that LPS could promote PKC translocation and change its distribution, but did not affect its total activity in rat PIM. Treating PIM with CCK-8 did not affect LPS-induced PKC translocation at 1×10⁻¹¹–1×10⁻¹⁰ mol/L, decreased it slightly at 1×10⁻⁹–1×10⁻⁸ mol/L (*P*<0.05), and inhibited it significantly at 1×10⁻⁷–1×10⁻⁵ mol/L (*P*<0.01), suggesting that CCK-8 inhibited LPS-induced PKC translocation in a concentration-dependent manner (Figure 3). The inhibitory effect of CCK-8 1×10⁻⁶ mol/L on LPS-induced PKC activity translocation in rat PIM was attenuated by proglumide, CR-1409, and CR-2945 at 1×10⁻⁴ mol/L, and their inverse rate (percentage of CCK-8) were 58.9%, 48.1%, and 21.5%, respectively (*P*<0.01) (Figure 4).

Immunoblot analysis For resting PIM, CCK-8 inhibited PKCζ translocation from cytosol to membrane only at high concentrations (1×10⁻⁶ mol/L) (*P*<0.05) (Figure 5). LPS promoted PKCζ translocation from cytosol to membrane (*P*<0.01) and CCK-8 inhibited LPS-induced PKCζ translocation

Figure 2. CCK-receptor non-selective and selective antagonists abrogated the inhibitory effects of CCK-8 on the increase in diacylglycerol (DAG) content induced by LPS. Pulmonary interstitial macrophages were isolated and pretreated with CCK receptor antagonists (proglumide, CR-1409, and CR-2945) for 10 min prior to addition of LPS (10 mg/L) and CCK-8 (1×10⁻⁶ mol/L), and then co-incubated for 1 h. DAG content was determined by radioenzymatic assay. *n*=3. Mean±SD.

significantly at 1×10⁻⁸ and 1×10⁻⁶ mol/L (*P*<0.01, Figure 6). The inhibitory effect of CCK-8 on LPS-induced PKCζ translocation was blocked by proglumide, CR-1409 (*P*<0.01), and CR-2945 (*P*<0.05) to some extent (Figure 7).

Discussion

CCK is a neuropeptide expressed in the endocrine I-cells of the small intestinal mucosa and in widespread central and peripheral neurons^[17]. Whereas intestinal CCK regulates the release of pancreatic enzymes and the contraction of the gall bladder, neuronal CCK is a transmitter or modulator assumed to be involved in a variety of CNS functions, such as feeding behavior, anxiety, analgesia, memory, immunomodulation, and anti-opioid effects^[1,18,19]. CCK receptor is a G protein-coupled receptor with seven-transmembrane domain that has attracted considerable interest as a target for drug-discovery efforts, based on its important physiological role in the gastric mucosa, CNS, and immune cells^[20]. CCK acting through its G protein-coupled receptor is now known to activate a variety of intracellular signaling mechanisms and, thereby, to regulate a complex array of cellular functions in different types of cells. Data from several labs indicates that CCK increases intracellular calcium in

human peripheral blood mononuclear cells and T lymphocyte cell lines^[21]. sCCK-8 can inhibit the mobility capacity and the mitogen-induced lymphocytic proliferation, but can increase the adherence and the spontaneous proliferation of lymphocytes^[22,23]. In addition, sCCK-8 is a negative modulator of several functions of resting murine peritoneal macrophages and human neutrophils, including the production of superoxide anion, phagocytosis and mobility, and the inhibition of these activities is carried out through an increase of intracellular cAMP levels and a decrease in PKC activity^[11]. In the present study sCCK-8 did not affect DAG content, PKC activities, and PKC ζ translocation at low concentrations, but decreased DAG content and inhibited PKC activities and PKC ζ translocation at high concentrations in rat resting PIM. Resting PIM were not sensitive to the stimulation by sCCK-8, and CCK-8 was a negative modulator of the DAG-PKC signaling pathway at physiological concentrations, which was very important for maintaining body homeostasis, and inhibited the DAG-PKC signaling pathway at high concentrations.

LPS is the major component of the outer leaflet of Gram-negative bacteria and has profound immunostimulatory and inflammatory capacity. LPS interacts with LPS-binding protein, therefore allowing binding to CD14 and association with the Toll-like receptor 4 (Tlr4) containing an intracellular signaling domain. Binding of LPS to these receptors results in the activation of several signaling cascades, such as PKC and MAPK^[24]. PKC isoforms are involved in a wide variety of intracellular signaling events and play a significant role in many aspects of immune response, from development, differentiation, activation, and survival of lymphocytes to macrophage activation^[25]. PKC ζ is a member of the atypical subfamily and has been widely implicated in the regulation of cellular functions, particularly in the LPS-induced inflammatory response^[9]. In the present study, stimulation of PIM by LPS increased DAG content, promoted PKC activities and PKC ζ translocation, and changed its distribution, but did not affect PKC total activity. In resting cells or in the absence of lipid hydrolysis, PKC are localized primarily to the cytosol. Translocation to the membrane from cytosol is an important step in PKC activation that can be initiated directly with phorbol esters or by receptor-stimulated increases in DAG. Activation of the enzyme might also be influenced by changes in membrane structure or constituents^[9]. Our results suggest that LPS could activate DAG-PKC signaling pathway in rat PIM, which is in accordance with previous reports.

Macrophages stimulated by LPS or other inflammatory factors produce and release large quantities of various proinflammatory cytokines, including TNF- α , IL-1 β , and IL-6. Overproduction of the cytokines can result in systemic inflammatory response syndrome, multiple organ dysfunction syndrome (MODS) and death. NF- κ B plays a pivotal role in LPS-induced TNF- α and IL-1 β gene expressions. The PKC signaling pathway is linked to the upstream regulation mechanism of NF- κ B activation. In particular, recent findings show that PKC ζ can regulate NF- κ B through an I κ B kinase (IKK)-independent pathway, by directly phosphorylating Ser³¹¹ of the p65 subunit (RelA), and play an important role in mediating inflammatory response induced by LPS^[26]. The present study showed that CCK-8 concentration-dependently inhibited LPS-induced DAG content, PKC activities, and PKC ζ translocation, and a significant inhibition was observed at high concentrations, but not at low concentrations. Cong *et al* reported that CCK-8 inhibited LPS-induced NF- κ B binding activity in a concentration-dependent manner^[21]. The present study demonstrated that CCK-8 significantly inhibited LPS-induced activation of the DAG-PKC signaling pathway at supraphysiological concentrations, which might be

one of the upstream mechanisms for modulating NF- κ B activity and exerting the anti-inflammatory effect of CCK-8.

However, it is unknown whether the inhibitory effect of CCK-8 on DAG-PKC signaling pathway induced by LPS was mediated through the CCK receptor or through which subtype of its receptor. Cong *et al* reported that CCK-8 inhibited NF- κ B binding activity and decreased I κ B- α degradation through CCK receptors in rat PIM stimulated by LPS^[21]. In the present study, the inhibitory effect of CCK-8 on LPS-induced DAG content, PKC activities and PKC ζ translocation was abrogated in part by proglumide, CR-1409, and CR-2945 in a concentration-dependent manner. Proglumide was so potent that it had an obvious effect on CCK-8-resulted inhibition of LPS-induced DAG content, PKC activities, and PKC ζ translocation at low concentrations, and even caused a full reversal of it at high concentrations. A similar effect was found for CR-1409, but not for CR-2945. CR-2945 showed a weak effect only at high concentrations. Our results indicate that the inhibitory effect of CCK-8 on the LPS-activated DAG-PKC signaling pathway in rat PIM was mediated through the CCK receptor, and that both CCK-AR and CCK-BR might be involved in this pathway. However, CCK-AR might play a major role in this process, which would be of benefit in the development of receptor-specific drugs in clinics.

In conclusion, CCK-8 was a negative modulator of the DAG-PKC signaling pathway in rat resting PIM, which was very important for maintaining body homeostasis, and significantly inhibited LPS-induced DAG content, PKC activity, and PKC ζ translocation in a concentration-dependent manner. CCK receptors, particularly CCK-AR, might play a major role in this process. Inhibitory effects of CCK-8 on LPS-induced activation of the DAG-PKC signaling pathway might be one of the upstream mechanisms for modulating NF- κ B activity and exerting its anti-inflammatory effect in rat PIM.

Abstract

Aim: To evaluate the analgesic effects of 2 celecoxib derivatives and their inhibitory effects on cyclooxygenase (COX). **Methods:** Four antinociceptive assays were used: the acetic acid-induced writhing test, hot plate test, hot tail-flick test and formalin test. Three doses were used in the analgesic assays and ED₅₀ values were calculated. For the selectivity assay, macrophages were incubated with test compounds at various concentrations and then stimulated with calcimycin or lipopolysaccharide (LPS). The amounts of 6-keto-prostaglandin F_{1α} (6-keto-PGF_{1α}) and prostaglandin E₂ (PGE₂) in the supernatant were examined by radioimmunoassay (RIA). The selectivity of the test compounds was expressed as the IC_{50,COX-1}/IC_{50,COX-2} value. **Results:** Celecoxib and its 2 derivatives had a significant analgesic effect. The ED₅₀ values of celecoxib, PC-406 and PC-407 were 94.2, 67.9, and 63.3 mg/kg, respectively, for the acetic acid-induced writhing test; 104.7, 89.1, and 30.0 mg/kg, respectively, for the hot tail-flick response test; 60.7, 56.7, and 86.2 mg/kg, respectively, for the hot plate response test; 67.1, 55.8, and 68.8 mg/kg, respectively, for the formalin-induced response. That is, the ED₅₀ of PC-406 was the lowest for the formalin and hot plate tests, which focus on changes above the spinal cord level; however, the ED₅₀ of PC-407 was lowest for the tail-flick and writhing tests, which focus on changes at the spinal cord level. Celecoxib and PC-407 inhibited COX-1 with IC₅₀ values of 39.8 and 27.5 nmol/L, respectively. PC-406 inhibited COX-1 with an IC₅₀ value of more than 1000 nmol/L. The IC₅₀ values for the effect of celecoxib, PC-406 and PC-407 on COX-2 were 4.8, 8.9, and 1.9 nmol/L respectively. The IC_{50,COX-1}/IC_{50,COX-2} ratios for celecoxib and PC-407 were 8.3 and 14.4, respectively. For PC-406, the ratio was greater than 112.2. **Conclusion:** Derivatives of celecoxib via substitution with an isopropyl or naphthyl group at the 5 position in the pyrazole ring still have analgesic effects and the ability to selectively inhibit COX-2. Substitution with a naphthyl group may have more effect on the peripheral pain pathway, whereas substitution with an isopropyl group may have more effect on the central pain pathway. This phenomenon occurs partly because substitution with an isopropyl group is more beneficial for COX-2 selectivity than is substitution with a naphthyl group.

Introduction

Humans have been using non-steroidal anti-inflammatory drugs (NSAIDs) for more than 3500 years. The first real

progress in our understanding of the mechanism of the action of NSAIDs occurred 30 years ago, when it was revealed that these chemically varied drugs reduced the formation of

Figure 1. Chemical structures of celecoxib, PC-406, and PC-407.

prostaglandins. This ability is associated with the inhibition of cyclooxygenase (COX), which converts arachidonic acid to its precursor prostaglandin (PG) H₂. Two isoforms of COX have been identified. The constitutively expressed COX-1 is the housekeeping enzyme mainly responsible for the physiological activities of prostaglandins, whereas COX-2, whose expression is mainly induced under inflammatory conditions, is responsible for pathological prostaglandins that produce pain and fever^[1]. On the basis of these observations, COX-2-selective drugs such as celecoxib were rapidly developed and became one of the most commercially successful classes of drugs^[2].

We synthesized 13 pyrazole derivatives based on the chemical structure of celecoxib^[3,4], including PC-406 and PC-407, which are derivatives of celecoxib created by changing the group at the 5 position in the pyrazole ring. For PC-406, the phenyl structure at the 5 position is replaced by an isopropyl group; for PC-407, it is replaced by a naphthyl group (Figure 1). The chemical structures of these derivatives have been confirmed by infrared absorption spectrum, ultraviolet absorption spectrum, ¹H nuclear magnetic resonance, ¹³C nuclear magnetic resonance and mass spectrum analysis. The purity values of PC-406 and PC-407 were found to be 99.5% and 97.5%, respectively, by high performance liquid chromatography. Using the mouse ear edema model, PC-406 and PC-407 were found to have more potential activity than celecoxib in anti-inflammation. PC-406 and PC-407 were also observed to have fewer gastrointestinal side effects. In the present study, we tried to evaluate the analgesic effects and inhibitory effects on COX-1/COX-2 of candidate compounds.

Materials and methods

Animals BALB/c mice obtained from the Experimental Animal Center of the Fourth Military Medical University were used. Half of the mice were males and half were females. All the animals weighed 18–22 g. Animals were housed in colonial stock following arrival. Food and water were available *ad libitum*. Temperature and humidity of the environment were controlled (23±1°C and 50.0%±1.3%, respectively), and

a 12 h day/night cycle was used. All the experiments were carried out during the light phase. The experimental design was approved by the relevant ethics board of the institution in which the study was carried out.

Drugs and reagents PC-406 and PC-407 were synthesized by our group. The celecoxib was a gift from Pharmacia (Rockville, MD, USA). Lipopolysaccharide (LPS) and calcimycin were purchased from Sigma (St Louis, USA). The Brewer thioglycollate medium was from (Difco Company, Detroit, USA). Newborn calf serum and RPMI-1640 were from (Hyclone, Logan, USA). The 6-keto-PGF_{1α} and PGE₂ radioimmunoassay (RIA) kits were from Chemclin Biotech (Beijing, China). For the analgesic effect assays, all the test compounds were dissolved in 3% Tween-80 and administered intragastrically in a volume of 0.3 mL. For the selectivity evaluation, all the tested samples were prepared in stock solution (0.01 mol/L) with Me₂SO and stored at -20 °C. Before use, the stock solution was diluted to a series of concentrations in RPMI-1640.

Antinociceptive assays Four antinociceptive assays were used: the writhing test, hot tail-flick test, hot plate test, and formalin test. Mice were fasted for 24 h with water given *ad libitum*, maintained at room temperature and were divided into 4 groups (*n*=6): control group, CEL group, PC-406 group, and PC-407 group, which received pretreatment with 3% Tween-80, celecoxib, PC-406, and PC-407, respectively. The 2nd, 3rd, and 4th groups were further divided into 3 subgroups (A,B,C), which received test compounds at 100, 50, and 25 mg/kg, respectively. Celecoxib was used as a positive control.

Writhing test All the pretreatments were carried out 1 h prior to intraperitoneal injection of 0.1 mL/10 g of 0.6% acetic acid, which caused a typical writhing response. The number of writhing responses was counted for 10 min by observers who were blinded to the treatment. The antinociceptive effects of drugs were measured by calculating the mean reduction in the number of abdominal constrictions for each drug, as compared to that produced by the Tween-80 vehicle.

Hot tail-flick test The antinociceptive effects of the test substances were determined by the hot tail-flick method as

described by Sewell and Spencer^[5]. The tails of mice (1–2 cm) were immersed in warm water kept constant at 53 °C, and the reaction time was measured as the time taken for the mice to deflect their tails. The first reading was ignored, and the reaction time was taken as the mean of the next 2 readings. The latent period until the tail-flick response was taken as the index of antinociception and was determined before and 1 h after the administration of drugs. The maximum reaction time was fixed at 3 s. The analgesia percentage (AP) was calculated as: $AP = (t_{\text{test reaction}} - t_{\text{control reaction}}) / (3 - t_{\text{control reaction}})$.

Hot plate test The method used has been described by Baker *et al*^[6]. A metal hot plate was heated to a constant temperature. Behavioral measurements were taken at 55±0.5 °C. The temperature of the plate was monitored at all times. To confine the animals to a certain observation area, a colorless acrylic cylinder of 20 cm diameter was placed on the hot plate. After each measurement the plate was wiped with a damp cloth to remove traces of urine and feces. Latency for the animal to lick its hindpaw was measured before and 1 h after pretreatment. The offset time was set at 30 s. AP was calculated as: $AP = (t_{\text{test reaction}} - t_{\text{control reaction}}) / (30 - t_{\text{control reaction}})$.

Formalin test Formalin solution (5 %, 50 mL) was injected subplantarily into the left hindpaws of the mice using a microsyringe with a 26-gauge needle. Animals were then placed in a Plexiglas chamber and observed for nociceptive behavior for 1 h. The amount and duration of licking or flinching were recorded at 5 min intervals over the next 60 min. The sum of the amount and duration of licking or flinching in the early phase (0–10 min, phase 1) and late phase (20–60 min, phase 2) were calculated, respectively. To calculate the ED₅₀, the decrease in the summed amount of licking or flinching during the whole observation period as compared with the control group was calculated.

Cell culture Adherent macrophages were harvested from the peritoneal cells of male mice 3 d after the intraperitoneal injection of Brewer thioglycollate medium (50 mL/kg). Peritoneal cells obtained from 2–3 mice were mixed and cultured in RPMI-1640 supplemented with 5% new-born calf serum. After settlement for 2 h, non-adherent cells were washed with cold phosphate-buffered saline (PBS). Then, macrophages were seeded in 96-well cell culture clusters (Gibco, USA) at a cell density of 1×10⁹/L. Almost all the adherent cells were macrophages as assessed by Giemsa staining. Cell viability was examined by Trypan blue dye exclusion. All the incubation procedures were performed with 5% CO₂ in humidified air at 37 °C.

COX-1 assay Macrophages were incubated with test compounds at different concentrations or with the solvent (Me₂SO) for 1 h and were stimulated with calcimycin (1 μmol/

L) for 1 h. The same volume of RPMI-1640 was added for the control groups. The amount of 6-keto-PGF_{1α} in the supernatant was measured by RIA, using the manufacturer's instructions. The inhibitory ratio (IR) was calculated as $IR = (C_{\text{calcimycin}} - C_{\text{test compound}}) / (C_{\text{calcimycin}} - C_{\text{control}})$, where C is the concentration of 6-keto-PGF_{1α} in the supernatants of the calcimycin, test compound or control groups.

COX-2 assay Macrophages were incubated with test compounds at different concentrations or with the solvent (Me₂SO) for 1 h and were stimulated with LPS (1 mg/L) for 9 h. The same volume of RPMI-1640 was added for the control groups. The amount of PGE₂ in the supernatant was measured by RIA, using the manufacturer's instructions. The IR was calculated as $IR = (C_{\text{LPS}} - C_{\text{test compound}}) / (C_{\text{LPS}} - C_{\text{control}})$, where C is the concentration of PGE₂ in the supernatants of the LPS, test compound or control groups.

Statistics Data are presented as mean±SD of *n* observations. The 95% confidence limits of the ED₅₀ and IC₅₀ values were also calculated. Comparisons between the groups were carried out by using one-way analysis of variance (ANOVA), followed by the least significant difference multiple comparisons test. A *P*-value of 0.05 was considered statistically significant. Dose-inhibitory effect curves were fitted by using sigmoidal dose-response curves (variable slope) (inhibitory effect on COX) or linear regression (analgesic effect) using Graphpad Prism (version 4.00, GraphPad Software Inc, San Diego, USA).

Results

Acetic acid-induced writhing Intraperitoneally injected acetic acid produced abdominal constrictions, which were characterized by a stretching response. The mean number of writhing motions observed in the animals of the control group over 10 min was 10.33±6.03. All the 3 test compounds at a high dose (100 mg/kg) significantly (*P*<0.05) reduced the number of writhing motions to 5.3±4.0, 1.3±2.3, and 1.7±1.5, respectively. However, test compounds at low doses (50 or 25 mg/kg) did not significantly reduce the number of writhing motions induced by acetic acid (Figure 2). The ED₅₀ values of celecoxib, PC-406 and PC-407 for acetic acid-induced writhing were 94.2, 67.9, and 63.3 mg/kg respectively (Figure 3, Table 1).

Hot tail-flick response The animals in the control group did not show any significant effects with respect to the latent period until tail-flick response. The antinociceptive effect of PC-406 at a high dose (100 mg/kg) was evident (*P*<0.05) and the duration of the tail-flick response increased from 0.87±0.27 to 1.92±0.15 s. PC-406 at lower doses (25 or 50

Table 1. ED₅₀ values (mg/kg) and 95% confidence limits for test compounds according to different antinociceptive assays.

Compound	Writhing test	Hot tail-flick test	Hot plate test	Formalin test
Celecoxib	94.2 (66.1–234.8)	104.7 (73.9–211.1)	50.6 (31.4–70.4)	67.1 (24.1–157.9)
PC-406	67.9 (24.7–140.5)	89.1 (73.0–119.3)	46.1 (30.3–65.2)	55.8 (15.4–125.0)
PC-407	63.3 (31.6–93.2)	30.0 (6.4–47.9)	76.8 (48.6–129.4)	68.8 (45.8–73.2)

mg/kg) did not have any significant analgesic effect as measured by this assay. However, PC-407 at all doses produced significant antinociception (*P*<0.05, Figure 5). The ED₅₀ values of celecoxib, PC-406, and PC-407 as assessed by the hot tail-flick assay were 104.7, 89.1, and 30.0 mg/kg, respectively (Figure 4, Table 1).

Figure 5. Effects of test compounds on latent period until hot tail-flick response. *n*=8. Mean±SD. ^b*P*<0.05 vs control group. CEL, celecoxib.

Hot plate response Animals in the control group did not show any significant effects with respect to the latent period until hot plate response. Both PC-406 and PC-407 produced a significant analgesic effect as measured by the hot plate response (*P*<0.05, Figure 5). The ED₅₀ values of celecoxib, PC-406 and PC-407 as measured by hot plate response were 50.6, 46.1, and 76.8 mg/kg, respectively (Figure 6, Table 1).

Formalin test All the mice exhibited elevating, shaking, licking or biting behaviors in the injected left hindpaw after subcutaneous injection of formalin into the plantar surface. These behaviors had 2 distinct phases: an early phase (phase 1), which appeared immediately after formalin injection and lasted 10 min, and a late phase (phase 2), which appeared about 20 min after injection and lasted 40 min. PC-406 and PC-407 (25–100 mg/kg) elicited a dose-dependent inhibitory effects on licking time, with a maximal reduction of approximately 85% of the control response (*n*=8). For animals treated with PC-406 or PC-407, the durations and amounts of flinching or licking were significantly decreased (*P*<0.05, Figures 8, 9). The ED₅₀ values of celecoxib, PC-406 and PC-407 were 67.1, 55.8, and 68.8 mg/kg, respectively (Figure 10, Table 1).

COX inhibitory effect The IC₅₀ values of celecoxib and PC-407 for COX-1 were 39.8 nmol/L and 27.5 nmol/L, respectively. For PC-406, the IC₅₀ value was more than 10 000 nmol/L (Figure 11A). The IC₅₀ of test compounds for COX-2 were 4.78, 8.9, and 1.9 nmol/L, respectively (Figure 11B). The selectivity of the test compounds for COX-1/COX-2 was expressed as the value of IC_{50,COX-1}/IC_{50,COX-2}. PC-406 showed a 112.2-fold preference for COX-2 versus COX-1 (Table 2).

Discussion

The discovery and characterization of the COX-2 enzyme early in the 1990s led to many studies on selective inhibitors of this isoform. It was hypothesized that COX-2 selective inhibitors would exhibit similar clinical efficacy but reduced ulcerogenicity relative to traditional NSAIDs. Less than a decade after the discovery of COX-2, celecoxib and rofecoxib were launched, and were very effective analgesics and anti-

Compound	IC ₅₀ /nmol·L ⁻¹		IC _{50,COX-1} / IC _{50,COX-2}
	COX-1	COX-2	
Celecoxib	39.8 (4.9–258.2)	4.8 (3.1–18.9)	8.3
PC-406	>1000	8.9 (4.6–18.9)	>112.2
PC-407	27.5 (4.0–140.0)	1.9 (1.4–8.1)	14.4

**Figure 10.** Inhibitory effects of test compounds on the amount of licking or flinching. *n*=8. Mean±SD.

inflammatory agents. Furthermore, in recent years, coxibs have been proved to have potential in the treatment of cancer and Alzheimer's disease. All things considered, the prospects for COX-2 selective inhibitors are good. Based on the chemical structure of celecoxib, we synthesized PC-406 and PC-407, 2 pyrazole derivatives, by retaining benzenesulfonamide, the necessary active component of the molecule. In the present study, their analgesic effects and selectivity for COX-2 were evaluated.

All the antinociceptive assays showed that derivatives of celecoxib made by substituting groups at the 5 position exhibited analgesic effects. However, the results from different assays were different. Four antinociceptive assays were used in our study. Among them, the hot plate and hot tail-flick tests test responses to thermal stimulations, whereas the writhing and formalin tests test responses to chemical stimulations. The pain pathways these tests focus on vary as well. The formalin and hotplate tests mainly focus on changes above the spinal cord level, whereas the tail flick and writhing tests emphasize changes at or under the spinal cord level. In the present study, the results of both the hot plate test and the formalin test show that PC-406 has the lowest ED₅₀ value. However, the results of the writhing and

**Figure 11.** Dose-response curve of test compounds for COX-1 (A) and COX-2 (B).

tail flick test show that PC-407 has the lowest ED₅₀ value. Thus we can infer that PC-406 exerts more effect on the pathways above the spinal cord level, whereas PC-407 exerts more effect on pathways peripherally.

Detailed data from the formalin test showed the same results. The formalin test is a well characterized and validated evaluation method in mice and rats. It is an accepted method for the rapid and easy screening of pharmacological targets in drug evaluation, because it can be performed in small animals, and the time course of the noxious stimulation is limited to 1 h. Subplantar injection of formalin results in flinching, licking or biting behavior during an early acute phase, which resembles acute pain, followed by a quiescent interphase, and then a second delayed phase representing chronic pain. The acute phase is believed to correspond to the peripheral pain pathways, whereas the second phase represents more central pain processing mechanisms. In our study, both phases of the formalin test were well delineated and could be quantified. Celecoxib and its 2 derivatives could significantly decrease both the duration and amount of pain behaviors during the formalin test (*P*<0.05). Celecoxib and PC-407 had more effect on behaviors in phase 1, whereas PC-406 affected behaviors in phase 2 more. That is, celecoxib and PC-407 affected the peripheral pain pathways more, whereas PC-406 affected the central pain pathways more. This is consistent with what we found in our analysis of

different ED₅₀ values.

The differences in the different analgesic effects of the test compounds are related to their different structures. So we subsequently investigated the relationships between the modifications of their chemical structures and their selectivity for COX-2. To evaluate the selectivity of compounds for COX-2, many models have been established^[7-10]. Macrophages are known to release prostanoids in 2 kinetically distinct patterns: the immediate and delayed phases^[11]. In the immediate phase, 6-keto-PGF_{1α} and TXB₂ are the major arachidonic acid metabolites. However, in the delayed phase, PGE₂ is produced depending on induced COX-2. Macrophages can spontaneously secrete low levels of 6-keto-PGF_{1α} and PGE₂. Stimulation with calcimycin or LPS promotes a dramatic enhancement of prostanoid production. Shen *et al* developed a whole-cell assay based on murine peritoneal macrophages and demonstrated that it was appropriate for drug design-oriented *in vitro* assay^[12]. This method was used in the present study.

The results of selectivity evaluation show that PC-407 and PC-406 provide stronger selectivity with respect to the inhibition of COX-2 than does celecoxib. PC-406 has the greatest selectivity. It might be the reason for their weak influence on stomach mucosa. The present study indicates that test compounds with a non-aryl group or an aryl group substituted at the 5 position in the pyrazole ring still retain their anti-inflammatory activity and their ability to inhibit COX-2 selectively. Furthermore, substitution at the 5 position with a non-aryl group might be more beneficial with respect to COX-2 selectivity than substitution with an aryl group.

It has been proved that COX-2 plays a more central role and is more highly expressed in the central nervous system than is COX-1, which is the basis of most of its therapeutic effects. The higher selectivity for COX-2 of PC-406 contributes to its central pain pathway effects. However, identification of the exact parts of the pain pathways that the 2 derivatives affect needs further investigation.

In conclusion, derivatives of celecoxib made by substituting with either a isopropyl or a naphthyl group at the 5 position in the pyrazole ring produced analgesic effects with respect to both thermal and chemical nociception. However, substitution with an isopropyl group improves the effect on the central pain pathway better, whereas substitution with a naphthyl group affects the peripheral pathway more. This is

correlated with the altered selectivity for COX-2. Both derivatives had greater selectivity than celecoxib. However, substitution with an isopropyl group was more beneficial with respect to COX-2 selectivity than substitution with an naphthyl group.

Abstract

Aim: To investigate the body distribution in mice of [¹⁴C]-labeled poly methoxyethyleneglycol cyanoacrylate-co-*n*-hexadecyl cyanoacrylate (PEG-PHDCA) nanoparticles and *in situ* evading of phagocytic uptake by mouse peritoneal macrophages. **Methods:** PEG-PHDCA copolymers were synthesized by condensation of methoxypolyethylene glycol cyanoacetate with [¹⁴C]-hexadecylcyanoacetate. [¹⁴C]-nanoparticles were prepared using the nanoprecipitation/solvent diffusion method, while fluorescent nanoparticles were prepared by incorporating rhodamine B. *In situ* phagocytic uptake was evaluated by flow cytometry. Body distribution in mice was evaluated by determining radioactivity in tissues using a scintillation method. **Results:** Phagocytic uptake by macrophages can be efficiently evaded by fluorescent PEG-PHDCA nanoparticles. After 48 h, 31% of the radioactivity of the stealth [¹⁴C]-PEG-PHDCA nanoparticles after iv injection was still found in blood, whereas non-stealth PHDCA nanoparticles were cleaned up from the bloodstream in a short time. The distribution of stealth PEG-PHDCA nanoparticles and non-stealth PHDCA nanoparticles in mice was poor in lung, kidney, and brain, and a little higher in hearts. Lymphatic accumulation was unusually high for both stealth and non-stealth nanoparticles, typical of lymphatic capture. The accumulation of stealth PEG-PHDCA nanoparticles in the spleen was 1.7 times as much as that of non-stealth PHDCA ($P < 0.01$). But the accumulation of stealth PEG-PHDCA nanoparticles in the liver was 0.8 times as much as that of non-stealth PHDCA ($P < 0.05$). **Conclusion:** PEGylation leads to long-circulation of nanoparticles in the bloodstream, and splenotropic accumulation opens up the potential for further development of spleen-targeted drug delivery.

Introduction

One of the major objectives of advanced drug delivery today is drug targeting with colloidal drug-delivery systems, such as nanoparticles and liposomes. However, these conventional carriers are rapidly cleaned from the systemic circulation, and end almost exclusively in the mononuclear phagocyte system (MPS) after iv injection, mainly in the macrophages in the liver and spleen^[1]. Of course, this extensive uptake is advantageous for treating illness of the reticuloendothelial system (RES) because it provides high local

concentrations of therapeutic agents. Unfortunately, delivering drugs to sites other than RES is often desired. To meet this requirement, stealth or long-circulating nanoparticles have been investigated.

In the past two decades, there has been an increasing interest in the development of stealth nanoparticles as drug carrier systems^[2,3]. One of the main methods for preparation of stealth nanoparticles is to modify their surface with a hydrophilic and non-ionic polymer, eg, poly methoxyethyleneglycol (PEG)^[4] or poloxamer derivatives^[5,6]. Previous studies demonstrate that the hepatic uptake of

nanoparticles can be reduced by coating these particles with certain modification. Several mechanisms are discussed for this modification of the body distribution^[6,8]: a dependence on the nanoparticle surface charge, a reduction in the surface hydrophobicity reducing phagocytic uptake, a steric hindrance preventing the contact between particles and blood cells (theory of steric stabilization), and a change in the adsorption of blood components determined by the surface properties of the particles. The adsorption patterns differ depending on the physicochemical properties of the particles.

According to Peracchia *et al*, PEGylated polycyanoacrylate nanoparticles are suitable for giving iv and capable of circumventing capture by hepatic Kupffer cells^[9]. The increment of splenic nanoparticles led the authors to conclude a splenic targeting mechanism. However, the investigation was taken for a duration of only 24 h, and detailed description of body distribution as a function of time in organs other than liver and spleen was absent. Other authors have studied the same vehicle by incorporating a protein drug, recombinant human tumor necrosis factor α ^[10]. In contrast to splenic accumulation, diversion of nanoparticles to tissues other than the liver and spleen, that is tumors, was observed.

Distribution of stealth nanoparticles to non-hepatic and non-splenic organs or tissues make them prospective vehicles for the delivery of active ingredients to these sites. In the present study, biodistribution of [¹⁴C]-labeled poly methoxyethyleneglycol cyanoacrylate-co-*n*-hexadecyl cyanoacrylate (PEG-PHDCA) nanoparticles was evaluated for the prolonged duration of 48 h. Distribution to organs other than the liver and the spleen was studied, which is also of interest for target stealth diversion. An *in situ* phagocytic evading was also investigated in mouse peritoneum using chemically induced macrophages and flow cytometry.

Materials and methods

Materials Methoxypolyethylene glycol (5000 Da of molecular weight, MePEG 5000) was obtained from Sigma Chemical Co. Cyanoacetic acid was obtained from Fluka Chemical Co and [^{3-¹⁴C}]-cyanoacetic acid was obtained from Moravек Biochemicals. *N, N'*-dicyclo-hexylcarbodiimide and 4-dimethylaminopyridine were obtained from Shanghai Chemical Reagent Co. Formaline (37%) was obtained from Shanghai Jianxin Chemical Co. Aqueous dimethylamine (34%) was provided by Shanghai Linfeng Chemical Co. Other reagents were of analytical purity.

Synthesis of [¹⁴C]-labeled PEGylated and non-PEGylated

PHDCA polymers Synthesis of poly PEG-PHDCA copolymers has been studied previously^[11]. The PEG-PHDCA 1:3 copolymer was synthesized by condensation of MePEG 5000 cyanoacetate with [¹⁴C]-hexadecylcyanoacetate in ethanol, in the presence of formaline and dimethylamine.

[^{3-¹⁴C}] Cyanoacetic acid (490.4 mg, 552 μ Ci=20.4 MBq) was dissolved in ethyl acetate (5 mL), and a solution of hexadecanol (697.6 mg, 1.75 mmol) and 4-dimethylaminopyridine (1.1906 g, 1.75 mmol) in dichloromethane (9 mL) was added. Then, *N, N'*-dicyclo-hexylcarbodiimide (129.38 mg, 0.63 mmol) was added. After stirring at room temperature for 16 h, the resultant mixture was filtered. Filtrate was concentrated under vacuum, and [¹⁴C]hexadecylcyanoacetate was collected as a waxy solid (1.0386 g, 87.4%, 400 μ Ci=14.8 MBq). [¹⁴C] Hexadecylcyanoacetate (519.3 mg, 1.68 mmol, 200 μ Ci=7.4 MBq) and MePEG 5000 cyanoacetate (2.9235 g, 0.56 mmol) was added to a 1:1 mixture of ethanol and dichloromethane (10 mL), sequentially, 37% formaline (305 μ L, 3.76 mmol) and 34% aqueous dimethylamine (515 μ L, 388 mmol) was added. After stirring at room temperature for 16 h, the reaction mixture was concentrated under reduced pressure. The residue was dissolved by dichloromethane (100 mL) and washed with 10 mL of water. The organic phase was dried over magnesium sulfate, and concentrated under vacuum. Non-PEGylated [¹⁴C]-polymer PHDCA was also synthesized by condensing [¹⁴C] hexadecylcyanoacetate with cyanoacetate.

Preparation of [¹⁴C]-labeled and fluorescent nanoparticles [¹⁴C]-labeled nanoparticles were prepared by a nanoprecipitation/solvent diffusion method^[11]. The [¹⁴C]labeled PEG-PHDCA (1:3) copolymer (100 mg) or the [¹⁴C]PHDCA polymer was dissolved in 4 mL of tetrahydrofuran, and the polymer solution was added, under magnetic stirring, to 100 mL of demineralized water. Particle formation occurred immediately. After solvent evaporation using a rotary evaporator, an aqueous suspension of nanoparticles (1 mg/mL) was obtained. The nanoparticles were washed twice with demineralized water after ultracentrifugation, and then filtered (Millex AP, Millipore, 1.2 μ m). The radioactivity of the nanoparticle solution was determined just before injection.

Fluorescent nanoparticles were prepared following similar procedures by incorporating 0.2% rhodamine B.

Characterization of nanoparticles The morphological examination of nanoparticles was performed using transmission electron microscopy (TEM) (HITACHI H-600) following negative staining with sodium phosphotungstate solution. The particle size and zeta potential of nanoparticles were determined, respectively, by photon correlation spec-

troscopy and laser Doppler anemometry (NICOMP 380/ZLS). Influence of organic solvent, polymer concentration in organic phase and preparation procedures on nanoparticle structure were previously reported^[11].

***In situ* evading of phagocytic uptake by macrophages**

The phagocytic evading effect of PEG-PHDCA was observed on chemically induced mouse peritoneal macrophages^[12]. The mice were injected with 1 mL of 3% sodium thioglycolate solution *ip* as a stimulant for macrophages. After 3 d of induction, fluorescent nanoparticles were injected *ip* and incubated together with the macrophages for 2 h. Then, the mice were killed by cervical dislocation, and each was peritoneally injected with 5 mL of saline. The peritoneum of the mouse was massaged for 1 min and the solution inside the abdominal cavity was drawn out. Macrophages were washed 3 times with 1 mL of phosphate buffer. Cellular uptake of PEG-PHDCA nanoparticles was examined with a FACScan flow cytometer, operated under activation wavelength of 585 nm. Each assay counted 20 000 macrophages. Non-stealth PHDCA nanoparticles were also studied as a contrast, and saline as a control.

***In vivo* tissue distribution of [¹⁴C]-labeled PEG-PHDCA nanoparticles** To evaluate the body distribution of PEG-PHDCA and PHDCA nanoparticles, 2 groups of mice (6 each) at 1 time interval were treated with [¹⁴C]-PEG-PHDCA and [¹⁴C]-PHDCA nanoparticles, respectively. A total of 200 μ L nanoparticle suspension at the dose of 150 mg/kg were injected into male mice (approximately 20 g in weight) through the tail vein. The amount of given radioactivity was 1.7×10^5 Bq/kg. Animals were killed after 0.05, 0.5, 3, 6, 15, 24, 36, and 48 h of injection. Meantime, blood samples were withdrawn, and hearts, livers, spleens, lungs, kidneys, brains, and lymph nodes were carefully collected. The organs were weighed immediately after removal. Alkaline tissue solubilizer (2 mol/L NaOH) was added to organ samples, and heated at 12°C for 30 min, then cooled to an ambient temperature, and 30% H₂O₂ was added with occasional swirling until the color subsided. After addition of 200 μ L of acetic acid and 3 mL of scintillation cocktail (PPO/POPOP), the prepared samples were stored for approximately 2 d and then counted in the scintillation counter (LKB 1210). For determining radioactivity in blood, plasma was separated to exclude interference of blood cell lysates. Recovery of radioactivity was found to be between 95% and 103% for all tissues.

For the calculation of the radioactivity of the total dose (percentage dose) and of 1 milligram of tissue (Bq/mg), the injected radioactivity was taken as the total dose.

To evaluate the effect of specific accumulation of nanoparticles in organs, areas under the radioactivity-time

curve (AUC_{0-48 h}) were calculated and compared.

Statistical analysis *In vivo* radioactivity values were calculated as a mean of the results of 6 mice determined separately, and presented as mean \pm SD. Statistical comparisons of the means were performed using multivariate analysis of variance with SARS software.

Results

Synthesis of the [¹⁴C] labeled PEGylated and non-PEGylated polymer According to our previous findings^[11], PEG-polycyanoacrylate copolymers were prepared by condensation of a mixture of MePEG-cyanoacetate and *n*-hexadecyl-cyanoacetate with high yields. After standing at room temperature for 16 h and drying under vacuum, the desired copolymers were obtained as pale yellow amorphous solids. The structure and ratio between hexadecyl chains and PEG chains were confirmed by integration of the respective signals in ¹H-nuclear magnetic resonance (¹H-NMR) spectroscopy. The structure of the material was also confirmed by Fourier transform infrared spectrometer (FTIR) and the molecular weight was determined by gel permeation chromatography.

The fact that radiolabeling was integrated in the cyano group, assured a great stability of the radiolabeled copolymer. PEG-PHDCA and PHDCA were synthesized using similar techniques, only substituting MePEG-cyanoacetate for cyanoacetate.

Characterization of [¹⁴C]-labeled nanoparticles Nanoparticles prepared with PEG-PHDCA or PHDCA were spherical in shape and uniform in size of approximately 200 nm (Figure 1). PEGylated nanoparticles contrasted greatly with non-PEGylated nanoparticles, with corolla-like stains.

Figure 1. Transmission electron microscopy photographs of stealth PEG-PHDCA (A, $\times 40\ 000$) and non-stealth PHDCA (B, $\times 50\ 000$) nanoparticles. PEG-PHDCA: poly methoxyethyleneglycol cyanoacrylate-co-*n*-hexadecyl cyanoacrylate. PHDCA: polyhexadecyl cyanoacrylate.

The zeta potential of PEG-PHDCA and PHDCA nanoparticles was -10.77 mV and -20.57 mV, respectively. A marked decrease in the surface charge for PEG-PHDCA nanoparticles was observed. Diameter of nanoparticles determined by photo correlation spectrometry was within the range of $188.7 \text{ nm} \pm 67.2 \text{ nm}$, in accordance with TEM observation.

In situ evading of phagocytic uptake of PEG-PHDCA nanoparticles Incorporation of fluorescent rhodamine B in nanoparticles was verified under a research inverted system microscope (IX-71, Olympus). Loading of rhodamine B was approximately 0.2%, determined by spectrofluorometer (LS-55, PerkinElmer), upon which the assumption that toxicity of fluorescent marker to macrophages was negligible was drawn. Flow cytometry diagrams are shown in Figure 2.

The value of relative fluorescence intensity of the saline, PEG-PHDCA nanoparticles and PHDCA nanoparticles samples were 54.9, 156.5, and 1726.7, respectively, each representing the stained cells. The higher the value was, the more that the nanoparticles were captured by macrophages. Fluorescence intensity for PEG-PHDCA nanoparticles was approximately 3 times as much as that of saline control, indicating limited phagocytosis by macrophages. For non-stealth PHDCA nanoparticles, fluorescence intensity was almost 11 times as much as that of stealth PEG-PHDCA nanoparticles, indicating profound phagocytosis by macrophages. Evading of phagocytosis by macrophages was achieved through PEGylation.

Long circulating in bloodstream PEG-PHDCA nanoparticles had a remarkably higher accumulation in the blood-

stream than PHDCA ($P < 0.01$). PEG-PHDCA nanoparticles exhibited long-circulating characteristics, with sustained high levels of blood-associated radioactivity, and 31% of the radioactivity was still found in the bloodstream 48 h after injection, assuming that radioactivity was still associated with intact nanoparticles. In contrast, PHDCA nanoparticles were cleaned up quickly from the bloodstream, and after 30 min, dropped abruptly to a much lower level, as expected. At the end of 48 h, only approximately 4% of the radioactivity was recovered from blood (Figure 3). The PEG-PHDCA nanoparticles exhibited a ‘brush’ PEG configuration at the particle surface, and therefore performed the steric repulsion efficiently^[13].

Organ accumulation The distribution of stealth PEG-PHDCA nanoparticles and non-stealth PHDCA nanoparticles in mice was poor in lung, kidney, and brain, and a little higher in heart (Table 1, Figure 4).

There was a relatively higher accumulation in the spleen and liver for both stealth PEG-PHDCA nanoparticles and non-stealth PHDCA nanoparticles compared with heart, lung, kidney, and brain (Table 1, Figure 4).

For stealth PEG-PHDCA nanoparticles, the accumulation in the spleen was higher than that in the liver ($P<0.05$). For non-stealth PHDCA nanoparticles, the accumulation in the spleen was lower than that in the liver ($P<0.05$). The accumulation of stealth PEG-PHDCA nanoparticles in the spleen was 1.7 times as much as that of non-stealth PHDCA ($P<0.01$, Table 1, Figure 4). But the accumulation of stealth PEG-PHDCA nanoparticles in the liver was 0.8 times as much as that of non-stealth PHDCA ($P<0.05$, Table 1, Figure 4).

The amount of radioactivity of stealth PEG-PHDCA recovered from the spleen was much higher than that from liver ($P<0.01$, Figure 5). Such a high spleen uptake was also observed by other authors with PEGylated nanoparticles^[9].

Accumulation in lymph nodes was unusually higher for both stealth PEG-PHDCA and non-stealth PHDCA nanoparticles compared with other organs. The radioactivity was maintained at a high level for at least 36 h, typical of lymphatic capture (Table 1). Lymphatic accumulation of stealth PEG-PHDCA was lower than that of non-stealth PHDCA nanoparticles ($P<0.05$, Figure 6).

The accumulation of stealth PEG-PHDCA nanoparticles in the blood was 3.5 times as much as that of non-stealth

Discussion

In the present study, PEG-PHDCA was synthesized as a diblock copolymer, where PEG chains brought about hydro-

philic modification of the nanoparticle surface, and hexadecyl cyanoacrylate moieties guaranteed enough hydrophobicity for the formation of nanoparticles. Structural importance was testified by ¹H-NMR and FTIR spectrum. Molecular weight determination by gel permeation chromatography showed a strong correlation between theoretical calculation of total amount of MePEG and hexadecyl cyanoacrylate present.

The nanoparticles were easily prepared by the nanoprecipitation/solvent diffusion method, with limited size distribution as determined by NICOMP 380/ZLS and TEM. The value of zeta potential of PEG-PHDCA nanoparticles was much lower negative than that of PHDCA nanoparticles. It should be mentioned that the PEG chains in nanoparticles would be oriented towards the outer aqueous medium, protecting the hydrophobic core. Change in surface zeta potential was also indicative of modifications by PEG chains.

Particles with hydrophobic surfaces are removed readily from the circulation through a mechanism of opsonization^[6], a process involving complement adsorption and following recognition and phagocytosis by macrophages^[14]. Stealth nanoparticles with “water”-like hydrophilic chains poking out interfered with adsorption of complements, and subsequent capture by macrophages. It was simple and informative to investigate interaction between vehicles and certain cell lines before taking out *in vivo* study. Stealth properties of nanoparticles have been studied *in vitro* in cultured macrophage cell lines with a fluorescent marker^[15-17]. To rule out disturbing uncertainty associated with an *in vitro* method, we developed a novel *in situ* model to study the effect of stealth evading of phagocytic capture by macrophages. Preliminary results were encouraging enough for us to take out *in vivo* distribution studies.

Findings that the studied vehicles are long-circulating in the bloodstream are similar to reports by Li *et al*^[10]. Sustained high levels of radioactivity of approximately one-third of the original injection for 48 h indicated longer circulation time of the vehicles, making it applicable carriers for delivering active ingredients to non-RES targets or for sustained release. Study on prolonged duration of long-circulating is needed in the future. Biodegradation of PEG-PHDCA nanoparticles has not been evaluated in the present study. However, rapid degradation was not observed in the present study, because radioactivity was embedded in the cyano groups, and if biodegradation took place, it was only associated with water-soluble small degradation remnants, which was readily eliminated from the body. For at least 48 h, nanoparticles did not undergo enormous degradation.

Splenotropic accumulation was also observed in the present study, the accumulation of stealth PEG-PHDCA nanoparticles in the spleen was 1.7 times as much as that of non-stealth PHDCA. The propensity of the mouse spleen to remove such particles from the blood was attributed to its unique architecture (reticular meshwork of the red pulp and interendothelial cell slits) and intrasplenic microcirculation (anatomically open and physiologically closed circulation)^[19]. The mode of particle clearance from the blood by the spleen appeared to be initially of mechanical filtration^[20]. Interestingly, large filtered sterically stabilized particles were eventually phagocytosed by the splenic red pulp macrophages^[21]. Phagocytosis of such particles was, presumably, derived either as a result of intrasplenic loss of the coating, the steric barrier, or of certain intrasplenic opsonization processes. Predosing dramatically decreased the spleen uptake of splenotropic spheres but had no effect on the filtration of small sized particles (<150 nm). It is now evident that opsonization of a ‘phagocyte-resistant’ particle can even occur, depending on the *in vivo* circumstances. Furthermore, even stimulated macrophages can effectively recognize and internalize ‘phagocyte-resistant’ substrates independent of opsonization processes. Spleen-targeted stealth nanoparticles have the potential to be used to deliver nuclear substances and active components for diagnostic purposes and the therapeutic treatment of spleen-born abnormalities. In contrast, because the spleen is the biggest resident site in the human body for immune cells, such as T and B lymphocytes, delivery of vaccines into it might cause profound immunoreactions.

In summary, PEGylation leads to long-circulation of nanoparticles in the bloodstream, and splenotropic accumulation which opens up the potential for further development of spleen-targeted drug delivery.

Abstract

Aim: To identify 4 unknown metabolites of benproperine (BPP, 1) in human urine after a *po* dose, and to investigate the antitussive effect of monohydroxylate metabolites. **Methods:** The putative metabolite references were prepared using chemical synthesis. Their structures were identified using ¹H and ¹³C nuclear magnetic resonance, and mass spectrometry. The metabolites in human urine were separated and assayed using liquid chromatography-ion trap mass spectrometry (LC/MS/MS), and further confirmed by comparison of their mass spectra and chromatographic retention times with those of synthesized reference substances. The antitussive effects of metabolites were evaluated on coughs induced by 7.5% citric acid in conscious guinea pigs. **Results:** 1-[1-Methyl-2-[2-(phenylmethyl)phenoxy]-ethyl]-4-piperidinol (2), 1-[1-methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-3-piperidinol (3) and their glucuronides 4 and 5 were obtained from chemical synthesis. Four urinary metabolites in human urine showed peaks with the same chromatographic retention times and mass spectra in LC/MS/MS as synthetic substances 2, 3, 4 and 5. Phosphates of compounds 2 and 3 prolonged the latency of cough and reduced the number of coughs during the 3 min test using citric acid, but did not reduce the number of coughs during the 5 min immediately after the test in conscious guinea pigs. **Conclusion:** Compounds 2, 3, 4, and 5 were identified as the metabolites of BPP in human urine. Among them, compounds 2 and 3 are inactive in the antitussive effect.

Introduction

Benproperine, 1-[1-methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-piperidine (BPP, 1, Figure 1) is widely used as a cough suppressant for non-productive coughs. It has a peripheral and central action and can be given to humans *po* in forms of embonate or phosphate^[1]. The antitussive activity is comparable to that of codeine, but is devoid of the undesirable codeine's side effects^[2].

In general, drugs are metabolized to more polar, hydrophilic entities, which can be excreted from the body more easily. At the same time, drugs can be inactivated, be activated or become a toxicant. There is a growing interest in identifying metabolites and in establishing their pharma-

cokinetic, pharmacological, and toxicological properties. Activated metabolites are sometimes drug candidates for the treatment of a variety of diseases.

In our previous research, 5 mono-hydroxylated metabolites of benproperine and their conjugates were detected in human urine and 2 of them that were hydroxylated in phenyl rings have been identified. Mass spectra indicated that the other 2 mono-hydroxylates were probably hydroxylated in the piperidyl ring^[3]. To identify metabolites, liquid chromatography-tandem mass spectrometry is an efficient approach, which is used widely^[4-6]. A comparison of the high performance liquid chromatography (HPLC) retention times, as well as MS/MS spectra of putative metabolite and authentic standard, might be sufficient to make a more definitive identification^[4].

The purposes of the present study was to synthesize 4 putative benproperine metabolites: 1-[1-methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-4-piperidinol (2), 1-[1-methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-3-piperidinol (3), as well as their glucuronides 1-*O*-[1-[1-methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-piperidin-4-yl]- β -*D*-glucopyranosiduronic acid (4) and 1-*O*-[1-[1-methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-piperidin-3-yl]- β -*D*-glucopyranosiduronic acid (5) (Figure 1), to identify the chemical structures of the metabolites and to evaluate the antitussive effects of 2 and 3 phosphates.

Figure 1. Benproperine and its possible metabolites

Materials and methods

Instruments and chemicals Melting points were determined in open capillary tubes and the thermometer was uncorrected. MS/MS spectra were recorded on a Finnigan LCQ ion trap mass spectrometer via an electrospray ionization (ESI) source in positive ion detection mode. ¹H and ¹³C

NMR spectra were recorded on a Bruker ARX-600 instrument with tetramethylsilane as an internal standard. Ultra-violet (UV) spectra were recorded on a Shimadzu UV-2201 instrument.

3-Piperidinol hydrochloride and 4-piperidinol were obtained from the Aldrich Chemical Co. We prepared 1-[2-(phenylmethyl)phenoxy]-2-propanol *p*-toluenesulfonate (6) ourselves, according to published procedures^[7,8], from *o*-benzylphenol, which was kindly supplied by Aosen Pharmaceutical Co. Methyl (2,3,4-tri-*O*-acetyl-1-*O*-trichloroacetimidoyl)- α -*D*-glucopyranuronate (7) was prepared by us, according to Soliman *et al*^[9] from *D*(+)-glucuronolactone, which was obtained from Wako Chemical Co. The structures of 6 and 7 were identified using ¹H and ¹³C NMR. Column chromatography was carried out on silica gel BW-820MH, which was obtained from Fuji Silysia Chemical Co. Benproperine phosphate capsule was obtained from Shenyang Pharmaceutical Co. Benproperine phosphate was kindly supplied by Aosen Pharmaceutical Co and was recrystallized by us; the purity was 98.5% by HPLC. Citric acid was obtained from Shenyang Dongxing Reagent Factory. Test compounds and citric acid used to investigate antitussive were all dissolved in physiological saline. Methanol was of HPLC grade, and the other chemicals used were of analytical grade. Distilled water, prepared from demineralized water, was used in LC/MS/MS.

The putative metabolites were synthesized with the procedure shown in Figure 2.

1-[1-Methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-4-piperidinol (2) A total of 3.64 g (36.0 mmol) of 4-piperidinol and 3.6 g (9.0 mmol) of 1-[2-(phenylmethyl)phenoxy]-2-propanol *p*-toluenesulfonate (6)^[7,8] were fused on an oil bath at 100°C for 3 h, and stirred. After cooling to an ambient temperature, 15 mL of water was introduced. The resultant was extracted with dichloromethane (20 mL×3). The combined dichloromethane extracts were washed with water and

Figure 2. Synthesis of benproperine metabolites 2, 3, 4, and 5.

brine, and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure, leaving a brown oil. The residue was purified using silica gel column chromatography, eluting with $\text{CHCl}_3/\text{MeOH}$ to leave the titled compound 2 (2.49 g, 85.3%) as a pale-yellow oil. The oil 2 (2.49 g, 0.77 mmol) was dissolved in an aqueous solution of 0.3 mol/L H_3PO_4 (25 mL) and the water was removed under reduced pressure. The residue was recrystallized from ethanol, leaving phosphate of 2 (2.60 g, 80.2%) as a colorless needle.

1-[1-Methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-3-piperidinol (3) 3-Piperidinol was treated as in the procedure described for 4-piperidinol, leaving 3 as a pale yellow oil (82.1%) and its phosphate of 3 as a white powder.

1-O-[1-[1-methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-piperidin-4-yl]- β -D-glucopyrano-siduronic acid (4) Phosphate of 2 (85 mg, 0.20 mmol) was suspended and stirred in CH_2Cl_2 (4.0 mL) at -15°C under N_2 atmosphere. $\text{BF}_3 \cdot \text{Et}_2\text{O}$ (10 μL) was added to in one portion. After 10 min of stirring, methyl (2,3,4-tri-*O*-acetyl-1-*O*-trichloroacetimidoyl)- α -D-glucopyranuronate(7)^[9] (95 mg, 0.20 mmol) was added. Stirring was continued for 48 h at an ambient temperature. EtOAc (50 mL) was added, and the mixture was washed with saturated Na_2CO_3 aqueous solution (10 mL \times 2) and brine (10 mL), and dried over Na_2SO_4 . The solution was evaporated and purified on silica gel column chromatography, eluted with *n*- C_6H_{14} - EtOAc - MeOH in gradient. 1-*O*-[1-[1-Methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-piperidin-4-yl]-2,3,4-tri-*O*-acetyl- β -D-glu-copyranosiduronic acid methyl ester (8, 65 mg, 50.4%) was obtained as a colorless syrup. Compound 8 was dissolved in MeOH (2 mL), and Na_2CO_3 aqueous solution (0.1 mol/L, 1 mL) was added at an ambient temperature and stirred. After 2.5 h of stirring, the mixture was desalted and concentrated. The titled compound 4 was obtained as a colorless syrup.

1-O-[1-[1-methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-piperidin-3-yl]- β -D-glucopyranosiduronic acid(3-OH-BPP glucuronide, 5) Phosphate of 3 was treated as in the procedure described above for phosphate of 2 to give the intermediate 9. Then, the titled compound 5 was obtained as a pale-yellow syrup after hydrolysis.

Urine sample Seven healthy male volunteers, whose mean (SD) age and weight were 22.7 (0.6) years and 62.2 (5.6) kg, gave written informed consent to take part in the study and local ethics approval was obtained. Each of the volunteers swallowed 3 benproperine phosphate capsules (60 mg BPP) with 200 mL of water. Urine samples were collected at 0 h–24 h. Blank urine was collected from the same volunteer directly before being given the capsules. The urine samples were stored at -20°C until analysis.

A 1.0 mL urine sample was filtered through 0.45 μm of precut membrane. The filter was applied to a 3.0-mL Bond-Elute C_{18} cartridge (0.5 g silica gel) preconditioned with 2 mL aliquots of methanol and water. After loading the sample, the column was washed with 1 mL of water. Metabolites were eluted with 1 mL of methanol. The eluate was evaporated to dryness at 40°C under a gentle stream of N_2 . The residue was dissolved in 100 μL of the mobile phase. A 20- μL aliquot of the resulting solution was injected onto the LC/MS/MS system for analysis.

A 1.0 mL portion of blank urine sample was treated as in the above procedure, in which the solutions of putative metabolites (2, 3, 4, or 5) in mobile phase were used instead of mobile phase to obtain the spiked urine sample for LC/MS/MS analysis.

LC/MS/MS analysis and identification of metabolites A Shimadzu LC-10AD pump was used in the LC/MS/MS system. Chromatography was performed on a Diamonsil C_{18} column (150 \times 4.6 mm inner diameter, 5 μm , Dikma), which was coupled with a Security Guard C_{18} guard column (4 \times 3.0 mm inner diameter, Phenomenex). The components were eluted with an isocratic mobile phase of methanol-water-formic acid (50:50:1, *v:v:v*), and the flow rate was 0.5 mL/min. The column temperature was maintained at 25°C . A Finnigan LCQ ion trap mass spectrometer interfaced with liquid chromatography via an electrospray ionization (ESI) source was used for mass analysis in positive ion detection mode. The capillary voltage was fixed at 16 V, and its temperature was maintained at 200°C . The spray voltage was set at 4.25 kV. The HPLC fluid was nebulized using N_2 as both the sheath gas at a flow rate of 0.75 L/min, and the auxiliary gas at a flow rate of 0.15 L/min. The MS/MS spectra were produced by collision-induced dissociation (CID) of the selected precursor ions with He present in the mass analyzer, and the relative collision energy was set at 30%–40%. Data were collected and analyzed using the Navigator software (version 1.2).

Animals Dunkin Hartley guinea pigs of both sexes, weighing 200–300 g (Experimental Animal Center of Shenyang Pharmaceutical University, Shenyang, China) were used. All animal studies were in accordance with the Regulations for the Administration of Affairs Concerning Experimental Animals (China, 1988) and Implementing Regulations of the Administration on Medical Experiments on Animals (China, 1989). The guinea pigs were maintained in standard animal rooms, with food and water freely available, and on a natural light-dark cycle. They were allowed to adapt to the conditions for at least 1 week before being used in experiments.

Investigation of antitussive effect The antitussive effect of BPP, 2 and 3 phosphates was evaluated in conscious guinea-pigs against citric acid-induced coughs^[10,11]. Guinea pigs were placed individually in a transparent plexiglass cylinder chamber (10 cm×10 cm×21 cm) and exposed to a nebulized solution of 7.5% citric acid for 3 min. An ultrasonic nebulizer (402 AI, Shanghai Yuyue Medical Facilities) was used to produce an aerosol with particles with an aerodynamic mass median diameter of 1 mm; the volume of solution aerosolized was approximately 0.6 mL/min. Animals were selected for the study according to the number of coughs observed 24 h before the test, and animals with more than 20 or fewer than 6 coughs during the 3 min test were not used. The compounds and the vehicle (physiological) saline were given ip (2 mL/kg) for 1.5 h (for BPP×H₃PO₄) or for 40 min (for 2×H₃PO₄ and 3×H₃PO₄) before the test. The number of coughs during the 3 min test and during the 5 min immediately after the test was determined. The animals with different doses (3 mg/kg, 9 mg/kg, 27 mg/kg for 2×H₃PO₄ and 3×H₃PO₄, 27 mg/kg for BPP×H₃PO₄) of drugs and the vehicle were grouped according to a random table. Animals were used only once because of tachyphylaxis of the cough response. Coughing sounds were recorded and amplified using a microphone and loudspeaker. During the experiment, the animals were continuously watched by a trained observer who was unaware of the treatment. Sneezes and coughs were differentiated by visual observation of the animals.

Statistical analysis Pharmacological results are represented as mean±SEM. Data were analyzed using one-way analysis of variance (ANOVA). Whenever ANOVA was significant, further comparisons between vehicle- and drug-treatment groups were performed using Dunnett's *t*-test. The above analysis was performed using the software SPSS V11.0 for Windows.

Results

Chemical synthesis Compound 6, which was synthesized from 2-benzylphenol^[8], was fused with 4-piperidinol to give 2 in 85% of yield. 3-Piperidinol was treated according to the procedure for 4-piperidinol to give 3 in 82% of yield. Glucuronides were synthesized from mono-hydroxylates (2 and 3) treated with trichloroacetimidate donor (7) followed by basic hydrolysis (Figure 2). The structures of products were identified using ESI-MS, ¹H NMR, and ¹³C NMR (Table 1).

Metabolites of benproperine Compared with corresponding blank samples, the urine after being given of BPP showed 5 peaks corresponding to hydroxylated metabolites and 5 peaks corresponding to their glucuronides in LC/MS/MS analysis (Figure 3).

Metabolites M1 and M2 M1 and M2 gave the same pseudo-molecular ions [M+H]⁺ at *m/z* 326, similar MS/MS spectra (Figure 4), but different retention times (Figure 3),

Figure 3. Liquid chromatography-ion trap mass spectrometry SIM chromatogram of blank urine spiked with synthetic references 2, 3, 4, and 5 (A and D), urine sample after benproperine administration (B and E), and blank urine sample (C and F). (SIM: Selected ion monitoring; NL: Normalized level).

5	CD ₃ OD, 1.00 (3H, d, J 7.2Hz, H-9), 1.50 (2H, m, H-4a and H-5a), 1.68 (2H, m, H-4e and H-5e), 2.42 (2H, m, H-2a and H-6a), 2.52 (2H, m, H-2e and H-6e), 2.81 (1H, m, H-7), 3.13 (1H, m, H-3'), 3.30 (2H, m, H-2' and H-4'), 3.45 (1H, m, H-5), 3.70-3.93 (3H, m, H-8 and H-3), 3.87 (2H, s, H-10), 4.46 (1H, d, J 7.8Hz, H-1'), 6.97 (1H, m, ArH), 7.03 (1H, m, ArH), 7.09 (4H, m, ArH), 7.10 (3H, m, ArH)		MS ¹ 502, MS ² 326, MS ³ 308, 142		

indicating that they were isomers. Their pseudo-molecular ions were 16 u higher than that of the parent drug, indicating the addition of a hydroxyl group to the parent drug.

The MS² spectra of M1 and M2 displayed the same fragment ions at *m/z* 308 and *m/z* 142 (Figure 4). The presence of the prominent ion at *m/z* 308 was 18 u lower than precursor ions, indicating the loss of a water molecule from pseudo-

molecular ions and further proving the presence of hydroxyl group. The presence of the ion at *m/z* 142 indicates that the hydroxyl group was in the piperidylpropanyl moiety. However, the MS/MS data did not provide useful information for assigning the exact site of hydroxylation. Therefore, M1 and M2 were definitely confirmed by comparing their retention time and mass spectra with synthesized 2 and 3

Figure 4. MS/MS spectra of benproperine metabolites (synthetic references 2, 3, 4, and 5).

(Figures 3 and 4). M1 possessed the same retention time and mass spectra with 2, and was confirmed as 1-[1-methyl-2-[2-(phenylmethyl)-phenoxy]ethyl]-4-piperidinol and, in the same way, M2 was identified as 1-[1-methyl-2-[2-(phenylmethyl)phenoxy]-ethyl]-3-piperidinol.

Metabolites M3 and M4 M3 and M4 gave the same

pseudo-molecular ions $[M + H]^+$ at m/z 502, which were 176 u higher than monohydroxylate metabolites, indicating conjugation of a glucuronic acid. The MS² spectra of M3 and M4 displayed same fragment ions at m/z 326, which possessed the same mass to charge ratio as the pseudo-molecular ions of M1 and M2. The MS³ spectra of M3 and M4 displayed

the fragment ions at m/z 308 and m/z 142, which were consistent with MS² spectra of M1 and M2, respectively (Figure 4). It indicated that M3 and M4 were the glucuronides of M1 and M2, respectively. The further confirmation was obtained by comparing their retention times and MS/MS spectra with the synthesized glucuronides 4 and 5 (Figure 3 and Figure 4). M3 was identified as 1-*O*-[1-[1-methyl-2-[2-(phenylmethyl)phenoxy]-ethyl]-piperidin-4-yl]-β-*D*-glucopyranosiduronic acid. In the same way, M4 was identified as 1-*O*-[1-[1-methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-piperidin-3-yl]-β-*D*-glucopyranosiduronic acid.

The peaks at 4.6 min and 6.7 min (Figure 3) corresponded to the two identified monohydroxylate metabolites^[3]. Two peaks gave the same pseudo-molecular ions [M + H]⁺ at m/z 326. The MS/MS spectra showed the fragment ion at m/z 163 and 126 for the peak at 4.6 min and m/z 126 for the peak at 6.7 min, respectively.

Pharmacology Exposure to a nebulized solution of 7.5% citric acid aerosol caused coughing in control animals within 88.1±5.9 s ($n=10$), and both test compounds prolonged the latency of cough without dose-dependency as shown in Table 2. Immediately after exposure to citric acid, there is a hypersensitive period and the animals tend to cough continuously. For the control group, the number of coughs during the 3 min test was 8.2±1.2; all three compounds significantly decreased the number of coughs during the 3 min test, but 2 and 3 failed to decrease the number of coughs during the 5 min immediately after the test (Table 2).

Discussion

In synthesis of putative metabolites 4 and 5, the form of basic acceptor, reaction promoter, and the order of addition are all important variables in glucuronidation. The strong electron-withdrawing character of the 6β-methoxycarbonyl

group in any activated glucuronate makes such species notoriously poor donors^[12], so that glucuronidation is difficult. The phosphate of 2 was treated with a trichloroacetimidate donor in the presence of BF₃×Et₂O to give protected glucuronide 4 in 52% of yield. However, in free form of 2, no desired product was obtained. The salt form of the basic acceptor was better than its free form for glucuronidation, with Lewis acid used as the promoter in the present study. When trimethylsilyl trifluoromethane sulfonate (TMSOTf)^[9] was used as a promoter instead of BF₃×Et₂O, more of the by-product, 2 acetylate, was obtained and the yield of the desired product was increased. An inverse addition, which means trichloroacetimidate 7 was added into the mixed solution of 2 phosphate and BF₃×Et₂O, improved the yield to 52% from 21%. This result is consistent with the prior report for glucuronidation of other compounds^[13].

In positive-ion mode, compounds 2 and 3 formed pseudo-molecular ions [M+H]⁺ at m/z 326. They are two isomers; each of them contains a hydroxyl group in the piperidyl ring and an ether bond. The same product ions were observed in the full scan of MS/MS spectra at m/z 308 and 142, with different relative abundance for 2 compounds. The fragment ion at m/z 142 was formed by cleavage of the ether bond (Figure 4). The fragment ion at m/z 308 was formed by dehydration, which was easier going in 3 than in 2 because *p*-π conjugated system was formed after dehydration in the former. Therefore, m/z 308 was the base peak for 3 and m/z 142 was the base peak for 2.

Hydroxylation and glucuronidation are 2 general pathways of drug metabolism, by which drug can be metabolized to more polar, hydrophilic entities, which can be excreted from the body more easily. The presence of M1 (2), M2 (3) and their glucuronides M3 (4) and M4 (5) is consistent with the general rule of metabolism. In human urine, some

Table 2. The antitussive effect of benproperine and its metabolites 2 and 3 phosphates using 7.5% citric acid aerosol in guinea pigs. $n=10$. Mean±SD. ^b $P<0.05$, ^c $P<0.01$ vs vehicle.

	9	131.3±11.0 ^c	5.0±1.2	16.9±1.9
	3	126.8±10.0 ^b	3.9±0.8 ^c	15.6±1.5

dihydroxylate metabolites besides monohydroxylate were detected; no dealkylation metabolite was detected. In the present study, 4 monohydroxylate metabolites and 2 glucuronide metabolites were identified. The chromatogram (Figure 3) indicates that the hydroxylated metabolites of benproperine were recovered in urine mainly as glucuronides, and in very low concentrations as free forms. M1 and M2 were also found in human plasma.

The free forms of compound 2 (M1) and 3 (M2) are oils, which are difficult to be weighed, and the water-solubility of the free forms are poor. They are not suitable for use in the study of antitussive activity. Benproperine is generally used in clinical treatments as dihydrogenphosphate. Therefore, we converted the free form of compounds 2 and 3 to their phosphates for pharmacological study.

The experimental model to induce coughing using citric acid is the model most frequently adopted and extensively studied in animals and in humans^[14]. Citric acid can induce coughing in guinea pigs by increasing the volume of bronchial secretion^[10], by acting on capsaicin sensitive sensory neurons^[15,16] or by disturbing the pH of the airway surface liquid^[17]. However, it induces the airway hyper-reactivity in guinea pigs^[18]. Although phosphates of 2 and 3 produced an increase in the latency of the first cough and decreased the number of coughs during the 3 min test using citric acid, they did not decrease the number of coughs during the 5 min immediately after the test. The results showed that phosphates 2 and 3 did not inhibit the coughing induced by citric acid in guinea pigs.

In conclusion, 8 novel compounds, 2–5, 8, 9, and phosphates of 2 and 3 were synthesized successfully for the first time. 1-[1-Methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-4-piperidinol (2), 1-[1-methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-3-piperidinol (3), 1-*O*-[1-[1-methyl-2-[2-(phenylmethyl)-phenoxy]ethyl]-piperidin-4-yl]-β-*D*-glucopyranosiduronic acid (4) and 1-*O*-[1-[1-methyl-2-[2-(phenylmethyl)phenoxy]ethyl]-piperidin-3-yl]-β-*D*-glucopyranosiduronic acid (5) were identified to be metabolites of benproperine in human urine. Compounds 2 and 3 are inactive metabolites of benproperine.

Abstract

Aim: To investigate the stereoselectivity in human metabolic 3-reduction of tibolone. **Methods:** Twenty healthy Chinese female volunteers were given a single oral dose of tibolone (2.5 mg), and serial blood samples were collected after treatment. The plasma concentrations of the two pharmacologically active 3-hydroxyl metabolites of tibolone, 3 α -hydroxyl-7-methyl-norethynodrel (3 α -HMN) and 3 β -hydroxyl-7-methyl-norethynodrel (3 β -HMN) in plasma were determined by using a validated liquid chromatography-mass spectrometry (LC-MS) method. **Results:** The apparent elimination half-life ($T_{1/2}$) of 3 α -HMN was 1.43 \pm 0.52 h, and that of 3 β -HMN was 1.53 \pm 0.60 h. Maximum plasma concentrations (C_{max}) were found to be 8.75 \pm 4.36 μ g/L for 3 α -HMN and 3.59 \pm 1.81 μ g/L for 3 β -HMN. Areas under the plasma concentration versus time curve (AUC_{0-t}) were 26.30 \pm 12.14 μ g \cdot h⁻¹ \cdot L⁻¹ for 3 α -HMN and 9.89 \pm 4.93 μ g \cdot h⁻¹ \cdot L⁻¹ for 3 β -HMN. **Conclusion:** Stereoselective differences exist in the pharmacokinetics of tibolone metabolism in humans.

Introduction

Tibolone, [7 α ,17 α -7-methyl-17-hydroxyl-19-norpregn-5(10)-en-20-yn-3-one], also called 7-methyl-norethynodrel (MN), is a synthetic steroid (Figure 1) used in hormone replacement therapy (HRT) for postmenopausal women. Clinical data indicates that tibolone can produce the hormonal

Figure 1. Structure of the 3-hydroxyl metabolites of tibolone.

effects needed to treat climacteric symptoms and to prevent the long-term effects of menopause without stimulating the breast or endometrial tissues^[1-3]. After administration to women, the compound is quickly metabolized into a 3 α -hydroxyl metabolite (3 α -hydroxyl-7-methyl-norethynodrel; 3 α -HMN) and a 3 β -hydroxyl metabolite (3 β -hydroxyl-7-methyl-norethynodrel; 3 β -HMN) by the enzymes 3 α /3 β -hydroxysteroid dehydrogenase in the intestine and the liver^[4,5]. Tibolone itself has weak binding affinities to human estrogen, progesterone and androgen receptors, whereas the two 3-hydroxyl metabolites bind solely to the estrogen receptor, and 3 α -HMN is approximately 3 times as effective as 3 β -HMN^[6]. The clinical merits of tibolone are thought to be a result of the tissue-specific activity of the drug and its main metabolites^[7, 8].

The pharmacokinetics of tibolone in female patients have been studied recently, and the plasma concentrations of 3 α -HMN and 3 β -HMN were determined by using a gas chromatography-mass spectrometry (GC-MS) method^[9]. However, the pharmacokinetics of tibolone metabolism in a Chinese human population have not been studied. The present study was undertaken to investigate stereoselectivity in the phar-

macokinetics of tibolone metabolism in healthy Chinese female subjects using a validated liquid chromatography-mass spectrometry (LC-MS) method.

Materials and methods

Subjects Twenty healthy Chinese female subjects ranging in age from 30 to 40 years (36.4 ± 3.6 years), in weight from 47 to 67 kg (56.1 ± 5.8 kg), and in height from 143 to 170 cm (157.1 ± 6.4 cm) were enrolled in the study. All subjects were in good health and underwent a pre-enrolment screening that included ascertaining the subjects' medical history, a physical examination, an electrocardiogram (ECG), laboratory tests and urinalysis. No medication was used by the subjects for at least 2 weeks before the study and alcohol was forbidden within the 72 h before drug administration. Approval was obtained from the Institutional Review Board of the Obstetrics and Gynecology Hospital, Medical Center of Fudan University, Shanghai, and all subjects gave written informed consent.

Clinical protocol After an overnight fast of at least 10 h, subjects took one tablet of Livial, which contained 2.5 mg tibolone, with 200 mL water and continued fasting for 2 h. Blood samples obtained from an antecubital vein prior to treatment and at 0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 4.0, 6.0, 8.0, 12.0, and 18.0 h after treatment were placed in heparinized tubes. The samples were immediately centrifuged at $3000 \times g$ for 15 min, and the plasma was separated and frozen at -20 °C until analysis.

LC-MS analysis of the metabolites in plasma Plasma concentrations of 3α -HMN and 3β -HMN were determined by using a LC-MS method described elsewhere^[10]. Plasma samples were derivatized with *p*-toluenesulfonyl isocyanate after extraction with ethyl acetate. Separation of the two derivatized 3-hydroxyl metabolites was carried out on a Diamonsil C₁₈ column with a linear gradient elution of mixtures of methanol and ammonia acetate aqueous solution. The analytes were detected with a mass spectrometry detector in the negative selected ion monitoring (SIM) mode.

The limit of quantitation for both 3α -HMN and 3β -HMN was 100 ng/L, and the accuracy was 91.6%–116% for 3β -HMN and 90.4%–104% for 3α -HMN. The inter-day and intra-day coefficients of variation for 3α -HMN and 3β -HMN were less than 13.8% and 11.3%, respectively, over the concentration range 0.1–30 $\mu\text{g/L}$.

Pharmacokinetic analysis Pharmacokinetic parameters were estimated by using non-compartmental analysis of curves of $3\alpha/\beta$ -HMN isomer plasma concentrations versus time. Maximum plasma concentrations (C_{max}) and the corresponding times (T_{max}) were read as the coordinates of the

highest raw data point for each volunteer. The area under the plasma concentration versus time curve (AUC_{0-t}) was estimated by using the linear trapezoidal rule up to the last measurable time. $\text{AUC}_{0-\infty}$ was obtained by adding the part of the area extrapolated to infinity (last measurable concentration/ k_e) to AUC_{0-t} , where k_e is the slope of the linear regression analysis of natural log concentrations against time. The elimination half-life ($T_{1/2}$) was estimated from the plasma data by using the equation $T_{1/2} = 0.693/k_e$. The values were expressed as mean \pm SD. Differences between 3α -HMN and 3β -HMN in the pharmacokinetic data were evaluated statistically by using the independent-samples *t*-test. $P < 0.05$ was considered statistically significant.

Results

Plasma drug concentration-time curves After subjects were given tibolone, the mean plasma concentrations of 3α -HMN and 3β -HMN were all below 10 ng/mL, and the mean plasma concentrations of 3α -HMN were much greater than those of 3β -HMN (Figure 2). The last time point for which all subjects had measurable concentrations of 3α -HMN and 3β -HMN was 18 h.

Figure 2. Mean plasma concentration-time curve for 3α -hydroxyl-7-methyl-norethynodrel (■) and 3β -hydroxyl-7-methyl-norethynodrel (○) after a single oral dose of 2.5 mg tibolone. $n=20$. Mean \pm SD.

Pharmacokinetic parameters of the metabolites After subjects were given tibolone at a dose of 2.5 mg, C_{max} values for 3α -HMN and 3β -HMN were estimated to be 8.75 and 3.59 $\mu\text{g/L}$, and the mean AUC_{0-t} values were 26.30 and 9.89 $\mu\text{g}\cdot\text{h}^{-1}\cdot\text{L}^{-1}$, respectively.

There was no significant difference in T_{max} and $T_{1/2}$ between 3α -HMN and 3β -HMN ($P > 0.05$, Table 1). After subjects were given tibolone, the two metabolites both reached peak concentrations in the blood at 1.5 h, and $T_{1/2}$ values for 3α -HMN and 3β -HMN were 7.45 ± 2.03 h and 7.50 ± 1.83 h, respectively.

Table 1. Mean pharmacokinetic parameters of 3 α -HMN and 3 β -HMN after a single dose of 2.5 mg tibolone in 20 volunteers. Data are mean \pm SD. ^c*P*<0.01 versus 3 α -HMN.

AUC _{0-∞} (μ g \cdot h ⁻¹ \cdot L ⁻¹)	30.97 \pm 14.10	11.77 \pm 5.63 ^c

Discussion

The mean pharmacokinetic parameters of 3 β -HMN were similar to those found by Timmer *et al*^[9], whereas the peak plasma concentration of 3 α -HMN in our study (8.75 \pm 4.36 μ g/L) was much lower than that reported elsewhere for early (14.6 \pm 5.4 μ g/L)^[9] or late postmenopausal women (16.7 \pm 6.6 μ g/L)^[9]. Moreover, the AUC_{0-∞} of 3 α -HMN in the present study (30.97 \pm 14.10 μ g \cdot h⁻¹ \cdot L⁻¹) was also lower than that reported elsewhere for early (49.6 \pm 14.6 μ g \cdot h⁻¹ \cdot L⁻¹) or late postmenopausal women (62.6 \pm 17.3 μ g \cdot h⁻¹ \cdot L⁻¹)^[9].

There was a significant difference between the two 3-hydroxyl metabolites in all mean pharmacokinetic parameters except for T_{max} and $T_{1/2}$ (Table 1). The mean C_{max} and AUC_{0-T} values of 3 β -HMN were approximately 59% and 62% lower than that of 3 α -HMN, respectively. Mean 3 α /3 β stereoisomer ratios for plasma concentrations of the two metabolites in 20 subjects ranged from 1.5 to 3.0 after administration (Figure 3). These results indicate that a stereoselective difference exists in the 3-hydroxylation metabolism of tibolone.

Although a 3 α -hydroxylation intensive metabolism was

Figure 3. Mean stereoisomer ratios (3 α /3 β) of the plasma concentrations of 3-hydroxyl-7-methyl-norethynodrel after a single oral dose of 2.5 mg tibolone. *n*=20. Mean \pm SD.

Figure 4. Stereoisomer ratios (3 α /3 β) for AUC_{0-T} of 3-hydroxyl-7-methyl-norethynodrel after a single oral dose of 2.5 mg tibolone in 20 healthy subjects. *n*=20.

found for the metabolism pharmacokinetics of tibolone in the 20 subjects as a whole (with a mean 3 α /3 β AUC_{0-T} ratio of 3.11), two 3 α -hydroxyl-poor metabolizers were found in the present study (with 3 α /3 β AUC_{0-T} ratios of 0.71 and 0.99; Figure 4). Differences in the 3 α / β -hydroxylation metabolism of tibolone, as well as desogestrel, by different species of animals have been confirmed by Verhoeven *et al*^[11,12]: both drugs had mainly 3 α -hydroxyl metabolites in rats, but 3 β -hydroxyl metabolites in dogs. Because 3 α -hydroxysteroid dehydrogenase and 3 β -hydroxysteroids dehydrogenase reduce 3-keto steroids, polymorphism for 3 α / β -hydroxylation metabolism can be explained by individual differences in 3 α -hydroxysteroid dehydrogenase activity and 3 β -hydroxysteroid dehydrogenase activity.

Acknowledgement

The authors express their thanks to Prof Shao-fen ZHANG (Department of Gynecology, The Obstetrics and Gynecology Hospital, Medical Center of Fudan University, Shanghai) and her group for their help in subject selection and drug administration, and assistance in the medical ward.

Erratum

Acta Pharmacol Sin 2005 Aug; 26(8):926-33. An error appeared in the Abstract. “The first selective COX-2 inhibitor, celecoxib, entered the market in December 1999” should be changed to “The first selective COX-2 inhibitor, celecoxib, entered the market in December 1998.” The journal regrets the error.
