Abstract

Bispecific antibodies can serve as mediators to retarget effector mechanisms to disease-associated sites. Studies over the past two decades have revealed the potentials but also the limitations of conventional bispecific antibodies. The development of recombinant antibody formats has opened up the possibility of generating bispecific molecules with improved properties. This review summarizes recent developments in the field of recombinant bispecific antibodies and discusses further requirements for clinical development.

Introduction

The concept of using bispecific molecules in therapy is based on the selective recruitment of an effector mechanism to a defined disease-related target structure. Thus, bispecific molecules serve as mediators (adaptors) between an effector and a target. A plethora of effector mechanisms can be envisaged for therapeutic applications and a large number have already been evaluated. These include the recruitment of effector molecules (e.g. toxins, drugs, prodrugs, cytokines, radionuclides), the retargeting of effector cells (e.g. cytotoxic T lymphocytes, NK cells, macrophages, granulocytes) and the retargeting of carrier systems (e.g. viral vectors for gene therapy)^[1].

Antibodies are ideally suited as starting material for the construction of bispecific molecules as they normally bind specifically and with high affinity to antigens. Using different technologies, for instance hybridoma or phage display technology, antibodies can be generated against virtually any given antigen. Smaller portions of an antibody retaining antigen-binding activity can be produced by proteolytic cleavage or in recombinant form. Several methods have been developed for the generation of bispecific antibodies. Besides chemical cross-linking of two IgG molecules or two Fab or Fab' fragments, bispecific antibodies can also be produced by fusion of two hybridomas. This hybrid-hybridoma

technology results in cell lines (quadroma) that produce bispecific IgG molecules. However, the production and random association of two different heavy chains and two different light chains within one cell leads to the assembly of a substantial proportion of non-functional molecules. Thus, the hybrid-hybridoma technology and also chemical methods produce poorly defined products and require elaborate purification steps to obtain defined and clinically useful material. Nevertheless, several clinical studies have been performed to analyze the therapeutic potentials of bispecific antibodies. Most of these studies were focused on the retargeting of effector cells (cytotoxic T lymphocytes, NK cells) of the immune system to tumor cells. Mostly disappointing findings were obtained from these studies^[1,2]. The main reasons were the induction of neutralizing antibodies against the murine bispecific antibodies and Fc-mediated side effects, including cytokine-release syndrome, thrombocytopenia and leukopenia, which limited the maximal applicable dose. Further studies indicate that the induction of inflammation within the tumor, for example, the co-application of inflammatory cytokines, is essential to achieve an effective treatment. It was concluded that besides strong and selective binding to a disease-related antigen clinically useful bispecific antibodies should fulfill several requirements^[2]: They should be non-immunogenic to avoid a neutralizing immune response. They should have a defined struc-

ture and should bind monovalently to the effector cells to induce activation of the effector cells only after binding to the target cells. They should not contain an Fc-region to avoid Fc-mediated side effects. They should have a size which allows penetration into the tumor tissue but should circulate sufficiently long to induce therapeutic effects.

Recombinant bispecific antibodies

Recombinant bispecific antibodies offer several advantages over conventional bispecific antibodies made by chemical cross-linking or fusion of two hybridoma clones and can be designed to meet the requirements described above. By using only the variable domains as building blocks, recombinant antibodies lack the Fc-region of an antibody, and thus do not induce Fc-mediated effects. Recombinant antibodies are constructed by genetic means allowing for the generation of human molecules in order to reduce or even avoid the induction of a neutralizing antibody response. Human antibody molecules used as starting blocks can be isolated, for instance, from human antibody libraries by means of phage display^[3] or by using transgenic mice expressing human antibodies^[4]. Recent studies have shown,

however, that even fully human antibodies can be immunogenic leading to the generation of human anti-human antibodies (HAHA)^[5]. By identification and removal of the responsible T cell epitopes (“deimmunization”) the immunogenicity risk associated with human antibodies can be further reduced^[6]. These developments in the generation of recombinant antibody molecules have led to a revival in the use of bispecific antibodies for therapeutic applications^[7].

A wide variety of different recombinant bispecific antibody formats have been developed over the past years^[8]. Amongst them tandem single-chain Fv molecules and diabodies and various derivatives thereof are the most widely used formats for the construction of recombinant bispecific antibodies (Figure 1). Routinely, construction of these molecules starts from two single-chain Fv (scFv) fragments that recognize different antigens^[9].

Tandem scFv molecules (taFv) represent a straightforward format simply connecting the two scFv molecules with an additional peptide linker (Figure 1). The two scFv fragments present in these tandem scFv molecules form separate folding entities. Thus various linkers can be used to connect the two scFv fragments and linkers with a length of up to 63 residues have been reported^[10]. Although the pa-

Figure 1. A) Structures of various recombinant bispecific antibody formats derived from single-chain Fv (scFv) fragments. B) Domain and linker arrangements in single-chain Fv fragments (scFv), diabodies (Db), single-chain diabodies (scDb), and tandem scFv molecules (taFv). Linker L in scFv consists of approximately 15 amino acid residues. In Db and scDb linkers A and B have a length of approximately 5 amino acids. Linker M in scDb is approximately 15 amino acids long. In taFv linkers A and B have a length of approximately 15 amino acids and linker M can be of varying length (e.g. from 0 to >25 amino acids). SP=signal peptide.

rental scFv fragments can normally be expressed in soluble form in bacteria, it is, however, often observed that tandem scFv molecules form insoluble aggregates in bacteria. Hence, refolding protocols or the use of mammalian expression systems are routinely applied to produce soluble tandem scFv molecules. In a recent study, *in vivo* expression by transgenic rabbits and cattle of a tandem scFv directed against CD28 and a melanoma-associated proteoglycan was reported^[11]. In this construct the two scFv molecules were connected by a C_H1 linker and serum concentrations of up to 100 mg/L of the bispecific antibody were found. Various strategies including variations of the domain order or using middle linkers with varying length or flexibility were employed to allow soluble expression in bacteria. A few studies have now reported expression of soluble tandem scFv molecules in bacteria^[12-14] using either a very short Ala₃ linker or long glycine/serine-rich linkers. In a recent study, we employed phage display of a tandem scFv repertoire containing randomized middle linkers with a length of 3 or 6 residues to enrich for those molecules which are produced in soluble and active form in bacteria. This approach resulted in the isolation of a preferred tandem scFv molecule with a 6 amino acid residue linker^[15]. At present it is unclear if this linker sequence represents a general solution to the soluble expression of tandem scFv molecules. Nevertheless, this study demonstrates that phage display of tandem scFv molecules in combination with directed mutagenesis is a powerful tool to enrich for those molecules which can be expressed in bacteria in active form.

Bispecific diabodies (Db) utilize the diabody format for expression. Diabodies are produced from scFv fragments by reducing the length of the linker connecting the V_H and V_L domain to approximately 5 residues^[16]. This reduction forces dimerization of two polypeptide chains by crossover pairing of the V_H and V_L domains (Figure 1). Bispecific diabodies are produced by expressing two polypeptide chains with either the structure V_HA-V_LB and V_HB-V_LA (V_H-V_L configuration) or V_LA-V_HB and V_LB-V_HA (V_L-V_H configuration) within the same cell. A large variety of different bispecific diabodies have been produced in the past and most of them could be expressed in soluble form in bacteria (Table 1). A recent comparative study demonstrates, however, that the orientation of the variable domains can influence expression and formation of active binding sites^[17]. Nevertheless, the soluble expression in bacteria represents an important advantage over tandem scFv molecules. However, since two different polypeptide chains are expressed within a single cell inactive homodimers can be produced together with active heterodimers. This puts some

obstacles towards the use as therapeutic molecules as it necessitates the implementation of additional purification steps in order to obtain homogenous preparations of bispecific diabodies.

One approach to force the generation of bispecific diabodies is the production of knob-into-hole diabodies^[18]. This was demonstrated for a bispecific diabody directed against HER2 and CD3. A large knob was introduced in the V_H domain by exchanging Val₃₇ with Phe and Leu₄₅ with Trp and a complementary hole was produced in the V_L domain by mutating Phe₉₈ to Met and Tyr₈₇ to Ala, either in the anti-HER2 or the anti-CD3 variable domains. By using this approach the production of bispecific diabodies could be increased from 72% by the parental diabody to over 90% by the knob-into-hole diabody. Importantly, production yields did only slightly decrease by these mutations. However, a reduction in antigen-binding activity was observed for several analyzed constructs. Thus, this rather elaborate approach requires the analysis of various constructs in order to identify those mutations which produce heterodimeric molecule with unaltered binding activity.

Single-chain diabodies (scDb) represent an alternative strategy to improve the formation of bispecific diabody-like molecules^[19,20]. Bispecific single-chain diabodies are produced by connecting the two diabody-forming polypeptide chains with an additional middle linker with a length of approximately 15 amino acid residues (Figure 1). Consequently, all molecules with a molecular weight corresponding to monomeric single-chain diabodies (50-60 kDa) are bispecific. Several studies have demonstrated that bispecific single-chain diabodies are expressed in bacteria in soluble and active form (Table 1) with the majority of purified molecules present as monomers^[19-22]. Thus, single-chain diabodies combine the advantages of tandem scFvs (all monomers are bispecific) and diabodies (soluble expression in bacteria).

Stability improvements

Stability of the recombinant bispecific antibodies under storage conditions as well as after *in vivo* application is a critical parameter with strong impact for clinical application. The antibody has to be sufficiently stable to allow the molecules to induce a therapeutic benefit before being degraded^[23]. Unfortunately, several studies showed that tandem scFv molecules as well as diabodies were inactivated under physiological conditions, with varying half-lives depending on the antibody construct tested^[15,20].

One approach to improve the stability of antibody molecules is the generation of disulfide-stabilized molecules

Table 1. Applications of recombinant bispecific antibodies for cancer therapy.

Format	Antibody	Target	Effector	Expression	Reference

Abbreviations: Ad, adenovirus knob domain; β -Gal, β -galactosidase; CEA, carcinoembryonic antigen; CTL, cytotoxic T lymphocytes; Db, diabody; DOTA, 1,4,7,10-tetraazacyclododecane-*N,N',N'',N'''*-tetraacetic acid; EGFR, epidermal growth factor receptor; EpCAM, epithelial cell adhesion molecule; FAP, fibroblast activation protein; HMW-MAA, high molecular weight melanoma-associated antigen; NK cells, natural killer cells; scDb, single-chain diabody; taFv, tandem scFv; tanDb, tandem diabody; TR, transferrin receptor.

introducing cysteine bridges between the V_H - V_L interfaces to inhibit dissociation of the V_H and V_L domains. That this results in an increased thermal stability has been shown for a bivalent anti-CEA diabody^[24]. A subsequent study with a disulfide-stabilized bispecific diabody demonstrated that this approach also resulted in an increase in the formation of heterodimers similar to the knob-into-hole approach^[18]. However, a marked reduction in production yield was reported for this disulfide-stabilized bispecific diabody in *E. coli*. Principally, this approach to improve stability by introducing disulfide-bonds between the V_H and V_L domains is applicable for any recombinant bispecific format including tandem scFv molecules.

Several comparative studies have revealed that single-chain diabodies are more stable than diabodies and tandem scFv molecules^[14,15,19,20]. This is probably a result of the physical linkage of the four variable domains, similar to the improved stability of single-chain Fv fragments compared to Fv fragments^[25]. A recent study demonstrated that the length and composition of the three linkers present in a single-chain diabody molecule and its dimeric tandem form had a strong influence on stability and functional activity^[26]. In this study tandem diabodies composed of 10 residue long flanking linkers and a long middle linker (27 residues) showed highest stability and activity. These results emphasize the fact that modest variations in the composition of recombinant bispecific antibodies have strong impacts on their biological properties.

Improvement of pharmacokinetics

One of the drawbacks of small recombinant bispecific antibodies for therapeutic applications is the short circulation time in the body. Diabodies, single-chain diabodies and tandem-scFv molecules have a molecular weight of 50-60 kDa. This causes rapid clearance from circulation by extravasation and renal elimination with an initial half-life ($t_{1/2\alpha}$) below 30 min^[20]. This is much shorter than the half-life of whole antibody molecules, which can be in the range of several weeks, due to its larger size and Fc receptor mediated recycling.

Several approaches have been undertaken to improve the pharmacokinetics of recombinant antibodies. One approach is to increase the size of these molecules. For example, this was achieved by fusion of a bispecific single-chain diabody to the IgG C_H3 or Fc region via an IgG hinge^[27]. A similar approach was also applied for bispecific diabodies fusing one of the two diabody chains to a C_H3 domain (diabody)^[28]. These fusions result in the formation of dimeric

molecules with molecular weights of 150-180 kDa containing four functional antigen-binding sites, two for each antigen. The advantage of using single-chain diabodies for this approach is that a single polypeptide chain is expressed resulting in the assembly of defined molecules with identical size and binding activity. In contrast, the usage of two different polypeptide chains for the expression of di-diabody may cause formation of a mixture of non-functional diabody molecules produced by homodimeric assembly of two identical polypeptide chains and functional diabody- C_H3 fusion proteins. Interestingly, Lu and co-workers^[28] could not detect such non-functional diabody molecules in their preparations indicating that heterodimeric assembly of the two polypeptide chains is favored, at least for the described construct. Heterodimer-forming C_H3 domains containing knob-into-hole structures were also used to generate bispecific antibodies by fusion of two different scFv fragments directed against HER2 and CD16 to these domains^[29]. Although not tested *in vivo* this bispecific minibody was stable in mouse and human serum at 37 °C for several days and biologically active.

Dimeric single-chain diabody molecules with a molecular weight of 100-115 kDa can also be generated by varying the length of the linkers connecting the variable domain. Reducing the middle linker of a single-chain diabody to less than 13 amino acid residues results in the formation of dimeric single-chain diabody (tandem diabodies, tanDb) most likely with a linear arrangement of the two polypeptide chains (Figure 1)^[20,21]. Similarly, reduction of the flanking linkers to 0-1 amino acid residue results also in dimeric molecules, presumably in a tetrabody-like arrangement^[21]. For tandem diabodies it has been shown that this dimerization results in a four- to eight fold increase in circulation time compared to diabodies and an improved therapeutic efficacy^[20,30].

The covalent attachment of polyethylene glycol (PEG) chains may represent another possibility to improve the pharmacokinetics of recombinant bispecific antibodies. Several PEGylated protein therapeutics which exhibit increased half-lives and improved therapeutic efficacy compared to their non-PEGylated forms have been clinically approved^[31]. Although as yet not applied for recombinant bispecific antibodies, it was shown for single-chain Fv fragments that PEGylation could prolong serum half-life up to 200-fold^[32]. In this study single reactive cysteine residues were introduced into the scFv molecules at defined positions, e.g. at the C-terminus or in the linker region. This additional cysteine residue allowed for a site-specific coupling of a single PEG chain without impairing binding activity of the scFv fragment.

A rather new approach is the combination of recombinant bispecific antibodies with gene-therapeutic protocols aiming at a direct *in vivo* expression of the antibody molecules^[33]. This should result in high and constant levels of antibody molecules over an extended period of time. Furthermore, this approach obviates the need for extensive purification and characterization of the therapeutic proteins. However, one has to keep in mind that for therapeutic applications it is essential that expression is tightly controlled in order to stall expression in the event of severe side effects. In 1999 we postulated that this approach should be applicable for the *in vivo* production of recombinant bispecific antibody molecules^[19]. In this study we show that bispecific single-chain diabodies are secreted in an active form from mammalian producer cells *in vitro* and are able to selectively recruit a prodrug-converting enzyme to tumor cells. Subsequently, we developed an adenoviral system containing the gene for an anti-CD3 x anti-CEA bispecific single-chain diabody. Injection of these recombinant adenoviruses into mice resulted in high-level expression of the antibody molecule over a period of several weeks^[34]. The therapeutic effects of *in vivo* produced proteins were recently demonstrated with an anti-CEA x anti-CD3 bispecific diabody in combination with a B7-anti-CEA scFv fusion protein^[35]. *In vivo* expression was achieved by implanting near the tumor site 293 producer cells stably transfected with the DNA encoding these proteins. After injection of human T cells, anti-tumor effects were observed in a colon carcinoma tumor model demonstrating the feasibility of this approach. Further studies are, however, needed to establish the most effective and safe protocol, including an evaluation of *in vivo* and *ex vivo* gene transfer, a comparison of local versus systemic production, identification of suitable transcriptional control elements and safe gene transfer vehicles.

Therapeutic applications

Recombinant bispecific antibodies have already been developed for a variety of different applications with potential use in cancer therapy. These applications include the retargeting of effector molecules (prodrug-converting enzymes, radio-isotopes, complement components), effector cells (CTLs, NK cells) and adenoviral vectors (Table 1), covering various therapeutic strategies, e.g. radiotherapy, chemotherapy, immunotherapy and gene therapy. In addition, recent work explored their use as intracellular bispecific antibodies (intrabodies)^[36]. In one study an intracellularly expressed diabody was used to induce a functional knockout of two cell surface receptors^[37]. In another study

a bispecific tandem scFv with cell-penetrating abilities was applied to restore p53 wild-type function by intracellular binding to p53^[38].

Most applications of recombinant bispecific antibodies for cancer therapy focus on the retargeting of effector cells of the immune system to tumor cells (Table 1). Extensive work has been done on the retargeting of cytotoxic T lymphocytes (CTLs) through binding to the T cell co-receptor molecule CD3. In addition, natural killer cells (NK) were retargeted with recombinant bispecific antibodies directed against Fcγ receptor III (CD16). A large variety of different target antigens have been evaluated. Most of them represent tumor-associated antigens (TAA) over-expressed by tumor cells, including CD19, CD20, epithelial cell adhesion molecule (EpCAM), epidermal growth factor receptor (EGFR), HER2, MUC-1, and carcinoembryonic antigen (CEA) (Table 1). In addition, recent focus has switched to tumor vasculature as a target structure. Targeting tumor vasculature of solid tumors has several advantages compared to direct targeting of tumor cells^[39]. Tumor endothelial cells are directly accessible for circulating agents, ie extravasation of effector molecules and cells is not necessary. All solid tumors depend on neovascularization to grow beyond a few millimeters in diameter. Thus, this approach is broadly applicable. Endothelial cells are genetically stable and do not become resistant to therapy. A few studies have demonstrated that recombinant bispecific antibodies can be employed to retarget effector cells (CTLs) or adenoviral vectors to endothelial cells *in vitro*. These studies used endoglin (CD105) or fibroblast activation protein (FAP) as vascular targeting structures^[22,40,41]. Other suitable antigens are described, e.g. vascular endothelial growth factor (VEGF) receptor, α_v -integrins and the ED-B domain of a tumor-associated fibronectin splice variant^[42], which allows these studies to be extended to other targets but also to other effector mechanisms.

Several animal studies have been performed with recombinant bispecific antibodies and curative effects have been demonstrated^[10,30,35,43-45]. Most studies with anti-CD3 bispecific antibody molecules have shown that T cells need a second stimulus to efficiently lyse target cells. This second stimulus can be provided by pre-activation of isolated T lymphocytes, e.g. with IL-2 and anti-CD28 antibodies. Several studies developed approaches to provide this co-stimulus *in vivo* by co-administering anti-CD28 antibodies or B7-scFv fusion proteins^[30,46]. Interestingly, one anti-CD3 antibody used for the construction of bispecific tandem scFv molecules was shown to induce a co-stimulation independent T cell response^[47,48].

Other studies evaluated various combinations of recom-

binant bispecific antibodies with other compounds to further improve anti-tumor responses. These approaches include the co-application of anti-CD19 x anti-CD3 diabodies, anti-CD28 antibodies and anti-CD19 x anti-CD16 bispecific diabodies targeting and activating two different effector cell types and the co-application of an anti-CD19 x anti-CD16 bispecific diabody together with thalidomide as chemotherapeutic drug^[49,50]. Interestingly, these studies described synergistic effects between the different compounds indicating that further dramatic improvements of the systems are possible.

Currently there is one bispecific tandem scFv molecule (MT103) directed against CD19 and CD3 in a clinical phase I safety trial for the treatment of Non-Hodgkin's Lymphoma (NHL). This antibody was shown to be very potent in destroying CD19-expressing tumor cells *in vitro* and *in vivo* in a T cell costimulation-independent way^[48]. A final report of the outcome is currently not available.

Conclusions

The past decade has led to enormous improvements in the generation and application of recombinant bispecific antibodies. These molecules combine the potentials of bispecific molecules for therapeutic applications with the advantages provided by antibody engineering technologies. Although further improvements are necessary, recent studies have shown that recombinant bispecific antibodies can find their way into the clinic.

Abstract

Aim: The subthalamic nucleus plays a critical role in the regulation of movement, and abnormal activity of its neurons is associated with some basal ganglia motor symptoms. We examined the presence of functional presynaptic GABA_B receptors on pallidosubthalamic terminals and tested whether they were tonically active in the *in vitro* subthalamic slices. **Methods:** Whole-cell patch-clamp recordings were applied to acutely prepared rat subthalamic nucleus slices. The effects of specific GABA_B agonist and antagonist on action potential-independent inhibitory postsynaptic currents (IPSCs), as well as holding current, were examined. **Results:** Superfusion of baclofen, a GABA_B receptor agonist, significantly reduced the frequency of GABA_A receptor-mediated miniature IPSCs (mIPSCs), in a Cd²⁺-sensitive manner, with no effect on the amplitude, indicating presynaptic inhibition on GABA release. In addition, baclofen induced a weak outward current only in a minority of subthalamic neurons. Both the pre- and post-synaptic effects of baclofen were prevented by the specific GABA_B receptor antagonist, CGP55845. Furthermore, CGP55845 alone increased the frequency of mIPSCs, but had no effect on the holding current. **Conclusion:** These findings suggest the functional dominance of presynaptic GABA_B receptors on the pallidosubthalamic terminals over the postsynaptic GABA_B receptors on subthalamic neurons. Furthermore, the presynaptic, but not the postsynaptic, GABA_B receptors are tonically active, suggesting that the presynaptic GABA_B receptors in the subthalamic nucleus are potential therapeutic target for the treatment of Parkinson disease.

Introduction

Being the only nucleus in the basal ganglia containing glutamatergic neurons, the subthalamic nucleus occupies a critical position in the 'indirect' pathway by providing an excitatory drive to the output nuclei of this motor circuit. Anatomical studies have shown that the subthalamic nucleus receives GABAergic innervation from the globus pallidus and glutamatergic innervation from the cortex as well as the thalamus. The subthalamic nucleus then sends glutamatergic projection back to the globus pallidus, and to the substantia nigra pars reticulata and entopeduncular nucleus^[1-7].

By influencing the output of the basal ganglia, the subthalamic nucleus plays a significant role in mediating move-

ment in health and in diseased state. It has been demonstrated that the modification of the activity of subthalamic nucleus neurons constitutes the central origin of parkinsonian symptoms. For example, in Parkinson disease and its animal models, it is widely believed that depletion of dopamine in the basal ganglia leads to overactivity of the subthalamic nucleus. The resulting increased glutamatergic output of the subthalamic nucleus contributes to excessive inhibition of basal ganglia targets leading to akinesia and hypokinetic symptoms^[8]. Recent studies on the firing properties of neurons from organotypic culture of the globus pallidus-subthalamic nucleus network^[9], and from the *in vivo* brain^[10,11] suggest that the reciprocally connected glutamatergic subthalamic and GABAergic pallidal neurons

are involved in the generation of low-frequency oscillatory activity in Parkinson disease, which is associated with tremor in parkinsonian subjects^[12]. Indeed, disruption of the activity of the subthalamic nucleus could alleviate both the pathological neuronal activity and motor symptoms observed in Parkinson disease^[13-15]. Thus, deep brain stimulation of the subthalamic nucleus has been introduced as a surgical procedure for the treatment of Parkinson disease^[16].

GABAergic innervation from the globus pallidus is the major inhibitory factor affecting the activity of the subthalamic nucleus. GABAergic input from the globus pallidus affects the oscillation frequency of burst firing cells in the subthalamic nucleus^[17]. There are two types of GABA receptors in the central nervous system: the ionotropic, bicuculline-sensitive GABA_A receptors and the metabotropic, G-protein coupled GABA_B receptors which are activated by baclofen. By inhibiting calcium influx and facilitating potassium conductance, activation of GABA_B receptors produces pre- and postsynaptic inhibitory effects, respectively. A previous report^[18] showed the presence of presynaptic GABA_B receptors in the subthalamic nucleus based on the changes of the paired-pulse ratio of evoked IPSCs. In the current study, the presence of presynaptic GABA_B receptors is studied by examining the direct effect of a GABA_B agonist on the constitutive release of GABA from the presynaptic terminals, with the aid of a more specific GABA_B antagonist. Because the differential activation of pre- and postsynaptic GABA_B receptors is a potential therapeutic strategy in the treatment of basal ganglia motor disorders, we also compared the degree of activation of the pre- and postsynaptic GABA_B receptors and tested whether they were tonically active.

Materials and methods

Brain slice preparation Sprague-Dawley rats aged 13–15 d were used for the preparation of acutely prepared brain slices. The animals were killed by decapitation. The brains were then immediately removed and placed in ice-cold artificial cerebrospinal fluid (ACSF) of the following composition (in mmol/L): NaCl 125, KCl 2.0, MgSO₄ 1.2, CaCl₂ 2.5, KH₂PO₄ 1.2, glucose 11, and NaHCO₃ 26, which was continuously bubbled with 95% O₂ and 5% CO₂. Thin hemispherical slices (250 μm) containing the subthalamic nucleus were sectioned using a vibrating microtome (Camden Instrument). After equilibration in a holding chamber for at least 30 min, the slices were transferred to a small volume chamber mounted on an upright microscope (Zeiss Axioskop), and superfused with ACSF at a rate of 1.5–2.0

mL/min maintained at a temperature of 34±1 °C. Neuronal soma and proximal dendrites of neurons were directly visualized by a combination of differential interference contrast (DIC) optics and contrast-enhanced infrared (IR) video microscopy.

Whole-cell patch-clamp recordings Whole-cell patch-clamp recordings from the subthalamic nucleus neurons were obtained using a patch-clamp amplifier (LM/PCA, List Medical). Whole-cell pipettes had a resistance of 3–4 MΩ, when filled with an internal solution of the following composition (in mmol/L): KCl 140, HEPES 10, EGTA 1, MgCl₂ 2, Na₂ATP 2, and Tris GTP 0.4. The inclusion of 140 mmol/L of KCl in the recording pipettes reversed the polarity of the inhibitory postsynaptic currents (IPSCs) from outward to inward and enhanced their detection. Capturing of data and subsequent analysis followed the procedure of our previous report^[19]. Monitoring through a television connected to the camera, a pipette was placed on the soma of a subthalamic nucleus neuron and conventional whole-cell recording was made. Normally no series resistance compensation was applied but the cell was rejected if the series resistance increased significantly (>20%) during recording. The voltage and current signals were filtered at 3 kHz and were taped using a DAT recorder (Sony) modified for recording AC and DC signals at a sampling rate of 32 kHz. On- or off-line digitization (10 kHz) was made via the Digidata-pClamp system (Axon Instruments). Synaptic currents were analyzed by a program developed in our laboratory^[19]. Once a synaptic current is detected, information on the time of occurrence, peak amplitude and kinetics are generated automatically. The program also performed statistical comparison of two cumulative probabilities using the Kolmogorov-Smirnov test.

Drugs and statistics (±)-Baclofen used in the present study will be referred to as baclofen and was obtained from RBI. CGP55845 was purchased from Tocris. (±)-2-Amino-5-phosphonopentanoic acid (AP5), 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX), bicuculline and tetrodotoxin (TTX) were also obtained from RBI.

The data were expressed as mean±SEM. Paired Student's *t*-test was used. The level of significance was presented by using a *P* value of 0.05.

Results

Pre- and postsynaptic GABA_B receptors activated by baclofen The GABA_A receptor-mediated miniature IPSCs (mIPSCs) were isolated by the addition of AP5 50 μmol/L and CNQX 20 μmol/L to eliminate glutamate receptor-

mediated synaptic currents and TTX 0.5 $\mu\text{mol/L}$ to block action potential-dependent transmitter release. These currents were sensitive to 10 $\mu\text{mol/L}$ GABA_A receptor antagonist bicuculline, confirming their GABAergic nature. Spontaneous synaptic currents were found in most subthalamic nucleus neurons. Superfusion of baclofen, a specific GABA_B receptor agonist, at 30 $\mu\text{mol/L}$ significantly reduced the frequency of mIPSCs. This effect was reversible when baclofen was removed (Figure 1A, 1B). The inhibitory effect of baclofen was selective to the frequency (control: 1.69 ± 0.27 Hz; baclofen: 0.64 ± 0.09 Hz; wash: 1.08 ± 0.16 Hz, $n=12$, $P < 0.01$) but not the amplitude of the mIPSCs (control: 31.4 ± 1.9 pA; baclofen: 32.5 ± 2.3 pA, $n=12$, $P > 0.05$), indicating that the effect was presynaptic (Figure 1C). Furthermore, in five cells, application of 200 $\mu\text{mol/L}$ of CdCl₂ reduced the mIPSC frequency (control: 1.58 ± 0.22 Hz; Cd²⁺: 0.86 ± 0.38 Hz; $P < 0.01$). In this case, the effect of baclofen was largely abolished (0.82 ± 0.38 Hz; $P > 0.05$ vs Cd²⁺ alone).

To study whether baclofen directly inhibits the subthalamic nucleus neurons through activation of postsynaptic GABA_B receptors, we also quantified the effect of baclofen in inducing an outward current in subthalamic nucleus neurons in the brain slice. In contrast to its presynaptic effect, which was observed in all neurons tested, baclofen at 30 $\mu\text{mol/L}$ induced a weak outward current in only six out of 23 neurons (21.7%), with a mean of 20.1 ± 3.1 pA.

Receptor specificity and tonic activity revealed by CGP55845 To confirm that baclofen acts on GABA_B receptors and to test whether the receptors are tonically active in the subthalamic nucleus, the effects of a recently introduced potent and specific GABA_B receptor antagonist, CGP55845, were studied. When CGP55845 2 $\mu\text{mol/L}$ was applied into the superfusion solution, there was no changes in the holding current in all six cells tested. In contrast, CGP55845 caused a clear increase in the frequency of the mIPSC, from 1.22 ± 0.29 Hz to 2.14 ± 0.56 Hz ($n=6$, $P < 0.05$). These data suggest that the pre- but not the postsynaptic GABA_B receptors are tonically active (The results from a typical cell were shown in Figure 2A, 2B). Consistent with a presynaptic site of action, the increase in the mIPSC frequency induced by CGP55845 was not accompanied by a change in the amplitudes (control: 38.3 ± 3.7 pA; CGP55845: 39.2 ± 3.7 pA; CGP55845+baclofen: 36.7 ± 3.5 pA, $n=6$, $P > 0.05$). Furthermore, in the presence of CGP55845, baclofen did not decrease the frequency of mIPSCs in these neurons (CGP55845+baclofen: 2.26 ± 0.48 Hz, $P > 0.05$ vs CGP55845 alone, Figure 2). These data indicate that the presynaptic inhibitory effect observed when baclofen was applied alone was mediated by GABA_B receptors (Figure 2).

In the presence of CGP55845, baclofen did not activate any outward current ($n=6$), suggesting that CGP55845 prevented the activation of postsynaptic GABA_B receptors. The receptor specificity of the postsynaptic effect of baclofen was also tested in those neurons that responded to baclofen. Addition of CGP55845 in the presence of baclofen completely reversed the effect of baclofen ($n=3$). A typical result was shown in Figure 3.

Discussion

In the present study, we provide evidence for the existence of functional presynaptic GABA_B receptors in the pallidosubthalamic pathway. This conclusion is based on the effect of baclofen on mIPSCs recorded from subthalamic neurons. This effect of baclofen is sensitive to specific GABA_B receptors antagonist CGP55845, and also the broad-spectrum calcium channel blocker Cd²⁺, which presumably blocks the influx of calcium into nerve terminals necessary for the release of GABA. Thus, Ca²⁺-influx is likely to be involved in the presynaptic effect of baclofen.

The pallidosubthalamic GABAergic pathway is the major inhibitory pathway controlling the activity of the subthalamic nucleus neurons. The present study revealed that activation of GABA_B receptors in this pathway could, in principle, exert two opposite effects on subthalamic nucleus neurons. On the one hand, by activating presynaptic GABA_B receptor, baclofen reduces the release of GABA from pallidosubthalamic GABAergic terminals and then disinhibits the subthalamic nucleus neurons. On the other hand, by activating postsynaptic GABA_B receptors, baclofen directly inhibits the subthalamic neurons. These electrophysiological results corresponded with anatomical observations in primates, which revealed the existence of pre- and postsynaptic GABA_B receptor type 1 subunits in the subthalamic nucleus^[20]. Since only a minority of subthalamic neurons responded to baclofen by exhibiting an outward current, which were nevertheless small in the amplitude, this implies that either there is a smaller number, or a less efficient coupling and signaling mechanism, of the postsynaptic GABA_B receptors compared with their presynaptic counterpart. However, subcellular immunolabelling under an electron microscope showed a dense postsynaptic GABA_B receptor labeling in the monkey subthalamic nucleus^[20]. Also, our recent pre-embedding immunolabelling in the adult rat globus pallidus showed a similar level of GABA_{B1} and GABA_{B2} subunits at pre- and postsynaptic sites of GABAergic synapses^[21] although the pharmacological data in young rats revealed a stronger presynaptic effects in this nucleus^[22,23].

Figure 1. Presynaptic inhibition of GABA release by baclofen. (A) Typical traces showing that 30 $\mu\text{mol/L}$ baclofen significantly and reversibly reduced the frequency of bicuculline-sensitive mIPSCs in the rat subthalamic nucleus neurons. (B) Cumulative probability distributions of the inter-event intervals and amplitudes of the mIPSCs from the experiment shown in panel A. Significant reduction was found in the distribution of the inter-event intervals. (C) Means values obtained from 12 neurons showing that the inhibitory effect of baclofen was selective to the frequency but not the amplitude. Mean \pm SEM. ^c $P < 0.01$ vs control.

Figure 2. Presynaptic effect of baclofen was sensitive to CGP55845. (A) Typical traces showing that CGP55845 2 $\mu\text{mol/L}$ increased the frequency and prevented the inhibitory effect of baclofen on the mIPSCs. (B) Cumulative probability distribution of the inter-event intervals and amplitudes of the mIPSCs from panel A. $^cP < 0.01$ vs control. (C) Pooled data obtained from 6 cells showing that CGP55845 significantly increased the frequency of mIPSCs and blocked the presynaptic inhibition of baclofen. Mean \pm SEM. $^bP < 0.05$ compared with control.

Figure 3. Postsynaptic effect of GABA_B receptor activation. Typical trace showing the outward current induced by 30 μmol/L baclofen which was reversed by CGP55845 2 μmol/L.

Therefore, other factors like species variation and age might affect the outcome of the electrophysiological studies.

The presence of presynaptic GABA_B receptors in the rat subthalamic nucleus has been reported by Shen and Johnson^[18], based on a study of evoked IPSCs and their paired-pulse ratio. Our present study confirmed their work by showing that baclofen directly decreased the probability of action potential-independent release of GABA from presynaptic terminals. The conclusion was also enhanced by the use of a more specific and potent GABA_B receptor antagonist, CGP55845. One surprising and intriguing finding of the present study is that CGP55845 increased the frequency of the mIPSCs but had no effect on the holding current, indicating that there is tonic activation of the pre- but not postsynaptic GABA_B receptors. These data therefore suggest that the tonic release of GABA from pallidosubthalamic terminals, either from tonic firing of pallidal neurons, or from action potential-independent activities, may play a significant role in controlling the activity of subthalamic neurons. This finding has interesting implications in the therapeutic management of Parkinson disease. It is known that, in parkinsonian subjects, decreased activity of the GABAergic projection from the globus pallidus disinhibits the activity of subthalamic nucleus neurons, which results in enhanced inhibition on the basal ganglia targets. Since the tonic activity of pre-

synaptic GABA_B receptor on GABA release is expected to maintain the excitability of subthalamic nucleus, selective blockade of this tonic inhibition would help suppressing the subthalamic nucleus hyperactivity and therefore beneficial to parkinsonian subjects. This reasoning is supported by recent morphological evidence that parkinsonism is associated with an increased GABA_B receptor immuno-reactivity, especially in the neurophil, of the subthalamic nucleus, reflecting an upregulation of presynaptic GABA_B receptors^[24].

In addition to the involvement in Parkinson's disease, the subthalamic nucleus has been reported to be involved in the genesis of epilepsy. Focal inhibition of the activity of the subthalamic nucleus by GABA_A receptor agonist or high frequency deep brain stimulation exerted anticonvulsant effect in animal model and epilepsy patients^[25-28]. Therefore, the results of the present study also provide a rationale for exploring the role of subthalamic GABA_B receptor systems in the etiology and the treatment of epilepsy.

Abstract

Aim: To study the role of dopamine (DA) in rotenone-induced neurotoxicity in PC12 cells. **Methods:** Cell viability was assessed by detecting the leakage of lactate dehydrogenase (LDH) into the medium. Apoptosis rate was measured by flow cytometry. Caspase-3-like activity was measured by fluorescence assay using the probe Ac-DEVD-AMC. The level of intracellular hydrogen peroxide and other peroxides in PC12 cells were quantified by loading cells with 2'-7'-Dichlorodihydrofluorescein diacetate (DCFH-DA) in fluorescence assay. Lactic acid was measured spectrophotometrically. The DA levels in PC12 cells were determined by HPLC-ECD. **Results:** A 48-h incubation of PC12 cells with rotenone caused an apoptotic cell death and elevated intracellular reactive oxygen species (ROS) and lactic acid accumulation. Intracellular DA depletion with reserpine significantly attenuated rotenone-induced ROS accumulation and apoptotic cell death. No change was found in rotenone-induced ROS accumulation when cells were co-treated with deprenyl. Brief treatment with reserpine at the end of rotenone treatment had no effect on rotenone-induced neurotoxicity. However, when cells were first incubated with deprenyl, a monoamine oxidase-B inhibitor for 30 min then co-incubated with rotenone plus deprenyl, a brief treatment with reserpine enhanced cell injury. **Conclusion:** Rotenone-induced apoptosis in PC12 cells was mediated by intracellular dopamine oxidation.

Introduction

Parkinson disease (PD) is a chronic neurodegenerative disorder characterized by the loss of dopamine (DA) neurons in the substantia nigra, decreased striatal DA levels, and consequent extrapyramidal motor dysfunction. Although the genes responsible for a few rare familial cases of PD have been discovered^[1-3], the causes of more prevalent idiopathic PD are still unknown. Substances that are toxic to dopaminergic cells have been proposed as contributors to this neurological disease^[4,5]. MPTP (1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine) is one of the best described neurotoxins. Evidence has shown that the neurotoxicity of MPTP depends on its active metabolite, 1-methyl-4-phenyl-pyridinium (MPP⁺), which inhibits mitochondrial complex I and depletes cellular ATP levels, resulting in cell death^[6]. Thus,

one hypothesis has focused on mitochondrial dysfunction^[7].

Rotenone, a naturally occurring, lipophilic compound from the roots of certain plants (*Derris* species), is a specific inhibitor of mitochondrial complex I and is used as the main component of many insecticides. Based on the mitochondrial dysfunction hypothesis of PD, a number of studies have evaluated the effects of rotenone on dopaminergic neurons both *in vitro* and *in vivo*^[8-15]. Treatment of mesencephalic cultures and striatal synaptosomes with rotenone caused neurotoxicity which was measured by a decreased uptake of neurotransmitters^[8,9]. Studies *in vivo* have shown that rotenone was capable of causing degeneration of dopaminergic neurons and induction of parkinsonian symptoms in animals^[10-15]. An important morphological finding in rotenone-treated rats was that the nigrostriatal DA neurons had accumulated fibrillar cytoplasmic inclusions containing

ubiquitin and alpha-synuclein, similar to Lewy bodies in idiopathic PD^[13,16]. This finding is interesting, because recent discoveries of the two causative gene products of familial PD, Parkin^[1,17,18] and alpha-synuclein^[3] indicate that failure of the ubiquitin-proteasome system might be common in both familial PD and idiopathic PD^[19]. Another reason is that rotenone is widely used as insecticide, and therefore is a real threat as an environmental substance to cause PD. Thus, elucidation of its mode of action is of high importance in understanding and potentially treating this disorder. The present study was designed to assess the neurotoxicity of rotenone on DA-producing PC12 cells and explore the possible mechanism.

Materials and methods

Reagents Dulbecco's modified Eagle's medium (DMEM) was purchased from GibcoBRL (Gaithersburg, MD, USA). Horse serum and fetal calf serum were obtained from Hyclone (Logan, UT, USA). Rotenone, reserpine, deprenyl, *N*-acetyl-*L*-cysteine (NAC), propidium iodide (PI), dihydroxybenzylamine (DHBA) and 2',7'-dichlorofluorescein-diacetate (DCFH-DA) were purchased from Sigma (St Louis, MO, USA). Caspase-3 substrate Ac-*L*-aspartic-*L*-glutamic-*L*-alanyl-*L*-aspartic acid-7-amino-4-methylcoumarin (Ac-DEVD-AMC) was obtained from Calbiochem (La Jolla, CA, USA).

Cell culture The rat pheochromocytoma cell line PC12 cells (American Type Culture Collection, Rockville, MD, USA) were propagated in DMEM, supplemented with heat-inactivated horse serum (10%, v/v) and fetal calf serum (5%, v/v), 100 g/L streptomycin and 100 kU/L penicillin. The cultures were maintained in an incubator at 37 °C in a high humidity atmosphere of 5% CO₂. The medium was changed every 2 d and cells were passaged once a week. Twenty-four hours before addition of various reagents, the cells were seeded on 60-mm-dishes (Falcon), covered with collagen (Sigma), at a density of 1×10⁵/cm² in normal medium. Rotenone and reserpine were first dissolved in dimethyl sulfoxide (Me₂SO) and then diluted in medium to a final concentration of Me₂SO less than 0.1%. Controls for each drug condition consisted of sister cultures treated with the vehicle used to dissolve that drug. Stock solutions of deprenyl and NAC were prepared in Hanks' balanced salt solution containing 2 mmol/L HEPES.

Assessment of cell viability Cell viability was assessed by detecting the leakage of lactate dehydrogenase (LDH) into the medium. Cells were treated with rotenone or other reagents, then an aliquot of medium was taken and centri-

fuged at 250×g for 5 min. Supernatant (10 mL) was added into phosphate buffer 0.1 mol/L (pH 7.0) containing sodium pyruvate 2.3 mmol/L and NADH 5 mmol/L to a total volume of 200 mL. The decrease in absorbance over time at 340 nm was monitored at 25 °C. Then the activity of LDH in medium was calculated. Cell total LDH was obtained after exposure of culture to 0.2% TritonX-100 at 37 °C for 30 min. LDH leakage was expressed as percentage of LDH in medium to total LDH.

Analysis of apoptosis by flow cytometry Apoptosis rate was measured by flow cytometry as reported previously^[19]. Briefly, PC12 cells were washed with PBS (pH 7.4), fixed in cold 70% (v/v) ethanol, and incubated under -20 °C for at least 2 h. The fixed cells were harvested by centrifugation at 250×g for 5 min. The cell pellets were resuspended in 1 mL PBS at room temperature for 10 min. After another centrifugation, the cell pellets were resuspended in 500 mL PBS containing 0.2 g/L RNase A and incubated at 37 °C for 30 min. After incubation, the cells were stained with 20 g/L PI at 4 °C for 30 min. The fluorescence of cells was measured with FACSCalibur flow cytometer (BD Immunocytometry Systems, San Jose, CA, USA). The relative content of DNA indicated the distribution of a population of cells throughout the cell cycle. Apoptotic cells caused the appearance of a sub-diploid peak in the cell-cycle profile. The percentage of apoptotic cells was determined by using BD CellQuest software.

Assay for caspase-3 activity Caspase-3-like activity was measured as described in a previous study with modification^[20]. In brief, the PC12 cells were collected and washed with PBS (pH 7.4). After centrifugation at 250×g for 5 min, cell pellets were lysed with NP-40 (0.5%)/HEPES (10 mmol/L) (pH 7.4), containing EDTA 2 mmol/L, PMSF 0.5 mmol/L and leupeptin 5 mg/L. The lysates were centrifuged at 7500×g for 10 min. The protein concentration in the supernatant was determined with Lowry method. Then 50 μg of protein was incubated with caspase-3 substrate Ac-DEVD-AMC 50 μmol/L. The increase of fluorescence was measured every 1 min in a 30 min period using a PolarStar plate reader (BMG labtechnologies, Australia) with an excitation wavelength of 380 nm and an emission wavelength of 450 nm. The enzyme activity was expressed as fluorescent units per min per mg protein.

Measurement of reactive oxygen species production The level of intracellular hydrogen peroxide and other peroxides in PC12 cells were quantified by loading cells with 2'-7'-dichlorodihydrofluorescein diacetate (DCFH-DA) as described previously^[19]. In brief, the PC12 cells were washed with PBS (pH 7.4), resuspended in Krebs-Ringer buffer

(HEPES 20 mmol/L, dextrose 10 mmol/L, NaCl 127 mmol/L, CaCl₂ 1 mmol/L, KCl 5.5 mmol/L, MgSO₄ 2 mmol/L, pH 7.4), and then loaded with DCFH-DA 5 mmol/L for 60 min. The cells were again washed with Krebs-Ringer buffer to remove the extracellular dye and lysed in Tris-HCl 10 mmol/L (pH 7.4) containing 0.5% Triton X-100. The fluorescence in lysates was detected using a PolarStar plate reader (BMG labtechnologies, Australia) with an excitation wavelength of 485 nm and an emission wavelength of 520 nm. The fluorescence intensity was normalized based on the protein concentration of individual extract. The ROS production was expressed as percentage compared with cells without treatment.

Determination of lactic acid accumulation Lactic acid accumulation was measured as described previously^[21]. In brief, PC12 cells were homogenized with sodium phosphate 50 mmol/L (pH 6.5) and boiled for 15 min. Lactic acid content was measured spectrophotometrically at 340 nm in a buffer containing LDH and hydrazine (0.4 mol/L)/glycine (0.5 mol/L) (pH 9.0). Lactic acid accumulation was normalized based on the protein concentration of individual extract, and expressed as percentage compared with cells without treatment. Protein concentration was detected by the Lowry method.

Measurement of dopamine in PC12 cells The DA levels in PC12 cells were determined by a modification of the methods described previously^[22-24]. In brief, cells were lysed in 1% metaphosphoric acid containing EDTA 1 mmol/L. Each sample added with 20 mL of DHBA was regarded as an internal standard. After centrifugation (17 500×g for 10 min at 4 °C), the supernatant was filtered, and a 20 mL aliquot was immediately injected into the HPLC system for DHBA and DA determination. The assay was done with a BAS PM80 pump, a Waters Nova-Pak C18 column, and an electrochemical detector (BAS LC-4C). The mobile phase was citric acid 0.1 mol/L, K₂HPO₄ 0.1 mol/L, EDTA 0.1 mmol/L, 5% methanol, and sodium octylsulfate 70 mg/L (pH 3.0); the flow rate was 1.0 mL/min. The potential of the electrode was set at +0.7 V. DA level in each sample was quantified by comparing DA and DHBA peak areas with those of standard solutions containing DA and DHBA, and then normalized based on the protein concentration of each individual sample. The DA level was expressed as percentage compared with control cells without reserpine treatment.

Statistics Data for cell viability, caspase-3 activity, ROS production and lactic acid accumulation were presented as mean±SD of four independent experiments. Data for dopamine levels in cells are means±SD of three experiments performed in triplicate. Statistical analysis was performed by

applying the Student's *t*-test and one-way ANOVA.

Results

Oxidative stress is involved in rotenone-induced neurotoxicity When PC12 cells were treated with 12.5 and 25 nmol/L rotenone for 48 h, LDH leakage increased from 7.8%±1.1% to 19.7%±1.1% and 30.1%±3.6% ($P<0.01$ vs control), respectively (Figure 1A). The rotenone-induced cell injury was associated with caspase-3 activation (Figure 1B), supporting the notion that an apoptotic cell death mechanism was involved in rotenone-induced neurotoxicity. Rotenone treatment induced a concentration-dependent increase of ROS levels within PC12 cells (Figure 1C). Rotenone treatment also induced an increase in lactic acid accumulation in PC12 cells (Figure 1D), suggesting that both oxidative stress and mitochondrial dysfunction were responsible for cell injury. The effects of rotenone were attenuated by 2.5 and 5 mmol/L NAC co-treatment (Figure 2A-2C), further supporting the notion that oxidative stress was involved in rotenone neurotoxicity. In addition, 2.5 and 5 mmol/L NAC also attenuated rotenone-induced increase in lactic acid accumulation (Figure 2D).

Rotenone-induced ROS accumulation is mediated by DA oxidation To test whether manipulation of DA levels would attenuate rotenone-induced cell death, PC12 cells were first depleted of intracellular DA using reserpine and then treated with rotenone. Reserpine (1 and 5 μmol/L) treatment for 3 h induced 66% and 87% depletions of DA respectively as compared with the control (Figure 3). The rotenone-induced elevation of LDH leakage and caspase-3 activation were attenuated in reserpine-pretreated PC12 cells (Figure 4A-4B), suggesting that DA played an important role in rotenone-induced cell injury. The rotenone-induced intracellular accumulation of ROS was also attenuated by this manipulation (Figure 4C). The results suggest that DA oxidation is involved in the production of ROS. In addition, lactic acid accumulation assay indicated that the rotenone-induced energy crisis was partially alleviated if PC12 cells were pretreated with reserpine (Figure 4D).

Analyzed quantitatively by flow cytometry, the apoptotic rates increased significantly in PC12 cells treated with rotenone (12.5 and 25 nmol/L) for 48 h (Figure 5A). The co-treatment with NAC 2.5 and 5 mmol/L or pre-treatment with reserpine 1 and 5 mmol/L for 3 h also decreased the rotenone-induced apoptotic rate (Figure 5B and 5C).

DA auto-oxidation is responsible for rotenone-induced neurotoxicity To test whether DA deamination or auto-oxidation was more responsible for rotenone-induced neuro-

toxicity in PC12 cells, deprenyl, a monoamine oxidase-B (MAO-B) inhibitor, was used. The treatment with deprenyl at concentration between 25 to 200 μmol/L for 48 h had no significant effects on the LDH leakage in PC12 cells (Figure 6). When PC12 cells were first treated with 100 μmol/L deprenyl for 30 min and then co-treated with deprenyl 100 μmol/L plus rotenone 25 nmol/L for 48 h, no significant difference was found in the LDH leakage, caspase-3 activa-

tion or ROS production if compared with PC12 cells treated with rotenone 25 nmol/L alone (Table 1). The results suggest that the oxidative deamination of DA catalyzed by MAO-B was not a major source of ROS in the present studies.

Vesicular monoamine transporter is crucial for cell survival when there is mitochondrial dysfunction plus enhanced DA auto-oxidation To examine whether vesicular monoamine transporter (VMAT) was involved in roten-

Figure 4. Effect of reserpine on rotenone-induced PC12 cell injury. Discussion

In the present study, the mechanisms of rotenone-induced neurotoxicity in DA-producing PC12 cells was investigated. We found that rotenone induced an apoptotic type of cell death. This result is similar to the results reported by Bal-Price and Brown^[25]. They found that a 24-h incubation of PC12 cells with nitric oxide donors or rotenone, in the presence of glucose, induced apoptosis of PC12 cells as determined by nuclear morphology and caspase-3 activation. We found that rotenone induced apoptosis in PC12 cells accompanied with an elevated ROS production. Given that mitochondria is a major cellular source of ROS^[26] and that rotenone is a kind of complex I inhibitor, it could be hypothesized that rotenone-induced ROS might be originated from mitochondria. Indeed, high concentrations of rotenone have been reported to induce superoxide production *in vitro* and *in vivo*^[27-30]. In isolated nerve terminals, Sipos *et al*^[31] found that inactivation of complex I to a small extent (16%) resulted in a significant increase in ROS formation. However, other studies have suggested converse results^[32-34]. Lotharius and O'Malley^[35] found that low doses (5-50 nmol/L) of rotenone killed dopaminergic neurons with a similar time course and morphology to MPP⁺. However, no increase was found in intracellular superoxide levels after the dopaminergic neurons were treated with rotenone for 0.5, 1, 3, and 6 h. Because the classic complex I inhibitor rotenone did not induce ROS, they concluded that MPP⁺-induced superoxide did not arise from blockade of electron transport. In the present study, however, we found a significant increase of ROS production from PC12 cells after rotenone treatment for 48 h. While DCFH-DA was used as a probe to measure the redox state of a cell, the results were validated carefully.

We found that the rotenone-induced ROS accumulation and cell death were attenuated by an antioxidant, NAC. This result supports the notion that an oxidative stress mechanism is involved in rotenone-induced neurotoxicity in PC12 cells.

If toxic agents were involved in the pathogenesis of PD, this should likely reflect a multifactorial etiology in which the effects of environmental insults are compounded by predisposing genetic traits, age-related changes and interactions with endogenous elements (i.e. factors inherent to the nigrostriatal tissue). The presence of dopamine within nigrostriatal neurons may itself constitute a risk factor that enhances their vulnerability to toxic events, such as increased production of oxidizing species. To test whether manipulation of DA levels would attenuate rotenone-induced cell death, cells were depleted of intracellular DA using reserpine prior to rotenone treatment. In the present studies, we demonstrated that reserpine induced a concentration- and time-dependent DA depletion in PC12 cells. When PC12 cells were treated with 1 and 5 mmol/L reserpine for 3 h, 66% and 87% decreases in DA levels were found respectively, as compared with the control (Figure 3). Our results were similar to those reported by Brautigam *et al*^[36] who reported more than 50% depletion of intracellular DA in PC12 cells after reserpine incubation. Our finding that DA depletion significantly attenuated rotenone-induced ROS production and cell death suggests that DA plays an important role in rotenone-induced ROS production and cell death. Since DA in the cytoplasm can be readily autoxidized^[37] or deaminated^[38] by MAO-B to produce ROS^[39], deprenyl, a MAO-B inhibitor, was used to test whether MAO-B inhibition could protect PC12 cells from rotenone-induced ROS accumulation and cell death. Although it has been shown that MAO-B inhibition by pretreatment with deprenyl significantly reduces cellular DOPAC formation in PC12 cells^[40], it had no effect on the rotenone-induced ROS accumulation and cell death in our studies, suggesting that the oxidative deamination of DA catalyzed by MAO-B was not the main source of ROS in rotenone-treated PC12 cells and that DA auto-oxidation is responsible for rotenone-induced oxidative stress.

The presence of dopamine within nigrostriatal neurons can itself constitute a risk factor that enhances their vulnerability to toxic agents. For example, rotenone-induced dendrite loss was severe in the substantia nigra, whereas noncatecholamine neurons, such as those in the perifornical nucleus, were more resistant^[41]. Other factors might also play roles in the vulnerability to toxic agents since some dopamine neurons in hypothalamic A11 and the ventral tegmental area were spared when treated with rotenone. By *in*

situ hybridization, a weaker expression of VMAT was found in the rat substantia nigra than in the ventral tegmental area^[42]. If VMAT effectively protects the cell against oxidative stress induced by dopamine, the weak expression of VMAT in substantia nigra might account for its particular vulnerability to toxic agents.

No change was found in the rotenone-induced neurotoxicity. However, when PC12 cells were pretreated with deprenyl and then with deprenyl plus rotenone for 48 h, significant increases in LDH leakage, caspase-3 activation, and ROS production were found. The results suggest that VMAT activity might be important for cell survival if there is mitochondrial dysfunction. In other words, disruption in dopamine disposition and/or metabolism could underlie the progressive degeneration of dopaminergic neurons in PD.

As a specific inhibitor of mitochondrial complex I, the metabolic consequence of mitochondrial electron flow blockage induced by rotenone would be the incomplete oxidation of glucose and consequent lactic acid accumulation. Indeed, we showed that rotenone treatment also induced an increase in lactic-acid accumulation. The results support the notion that mitochondrial dysfunction is responsible for rotenone-induced cell death in PC12 cells. Mitochondria in PC12 cells can become more vulnerable to hydrogen peroxide-induced oxidative stress when complex I is inhibited.

Taken together, our results demonstrated that both oxidative stress and mitochondrial dysfunction were responsible for rotenone-induced apoptotic cell death in PC12 cells, and that rotenone-induced ROS accumulation was mainly DA auto-oxidation mediated.

Abstract

Aim: To construct an HEK293 cell line stably expressing human dopamine D₁ receptor (D₁R). **Methods:** cDNA was amplified by RT-PCR using total RNA from human embryo brain tissue as the template. The PCR products were subcloned into the plasmid pcDNA3 and cloned into the plasmid pcDNA3.1. The cloned D₁R cDNA was sequenced and stably expressed in HEK293 cells. Expression of D₁R in HEK293 cells was monitored by the [³H]SCH23390 binding assay. The function of D₁R was studied by the cAMP accumulation assay, CRE-SEAP reporter gene activity assay, and intracellular calcium assay. **Results:** An HEK293 cell line stably expressing human D₁R was obtained. A saturation radioligand binding experiment with [³H]SCH23390 demonstrated that the K_d and B_{max} values were 1.5 ± 0.2 nmol/L and 2.94 ± 0.15 nmol/g of protein, respectively. In the [³H]SCH23390 competition assay, D₁R agonist SKF38393 displaced [³H]SCH23390 with an IC_{50} value of 2.0 (1.5–2.8) μ mol/L. SKF38393 increased the intracellular cAMP level and CRE-SEAP activity through D₁R expressed in HEK293 cells in a concentration-dependent manner with an EC_{50} value of 0.25 (0.12–0.53) μ mol/L and 0.39 (0.27–0.57) μ mol/L at 6 h/0.59 (0.22–1.58) μ mol/L at 12 h, respectively. SKF38393 also increased the intracellular calcium level in a concentration-dependent manner with EC_{50} value of 27 (8.6–70) nmol/L. **Conclusion:** An HEK293 cell line stably expressing human D₁R was obtained successfully. The study also demonstrated that the CRE-SEAP activity assay could be substituted for the cAMP accumulation assay for measuring increase in cAMP levels. Thus, both intracellular calcium measurements and the CRE-SEAP activity assay are suitable for high-throughput screening in drug research.

Introduction

The neurotransmitter dopamine (DA) plays a prominent role in a variety of vital brain functions including motor control, short-term memory, attention and reward^[1–3]. In the CNS, DA modulates neuronal excitability by regulating ligand- and voltage-gated ion channels^[4]. The actions of DA are mediated by a family of seven-transmembrane G protein-coupled receptors (GPCRs), i.e., D₁, D₂, D₃, D₄, and D₅, encoded by five distinct genes^[5]. These five subtypes have been grouped into two different classes based on phar-

macology and biochemistry: the D₁-like and D₂-like receptors. The D₁-like receptors, D₁ and D₅, mediate dopamine stimulation of adenylyl cyclase, whereas D₂-like receptors, D₂, D₃ and D₄, mediate dopamine inhibition of adenylyl cyclase^[5,6].

Assays capable of detecting and quantifying GPCR-ligand interactions are valuable tools for both fundamental studies of cell signaling and drug development. Drug screening has mainly relied upon binding assays on membrane preparations using radioligands or assays measuring second messengers or enzymes modulated by these receptors. The abil-

ity to conduct high-throughput screening based upon functional activity of a given GPCR in a cell-based assay offers a more direct way of identifying lead agonists or antagonists^[7-9].

In the present study, by using HEK293 cell lines stably expressing human D₁R, we developed a series of method check character for analyzing GPCR activities in cell lines including CRE-SEAP activity assay and the intracellular calcium assay.

Materials and methods

Materials High glucose Dulbecco's modified Eagle's medium (DMEM), fetal calf serum, G418, penicillin and streptomycin were obtained from Gibco. Restricted enzyme (*Hind*III, *Eco*RI, *Xho*I, *Bam*HI), T4 DNA ligase, reverse transcriptase and buffer were purchased from Promega (USA). Pyrobest DNA polymerase and buffer for PCR were obtained from TaKaRa (Dalian, China). (±)-SKF-38393 hydrochloride (SKF38393) and (+)-Butaclamol hydrochloride (Butaclamol) were obtained from RBI (Natick, MA, USA). Forskolin, Fluo-3/AM, p-(dipropylsulfamoyl)benzoic acid, 3-isobutyl-1-methyl-2,6(1*H*,3*H*)-purine-dione (IBMX), pluronic F-127, 4-methyl-umbelliferyl phosphate (4-MUP), HEPES, Triton X-100, bovine serum albumin leupeptin, pepstatin A, aprotinin and PMSF were purchased from Sigma (USA). [³H]SCH23390 was purchased from Amersham (USA). Plasmids pcDNA3, pcDNA3.1(+) and Lipofectamine²⁰⁰⁰ were purchased from Invitrogen (USA), and pCRE-SEAP was from BD Biosciences Clontech (USA). cAMP assay kit was purchased from Shanghai Second Medical University (Shanghai, China). Human embryo brain tissue was donated by Huashan Hospital (Shanghai, China). PCR primers were synthesized by Shenyou (Shanghai, China).

Cloning of the human dopamine D₁R cDNA Human brain total RNA was obtained from human embryo brain tissue. The total RNA was reverse-transcribed using oligo-dT18 as a primer. With the cDNA, PCR was carried out using the primers D₁R-1SE and D₁R-1AS (Table 1). Gel-purified PCR product was treated with *Bam*HI/*Xho*I and subcloned into the *Bam*HI/*Xho*I site of the mammalian expression vector pcDNA3. With the subcloned D₁R-pcDNA3 plasmid as a template, PCR was carried out using the primers D₁R-2SE and D₁R-2AS (Table 1), which resulted in full length codon sequence of cDNA. Gel-purified PCR product was treated with *Bam*HI/*Eco*RI and cloned into the *Bam*HI/*Eco*RI site of the mammalian expression vector pcDNA3.1(+).

Production of HEK293 cell lines stably expressing human dopamine D₁R HEK293 Cells were transfected with

the D₁R-pcDNA3.1(+) expression vector, using the Lipofectamine reagent. Cells were treated with selection medium containing G418 (1 g/L) for 3 weeks to select stably transfected cells displaying neomycin resistance. Between 2 and 3 weeks into the selection process, resistant cells began to appear. They were separated out by serial dilution and allowed to grow from single cells. Receptor expression of single cell-derived colonies was tested by the radioligand binding assay.

Cell culture Human embryonic kidney (HEK293) cell lines were cultured in DMEM containing streptomycin (100 µg/mL), penicillin G (1000 kU/L) and fetal bovine serum (10%). Cells were incubated at 37 °C in 5% CO₂. Stably transfected HEK293 cell lines were cultured in DMEM high glucose medium containing streptomycin (100 mg/L), benzylpenicillin (1000 kU/L), G-418 (200 mg/L) and fetal bovine serum (10%). Cells were incubated at 37 °C in 5% CO₂. For passaging, the cells were detached from the cell culture flask by washing with phosphate-buffered saline (PBS) and brief incubation with trypsin (0.5 g/L)/EDTA (0.2 g/L). The cells were passaged every 3 d.

Membrane preparation The D₁ cells were lifted from Petri dishes with a cell scraper. Harvested cells were washed twice with ice-cold PBS and centrifuged at 420×g for 5 min at 4 °C. The cell pellet was resuspended with hypotonic buffer (5 mmol/L Tris-Cl, 2 mmol/L EDTA, pH7.4, leupeptin 1 mg/L, pepstatin A 1 mg/L, aprotinin 1 mg/L, PMSF 1 mmol/L) and sonicated (18 s) three times on ice. The homogenate was centrifuged at 960×g for 10 min at 4 °C. The precipitated nucleic fraction was discarded and the supernatant was centrifuged at 40 000×g for 30 min at 4 °C. The pellet was washed with 50 mmol/L Tris-Cl buffer (pH 7.4) and centrifuged again with the same conditions. Finally, the pellet was resuspended in the same buffer, and protein concentration was determined by the BCA Kit (Pierce) as described previously^[10].

[³H]SCH23390 binding assay Membranes (30–50 µg protein) from D₁ cells were resuspended in 50 mmol/L Tris-Cl (pH 7.4, 120 mmol/L NaCl, 5 mmol/L KCl, 2 mmol/L CaCl₂ and 1 mmol/L MgCl₂). Saturation assays were performed at different concentrations of [³H]SCH23390 (0.05–6 nmol/L), using butaclamol (10 µmol/L) to obtain nonspecific binding. Competition curves were obtained by using 0.5 nmol/L [³H]SCH23390 and different concentrations of dopamine D₁R agonist SKF38393. The incubation was carried out at 37 °C for 30 min.

Binding assays were stopped by rapid filtration through Whatman GF/B filters, which were immediately washed three times with ice-cold buffer. Filters were then transferred to

Eppendorf tubes, and scintillation liquid was added to measure the radioactivity.

cAMP accumulation experiment After scraping the cells off the culture plates, they were washed twice with PBS and resuspended in PBS at a concentration of 0.5×10^6 – 1.0×10^6 cells/mL. Aliquots of 0.2 mL were transferred to test tubes along with the phosphodiesterase inhibitor IBMX (100 μ mol/L) and different concentrations of dopamine D₁R agonist SKF38393 added to a final volume of 0.3 mL. The reaction was terminated with 1 mol/L perchloric acid to a final concentration of 0.5 mol/L after a 15 min incubation at 37 °C. Samples were neutralized with 75 μ L 2 mol/L KOH, and the cAMP content in the supernatants were determined with a protein binding assay^[11]. cAMP concentrations were calculated using a standard curve according to the protocol of the assaykit.

CRE-SEAP activity assay Using the secreted form of human placental alkaline phosphatase (SEAP) as the reporter enzyme transcriptionally regulated by cAMP response elements (CREs)^[12,15], CRE-SEAP activity was measured. The pCRE-SEAP plasmid was transfected into D₁ cells using the calcium phosphate precipitation method (Promega). Cells were seeded in 100 m² plates, and transfection was performed when cells were 50% confluent. DNA 25 μ g and 60 μ L CaCl₂ 2 mol/L were mixed in H₂O in a total volume of 500 μ L and then slowly mixed with HEPES buffered saline (HBS). The reaction mixture was incubated at room temperature for 30 min and then evenly added to the cell culture dish containing 10 mL of fresh media. After 12 h, the transfection media was replaced with fresh media, and the transfected D₁ cells were seeded into 24-well plates (1.5×10^5 cells per well) and cultured overnight before experiment^[12]. The medium was then replaced with 500 μ L of free serum DMEM containing 100 μ mol/L IBMX and the different concentrations of SKF38393 then cells were incubated for 6 h and 12 h, respectively. The SEAP assay was subsequently performed (see below).

Following the incubation period of transiently transfected cells, the culture medium was inactivated for 30 min at 65 °C and centrifuged at 15 000 \times g at 4 °C. The supernatant (80 μ L), was transferred to a new 96-well plate and mixed with 100 μ L SEAP assay buffer (50 mmol/L Tris/0.1% BSA buffer, pH 8.0) containing 36 μ mol/L 4-methylumbelliferyl phosphate (4-MUP). The mixture was incubated for 1 h at 37 °C, and the fluorescence intensity was measured at 460 nm using FLUOstar plate reader. Excitation wavelength was 355 nm.

Intracellular Ca²⁺ concentration ([Ca²⁺]_i) measurement Ca²⁺ fluorescence measurements were performed using a NOVOstar plate reader with a pipettor system (BMG

Labtechnologies, Offenburg, Germany). D₁ cells were harvested with 0.05% trypsin/0.02% EDTA and rinsed with high glucose DMEM containing 10% fetal bovine serum, 100 mg/L streptomycin, 1000 U/mL penicillin G. Pelleted cells were resuspended in fresh medium and kept under 5% CO₂ at 37 °C for 1h and vortexed every 15 min. After twice washes with Krebs-HEPES buffer, cells were loaded with 5 μ mol/L Fluo-3/AM containing 1% pluronic F-127 and 2.5 mmol/L p-(Dipropylsulfamoyl)benzoic acid for 30 min. Then cells were rinsed three times with Krebs-HEPES buffer containing 0.5% bovine serum albumin, diluted, and evenly plated into 96-well plates at a density of 1×10^4 cells/well. Microplates were kept at 37 °C for 15 min^[13]. Buffer alone or different concentrations of SKF38393 were then injected sequentially into separate wells, and fluorescence intensity was measured at 520 nm for 50 s at 0.2 s intervals. The excitation wavelength was 485 nm.

[Ca²⁺]_i was calculated as follows: $[Ca^{2+}]_i = K_d (F - F_{min}) / (F_{max} - F)$. F_{max} refers to the fluorescence intensity measured after permeabilization of the cells with 1% Triton X-100. Ten mmol/L EDTA was added to chelate Ca²⁺ and minimum fluorescence intensity was obtained (F_{min}). A K_d value of 324 nmol/L was used for Fluo-3.

Data analysis Experiments were performed in triplicate. All data were expressed as mean \pm SD and analyzed with the GraphPad Prism 4.0 program (GraphPad Software, San Diego, CA, USA). Student's *t*-test was used for statistical analysis.

Results

Cloning of the human dopamine D₁R cDNA To obtain the cDNA with full length codon sequence of D₁R, a reverse transcription reaction was carried out using the total RNA extracted from embryo brain tissue. Using cDNA with the full length codon sequence of D₁R, a PCR product (1707 bp) was obtained using primers described previously. The PCR product was subcloned into pcDNA3 plasmid and a cDNA (1341 bp) containing the full D₁R codon sequence was obtained using this subcloned vector as a template. The cDNA was then cloned into the mammalian expression vector pcDNA3.1. Sequence analysis demonstrated that the sequence of the constructed D₁-pcDNA3.1 expression vector was identical to that of human D₁R cDNA in the gene bank.

Selection of cell clones Colonies of the selected stable integrants were initially analyzed for human D₁R expression by receptor binding assay using [³H]SCH23390. From the transfected HEK293 cell clones, one cell line was obtained with specific [³H]SCH23390 binding.

Binding assays with the D₁R antagonist [³H]SCH-23390 Scatchard analysis revealed a K_d value of 1.5 ± 0.2 nmol/L) and B_{max} value of 2.95 ± 1.53 nmol/g of protein (Figure 1). Figure 2 shows a competition of a D₁R agonist SKF38393 for [³H]SCH23390 with an IC_{50} value of 2.0 (1.5–2.8) μ mol/L (means, 95% confidence intervals, $n=3$).

Figure 1. Saturation curve of [³H]SCH23390 binding to dopamine D₁ receptors in plasma membrane isolated from D₁ cells. Inset: Scatchard plot of the data and analysis gave the K_d and B_{max} values indicated in RESULTS. Mean \pm SD from three independent experiments performed in triplicate.

Figure 2. Representative competitive inhibition curve of the dopamine D₁ receptor agonist SKF38393 versus the D₁ receptor antagonist [³H]SCH23390 in membrane preparations from D₁ cells. IC_{50} values were expressed as means (95% confidence intervals) obtained from three independent experiments performed in triplicate.

D₁R agonist SKF38393 induced accumulation of cAMP D₁R agonist SKF38393 induced a concentration-dependent accumulation of cAMP with a EC_{50} value of 0.25 μ mol/L (0.12–0.53) (means, 95% confidence intervals, $n=3$, Figure 3).

Figure 3. The cAMP accumulation induced by the D₁ receptor agonist SKF38393 in D₁ cells. The EC_{50} value was expressed as a mean (95% confidence intervals) obtained from three independent experiments performed in triplicate.

D₁R agonist SKF38393 induced CRE-SEAP activity

In D₁ cells transiently transfected with pCRE-SEAP reporter vector, SKF38393 induced a concentration-dependent increase in the CRE-SEAP activity. EC_{50} values at 6 h and 12 h were 0.39 (0.27–0.57) and 0.59 (0.22–1.58) μ mol/L (means, 95% confidence intervals, $n=3$), respectively. No significant difference was found between these two values (Figure 4).

D₁R agonist SKF38393 induced elevated intracellular calcium level D₁R agonist SKF38393 induced a concentration-dependent increase in the intracellular calcium level. The EC_{50} value was 27 (8.5–70) nmol/L (means, 95% confidence intervals, $n=3$). The SKF38393-induced increase of the intracellular calcium level was completely blocked by butaclamol (100 μ mol/L), a DA receptor antagonist (Figure 5).

Discussion

In the present study, a HEK293 cell line stably expressing human D₁R was constructed. Functional analysis with cAMP accumulation assay, the CRE-SEAP activity assay, and intracellular calcium assay demonstrated that their EC_{50} values were 0.25 (0.12–0.53) μ mol/L, 0.39 (0.27–0.57) μ mol/L for 6 h and 0.59 (0.22–1.58) μ mol/L for 12 h and 27 (8.6–70) nmol/L, respectively. No significant difference in the EC_{50} values was found between SKF38393-induced cAMP accumulation and CRE-SEAP activation.

D₁R can activate adenylyl cyclase, which then results in cAMP production. At present, radioimmunoassay is one of the most widely used methods for the measurement of cAMP accumulation^[14]. Cell based assays relying on transcriptionally controlled reporter gene have been developed and are suited to monitoring the cellular responses induced by

Figure 4. CRE-SEAP activity induced by dopamine D₁ receptor agonist SKF38393. (A) incubation with SKF38393 for 6 h; (B) incubation with SKF38393 for 12 h. EC₅₀ values were expressed as mean (95% confidence intervals) obtained from three independent experiments performed in triplicate.

GPCRs. Since CRE is a pivotal target in GPCR signaling pathways, it has become one of the most widely used response elements in reporter gene assays. The cAMP response element binding protein (CREB), a transcription factor, is the major regulator of CREs. It can be activated (phosphorylated) by protein kinase A (PKA) and members of calcium/calmodulin kinase (CaMK) family *in vitro*. Both G_{os}- and G_{oq}-coupled receptors are signaled through CREs [12,15,16]. Since the transcription of CRE-SEAP reporter genes is controlled by CRE-containing promoters, CRE-SEAP activity can be used to monitor the activation of receptors. In the present study, the EC₅₀ value obtained using CRE-SEAP activity assay is similar to that obtained from cAMP accumulation assay. These results suggest that CRE-SEAP activity assay can be used to estimate the G_{os}-coupled receptor function.

G_{os}-coupled receptors activate adenylyl cyclase, leading to an increase in cAMP level. cAMP activates PKA, which subsequently phosphorylates different targets. This pathway can lead to an increase in intracellular [Ca²⁺] either from intracellular Ca²⁺ stores or from the extracellular matrix [13,17].

Figure 5. Concentration-response curves for the effect of SKF38393 on intracellular [Ca²⁺]_i in D₁ cells. *n*=3. Mean±SD. EC₅₀ value was mean (95% confidence intervals) obtained from three independent experiments performed in triplicate.

Direct activation of Ca²⁺ ion channels by G_{os} is also possible [13,18]. We found that a significant difference was observed in the EC₅₀ value of the intracellular calcium assay and cAMP accumulation assay. While the EC₅₀ value to induce the cAMP accumulation was 0.25 (0.12–0.53) μmol/L, the EC₅₀ value to induce an increase in the intracellular calcium was 27 (8.6–70) nmol/L. This is likely to reflect the difference in signaling between intracellular calcium increase and cAMP accumulation. Intracellular calcium signals may be directly transduced, bypassing the adenylyl cyclase pathway and representing transient binding with ligand. Therefore, combination CRE-SEAP activity assay or a cAMP accumulation assay with an intracellular calcium assay will obtain more information on the effect of ligands. Our study demonstrates that the CRE-SEAP activity assay and intracellular calcium assay are suitable for high-throughput screening in drug research.

Abstract

Aim: To evaluate the antiapoptotic effect of the A20 gene in primary hippocampal neurons both *in vivo* and *in vitro*. **Methods:** Primary hippocampal neurons in embryonic day 18 (E18) rats were transfected with the A20 gene by using the new Nucleofector electroporation transfection method. We then examined, whether A20 -neurons possessed anti-apoptotic abilities after TNF- α stimulation *in vitro*. A20-neurons and pcDNA3 -neurons were transplanted into the penumbra of the brains of rats that had been subjected to 90-min of ischemia induced by left middle cerebral artery occlusion (MCAO). **Results:** A20-neurons resisted TNF- α induced apoptosis *in vitro*. The apoptosis rate of neurons overexpressing A20 (28.46% \pm 3.87%) was lower than that in neurons transfected with pcDNA3 (53.06% \pm 5.36%). More A20-neurons survived in the penumbra both 3-d and 7-d after transplantation than did sham pcDNA3 neurons. **Conclusion:** The novel function of A20 may make it a potential targets for the gene therapy for neurological diseases.

Introduction

Uncontrolled gene expression and apoptosis result in the development of various diseases. Excessive apoptosis plays a role in the pathogenesis of AIDS and neurological diseases such as Alzheimer disease and stroke^[1].

The zinc finger protein A20 is a novel protein type in that it seems to have a dual activity, both as an inhibitor of NF- κ B activation and as an antiapoptotic molecule in some cell systems, but not in the case of human cervix carcinoma HeLa cells, lung epithelial A549 cell, or human hepatoma HepG2 cells^[2–6]. The reason why some cell lines are protected by A20 and others not are still unclear.

Little research work has been done on the functions of A20 in primary cultured neurons, although cell apoptosis is involved in many neurological diseases. The poor transfection efficiency resulting from the extreme resistance of cultured neurons to chemical transfection vectors has limited further research^[7].

In this study, we overexpressed A20 by means of electroporation gene transfer into neurons to investigate whether

A20 can inhibit TNF-induced apoptosis in primary cultured neurons both *in vivo* and *in vitro*.

Materials and methods

Cloning of the A20 gene Human umbilical vein endothelial cells were treated with TNF- α 1000 kU/L and cycloheximide 10 μ g/L for 4 h. Poly(A)⁺-mRNA was extracted with Trizol Reagents (Gibco) and identified by electrophoresis on a 1.2% agarose gel. cDNA was obtained by using reverse transcription-polymerase chain reaction (PCR). The PCR was performed with a sense primer (5'-AAC GAGCG-GTTCCGATGCC-CTGAG-3') and an anti-sense primer (5'-TGTCGCCTTCACCGTTC-CAGTT-3') using 30 cycles of 95 °C for 1 min, 62 °C for 1.5 min, 72 °C for 2.5 min. The pcDNA3 expression vector containing the CMV immediate early promoter was used for this study.

Analysis of A20 mRNA contents Isolation of total mRNA from the transfected neurons cultured *in vitro* or in the penumbra tissue was performed using Trizol reagent (Promega, Charbonnieres, France), followed by RT-PCR

using the following primers: forward 5'-CGGTACCGCACA-ATGGCTGAACAAGTCCTTCCT-3' and reverse 5'-CGTC-TAGAGTTAGCCATACATC-TGCTTGAAGT-3'. The PCR was run at 95 °C for 5 min, followed by 30 cycles of 95 °C for 1 min, 62 °C for 1.5 min, and 72 °C for 2.5 min, with a 10 min final extension period at 72 °C. The house-keeping gene β -actin was used as a control.

Western blotting Protein was isolated from the transfected neurons and the penumbra of the MCAO rats using RIPA reagent 10 d after transfection. The samples were then resolved on a 15% SDS-PAGE gel and electrophoretically transferred onto poly-vinylidene difluoride membranes. The membranes were probed overnight at 4 °C with mouse monoclonal anti-human A20 antibody (1/2000, Oncogene). After being incubated with goat anti-mouse-HRP (1/5000) for 1 h at room temperature, antigens were revealed by enhanced chemiluminescence reaction buffer.

Cell culture Hippocampal neurons from embryonic day 18 were freshly prepared by hippocampal dissection. The C-shaped hippocampus was cut off and trypsinized for 20 min at 37 °C in a 5% CO₂ incubator. The cells were broken apart by pipetting with complete media and were then plated with a density of 3×10^8 cells/L in neurobasal medium supplemented with B27 (all materials from Gibco Invitrogen, Grand Island, NY).

Rat neuron Nucleofector transfection Transfection was accomplished using a Rat Neuron Nucleofector kit and the device from Amaxa. For each example, the prepared neurons were resuspended in Rat Neuron Nucleofector Solution to a final concentration of 1×10^6 – 6×10^6 cells/L. Then, 100 μ L of cell suspension was mixed with 1–3 μ g DNA (in 1–5 μ L H₂O or TE). Each nucleofection sample was transferred into an Amaxa certified cuvette. Insert the cuvette into the cuvette holder (Amaxa, Germany) and rotate the turning wheel clockwise to the final position. And transfection program G-13 was initiated. The transfections efficiencies were evaluated and cell transplantation was carried out 3 d later.

Immunocytochemistry Three days after transfection, the wells were fixed with 4% paraformaldehyde for 15 min. Then the wells were incubated for 12 h at 4 °C with mouse anti-rat NF antibody (1:100, DAKO) and mouse anti-human A20 antibody (1:200, Oncogene), diluted in blocking buffer. The wells were incubated with rhodamine-labeled secondary antibodies (1/500, Kirkegaard Perry Laboratories, MD, USA) and FITC-labeled secondary antibodies (1/200, DAKO) in blocking buffer for 60 min at room temperature. Fluorescence staining was evaluated using a Leica fluorescent microscope.

Cell counting Neurons stained positively for A20 were counted on coded slides using an Olympus CAST Grid system (Denmark). The area of each culture well was delineated and a counting frame was randomly placed to mark the first area to be sampled. The frame was then systematically moved through the delineated area. The total number of neurons and A20-immunoreactive neurons was extrapolated from the data, and the transfection efficiency was evaluated.

For the experiments *in vivo*, 3 d and 7 d after transplantation, rats were anesthetized and perfused intracardially with phosphate buffered saline (PBS, pH 7.4) followed by 4% paraformaldehyde dissolved in PBS (pH 7.4). Then, serial coronal brain cryostat sections were cut at 20 μ m thickness and every third section was used to count the surviving cells. To assess the survival of grafted Hoechst-stained neurons, a similar method was employed^[8].

Neurons cultured with TNF- α Three days after transfection, TNF- α was added to A20-neurons and pcDNA3-neurons to a final concentration of 2000 kU/L, and the cells were incubated at 37 °C in 5% CO₂ for 8 h. Then, the apoptosis rates were accessed by flow cytometry using a FACStar (Becton Dickinson) with excitation wavelength set at 585 nm.

Labeling of neurons for transplantation Seventy-two hours after transfection, Hoechst 33258 (Sigma) was added to each well to achieve a final concentration of 10 mg/L. One hour later, cells were rinsed 3 times with PBS to completely flush out excess fluorescence and the cells were then collected for transplantation.

Surgical procedure All animal experimental procedures were approved by the local animal protection authority. Twenty-four male Sprague-Dawley rats (250–300 g) were randomly allocated to four groups of equal size (group A–D). Rats in groups C and D were anesthetized with 10% chloralhydrate, a midline neck incision was made and a 30-mm long piece of 4–0 monofilament nylon suture was advanced from the external carotid artery (ECA) through the common carotid artery (CCA) and into the lumen of the internal carotid artery (ICA) until it blocked the origin of the middle cerebral artery (MCA). One and a half hours after the occlusion, the filament was withdrawn^[9]. The rats were allowed to recover and were monitored daily for behavioral and neurological deficits (motor weakness of extremities). The rats that did not show neurological deficits were excluded^[10].

Transplantation surgery Immediately after MCAO, the rats' heads were immobilized in a stereotaxic frame. Either A20 or pcDNA3 neurons (3×10^5 cells) 2 μ L were injected

into the penumbra at the following coordinates: 1.00 mm rostral to bregma, 3.0 mm right of the midline, and 1.2 mm ventral from the dural surface, with the incisor bar set at zero. Another 12 normal rats serving as controls received identical grafts^[11]. Rats were divided into 4 groups: normal rats with A20-neurons (group A), normal rats with pcDNA3-neurons (group b), MCAO rats with A20-neurons (group C), MCAO rats with pcDNA3-neurons (group D).

Statistical analysis Data are expressed as mean±SD. Statistical analysis was performed by one-way ANOVA and the *t*-test, using statistical software package SPSS 10.0. Statistical significance was set at a level of *P*<0.05.

Results

Identification of primary cultured cells and evaluation of transfection efficiency The fact that most cells were immunoreactive for NF indicates that most cells were neurons (Figure 1). Seventy-two hours after gene delivery, neurons immunoreactive for A20 were counted as described above for quantitative determination of transfection effi-

Figure 1. E18 hippocampal neurons tagged with anti-NF antibody on day 3 after plating (×100).

ciency (Figure 2). The percentage of neurons successfully transfected with A20 was 52.46%±5.26%.

Expression of A20 in neurons *in vitro* and after transplantation into MCAO brains Activation of A20 was detected 10 d after transfection by both RT-PCR (Figure 3A) and Western blot analysis (Figure 3B).

Induction of apoptosis by TNF-α *in vitro* The results of FACS analysis showed that after the proapoptotic insult with TNF-α, the apoptosis rate of neurons overexpressing

Figure 2. The immunocytochemical staining for protein A20 of the rat E18 primary hippocampal neurons 3 d after transfection (×100).

Figure 3. A) RT-PCR showed the expression of A20 in neurons 10 d after transfection both *in vivo* (lane 2) and *in vitro* (lane 4). Neurons transfected with pcDNA3 were chosen as the negative control both *in vivo* (lane 7) and *in vitro* (lane 9). The β-actin was selected as intrinsic standard (lanes 1, 3, 6, 8). B) Western blot analysis showed the expression of protein A20 in neurons 10 d after transfection both *in vivo* (lane 1) and *in vitro* (lane 3). Neurons transfected with pcDNA3 were chosen as the negative control both *in vivo* (lane 2) and *in vitro* (lane 4).

A20 (28.46%±3.87%) was lower than that in neurons transfected with pcDNA3 (53.06%±5.36%) (*P*<0.05, Figure 4A, 4B).

A20 protected the transplanted neurons from apoptosis in the penumbra of the MCAO brain Cells derived from the hippocampus of E18 Sprague-Dawley rats were transfected with A20 or pcDNA3 and grafted into the apoptotic zone (penumbra) of MCAO rats, and at an identical position in normal rats. Grafts were identified *in vivo* 3 d and 7 d after transplantation by staining using the Hoechst 33258 stain. A large number of cells implanted into the nor-

Figure 4. The apoptosis rate of the cultured neurons at 3 d after transfected with A20 under TNF- α stimulus (B). The neurons transfected with native pcDNA3 was as the control group (A).

mal rat brain survived, with no significant difference in the cell survival rate between the A20 group and the pcDNA3 group on d 3 or d 7 ($P > 0.05$). On the other hand, a great deal of grafted cells died when transplanted into the apoptotic zone of the ischemic brain. In this case, neurons with A20 that were grafted into MCAO rats had a greater survival rate compared to pcDNA3 cells both on d 3 and d 7 ($P < 0.05$, Figure 5A-5H, 6).

Discussion

A20 is encoded by a primary response gene which was originally identified as a TNF-inducible gene in human umbilical vein endothelial cells^[12]. It seems to have a dual activities, serving not only as an inhibitor of NF- κ B activation, but also as an antiapoptotic gene in some cell systems. Primary cells that are taken directly from the body are morphologically and physiologically similar to the parent tissue. Gene transfer using primary cells is a much better way to mimic the *in vivo* situation. This method permits much more precise medical and scientific conclusions than when genes are transferred into degenerated cell lines^[14].

In our research, we used rat primary hippocampal neurons, which form an important *in vitro* model for the research of many central nervous system diseases (such as brain ischemia and Parkinson disease) and for studying routine events in most parts of the brain. And a newly developed electroporation method known as Nucleofector technology was employed in the study of the rat primary hippocampal neurons. It is a physical method that is suitable for the transfection of nonphagocytic and nonproliferating cells, such as

peripheral leukocytes and stem cells, which are usually refractory to chemical transfection vectors. In addition, it is free of biocontaminants and does not induce immune reactions^[15]. The results of immunocytochemical analysis indicated that Nucleofector technology obtained a $52.46\% \pm 5.26\%$ transfection efficiency for the A20 gene, which is the highest transfection efficiency reported so far involving nonviral gene transfer of primary cell cultures. This high rate of efficiency is important for advanced functional experiments. RT-PCR and Western blotting analysis further proved the continuous expression of A20 proteins both *in vitro* and *in vivo* 10 d after transfection.

FACS analysis demonstrated that the A20 could protect the primary culture neurons from TNF-induced apoptosis *in vitro*. The mechanism of action has not yet been completely clarified. Some researchers speculate that A20 might interfere with TNF-R-associated death domain (TRADD) binding to TNF-R1 and might, thus, negatively regulate TNF induced cytotoxicity^[6].

Most of the evidence supporting the role of apoptosis in neuronal cell death comes from studies using animal models of global or focal cerebral ischemia. In the focal ischemia models, which create a condition emulating human strokes, transient ischemia followed by reperfusion is often associated with massive induction of apoptosis-like cell death^[16]. After reversible middle cerebral artery occlusion in adult rats, both TNF and TRAIL proteins are expressed in the apoptotic areas of the post-ischemic brain (the penumbra), thus providing conditions for inducing apoptosis. TRAIL mRNA levels increase in response to ischemia and reperfusion, reaching a maximum after 3 d. In contrast to TRAIL, TNF- α mRNA is not consistently upregulated in the ischemic hemisphere. TNF- α mRNA exhibits a first peak after 24 h, followed by a decline after 3 d, and a second rise after 5 d^[17]. Furthermore, in focal cerebral ischemia, NF- κ B is activated and promotes cell death^[17,18]. So when cultured neurons are injected into this zone, apoptosis is expected to occur. Cell counting of surviving neurons in the present study confirmed this speculation. Higher levels of cell death were observed in the case of both A20-neurons and pcDNA3-neurons when grafted into MCAO rats than when grafted into normal rats. This result proves that apoptosis-inducing circumstances definitely exist in the penumbra following transient cerebral ischemia. On the other hand, among the two groups of MCAO rats, more A20-neurons survived than the sham group pcDNA3-neurons. This result indicates that A20 protein can protect the neurons from the cytotoxicity associated with the ischemic zone. Some further points should be made. First, the transfection efficiency was approximately 50%, and neu-

Figure 5. Immunostained 20- μ m cryosections of surviving neurons from Sprague-Dawley rats subjected to MCAO and subsequently reperfused for different lengths of time ($\times 200$). Hoechst reactive neurons which had been transfected with A20 and pcDNA3 were seen scattered throughout the penumbra at 3 d after A20-neurons (E) and pcDNA3-neurons (F) transplanted to the penumbra of MCAO rats, and 7 d after A20-neurons (G) and pcDNA3-neurons (H) transplanted to the penumbra of MCAO rats. There were corresponding controls to normal rats at 3 d after A20-neurons (5A) and pcDNA3-neurons (B) transplanted to the normal rats, and 7 d after A20-neurons (C) and pcDNA3-neurons (D) transplanted to the normal rats.

Figure 6. Number of the surviving cells at 3 d and 7 d after transfected neurons were transplanted into the brains of MCAO rats and normal rats. $n=3$. Mean \pm SD. ^b $P<0.05$ vs A group. ^c $P<0.05$ vs D group.

rons that did not express the A20 protein would likely be induced to undergo apoptosis. Second, the transplanted neurons were influenced not only by TNF and TRAIL, but also by multiple other toxic factors, such as the CD95-ligand, starvation, etc. Thus 7 d after transplantation into the ischemic zone, the fact that large number of A20-neurons nevertheless died indicates that the function of A20 protein can only partly and not completely protect the neurons *in vivo*.

In conclusion, our study showed that the zinc finger protein A20 was an effective neuroprotective agent that improved the survival of both cultured and grafted embryonic hippocampal neurons, which suggests that the A20 may have therapeutic potential in gene therapy for diseases of the central nervous system.

Abstract

Aim: To investigate the validity and sensitivity of an automatic movement detection system developed by our laboratory for the formalin test in rats. **Methods:** The effects of systemic morphine and local anesthetic lidocaine on the nociceptive behaviors induced by formalin subcutaneously injected into the hindpaw were examined by using an automated movement detection system and manual measuring methods. **Results:** Formalin subcutaneously injected into the hindpaw produced typical biphasic nociceptive behaviors (agitation). The mean agitation event rate during a 60-min observation period increased linearly following increases in the formalin concentration (0.0%, 0.5%, 1.5%, 2.5%, and 5%, 50 μ L). Systemic application of morphine of different doses (1, 2, and 5 mg/kg) 10-min prior to formalin injection depressed the agitation responses induced by formalin injection in a dose-dependent manner, and the antinociceptive effect induced by the largest dose (5 mg/kg) of morphine was significantly antagonized by systemic application of the opioid receptor antagonist naloxone (1.25 mg/kg). Local anesthetic lidocaine (20 mg/kg) injected into the ipsilateral ankle subskin 5-min prior to formalin completely blocked the agitation response to formalin injection. These results were comparable to those obtained from manual measure of the incidence of flinching or the duration time of licking/biting of the injected paw. **Conclusion:** These data suggest that this automated movement detection system for formalin test is a simple, validated measure with good pharmacological sensitivity suitable for discovering novel analgesics or investigating central pain mechanisms.

Introduction

The formalin test, first established by Dubuisson and Dennis^[1], is a model of acute and tonic pain that is commonly used in studies of nociception in rodents and in the discovery of novel analgesics. The test has been characterized most extensively in rats, cats, and mice^[1–3]. The injection of diluted formalin into the hindpaw of rats elicits a biphasic nociceptive behavioral response. This response is complex and includes such behavior as rearing, turning, jumping, crossings, flinching, shaking, elevating, clutching, and licking the affected paw and dysphoria. These responses have been most frequently monitored either by assessing a single,

presumably representative, behavior (eg, the incidence of flinching, the duration of licking/biting)^[4–7], or by using a weighted-scored measure^[1] to evaluate the global response. However, these measurements, based on a subjective interpretation of the behaviors, are labor-intensive, time-consuming, tedious, and dependent on human judgement. The need to automate behavioral pain tests is obvious not only to facilitate their use but also to allow researchers from academic institutes and pharmaceutical companies to easily use more sophisticated and perhaps more predictive tests than the usual acute pain test. Therefore, different automated detection systems have been established for nociceptive behavior in the formalin test^[8–10]. However, the computer-

driven, dynamic-force automatic system^[8] or the automated method of pain scoring^[9–11] were difficult to purchase. Recently, a simple automated movement detection system has been described primarily by our laboratory to quantify the agitation responses elicited by subcutaneous (sc) formalin injection into the rats' hindpaw^[12]. The purpose of the present study was to further investigate the pharmacological sensitivity and validity of this system. The agitation responses elicited by different concentrations of formalin (50 μ L) sc injected into the rat hindpaw were determined with this automated system, and then the effects of systemic morphine of different doses and local anesthetic lidocaine on the agitation responses induced by the largest concentration of formalin (5%) were examined in the rat. As comparable control, manual measurement of the duration of licking/biting and the incidence of flinching of the injected paw were also simultaneously monitored in each test.

Materials and methods

Subjects Sixty adult male Sprague-Dawley rats weighing 260–280 g were provided by the Experimental Medical Animal Center of Shaanxi Province, China. Animals were housed in cages in groups of six with food and water available *ad libitum* on a 12 h light/dark schedule (lights on at 8:00 AM). The experiment was performed according to the Guidelines of the International Association for the Study of Pain^[13] and approved by the Institutional Animal Care Committee of Xi'an Jiaotong University.

Formalin test

Automated movement detection system The transformed part of the automated movement detection system consisted only of a spring balance (0–2.0 kg) and an electromagnetic transducer, a permanent magnet (1.5 cm \times 1.5 cm \times 1.0 cm) with an intensity of 0.5 T connected to the plane of the balance, which placed both the N and S poles of the magnet in a horizontal plane. One thousand five-hundred turns were wound on an E6 electric core and then installed in the magnetic field. Such an electromagnetic transducer was able to pick up and transform the mechanical movement of the spring balance plane into the induced current in the winding in the magnetic field, as shown in Figure 1. On the day of testing, each rat was moved to the laboratory and placed in a hexagonal polycarbonate chamber (L:16 cm; H:8 cm) for about 15–20 min to acclimate it to the experimental environment. The criterion for adequate acclimation was that rats did not freeze or defecate in the test chamber^[14] and rarely exhibited spontaneous activities. Then, the rat was taken from this chamber and formalin (50 μ L) was adminis-

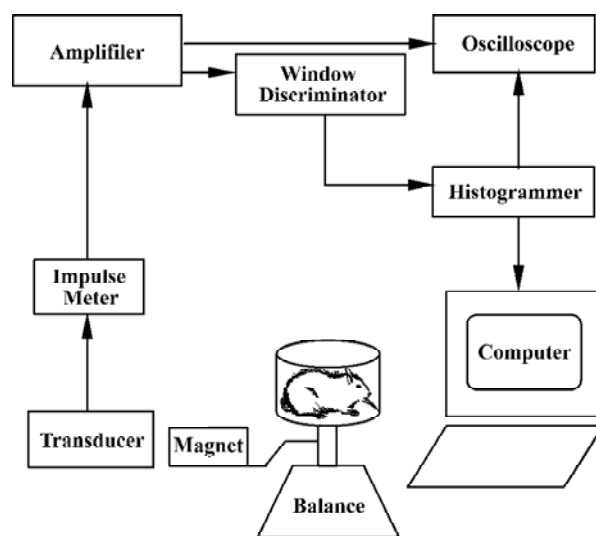

Figure 1. Schematic diagram of the automated movement detection system for recording the agitation response induced by formalin.

tered sc into the hindpaw pad. The rat was immediately replaced in the chamber, which was placed on the spring balance with the electromagnetic transducer. Nociceptive behavior (agitation) elicited by the formalin injection such as flinching shaking, elevating, clutching, and favoring the affected paw, and dysphoria activities-induced movements of the balance, which was picked up and transformed into electrical signals via the electromagnetic transducer. The electrical signals were amplified, filtered (100 Hz), and displayed on an oscilloscope, and fed into a window discriminator to minimize the non-specific signals induced by spontaneous movement of the animal. A computer system that allowed quantitative recording of the number of agitation events and construction of time histograms over a 60-min observation period. To examine the different concentrations of formalin-induced agitation responses, rats were restrained lightly and received a single sc injection of saline (50 μ L) or formalin (0.5, 1.5, 2.5, 5.0%, 50 μ L, respectively) into the plantar surface of right hindpaw. Each rat was used only once and was killed by a lethal dose of pentobarbital at the end of the experiment.

Manual detection method To evaluate the validity of the automated movement detection system for formalin test, the classical manual detection methods were also used synchronously. A mirror was positioned below the chamber at a 45° angle for unobstructed observation of the rats' paws. The response to formalin injection was monitored by measuring the total duration(s) of licking/biting and the incidence (times) of flinching of the injected hindpaw over 5-min in the 60-min observation period, respectively, by two

experimenters, as reported previously⁴⁻⁶.

Pharmacological experiment To determine the pharmacological validity of the automated movement detection system, the effects of sc injection of morphine hydrochloride of different doses (1, 2, and 5 mg/kg, dissolved in 0.9% saline) 10 min before formalin injection on the formalin-induced agitation responses were observed. In the subsequent experiments, the blocking effects of opioid receptor antagonist naloxone on morphine-induced inhibition of the agitation responses were further examined, ie, after administration of the largest dose (5.0 mg/kg) morphine, which produced a maximal antinociceptive effect, naloxone hydrochloride (1.25 mg/kg, dissolved in 0.9% saline, Sigma, MO, USA) was administered sc just before formalin injection. The doses of morphine and naloxone were selected according to previous studies by using the weighted-scores method for behavioral measurement of nociception in the formalin test^{8,15}. In another experimental group rats received an injection of lidocaine (2%, 20 mg/kg) into the ipsilateral ankle subskin of the rat 5 min prior to formalin (5%, 50 μ L) injection to observe the effects of the local anesthetic on the formalin-induced agitation responses. The same volume of saline was injected before formalin injection in the control experiment. In all these experiments, after formalin injection, the nociceptive agitation responses were monitored for 60-min by using both the automated movement detection system and the manual detection method.

Data analysis Data were expressed as the agitation event rate (Hz), the duration(s) of licking/biting and the incidence (times) of flinching of the injected paw per 5-min observation period. The correlation coefficient between the concentration or dose of drug and effect on nociceptive behavior was calculated with linear regression. Differences in drug effects among groups were tested statistically by two-way repeated measures of analysis of variance (two-way RM ANOVA) with a *post hoc* multiple comparison (Bonferroni *t*-test) for analysis of the differences over the entire observation time or at each time point among different groups. $P < 0.05$ was considered to indicate statistical significance.

Results

Nociceptive behavior induced by formalin injection to the hindpaw Injection of formalin into the rat hindpaws elicited a characteristic biphasic nociceptive agitation response when the response was monitored with the automatic system. The first phase (early phase) began immediately after formalin injection and lasted for approximately 5-6 min. After the first phase, there was one 6-10 min interphase,

during which the rat was relative quiet in the chamber and rarely exhibited nociceptive agitation activities. The second phase (late phase) began approximately 10-15 min after formalin injection and lasted for approximately 40-50 min. In the second phase, the response peak appeared at about 35 min after formalin injection. The time histograms of the mean agitation events induced by formalin of different concentration (saline, 0.5, 1.5, 2.5, and 5.0%, 50 μ L, $n=6$ for each treated group) was shown in Figure 2A-2E. The agitation event rate induced by 5.0% formalin during a 60-min observation period was significantly larger than that of the saline, 0.5% or 1.5% formalin group ($P < 0.01$, $n=6$) and that induced by 2.5% formalin was significantly larger than that of the saline group ($P < 0.05$). Although there was no significant difference between the 5.0% and 2.5% formalin groups in overall effects, there were significant differences at three of 12 time points ($P < 0.05$, Figure 2E). Linear regression analyses indicated that the nociceptive agitation response to formalin increased following the formalin concentration increase with a correlation coefficient (r) of 0.781 ($P < 0.01$).

Similarly, the formalin-elicited biphasic response measured manually was comparable to that obtained with the automatic detection system (Figure 2G, 2H). These results were similar to previous reports using either automatic or manual methods^{8,10,15}.

Effect of morphine on formalin-elicited nociceptive behavior Injection of morphine (0, 1, 2, and 5 mg/kg) depressed the nociceptive agitation response to the largest dose (5%, 50 μ L) of formalin injection in a dose-dependent manner with a correlation coefficient (r) of 0.876 as monitored by the automatic detection system (Figure 3A-3D). The inhibitory effect induced in both the 2 and 5 mg/kg morphine group during the 60-min observation period was significantly larger than that of the saline group ($P < 0.01$, $n=6$). Although there was no significant difference between the 1.0 mg/kg morphine and saline groups ($P > 0.05$, $n=6$) in the overall effect, the differences were significant at two of 12 time points ($P < 0.05$). The inhibitory effect of the 1 mg/kg morphine group was significantly smaller than that of 2 mg/kg and 5 mg/kg morphine groups ($P < 0.05$) at the 35 min time point after formalin injection (Figure 3E).

The inhibitory effect of morphine to the formalin-evoked nociceptive behavior was also measured manually. The decreases in the licking/biting duration induced in the 2 and 5 mg/kg morphine groups were significantly different from that of the saline group ($P < 0.05$, $P < 0.01$, $n=6$) during the 60-min observation period. At two time points the effect in 1 mg/kg morphine group was different from saline group

Figure 2. Left side (A-E): Mean time histograms showing the nociceptive agitation responses induced by different concentrations of formalin injected into the hindpaw detected using the automatic detection system. Bin=2 s. Right side: Time course curves showing the nociceptive behavior induced by different concentrations of formalin injected into rat hindpaw per 5-min observation period. (F) Agitation event rate (Hz) recorded using automated system; (G) duration time (s) of licking/biting the injected paw; (H) incidence (times) of flinching the injected paw. Mean±SEM. $n=6$. ^b $P<0.05$, ^c $P<0.01$ vs saline. ^e $P<0.05$, ^f $P<0.01$ vs 0.5 % formalin. ^h $P<0.05$, ⁱ $P<0.01$ vs 1.5 % formalin. ^k $P<0.05$ vs 2.5 % formalin.

($P<0.05$). The inhibitory effect of 5 mg/kg morphine was significantly different from those of the 1 and 2 mg/kg morphine in overall effects ($P<0.01$, $n=6$). Similarly, the decreases in the flinching incidence in the 1, 2, or 5 mg/kg morphine group were all different from the saline group ($P<0.01$, $n=6$). However, no-significant differences were found among the three morphine groups either in the entire effects or at any time point, as shown in Figure 3F, 3G.

Effect of naloxone on morphine-induced inhibition of nociceptive behavior in the formalin test Injection of the opioid receptor antagonist naloxone 1.25 mg/kg after morphine (5.0 mg/kg) application completely antagonized the morphine-evoked inhibition of agitation responses induced by formalin injection (Figure 4A–4C). There was statisti-

cally significant difference ($P<0.01$, $n=6$) between the effects induced by naloxone plus morphine and those by morphine alone, but no significant difference ($P>0.05$) was detected between effects in the naloxone plus morphine group and the saline group (Figure 4E).

When manual detection methods were used, naloxone significantly blocked the decrease in the licking/biting duration ($P<0.01$) and flinching incidence ($P<0.01$) elicited by morphine (Figure 4F, 4G).

Effect of lidocaine on the nociceptive behavior induced by formalin Injection of lidocaine 20 mg/kg into the ipsilateral ankle subskin completely blocked the agitation response to formalin injection as measured by the automatic system. There was a statistically significant difference

Figure 3. Left side (A-D): Mean time histograms showing the inhibitory effects of different doses of morphine on the agitation responses induced by 5.0 % formalin injection using the automatic detection system. Bin=2 s. Right side: Time course curves showing the effects of different doses of morphine (0, 1, 2, 5 mg/kg) on 5.0 % formalin-evoked nociceptive behavior per 5 min observation period. (*P*<0.01) between the effects in saline group and the lidocaine group (Figure 4A, 4D).

When manual detection methods were used, there were also significant differences in the duration of licking/biting (*P*<0.01) and flinching incidence (*P*<0.01) between the saline and the lidocaine groups (Figure 4F, 4G).

Discussion

The present study found that a typical biphasic nociceptive behavior (agitation) induced by formalin injection into the rat hindpaw could be detected by the automated movement detection system developed by our laboratory^[12], and that this response was proportional to those obtained from manual scoring method both in the time course and the mag-

nitude of change. It is identical to previously reports about the formalin test in rats^[1,9,10], either using a weighted-scores measurement or a single nociceptive behavior measurement such as licking/biting or flinching the injected paw. This indicates that the simple automated movement detection system for quantifying the nociceptive behavior elicited in the formalin test is a validated measure and produces results that are comparable to those found using a computer-driven, dynamic-force automatic detection system^[7] or a new automated method of pain scoring^[9,11].

The first phase of response elicited in the formalin test was believed to be a result of direct activation of peripheral nociceptors, whereas the second was mediated by a combination of low ongoing activity in primary afferents and increased sensitivity of spinal cord neurons (inflammatory

Figure 4. Left side (A–D): Mean time histograms showing the blocking effects of naloxone on 5 mg/kg morphine-evoked inhibition of agitation responses and of lidocaine on agitation responses induced by 5% formalin applied to rat hindpaw using the automatic detection system. Bin=2 s. Right side: Time course curves indicating the blocking effects of naloxone on morphine-evoked inhibition of nociceptive behavior and of lidocaine on nociceptive behavior induced by 5% formalin applied to rat hindpaws per 5-min observation period. (E) Agitation event rate (Hz) recorded by using the automatic detection system; (F) duration time (s) of licking/biting the injected paw; (G) incidence (times) of flinching the injected paw. Mean \pm SEM. ^b P <0.05, ^c P <0.01 vs saline. ^e P <0.05, ^f P <0.01 vs morphine.

hyperalgesia)^[16,17]. Therefore, the intensity of the agitation response to formalin recorded by using the automatic system should be of a stimulation-response relationship. The results of this study demonstrated that the nociceptive agitation response increased linearly following the increase of stimulation intensity with a greater correlation coefficient which is similar to the results that obtained from manual detection methods. These results were also consistent with those obtained by using a weighted-scores method of behavioral pain rating^[4] and using a computer-driven, dynamic-force automatic detection system^[7]. Therefore, the results reinforced the validity of the new automatic detection system for monitoring the nociceptive response to formalin injection.

The validity of the automatic system was further con-

firmed by the results obtained from systemic morphine-evoked analgesia. The nociceptive agitation response to formalin as monitored by the automatic detection system was inhibited by sc injection of morphine in a dose-dependent manner which was similar to that described in other studies^[8,9,15]. The antinociceptive effect of the largest dose (5.0 mg/kg) of morphine could be effectively antagonized by opioid receptor antagonist naloxone. These results were also comparable to those obtained using manual methods suggesting that the automatic system has a good sensitivity to analgesics and therefore provides a good measurement to evaluate the effect of analgesics.

In the present study, the data obtained with both the automatic detection system and manual methods indicated that the nociceptive response could be completely blocked by

pre-administration of the local anesthetic lidocaine. The results are identical to those reported previously^[18,19]. It has been demonstrated that intraperitoneal injection of lidocaine (10–30 mg/kg) induced significant antinociceptive effect in both phases of the formalin test using the paw-licking measurement^[18]. A pre-injection of lidocaine (sc) into the ankle before formalin could markedly decrease the formalin-evoked Fos-immunoreactivity in the dorsal horn neurons^[19]. These studies showed that the automated movement detection system provided a good pain measurement and a pharmacological validation for the system. The results correlate well with the licking duration and incidence of flinching measures for invention and detection of new analgesic drugs.

In summary, the data from the present study show the validity of an automatic detection system with following advantages: (1) it is an objective measure; (2) global analysis of pain-induced behaviors superior to the recording of a single parameter such as licking duration or flinching incidence; (3) the system is less time consuming spent by the experimenter; (4) that the new automatic detection system could be used in pharmacological studies in inflammatory pain; and (5) the transducer equipment in the automatic system is very simple and cheap. In a general electrophysiological laboratory, this system can be easily made and used in studies of nociception and antinociception. Although the automatic system cannot clearly distinguish the agitation response and the spontaneous activities, the latter can be reduced to smallest if the animal adequately habituated to the experimental arena and were kept quiet in the chamber before formalin administration.

Abstract

Aim: To investigate effects of the cyclin-dependent kinase5 (Cdk5) inhibitor roscovitine on formalin-induced nociceptive responses in rats. **Methods:** The flinch response as a method of pain threshold measurement and intrathecal injection techniques were used. Cdk5 and phosphorylation of its downstream target, DARPP-32 (dopamine- and cAMP-regulated phosphoprotein of M_r 32 kDa), were investigated by Western blot analysis. **Results:** Rats demonstrated a typical flinch response after formalin injection. Intrathecal roscovitine injections significantly suppressed the flinch response in a dose-dependent manner. Western blot analysis showed that phosphorylated DARPP-32 at Thr75 increased in concentration after formalin hyperalgesia, with this effect reduced by roscovitine administration. This antinociception was partially attenuated by administration of naloxone before the formalin test. **Conclusion:** DARPP-32 phosphorylation is involved in acute inflammatory pain response. Intrathecal roscovitine administration attenuates formalin-induced nociceptive responses and there is potential for further application.

Introduction

Tissue injury is associated with sensitization of nociceptors and subsequent changes in the excitability of central neurons, known as central sensitization. Nociceptor sensitization and central sensitization are believed to underlie the development of primary and secondary hyperalgesia^[1]. Glutamate, acting at the spinal *N*-methyl-*D*-aspartate (NMDA) receptor, has been implicated in the development of secondary hyperalgesia^[2,3]. Downstream of NMDA receptor activation, spinal nitric oxide (NO), protein kinase C, and other mediators have been implicated in maintaining such hyperalgesia^[4]. Among these mediators, cyclin-dependent kinase-5 (Cdk5) has been found to be involved in modulation of the NMDA and metabotropic glutamate receptors^[5].

DARPP-32 (dopamine- and cAMP-regulated phosphoprotein of M_r 32 kDa) is a cytosolic protein that is selectively enriched in medium spiny neurons in the neostria-

tum^[6]. When DARPP-32 is phosphorylated by cAMP-dependent protein kinase (PKA) on Thr34, it is converted into a potent inhibitor of protein phosphatase-1 (PP-1)^[7]. This leads to an increase in the phosphorylation of downstream PP-1 substrates, including various neurotransmitter receptors and voltage-gated ion channels^[6]. If DARPP-32 is phosphorylated at Thr75 by Cdk5, it inhibits PKA activity and thereby reduces the efficacy of dopamine signaling^[8]. Thus, DARPP-32 is a bi-functional signal transduction molecule that controls the activity of PP-1 and PKA by phosphorylation at different sites.

Roscovitine is a potent selective inhibitor of Cdk5, and competes for the ATP-binding site of the kinase (ED_{50} =0.16 μ mol/L)^[9]. Injection of roscovitine inhibits Cdk5 activity in the hippocampus and reduce the NMDA-evoked currents^[10]. Recently, we demonstrated roscovitine mediated antinociception and attenuated morphine tolerance in rats^[11]. Therefore, in the present study, the effect of roscovitine on the nocice-

ptive flinch response, evoked by subcutaneous formalin injection, and its possible molecular mechanism, was investigated.

Materials and methods

Drug Roscovitine was obtained from LC Laboratories (Woburn, MA, US) and Me₂SO was purchased from Sigma-Aldrich (St Louis, MO, USA).

Animal care and intrathecal catheterization Male Sprague-Dawley rats (250–300 g) were provided by the “National” Science Council, Taiwan, China. The rats were housed in a room with a 12:12 h dark-light cycle, and a temperature of 22±0.5 °C, with food and water *ad libitum*. The ethical guidelines specified by the Chang-Gung Memorial Hospital Animal Ethics Committee were followed throughout the study. Chronic intrathecal catheters were implanted under isoflurane anesthesia. Through an incision in the atlanto-occipital membrane, a polyethylene (PE-5) catheter, filled with 0.9% saline, was advanced 8.5 cm caudally to position its tips at the level of the lumbar enlargement. The rostral tip of the catheter was passed subcutaneously, externalized on top of the skull, and sealed with a stainless-steel plug. Rats showing neurological deficits after implantation were excluded from the study. Rats were used for experimentation three days after implantation.

Behavioral testing and animal grouping For formalin injection, 50 µL of a 5 % formalin solution was injected subcutaneously into the dorsal surface of the right hind paw using a 27-gauge needle. Animals were then placed in a clear Plexiglas cylinder (30 cm×30 cm) for observation. A mirror was placed below the floor (Plexiglas) at a 45° angle, to enable unencumbered observation during the test. Within 1 min of the injection, the rats displayed the typical behavior of this model, holding the paw just off the floor. During this period, spontaneous flinching of the injected paw was also observed. Flinching was readily discriminated, and was characterized as a rapid and brief withdrawing or flexing of the injected paw. Pain-related behavior was quantified by counting the number of flinches over 1 min intervals during the first 5 min, and then at 5 min intervals 10–60 min after formalin injection. Two phases of spontaneous flinching responses were observed. An initial acute pain response (phase I, during the first 1–5 min after formalin injection) was followed by a relatively short quiescent period and then by a prolonged tonic phase (phase II, beginning approximately 10–60 min after formalin injection). Criteria for exclusion from the study included incomplete formalin injection, or excessive bleeding from the injection site. Time-response

data was presented as the mean±SD per minute for the period of 1–9 min, and then at 5 min intervals up to 60 min. For the dose-response analysis, data from phase I and phase II observations were considered separately. In each case, the observation interval was calculated for each rat. The cumulative flinching response was calculated for each animal, and the dose-response curve represents the mean±SD. To determine the dose dependency and time course of the antinociceptive action of an intrathecal injection of roscovitine, animals were randomly assigned to five groups receiving different doses of roscovitine: 0, 10, 50, 100, 200 µg (*n*=6 in each group), injected intrathecally 30 min before formalin administration. For exploring possible µ-opioid involvement in the effect of intrathecal roscovitine, naloxone (1 mg/kg) was given intraperitoneally 1 h before the formalin test in the 200 µg roscovitine group (*n*=6). Roscovitine was dissolved in dimethyl sulfoxide (Me₂SO) and delivered with a microsyringe in a total volume of 10 µL, followed immediately by 5 µL of Me₂SO to flush out the catheter.

Western blot analysis One hour after formalin injection, the rats were killed under deep isoflurane anesthesia, then decollated and spinal cord was removed. The lumbar spinal cords were homogenized in a lysis buffer (20 mmol/L Tris pH 7.6, 150 mmol/L NaCl, 1 mmol/L EGTA, 5 mmol/L NaF and 1 mmol/L dTT, supplemented with protease inhibitor cocktail tablets (Roche, Mannheim, Germany) and complete phosphatase inhibitors. For analysis of Cdk5 and DARPP-32 protein expression after the formalin test, 25 µg protein extracts were electrophoresed on a 12% acrylamide SDS polyacrylamide gel electrophoresis and immunoblotted onto polyvinylidene fluoride membranes. The membranes were blocked for 1 h at room temperature and incubated overnight with Cdk5 (C-8) (1:1000) (Santa Cruz Biotechnology, Santa Cruz, CA, USA), DARPP-32 (1:1000) (Cell Signaling Technology, Beverly, MA, USA), phospho-DARPP-32 (Thr-75) antibody (1:500) (Cell Signaling Technology), and α-tubulin antibody (1:1000) (Santa Cruz Biotechnology) was used as an internal control. Antibody binding was detected using a goat anti-rabbit horseradish peroxidase-linked IgG. The bands were visualized by an ECL detection system (Amersham-Pharmacia Biotech, Little Chalfont, England). Band intensities were quantified by using an image analyzer (Densitograph AE-6900M, Atto, Tokyo, Japan).

Statistical analysis All the data in this study are presented as means±SD and analyzed by one-way ANOVA followed by Dunnett's test for *post-hoc* analysis. *P*<0.05 was considered significant.

Results

Roscovitine attenuated the formalin-induced flinch response

Formalin (5%, 50 μ L) injected into the dorsal surface of a rat hind paw produced characteristic behaviors. The intrathecal administration of 0, 10, 50, 100, and 200 μ g roscovitine produced a dose-dependent decrease in the flinch response to formalin (Figure 1). The cumulative phase I flinch counts were 79 ± 6 , 81 ± 4 , 60 ± 7 , 60 ± 6 , and 23 ± 2 , respectively. There was a statistically significant difference between the 200 μ g group and the 0 μ g group ($P<0.01$). The cumulative phase II flinch counts were 117 ± 6 , 112 ± 7 , 65 ± 25 , 46 ± 11 , and 16 ± 2 . The 50, 100, and 200 μ g groups all showed significant inhibition of the phase II flinch response compared to the 0 μ g group ($P<0.01$).

Naloxone reversed the roscovitine mediated antinociception Another six rats were given naloxone (1 mg/kg) 1 h before the formalin test in the 200 μ g roscovitine group. The cumulative phase I flinch count was 48 ± 5 and the phase II flinch counting was 92 ± 10 . The difference in phases I and II were statistically significant compared to the 200 μ g group ($P<0.01$) (Figure 1).

Roscovitine attenuated the phosphorylated DARPP-32 upregulation after formalin hyperalgesia Western blot analysis showed that the Cdk5 expression did not change significantly in any groups, and neither did the total DARPP-32, the downstream target of Cdk5 (Figure 2). However, the phosphorylated-DARPP-32 at Thr-75 was upregulated significantly after formalin hyperalgesia compared to the sham

Figure 2. Western blot analysis of the effect of intrathecal roscovitine administration on Cdk5, total DARPP-32, and α -tubulin after the formalin test. α -Tubulin was used as an internal control. There was no significant change in Cdk5 and total DARPP-32 between groups.

group, which did not receive formalin injection on the paw. Intrathecal roscovitine attenuated the increase in the proportion of phosphorylated DARPP-32 proportion significantly as compared to the 0 μ g group [25 ± 6 , 10 ± 5 , 15 ± 6 , 20 ± 7 , and 10 ± 4 (arbitrary percentage calculated by phosphorylated-DARPP-32 Thr-75/DARPP-32) in 10 μ g, 50 μ g, 100 μ g, 200 μ g, and sham groups respectively after three separate experiments, $P<0.01$] (Figure 3).

Discussion

The formalin test is a model that is believed to underlie abnormal pain perception in humans following injury^[12,13]. Following subcutaneous injection of formalin into the hind paw of a rat, the animal displays spontaneous pain behavior,

Figure 1. Number of flinches per minute in the formalin test over time, assessed after intrathecal administration of the Cdk5 inhibitor roscovitine. Mean \pm SEM. $n=6$.

Figure 3. A) Immunoblotting of phosphorylated DARPP-32 at Thr-75. B) Quantitative analysis of the proportion of phosphorylated DARPP-32 at Thr-75 after formalin hyperalgesia. Intrathecal roscovitine attenuated the increase of phosphorylated form with statistical significances as compared to the 0 µg group ($P < 0.01$ vs 0 µg group. Three separate experiments). Arbitrary unit (100 %) was defined as percentage of phosphorylated DARPP-32 in the formalin+roscovitine 0 µg group.

that is, increased hind paw flinching and licking^[14]. Two distinct phases were observed, an early acute phase (phase I) followed by a later tonic phase (phase II). The response to formalin during the acute phase is attributed to the pain intensity itself. The response during tonic phase is believed to be mediated through increased spontaneous activity of the spinal cord dorsal horn neurons^[15].

Cdk5 is a member of the Cdk family of serine/threonine kinases. Recently, both NMDA and metabotropic glutamate receptors have been shown to be modulated by Cdk5^[5]. Previous experiments have shown that inhibition of Cdk5 activity in hippocampal CA1 neurons by roscovitine injection results in a reduction of long-term potentiation and NMDA-evoked currents^[10]. Cdk5 may be one of the most important kinases in the regulation of neurotransmitter release. The induction of neurotransmitter release by Cdk5 inhibitors is caused by the regulation of P/Q-type voltage-dependent cal-

cium channel activity^[16]. Therefore, Cdk5 might play an important role in nociception by controlling neurotransmitter release.

In this study, intrathecal roscovitine reduced the flinch response after formalin hyperalgesia in a dose-dependent manner. Western blot analysis revealed that the levels of phosphorylated DARPP-32 at Thr-75 were increased after formalin hyperalgesia, and this upregulation was blocked by intrathecal roscovitine administration. Hence, Cdk5 may affect this inflammatory pain model through the DARPP-32 pathway.

Interestingly, naloxone markedly decreased intrathecal roscovitine-induced antinociception, suggesting the involvement of μ -opioid receptors. It is noteworthy that naloxone did not completely block roscovitine-induced antinociception. The exact underlying mechanism is not clear. However, it might suggest that the μ -opioid receptor and Cdk5 are integrated in the DARPP-32 pathway as reported by Greengard^[6].

This is the first study exploring the antinociceptive effect of intrathecal roscovitine on formalin-induced pain. Our findings suggest an induction of phosphorylated-DARPP-32 at Thr-75 after formalin hyperalgesia. Intrathecal roscovitine administration attenuated these flinch responses, at least in part, through inhibition of Cdk5 activity. Taken together, these data suggest that spinal Cdk5 activity might play an important role in nociception, and that its inhibitor, roscovitine, could be applied in the management of acute inflammatory pain.

Abstract

Aim: To construct a recombinant adeno-associated virus (rAAV) vector containing gene encoding phospholamban antisense RNA (asPLB), and analyse its effect on expression of PLB, expression and activity of sarco-endoplasmic reticulum Ca²⁺-ATPase (SERCA), and the change of intracellular free Ca²⁺ concentration ([Ca²⁺]_i) in rat cardiomyocytes. **Methods:** The target gene encoding PLB antisense RNA was inserted inversely into the adeno-associated virus plasmid pAAV-MCS digested by corresponding restricted endonuclease enzyme. The recombinant plasmid and pAAV-RC and pHelper were co-transfected into 293 cell. At the same time, a viral production positive control (rAAV-LacZ) and negative control were performed. The recombinant viruses were used to transfect the cultured rat cardiomyocytes. Site β-Galactosidase staining were performed to observe the transfer efficiency. Reverse transcription-PCR and Western blot were used to determine the mRNA and protein expression of PLB and SERCA. The activity of SERCA and the [Ca²⁺]_i were measured. **Results:** The rAAV vectors were constructed successfully and were transfected into rat cardiomyocytes effectively. The PLB mRNA and protein expression were reduced in rat cardiomyocytes transfected by rAAV-asPLB compared with controls. The activity of SERCA was increased. In rest state, the level of [Ca²⁺]_i in the rAAV-asPLB transfected group decreased. The level of [Ca²⁺]_i increased when induced by isoproterenol. **Conclusion:** AAV-asPLB vector was constructed successfully, which disrupted the expression of PLB, enhanced the activity of SERCA, reduced the resting [Ca²⁺]_i, and improved the cardiac function.

Introduction

Alterations in intracellular calcium signaling has played a key role in the pathophysiology of heart failure, and gene therapy has been identified as an important tool to help understand the relative contribution of specific calcium-handling proteins in heart failure^[1].

Phospholamban (PLB) was a critical regulator of the Ca²⁺ affinity of the cardiac sarcoplasmic reticulum Ca²⁺ ATPase (SERCA2a) and of cardiac contractility^[2]. Studies on PLB-knockout and PLB-over expression mice have indicated that the expression ratio of PLB to SERCA2a was a potential target for improvement of diastolic function of the failing

heart^[3]. The ablation of PLB in mice resulted in stimulated SR Ca²⁺ uptake and enhanced contractile performance, whereas PLB over expression resulted in opposite effects^[4,5]. Thus, PLB is an attractive target for treatment of cardiovascular diseases, and decreasing the level of PLB through the use of PLB antisense RNA (asPLB) would be a novel strategy for gene therapy of heart failure^[6,7].

The ideal vector for myocardial gene delivery would allow the efficient and stable transduction of cardiomyocytes. The method of injection of plasmid DNA vectors directly into the left ventricular myocardium has been limited by the lower efficiency of cardiomyocyte transduction, while, the adenovirus-mediated gene transfer had been limited by

immune responses to viral and foreign transgene protein. In the present study, adeno-associated viruses (AAV) were chosen as the gene transfer vector because AAV featured versatility in the host range, long-term gene transfer potential, and minimum immune response. Recombinant adeno-associated viruses (rAAV) of rAAV-asPLB and rAAV-LacZ were constructed by AAV Helper-Free system, and the effect on expression of PLB in cultured rat cardiomyocytes was analyzed. This was to make arrangements for future PLB gene therapy in animal models.

Materials and methods

Plasmids and reagents The AAV Helper-Free System was obtained from Stratagene. The system includes: pAAV-MCS containing inverted terminal repeat (ITR) of adeno-associated virus, multiple clone site (MCS), and cytomegalovirus enhance/promotor and SV 40 poly-adenylation; pAAV-RC containing AAV replication and capsid genes; pHelper contains adenovirus-derived genes (i.e. E2A, E4, and VA RNA gene); pAAV-LacZ containing ITR and report gene *lacZ*. AAV-293 cells and XL10-Gold ultracompetent *E coli* cells, were also obtained from Stratagene, too. Restriction enzymes were obtained from Promega. Mouse monoclonal antibody and IgG were from ABR. Fluo 3-AM was from Molecular Probes, Eugene, OR, USA.

Cloning of rat PLB cDNA and construction of PLB antisense RNA plasmid vector (pAAV-asPLB) Rat PLB cDNA fragment (695 bp) was synthesized by reverse transcription-polymerase chain reaction (RT-PCR) from total RNA isolated from the heart of Wistar rats. The primers used for PCR contained a *Bam*HI (5') and *Eco*R I (3') linker (in lower-case letters): 5'-cgggatccCGCAGCTGAGCTGAGCTCCAGACTTCA-3', and 5'-cggaattcTTTAAATTTCA-TTTATTTCCCAA-3'. PCR was carried out as follows: 94 °C for 5 min followed by 30 cycles at 94 °C for 30 s, 55 °C for 60 s, and 72 °C for 60 s, followed by the final step at 72 °C for 10 min.

The synthesized PLB cDNA was subsequently digested by *Bam*H I and *Eco*R I simultaneously, while the adeno-associated virus plasmid pAAV-MCS digested by corresponding restricted endonuclease enzyme. The ligation reaction was conducted with DNA ligase at 4 °C for 16 h. The pAAV-asPLB was generated by cloning the PLB cDNA into *Eco*R I/*Bam*H I sites of pAAV-MCS reversed orientation relative to the promoter. Identification of the gene was confirmed by restriction enzymes digestion and sequencing.

Construction of recombinant adeno-associated virus To construct the rAAV, AAV-293 cells were co-transfected

with three AAV Helper-Free System plasmids: an ITR-containing plasmid (pAAV-asPLB or pAAV-LacZ), pAAV-RC, and pHelper. AAV-293 cells maintained in DMEM medium supplemented with 10% fetal calf serum, in a 37 °C incubator at 5% CO₂. When 293 cells reached 70%–80% confluence in 100-mm culture plate, the concentration of each plasmid was adjusted to 1 g/L in TE buffer, pH 7.5. The three plasmids (10 μL of each) and CaCl₂/HBS were mixed gently, and the mixture were co-transfected into 293 cells immediately. After 6 h, the medium was replaced with 10 mL of fresh DMEM medium, and 293 cells were cultured for an additional 66–72 h.

To monitor the progress of AAV particle production, 293 cells were divided into four groups according to the difference of mixture: (1) AAV-asPLB group: pAAV-asPLB, pAAV-RC, pHelper, and CaCl₂/HBS; (2) AAV-LacZ group: pAAV-LacZ, pAAV-RC, pHelper, and CaCl₂/HBS, which served as a positive control; (3) pAAV-RC, pHelper, and CaCl₂/HBS, which served as a negative control; (4) only CaCl₂/HBS served as a blank control.

The 293 transfected cells were subject to four rounds of freeze/thaw and centrifugation at 10 000×g for 10 min. The supernatant (primary rAAV) was purified by CsCl gradient centrifugation. rAAV was verified by PCR. The genome titer and infectious titer of rAAV were measured by PCR and in site β-galactosidase staining according to instruction [8,9].

Rat cardiomyocytes culture and infection Rat neonatal cardiomyocytes were isolated, cultured conventionally, and infected with the rAAV at a multiplicity of infection (MOI) of 100 for 48 h^[10]. Cardiomyocytes were divided into three groups: (1) infected with rAAV-asPLB; (2) infected with rAAV-LacZ; (3) normal control.

X-gal staining to detect the infection efficiency Cardiomyocytes were fixed with glutaraldehyde-formaldehyde solution for 10 min at room temperature, stained overnight with staining solution that contains X-gal. In infected cells, β-galactosidase cleaves X-gal to produce a blue stain. The infection efficiency was the percentage of stained cells in the total population.

Semi-quantitative RT-PCR analysis of PLB and SERCA gene expression Total cellular RNA was isolated from cells using TRIzol. Semiquantitative RT-PCR was performed to analyse PLB and SERCA gene expression. β-actin (332 bp) served as endogenous control. The primers of β-actin used for PCR were: 5'-GAGACCTTCAACACC-CCAGCC-3', and 5'-GGCCATCTCTTGCTCGAAGTC-3'. The primers of PLB gene were described in previous text. The primers of SERCA (134 bp) gene were: 5'-AAGCAGT-

TCATCCGCTACCT-3', and 5'-AGACCATCCGTCACCA-GATT-3'. PCR products were resolved on a 2% agarose gel and the bands could be seen using ethidium bromide staining. Each band was analyzed on Kodak Digital Science Image Analysis System. The gene expression level was determined semi-quantitatively by calculating the ratio of density metric value from the PLB gene in relation to internal standards.

Western blot analysis of PLB and SERCA protein expression Cells were lysed in lysis solution at 4 °C. The concentration of the protein in each lysate was determined with Coomassie Brilliant Blue G-250. Protein was fractionated on sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and transferred onto nitrocellulose membranes. The membrane was incubated with monoclonal antibody (1:1000) and IgG (1:500). The immune complexes were visualized by the ECL chemiluminescence method. Each protein band was analyzed on Kodak Digital Science Image Analysis System. The protein expression level was determined by calculating the ratio of density metric value from rAAV infected group in relation to normal control.

SERCA activity The activity of SERCA was determined following the methods of Larsen^[11]. Assays for complete quantification of Ca²⁺-ATPase in homogenates of rat ventricular myocardium by determination of Ca²⁺-dependent *p*-nitrophenyl phosphatase (pNPPase) activities were evaluated and optimized.

Measurement of [Ca²⁺]_i^[12] After Fluo 3-AM (5 μmol/L) loading, the coverslip was mounted in the cell chamber with 200 μL Hanks' solution. The fluorescence intensity (FI) was detected by confocal microscope (Leica, Mannheim, Germany) and inverted microscope with 40×objective and 488 nm blue laser for excitation and 530 nm for emission at room temperature. Stimulating agent (isoproterenol, 50 μmol/L) 10 μL was added to the preparation and the data were stored in disk. The fluorescence signals were normalized as Δ*F*/*F*₀ (%), where *F*₀ was the resting fluorescence and Δ*F* was Ca²⁺ change relatively the resting fluorescence.

Statistical analysis Data were expressed as mean±SD and statistically compared by one-way ANOVA with Dunnett's test. *P*<0.05 was taken as statistically significant.

Results

Construction and infection efficiency of recombinant adeno-associated virus The results of pAAV-asPLB restriction enzymes digestion and sequencing demonstrated that the sequence and direction of PLB cDNA fragment (695 bp) were precise (Figure 1). The rAAV-asPLB and rAAV-LacZ were harvested in rAAV-asPLB group and rAAV-LacZ group,

Figure 1. Identification of the pAAV-asPLB by restriction enzymes digestion. Lane 1: pUC Mix Marker; Lane 2: PCR production of PLB cDNA fragment (695 bp); Lane 3: pAAV-asPLB digested by *EcoR* I and *Bam*H I; Lane 4: λDNA/*EcoR* I+*Hind*III Marker.

respectively. However, the negative control and blank control showed nothing. The genome titer and infectious titer of rAAV were 1×10¹⁵ particles/L and 3×10¹³ infectious units/L, respectively. Cardiomyocytes were infected with rAAV-LacZ and stained with X-gal, the percentage of blue stained cells is approximately 80% (Figure 2).

Figure 2. Infection efficiency of rAAV were detected by X-Gal staining (×200). A blue stain was produced in infected cardiomyocytes.

PLB mRNA expression in infected cardiomyocytes Total RNA was extracted from rAAV-asPLB infected cardiomyocytes, rAAV-LacZ infected cardiomyocytes, and normal control cardiomyocytes, respectively. The result of RT-PCR showed that the level of PLB mRNA expression was decreased in rAAV-asPLB infected cardiomyocytes compared with rAAV-LacZ infected cardiomyocytes and normal

control cardiomyocytes ($P<0.05$, Figure 3).

Figure 3. PLB mRNA expression in normal control, rAAV-LacZ infected, and rAAV-asPLB infected cardiomyocytes. β -Actin (332 bp) served as an endogenous control. Data from three independent experiments were expressed as % vs endogenous control. ^b $P<0.05$ vs normal control.

PLB protein expression in infected cardiomyocytes

The level of PLB protein expression was decreased in rAAV-asPLB infected cardiomyocytes compared with rAAV-LacZ infected cardiomyocytes and normal control cardiomyocytes ($P<0.05$, Figure 4).

Figure 4. Analysis of PLB protein expression in normal control, rAAV-LacZ infected, and rAAV-asPLB, infected cardiomyocytes. Data were expressed as % of control. $n=3$. Mean \pm SD. ^b $P<0.05$ vs control.

SERCA mRNA and protein expression and activity

The level of SERCA mRNA and protein expression was not changed in rAAV-asPLB infected cardiomyocytes. However, the PLB/SERCA ratio was decreased because of a decrease of PLB expression. While the activity of

SERCA was higher in rAAV-asPLB group than that in rAAV-LacZ group (2.04 ± 0.09 vs 1.83 ± 0.22 $\mu\text{mol}\cdot\text{g}^{-1}$ protein $\cdot\text{min}^{-1}$) and normal control (2.04 ± 0.09 vs 1.84 ± 0.03 $\mu\text{mol}\cdot\text{g}^{-1}$ protein $\cdot\text{min}^{-1}$) ($P<0.05$).

Effect of rAAV-asPLB on $[\text{Ca}^{2+}]_i$ Resting state, fluorescent intensity of $[\text{Ca}^{2+}]_i$ in rAAV-asPLB group (9.13 ± 0.80) was lower than that in rAAV-LacZ group (13.82 ± 0.80) and normal control (14.98 ± 1.08) ($P<0.05$). Isoproterenol induced $[\text{Ca}^{2+}]_i$ increase in cultured cardiomyocytes. The $\Delta F/F_0$ of $[\text{Ca}^{2+}]_i$ in rAAV-LacZ group and normal control was 354% and 324%, respectively. However, the level of $\Delta F/F_0$ in rAAV-asPLB group was 459%.

Discussion

Heart failure represents an enormous clinical challenge in need of effective therapeutic approaches. The possibility of gene therapy for heart failure merits considerations at this time because of improvements in vector technology, cardiac gene delivery, and most importantly, our understanding of the molecular pathogenesis of heart failure. PLB is an endogenous muscle-specific inhibitor of SERCA2, cardiac-specific disruption of PLB in mice results in a marked increase in myocardial contractility^[13]. In this study, PLB cDNA fragment was cloned and inserted inversely into pAAV-MCS, which constructed the plasmid vector of pAAV-asPLB.

Previous gene transfer approaches that used direct injection of plasmid DNA or replication-defective adenovirus vectors have been limited by low transduction frequencies and transient transgene expression due to immune response, respectively^[14]. In this study, adeno-associated virus (AAV) was chosen as the gene transfer vector. In traditional AAV recombinant systems, the requirement for wild-type adenovirus co-infection, the contamination of adenovirus and the regeneration of wild-type AAV are major problems. However, the AAV Helper-Free system allows the production of infective recombinant AAV-2 virus without the use of a helper virus. Most of the adenovirus gene products required for the production of infective AAV particles are supplied on the plasmid pHelper that is co-transfected into 293 cells.

We constructed the rAAV vectors containing target gene (*PLB*) and reporter gene (*lacZ*) with AAV Helper-Free system. The rAAV vectors were identified and measured by PCR and in site β -galactosidase staining. Cardiomyocytes was infected with rAV-LacZ and stained with X-gal. The result shows that the rAAV is able to infect the cardiomyocytes effectively.

The antisense RNA can bind to its target RNA (sense RNA) thereby controlling expression of the target gene. In comparison to the ribozyme technique, antisense RNA technique has the advantages of simple designing, strong specialty, easy operating, and being economic and time saving^[15]. In the present study, rat neonatal cardiomyocytes were cultured and infected by rAAV vectors. RT-PCR and Western blot results showed that the expression of PLB was decreased as compared with normal group and the rAAV-*LacZ* infected group. This indicated that the as *PLB* had partly blocked the transcription of PLB mRNA and inhibited the translation of PLB protein.

The PLB/SERCA ratio was decreased in rAAV-asPLB infected cardiomyocytes because the SERCA mRNA and protein expression had no change. While, the activity of SERCA was enhanced. Our results demonstrated that reducing *PLB* inhibition to SERCA enhanced the SERCA activity. Further study on $[Ca^{2+}]_i$ showed the concentration of resting $[Ca^{2+}]_i$ was decreased in rAAV-asPLB-infected cardiomyocytes. The $[Ca^{2+}]_i$ was elevated after isoproterenol was induced. However, a higher $[Ca^{2+}]_i$ was observed in rAAV-asPLB infected cardiomyocytes. These data suggested that asPLB enhanced the affinity of SERCA for Ca^{2+} and therefore improved diastolic/contractile function in rAAV-asPLB-infected cardiomyocytes.

Abstract

Aim: To investigate the effect of ginsenoside Rg1, an effective ingredient from ginsenoside, on 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced substantia nigra neuron lesion. **Methods:** C57-BL mice were given MPTP to prepare Parkinson disease mice model. Different doses of Rg1 (5, 10, and 20 mg·kg⁻¹·d⁻¹) or *N*-acetylcystein (NAC) (300 mg·kg⁻¹·d⁻¹) were given 3 d prior to MPTP in the pretreatment groups. Glutathione (GSH) level and total superoxide dismutase (T-SOD) activity in substantia nigra were determined by spectrophotometry. Nissl staining, tyrosine hydroxylase immunostaining, and TUNEL labeling were used to observe the damage and apoptosis of nigral neurons. Western blot analysis was used to detect the phospho-JNK and phospho-c-Jun levels in midbrain homogenates. **Results:** Pretreatments of C57-BL mice with different doses of Rg1 or NAC were found to protect against MPTP-induced substantia nigra neurons loss. Rg1 or NAC prevented GSH reduction and T-SOD activation in substantia nigra, and attenuated the phosphorylations of JNK and c-Jun following MPTP treatment. **Conclusion:** The antioxidant property of Rg1 along with the blocking of JNK signaling cascade might contribute to the neuroprotective effect of ginsenoside Rg1 against MPTP.

Introduction

The pathological hallmark of Parkinson disease (PD) is the loss of dopaminergic neurons in the substantia nigra (SN), which leads to the major clinical and pharmacological abnormalities that characterize the disease. Although the exact cause of neuronal loss is still unknown, current evidence points to the presence of ongoing oxidative stress and the generation of radical oxygen species (ROS) selectively in the pars compacta of substantia nigra (SNPC) of parkinsonian brains^[1, 2]. Human postmortem studies also suggested that oxidative damage to lipids, proteins, and DNA occurred in the SNPC of PD patients^[3–5]. The neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is metabolized in the brain by monoamine oxidase-B to its toxic metabolite, 1-methyl-4-phenylpyridinium ion (MPP⁺), which is then selectively taken up into the dopaminergic neurons. MPP⁺ exerts its toxic effect in the dopaminergic neurons by inhib-

iting mitochondrial NADH dehydrogenase (NADH-DH)^[6]. MPTP could induce PD-like symptoms in humans and primates and causes degeneration of dopaminergic neurons in several animal species. The MPTP animal model is the ideal PD model for studying the pathogenesis of the disease.

The c-Jun NH₂-terminal kinase (JNK) signaling cascade has been implicated as a mediator of MPTP-induced apoptotic neuronal death^[7, 8]. Oxidative stress is an important activator of the JNK signaling cascade. In differentiated PC12 cells and cultured sympathetic neurons, increases in oxidative stress induced by antisense inactivation of superoxide dismutase led to increased JNK activity^[9].

Current treatments of PD are symptomatic and lack neuroprotective effect. Antioxidants have been focused on as candidates for the future treatment of PD. Ginsenoside Rg1, one of the active ingredients of ginseng, has potential neurotrophic and neuroprotective effects^[10]. In our previous study, we found Rg1 could protect substantia nigra neu-

rons against MPTP-induced apoptosis^[11], and in a *in vitro* study we revealed that Rg1 could suppress intracellular oxidative stress to prevent PC12 cells from dopamine-induced apoptosis^[12]. The aim of the current study is to further investigate whether Rg1 could suppress oxidative stress and block the activation of the JNK signaling cascade, and therefore protects dopaminergic neurons from apoptosis in an MPTP animal model. One antioxidant *N*-acetylcystein, which has been proved to protect against MPTP-induced substantia nigra neurons loss^[13], was used as a positive contrast in this study.

Materials and methods

Animals and treatment Male C57-BL mice weighing 18-22 g were divided into six groups ($n=8$). MPTP (Sigma, St Louis, MO, USA) was dissolved in saline at concentrations of 4 g/L. Ginsenoside Rg1 (purity >98 %), obtained from the Department of Organic Chemistry of Norman Bethune Medical University (Changchun, Jilin, China), was also dissolved in saline at concentrations of 1 g/L. Model animals were injected subcutaneously with saline for 3 d, followed by injection (subcutaneously) of MPTP (30 mg·kg⁻¹·d⁻¹) for 5 consecutive days. Three preventive groups were injected (ip) with Rg1 (5 mg·kg⁻¹·d⁻¹, 10 mg·kg⁻¹·d⁻¹, 20 mg·kg⁻¹·d⁻¹). Positive contrast group was injected (sc) with NAC (Jingke, Beijing, China, 300.0 mg·kg⁻¹·d⁻¹) for 8 days, and from the fourth day both Rg1 preventive groups and the positive contrast group were received injection (sc) of MPTP (30 mg·kg⁻¹·d⁻¹, 2 h after Rg1 or NAC injection) for 5 consecutive days. The control group received saline only. The animals were killed 24 h after the last injection. The mice were anaesthetized with euthanal and perfused transcardially with ice-cold saline prior to decapitation. The midbrain containing the substantia nigra was dissected, and quickly frozen at -80 °C until ready for later analysis. For immunohistochemistry analysis, the midbrain was fixated in 4 % formal-dehydum polymerisatum-PB and imbedded in paraffin. Serial 5- μ m-thick sections were cut transversely from the middle of the midbrain.

Spectrophotometry Substantia nigra were homogenized with 0.01 mol/L Tris-HCl (pH 7.4) consisting of 0.01 mol/L sucrose and 0.1 mmol/L EDTA, followed by centrifugation at 4000×g for 15 min. The supernatant was saved and analyzed. The dithio-binitrobenzoic acid method and xanthine/xanthine oxidase method were used to test glutathione (GSH) level and total superoxide dismutase (T-SOD) activity. Reaction product was determined by spectrophotometry. Test Kits were purchased from Jian Cheng Bioengineering Insti-

tute (Nanjing, China).

TUNEL Deparaffinized and hydrated sections were incubated with proteinase K (20 mg/L in 10 mmol/L Tris/HCl, pH=7.4-8.0) for 30 min at 37 °C, then incubated with TdT reaction mixture and AP-conjugated anti-fluorescein antibody (TUNEL detection kit, BM, Germany) for 1 h at 37 °C. Finally sections were visualized with NBT-BCIP. The nuclei of positive cells were stained blue-black.

Nissl staining Paraffin sections were deparaffinized and hydrated, stained with methylene blue buffer for 10 min and then immersed into acetic acid buffer for 2 min.

Immunohistochemistry Paraffin sections were deparaffinized and hydrated, then incubated with a goat anti-mouse TH polyclonal antibody (1:40 dilution in 0.01 mmol/L phosphate buffer saline, pH 7.4) at 4 °C overnight. Slides were then incubated with a biotinylated rabbit anti-goat IgG and SABC-reagent (SABC kit, BOSTER, Wuhan, Hubei, China), respectively for 30 min at 37 °C. At last, sections were stained with diaminobenzidine (DAB). Hemotoxylin was used to counterstain nuclei for one minute.

Western blot analysis Substantia nigra was homogenized (50 g/L) in lysis buffer (10 mmol/L Tris, 50 mmol/L NaCl, 0.03 μ mol/L sodium pyrophosphate, 50 mmol/L sodium fluoride, and 1% Triton X-100) containing 1 mmol/L phenylmethylsulfonyl fluoride, 20 mg/L aprotinin, and 1 mmol/L sodium vanadate^[14]. After homogenization, samples were centrifuged at 15 000×g for 15 min. The supernatants were taken for further analysis. Protein concentration was determined by the Bradford method^[15]. Approximately 10 μ g of total protein was separated by 12% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and transferred to nitrocellulose membranes. The membranes were probed with polyclonal anti-p-JNK1/2 or anti-p-c-Jun rabbit antibody (Cell Signaling, Beverly, MA, USA). Immunoreactive bands were visualized by the addition of horseradish peroxidase-conjugated antibodies against rabbit Fab and chemiluminescent substrates (Pierce, Rockford, IL, USA), according to the manufacturer's instruction.

Image analysis The numbers of Nissl, TH, TUNEL-positive neurons in full microscopic fields of SN were counted with a digital medical image analysis system (Motic, Beijing, China). Three tissue sections per animal were counted for each index.

Data analysis Data were expressed as means±SEM. TUNEL-positive cells were calculated as: [TUNEL-positive cells/(TUNEL-positive cells+Nissl staining cells)]×100%. For statistical evaluation one-way analysis of variance (ANOVA) was employed. Student Newman Keuls test was performed when variance was equal, and Games-Howell test

was performed when variance was not equal. *Pearson* correlation analysis was also carried out to some indices. Statistical difference was considered to be significant only if $P < 0.05$.

Results

Effect of ginsenoside Rg1 on MPTP-induced apoptosis of substantia nigra neurons MPTP clearly had a detrimental effect on dopaminergic neurons. Treatment with MPTP decreased the numbers of TH-positive and Nissl-positive neurons and increased the percent of TUNEL-positive neurons in SN. Pretreatment with ginsenoside Rg1 or NAC significantly ameliorated the neuronal loss and apoptosis induced by MPTP ($P < 0.01$) (Figure 1–3). Rg1 at 10 mg/kg showed the best protective effect among all the doses but made no significant difference ($P > 0.05$) at 5 mg/kg and 20 mg/kg, which suggested that the effect of ginsenoside Rg1 might have an optimal dose range. There was no significant difference between NAC and Rg1 (10 mg/kg) treatment group.

Effect of ginsenoside Rg1 on GSH level and T-SOD activity in SN Decreased GSH level and increased T-SOD activity were detected in the substantia nigra of MPTP-treated mice. Both changes were attenuated by pre-administration with ginsenoside Rg1 or NAC (Table 1, $P < 0.01$). Better preventive effects were observed at doses of 10 and 20 mg/kg than at 5 mg/kg among Rg1 treated groups, but there was no significant difference among 10 mg/kg, 20 mg/kg of Rg1, and NAC (300.0 mg/kg). Correlation analysis showed a positive correlation between the positive neuron ratio of TH and the GSH level ($r = 0.885$, $P < 0.01$), and negative correlation between the positive neuron ratio of TH and the T-SOD activity ($r = -0.882$, $P < 0.01$). These results indicate that

enhanced oxidative stress was involved in the neurotoxicity of MPTP; and suitable doses of Rg1 could attenuate the oxidative stress induced by MPTP, while overdoses of Rg1 did not show better preventive effect.

Influence of MPTP-induced JNK and c-Jun phosphorylation by ginsenoside Rg1 MPTP treatment increased the levels of p46 and p54 phospho-JNK protein, as compared with the control. Preadministration of Rg1 or NAC partially attenuated the MPTP-mediated elevation in phospho-JNK and phospho-c-Jun levels in midbrain homogenates. A 10 mg/kg dose of Rg1 showed the greatest inhibition as did NAC, but the weak inhibition was observed at the dose of 20 mg/kg. These results suggested that Rg1 attenuated MPTP-induced phosphorylation of JNK and c-Jun, but a higher dosage was detrimental.

Discussion

Ginseng has been used in traditional Chinese medicine to enhance stamina and capacity to deal with fatigue and physical stress for thousands of years. Ginsenoside Rg1 is one of the active ingredients of ginseng. Previous *in vitro* studies showed that Rg1 could save cell from oxidative stress induced-apoptosis^[16]. In the current study, we observed that TH-positive neurons loss in SN caused by MPTP could be attenuated by Rg1 or NAC pretreatment; the result showed the neuronal protective effect of ginsenoside Rg1 against MPTP. Our study also revealed the neuroprotective mechanisms of Rg1 in preventing MPTP-induced loss of dopaminergic neurons in SN. The neurotoxin of MPTP is dependent on the inhibition of Complex I in the mitochondrial respiratory chain by MPP^+ , subsequently followed by ATP depletion and increased production of ROS^[17], eventually leads to the cell death. As one of the most important antioxidant molecule, GSH could clear H_2O_2 and prevent its reaction with iron to form the highly reactive OH radical in the Fenton reaction. Following MPTP treatment, GSH was consumed and its level dropped^[18,19]. We also observed the activity of T-SOD (including Cu/Zn-SOD and Mn-SOD), another important radical scavenger, was elevated in SN of MPTP treated mice; this change corresponded with those observed in PD patients^[20–22]. NAC is a free radical oxygen scavenger. Furthermore, it can be converted into cysteine after entering cells, and is an important substrate for GSH production. In our current study, pretreatment with NAC could attenuate the loss of GSH and the increased activity of T-SOD following MPTP treatment, same changes were observed among Rg1 pretreatment groups. We found that the antioxidative effect of Rg1 had an optimal dose of 10 mg/kg, this dosage

of Rg1 showed the similar effect as NAC, but there was no improvement beyond this dose. The results demonstrated that Rg1 possessed the same antioxidant property as NAC.

There has been no direct evidence indicating that Rg1 could scavenge radical by itself, therefore we tried to investigate whether Rg1 act as an antioxidant through mediator. In our previous study, we found the protective effect of Rg1 against MPTP-induced nigral neurons apoptosis was related to enhancing Bcl-2 expression and reducing iNOS expression^[11]. Bcl-2 is an anti-apoptotic protein located in the outer mitochondrial membrane, nuclear membrane and endoplasmic reticulum membrane. Bcl-2 participates in the regulation of cell death through multiple mechanisms, one of which

regulates the steady state of cellular ROS levels. This can be achieved either by modulating their production, usually by the mitochondria, or by affecting the antioxidant capacity of the cells. *In vitro* and *in vivo* studies provided evidences that Bcl-2 could attenuate cell injuries caused by oxidative stress. Bcl-2 could protect against the increased level of ROS caused by dopamine metabolism in PC12 cells^[23]. Transfection with Bcl-2 provided the PC12 cells with marked protection against dopamine-induced apoptosis and inhibited dopamine oxidation to dopamine-melanin^[24]. Further studies demonstrated enhanced oxidative stress and susceptibility to oxidants in the brains of Bcl-2-deficient mice^[25]. Our previous study showed that Rg1 could prevent

Figure 2. Number of Nissl (black) and TH (white) staining-positive neurons in SN. Pretreatment with Rg1 significantly increased the number of survival neurons and TH-positive neurons, as determined by one-way ANOVA. A 10 mg/kg dose of Rg1 showed the best protective effect among all the doses, and showed no significant difference with NAC. $n=8$. Mean \pm SEM. $^{\circ}P<0.01$ vs the model group.

Figure 3. Percentage of TUNEL-positive neuron numbers in SN. The percentage of TUNEL-positive neurons in the model group increased significantly compared with other groups. Pretreatment with Rg1 significantly decreased the percentage of TUNEL-positive neurons. A 10 mg/kg dose of Rg1 showed the best preventive effect of all the doses, and showed no significant difference with NAC. $n=8$. Mean \pm SEM. $^{\circ}P<0.01$ vs the model group.

Figure 4. Western blot detection of phospho-JNK and phospho-c-Jun levels respectively. The histogram showed the comparisons of OD odds among different groups. 1: NAC; 2: model; 3: control; 4: 5 mg/kg Rg1+MPTP; 5: 10 mg/kg Rg1+MPTP; 6: 20 mg/kg Rg1+MPTP. $n=3$. Mean \pm SEM. $^{\circ}P<0.01$ vs the MPTP group.

the decrease of Bcl-2-positive cell numbers following MPTP treatment, so this might contribute to the antioxidant property of Rg1.

Another important protein involved in oxidative stress is nitric oxide synthase (NOS), of which three isoforms have been described: neuronal NOS (nNOS) and endothelial NOS

are calcium-calmodulin-dependent enzymes, while inducible NOS (iNOS) activity is independent of intracellular calcium levels. Nitric oxide (NO), an important free radical generated by NOS, can react with superoxide radicals to form the oxidizing agents peroxynitrite (ONOO $^{-}$) and OH $^{-}$ [26], and eventually induce DNA strand breakage and apoptosis [27].

Numerous experimental studies have shown that iNOS play an important role in MPTP-induced dopaminergic neuron injury or in PD patients^[28,29], it is in agreement with our previous observation that MPTP increased the numbers of iNOS-positive cells. Therefore, changes of Bcl-2 and iNOS expressions could play important roles in the antioxidative effect of Rg1, this could explain the antioxidant property of Rg1. However, the exact pathway leading to the changes of Bcl-2 and iNOS expression in SN is still unclear.

The JNK signaling cascade is a main pathway that mediates the neurotoxicity of MPTP^[14], CEP-1347/KT-7515, an inhibitor of JNK activation, can attenuate MPTP-induced nigrostriatal dopaminergic degeneration^[7]. Transgenic mice expressing the JNK binding domain (JBD) of JNK interacting protein 1 could resist the neurotoxicity of MPTP^[8]. Oxidative stress is an important activator of the JNK signaling cascade. In differentiated PC12 cells and cultured sympathetic neurons, oxidative stress induced by antisense inactivation of superoxide dismutase increased JNK activity^[9]. In our previous study, we observed that JNK pathway was activated after the exposure of SHSY5Y cells to the mitochondrial complex I inhibitor MPP⁺, Rg1 could attenuate the elevation of ROS and reduce the JNK activation after MPP⁺ treatment^[30]. In the present *in vivo* study, we also found that pretreatment with Rg1 or NAC could attenuate the elevated phosphorylation of JNK and c-Jun induced by MPTP in SN. The dose of 10 mg/kg of Rg1 showed better effect than dose of 5 mg/kg and 20 mg/kg. There was no significant difference between NAC and 10 mg/kg Rg1, but it is a puzzle why 20 mg/kg Rg1 had weaker inhibition than 10 mg/kg Rg1. The toxicity of higher doses of Rg1 could compromise its ability as a radical scavenger. However, this change is associated with the loss of dopaminergic neurons at different Rg1 doses. This results confirms previous studies that JNK signaling cascade play an important role in dopaminergic neuron apoptosis induced by MPTP, and appropriate dose of Rg1 could attenuate the MPTP induced activation of JNK signaling cascade. It requires further study to find out whether Rg1 influences JNK pathway through mechanisms other than antioxidation.

In conclusion, the present study indicates that pretreatment with certain doses of Rg1 could reduce the loss of dopaminergic neurons caused by MPTP in SN. The neuroprotective effects of Rg1 are potentially due to its antioxidant property that involves Bcl-2 and iNOS, and its inhibitory effect on JNK signaling cascade activation. Further studies will be carried out to evaluate whether ginsenoside Rg1, an important ingredient of ginsenoside, could benefit as a future preventive and therapeutic drug of PD.

Abstract

Aim: To investigate neuropeptide Y (NPY) expression in mouse hippocampus within early stages of kainic acid (KA) treatment and to understand its role in neuronal excitotoxicity. **Methods:** NPY expression in the hippocampus within early stages of KA intraperitoneal (ip) treatment was detected by immunohistochemistry (IHC) and *in situ* hybridization (ISH) methods. The role of NPY and Y5, Y2 receptors in excitotoxicity was analyzed by terminal deoxynucleotidyl transferase-mediated UTP nick end-labeling (TUNEL) assay. **Results:** Using IHC assay, in granule cell layer of the dentate gyrus (DG), NPY positive signals appeared 4 h after KA injection, reached the peak at 8 h and leveled off at 16 and 24 h. In CA3, no positive signal was found within the first 4 h after KA injection, but strong signal appeared at 16 and 24 h. No noticeable signal was detected in CA1 at all time points after KA injection. Using the ISH method, positive signals were detected at 4, 8, and 16 h in CA3, CA1, and hilus. In DG, much stronger ISH signals were detected at 4 h, but leveled off at 8 and 16 h. TUNEL analysis showed that intracerebroventricularly (icv) infusion of NPY and Y5, Y2 receptor agonists within 8 h after KA insult with proper dose could remarkably rescue pyramidal neurons in CA3 and CA1 from apoptosis. **Conclusion:** NPY is an important anti-epileptic agent. The preceding elevated expression of NPY in granule cell layer of DG after KA injection might partially explain its different excitotoxicity-induced apoptotic responses in comparison with the pyramidal neurons from CA3 and CA1 regions. NPY can not only reduce neuronal excitability but also prevent excitotoxicity-induced neuronal apoptosis in a time- and dose-related way by activation of Y5 and Y2 receptors.

Introduction

Excitotoxicity is a process by which glutamate or other excitatory amino acids induce neuronal cell death in the central nervous system^[1,2]. It is thought that excitotoxicity might contribute to the pathogenesis of human neuronal cell loss by sustained epilepsy, trauma, ischemia, and hypoglycemia, and might also underlie certain neurodegenerative diseases^[3–5]. Excessive stimulation of the three types of ionotropic glutamate receptors, including the *N*-methyl-*D*-aspartate (NMDA), α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and KA receptors, produces neuronal cell death by increasing intracellular Ca²⁺ and Na⁺, and therefore

drastically changing normal cellular physiology^[1,2].

KA is an analog for glutamate and is also an excitotoxin in the hippocampus^[6–8] that induces ongoing convulsions by directly stimulating KA receptors and indirectly increasing the release of excitatory amino acids from nerve terminals, degeneration of *cornu ammonis* (CA) pyramidal neurons in the hippocampus, and hyper-excitability of surviving CA neurons^[9–11]. Thus, KA-induced seizures have been widely used as an epilepsy model for studying mechanisms underlying both seizure susceptibility and neuronal cell loss^[12–14].

Increasing evidence suggests that NPY is a powerful endogenous anticonvulsant in the hippocampus^[12,15–17]. NPY knockout mice exhibit uncontrollable seizures and enhanced

fatality in response to KA administration^[12]. Moreover, intracerebroventricular infusion of NPY reduces epileptiform after discharges and inhibits KA-induced seizures^[18]. The possible mechanism for the anticonvulsant properties of NPY is the inhibition of calcium influx and glutamate release^[12,15,17]. However, the exact role of NPY *in vivo* in excitotoxicity is unknown. Although excitotoxicity induced an ongoing neuronal apoptosis, it was mainly determined at early stages after excitatory amino acids treatment^[7,8,14]. Thus, to investigate the sequential and spatial expression of NPY in the hippocampus within early stage of KA injection, and to understand its role in excitotoxicity, could be of unique importance.

Materials and methods

Animals and drugs Mice of 8 to 9 weeks age were used for analysis. All mice were housed with food and water *ad libitum* in a 12-h light cycle room. Our protocol was approved by the Institutional Animal Care and Use Committee of Xi'an Jiaotong University, and we strictly followed NIH guidelines for the care and use of laboratory animals. All efforts were taken to minimize both animal suffering and the number of mice used. KA (Sigma Chemical, St Louis, MO, USA) was dissolved in ddH₂O, neutralized by NaOH and injected (ip) in a dose of 20 mg/kg of body weight to the mice. Human NPY, NPY13-36 (Y2 agonist), or human pancreatic polypeptide (hPP) (Y5 agonist) were purchased from Bachem (Torrance, CA, USA).

IHC analysis of NPY expression At 0 (normal control treated with saline), 2, 4, 8, 16, or 24 h (8 each group) after KA injection, surviving mice were deeply anesthetized with sodium pentobarbital (60 mg/kg of body weight, ip), and then transcardially perfused with phosphate buffered saline (PBS), pH 7.4, and 4% paraformaldehyde in PBS for 15 min. After perfusion, their brains were removed, postfixed overnight with 4% paraformaldehyde in PBS at 4 °C, submerged in 20% sucrose at 4 °C for 48 h, and then sections were cut coronally at 40 μm to encompass the entire hippocampus using a freezing microtome. Every eighth of serial coronary brain sections through the rostral-caudal extent of the hippocampus in 40-μm thickness were selected for immunohistochemistry (IHC) detection of NPY expression in the hippocampus using rabbit anti-NPY antibody (1:1,000, Chemicon, CA, USA) as previously described^[14,19].

Probe preparation for *in situ* hybridization (ISH) analysis The plasmid construct pT7T3D-Pac, containing 561 bp mouse NPY gene, was from the University of Cincinnati Microarray Center. The construct was first linearized by *EcoR* I or *Hind* III respectively. The *EcoR* I linear-

ized template containing T3 promoter was used for anti-sense probe transcription. The *Hind* III linearized template containing T7 promoter was used for sense probe transcription (negative control). Transcription reaction mixture 20 μL in a RNase free eppendorf tube [4 μL 5×transcription buffer (Promega, USA), 1 μL linearized DNA (1 μg), 2 μL NTP mix (Dig-UTP) (Roche, Germany), 2 μL 0.1 mol/L DTT, 9 μL H₂O, 1 μL RNase inhibitor (Invitrogen, USA), 1 μL RNA polymerase (T3 or T7) (Promega, USA)] was incubated at 37 °C for 2 h, then 2U DNase I (RNase free) (Promega) was added, incubated at 37 °C for 15 min to digest DNA template. Reaction was stopped with 2 μL of 0.2 mol/L EDTA, pH 8.0. Then 2.5 μL LiCl 4 mol/L and 75 μL prechilled (-20 °C) 100% EtOH was added and mixed well. It was placed at -20 °C for 2 h and centrifuged at 2–8 °C, 44 500×g, for 15 min. The supernatant was discarded carefully. Samples were dried under a vacuum and then dissolved for 30 min at 37 °C in 100 μL diethyl-pyrocabonate (DEPC) H₂O. RNA probe was quantified by spectrophotometric analysis (OD_{260}/OD_{280}) and stored at -80 °C, or stored in aliquots at -20 °C.

ISH detection of NPY expression For ISH analysis, 0 (normal control), 4, 8, or 16 h (8 each group) after KA injection, mice were killed by cervical dislocation, brains were removed quickly and kept in dry ice powder for 5 min and then stored at -80 °C for at least 48 h before sectioning. Brain sections of 12 μm, containing hippocampal formation, were cut and placed on Superfrost Plus slides (pretreated with 0.1% DEPC H₂O for 2 h at 37 °C) and air dried at room temperature for 30 min and then stored at -80 °C before use. Every fifteenth of serial coronary brain sections through the rostral-caudal extent of the hippocampus were analyzed by ISH as described previously^[20].

Cannula implantation and infusion of NPY and its agonists Mice were anesthetized with an injection of Equithesin (34 mg/kg of body weight, ip) and atropine (0.35 mg/kg of bodyweight, ip). Animals were placed in a stereotactic device (Kopf Instruments), and cannulas were implanted into the lateral ventricle (0.6 mm posterior; 1.9 mm lateral; and 2.0 mm ventral to bregma). Mice were allowed to recover from surgery for 2 d. First, to determine the timing of NPY infusion after KA injection, icv injection of human NPY (5.0 μg in 1 μL of neutral buffered solution) or saline was performed 2, 8, or 24 h after KA injection (8 to 10 each group) using an infusion pump (KD Scientific) at a constant rate of 1 μL/min as described^[12]. Then, to determine the dose of NPY infusion, 8 h after KA injection, the effect of icv infusion of NPY at a dose of 2.5, 5.0, and 10.0 μg was compared. Finally, to investigate the receptors that mediate its role in excitotoxicity, icv infusion of 3.0 μg

NPY13-36 or 5.0 μ g hPP was carried out 8 h after KA injection. The dose of NPY and its agonists were based on previous studies^[12,16]. Cannula placement was verified *post-hoc* in all animals by injection of 1% cresyl violet solution before brain dissection. Three days after KA injection, brain sections were made as IHC assay above for TUNEL staining.

TUNEL assays Every eighth of serial coronary brain sections through the rostral-caudal extent of the hippocampus in 40- μ m thickness were used for TUNEL staining using the *in situ* Cell Death Detection Kit (TUNEL POD) (Roche Applied Science, Germany) as described^[14].

Statistical analysis IHC and ISH signal is in every of sub-region of each section was obtained with densitometric scanning, and data were analyzed by one-way ANOVA. All TUNEL positive cells in every sub-region of each section were counted regardless of sizes and shapes. The mean number of cells per section was used for comparison. Data were analyzed by one-way ANOVA and *post-hoc* Student-Newman-Keuls (SNK) test. Statistical significance was set as $P < 0.05$.

Results

NPY expression in the hippocampus by IHC method

In the granule cell layer of DG, no NPY positive cell was detected at basal condition (0 h) and 2 h after KA injection (Figure 1A, 1B). NPY positive cells appeared at 4 h (Figure 1C), reached the peak at 8 h (Figure 1D), and were reduced remarkably at 16 and 24 h (Figure 1E, 1F). In the CA3 sub-region, no positive signal was found within the first 4 h after KA injection (Figure 1A, 1C), NPY positive signals appeared at 8 h (Figure 1D), strong signals appeared at 16 and 24 h (Figure 1E, 1F). No noticeable signal was detected in the CA1 sub-region at all time points within the first 24 h after KA injection. In the hilus, NPY positive signals were noticeably intensified at 8 h (Figure 1D), and reached the peak at 16 and 24 h (Figure 1E, 1F). One-way ANOVA results showed a significant time-dependent effect ($P < 0.05$) in both DG and CA3 regions (Figure 2).

NPY expression in the hippocampus by ISH analysis

Under physiological condition, NPY expression in the granule cell layer of DG, CA3, and CA1 was less noticeable (Figure 3A). Positive ISH signals were detected in DG, CA3, and CA1 sub-regions at each time point after KA treatment (Figure 3B–3D). Four hours after KA injection, ISH signals in the DG sub-region were stronger than those in CA3 and CA1 (Figure 3B). Eight and sixteen hours after KA injection, ISH signals were significantly reduced in DG sub-region but remarkably elevated in CA3, CA1, and hilus sub-regions (Figure 3C, 3D, $P < 0.05$). One-way ANOVA result showed

Figure 1. Expression of NPY in the hippocampus by IHC method. In the granule cell layer of DG region, no positive signals were detected at 0 (control) and 2 h (A, B), positive signals appeared at 4 h (C), reached the peak at 8 h (D), were remarkably reduced at 16 and 24 h (E, F). In CA3 regions, no positive signals were detected at 0, 2, and 4 h (A–C), positive signal appeared at 8 h (D), reached the maximum at 16 h (E), and became less stronger at 24 h (F). No obvious signal was detected at all time points in CA1. Arrow denotes positive signal. Scale bar: 100 μ m. $\times 40$.

Figure 2. Quantitative analysis of NPY expression from IHC results. NPY expression in the hippocampus was detected by IHC and followed by analysis with densitometric scanning. Data represent the ratio of mean signal density relative to background \pm SEM. NPY expression was in a time-dependent manner in DG and CA3 regions ($P < 0.05$).

a significant time-dependent effect ($P < 0.05$) in all regions (Figure 4).

Figure 3. ISH analysis of NPY expression in the hippocampus. Weak signal was detected under physiological condition (A). Positive signals were elevated in DG, CA3, and CA1 4 h after KA injection (B), but signals in DG were much stronger than that in other regions. At 8 and 16 h (C, D), NPY positive signals in DG were remarkably leveled off, but in CA3 and CA1, signals were more intensified in comparison with the 4 h-group. Scale bar: 100 μ m. $\times 40$.

Figure 4. Quantitative analysis of NPY expression from ISH results. NPY expression in the hippocampus was detected by ISH and followed by analysis with densitometric scanning. Data represent the ratio of mean signal density relative to background \pm SEM. NPY expression was time-dependent in DG, CA3, and CA1 regions ($P<0.05$).

NPY prevents neuronal cells from apoptosis in a time- and dose-related manner In CA3 and CA1, less massive apoptotic pyramidal cells were detected in mice with NPY infusion at 2 and 8 h after KA treatment (Figure 5A-5D) compared with control mice (Figure 5G, H). Similar TUNEL signals were detected in CA3 and CA1 between mice infused with NPY at 24 h after KA injection and control mice (Figure 5E-H). One-way ANOVA showed significant time-dependent effects in both CA3 and CA1 ($P<0.05$, Figure

Figure 5. NPY prevents neuronal cells from excitotoxic-induced apoptosis in a time related manner. In CA3 and CA1, less massive apoptotic pyramidal cells were detected in NPY treated mice at 2 and 8 h after KA injection (A, C, and B, D) than in control mice (G, H). But NPY infusion at 24 h after KA treatment (E, F) had no noticeable effect in comparison with control mice (G, H). Scale bar: 100 μ m. $\times 200$.

6A). *Post hoc* SNK test showed a more noticeable effect at 2 h than that at 8 h of NPY infusion ($P<0.05$) though they both significantly reduced apoptosis in comparison with control mice ($P<0.05$) (Figure 6A). Figure 6B shows the quantitative results of TUNEL staining in CA3 and CA1 sub-regions 3 d after KA treatment with icv infusions of 2.5, 5.0, or 10.0 μ g human NPY or saline (8 to 10 mice each group) at 8 h after KA injection. One-way ANOVA showed significant dose-dependent effect in both CA3 and CA1 among

Figure 6. Quantitative analysis of neuronal apoptosis from TUNEL results. (A) The time-related effect of NPY on neuronal apoptosis. (B) The dose-related effect of NPY on neuronal apoptosis. A significant anti-apoptotic effect with infusion of 10.0 and 5.0 μg NPY at 8 h after KA injection was shown ($P<0.05$). (C) Neuronal protective role of Y5 and Y2 receptors. Y5 and Y2 agonists could both prevent neuronal cells from death in comparison with control ($P<0.05$), but there was no additive effect between them ($P>0.05$). Data represent means±SEM/each section. ^b $P<0.05$ vs control. ^h $P<0.05$ vs 8 h.

four groups ($P<0.05$). *Post hoc* SNK test showed a significant effect with infusion of 10.0 and 5.0 μg NPY at 8 h in comparison with control ($P<0.05$).

NPY prevents neuronal cells from apoptosis by activating both Y5 and Y2 receptors Y5 and Y2 agonists icv could both prevent neuronal cells from death 8 h after KA

injection, but there was no additive effect between them. One-way ANOVA showed significant effects in both CA3 and CA1 ($P<0.05$). *Post hoc* SNK test showed no significant difference among Y5, Y2, and Y5/Y2 agonists treated three groups, but significant difference was detected between these three groups and control mice, respectively (Figure 6C, $P<0.05$).

Discussion

Increasing evidence suggests that NPY is a powerful endogenous anticonvulsant in the hippocampus^[12,15-17]. Its expression can be elevated by experimentally induced seizures initiated by electrical kindling, kainic acid, and pentylenetetrazol^[21-25]. Excitotoxicity induced an ongoing neuronal apoptosis, which was mainly determined at early stage after excitatory amino acid treatment^[7,8,14]. According to these findings, we for the first time focused on NPY expression pattern in the hippocampus within early stages after KA injection using both IHC and ISH methods, and tried to understand its implication in excitotoxicity. From our IHC and ISH results (Figure 1-4), we concluded that NPY expression in the granule cell layer of DG sub-region was prior to CA3 and CA1 after KA-treatment, seizure-induced increase of NPY in the hippocampus was the result of transcriptional activation, and might be a compensatory mechanism to reduce excitatory neurotransmission. ICV infusion of NPY and its Y5, Y2 receptor agonists at 2 and 8 h after KA insult could rescue pyramidal neurons in CA3 and CA1 regions from apoptosis (Figure 3-6). It is also well established that the pyramidal cells in CA3 and CA1 are more susceptible to KA-induced apoptosis than the granule cells in DG^[7,8,14]. Taken together, we presume that the preceded elevation of NPY expression in the granule cell layer of DG after KA injection might partially explain its different excitotoxicity-induced apoptotic responses in comparison with the pyramidal neurons from CA3 and CA1 regions.

Activation of NPY receptors is neuroprotective against excitotoxicity in rat hippocampal slice cultures^[26]. For dentate granule cells and CA3 pyramidal cells, selective activation of Y1, Y2, or Y5 receptors, respectively had a neuroprotective effect against AMPA and KA, whereas only the activation of Y2 receptors was effective for CA1 pyramidal cells in the rat. Some physiological and pharmacological work showed intracerebroventricular administration of NPY reduced epileptiform afterdischarges and inhibited KA-induced seizures in rats; and Y5 and/or Y2 receptors were responsible for modulation of seizure activity in mouse hippocampal slices^[18,27]. But, to date, whether NPY can pre-

vent neuronal cells from excitotoxicity-induced apoptosis *in vivo*, what receptors are responsible for this function, what is the effective time and dose of NPY and its agonists infusion, are not known. We found icv infusion of NPY and its Y5, Y2 agonists within 8 h of a proper dose, after excitatory amino acid injection, could rescue neuronal cells from apoptosis in mice (Figure 5, 6). These data are quite useful for the potential clinical application of NPY in anti-epilepsy. The protective signal transduction pathway of its different receptors should be included in our future research.

With IHC detection, NPY positive or negative signal does not mean that NPY is synthesized or is not synthesized. As a neurotransmitter^[28], NPY can be released from one cell where it is synthesized and be taken up by other cells through synaptic formation. Comparing the IHC result (Figure 1) with the ISH result (Figure 3), we found although NPY mRNA transcripts were synthesized in all regions of the hippocampus at 4, 8, and 16 h after KA treatment, no noticeable signals were detected in the CA1 region by IHC assay at any point. Probably, NPY in this region was transmitted to other places as a neurotransmitter after translation. Or the sensitivity of IHC is not high enough to detect NPY expression in this region.

In conclusion, the preceding elevated expression of NPY in granule cell layer of DG after KA injection may explain partially its different excitotoxicity-induced apoptotic responses in comparison with the pyramidal neurons from CA3 and CA1 regions. NPY can not only reduce neuronal excitability but also prevent excitotoxicity-induced neuronal apoptosis by activation of Y5 and Y2 receptors.

Abstract

Aim: The alterations of the binding sites for ATP-sensitive K⁺ channel (K_{ATP}) openers and blockers in aortic strips were investigated in hypertensive rats. **Methods:** Radioligand binding techniques were used to compare the specific binding properties of [³H]P1075 and [³H]glibenclamide (Gli) in normotensive (NWR) and reno-vascular hypertensive rat (RVHR) aortic strips. **Results:** The K_D values of [³H]P1075 binding were increased by 1.5-fold, while the B_{max} values were unchanged in RVHR. The IC₅₀ values of P1075 and pinacidil (Pin) for displacing the [³H]P1075 binding in RVHR were increased by 1.8- and 1.7-fold, respectively. The kinetic processes of association and dissociation of [³H]P1075 binding were slower in RVHR. Glibenclamide pretreatment slowed down the kinetic processes of the association and dissociation of [³H]P1075 binding in NWR, but failed to alter the kinetic processes of [³H]P1075 binding in RVHR. The IC₅₀ values of Gli for displacing the [³H]Gli binding at high-affinity sites were increased by 3-fold, while those at low-affinity sites remained to be unchanged in RVHR. The kinetic processes of association of [³H]Gli binding were decreased and those of the dissociation were accelerated in RVHR. The treatment with Pin slowed down the association kinetic processes but accelerated the process of the dissociation of [³H]Gli binding in NWR, but did not alter the kinetics of [³H]Gli binding in RVHR. **Conclusion:** The affinity of binding sites for [³H]P1075 and of high-affinity binding sites for [³H]Gli are decreased, and the negative allosteric interactions between the two binding sites are impaired in RVHR aorta.

Introduction

ATP-sensitive K⁺ channels (K_{ATP}) have been identified in multiple cells^[1,2]. In vascular smooth muscles, K_{ATP} can regulate vascular tone^[3]. The functions of vascular K_{ATP} can be modulated by nucleotides, potassium channel blockers, sulfonylureas, such as glibenclamide (Gli), and K_{ATP} openers, such as pinacidil (Pin)^[4]. Recent molecular biological and electrophysiological studies on recombinant K_{ATP} have identified that K_{ATP} is a hetero-octameric complex composed of an inwardly rectifying K⁺ channel (Kir_{6,x}) serving as a pore-forming subunit and regulatory sulfonylurea receptors (SURs) belonging to the ATP-binding cassette protein superfamily^[5]. The binding sites for nucleotides, sulfonylureas,

and potassium channel openers are localized in the SURs, which explains the complex sensitivity to these drugs^[6]. Furthermore, it has been found that binding experiments have been carried out in vascular smooth muscles, using [³H]Gli and [³H]P1075, that the binding sites of K_{ATP} openers are different from those of blockers, and negatively allosteric interaction exists between these two binding sites^[7,8]. The functional alterations of K_{ATP} in vascular smooth muscles from hypertensive animals have been investigated by using patch-clamp techniques; the dose-response curves of the K_{ATP} openers pinacidil and aprikalim, for inducing relaxation of isolated aorta and basilar arteries, were shifted rightward^[9], and the effects of levcromakalim on K_{ATP} currents in mesen-

teric arteries were decreased in SHR^[10]. But the mechanisms underlying the hypertensive changes of K_{ATP} remain to be investigated.

In the present study, the characteristics of [³H]P1075 and [³H]Gli binding in aortic strips, derived from normotensive and hypertensive rats, were compared for investigation of the hypertensive changes of K_{ATP} in vascular smooth muscles.

Materials and methods

Drugs [³H]Gli (specific activity 1850 GBq/mmol=50 Ci/mmol) was purchased from Dupont/ New England Nuclear (Boston, MA, USA). [³H]P1075 (specific activity 121 Ci/mmol) from Amersham International (Buckinghamshire, United Kingdom). The radiolabels were stored in ethanol at -20 °C. Gli, Pin, and Tris from Sigma Chemical Co (St Louis, MO, USA). HEPES from Boehringer Mannheim (Baden-Wuerttemberg, Germany). Dimethylsulphoxide (Me_2SO) from Merck Company (West point, USA). P1075 was kindly donated by Leo Pharmaceuticals (Ballerup, Denmark). All other chemicals and reagents were of analytical grade. Both P1075 and Pin were dissolved in Me_2SO (25 g/L) and were diluted as appropriate so that the final concentration of Me_2SO was less than 0.1%.

Animals Wistar rats (NWR, male, weighing 235±21 g, $n=106$), were provided by the Laboratory Animal Center of Institute of Pharmacology and Toxicology, Academy of Military Medical Sciences, Beijing, China.

Reno-vascular hypertension Reno-vascular hypertension was produced by coarctation of the abdominal aorta between the origin of the renal arteries, under ether anesthesia, as described by Liu *et al*^[11]. The rats were used 30 d after the surgery. One day before the experiment, a polyethylene catheter was inserted into the carotid artery for blood pressure measurements with a two-channel physiological recorder (LMS-LB). Mean arterial pressure was 202±25 mmHg in RVHR and 140±11 mmHg in NWR. All animals were kept in a temperature-controlled room on a 14 h/10 h light/dark cycle and had free access to a standard rat chow diet and tap water.

Aorta strips All rats (NWR, $n=55$; RVHR, $n=51$) were decapitated and exsanguinated. Aorta strips were prepared as described in a previous study^[12]. The preparations were then weighed and assigned into tissue holders and immersed in ice-cold HEPES-buffered physiological salt solution (PSS) containing (in mmol/L): NaCl 139, KCl 5, CaCl₂ 25, MgCl₂ 1.2, glucose 11, HEPES 5, gassed with 95% O₂/5% CO₂ and titrated to pH 7.40 with NaOH at 37 °C.

Equilibrium binding experiments

Saturation assay Binding assays of [³H]P1075 or [³H]Gli were routinely performed in duplicate in 0.50 mL PSS containing 3–5 mg wet weight of aorta strips at 25 °C or 37 °C. Nonspecific binding, determined in the presence of 50 μmol/L unlabeled P1075 or 30 μmol/L Gli, accounted for 48.6%±6.4% or 44%±6% of total bound ligand under the conditions employed. Specific binding was obtained by subtracting the nonspecific binding from the total binding.

For saturation experiments, aorta strips were incubated with different concentrations of label (0.25–30 nmol/L) for 90 min. They were then washed by adding 9 mL of ice-cold quench solution (NaCl 154 mmol/L, Tris 50 mmol/L, pH 7.40) for 1 min, blotted, and dissolved hermetically over 2 h in 50 μL of 60% perchloric acid and 100 μL of 30% H₂O₂ at 80 °C. The samples were supplemented with 2.5 mL of ethylene glycol ethyl ether and 5 mL of dimethylbenzene containing 1% 2-(4-tert-butylphenyl)-5-(4-biphenyl)-1,3,4-oxadiazole for 8 h. Radioactivity was determined with liquid scintillation spectrometry (at an efficiency of 42%–55%). The equilibrium dissociation (K_D) and the maximum number of binding sites (B_{max}) of label were determined by Scatchard analysis, and Hill coefficient (n_H) was calculated from Hill equation.

Displacement assay Aorta strips were incubated with 5 nmol/L [³H]P1075 or 3 nmol/L [³H]Gli and unlabeled inhibitors of interest, then washed and determined as described above. Specific binding of [³H]P1075 or [³H]Gli in the presence of unlabeled drugs was normalized to percentage of specific binding in the absence of these drugs. The concentration of drug inhibiting 50% of specific labeled-ligand binding (IC_{50}) was analyzed using the weighted non-linear least-squares regression program. This program fits data assuming the presence of one or more binding sites and allows comparison of the relative goodness-of-fit using *F*-test. A two-site fit was accepted as superior to one-site fit only if significance exceeded $P<0.05$.

Kinetic assay To determine the association kinetics, the aorta strips were incubated with 3 nmol/L [³H]Gli or 5 nmol/L [³H]P1075 and aliquots were withdrawn at various time points for separation of bound and free ligand as described above. To measure the dissociation kinetics, the labels were equilibrated with aorta strips for 90 min. Dissociation was initiated by addition of a large excess of unlabeled ligands (Gli 30 μmol/L, P1075 50 μmol/L) and bound-label was determined at various time intervals ranging from 1 to 90 min. The constants of association and dissociation were calculated according to equations (1) $LN[B_{eq} \cdot (B \cdot B)^{-1}] = K_{app} \cdot t$, (2) $K_{app} = K_1 \cdot [L] + K_2$, and (3) $LN(B \cdot B_{eq}^{-1}) = -K_2 \cdot t$ where *B* represents the amount of specific [³H]Gli or [³H]P1075 binding at dif-

ferent time points, B_{eq} denotes the amount of the receptor-label complex at equilibrium and K_{app} the apparent rate constant of association, which depends on the rate constants of the association and dissociation (K_1, K_2), and on the concentration of labeled ligand employed ($[L]$).

Statistical analysis Results are expressed as mean±SD. Statistical significance of differences between groups of means was assessed by ANOVA followed by Dunnet's test using the Instat Programme (Graphpad SAS Software, San Diego, USA) and was accepted at the $P<0.05$ level.

Results

[³H]P1075 bindings [³H]P1075 bound in a saturated manner to aorta preparations in NWR and RVHR within the concentration range employed. Scatchard analysis of the data suggested that in NWR aorta strips [³H]P1075 bound to a single class of sites with a K_D value of 7.7 ± 2.0 nmol/L, and B_{max} value of 26 ± 8 pmol/g wet weight. In RVHR, [³H]P1075 also bound to a single class of sites. The K_D value, however, increased ~1.5-fold and the B_{max} value showed no change compared with those in NWR (Figure 1, Table 1).

K_{ATP} opener P1075 and Pin, as well as blocker Gli, concentration-dependently inhibited specific [³H]P1075 binding. However, only K_{ATP} opener P1075 and Pin were able to inhibit the specific [³H]P1075 binding completely, whereas inhibition at saturation by Gli was incomplete only by up to 72% of maximal specific binding in NWR and RVHR

Figure 1. Equilibrium binding of [³H]P1075 to aorta strips in normotensive Wistar rats (NWR, open circle) and reno-vascular hypertensive rats (RVHR, solid circle). Strips were incubated with varying concentrations (0.01–25.00 nmol/L) of [³H]P1075 in a 0.50 mL assay volume at pH 7.40 and 37 °C. Inset: Scatchard analysis of the specific binding data. The data are summarized in Table 1.

Table 1. Scatchard analysis of [³H]P1075 binding in normotensive Wistar rats (NWR) and reno-vascular hypertensive rats (RVHR). Mean±SD. ^b $P<0.05$ vs NWR.

Animals	<i>n</i>	K_D / nmol·L ⁻¹	B_{max} / pmol·g ⁻¹ wet weight	n_H

RVHR	4	11.2 ± 4.0^b	25 ± 4	1.1 ± 0.2

aorta preparations. Compared with those in NWR, inhibition curves of [³H]P1075 binding to aorta strips in RVHR by these modulators were shifted to the right along the concentration axis (Figure 2). Statistical analysis with the F -test showed that the fit of inhibition curves by P1075 and Pin to the one-site model was significantly superior to two-site model, which corresponded to their n_H being close to unity. IC_{50} for the inhibition of [³H]P1075 binding to RVHR aorta preparations by P1075 and Pin were increased by approximately 1.8- and 1.7-fold, respectively, compared with those in NWR. The change in IC_{50} value for inhibition of [³H]P1075 binding by P1075 in RVHR aorta strips was in fair agreement with that in the K_D value obtained in the saturation equilibrium experiments in Figure 1.

Inhibition of [³H]P1075 binding by Gli exhibited a biphasic plot (Figure 2) with n_H significantly different from unity (Table 3). In addition, statistical analysis with the F -test showed the fit of inhibition curve by Gli to the two-site

Figure 2. Inhibition of [³H]P1075 binding to aorta strips by P1075, Pin, or Gli in NWR and RVHR. Aorta strips were incubated with 5 nmol/L [³H]P1075 and increasing concentrations of these compounds for 90 min at 37 °C. Specific binding (B_s) was 10.5 ± 1.5 fmol·mg⁻¹ wet weight, corresponding to $51.4\pm 6.4\%$ of total binding. Data (as B_s) were fitted with one-site and two-site model; the fitting parameters were listed in Table 2. Depicted were representative plots of 4–5 separate experiments performed in duplicate.

¹⁾ If $P>0.05$, the hypothesis will be accepted; If $P<0.05$, the hypothesis is rejected, and the fit of the two-site model is significantly superior, statistically, to the one-site model.

**Figure 3.** Modulation of association (A) and dissociation (B) kinetics of [³H]P1075 (5 nmol/L) with aorta strips in NWR and RVHR by vehicle or Gli 100 μmol/L preincubated for 10 min. Data fitted equation 1 and 3, respectively. The traces were representative of 4-7 experiments.

model was significantly superior to one-site model (Table 2). These results suggested that two binding sites for Gli were present. The IC₅₀ values for the high- and low-affinity binding sites of Gli were shown in Table 2. Their respective n_H values were found to be close to unity (not shown). IC₅₀ value for inhibition of [³H]P1075 binding in RVHR aorta strips by Gli at high affinity site increased by more than 2-fold compared with that in NWR aorta preparation, but there was no significant difference between IC₅₀ values at the low

affinity site in RVHR and in NWR (Table 2).

The kinetics of association and dissociation of [³H]P1075, measured at large excess of label over binding sites, are illustrated in Figure 3. In NWR, association kinetics of [³H]P1075 at 5 nmol/L followed a pseudo first-order kinetics, and the fit of this kinetics to equation 1 yielded a K_{app} value of 0.044 \pm 0.004 min⁻¹. After equilibrium was reached, dissociation of the receptor-label complex was initiated by addition of 50 μmol/L unlabeled P1075. The dissociation also followed a pseudo first-order kinetics with a K_2 value of 0.029 \pm 0.005 min⁻¹. Using equation 2, these values of K_{app} and K_2 allowed calculation of the second order rate constant of association, K_1 to 0.009 \pm 0.001 nmol·L⁻¹·min⁻¹. From these rate constants, K_D value of 3.3 \pm 1.0 nmol/L, where the large error in this value is explained by the propagation of errors, was calculated.

After NWR aorta strips were pretreated with Gli 100 μmol/L for 10 min, association and dissociation kinetics of [³H]P1075 still followed the pseudo first-order kinetics. However, association and dissociation were slowed down with the reduced K_{app} and K_2 value, but with increased K_D value compared to those in vehicle (Table 3).

In RVHR, the association and dissociation of [³H]P1075 with aorta strips were also fitted the pseudo first-order kinetics, but slower association and dissociation kinetics were observed with increased K_D value compared to those in NWR. Gli at 100 μmol/L preincubated with aorta strips for 10 min, did not alter the association and dissociation of [³H]P1075 with RVHR aorta strips (Figure 3, Table 3).

[³H]Gli binding experiments The competitive inhibition curve of 3 nmol/L [³H]Gli binding to aorta strips in NWR and RVHR by unlabeled Gli exhibited biphasic plots with

*n*_H significantly different from unity (Figure 4, Table 4). Inhibition curves were fitted with the one-site and two-site model, respectively. Statistical analysis with the *F*-test showed that the fit of curves of the two-site model was significantly superior to the one-site model (Table 4). Thus,

Figure 4. Inhibition of [³H]glibenclamide (Gli) binding to aorta strips in NWR and RVHR by unlabeled Gli and Pin. Aorta strips were incubated with [³H]Gli 3 nmol/L in the presence of various concentrations of unlabeled Gli or pinacidil for 90 min at 25 °C. Depicted are representative plots. *B*_{tot} was 30.5±2.5 pmol·g⁻¹ wet weight. The Data are summarized in Table 4.

two distinct binding sites for [³H]Gli were present in NWR and RVHR aorta preparations. In NWR aorta strips, the IC₅₀ value for the inhibition of [³H]Gli binding at the high- and low-affinity sites by unlabeled Gli was 18±2 nmol/L and 21±4 μmol/L, respectively. The fit of one-site model gave *n*_H equal to 0.80±0.09; a value in favor of heterogeneous class of binding sites with a negative cooperativity. In RVHR aorta strips, the IC₅₀ value for inhibition of [³H]Gli binding at low-affinity sites by unlabeled Gli showed no difference from that in NWR aorta preparations, but IC₅₀ at high-affinity sites increased approximately 4 fold. Pin, at concentrations up to 500 μmol/L neither inhibited the [³H]Gli binding to aorta strips in NWR nor in RVHR (Figure 4).

[³H]Gli binding to NWR aorta strips was rapid and approached equilibrium after a 40-50 min incubation period at 25 °C (data not shown). After equilibrium was reached, the dissociation of [³H]Gli-receptor complex was initiated by the addition of 30 μmol/L unlabeled Gli. Association and dissociation of [³H]Gli followed pseudo first-order kinetics. The fit of the association and dissociation to equation 1 and 3 yielded *K*_{app} and *K*₂ of 0.046±0.004 and 0.007±0.001 min⁻¹, respectively. After NWR aorta strips were pretreated with Pin (100 μmol/L) for 10 min, association and dissociation

Table 4. Displacement of [³H]Gli binding to aorta strips in NWR and RVHR by unlabeled Gli. For experiment details see Fig 4. Analysis with one-site model showed *n*_H was significantly different from unity. *n*=4-5 experiments performed in duplicate. Mean±SD. ^b*P*<0.05, ^c*P*<0.01 vs NWR.

¹⁾ If *P*>0.05, the hypothesis will be accepted; If *P*<0.05, the hypothesis is rejected, and the fit of the two-site model is significantly superior, statistically, to the one-site model.

of [³H]Gli still followed pseudo first-order kinetics. However, when the association was retarded, K_{app} was reduced by 45.6%, but when the dissociation was accelerated, K_2 was increased approximately 2 fold (Table 5).

In RVHR aorta strips, association and dissociation of [³H]Gli were also fitted pseudo first-order kinetics, but when association became slower, K_{app} was reduced by 39%, but when dissociation was faster, K_2 was increased 1.5-fold. From these kinetics, the K_D value calculated was increased 3.3-fold compared with those in NWR aorta strips. After RVHR aorta strips were pretreated with Pin 100 μ mol/L for 10 min, the association and dissociation of [³H]Gli were not altered. From these kinetics, the K_D value calculated was also unchanged (Table 5).

Discussion

Comparison of [³H]P1075 binding in NWR with that in RVHR In the present study, saturation experiments in NWR showed that aorta strips [³H]P1075 bound to a single class of sites with high affinity ($K_D=7.7\pm 2.0$ nmol/L) and relatively low density ($B_{max}=26\pm 4$ nmol·g⁻¹ wet weight). These results are similar to those reported by Quast *et al*^[13]. The K_D value determined here corresponded well to the potency of P1075 as a vasorelaxant agent^[14]. The K_{ATP} opener P1075 and Pin, as well as blocker Gli, inhibited [³H]P1075 binding according to the Law of Mass Action. The IC_{50} value (9.1 ± 1.3 nmol/L) for inhibition of [³H]P1075 binding by P1075 was in fair agreement with the K_D value obtained in the saturation experiments. The association and dissociation of [³H]P1075 with NWR aorta strips were time-dependent and monoexponential, these kinetic experiments allow a calculation of K_D value of 3.3 ± 1.0 nmol/L in reasonable agreement with the result of the saturation experiments (Table 1) and of competitive inhibition experiments (Table 2).

In the present study, [³H]P1075 binding in RVHR aorta strips was reported. The binding data showed that [³H]P1075 binding sites in RVHR aorta strips had similar qualities to those in NWR aorta preparations. However, some differences in [³H]P1075 binding in RVHR aorta strips were found: (1) K_D value of [³H]P1075 binding increased approximately 1.5-fold; (2) IC_{50} value for the inhibition of [³H]P1075 binding by P1075 and Pin increased by 1.8- and 1.7-fold, respectively; (3) association and dissociation became slower. These results suggest that the affinity of [³H]P1075 binding sites to K_{ATP} openers is reduced in RVHR aorta strips. Therefore, we suggest that chronic hypertension might reduce the affinity of binding sites for K_{ATP} openers in aorta. Furthermore, the B_{max} value of [³H]P1075 binding to aorta strips and the maximum inhibition of [³H]P1075 binding by P1075 and Pin showed no difference between RVHR and NWR. It is suggested that the number of [³H]P1075 binding sites is not altered in RVHR aorta strips. The present findings might explain why the dilatation of isolated aorta precontracted with norepinephrine or KCl in response to activation of K_{ATP} channels by Pin was impaired in SHR, why dilatation of the basilar artery by aprikalim was impaired in stroke-prone SHR *in vivo*^[9]; and why the action of levromakalim on K_{ATP} channels in mesenteric artery muscle cells of SHR was decreased compared to normotensive rat cells^[10]. The present findings also exclude the possibility that differences in response to Pin, aprikalim and levromakalim are related to genetic differences between normotensive rats and SHR that are unrelated to hypertension.

Comparison of [³H]Gli binding in NWR with RVHR In the present study, the binding of [³H]Gli in NWR aorta strips was specific and reversible. Using a wide range of concentrations for Gli, we obtained evidence for the presence of both high and low affinity Gli-binding sites in aorta preparations: the former ranging from 1×10^{-11} to 1×10^{-7} mol/L

with nanomolar affinity constant, and the latter from 1×10^{-7} to $1 \times 10^{-3.5}$ mol/L with micromolar affinity constant. Our results are consistent with those reported previously in retarding vascular smooth muscle^[12].

[³H]Gli binding in these preparations had similar qualities to those in NWR. However, [³H]Gli exhibited slower association and faster dissociation with an increased K_D value in RVHR than in NWR (Table 5). The IC_{50} value for the inhibition of [³H]Gli binding by Gli at the high affinity component was increased, but was unchanged at the low affinity component. This indicates that the affinity of high affinity sulfonylurea sites is decreased in RVHR aorta strips.

Interaction of binding sites for K_{ATP} openers and blockers in NWR In the present study, [³H]P1075 bound to a single site in NWR aorta strips, whereas [³H]Gli bound to both high and low affinity sites in NWR aorta strips. [³H]P1075 binding can be inhibited by opener P1075 and Pin, but not completely by blocker Gli, whereas [³H]Gli binding could be inhibited by Gli, but not by Pin. Furthermore, [³H]P1075 and [³H]Gli binding present a similar association rate (0.044 and 0.046 nmol·L⁻¹·min⁻¹) but different dissociation rate (0.029 and 0.007 nmol·L⁻¹·min⁻¹, respectively). The most plausible explanation for these results is that K_{ATP} openers and blockers bind to different binding sites. In addition, Pin, preincubated with NWR aorta strips, slowed down the association of [³H]Gli and sped up the dissociation of [³H]Gli-receptor complex. It is suggested that the binding sites for K_{ATP} channel opener Pin negatively allosterically couple to the binding sites for K_{ATP} channel blocker Gli. The plausible mechanism is that the binding of Pin to its sites in SURs brings about configuration alteration in the Gli-sites, which hinders the binding of [³H]Gli to its sites and facilitates faster release of the radiolabel from receptor-label complex. Likewise, Gli, preincubated with NWR aorta strips, also slowed down the association of [³H]P1075 and sped up the dissociation of [³H]P1075-receptor complex. It was indicated that the sites for K_{ATP} channel blocker Gli also negatively allosterically coupled to the sites for K_{ATP} channel opener P1075. Alternatively, Gli down-regulates the affinity of the P1075 binding sites through inducing its configuration alteration. The evidence for a negative allosteric coupling between the sites for P1075 and Gli has been previously obtained for the rat aorta^[8]. In the experiments, however, rat aorta preparations were only labeled with [³H]P1075, and the dissociation of [³H]P1075-receptor complex was initiated by addition of an excess of Gli rather than P1075 after [³H]P1075 binding reached equilibrium. In the present study, aorta strips were pretreated with Gli, and dissociation was initiated by addition of an excess of P1075

rather than Gli. A negative allosterism between the sites for openers and blockers was identified in a different experimental protocol in this study.

Interaction of binding sites for K_{ATP} openers and blockers in RVHR In the present paper, we studied the interaction between the binding sites for K_{ATP} openers and blockers in RVHR aorta strips. The evidence that K_{ATP} openers and blockers bound to different binding sites was also obtained in RVHR. In contrast to NWR, pretreatment with Gli failed to alter the association and dissociation kinetics of [³H]P1075 with aorta strips in RVHR. It is suggested that the negative allosteric action of sulfonylurea Gli on the binding sites for the opener P1075 was damaged in RVHR aorta strips. Similarly, pretreatment of Pin did not alter the association and dissociation kinetics of [³H]Gli with RVHR aorta strips. It is indicated that the negative allosteric action of opener Pin on the binding sites for sulfonylurea Gli is also damaged in SHR aorta strips.

In conclusion, the affinity of P1075 binding sites and high-affinity sulfonylurea binding sites are reduced, and the negative allosteric interactions between the two binding sites are impaired in RVHR aorta strips.

Abstract

Aim: To investigate the α_{1B} -adrenoceptor (α_{1B} -AR)-mediated cAMP response and underlying mechanisms in HEK293 cells. **Methods:** Full-length cDNA encoding α_{1B} -AR was transfected into HEK293 cells using the calcium phosphate precipitation method, and α_{1B} -AR expression and cAMP accumulation were determined by using the saturation radioligand binding assay and ion-exchange chromatography, respectively. **Results:** Under agonist stimulation, α_{1B} -AR mediated cAMP synthesis in HEK293 cells, and blockade by PLC-PKC or tyrosine kinase did not reduce cAMP accumulation induced by NE. Pretreatment with pertussis toxin (PTX) had little effect on basal cAMP accumulation as well as norepinephrine (NE)-stimulated cAMP accumulation. In addition, pretreatment with cholera toxin (CTX) neither mimicked nor blocked the effect induced by NE. The extracellular Ca²⁺ chelator egtazic acid (EGTA), nonselective Ca²⁺ channel blocker CdCl₂ and calmodulin (CaM) inhibitor W-7 significantly reduced NE-induced cAMP accumulation from 1.59%±0.47% to 1.00%±0.31%, 0.78%±0.23%, and 0.90%±0.40%, respectively. **Conclusion:** By coupling with a PTX-insensitive G protein, α_{1B} -AR promotes Ca²⁺ influx via receptor-dependent Ca²⁺ channels, then Ca²⁺ is linked to CaM to form a Ca²⁺-CaM complex, which stimulates adenylyl cyclase (AC), thereby increasing the cAMP production in HEK293 cell lines.

Introduction

It is well known that the classic signaling pathway of α_1 -adrenoceptor (AR) is to couple with the G_{q/11} protein and then stimulate phosphatidylinositol turnover^[1,2]. However, it has been recently discovered that α_1 -AR can also stimulate adenosine 3':5'-cyclic monophosphate (cAMP) accumulation in several cell lines, tissues and organs^[3–12]. Our previous study showed that each of the three α_1 -AR subtypes was able to mediate cAMP generation in human embryonic kidney 293 (HEK293) cells. As for the signal transduction pathway by which α_1 -AR mediates cAMP production, several studies have shown that cAMP production is secondary to the α_1 -AR-induced phospholipase C (PLC)-phosphokinase C (PKC) stimulation^[10–12], which cross-talked with AC^[13]. Horie *et al*^[14] found that in a Chinese hamster ovary (CHO) cell line transfected with α_{1B} -AR, none of the PKC inhibitor, the Ca²⁺ ionophore, or the pertussis toxin (PTX) was able to

inhibit NE-induced cAMP accumulation, whereas anti-G_{s α} antiserum inhibited the response, which suggests that α_{1B} -AR activates AC and increases intracellular cAMP by directly coupling with G_{s α} . In fact the signal transduction pathway involved in α_{1B} -AR-mediated cAMP generation remains unclear. Therefore, we transfected HEK293 cells (human embryonic kidney 293 cell line, which does not express any other adrenoceptors except native β_2 -AR) with full-length cDNA encoding α_{1B} -AR and selected for subcloning cell lines stably expressing α_{1B} -AR. This was a good model to investigate the regulating effects of the PLC-PKC pathway, the tyrosine kinase pathway, the Ca²⁺ signal system, and G proteins on cAMP production.

Materials and methods

Norepinephrine (NE), phenylephrine (PE), methoxamine (ME), prazosin (PRZ), propranolol (Prop), Triton X-100,

cAMP, 3-isobutyl-1-methyl-xanthine (IBMX), pyruvic acid, hygromycin B, cyclopiazonic acid (CPA), phorbol 12-myristate 13-acetate (PMA), genistein, tyrphostin A25, egtazic acid (EGTA), nifedipine (Nif), CdCl₂, PTX, and cholera toxin (CTX) were from Sigma Chemical Co (St Louis, USA); BAPTA/AM, Ro-31-8220, calphostin C, and W-7 were products of Calbiochem-Novabiochem International (San Diego, USA). BE2254 {[2-β(4-hydroxyphenyl)-ethylaminomethyl]-tetralone} was from Beiersdorf Co (Hamburg, Germany); [³H]adenine was from Amersham Biosciences (Piscataway, United States); 2,5-diphenyl-oxazole (PPO) was bought from Farco-Pharma (Koln, Germany); fetal bovine serum (FBS) and Dulbecco's Modified Eagle's Medium (DMEM) were from Hyclone China (Beijing, China); HEK293 (human embryonic kidney 293) cells and full-length cDNA of hamster α_{1B}-AR (pREP4) were kindly provided by Prof Kenneth P MINNEMAN (Emory University, USA).

Transfection of HEK293 cells with cDNA encoding α_{1B}-AR using the calcium phosphate precipitation method HEK293 cells were cultured in DMEM containing 10% FBS at 5% CO₂ at 37 °C. The cells were transfected with pREP4/α_{1B}-AR by calcium phosphate precipitation at 70% confluence and selected with hygromycin B (0.05 g/L). Three days later the cells were diluted and planted in a 96-well dish, with 0-5 cells in each well. After 2 to 3 cloning sessions, a cell line stably expressing α_{1B}-AR was obtained. The cells were continuously cultured and kept in DMEM containing selective antibiotics.

Determination of α_{1B}-AR expression by a saturation radioligand binding assay The cells were grown in 75-mL flasks and harvested in PBS. After centrifugation at 3000×g, 4°C for 10 min then at 21 000×g, 4°C, for 20 min, the pellet was resuspended with 30 mL PBS and kept on ice. The ligand-binding properties of the receptors were determined in a series of radioligand binding studies using the α₁-AR antagonist radioligand [¹²⁵I]BE2254, which was radioiodinated to theoretical specific activity as described by Engel and Hoyer^[19]. Saturation reactions (total volume 250 μL) containing 100 μL or 50 μL PBS with 1% bovine serum albumin (BSA), 50 μL of [¹²⁵I] BE2254 at different concentrations (15 000-500 000), and 100 μL cell membranes. Nonspecific binding was determined in the presence of 50 μmol/L phentolamine. Reactions were allowed to proceed for 20 min at 37 °C. Reactions were terminated by adding 7 mL ice-cold Tris-HCl buffer (pH 7.4) and the mixture was filtered onto glass fiber filters. Filters were washed twice with 7 mL ice-cold Tris-HCl buffer and then dried. Bound radioactivity was measured using an auto-gamma counter.

Binding data were analyzed by using nonlinear regression and Scatchard analysis (GraphPad Prism Software) on a computer and thus the dissociation constant (K_D) between the receptor and antagonist and maximal bound capacity (B_{max}) could be obtained. Protein content was determined by using the Coomassie protein quantitation method.

cAMP determination in intact cells using ion-exchange chromatography HEK293 cells expressing α_{1B}-AR were cultured in 24-well dishes at 37 °C, 5% CO₂, with 2.5×10⁵ cells per mL medium. When the cells were fully confluent, the medium was changed, and [³H]adenine 18.5 MBq (0.5 mCi) was added into each well. After incorporation for 4 h at 37 °C in 5% CO₂, the medium was discarded and the cells were washed twice with pre-warmed Krebs' solution. After addition of antagonists in 1 mL Krebs' solution containing 200 μmol/L IBMX and incubation for 30 min, the cells were incubated for a further 20 min with different concentrations of agonists. The reaction was terminated by adding 100 μL of 77% trichloroacetic acid, followed by a centrifugation at 3000×g, 4 °C, for 20 min. Then 50 μL supernatant was transferred into 3 mL scintillation liquid to measure radioactivity as total activity (cpm). The remaining supernatant was applied to Dowex columns and aluminal columns. After being washed with distilled water, the aluminal columns were eluted with 2 mL Tris-HCl (pH 8.0), and the radioactivities of the eluates were measured as newly-produced cAMP. cAMP accumulation is equal to proportion of total radioactivity represented by newly-produced cAMP as a percentage. The formula is as follows:

$$\text{cAMP accumulation} = \frac{\text{Radioactivity of newly-produced cAMP (cpm)} \times 100 \%}{\text{Total radioactivity (cpm)} \times 22}$$

Twenty-two is the volume constant.

Statistical analysis Results are expressed as mean±SD. To compare mean values between two groups, Student's *t*-test was used; ANOVA was used for comparison among three or more groups. *P*<0.05 was considered statistically significant.

Results

Density of α_{1B}-AR HEK293 cells transfected with α_{1B}-AR were cultured under selective pressure from hygromycin B for several passages, thus we obtained a cell line stably expressing α_{1B}-AR. The density of α_{1B}-AR was 2004±138 pmol/g as determined by a radioligand binding assay (*n*=5, data not shown).

cAMP accumulation induced by stimulation of α_{1B}-AR In blank HEK293 cells, NE (100 nmol/L–30 μmol/L),

PE (100 nmol/L–300 μmol/L), or ME (1 μmol/L–1 mmol/L) did not cause cAMP accumulation in the presence of propranolol, an antagonist of β-AR (data not shown).

However, NE, PE, and ME all increased cAMP accumulation in HEK293 cells transfected with α_{1B}-AR in a dose-dependent manner, with R_{max}/pD₂ of (3.32%± 0.34%)/(6.15±0.33) (n=7), (2.43%±0.46%)/(5.37±0.55) (n=8), and (0.66%±0.17%)/(3.79±0.39) (n=6), respectively (Figure 1), all of which were antagonized by prazosin (100 nmol/L) (Data not shown).

Figure 1. NE (■, n=7), PE (◆, n=8) and ME (●, n=6) induced cAMP synthesis in a dose-dependent manner in the presence of propranolol (1 μmol/L) in HEK293 cells transfected with α_{1B}-AR.

PLC-PKC pathway In the presence of propranolol (10 μmol/L) to block β₂-AR in HEK293 cells, NE (10 μmol/L) increased cAMP accumulation from a basal level of 0.28%± 0.07% to 4.93%±1.13% (n=11, P<0.01). The PLC inhibitor, U73122, had no effect on the NE-induced cAMP accumulation at 1 μmol/L (4.91%±1.43%, n=11) or 10 μmol/L (4.97%±1.15%, n=11, Fig 2A) for 1 h incubation. Neither U73122 itself (0.26%±0.09%, n=5) nor the vehicle alone (Me₂SO, 0.1% v/v final, 0.26%±0.05%, n=3) affected the basal level of cAMP (0.28%±0.07%, n=11). Similarly, when PKC inhibitors were added, neither Ro31-8220 (5.37%± 1.33%) and (4.99%±1.56%, n=8) nor calphostin C (5.14%± 1.09%) and 4.70%±1.28%, n=8) at 10 nmol/L and 100 nmol/L affected NE-induced cAMP production (4.93%± 1.13%, n=11, Figure 2B). The two inhibitors had no effect on the basal cAMP level (0.24%±0.07%, n=5, and 0.22%± 0.09%, n=5, respectively, vs 0.28%±0.07%, n=11). To further clarify the role of PKC in this response, we examined whether PKC activator had any effect on cAMP synthesis. Without any AR agonist or antagonist, pretreatment with 1, 10, and 100 nmol/L PMA did not increase cAMP synthesis,

Figure 2. (A) NE-induced cAMP accumulation and the effect of U73122 (n=11) in the presence of 10 μmol/L propranolol in HEK293 cells expressing α_{1B}-AR. (B) NE-induced cAMP accumulation and the effects of Ro31 and calphostin C (n=8) in the presence of 10 μmol/L propranolol and cAMP accumulation in the presence of PMA at 1–100 nmol/L (n=7), respectively. Mean±SD. ^bP<0.05 vs basal accumulation.

the levels of which were (0.23%±0.03%, n=7), (0.22%± 0.08%, n=7), and (0.24%±0.08%, n=7), respectively, showing no significant difference compared with the basal level (0.28%±0.07%, n=11).

Tyrosine kinase signaling pathway The effects of two kinds of tyrosine kinase inhibitors, tyrphostin A25 and genistein, on NE-induced cAMP synthesis were examined. Tyrphostin A25 and genistein (0.30%±0.07% and 0.30%± 0.04%, n=5, respectively) or the vehicle alone (Me₂SO, 0.1% v/v final, 0.26%±0.03%, n=3) had no effect on the basal cAMP level (0.28%± 0.07%, n=11). After pretreating cells with tyrphostin A25 or genistein at 1 μmol/L and 10 μmol/L for 1 h, neither tyrphostin A25 (4.98%±1.33% and 4.75%± 1.07% at the two concentrations, respectively, n=7) nor genistein (4.97%±1.30% and 4.69%±0.62%, respectively,

$n=7$) influenced NE-induced cAMP synthesis ($4.93\% \pm 1.13\%$, $n=11$ in the presence of propranolol $10 \mu\text{mol/L}$) (Figure 3).

Figure 3. The effects of tyrrhostin A25 and genistein ($n=7$) on NE-induced cAMP accumulation in the presence of $10 \mu\text{mol/L}$ propranolol in HEK293 cells transfected with α_{1B} -AR. Mean \pm SD. ^b $P<0.05$ vs basal accumulation.

Regulation of cAMP response by G proteins After incubating cells with PTX $500 \mu\text{g/L}$ for 16 h, the effects of PTX on basal or NE-induced cAMP accumulation were examined. The results showed that PTX neither had any effect on basal cAMP ($0.31\% \pm 0.07\%$ vs $0.23\% \pm 0.07\%$, $n=8$) nor affected the NE-induced cAMP response ($1.76\% \pm 0.50\%$ vs $1.52\% \pm 0.44\%$, $n=8$, Figure 4). In order to examine whether α_1 -AR mediates cAMP response by directly coupling with the G_s protein, we compared cAMP accumulation upon stimulation of the G_s protein after incubation with $500 \mu\text{g/L}$ CTX for 3 h with NE-induced cAMP accumulation. The results showed that cAMP accumulation induced by CTX alone was significantly higher than that induced by $10 \mu\text{mol/L}$ NE ($2.50\% \pm 0.60\%$ vs $1.52\% \pm 0.44\%$, $n=8$, $P<0.05$), and when CTX and NE were used simultaneously, cAMP accumulation ($5.24\% \pm 1.37\%$, $n=8$) was significantly higher than their combined effect when used alone ($P<0.05$, Figure 4).

Regulating effects of Ca^{2+} signaling system Because α_1 -AR can induce the release of the IP_3 -sensitive Ca^{2+} store, CPA, a Ca^{2+} -ATPase inhibitor, was used to block Ca^{2+} being taken in sarcoplasmic reticulum again so as to increase $[\text{Ca}^{2+}]_i$ and deplete the Ca^{2+} store. The results showed that CPA $10 \mu\text{mol/L}$ alone did not increase cAMP accumulation ($0.20\% \pm 0.03\%$ vs $0.22\% \pm 0.12\%$, $n=8$), neither did it have any effect on NE-induced cAMP production ($1.63\% \pm 0.56\%$,

Figure 4. The effects of PTX $500 \mu\text{g/L}$ and CTX on basal and NE-induced cAMP accumulation ($n=8$) in the presence of propranolol $10 \mu\text{mol/L}$ in HEK293 cells transfected with α_{1B} -AR. Mean \pm SD. ^b $P<0.05$ vs basal accumulation. ^e $P<0.05$ vs NE-induced cAMP accumulation. ^{beh} $P<0.05$ vs CTX-induced cAMP accumulation.

$n=8$ vs $1.59\% \pm 0.47\%$, $n=9$, Figure 5A).

In addition, the influence of the Ca^{2+} influx on cAMP synthesis was studied. It was found that NE-induced cAMP accumulation under Ca^{2+} -free condition was equal to that when Ca^{2+} was present ($1.63\% \pm 0.40\%$ vs $1.59\% \pm 0.47\%$, $n=9$). However, when an extracellular Ca^{2+} chelator, EGTA ($50 \mu\text{mol/L}$), was added in Ca^{2+} -free Krebs buffer to pretreat the cells for 1 h, the NE-induced cAMP synthesis was obviously reduced ($1.00\% \pm 0.31\%$, $n=9$, $P<0.05$, Figure 5B), whereas $10 \mu\text{mol/L}$ intracellular Ca^{2+} chelator, BAPTA/AM, had no effect on the NE-induced cAMP response under Ca^{2+} -free conditions ($1.62\% \pm 0.58\%$ vs $1.59\% \pm 0.47\%$, $n=9$). There was no further inhibition on cAMP synthesis when BAPTA was used in combination with EGTA ($1.03\% \pm 0.28\%$ vs $1.00\% \pm 0.31\%$, $n=9$, Figure 5B).

To find out what type of Ca^{2+} channel admitted Ca^{2+} , we examined the effects of two kinds of Ca^{2+} channel blockers on cAMP response and found that nifedipine $10 \mu\text{mol/L}$ (L-type Ca^{2+} channel blocker) did not affect the NE-induced cAMP synthesis ($1.47\% \pm 0.38\%$ vs $1.59\% \pm 0.47\%$, $n=9$), whereas CdCl_2 1 mmol/L (nonselective Ca^{2+} channel blocker) obviously reduced NE-induced cAMP accumulation (from $1.59\% \pm 0.47\%$ to $0.78\% \pm 0.23\%$, $n=9$, $P<0.05$, Figure 5C). Moreover, when pretreating cells with W-7, a calmodulin (CaM) inhibitor, NE-induced cAMP synthesis decreased markedly ($0.90\% \pm 0.40\%$, $n=8$, $P<0.05$, Figure 5C), and the extent of decrease was similar to that induced by EGTA or CdCl_2 ($P>0.05$), while neither of them had any effect on the basal cAMP level.

Figure 5. (A) NE-induced cAMP accumulation ($n=9$) and the effect of CPA $10\ \mu\text{mol/L}$ ($n=8$) in the presence of propranolol $10\ \mu\text{mol/L}$ in HEK293 cells transfected with α_{1B} -AR. (B) NE-induced cAMP response in Krebs' buffer and in Ca^{2+} -free Krebs' buffer, and the effects of EGTA $50\ \mu\text{mol/L}$, BAPTA $10\ \mu\text{mol/L}$, and EGTA plus BAPTA ($n=9$) on NE-induced cAMP response under Ca^{2+} -free conditions in the presence of propranolol $10\ \mu\text{mol/L}$. (C) NE-induced cAMP response and the effects of nifedipine $10\ \mu\text{mol/L}$ ($n=9$), CdCl_2 $1\ \text{mmol/L}$ ($n=9$), and W-7 $500\ \mu\text{mol/L}$ ($n=8$) in the presence of propranolol $10\ \mu\text{mol/L}$ in HEK293 cells transfected with α_{1B} -AR. Mean \pm SD. ^b $P<0.05$ vs basal accumulation. ^e $P<0.05$ vs NE-induced cAMP accumulation.

Discussion

Several studies have demonstrated that α_{1B} -AR mediates the cAMP response in HEK293 cells. However, the signaling pathway through which α_1 -AR mediates the cAMP response is unknown. Many studies have indicated that besides its classical signaling pathway, α_1 -AR can stimulate many other signal transduction pathways as well, such as the tyrosine kinase pathway^[15-18], the phospholipase A_2 -arachidonic acid (PLA_2 -AA) signaling system^[20], etc. Moreover, α_1 -AR also associates with other signaling pathways through its classical signal transduction pathway and consequently produces cross-talk. cAMP is a second messenger, a product of ATP catalyzed by adenylyl cyclase (AC), and a substrate of phosphodiesterase (PDE). There are at least 10 isozymes of AC. Besides the G_s and G_i proteins, many factors have been found to regulate their activities^[21,22]. In the present study, we investigated the underlying mechanism involved in α_1 -AR-mediated cAMP synthesis using HEK293 cells transfected with α_{1B} -AR.

PLC-PKC pathway α_1 -AR preferentially activates its classical signaling pathway. It stimulates PLC by coupling with the $\text{G}_{q/11}$ protein, then PLC hydrolyzes PIP_2 to produce IP_3 and DAG, which induces Ca^{2+} release and stimulates PKC, thereby producing biological effects. It has been reported that in some cell lines transfected with α_1 -AR subtypes, α_1 -AR first stimulates PI turnover to activate PKC, and then stimulates AC. This means that α_1 -AR-mediated cAMP response is secondary to the PLC-PKC pathway^[10-12]. However, our results indicated that neither the PLC antagonist, U73122, nor the PKC antagonists, Ro31 and calphostin C, inhibited α_1 -AR-mediated cAMP synthesis, and the PKC activator, PMA, did not increase cAMP accumulation. Furthermore, there was no influence on cAMP synthesis when using the Ca^{2+} -ATPase inhibitor, CPA, to block Ca^{2+} restoration and thus deplete the Ca^{2+} pool. All of the above suggests the taches lying in downstream of PLC in the classical pathway are not connected with α_1 -AR-mediated cAMP response.

Tyrosine kinase signal transduction pathway The tyrosine kinase signal transduction pathway relates closely to the classical signaling pathway of α_1 -AR. Some studies have shown that tyrosine kinase probably participates in α_1 -AR-mediated biological effects^[15-18]. In our previous study, we found that the major functional α_1 -AR subtype of the vascular bed in rat hind legs was α_{1A} -AR, and that tyrosine kinase antagonists could dose-dependently reduce the vascular contractive response to NE. Moreover, tyrosine kinase antagonists can inhibit α_1 -AR-mediated increase in intracellular Ca^{2+} in HEK293 cells^[23], showing that α_1 -AR can

activate tyrosine kinase. It is also known that tyrosine kinase can indirectly stimulate AC through the PLC- γ -IP₃/DAG pathway, which results in intracellular Ca²⁺ mobilization and stimulation of PKC^[22]. Since we have confirmed that α_1 -AR does not mediate cAMP synthesis through the PLC-PKC pathway in HEK293 cells, the possibility mentioned above can be excluded. Although it is known that tyrosine kinase can indirectly stimulate AC through the PLC- γ -IP₃/DAG pathway^[21], this would not happen in HEK293 cells because our study indicated that the PLC-PKC pathway was not involved in α_1 -AR-mediated cAMP accumulation. However, whether tyrosine kinase plays a role through other pathways or taches is unclear. In our present study, two kinds of tyrosine kinase inhibitors, different in structure and mechanism, exerted no influence on NE-induced cAMP synthesis, suggesting that tyrosine kinase is not involved in α_{1B} -AR-mediated cAMP response in HEK293 cells.

Regulation of cAMP response by G proteins α_1 -AR is a typical G protein coupled receptor, whose classical signaling pathway is to couple with the G_{q/11} protein. But it has been found that α_1 -AR also couples with G_s and G_i proteins^[14,24]. Overexpressed α_1 -AR in the heart of transgenic mice can couple with the G_i protein and inhibit AC^[24]. Horie *et al*^[14] found that stimulation of transfected α_1 -AR directly activated G_s and increased cAMP accumulation. These phenomena occur when the density of α_1 -AR is much higher than normal. Some researchers^[14,25] consider that receptor-G promiscuity happens when receptors are overexpressed, ie, receptors not only couple with their traditional G proteins, but also couple with irrelevant G proteins under normal conditions, and then produce new biological effects. This phenomenon is called receptor-G protein promiscuity, which would occur when receptors are overexpressed^[14,25]. Since our experiments were performed under similar conditions, this leads to the following question: did promiscuity occur between α_1 -AR and other G proteins? Firstly, the results showed α_{1B} -AR-mediated cAMP response was not affected by PTX, thereby excluding the possibility that G_i protein or G _{$\beta\gamma$} , which is sensitive to PTX^[27] and activates ACII and IV^[21,22,28], which is involved in the response. Secondly, cAMP accumulation induced by CTX alone was markedly higher than that induced by NE, and when CTX and NE worked together cAMP accumulation was far higher than the sum of cAMP accumulation when each of them worked alone. The response induced by NE 10 μ mol/L almost reached a maximum, and since there is no receptor reserve in cloned HEK293 cells^[25], if α_{1B} -AR directly coupled with the G_s protein while the number of G_s were relatively insufficient or equally by the number of α_{1B} -AR, cAMP

accumulation induced by NE should equal that induced by CTX, and should not increase further when NE was added together with CTX. However, it did not occur. Thus there are two possibilities, one is that α_{1B} -AR directly couples with the G_s protein but that the amount of G_s protein far exceeds what α_{1B} -AR requires; another is that α_{1B} -AR itself does not couple with the G_s protein, which is more likely, because in our study, stimulation of α_{1B} -AR and the G_s protein at the same time induced a synergistic effect. In addition, the G _{α} , G _{$\beta\gamma$} subunit should not be ignored, because it has been shown to activate ACII and IV^[21,22,28]. However, because G _{$\beta\gamma$} is PTX-sensitive^[27], and PTX did not inhibit NE-induced cAMP synthesis in our study, we conclude that G _{$\beta\gamma$} does not participate in the response.

Regulating effects of Ca²⁺ signaling system α_1 -AR can induce the mobilization of intracellular Ca²⁺ as well as the influx of extracellular Ca²⁺. As the most ubiquitous and most active second messenger in cells, Ca²⁺ not only mediates many physiological effects directly, but also regulates many signaling pathways and molecules. It has been shown that the Ca²⁺-CaM complex can stimulate ACI, III, and VIII^[21,22]. For this reason the effect of Ca²⁺ on α_{1B} -AR-mediated cAMP response was investigated. Our results showed that the Ca²⁺-ATPase inhibitor, CPA, had no effect on NE-induced cAMP accumulation, indicating that mobilization of intracellular Ca²⁺ was not involved in the response. NE-induced cAMP accumulation was not reduced under Ca²⁺-free condition, but reduced after addition of the extracellular Ca²⁺ chelator, EGTA. We speculate that it is because even under Ca²⁺-free conditions, there inevitably existed a little Ca²⁺ in the buffer, which is enough to meet with the needs of the α_{1B} -AR-mediated cAMP response. When extracellular Ca²⁺ is chelated by EGTA, Ca²⁺ cannot flow into cells, thereby reducing cAMP production. So cAMP production was reduced. All of the above shows that extracellular Ca²⁺ influx plays a role in the α_{1B} -AR-mediated cAMP response. It is well known that extracellular Ca²⁺ enters cells mainly via voltage-dependent Ca²⁺ channels (VDCC) or voltage-independent Ca²⁺ channels, which includes Ca²⁺ store depletion-dependent Ca²⁺ channels (SDDCC), receptor-dependent Ca²⁺ channels, and so on. Then arises the new question of what kind of channel is involved in this response. It has been proving that there is no VDCC in HEK293 cells^[29], and in our study, the L-type Ca²⁺ channel inhibitor nifedipine did not affect NE-induced cAMP synthesis. The nonselective Ca²⁺ channel inhibitor CdCl₂ obviously reduced NE-induced cAMP accumulation, and the extent of reduction was the same as that with EGTA. If these facts are taken together with the fact that CPA-induced Ca²⁺ store depletion did not increase cAMP

accumulation, it seems that it was via receptor-dependent Ca^{2+} channels that extracellular Ca^{2+} entered the cells. CaM inhibitor W-7 significantly reduced NE-induced cAMP accumulation, with the extent of reduction almost equal to that induced by EGTA and CdCl_2 , which indicates that it is Ca^{2+} -CaM that activates AC. Intracellular Ca^{2+} chelator BAPTA can chelate Ca^{2+} released from the Ca^{2+} store as well as Ca^{2+} entering cells from the outside, so theoretically it should have an effect similar to EGTA. In fact, it neither inhibited NE-induced cAMP synthesis nor enhanced the inhibitory effect of EGTA. As for the reason why intracellular Ca^{2+} chelator BAPTA could not inhibit NE-induced cAMP synthesis, we suppose either that the penetrability of BAPTA/AM into HEK293 cells was rather weak, or that the activity of esterase in HEK293 cells is so low that BAPTA/AM cannot be degraded to active BAPTA. Furthermore, our previous study showed that $[\text{Ca}^{2+}]_i$ increased to 4-5 times the basal level 8 s after activation of α_1 -AR. Active BAPTA was perhaps not enough to chelate all intracellular Ca^{2+} completely and rapidly, so BAPTA/AM had little effect. However, the exact mechanism by which the system functions remains to be studied. In summary, the results suggest that stimulation of α_{1B} -AR triggers the receptor-dependent Ca^{2+} channel via an unknown pathway and lets extracellular Ca^{2+} in, then Ca^{2+} links CaM into a Ca^{2+} -CaM complex, which activates AC to increase cAMP synthesis. However none of EGTA, CdCl_2 , and W-7 are able to completely inhibit NE-induced cAMP accumulation, suggesting that the Ca^{2+} influx is only partly involved in the response.

In conclusion, by coupling with a PTX-insensitive G protein, α_{1B} -AR promotes Ca^{2+} influx via receptor-dependent Ca^{2+} channels, then Ca^{2+} links to CaM to form a Ca^{2+} -CaM complex, which stimulates adenylyl cyclase (AC) and thereby increases the cAMP production in HEK293 cell lines. But Ca^{2+} only partly contributes to α_{1B} -AR-mediated cAMP accumulation. The other mechanisms remain to be investigated.

Abstract**Aim:** To elucidate the mechanisms underlying homocysteine (Hcy)-induced chemokine production. **Methods:** Human whole blood was pretreated with inhibitors of calmodulin (CaM), protein kinase C (PKC), protein tyrosine kinase (PTK), mitogen-activated protein kinase (MAPK), and NF- κ B and activators of PPAR γ for 60 min followed by incubation with Hcy 100 μ mol/L for 32 h. The levels of mitogen chemokine protein (MCP)-1 and interleukin-8 (IL-8) were determined by enzyme-linked immunosorbant assay (ELISA). **Results:** Inhibitors of PKC (calphostin C, 50-500 nmol/L and RO-31-8220, 10–100 nmol/L), CaM (W7, 28–280 μ mol/L), ERK1/2 MAPK (PD 98059, 2–20 μ mol/L), p38 MAPK (SB 203580, 0.6–6 μ mol/L), JNK MAPK (curcumin, 2–10 μ mol/L), and NF- κ B (PDTIC, 10-100 nmol/L) markedly reduced Hcy 100 μ mol/L-induced production of MCP-1 and IL-8 in human cultured whole blood, but the inhibitors of PTK (genistein, 2.6–26 μ mol/L and tyrphostin, 0.5-5 μ mol/L) had no obvious effect on MCP-1 and IL-8 production. PPAR γ activators (ciglitazone 30 μ mol/L and troglitazone 10 μ mol/L) depressed the Hcy-induced MCP-1 production but not IL-8 production in the cultured whole blood. **Conclusion:** Hcy-induced MCP-1 and IL-8 production is mediated by activated signaling pathways such as PKC, CaM, MAPK, and NF- κ B. Our results not only provide clues for the signal transduction pathways mediating Hcy-induced chemokine production, but also offer a plausible explanation for a pathogenic role of hyperhomocysteinemia in these diseases.**Introduction**

Hyperhomocysteinemia is an independent risk factor for atherosclerosis and venous thrombosis. We have found that an increased homocysteine (Hcy) levels in cultured whole blood can promote the production of monocyte chemoattractant protein-1 (MCP-1) and interleukin-8 (IL-8)^[1]. As potent proatherosclerotic factors, MCP-1 and IL-8 are considered to be vital contributing factors in the pathogenesis of atherosclerosis and venous thrombosis^[2–6]. Therefore, increased MCP-1 and IL-8 levels in plasma may be an important mechanism by which hyperhomocysteinemia promotes the progression of atherosclerosis.

In addition, the relationship between hyperhomocys-

teinemia and the cardiovascular disease and thrombosis has been well established. Recent clinical investigations have found that hyperhomocysteinemia is also associated with many different diseases such as inflammation, autoimmune diseases, and cognitive diseases^[7–13]. These new findings imply that Hcy may also mediate the development of these medical conditions by presently-unknown mechanism(s).

Previous studies have found that the signaling pathways involving protein kinase C (PKC), protein tyrosine kinase (PTK), or mitogen-activated protein kinase (MAPK) play a vital role in the mediation of MCP-1 and IL-8 production in response to other stimuli^[14–18]. Thus, these signaling pathways are examined in the present study to explore which

signaling pathways are involved in the Hcy-induced production of MCP-1 and IL-8. Our results presented here demonstrate that inhibitors of PKC, CaM, MAPK and NF- κ B inhibit Hcy-induced MCP-1 and IL-8 production in cultured whole blood. Our results suggest that activation of these signaling pathways is involved in Hcy-induced chemokine production. Considering the fact that abnormally activated PKC, CaM, MAPK, and NF- κ B play important roles in the initiation and progression of autoimmune and cognitive diseases^[19-22], our study provides useful clues as to why Hcy may be involved in these diseases.

Materials and methods

Human whole blood culture The investigation conforms to the principles outlined in the Declaration of Helsinki. The human whole blood cultures were slightly modified from our previous studies^[23,24]. Briefly, blood from healthy donors was drawn into heparinized syringes. Whole blood was then placed on a rotator and incubated at 37 °C in an atmosphere containing 5% CO₂. Cell viability was evaluated by Trypan blue exclusion. Only cell preparations with a 95% or greater viability were used.

Measurement of MCP-1 and IL-8 protein secretion Human whole blood was treated with Hcy for indicated times and/or preincubated for 60 min with genistein, tyrphostin, calphostin C, RO-31-8220, W7, SB 203580, PD 98059, and curcumin or other pharmacological reagents. The plasma was harvested and transferred to other polypropylene tubes and stored at -30 °C for not more than 1 week before measurement of chemokines MCP-1 and IL-8 protein concentrations in the plasma, which were determined by ELISA (R&D Systems Inc, Minneapolis, MN).

Chemicals *L*-homocysteine (*L*-Hcy), *L*-cysteine,

L-methionine, genistein, tyrphostin, and pyrrolidine dithiocarbamate (PDTC) were purchased from Sigma Co (St Louis, MO). Calphostin C, RO-31-8220, W7, SB 203580, PD 98059, and curcumin were purchased from Calbiochem Co (La Jolla, CA). 2'-7'-DCFH-DA was obtained from Molecular Probes (Eugene, OR). RPMI-1640 was purchased from Gibco Laboratories (Grand Island, NY). Other chemicals were purchased from the Chinese Chemical Co (Beijing, China).

Statistical analysis Results are expressed as mean \pm SEM. The number of samples used for each group is presented in the figure legends. The data were analyzed using one-way ANOVA and further analyzed using the Student-Newman-Keuls test for multiple comparisons within treatment groups or the *t*-test (unpaired test with Welch's correction) for comparison between two groups with non-normal distribution. *P*<0.05 was considered a significant difference between treatment groups.

Results

Effect of *L*-methionine and *L*-cysteine on MCP-1 and IL-8 production from human whole blood To understand the role of thiol residues in Hcy-induced chemokine production, human whole blood was treated with sulfur-containing amino acids, *L*-methionine and *L*-cysteine 100 μ mol/L for 32 h. Neither *L*-methionine nor *L*-cysteine elevated the production of MCP-1 and IL-8 in cultured human whole blood (Figure 1A, 1B). These data suggest that the thiol residues do not play an important role in the Hcy mechanisms.

PKC, PTK, and CaM in Hcy-induced secretion of MCP-1 and IL-8 A substantial body of evidence indicates that activation of PKC, CaM, PTK, MAPK, and NF- κ B may

Figure 1. Effects of *L*-methionine (Met) and *L*-cysteine (Cys) on the secretion of MCP-1 and IL-8 in cultured human whole blood. The levels of MCP-1 (A) and IL-8 (B) in cultured human whole blood were measured by ELISA assays after incubation with Met or Cys 100 μ mol/L for 32 h. *n*=6. Mean \pm SEM. ^b*P*<0.05 vs corresponding untreated control (con) group.

be involved in chemokine production. Therefore, we hypothesize that such signaling pathways might contribute to Hcy-induced chemokine expression and secretion in cultured whole blood. Human whole blood was pretreated with inhibitors of CaM (W7, 28–280 $\mu\text{mol/L}$), PKC (calphostin C, 50–500 nmol/L and RO-31-8220, 10–100 nmol/L), PTK (genistein, 2.6–26 $\mu\text{mol/L}$ and tyrphostin, 0.5–5 $\mu\text{mol/L}$). CaM and PKC inhibitors significantly inhibited Hcy-induced MCP-1 and IL-8 production in cultured human whole blood (Figure 2). However, the inhibitors of PTK had no obvious effect on chemokine production (Figure 3). These data show that the activated signaling pathways of PKC and CaM are involved in the Hcy-induced production of MCP-1 and IL-8 in cultured whole blood.

Figure 2. Effects of CaM and PKC inhibitors on Hcy-induced MCP-1 (A) and IL-8 (B) production in cultured human whole blood. Cultured whole blood was pretreated with the CaM inhibitor W7 or the PKC inhibitors calphostin C (Cal) and RO 31-8220 (RO) for 60 min and then stimulated by Hcy 100 $\mu\text{mol/L}$ for 32 h. $n=4$. Mean \pm SEM. ^b $P<0.05$ vs the Hcy only group.

Figure 3. Effects of PTK blockers on Hcy-induced MCP-1 (A) and IL-8 (B) in cultured human whole blood. Cultured whole blood was pretreated with the PKC inhibitors tyrphostin and genistein for 60 min and then stimulated by Hcy 100 $\mu\text{mol/L}$ for 32 h. $n=4$. Mean \pm SEM. ^b $P<0.05$ vs the Hcy-treated only group.

MAPK and NF- κ B in Hcy-induced MCP-1 and IL-8 production To further study the role of the downstream signaling molecules of PKC and CaM, such as MAPK and NF- κ B, in the Hcy-induced MCP-1 and IL-8 production, the inhibitors of ERK1/2 MAPK (PD 98059, 2–20 $\mu\text{mol/L}$), p38 MAPK (SB 203580, 0.6–6 $\mu\text{mol/L}$), JNK MAPK (curcumin, 2–10 $\mu\text{mol/L}$), and NF- κ B (PDTC, 10–100 nmol/L) were added to cultured whole blood for 60 min, respectively. This was followed by stimulation with Hcy 100 $\mu\text{mol/L}$ for 32 h. As shown in Figure 4, MAPK (p38, ERK1/2, and JNK) inhibitors significantly inhibited Hcy-induced MCP-1 and IL-8 production in cultured human whole blood. In addition, the NF- κ B inhibitor PDTC also prevented Hcy-induced

Figure 4. Effects of MAPK blockers on Hcy-induced MCP-1 (A) and IL-8 (B) in cultured human whole blood. Cultured whole blood was pretreated with the p38 MAPK inhibitor SB 203580 (SB), or the ERK1/2 inhibitor PD 98059 (PD) or the JNK inhibitor curcumin (CU) for 60 min and then stimulated by Hcy 100 μmol/L for 32 h. $n=3$. Mean±SEM. ^b $P<0.05$ vs the Hcy-treated only group.

MCP-1 and IL-8 production in the cultured whole blood (Figure 5A, 5B). These data show that the activation pathways of MAPK and NF-κB are involved in the regulation of the Hcy-induced secretion of MCP-1 and IL-8. In the range of inhibitors examined, Hcy (10–1000 μmol/L) did not significantly increase LDH release as compared with the control (data not shown), indicating that Hcy plus the inhibitors did not have an obvious toxic effect on human whole blood.

Influence of PPAR γ activators on Hcy-induced MCP-1 and IL-8 production Cultured whole blood was pretreated with the activators of PPAR γ (ciglitazone 30 μmol/L and troglitazone 10 μmol/L) for 60 min, respectively. It is followed by stimulation with Hcy 100 μmol/L for 32 h. The

Figure 5. Effects of NF-κB on Hcy-induced MCP-1 (A) and IL-8 (B) in cultured human whole blood. Cultured whole blood was pretreated with the NF-κB inhibitor, PDTC (10–100 nmol/L) for 60 min and then stimulated with Hcy 100 μmol/L for 32 h. $n=3$ independent experiments. Mean±SEM. ^b $P<0.05$ vs the Hcy-treated only group.

data showed that PPAR γ activators depressed the Hcy-induced MCP-1 production but not IL-8 production in the cultured whole blood (Figure 6A, 6B).

Discussion

Our previous work showed that an increased Hcy level promoted the production of MCP-1 and IL-8 in cultured whole blood. This suggests that hyperhomocysteinemia may upregulate MCP-1 and IL-8 levels in plasma and consequently promote the initiation and progression of atherosclerosis and venous thrombosis. Our present study demonstrated that activated signaling pathways such as PKC, CaM,

Figure 6. Effects of PPAR γ agonists on Hcy-induced MCP-1 (A) and IL-8 (B) in cultured human whole blood. Cultured whole blood was pre-treated with PPAR γ activators, ciglitazone (30 μ mol/L) and troglitazone (10 μ mol/L) for 60 min and then stimulated by Hcy 100 μ mol/L for 32 h, respectively. $n=3$ independent experiments. Mean \pm SEM. ^b $P<0.05$ vs the Hcy-treated only group.

MAPK, and NF- κ B were involved in the mediation of Hcy-induced MCP-1 and IL-8 production. These data indicate that Hcy promotes MCP-1 and IL-8 production in cultured whole blood by activating these signaling pathways. It further suggested that abnormally activated signaling pathways, which were caused by Hcy, might play roles as vital mechanisms underlying Hcy-mediated inflammatory, autoimmune, and cognitive diseases.

PKC is thought to play an important role in Hcy-induced MCP-1 production in cultured vascular smooth muscle cell lines, but not in endothelial lines^[25,26]. Our present results shows that the activation of PKC is necessary for both IL-8 and MCP-1 production induced by Hcy, since calphostin C and RO31-8220, inhibitors of PKC, significantly reduced MCP-

1 and IL-8 synthesis. No inhibitory effect was observed with the PTK inhibitors, genistein and tyrphostin, which indicates that protein tyrosine kinase might not be involved in Hcy-mediated MCP-1 and IL-8 synthesis. Previous studies have also shown that calcium/CaM plays an important role in the mediation of IL-8 production in several other cell systems^[27,28]. To test whether calcium/CaM is involved in the Hcy-induced chemokine synthesis, we used W7, a potent inhibitor of CaM, to study its influence on Hcy-induced chemokine synthesis in cultured whole blood. Our data demonstrated that W7 significantly decreased both MCP-1 and IL-8 production. Taken together, these results reveal that both activated PKC and CaM are involved in Hcy-induced MCP-1 and IL-8 production in cultured whole blood. PTK, however, had no significant effect on Hcy action.

MAPKs represent a family of eukaryotic protein kinases involved in various cellular processes. Three parallel cascades are now commonly described, each of which is named after its end-moiety: p38, the extracellular signal regulated protein kinases (ERK), and stress activated protein kinase/c-Jun N-terminal kinases (JNK)^[29]. As the upstream signaling molecules of MAPK, the activated PKC and CaM may mediate the activation of MAPK, such as MEK, p38MAPK, and JNK. For example, as the intermediate signaling pathway molecules, MAPK is indispensable in the PKC-mediated signaling transduction system^[30,31]. Thus, we investigated specific downstream signaling molecules that could be potentially important as the targets of activated PKC and CaM. We demonstrated that PD98059, SB 203580, and curcumin, the selective inhibitors of MEK1, p38 MAPK, and JNK respectively, significantly decreased IL-8 and MCP-1 production. This data is consistent with other reports that MAPK is required for IL-8 and MCP-1 production in several other cell systems in response to various stimuli^[30].

NF- κ B is an important transcription factor in the initiation of cell growth and secretion. Consistent with its role as a primer in synthesis, NF- κ B binds to the I κ B site of various gene promoter regions^[32]. Our data demonstrate that Hcy-induced chemokine production is almost competently blocked by PDTTC, a specific inhibitor of NF- κ B. These results agree with those obtained in other studies^[33], suggesting that NF- κ B has a role in the regulation of IL-8 and MCP-1 production.

Another interesting finding is that PPAR- γ activation can lead to a decrease in Hcy-induced MCP-1 production in cultured whole blood. PPAR- γ is a ligand-activated transcription factor belonging to the nuclear receptor family. PPAR- γ is expressed in differentiated human mono/macrophages and functions as a regulator of cellular proliferation, differen-

tiation, and apoptosis^[34]. Although PPAR- γ seems to be absent from isolated monocytes, PPAR- γ can regulate monocyte/macrophage physiology^[34,35]. Furthermore, Jiang *et al*^[36] reported that incubation of human monocytes with the natural PPAR- γ ligand, or with synthetic agonists, inhibited the production of proinflammatory cytokines. Other studies showed that PPAR- γ inhibited the transcriptional activity of genes by interfering with transcription factors such as NF- κ B^[37]. Our data showed that Hcy-mediated MCP-1 and IL-8 production was NF- κ B-dependent, thereby the influence of activated PPAR- γ in the Hcy-induced chemokine production was detected. The activators of PPAR- γ significantly depressed the production of MCP-1 but not IL-8. It suggests that this is an important pathway for attenuating the damage of Hcy or other inflammatory mediators. The different inhibitory effects on MCP-1 and IL-8 production imply that the regulation of Hcy-induced MCP-1 and IL-8 production is slightly different, at least in the cultured whole blood system.

Our previous studies and other work showed that Hcy potentiated lymphocyte proliferation. Also the thiol-containing compounds, such as cysteine had similar effects on lymphocyte proliferation^[17,18]. The other compounds without thiol have no such effect. This suggests that thiol residue plays a key role in Hcy-induced lymphocyte proliferation. Our current studies found that thiol-containing compounds, such as cysteine and methionine, failed to promote MCP-1 and IL-8 production in the cultured whole blood. These results are consistent with previous work^[38], suggesting that thiol may play a less important role in Hcy-induced chemokine production. Thus, there is the possibility that different sites of Hcy are responsible for different Hcy action.

Our current research has three implications; first, Hcy-induced MCP-1 and IL-8 production is mediated by activated signaling pathways such as PKC, CaM, MAPK, and NF- κ B. Second, although the exact mechanism is unclear, current studies suggest that Hcy is able to activate the PKC, CaM, MAPK, and NF- κ B signaling pathways. When we take the consideration that these activated signaling pathways are involved in many pathological and physiological functions, especially, in the initiation and progression of many immune and cognitive diseases, our findings shed light on a possible answer to why hyperhomocysteinemia has been found to be linked with not only cardiovascular diseases, but also so many inflammatory, autoimmune and cognitive diseases. Finally, activated PPAR- γ inhibited Hcy-induced MCP-1 production. This study provides a novel approach to partly attenuate the proatherogenic effect of hyperhomocysteinemia.

Abstract

Aim: To investigate the effects of pravastatin, a potent 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor, on impaired endothelium-dependent relaxation induced by lysophosphatidylcholine (LPC), the major component of oxidized low-density lipoprotein, in rat thoracic aorta. **Methods:** Both the endothelium-dependent relaxation response to acetylcholine and the endothelium-independent relaxation response to sodium nitroprusside of aortic rings were measured by recording isometric tension after the rings were exposed to LPC in the absence or presence of pravastatin to estimate the injury effect of LPC and the protective effect of pravastatin on the aortic endothelium, respectively. **Results:** Exposure of aortic rings to LPC (1–10 $\mu\text{mol/L}$) for 30 min induced a significant concentration-dependent inhibition of endothelium-dependent relaxation to acetylcholine, but did not affect endothelium-independent relaxation in response to sodium nitroprusside. Pre-incubation of aortic rings with pravastatin (0.3–3 mmol/L) for 15 min and then co-incubation of the rings with LPC (3 $\mu\text{mol/L}$) for another 30 min significantly attenuated the inhibition of endothelium-dependent relaxation induced by LPC. This protective effect of pravastatin (1 mmol/L) was abolished by *N*^G-nitro-*L*-arginine methyl ester (30 $\mu\text{mol/L}$), an inhibitor of nitric oxide synthase, but not by indomethacin (10 $\mu\text{mol/L}$), an inhibitor of cyclooxygenase. Moreover, protein kinase C inhibitor chelerythrine (1 $\mu\text{mol/L}$), the superoxide anion scavenger superoxide dismutase (200 kU/L), and the nitric oxide precursor *L*-arginine (3 mmol/L) also improved the impaired endothelium-dependent relaxation induced by LPC, similar to the effects of pravastatin. **Conclusion:** Pravastatin can protect the endothelium against functional injury induced by LPC in rat aorta, a fact which is related to increasing nitric oxide bioavailability.

Introduction

Endothelial dysfunction is an early step in the pathogenesis of atherosclerosis and is characterized by an impaired endothelium function associated with a decreased production of nitric oxide (NO), reduced vasodilatation or abnormal vasoconstriction in response to acetylcholine. Oxidized low-density lipoprotein (ox-LDL) is an oxidative product of native LDL *in vivo*. It has been well established that ox-LDL plays an important role in the development of atherosclerosis^[1]. Lysophosphatidylcholine (LPC) is the major

component of ox-LDL^[2–3]. LPC has been shown to increase the production of superoxide anions by activation of protein kinase C (PKC)^[4] and has been implicated in impaired endothelium-dependent relaxation^[2,3]. Exposure of normal blood vessels to LPC *in vitro* also mimicked the inhibitory effects of ox-LDL on endothelium-dependent relaxation^[2,3]. Therefore, preventing the deleterious effects of LPC on endothelium is an effective approach for preventing the development of atherosclerosis.

Statins, 3-hydroxy-3-methylglutaryl coenzyme A (HMG-

CoA) reductase inhibitors, are cholesterol-lowering drugs and widely used in the treatment of hypercholesterolemia to prevent the development of atherosclerosis^[5,6]. However, many studies have shown that statins have some beneficial effects on the cardiovascular system-independent of their cholesterol-lowering effect, such as restoring the endothelium-dependent relaxation function^[7,8], preventing the adhesion of monocytes to endothelial cells^[8], inhibiting the aggregation of platelets^[9], suppressing the proliferation of vascular smooth muscle cells^[10], and regulating angiogenesis^[11] and blood pressure^[12], which may be related to the up-regulation of nitric oxide synthase (NOS) expression. In addition, statins have been demonstrated to have anti-oxidative properties, as shown by their ability to reduce LDL oxidation^[13] and scavenge oxygen-derived free radicals^[14]. Pravastatin is a potent inhibitor of HMG-CoA reductase. Recently, a number of studies have demonstrated that pravastatin significantly inhibits the production of superoxide anions stimulated by phorbol ester in vascular endothelial cells^[14], suppresses the increase in oxidative stress induced by LPC in vascular smooth muscle cells^[15], and improves the impairment of endothelium-dependent relaxation in humans and animals with atherosclerosis and diabetes^[16-18]. Therefore, it is important to determine whether pravastatin protects the vascular endothelium against damage due to LPC. In the present study, we sought to investigate the effects of pravastatin and its mechanisms on impaired endothelium-dependent relaxation induced by LPC in isolated rat aortic rings.

Materials and methods

Chemicals All chemicals were of the highest purity available. LPC, phenylephrine, acetylcholine, sodium nitroprusside, *L*-arginine, *N*^G-nitro-*L*-arginine methyl ester (*L*-NAME), indomethacin, and chelerythrine were purchased from Sigma Chemical Co (St Louis, MO, USA). Superoxide dismutase (SOD) was the product of Changsha Biological Pharmaceutical Factory (Hu-nan, China). Pravastatin was kindly presented by Blue Treasure Pharmaceutical Factory (Guangdong, China). They were dissolved in distilled water and diluted with Krebs' buffer before use.

Organ chamber experiments The study protocol was approved by the Animal Care and Use Committee of Central South University. Male Sprague-Dawley rats weighing 200-220 g were used. Rats were anaesthetized by intraperitoneal injection of sodium pentobarbital (30 mg/kg). The thoracic aorta was immediately isolated and placed in 4 °C Krebs' bicarbonate buffer of the following composition (in mmol/L): 118.3 NaCl, 4.7 KCl, 2.5 CaCl₂, 1.2 MgSO₄, 1.2 KH₂PO₄,

25.0 NaHCO₃, 11.0 glucose. The thoracic aorta was then dissected free of adherent connective tissue. The aortic segment was cut into rings of 3-4 mm in length, taking special care to avoid stretching or touching the luminal surface of the rings. The rings were suspended horizontally between two stirrups in organ chambers filled with 5 mL Krebs' solution at 37 °C and aerated continuously with 95 % O₂ and 5 % CO₂. One stirrup was connected to an anchor and the other was connected to a force transducer for recording isometric tension. The solution in the chambers was changed every 15-20 min. Rings were equilibrated for 60 min under 2 g resting tension and then challenged with 60 mmol/L KCl at least three times until a reproducible maximal contractile response was obtained. After repeated washing and a further equilibration period of 30 min, rings were contracted with a submaximal concentration of phenylephrine (1 μmol/L) and relaxed with cumulative concentrations of acetylcholine (0.03-3 μmol/L) at the plateau phase of the phenylephrine contraction to assess the integrity of the endothelium. The rings with the maximal relaxation (E_{max}) to 3 μmol/L acetylcholine of more than 80 % were considered to be endothelium-intact and used in the study.

Experimental protocol After each ring was serially washed and re-equilibrated, the rings of the control group were incubated for 45 min with Krebs' buffer. The rings of LPC group were incubated with Krebs' buffer for 15 min and then exposed to LPC (1-10 μmol/L) for 30 min. In the pravastatin group, the rings were pre-incubated with various concentrations of pravastatin (0.3-3 mmol/L) for 15 min before exposure to 3 μmol/L LPC for 30 min, respectively. To determine whether increasing prostacyclin or NO production is involved in the protective effect of pravastatin on impaired endothelium-dependent relaxation induced by LPC, aortic rings were pretreated with indomethacin 10 μmol/L, an inhibitor of cyclooxygenase or *L*-NAME 30 μmol/L, an inhibitor of NOS in the presence of pravastatin (1 mmol/L) for 15 min and then exposed to 3 μmol/L LPC for 30 min.

To determine whether the activation of PKC, increased production of superoxide anions, and decreased NO synthesis contribute to the detrimental effects of LPC, rings were pre-incubated with chelerythrine (1 μmol/L), an inhibitor of PKC, SOD (200 kU/L), a scavenger of superoxide anions, or *L*-arginine (3 μmol/L), a precursor of NO for 15 min and then exposed to LPC (3 μmol/L) for another 30 min.

After the above incubations, all rings were re-contracted with 1 μmol/L phenylephrine and concentration responses to acetylcholine (0.03-3 μmol/L) were repeated. Before finishing the experiment, the relaxation response to sodium ni-

tropresside (10 $\mu\text{mol/L}$) at the plateau phase of the phenylephrine contraction was also tested in isolated aortic rings.

Statistical analysis Results are expressed as Mean \pm SEM. Relaxation and the maximal relaxation (E_{max}) produced by acetylcholine was calculated and expressed as the percentage of contraction elicited by phenylephrine. The half-maximal relaxation (EC_{50}) response to acetylcholine was estimated by linear regression from log concentration-effect curves. Differences between groups were tested for statistical significance by analysis of variance followed by the Newman-Keuls test. $P<0.05$ was considered significant.

Results

Effects of LPC on endothelium-dependent relaxation

There was no difference in the relaxation response to acetylcholine in rat aortic rings during the initial examination between groups (data not shown). After incubation with Krebs' solution for 45 min, acetylcholine (0.03–3 $\mu\text{mol/L}$) still evoked a significant concentration-dependent relaxation in aortic rings in the control group during the later repeat examination (Figure 1), in which the E_{max} value reached 90.4% \pm 4.3%, and the EC_{50} value was 74.9 \pm 9.6 nmol/L (Table 1). Exposure of aortic rings to LPC (1–10 $\mu\text{mol/L}$) for 30 min significantly inhibited the endothelium-dependent relaxation response to acetylcholine in a dose-dependent manner; there were lower E_{max} and higher EC_{50} values in aortic rings of the LPC groups compared with the control rings

Figure 1. Effect of lysophosphatidylcholine on the endothelium-dependent relaxation in isolated rat aortas. $n=5$. Mean \pm SEM. ^b $P<0.05$, ^c $P<0.01$ vs control group.

The maximal relaxation (E_{max}) response to acetylcholine (ACh) 3 $\mu\text{mol/L}$ of rat aortic rings was expressed as percentage of contraction elicited by phenylephrine 1 $\mu\text{mol/L}$. The half-maximum effective concentration (EC_{50}) response to ACh was calculated by linear regression from lg concentration-effect curves of ACh. Pravastatin: PT; lysophosphatidylcholine: LPC; indomethacin: Indo; chelerythrine: Che; *L*-arginine: *L*-Arg.

(Figure 1, Table 1). These results indicated that LPC impaired the endothelium-dependent relaxation response to acetylcholine in rat aortic rings.

Effects of pravastatin on the inhibition by LPC Pre-incubation of rat aortic rings with pravastatin (0.3–3 mmol/L) for 15 min and then co-incubation of rat aortic rings with LPC 3 $\mu\text{mol/L}$ for 30 min attenuated the inhibitory effect of LPC on endothelium-dependent relaxation. The E_{max} value increased and the EC_{50} value was reduced in aortic rings of pravastatin groups compared with the LPC 3 $\mu\text{mol/L}$ group (Figure 2, Table 1).

Incubation of aortic rings with *L*-NAME (30 $\mu\text{mol/L}$) in the presence of pravastatin (1 mmol/L) for 15 min abolished the protective effect of pravastatin on the impairment of endothelium-dependent relaxation induced by LPC, whereas indomethacin did not change the beneficial effects of pravastatin. Significant differences were obtained when the E_{max} and EC_{50} values of the *L*-NAME group, but not of the indomethacin group were compared with those of pravastatin group (Figure 3, Table 1). In addition, pravastatin per se did not affect the endothelium-dependent relaxation of aortic

rings in the absence of LPC or endothelium-independent relaxation of aortic rings in the presence of LPC (data not shown).

Effects of chelerythrine, *L*-arginine, and SOD on the inhibition by LPC In an analogous manner, pre-incuba-

Figure 4. Effects of chelerythrine (Che), superoxide dismutase (SOD), and *L*-arginine (*L*-Arg) on the impaired endothelium-dependent relaxation of rat aortas induced by lysophosphatidylcholine (LPC). *n*=5. Mean±SEM. ^c*P*<0.01 vs control group. ^e*P*<0.05, ^f*P*<0.01 vs LPC 3 μmol/L group.

tion of aortic rings with chelerythrine (1 μmol/L), *L*-arginine (3 mmol/L), or SOD (200 kU/L) also decreased the inhibition of endothelium-dependent relaxation by LPC. Significant differences were observed when the *E*_{max} and *E*₅₀ values of chelerythrine, *L*-arginine, or SOD group were compared with those of LPC group (Figure 4, Table 1).

Discussion

The present study confirmed previous reports that LPC inhibited endothelium-dependent relaxation of isolated rat aortas in a concentration-dependent manner^[2], and demonstrated that pravastatin, an inhibitor of HMG-CoA reductase, reduced the inhibition by LPC on endothelium-dependent relaxation. The protective effect of pravastatin on the impairment of endothelium-dependent relaxation induced by LPC is very similar to that of chelerythrine, SOD, and *L*-arginine. These results suggest that pravastatin protects endothelium against injury from LPC and this may be related to enhancing the bioavailability of NO through increasing NO synthesis and decreasing NO oxidative inactivation in endothelial cells.

NO-mediated and endothelium-dependent relaxation is inhibited early in the atherosclerotic process, even before histological evidence of plaque formation is evident. Ox-LDL, an oxidative product of native LDL in endothelial

cells and/or macrophages which presents in atherosclerotic lesions, is primarily responsible for this inhibition^[1-3]. The inhibitory action of ox-LDL has generally been attributed to LPC, which is abundant in oxidized LDL and also accumulates in atherosclerotic lesions^[1-3]. Removal of LPC from ox-LDL with phospholipase B^[3] or albumin^[19] has been shown to render ox-LDL inactive, and conversely, direct treatment of arterial rings with LPC can mimic the inhibitory effects of ox-LDL on endothelium-dependent relaxation^[2,3]. In the present study, we also confirmed that exposure of rat aortic rings to LPC (1–10 $\mu\text{mol/L}$) did inhibit the endothelium-dependent relaxation response to acetylcholine, but did not affect the endothelium-independent relaxation response to sodium nitroprusside. These results are consistent with other studies^[2,3], and suggest that the concentrations of LPC used in the current study had endothelium-specific effects that were not due to its cytotoxicity.

Although the precise mechanisms responsible for the inhibition of endothelium-dependent relaxation induced by LPC have not been elucidated, increasing oxidative degradation of NO and decreasing production of NO in endothelial cells could be implicated in this inhibition. A number of studies^[4,20] have suggested that LPC stimulates superoxide anion production by activating PKC in vascular cells, which can inactivate NO by oxidation. In addition, LPC has been shown to inhibit the high-affinity arginine transporter in endothelial cells, decrease the availability of arginine, and subsequently reduce the synthesis of NO; supplementation with exogenous *L*-arginine reversed the inhibition by LPC^[21]. In the present study, we found that chelerythrine, an inhibitor of PKC, improved the impairment of endothelium-dependent relaxation by LPC. Furthermore, the current study also demonstrated that the inhibition of endothelium-dependent relaxation induced by LPC was completely reversed by SOD, a scavenger of superoxide anions and by *L*-arginine, a precursor of NO. Taken together, these findings strongly support the proposal that LPC-induced inhibition of endothelium-dependent relaxation may be due to decreasing the bioavailability of NO via increasing the oxidative degradation of NO and reducing the synthesis of NO.

Evidence has accumulated that ox-LDL plays a critical role in atherogenesis, and LPC, the major lipid constituent of ox-LDL, has been recognized as an important factor that triggers disturbed endothelium-dependent vasodilatation of atherosclerosis. Therefore, finding effective drugs to reverse endothelial dysfunction induced by LPC may prevent the development of atherosclerosis. Pravastatin, like the other statins, is a competitive inhibitor of HMG-CoA reductase, which markedly reduces hepatic cholesterol *in vivo* by in-

hibiting the rate-limiting step in cholesterol synthesis catalyzed by HMG-CoA reductase^[5]. A number of studies have demonstrated that pravastatin can reduce adverse cardiovascular events in patients suffering from coronary artery disease with or without hypercholesterolemia^[5,22]. Recently, some authors have reported that pravastatin improved the defective endothelium-dependent vasodilatation of atherosclerotic vessels before the reduction of plasma cholesterol levels in humans and animals^[16-18]. However, it is still unknown that whether pravastatin acts directly against the adverse effect of LPC on endothelium-dependent relaxation in addition to its cholesterol-lowering action. This study provides the first evidence that pravastatin protects endothelium against injury induced by LPC in isolated rat aortas. Although experiments *in vitro* can not completely mimic the conditions *in vivo* and are not good for studying the chronic effects of drugs, they are useful because they can exclude the effects of many factors *in vivo* and directly investigate the effects of drugs in some (pathological) conditions. Therefore, the endothelium-dependent relaxation of isolated aortic rings is extensively used to measure the function of endothelium in physiological conditions and some pathological conditions, such as atherosclerosis, or mimic intervention with ox-LDL or LPC.

The mechanisms by which pravastatin improves endothelial function are not completely understood. Results from the present study indicate that the protective effect of pravastatin on vascular endothelium is related to increasing the synthesis of endothelial NO. We found that the protective effect of pravastatin on the inhibition of endothelium-dependent relaxation induced by LPC was similar to that of *L*-arginine. Furthermore, the beneficial effect of pravastatin was reversed by *L*-NAME, but not by indomethacin. Another study has reported that pravastatin can up-regulate the expression of NOS and enhance the production of NO in endothelial cells^[23]. Treatment with statins including pravastatin of patients and rabbits with atherosclerosis results in up-regulated eNOS expression, increased NO synthesis, and simultaneously improved endothelium-dependent relaxation, which was reversed by *N*^o-nitro-*L*-arginine^[24,25]. These findings suggested that pravastatin enhanced the production and release of NO from endothelium to improve endothelial function. However, Parker *et al*^[26] reported that treatment of normal rats with simvastatin, but not with pravastatin, impaired the endothelium-dependent relaxation of their isolated aortic rings although it was able to enhance eNOS expression in endothelial cells. Chen *et al*^[27] reported that pravastatin did not influence IL-1 β -induced NO synthesis in vascular smooth muscle cells. The discrepan-

cies between our findings and theirs could be attributed to the different functional states of vascular endothelium, in different cells and under treatment with different stimulated factors or different drugs. In fact, many studies have shown that pravastatin did increase NO production and restore endothelium-dependent relaxation in atherosclerotic animals and humans^[16–18,25]. Another potential mechanism by which pravastatin improved endothelial function is by reducing the oxidative inactivation of NO. Recent investigations have demonstrated that statins can decrease lipid peroxidation production^[7], suppress NADPH oxidase activity^[28], and increase the activity of catalase^[29], and superoxide dismutase^[7], which decreases the generation of oxygen free radicals resulting in reduction of NO activation. Moreover, a number of studies have shown that pravastatin can also reduce superoxide anion production by suppressing PKC activity in vascular cells^[14,15]. In the present study, we demonstrated that chelerythrine, an inhibitor of PKC and SOD, a scavenger of superoxide anions, reversed the inhibition of endothelium-dependent relaxation induced by LPC, which was similar to effects of pravastatin. These results indirectly suggest that the protective effect of pravastatin against the damage to endothelium induced by LPC is related to decreasing NO oxidative inactivation via suppressing PKC activity and reducing superoxide anion production.

In conclusion, the present study demonstrates for the first time that pravastatin has a protective effect on endothelium against injury elicited by LPC, and that this protective effect is related to enhancing the bioavailability of NO through increasing NO synthesis and decreasing NO oxidative inactivation in endothelial cells.

Introduction

Between the end of 2002 and June 2003, a severe epidemic disease called severe acute respiratory syndrome (SARS) broke out in China and quickly spread to more than 30 other countries. A novel coronavirus, SARS-CoV, was identified as the etiological agent of SARS infection by using biophysical and biochemical techniques^[1–3]. Coronavirus (CoV) is a positive-stranded RNA virus and involves the largest viral RNA genome known to date. Phylogenetic studies have shown that SARS-CoV is a previously unknown coronavirus, which is neither a member nor a mutant of any known coronavirus group, and is believed to be a novel human

Abstract

Aim: To characterize enzymatic activity of severe acute respiratory syndrome (SARS) coronavirus (CoV) 3C-like protease (3CL^{pro}) and its four site-directed mutants. **Methods:** Based on the fluorescence resonance energy transfer (FRET) principle using 5-[(2'-aminoethyl)-amino] naphthalenesulfonic acid (EDANS) and 4-[[4-(dimethylamino) phenyl] azo] benzoic acid (Dabcyl) as the energy transfer pair, one fluorogenic substrate was designed for the evaluation of SARS-CoV 3CL^{pro} proteolytic activity. **Results:** The kinetic parameters of the fluorogenic substrate have been determined as $K_m=404 \mu\text{mol}\cdot\text{L}^{-1}$, $k_{\text{cat}}=1.08 \text{ min}^{-1}$, and $k_{\text{cat}}/K_m=2.7 \text{ mmol}^{-1}\cdot\text{L}\cdot\text{min}^{-1}$. SARS-CoV 3CL^{pro} showed substantial pH and temperature-triggered activity switches, and site-directed mutagenesis analysis of SARS-CoV 3CL^{pro} revealed that substitutions of His⁴¹, Cys¹⁴⁵, and His¹⁶³ resulted in complete loss of enzymatic activity, while replacement of Met¹⁶² with Ala caused strongly increased activity. **Conclusion:** This present work has provided valuable information for understanding the catalytic mechanism of SARS-CoV 3CL^{pro}. This FRET-based assay might supply an ideal approach for the exploration SARS-CoV 3CL^{pro} putative inhibitors.

coronavirus, possibly originating from a non-human host^[4].

Proteolytic processing of viral polyproteins is a vital step in the replication cycle of many positive-strand RNA viruses and such processing is commonly performed by virus-genome encoded protease^[5,6]. The open reading frame (ORF) of the coronavirus replicase gene for encoding the proteins which is required for virus replication and transcription, encompasses more than 20 000 nucleotides^[7,8] and encodes two overlapping polyproteins, pp1a (replicase1a, around 450 kDa) and pp1ab (replicase1ab, approximately 750 kDa). It is known that the replicase gene features the sequence motifs of both papain-like protease and 3-chymotrypsin like pro-

tease (3CL^{pro})^[9,10]. 3CL^{pro}, which is also called main protease, functions as a key protease to control the activities of coronavirus replication complexes.

It has been concluded from previous research data that 3CL^{pro}-mediated processing pathways are conserved in coronaviruses. Coronavirus main proteases employ cysteine and histidine residues as the catalytic dyad in the catalytic site but lack a corresponding third catalytic site^[5,11–13], which is an acidic residue in chymotrypsin. Previous research has also confirmed that substrate specificities for the coronavirus main proteases are well defined, with the known proteolytic sites involving bulky hydrophobic residues (mainly leucine/ isoleucine) at the P2 position, conserved glutamine at the P1 position, and small aliphatic residues at the P1' position^[14,15]. In addition, secondary structural studies for substrates of SARS-CoV 3CL^{pro} have revealed that substrates with more beta-sheet like structures tend to be cleaved quickly^[16]. The determination of the crystal structures for human coronavirus (strain 229E) 3CL^{pro} and the inhibitor complex of porcine coronavirus (transmissible gastroenteritis virus, TGEV) 3CL^{pro} also confirmed a remarkable degree of conservation of the substrate binding sites for coronavirus 3CL^{pro}^[17]. The recently reported crystal structures of SARS-CoV 3CL^{pro} and its complex with an inhibitor revealed substantial pH-dependant conformational changes that correlate well with the varying activity of 3CL^{pro} at different pH levels, and an unexpected model of inhibitor binding^[18]. In fact, it has already been shown that 3CL^{pro} is an ideal target for screening anti-virus agents^[15,19,20]. Like other 3CL^{pro}, SARS-CoV 3CL^{pro} might become an attractive target in discovering new agents for the treatment of SARS^[17].

In our previous work, we reported a 3D model of SARS-CoV 3CL^{pro} with its inhibitors, designed by virtual screening^[21], and the molecular cloning, expression and purification of SARS-CoV 3CL^{pro}, with a preliminary study on its mass spectral characterization^[22].

To date, the proteolytic activity of SARS-CoV 3CL^{pro} has been almost determined by substrate-analog peptide cleavage assays using conventional RP-HPLC techniques^[16]. In fact, the fluorescence-based assay is another method for quantitative protease activity assay, eg fluorescence resonance energy transfer (FRET) has been successfully used to develop spectrophotometric assays for many proteases^[23–25]. The FRET-based method is more sensitive and less time-consuming compared with the RP-HPLC technique. Recently, a fluorogenic 14-amino acid peptide has been reported to measure SARS-CoV 3CL^{pro} enzymatic activity^[26]. In the present report, we describe how this methodology can be used to design a 12-amino acid fluorogenic peptide with

EDANS/ Dabcyl as the fluorescence quenching pair. This fluorogenic substrate has been successfully used to characterize the proteolytic activities of wild type SARS-CoV 3CL^{pro} at different pH levels and temperatures, and its four site-directed mutants including two catalytic residues and two substrate-binding sites as well. To our knowledge, such a fluorescence-based assay is the first to be used for site-directed mutation analysis of SARS-CoV 3CL^{pro}. We hope that this present FRET-based assay will supply an ideal platform for the exploration of SARS-CoV 3CL^{pro} putative inhibitors.

Materials and methods

Materials All chemicals were of HPLC grade and purchased from Sigma (St Louis, MO). The Ni-NTA chelating affinity column, protease for tag-cleavage and low molecular weight marker for SDS-PAGE were from Amersham Pharmacia Biotech (Uppsala, Sweden).

Cloning, expression and purification of SARS-CoV 3CL^{pro} SARS-CoV 3CL^{pro} was cloned, expressed, and purified, as described by Sun *et al*^[22]. The purified His-tagged SARS-CoV 3CL^{pro} was analyzed by SDS-PAGE, concentrated by centrprep (Milipore), and stored in sodium phosphate 20 mmol·L⁻¹ pH 7.5/NaCl 100 mmol·L⁻¹/dithiothreitol (DTT) 5 mmol·L⁻¹/ethylene diaminetetraacetic acid (EDTA) 1 mmol·L⁻¹ at 4 °C. The structural integrity was analyzed by circular dichroism (CD).

Site-directed mutagenesis of SARS-CoV 3CL^{pro} Site-directed mutagenesis was effected by using a modified recombinant PCR method. Four mutant SARS-CoV 3CL^{pro} (SARS-CoV 3CL^{pro} His⁴¹Ala, Cys¹⁴⁵Ala, His¹⁶³Ala, and Met¹⁶²Ala) were prepared with the QuickChange site-directed mutagenesis kit (Stratagene) using pQE30-SARS-CoV 3CL^{pro} as a template. The nucleotide sequences of the primers used for site-directed mutagenesis were given in Table 1. The pQE30-SARS-CoV 3CL^{pro} plasmids encoding mutant forms of SARS-CoV 3CL^{pro} were verified by sequencing and then transformed into *E coli* M15 cells, and the mutant proteins were expressed and purified in a similar procedure to that for the wild type protease. The purity and structural integrity of the mutant proteins were analyzed by SDS-PAGE. The circular dichroism (CD) spectra of four site-directed mutants were compared with those of wild type SARS-CoV 3CL^{pro} to exclude the possibility of structural misfolding caused by site-directed mutation (data not shown).

Synthesis of fluorogenic substrate The 12-amino acid fluorogenic substrate EDANS-Val-Asn-Ser-Thr-Leu-Gln-Ser-Gly-Leu-Arg-Lys(Dabcyl)-Met was synthesized and

characterized using a modified procedure described by Garcia-Echeverria and Rich^[27]. *N*^α-tert-butyloxycarbonyl (Boc)-protected amino acids were used in all coupling steps. The base liable-protecting group, 9-fluorenylmethoxycarbonyl (Fmoc), was used for the protection of the side chain of lysine, while the benzyl (Bzl) group was employed for the protection of C-terminal carboxyl group of the peptide. The Boc protecting group was removed before coupling by using HCl 4 mol/L in dioxane. Peptide couplings were achieved by overnight reaction with 1,3-dicyclohexylcarbodiimide (DCC) or 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride and 1-hydroxybenzotriazole (HOBT) in *N,N*-dimethylformamide (DMF). After completion of synthesis, the benzyl group was removed by hydrogenolysis in methanol. The commercially available 5-[(2'-aminoethyl)-amino] naphthalenesulfonic acid (EDANS) and 4-[[4-(dimethylamino) phenyl] azo] benzoic acid (Dabcyl) groups were attached to the peptides with conventional condensation reactions^[28], and the Fmoc group was removed from the lysine ε-amine group by treatment with piperidine-*N,N*-dimethylformamide (1:1 v/v) to give the final fluorogenic substrate. The crude products were purified by means of HPLC on a Kromasil 7-μm C₈ column (25 mm×250 mm). The purity of the final products was evaluated by reversed-phase HPLC on a Kromasil 5-μm C₈ column (4.6 mm×250 mm). The integrity of the purified peptides was determined by LCQ-DECA mass spectrometry (ThermoFinnigan, San Jose, CA), and the observed molecular mass was found to agree with the calculated value.

Enzymatic activity assay Stock solution for the fluorogenic substrate was prepared in Me₂SO and stored at 4 °C. Subsequent dilutions were performed using the assay buffer (sodium phosphate 20 mmol/L, pH 7.5, NaCl 100 mmol/L,

DTT 5 mmol/L, EDTA 1 mmol/L) with the final concentration of Me₂SO less than 1 % (v/v).

Initial fluorimetric assays were performed in a 1 mL quartz cuvette with a 1 cm path length at 25 °C. During the assay, SARS-CoV 3CL^{pro} (final concentration 1 μmol/L) was preincubated at 25 °C for 30 min in the cuvette containing the assay buffer, followed by the addition of the fluorogenic substrate stock solutions to a final concentration of 10 μmol/L. The increase in emission fluorescence intensity was recorded at 10 min intervals on a Hitachi F-2500 fluorescence spectrophotometer connected to a thermostat. When fluorescence was being measured, the instrument was first set to zero with the fluorogenic substrate itself in the assay buffer. Cleavage of the peptide as a function of time was followed by monitoring the emission fluorescence intensity at a wavelength of 490 nm upon excitation at 340 nm (slit width 10 nm), and the initial reaction velocity (*v*₀) was determined from the linear portion of the progress curve. The final emission fluorescence intensity of the totally hydrolyzed substrate was determined by adding excess SARS-CoV 3CL^{pro} until no emission fluorescence intensity change at a wavelength of 490 nm was recorded.

Kinetic parameters (*K*_m and *k*_{cat}) of SARS-CoV 3CL^{pro} for the fluorogenic substrate were determined by incubation of the substrate at different concentrations ranging from 1 mmol/L to 5 μmol/L with SARS-CoV 3CL^{pro} 1 μmol/L at 25 °C in the assay buffer. The reaction velocity (*v*₀) for each substrate concentration was averaged from three assay results. *K*_m and *k*_{cat} values were calculated by using a Lineweaver-Burk plot.

The relative enzymatic activity at varying pH levels was investigated at 25 °C in citric acid/phosphate buffer (pH =5, 6, 7, and 8) and glycine/NaOH buffer (pH=9, 10) containing

Table 1. Nucleotide sequences of the primers used for site-directed mutagenesis of SARS-CoV 3CL^{pro}*

CCTGTTGGAAGCTCCATATGAGCCATATAGCAGAAAGACAC	Reverse	SARS-CoV 3CL ^{pro} His ¹⁶³ Ala
GCGTGTCTTTCTGCTATGCGCATCATATGGAGCTTCC	Forward	SARS-CoV 3CL ^{pro} Met ¹⁶² Ala
GGAAGCTCCATATGATGCGCATAGCAGAAAGACACCG	Reverse	SARS-CoV 3CL ^{pro} Met ¹⁶² Ala

* The mutant codons in the oligonucleotide sequences are highlighted in boldface. SARS-CoV 3CL^{pro} amino acids are numbered continuously from the N-terminal residue, Ser¹, to the C-terminal residue, Gln³⁰³.

DTT 5 mmol/L, EDTA 1 mmol/L, SARS-CoV 3CL^{pro} 1 $\mu\text{mol/L}$ and fluorogenic substrate 10 $\mu\text{mol/L}$. The reaction velocity (v_0) at each pH value was measured in triplicate and averaged.

The enzymatic activity at different temperatures (10, 20, 30, 40, and 50 °C) was measured in an assay buffer containing SARS-CoV 3CL^{pro} 1 $\mu\text{mol}\cdot\text{L}^{-1}$ and substrate 10 $\mu\text{mol/L}$. The enzyme was equilibrated at the same temperature as that for the assay buffer and substrate solution before mixing. During the assay, the cuvette temperature was stabilized by a thermostat connected to a Hitachi F-2500 fluorescence spectrophotometer. The reaction velocity (v_0) at each temperature was the average of the three parallel assays and the reaction velocity at 40 °C was taken as 1.0.

The enzymatic activity of four site-directed mutants of SARS-CoV 3CL^{pro} (SARS-CoV 3CL^{pro} His⁴¹Ala, Cys¹⁴⁵Ala, His¹⁶³Ala, and Met¹⁶²Ala) was the average of three parallel assays performed in an identical way as described above for wild type SARS-CoV 3CL^{pro}.

Results and discussion

Fluorogenic substrate design and initial fluorimetric assay It is well established that the specificities of CoV 3CL^{pro} for the substrate involves bulky hydrophobic residues (mainly leucine/isoleucine) at the P2 position, conserved glutamine at the P1 position, and small aliphatic residues at the P1' position. A 12-amino acid peptide representing the NH₂-terminal autoprocessing site of TGEV 3CL^{pro} with the sequence of substrate-analog chloromethyl ketone inhibitor Cbz-Val-Asn-Ser-Thr-Leu-Gln-CMK was devised to separate the quencher from the fluorescent donor chromophore for designing the fluorogenic substrate in this study (Figure 1A), considering that a published cleavage experiment found that a 15-amino acid substrate involving these sequences could be efficiently cleaved by SARS-CoV 3CL^{pro}[17]. To ensure efficient internal quenching, a commercially available donor/quencher pair was chosen for this study: 5-[(2'-aminoethyl)-amino] naphthalenesulfonic acid (EDANS) and 4-[[4-(dimethylamino) phenyl] azo] benzoic acid (Dabcyl) (Figure 1B). These dyes had already been used in FRET-based procedures[25,29,30]. Most importantly, the EDANS/Dabcyl pair possessed adequate spectral overlap which allowed almost complete quenching of EDANS's fluorescence. The detailed experimental procedure for characterizing the enzymatic activity of SARS-CoV 3CL^{pro} was illustrated in Figure 2.

To evaluate the availability of the synthesized peptide as a potential substrate of SARS-CoV 3CL^{pro}, an initial fluo-

Figure 1. (A) Proposed design of fluorogenic substrate. Cleavage site is highlighted in boldface; D, the fluorescent donor chromophore; Q, quencher. (B) Structures and fluorescent properties of the donor/quencher pair EDANS/Dabcyl.

rimetric assay was performed. Comparison of the fluorescence emission spectrum of only the fluorogenic substrate (data not shown) with those spectra incubated with SARS-CoV 3CL^{pro} (Figure 3A) clearly showed that the Dabcyl group almost exclusively quenched the donor emission of the EDANS fluorophore in the fluorogenic substrate and the fluorogenic substrate was efficiently hydrolyzed by SARS-CoV 3CL^{pro}. The obvious emission fluorescence intensity enhancement over time implies that the fluorogenic substrate is ideal for subsequent enzymatic activity assays against SARS-CoV 3CL^{pro}.

Enzymatic activity assays Considering the data obtained from the initial fluorimetric assay, SARS-CoV 3CL^{pro} proteolysis against the fluorogenic substrate resulted in an appreciable increase in emission fluorescence intensity at a wavelength of 490 nm as a function of time, and a typical fluorescence profile following hydrolysis of the substrate is shown in Figure 3B. As a control, incubation of the substrate in assay buffer in the absence of SARS-CoV 3CL^{pro} showed no fluorescence intensity change over time (data not shown).

Measurement of the kinetic parameters (K_m and k_{cat}) was accomplished by conducting hydrolysis of the fluorogenic substrate at various concentrations. A typical Lineweaver-Burk plot is shown in Figure 4, which plots the reciprocal of the initial velocity (v_0) versus the reciprocal of the substrate concentration. The data for each concentration were ob-

Figure 3. Initial fluorimetric assay and representative fluorescence profile of hydrolysis of the substrate by SARS-CoV 3CL^{pro}. (A) Emission spectra of the synthesized substrate incubated with SARS-CoV 3CL^{pro} recorded at 10 min intervals; $\lambda_{EX} = 340 \text{ nm}$; $\lambda_{peak EM} = 490 \text{ nm}$. (B) The initial reaction velocity (v_0) was determined from the linear portion of the progress curve, which corresponded to between 2% and 10% hydrolysis of the substrate.

tained in triplicate. The calculated K_m and k_{cat} values were

Figure 4. Determination of the kinetic parameters (K_m and k_{cat}) by Lineweaver-Burk plot. Enzymatic activity at different substrate concentrations varying from 1 mmol/L to 5 $\mu\text{mol/L}$ was measured. The K_m and k_{cat} values were calculated by linear fitting method using ORIGIN 7.0. V: $\mu\text{mol}\cdot\text{L}^{-1}\cdot\text{min}^{-1}$; S: $\mu\text{mol}\cdot\text{L}^{-1}$.

$404 \pm 9 \mu\text{mol/L}$ and $1.08 \pm 0.14 \text{ min}^{-1}$, respectively. Obviously, the relatively small k_{cat}/K_m value ($2.7 \pm 0.3 \text{ mmol}^{-1}\cdot\text{L}\cdot\text{min}^{-1}$) indicated that the *in vitro* activity of SARS-CoV 3CL^{pro} was low, in common with other reported coronavirus 3CL^{pro}[5]. Such a low activity for SARS-CoV 3CL^{pro} may be due to the fact that only the dimer of 3CL^{pro} was the active form, and efficient active dimeric form was often at relatively low concentrations during the enzyme assay^[16,26].

Figure 5 showed the results concerning the relative enzymatic activity at various pH values for SARS-CoV 3CL^{pro}. The protease exhibited a stable proteolytic activity at pH 7.0–9.0, and displayed only 50% activity at pH 6.0 and 10.0.

Figure 5. Enzymatic activity of SARS-CoV 3CL^{pro} at different pH. The reaction velocity (v_0) was determined in citric acid/phosphate buffer (pH=5, 6, 7, 8) or glycine/NaOH buffer (pH=9, 10). The curve was fitted by an equation described by Copeland^[32] using ORIGIN 7.0.

However, when pH decreased to 5.0, it almost lost its activity completely. These results were strongly supported by a recent study, which discussed the pH dependence and the catalytic mechanism of SARS-CoV 3CL^{pro}^[31]. The pH profile shown in Figure 5 can be fitted by the following equation^[32]:

Where v is the measured reaction velocity that is plotted on the y axis, v_{\max} is the observed maximum value of the reaction velocity, and pK_{a1} and pK_{a2} refer to the pK_a values for the two relevant acid-base catalytic groups being titrated. A fit of the curve in Fig 5 to the equation yielded values of pK_{a1} and pK_{a2} of 6.31 ± 0.12 and 9.95 ± 0.11 , respectively, and Cys¹⁴⁵ formed a catalytic dyad in the active site of SARS-CoV 3CL^{pro}, and ionization of sulfhydryl group of Cys¹⁴⁵ and imidazole group of His⁴¹ played an important role in catalytic processing of substrate hydrolysis^[18].

The relative enzymatic activity of SARS-CoV 3CL^{pro} at different temperatures was depicted in Figure 6; the activity of SARS-CoV 3CL^{pro} nearly doubled with every 10 °C increase from 10 to 40 °C, and such a result accorded well with the thermodynamics of a typical chemical reaction. Like all proteins, SARS-CoV 3CL^{pro} undergoes thermal denaturation at elevated temperatures, hence the increases in the catalytic efficiency of the protease with increasing temperature might be compromised by the competing effects of the enzyme denaturation at high temperature. As indicated in Figure 6, the enzymatic activity diminished significantly at

Figure 6. Enzymatic activity of SARS-CoV 3CL^{pro} at varying temperatures. The reaction velocity (v_0) was determined at 10, 20, 30, 40 and 50 °C respectively. The reaction velocity (v_0) at 40 °C was taken as 1.0.

50 °C which was consistent with thermal denaturation of SARS-CoV 3CL^{pro} as monitored by circular dichroism^[16].

Mutation analysis of the catalytic dyad and two substrate-binding residues Based on the sequence alignments, previous mutagenesis studies with other CoV 3CL^{pro}^[7,9,33,34] and the recently reported crystal structure of SARS-CoV 3CL^{pro}^[18], the two residues His⁴¹ and Cys¹⁴⁵ are fully conserved and considered to be the principal catalytic residues of CoV 3CL^{pro}. Therefore, to confirm these two residues' functions in the enzymatic activity of SARS-CoV 3CL^{pro}, both residues were mutated into Ala. As indicated in Table 2, the proteolytic activity in SARS-CoV 3CL^{pro} His⁴¹Ala and Cys¹⁴⁵Ala mutants were below the detection limit of the enzyme assay, which suggested a complete loss of enzymatic activities for these two mutants. Furthermore, these data strongly supported an indispensable catalytic function for His⁴¹ and Cys¹⁴⁵, and were fully consistent with the mutagenesis data analysis published previously on the HCoV, IBV, MHV, and FIPV 3CL^{pro}^[5,11,35,36].

Additionally, it has been proposed that coronavirus 3CL^{pro} might employ the characteristic sequence signature Tyr¹⁶¹-Met¹⁶²-His¹⁶³ for substrate binding^[33]. However, to date, this theoretical functional character has not been tested experimentally for SARS-CoV 3CL^{pro}. The need for experimental data becomes more evident considering the relatively low sequence identity between SARS-CoV 3CL^{pro} and 3CL^{pro} of other coronavirus groups. With these facts in mind, we focused on the Met¹⁶² and His¹⁶³ residues of SARS-CoV 3CL^{pro} by site-directed mutagenesis analysis.

First of all, we exchanged Ala for the conserved His¹⁶³.

Table 2. Enzymatic activities of wild type and site-directed mutants of SARS-CoV 3CL^{pro}*

Protein	Proteolytic activity/%
SARS-CoV 3CL ^{pro}	100 %
SARS-CoV 3CL ^{pro} His ⁴¹ Ala	<1 %
SARS-CoV 3CL ^{pro} Cys ¹⁴⁵ Ala	<1 %
SARS-CoV 3CL ^{pro} His ¹⁶³ Ala	<1 %
SARS-CoV 3CL ^{pro} Met ¹⁶² Ala	182 %

* Enzymatic activities were averages determined in three parallel experiments. The activity of wild type SARS-CoV 3CL^{pro} was taken as 100 %.

As shown in Table 2, the proteolytic activity of this mutant dropped below the detection limit of the enzyme assay. Such an obvious indispensability of His¹⁶³ for proteolytic activity supported the conclusion that His¹⁶³ remained uncharged at physiological pH to facilitate optimal interaction with the Gln-P1 of the substrate in substrate-binding subsite S1 as determined by the recently reported crystal structure of SARS-CoV 3CL^{pro} [18]. This was also consistent with the mutagenesis data obtained previously for the same His residue in other CoV 3CL^{pro}[36]. Secondly, when Met¹⁶² residue was substituted with Ala, it was found that such a mutation did not decrease the proteolytic activity. On the contrary, it exhibited strongly increased activity: almost double compared with the wild type SARS-CoV 3CL^{pro}. This result was consistent with the corresponding research for FIBV 3CL^{pro} [36], and indicated that Met¹⁶² was not indispensable for proteolytic activity even though it was conserved among CoV 3CL^{pro}. It was tentatively suggested that such an increase of proteolytic activity for SARS-CoV 3CL^{pro} caused by Met¹⁶² mutation might be due to the fact that the substitution changed the spatial properties of the substrate-binding subsite S1 and facilitated substrate binding.

In summary, in this report, based on FRET theory, a fluorogenic substrate for detection of proteolytic activity of SARS-CoV 3CL^{pro} was successfully synthesized and evaluated. The kinetic parameters showed that the *in vitro* activity of SARS 3CL^{pro} was relatively low, perhaps due to the low concentration of the active dimeric form under the enzyme assay conditions. The pH profile of enzymatic activity yielded pK_{a1} and pK_{a2} values of 6.2 and 10.0, respectively, which correlated well with the finding that ionization of the catalytic dyad of His⁴¹ and Cys¹⁴⁵ was perhaps vital during the catalytic processing of substrate hydrolysis. In addition, SARS-CoV 3CL^{pro} displayed nearly a twofold

increase in activity with every 10 °C increase at 10–40 °C, and diminished its activity significantly at 50 °C owing to thermal denaturation. Mutation analysis revealed that substitution of either His⁴¹ and Cys¹⁴⁵ residues resulted in complete loss of proteolytic activity, which was also observed for the residue His¹⁶³ in the substrate-binding subsite S1. Replacement of Met¹⁶² with Ala caused increased activity, although the detailed mechanism was still unknown. The present FRET-based assay might supply an ideal platform for the exploration of SARS-CoV and other CoV 3CL^{pro} putative inhibitors, given the conserved substrate specificities of CoV 3CL^{pro}.

Abstract

Aim: To discriminate between fentanyl derivatives with high and low activities. **Methods:** The support vector classification (SVC) method, a novel approach, was employed to investigate structure-activity relationship (SAR) of fentanyl derivatives based on the molecular descriptors, which were quantum parameters including ΔE [energy difference between highest occupied molecular orbital energy (HOMO) and lowest empty molecular orbital energy (LUMO)], MR (molecular refractivity) and M_r (molecular weight). **Results:** By using leave-one-out cross-validation test, the accuracies of prediction for activities of fentanyl derivatives in SVC, principal component analysis (PCA), artificial neural network (ANN) and K-nearest neighbor (KNN) models were 93%, 86%, 57%, and 71%, respectively. The results indicated that the performance of the SVC model was better than those of PCA, ANN, and KNN models for this data. **Conclusion:** SVC can be used to investigate SAR of fentanyl derivatives and could be a promising tool in the field of SAR research.

Introduction

Fentanyl, a synthetic opioid commonly used during anesthesia, is also used to relieve pain in terminally ill patients^[1]. Fentanyl is lipophilic and has high potency as an analgesic or anesthetic, which can rapidly penetrate the central nervous system once taken by patients^[2].

Support vector classification (SVC) is a machine learning method based on the support vector machine (SVM) proposed by Vladimir N Vapnik^[3]. It has been recently proposed as a very effective method for pattern recognition. It has also been successfully used in such research fields as vowel recognition^[4], drug design^[5], combinatorial chemistry^[6], prediction of beta-turn and alpha-turn types of proteins etc^[7,8]. In the present work, the qualitative model was built based on SVC, with structural descriptors calculated by using the software Hyperchem, to explore the structure-activity relationship of fentanyl derivatives. The outstanding performance of the SVC model proved the significance of this method.

Methodology

Computational theory The SVC method was used in this work. The geometrical interpretation of SVC is that it chooses the optimal separating surface, ie the hyperplane equidistant from two classes. This optimal separating hyperplane has many nice statistical properties, which are detailed by Vapnik^[3,9].

Consider the problem of separating the set of training vectors belonging to two separate classes, $(y_1, \mathbf{x}_1), \dots, (y_n, \mathbf{x}_n)$, $\mathbf{x} \in R^m$, $y \in -1, +1$, with a hyperplane

$$\mathbf{w}^T \mathbf{x} + b = 0$$

If the training data are linearly separable, then there exists a pair (\mathbf{w}, b) such that:

$$y_i(\mathbf{w}^T \mathbf{x}_i + b) - 1 \geq 0, \quad i = 1, 2, \dots, l$$

$$\mathbf{w}^T \mathbf{x} + b \geq +1, \quad \text{for all } \mathbf{x} \in T;$$

$$\mathbf{w}^T \mathbf{x} + b \leq -1, \quad \text{for all } \mathbf{x} \in F;$$

The decision rule is:

$$f_{\mathbf{w},b}(\mathbf{x}) = \text{sgn}(\mathbf{w}^T \mathbf{x} + b)$$

where \mathbf{w} is termed the weight vector and b the bias. Without loss of generality the pair (\mathbf{w}, b) can be rescaled such that:

$$\min_{i=1,2,\dots,l} |\mathbf{w}^T \mathbf{x}_i + b| = 1$$

The learning problem is hence reformulated as: minimize $\|\mathbf{w}\|^2$ subject to the constraints of linear separability. This is equivalent to maximizing the distance, normal to the hyperplane, between the convex hulls of two classes. The optimization is now a quadratic programming (QP) problem:

$$\text{Minimize } \phi(\mathbf{w}) = \frac{1}{2} \|\mathbf{w}\|^2$$

subject to $y_i(\mathbf{w}^T \mathbf{x}_i + b) \geq 1, i=1, 2, \dots, l$.

This problem has a global optimum. The Lagrangian for this problem is:

$$L(\mathbf{w}, b, \Lambda) = \frac{1}{2} \|\mathbf{w}\|^2 - \sum_{i=1}^l \lambda_i [y_i(\mathbf{w}^T \mathbf{x}_i + b) - 1]$$

where $\Lambda = \{\lambda_1, \lambda_2, \dots, \lambda_l\}$ are the Lagrange multipliers, one for each data point.

Hence we can write:

$$F(\Lambda) = \sum_{i=1}^l \lambda_i - \frac{1}{2} \|\mathbf{w}\|^2 - \frac{1}{2} \sum_{i=1}^l \sum_{j=1}^l \lambda_i \lambda_j y_i y_j \mathbf{x}_i^T \mathbf{x}_j$$

note that the Lagrange multipliers are only non-zero when $y_i(\mathbf{w}^T \mathbf{x}_i + b) = 1$, vectors for these cases are called support vectors since they lie closest to the separating hyperplane. Then the optimal separating hyperplane is given by:

$$\mathbf{w}^* = \sum_{i=1}^l \lambda_i^* \mathbf{x}_i y_i$$

and the bias is given by:

$$b^* = -\frac{1}{2} (\mathbf{w}^*)^T (\mathbf{x}_s + \mathbf{x}_r)$$

where \mathbf{x}_r and \mathbf{x}_s are any support vector from each class satisfying

$$y_r = 1, y_s = -1$$

The hard classifier is then,

$$f(\mathbf{x}) = \text{sgn}[(\mathbf{w}^*)^T \mathbf{x} + b^*]$$

In the case where a linear boundary is inappropriate the SVC can map the input vector, \mathbf{x} , into a high dimensional feature space, F . By choosing a non-linear mapping Φ , the SVC constructs an optimal separating hyperplane in this higher dimensional space. Among the acceptable mappings are polynomials, radial basis functions and certain sigmoid functions. Then the optimization problem becomes,

$$W(\alpha) = \sum_{i=1}^l \alpha_i - \frac{1}{2} \sum_{i=1}^l \sum_{j=1}^l y_i y_j \alpha_i \alpha_j \langle \Phi(\mathbf{x}_i) \cdot \Phi(\mathbf{x}_j) \rangle$$

In this case, the decision function in SVC is as follows:

$$\begin{aligned} g(\mathbf{x}) = \text{sgn}(f(\mathbf{x})) &= \text{sgn} \left\{ \sum_{i \in SV} \alpha_i y_i \langle \Phi(\mathbf{x}) \cdot \Phi(\mathbf{x}_i) \rangle + b \right\} \\ &= \text{sgn} \left\{ \sum_{i \in SV} \alpha_i y_i K(\mathbf{x}, \mathbf{x}_i) + b \right\} \end{aligned}$$

where \mathbf{x}_i is the support vectors and $K(\mathbf{x}, \mathbf{x}_i)$ is called kernel function.

Implementation of SVC The SVM software package including SVC was programmed according to the literature^[3]. The software was tested in some applications in chemistry and chemical engineering^[9,10]. All computations were carried out on a Pentium IV computer with a 1.3G Hz processor.

Results

Data set The data set consists of 14 fentanyl derivatives available^[11]. The molecular formula investigated in this work is shown in Figure 1. The substituents of the compounds include R_1 , R_2 , and R_3 . The data set can be divided into two classes according to the analgesic bioactivities ED_{50} (hot plate method in mice)^[11] of samples. Here Class 1 contains the compounds with high activities, ie the molecules with $ED_{50} < 1.0 \times 10^{-6}$ (mol/kg). Class 2 contains the compounds with low activities, ie the molecules with $ED_{50} > 1.0 \times 10^{-6}$ (mol/kg).

Figure 1. Structure of fentanyl derivatives.

Computation of descriptors The three-dimensional structures of the molecules were drawn, and optimized with the software Hyperchem3 (Release 7.0 for Windows Molecular Modeling System, Hypercube Inc. 2002), which was utilized for the computation of MM+ and PM3 later. Prior to the semi-empirical computation of quantum chemistry, all structures of the compounds were submitted to MM+ computation of molecular mechanics for energy optimization. The computations were carried out at a restricted Hartree-Fock level with no configuration interaction. The molecular structures were optimized using the Polak-Ribiere algorithm until the root-mean-square gradient was 0.001. Only the most stable conformation of molecule has been used to obtain the structural descriptors via the computational results of semi-empirical method PM3. Using the software Hyperchem3, the descriptors obtained were as follows: HOMO (highest occupied molecular orbital energy), LUMO (lowest empty molecular orbital energy), ΔE (energy difference between HOMO and LUMO), TE (total energy), HF (heat of formation), EE (electronic energy), SA (surface area), MV (molecular volume), lgP (partition coefficient), MR (molecular refractivity), MP (molecular polarizability), M_r (molecular weight), N1 (charge density of the atom N connecting with R_1), C2 (charge density of the atom C connecting with R_2), N3 (charge density of the atom N connecting

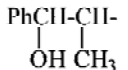

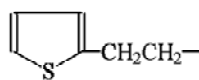

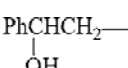

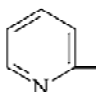

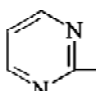

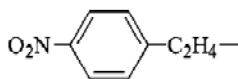

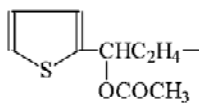

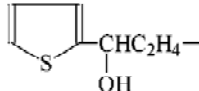

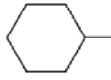

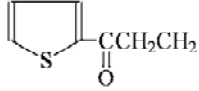

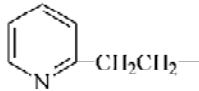

with R_3).

Selection of descriptors The selection of descriptors is a relatively tough job due to the redundancy of some parameters. The result used to depend on the experience of the researcher. Recently, some of promising results have been reported on the problem of feature selection^[12,13]. In this work, the entropy method was applied to the selection of descriptors^[14]. Through the computation of entropy for the data set available, the three descriptors (ΔE , MR, M_r) are determined to be more important than the others. Table 1 lists the samples with bioactivity ED_{50} and selected

descriptors, including ΔE , MR, and M_r . It should be mentioned that there possibly exist other combinations of descriptors useful for the classification of data set used here, but the three descriptors above are enough to be used as the determining factors for the prediction of activities of the compounds (refer to the good results described in the following sections).

Selection of the kernel function and the capacity of parameter C used in the SVC model Similar to other multivariate statistical models, the performance of SVC is related to dependent and independent variables as well as the

combination of parameters used in a model. In the computation of SVC, we have to deal with the capacity parameter C (also called the regularization parameter) and the kernel type used in modeling.

In this work, the cross validation test, using the leaving-one-out (LOO) method was undertaken to find a suitable capacity parameter C and the appropriate kernel function for the SVC model. Suppose that P_w is the number of samples misclassified using the LOO method; it can then be employed as a criterion to obtain the appropriate kernel function and the optimal capacity parameter C . Figure 2 illustrated P_w (concerned with different kernel functions including linear, radial, polynomial and sigmoid functions) versus the capacity parameter C from 0.1 to 250. It was found that the SVC model with the best performance could be ascertained by using the radial kernel function with capacity parameter C from 50 to 100.

Figure 2. P_w (the number of samples misclassified using LOO method) versus the C (capacity parameter) using LOO method with different kernel functions.

Modeling of SVC According to the results we obtained, the optimal model of SVC for discriminating between high and low activities of compounds could be built as follows, using the radial kernel function with capacity parameter $C=100$:

$$g(\mathbf{x}) = \text{sgn} \left(\sum_{i \in SV} \alpha_i y_i \exp \left\{ -\frac{\|\mathbf{x} - \mathbf{x}_i\|^2}{\sigma^2} \right\} + b \right)$$

where $\sigma=1$, $b=0.68$, $\alpha_i=36.1$ ($i=2$), 21.8 ($i=3$), 55.1 ($i=5$), 19.3 ($i=7$), 0 ($i=10$), 30.5 ($i=11$), 100 ($i=13$), 1.84 ($i=14$), correspond to the Lagrange multipliers of support vectors, while all the others. $\alpha_i=0$. $y_i=1$ for the samples of class 1; $y_i=-1$ for the samples of class 2. \mathbf{x}_i is a vector (pattern of sample) with unknown activity to be discriminated, \mathbf{x}_i is one

of the support vectors. Based on this SVC model, the samples were discriminated as those of high bioactivities ($ED_{50} < 1.0 \times 10^{-6}$ mol/kg), if $g(\mathbf{x}) \geq 0$. Using SVC model for the classification of activities of fentanyl derivatives, the accuracy of classification was 93% by using radial basis kernel functions with the capacity parameter $C=100$. Table 2 lists the trained results from SVC model obtained above. Figure 3 illustrated the effect of classification with trained SVC model. It was found that only one sample (compound No 13) was misclassified.

Figure 3. Effect of classification with trained SVC model.

Results of cross validation tests Figure 4 illustrated the effect of the cross validation test using LOO method of SVC. It is obvious that the quality of prediction results (Figure 4) is as good as that of trained results (Figure 3), also with only one sample (compound No 13) discriminated wrong. Table 2 lists the predicted results obtained by using LOO method of SVC model.

component analysis (PCA), K-nearest neighbor (KNN) and artificial neural network (ANN) were utilized to investigate SAR of fentanyl derivatives, with special consideration of their predictive ability (generalization ability) from cross validation tests using LOO method.

Figure 5 illustrated the trained results of classification for the same data set using PCA method. It could be seen from Figure 5 that the quality of classification results was as good as those from the SVC model, with only one sample misclassified. However, there were two samples predicted

Figure 6. Location of N_0 3 sample predicted using PCA

wrong from the results of cross validation test using LOO method of PCA. Figure 6 and Figure 7 illustrated the locations of samples marked N_0 3 and N_0 13, whose predicted classes did not agree with the actual ones determined using the LOO test of PCA method.

KNN method, as a helpful pattern recognition tool, was utilized to discriminate between high and low activities of compounds for the same data set, with the accuracy of prediction being 71% (K=5). Obviously, the predictive ability of KNN model was poor compared to that of SVC model in this situation.

So far as BP ANN model is concerned, ANN with three

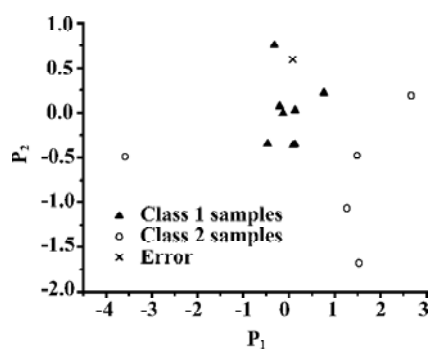

Figure 7. Location of N_{13} sample predicted using PCA method.

layers was used to build the relationship between the features and activities of compounds. The number of hidden nodes was three; the transformation function used was Sigmoid; the number of training steps was 250 000. Table 2 lists both trained results and predicted results using LOO method, based on the ANN model built. It was found from Table 2 that the trained results of classification were not as good as the predicted ones. There were only three (N_{11} , N_{13} , and N_{15}) samples misclassified for the trained set, with the accuracy of classification being 79%. However, there were six samples that were wrongly classified from the results of the cross validation test using LOO method of ANN model. Table 3 lists N_w (the number of samples to be predicted wrong) using LOO test of different models. It could be concluded that the predictive ability of SVC model was superior to that of PCA, KNN, and ANN models for the data set available.

Discussion

The SVC has been introduced as a robust and highly accurate intelligent classification technique, likely to be a useful chemometrics tool. On a simple but real chemometric problem the predictive ability of SVC for the data set available here outperforms that of PCA, KNN and ANN methods, which are the most frequently used chemometric techniques. The SVC exhibits better overall performance because it embodies the structural risk minimization principle. It has an advantage over the other techniques because it converges to the global optimum, and not to a local optimum that depends on the initialization and parameters affecting the rate of convergence. It can be concluded that (1) the selected descriptors can account for the features of the fentanyl derivatives; (2) the SVC is a very promising tool for the approximation of qualitative classification and (3) the SVC is especially suitable for finding the regularities of the small data set, ie, data set with fewer samples, giving modeling

results with good generalization ability.

Training and optimization using SVC are easier and faster compared with other machine learning techniques, because there are fewer free parameters and only support vectors (only a fraction of all data) are used in the generalization process. The results show that the SVC is a good approach for predicting the classes of fentanyl derivatives. At the same time, the models proposed could identify and provide some insight into what features are related to the classification of these compounds and afford some instruction for further recognizing new fentanyl derivatives. It should be noted that no single method or paradigm is uniformly superior, although the preliminary evidence presented in this work suggests that the SVC is a data-mining tool with great potential in chemometric application.

Abstract

Aim: To study if cell membrane chromatography (CMC) could reflect drug-receptor interaction and evaluate the affinity and competitive binding to muscarinic acetylcholine receptor (mAChR). **Methods:** The cell membrane stationary phase (CMSP) was prepared by immobilizing guinea pig jejunum cell membrane on the surface of a silica carrier, and was used for the rapid on-line chromatographic evaluation of ligand binding affinities to mAChR. The affinity to mAChR was also evaluated from radioligand binding assays (RBA) using the same jejunum membrane preparation. **Results:** The capacity factor (k') profiles in guinea pig jejunum CMSP were: (-)QNB (15.4)>(+)QNB (11.5)>atropine (5.35)>pirenzepine (5.26)>4-DAMP (4.45)>AF-DX116 (4.18)>pilocarpine (3.93)>acetylcholine (1.31). These results compared with the affinity rank orders obtained from radioligand binding assays indicated that there was a positive correlation ($r^2=0.8525$, $P<0.0001$) between both data sets. **Conclusion:** The CMC method can be used to evaluate drug-receptor affinities for drug candidates.

Introduction

Radioligand binding assay (RBA) is a traditional method in studying drug-receptor interactions. Although radioligand binding assay has some advantages, such as high sensitivity, it results in radioactive pollution and needs special separation methods. Cell membrane chromatography (CMC), a new bio-affinity chromatography technique originated by Dr He in 1999^[1], can be used to observe the binding of a drug and target (including receptor), simply and conveniently.

Previous experiments have indicated that the receptors immobilized on the cell membrane stationary phase (CMSP) remain bio-active^[2,3]. However, it is necessary to study whether this approach can be adopted to evaluate drug-receptor interaction and reflect affinity and competitive binding, although CMC has previously been used to screen for drug and herb candidates^[4,5].

Materials and methods

Animals and drugs Adult guinea pigs (350–400 g) of either sex were provided by the Experimental Animal Cen-

ter of Xi'an Jiaotong University, China. Atropine, pirenzepine, nicotine, pilocarpine, 4-diphenylacetoxy-*N*-methylpiperidine (4-DAMP), 11-2-[2-[(diethylamino) methyl]-1-piperidinyl]acetyl]-5,11-dihydro-6*H*-pyrido-(2,3-*b*) (1,4) benzodiazepine-6-one (AF-DX116) were purchased from Sigma Co. Acetylcholine (ACh) was purchased from Shanghai Medical Co. (-)QNB and (+)QNB was provided by RBI Co. Tritiated quinuclidinyl benzilate (³H]QNB) was purchased from Amersham Radio-Chemical Center with a radioactivity of 1813 TBq/mol.

Membrane preparation of jejunum vertical muscle Guinea pigs were killed and the jejunum was removed immediately. The intestine was washed thoroughly in normal saline and the canal was rubbed vertically using a tampon; then the vertical muscle was cut into small pieces and added to ice-cold PBS buffer. The tissue suspension was homogenized under a cradle at 4 °C (twice, for 1 min each). The crude homogenate was centrifuged at 600×*g* for 10 min to remove cellular debris. The supernatant was filtered through cheesecloth and then centrifuged for 40 min at 20 000×*g*. The buff-colored layer around the pellet was gen-

tly resuspended in the above buffer and centrifuged as previously explained^[6,7].

Radioligand-receptor binding assay [³H]QNB with a radioactivity of 37 PBq/L, was used as a ligand to label muscarinic binding sites in membrane prepared from guinea pig jejunum. Aliquots (200 μL) of the membrane suspensions were incubated with 0.5 nmol/L [³H]QNB in 50 mmol/L PBS buffer for 40 min at 37 °C. Non-specific binding was estimated from the duplicate tube containing 0.01 mmol/L atropine. The drug-receptor affinities were estimated by pK_D.

$$pK_D = -\lg K_D$$

Chromatography experiment With a known concentration-competitive ligand added in the mobile phase, the combination between ligand and receptor protein was saturated on the CMSP. At the key time, the solute eluted from CMSP was increased drastically, thus forming a characteristic curve breakage. Conceptually, there are mean breakage sites in the curve, which only relate to the equilibrium dissociation constant or relationship between drug concentration and the number of receptors on the CMSP column. Moreover, in the solute disassociation process, the result can be analyzed by Scatchard-Plot method:

$$\frac{1}{M_{Lapp}} = \frac{1}{K_a M_L [D]} + \frac{1}{M_L}$$

where M_{Lapp} is the mole number of drug at mean breakage site, $[D]$ is drug concentration, K_a is association constant of the drug, and M_L is the total number of combination site of receptor protein on the column. If non-specific combination can not be neglected, the following formula is obtained: where V is the retention volume of drug, $[P]$ is the concentration of receptor combination site, V_{min} is retention volume

$$\frac{1}{V_{max} - V_i} = \frac{1 + [D]K_a}{V_{min}[P]K_a} + \frac{(1 + [D]K_a)^2}{V_{min}[P]K_a} \cdot \frac{1}{[X]}$$

of drug when the specific interaction is completely inhibited, and V_{max} is obtained from the formula. $[X]$ is the concentration of additive, which completes the same site of D . V_{max} is the retention volume of $[D]$ at low concentration ($[D] \ll 1/K_a$, $V = V_{max}$) and V_x is the retention volume of D when competitive interaction exists. The value of V_{min} can be determined by regressing $1/(V_{max} - V)$ versus $1/[D]$ extrapolating to infinite ($V_i = V_{min}$).

$$\frac{1}{V - V_{min}} = \frac{1}{V_{min}[P]K_a} + \frac{1}{V_{min}[P]} \cdot [D]$$

In the chromatographic system, the capacity factor (k') can reflect the mole fraction ratio of stationary and mobile phase at equilibrium. The silica surface is completely coated

by the cell membrane in CMSP, so k' is characteristic of the action between the drug and the cell membrane, which means, the larger k' shows a stronger affinity for the same chromatographic condition.

CMSP was prepared by immobilizing above guinea pig jejunum cell membrane on the surface of a silica carrier, provided by the Pharmacy Center of Xi'an Jiaotong University^[4], China. CMSP was packed in the chromatography column (50 mm×2 mm, id, 7 μm) and equilibrated with at least 15 mL PBS buffer 50 mmol/L before running different ligands. The mobile phase was pumped through the column at a flow rate of 0.5 mL/min at 37 °C. Before different ligands were injected, the column was equilibrated with at least 15 mL PBS mobile phase 50 mmol/L. When 0.01 mmol/L atropine was added to the PBS buffer, the column was equilibrated again with this mobile phase before injection. Capacity factors were calculated from:

$$k' = (t_R - t_0) / t_0$$

where t_R is retention time of ligands, and t_0 is retention time of solvent. Ligand retention time was detected by ultraviolet on-line in 190-230 nm wavelength.

Statistical analysis Values were presented as mean±SD. Correlation between both data sets were analyzed by linear regression using GraphPad Prism 2.01.

Results

Radioligand-receptor binding experiment Competition for [³H]QNB binding by unlabelled ligands showed different affinity in guinea pig jejunum membrane. None of the Hill coefficient was significantly different from unity. The rank orders of potency (pK_d) were (-)QNB > (+)QNB > atropine > 4-DAMP > AF-DX116 > pirenzepine > pilocarpine > ACh. Nicotine had little affinity with muscarinic receptor (Table 1).

Cell membrane chromatography experiment In the CMC experiment, capacity factors (k') were used to describe the ligand-CMSP affinity. The bigger the capacity factor, the stronger the affinity will be. The sequence of the relative affinities of selected ligands were (-)QNB > (+)QNB > atropine > pirenzepine > 4-DAMP > AF-DX116 > pilocarpine > ACh, which were consistent with results calculated from radioligand binding assays, except for pirenzepine. Yet and nicotine had some capacity factor. When atropine was added in the mobile phase the capacity factor of (-)QNB, (+)QNB, atropine, pirenzepine, 4-DAM, AF-DX116, pilocarpine and ACh could be reduced, while the capacity factor of nicotine could not be reduced (Table 2).

QNB: quinuclidinyl benzilate; 4-DAMP: 4-diphenylacetoxy-*N*-methylpiperidine; AF-DX116: 11-2{[2-[(diethylamino)methyl]-1-piperidinyl]acetyl}-5,11-dihydro-6*H*-pyrido-(2,3-*b*)(1,4) benzodiazepine-6-one; ACh: acetylcholine. The guinea pig jejunum homogenates were incubated with 0.5 nmol/L [³H]QNB for 40 min at 37 °C in the presence of tested ligands.

Discussion

The results of the present study demonstrated that membrane preparation including mACh receptor could be immobilized on the stationary phase with retention of their binding activities. Different ligands had different capacity factors and the rank orders were consistent with results from radioligand binding assay except for pirenzepine. During the experiment, when atropine was added to the mobile phase the capacity factor of (-)QNB, (+)QNB, atropine, pirenze-

pine, 4-DAMP, AF-DX116, pilocarpine, and ACh decreased. This indicated that those ligands could bind to mACh receptor on CMSP and the affinity could be inhibited in competitive displacement by atropine. The capacity factor of nicotine could not be decreased in competitive displacement, so the ligands have no competitive site with atropine. Therefore, we can infer that capacity factor can evaluate the affinity of ligand-mACh receptor and reflect the selectivity and specificity of drug-receptor interaction. While at present the equilibrium dissociation constant can not be calculated by CMC method directly, linear regression analysis showed that both the data sets correlated with $r^2=0.8525$ ($n=24$), $P<0.0001$ in PBS mobile phase, or with $r^2=0.8461$ ($n=24$), $P<0.0001$ in PBS mobile phase with 0.01 mmol/L atropine (Figure 1).

It was demonstrated that the CMC model could be used to observe binding of the drug and receptor on a dynamic condition, and the characters of drug-receptor interactions can be shown by chromatographic parameters of drugs on the CMC model. However, we noticed that affinity rank orders from different methods were not entirely consistent. In the CMC model, affinity of pirenzepine according to the k' value was relatively higher than the corresponding affinity determined using radioligand binding assay. Similar results about pirenzepine were observed in other study^[8]. When atropine was added in the mobile phase, the affinity discrepancy was not eliminated. The source of the different affinity orders is not readily elucidatory. It would be likely to blame low sensitivity of the CMC model for the ligands, because most ligands of mACh receptor are at the margin of ultraviolet on-line in 190–230 nm wavelength, or outward of the range. It is necessary for us to improve the sensitivity of the

CMC model by using other detectors, like a fluorescence detector or laser detector. Before further study, CMC can

be used to screen for drug candidates and accuracy can be validated by traditional radioligand binding assay. The development of CMC could offer a number of unique advantages. The receptors can be placed in a stabilized format and could therefore be reused over a long period of time. Thus, it might be possible to perform multiple experiments with hard-to-obtain receptors using an immobilized format.

Abstract

Aim: To explore the effect of melatonin on PC12 cell death induced by 1-methyl-4-phenylpyridinium (MPP⁺). **Methods:** MTT assay, lactate dehydrogenase (LDH) efflux assay, and immunohistochemistry methods were used to measure neurotoxicity of PC12 cells treated acutely with MPP⁺ in low glucose and high glucose conditions, and to assess the neuroprotective effect of melatonin on PC12 cell death induced by MPP⁺. **Results:** In a low glucose condition, MPP⁺ significantly induced PC12 cell death, which showed time and concentration dependence. In a serum-free low glucose condition, the percentages of viability of cells treated with MPP⁺ for 12, 24, 48, 72, and 96 h were 85.1%, 75.4%, 64.9%, 28.15%, and 9%, respectively. The level of LDH in the culture medium increased and tyrosine hydroxylase positive (TH⁺) cell count decreased. However, in a serum-free high glucose condition, MPP⁺ did not significantly induce PC12 cell death compared with control at various concentrations and time regimens. When the cells were preincubated with melatonin 250 μmol/L for 48, 72, and 96 h in a serum-free low glucose condition, cell survival rate significantly increased to 78.1%, 58.8%, and 31.6%, respectively. Melatonin abolished the LDH leakage of cells treated with MPP⁺ and increased TH⁺ cells count. **Conclusion:** MPP⁺ caused concentration-dependent PC12 cell death. The level of glucose was an important factor to MPP⁺ induced dopaminergic PC12 cell death. Low glucose level could potentiate MPP⁺ toxicity, while high glucose level could reduce the toxicity. In addition, melatonin attenuated PC12 cell death induced by MPP⁺.

Introduction

1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-mediated selective damage to dopaminergic neurons of the nigrostriatal pathway has been widely used as a model of Parkinson's disease (PD)^[1–3]. MPTP is a lipophilic molecule that is able to cross the blood-brain barrier. This cytotoxin has provided important information on the potential mechanisms of PD. It induces toxicity through its conversion of astrocytes to 1-methyl-4-phenylpyridinium (MPP⁺) in the reaction catalyzed by monoamine oxidase type B (MAO-B)^[4]. MPP⁺ is selectively transported into the dopaminergic neurons through a high-affinity dopamine (DA) transporter and accumulates in the neuronal mitochondria, where it disrupts

cellular respiration inhibiting complex I of the electron transport chain, depletes adenosine triphosphate (ATP) in the mitochondria^[5,6], increases sensitivity to oxidative attack, and eventually causes apoptotic or necrotic neuronal cell death. It is reported that the deleterious effects of MPTP are results of the generation of oxygen free radicals either during oxidation of MPTP to MPP⁺ or during electron transport chain disruption by MPP⁺. In addition, MPP⁺ might induce the release of DA, which in turn could generate free radicals from auto-oxidation^[7,8]. Although it has been found that the accumulation of MPP⁺ in dopaminergic neurons is a critical step for DA neurotoxicity, the exact molecular mechanisms underlying MPP⁺-induced neuronal death have not been clear. Thus, elucidating the molecular basis of the cell death trig-

gered by MPP⁺ could provide valuable insight into the pathogenesis of PD.

Melatonin is an indole hormone produced primarily in the pineal gland and the retina. It is classically known to be involved in the regulation of circadian and seasonal rhythms and sleep-inducing properties. In 1993, it was first reported by Tan *et al* as an efficient endogenous antioxidant^[9]. Since then, evidence is shown that this molecule is one of the best physiological antioxidants. Different from other potent antioxidants, melatonin is soluble in both lipids and water, allowing itself to easily enter cells or pass the blood-brain barrier. So melatonin is available to all nerve cell compartments and shows high levels, especially in the nucleus and mitochondria. Recently, it has been proposed that the most important function of this hormone is scavenging harmful free radicals, especially hydroxyl radicals. Tan *et al*^[9] made the unexpected observation that melatonin was much more efficient than the important intracellular antioxidant glutathione (GSH) in scavenging ·OH. Mayo *et al*^[10] also reported that melatonin regulated the mRNA of antioxidant enzymes in dopaminergic cells after addition of the neurotoxin 6-OHDA, which might indicate a neuroprotective mechanism. However, intracellular effects of melatonin are largely unknown at present, in contrast to well-studied antioxidant activity.

PC12 cell is a clonal cell line of rat pheochromocytoma cells that respond to nerve growth factor by extending neurites and acquiring the appearance of neurons. Cells with and without nerve growth factor treatment synthesize, store, secrete, and take up dopamine by similar processes to those of dopaminergic neurons^[11], and express DA transporter^[12]. Although they are not true brain DA neurons, PC12 cells have been used extensively as an experimental system for the study of various aspects of dopaminergic neurons and neurotoxins^[13–15]. In this study, we used PC12 cells as a model cell line of DA-containing neurons and investigated the effects of melatonin on MPP⁺-induced cell death.

Materials and methods

Materials Dulbecco's modified Eagle's medium (DMEM), fetal calf-serum and benzylpenicillin/streptomycin were purchased from GIBCO (Langley, OK, USA). Poly-*L*-lysine, trypsin, dimethylsulfoxide (Me₂SO), diaminobenzidine (DAB), 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma (St Louis, MO, USA). MPP⁺-iodine was purchased from Sigma-Aldrich. Rabbit polyclonal anti-tyrosine hydroxylase (TH) antiserum was purchased from Chemicon

(Tencula, CA, USA). Biotinylated goat anti-rabbit IgG, horseradish peroxidase-conjugated secondary antibodies, ABC kit were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Melatonin was purchased from Sigma and dissolved in absolute ethanol before being diluted with saline. All other chemicals were of analytical grade and commercially available.

PC12 cells culture and treatment PC12 cells were obtained from the Shanghai Cell Research Institute and cultured at a density of 1×10^4 cells/cm² on poly-*L*-lysine-coated plates. Cells were cultured in high-glucose DMEM supplemented with heat-inactivated 10% fetal bovine serum, 5% horse serum, benzylpenicillin 100 kU/L, and streptomycin 100 mg/L. They were grown at 37 °C in a humidified atmosphere containing 5% CO₂ and subcultured every 2–3 d at approximately 70%–80% confluence. Cells were subsequently switched to 5% fetal calf serum low glucose, serum-free high glucose, and serum-free low glucose DMEM medium, containing various experimental reagents, and further incubated for the indicated intervals. Drugs and other agents were dissolved in Me₂SO, which was added at a maximum ratio of 1:1000 to the culture media. Cultures were used for no more than 20 passages. Cell viability experiments were performed in 96-well plates, 8 times, using 2–3 replicates per treatment. In dose-response studies, cells were treated with MPP⁺ (0–500 μmol/L) for 48 h with or without melatonin (0.1–1000 μmol/L). In time course studies, cells were exposed to MPP⁺ (200 μmol/L) for 0, 24, 48, 72, and 96 h with or without melatonin 250 μmol/L. The cells were preincubated with melatonin for 1 h before treatment with MPP⁺. The final concentration of ethanol per well did not exceed 0.01% for all melatonin concentrations used. The vehicle-treated control cultures received an equal amount of ethanol (0.01%). For cytotoxicity, cells were seeded on plates previously coated with poly-*L*-lysine. Untreated cells were used as control. For TH immunocytochemistry, the cells were subcultured for 48 h before use of 22-mm coverslips (Fisher Scientific, Pittsburgh, PA, USA), coated with poly-*L*-lysine in 35-mm culture dishes (Fisher Scientific).

MTT assay Cell viability was measured by MTT assay^[16], which was based on the conversion of MTT to formazan crystals by mitochondrial dehydrogenase. Cells were plated at a density of 2×10^4 cells in 96-well dishes in 10% serum high-glucose DMEM medium for 2 d, and switched to 5% fetal calf serum low glucose, serum-free high glucose, and serum-free low glucose DMEM medium containing the experimental reagents. Four hours before the desired end point, MTT (5 g/L in PBS, final concentration 0.5 g/L) was added at 1/10 culture volume and cells were returned to the

incubator. After the end point, culture medium was removed, and 100 μL of Me_2SO was added to each well to dissolve formazan. Absorbance (OD value) was measured at 570 nm in a microplate reader (Bio-Rad model 550). Cell viability was expressed by OD value.

LDH release assay^[15] Cytotoxicity of MPP^+ was evaluated by colorimetric assay based on the measurement of LDH activity. Briefly, after cells were treated with MPP^+ , an aliquot of medium was taken and centrifuged at $250\times g$ for 5 min. Supernatant (10 μL) was added to the LDH buffer [lactic acid 50 mmol/L/Tris (pH 8.9) 0.1 mol/L and NAD^+ (the oxidized form of nicotinamide-adenine dinucleotide) 4.6 g/L] to a total volume of 200 μL . Intracellular LDH content was determined by lysing the cells with Triton X-100 detergent. Spectrophotometric analysis was performed at room temperature (20–24 $^\circ\text{C}$) using a Bio-Rad microplate reader measuring optical density at 340 nm in both the medium and lysis buffer. LDH release values were calculated by subtracting the background reading (media only) from the observed reading. LDH leakage was expressed as a percentage of the total LDH release (extracellular LDH extracellular+intracellular LDH).

Tyrosine hydroxylase (TH) immunocytochemistry TH activity was identified using the streptavidin-biotin-peroxidase complex. Cultured in poly-*L*-lysine coated coverslips, PC12 cells (2×10^4) were treated with MPP^+ 200 $\mu\text{mol/L}$ with or without melatonin in serum-free low glucose medium. Melatonin was added 1 h before MPP^+ treatment. Cultures were incubated at 37 $^\circ\text{C}$, 5% CO_2 for a further 48 h, PC12 cells were washed with phosphate-buffered saline 0.1 mol/L (PBS, pH 7.4) and then fixed in 4% paraformaldehyde (pH 7.4) in PBS for at least 1 h. PC12 cells were incubated with 1% H_2O_2 and 30% methanol in 0.3 mol/L PBS to block endogenous peroxidases. The sections were rinsed three times in PBS and incubated successively with 1) normal sheep serum (20% in PBS) to reduce nonspecific binding for 30 min in a moisture-saturated chamber at 37 $^\circ\text{C}$; 2) antityrosine hydroxylase rabbit antiserum at 1/300 overnight in a moisture-saturated chamber at 4 $^\circ\text{C}$ for 48 h; 3) biotinylated anti-rabbit IgG at 1:200 for 30 min in a moisture saturated-chamber at room temperature (20–24 $^\circ\text{C}$); and 4) streptavidin-peroxidase complex at 1:100 for 30 min in a moisture-saturated chamber at room temperature (20–24 $^\circ\text{C}$). Sections were rinsed with PBS after each step (3 \times 5 min). In step 2, control sections were incubated with an equal volume of PBS, rather than antiserum, as negative controls. The streptavidin-biotin-peroxidase activity was revealed using 3,3'-diaminobenzidine tetrachloride (DAB, 0.5 g/L), in the presence of 0.03% H_2O_2 in PBS for 5 min. Coverslips were washed with

PBS and dehydrated through ethanol. Finally, sections were mounted on gelatin-coated slides, air-dried, dehydrated, and coverslipped with permount. Immunocytochemical staining was analyzed at 400 \times magnification on an Olympus inverted phase-contrast microscope. Micrographs were taken with a camera mounted on the phototube using a Kodak film.

Statistical analysis Statistical analysis was performed using *t*-test for paired data. Data were expressed as the mean \pm SD. $P<0.05$ was considered to be statistically significant.

Results

Effect of MPP^+ on PC12 cells viability The reduction was markedly decreased after PC12 cultures were exposed to MPP^+ (200 $\mu\text{mol/L}$) in low glucose condition. MTT reduction was significantly decreased after MPP^+ treatment in serum low glucose condition. The percentage of cell viability was approximately 50%, 44%, and 30% at 48, 72, and 96 h, respectively. In serum-free low glucose condition, the percentages of cell viability were 85.1%, 75.4%, 64.9%, 28.1%, and 9% at 12, 24, 48, 72, and 96 h after MPP^+ treatment, respectively. However, when cells were exposed to MPP^+ 200 $\mu\text{mol/L}$ in high glucose condition, no significant cell death appeared compared to control. MPP^+ induced a slight decrease in cell viability at 25 and 50 $\mu\text{mol/L}$, and more significantly at 100 $\mu\text{mol/L}$ in the serum-free low glucose condition. In the 5% serum low glucose condition, the cell viabilities after MPP^+ (25, 50, and 100 $\mu\text{mol/L}$) treatment had no obvious changes compared with control, and significant cell death was observed at MPP^+ 200 $\mu\text{mol/L}$. Therefore, MPP^+ induced dose-dependent cell death in the low glucose condition. However, in the high glucose condition, no cell death was seen for all concentrations of MPP^+ . We found that supplementing glucose increased the number of surviving cells for all concentrations of MPP^+ .

Melatonin promotes PC12 survival after MPP^+ treatment The percentage of viable cells in serum-free low glucose condition with low dose melatonin (0.1, 1, and 10 $\mu\text{mol/L}$) did not change after treatment with MPP^+ . However, when the cells were preincubated with melatonin (100, 250, 500, 1000 $\mu\text{mol/L}$), MPP^+ -induced cell toxicity was significantly attenuated. Surviving PC12 cells were significantly increased from 53% in MPP^+ to 80% when melatonin was added. Melatonin was protective against MPP^+ toxicity in PC12 cells. Melatonin at 500 and 1000 $\mu\text{mol/L}$ showed similar protection as 250 $\mu\text{mol/L}$ melatonin, although a tendency to increase effects with higher doses was observed, indicating that the dose of 250 $\mu\text{mol/L}$ might be close to the maxi-

Figure 1. Melatonin protected PC12 from MPP⁺-induced cytotoxicity. Cell viability monitored by MTT assay following 48-h exposure to various concentrations of melatonin in MPP⁺ (200 μmol/L) in serum-free low glucose condition. mal effect (Figure 1).

The cultures were preincubated with melatonin (250 μmol/L) for 1 h and then exposed to MPP⁺ (200 μmol/L) for 0, 12, 24, 48, 72, and 96 h in serum or serum-free low glucose condition. At the end of each time period, cell viability was assessed by MTT reduction. In serum-free low glucose condition, cell viability was decreased at 24, 48, 72, and 96 h to 75.4%, 64.9%, 28.1%, and 9% respectively, after MPP⁺ treatment (200 μmol/L). Melatonin (250 μmol/L) significantly increased survival of cells exposed to MPP⁺ (200 μmol/L), cell viability was 78.1%, 58.8%, and 31.6% at 48, 72, and 96 h, respectively. In 5% serum low glucose condition, melatonin also significantly enhanced survival of cells exposed to MPP⁺ (*P*<0.05) (Figure 2).

LDH release MPP⁺ caused membrane damage, which was determined by the release of the 24 kDa cytosolic enzyme LDH into the culture medium. The level of LDH into the culture medium was found to be 2-fold lower after MPP⁺ treatment in 5% serum condition than after treatment with MPP⁺ in serum-free medium for 48 h (16.3%±1.3%, and 29.4%±1.4%, respectively). MPP⁺ treatment for 12 h at 200 μmol/L did not affect cell viability as revealed by lactate LDH (data not shown). However, after PC12 cells were incubated for 48 h with MPP⁺, in either serum or serum-free condition, there was a significant increase in LDH leakage into the medium. LDH levels were further increased after MPP⁺ treatment for 72 and 96 h. Melatonin 250 μmol/L significantly abolished the increment in LDH leakage pro-

duced by MPP⁺ (Figure 3).

Figure 3. Effect of melatonin on MPP⁺-induced LDH release in PC12 cells. Efflux of LDH from the cells was expressed as a percentage of total LDH (extracellular plus intracellular). The bars are mean±SD of eight experiments. ^c*P*<0.01 vs serum+MPP⁺. ^f*P*<0.01 vs serum free+MPP⁺.

TH immunocytochemistry Tyrosine hydroxylase immunocytochemistry studies showed loss of the TH immunoreactivity in the PC12 cells after MPP⁺ treatment. Addition of melatonin 250 $\mu\text{mol/L}$ significantly increased the survival of TH⁺ cells. The number of TH-immunoreactive cells after melatonin treatment was greater than that in MPP⁺-treated only cells, but less than that in control cells (Figure 4).

Discussion

An increasing body of evidence suggests that the cell energy path is an important target in the pathogenesis of neurodegenerative diseases. MPTP induces direct inhibition of complex I of the mitochondrial respiratory chain, which produces a large number of free radicals and energy crisis in the mitochondria. An excess of free radicals leads to mitochondrial damage, causing a failure of cellular energy metabolism followed by a secondary excitotoxicity. During our research, on the effect of melatonin on PC12 cell death induced by MPP⁺, we noticed that melatonin at low glucose condition had a neuroprotective effect. The neurotoxicity of MPP⁺ is widely acknowledged. In addition, we discovered that this neurotoxicity was dependent on the glucose level. MPP⁺ had obvious toxicity in low glucose condition but not in high glucose condition. Our results suggested that PC12 cells might be vulnerable to MPP⁺ in a low glucose condition but resistant to the injury induced by MPP⁺ in

a high glucose condition. Basma *et al*^[17] demonstrated that the toxicity of an MPTP derivative to PC12 cells was exacerbated by inhibiting glycolysis. This was consistent with our results. Indeed, increasing the concentration of glucose reduced MPP⁺-induced cytotoxicity at all MPP⁺ concentrations accordingly. Depletion of glucose in the medium limited the ability of the cells to drive energy from glycolysis and, furthermore, rapid depletion of limited ATP supply through inhibition of mitochondrial function by MPP⁺ resulted in cell death. At lower glucose concentrations, the depletion would occur more rapidly, which resulted in higher toxicities. At higher glucose concentrations, glycolysis was able to compensate longer for loss of ATP as a result of the MPP⁺-induced inhibition of mitochondrial respiration and hence attenuated cell death. Kutty *et al*^[18] reported similar findings using the neuroblastoma glioma hybrid NG 108-15 neuronal cell culture system. Using leakage of LDH and release of adenine as indices of toxicity, they found that the death of cells exposed to MPTP, MPP⁺, or 2'Et-MPP⁺, and the depletion of ATP caused by the neurotoxins, was markedly reduced owing to high glucose concentration (25 $\mu\text{mol/L}$) in the medium. The enhanced susceptibility of the cells grown in low glucose medium to the toxic effects of the neurotoxins was, most likely, caused by the action of the toxins on the glucose-depleted cells rather than directly because of the depletion of glucose.

The conversion of dye MTT to formazan crystals in cells

Figure 4. The effect of melatonin on TH immunoreaction on PC12 cells. Representative photomicrographs of TH-immunostained PC12 cells following MPP⁺ and/or melatonin treatments ($\times 400$). Cells were cultured for 2 d and then treated for 48 h with A: Negative control; B: vehicle; C: MPP⁺ 200 $\mu\text{mol/L}$; D: MPP⁺ and melatonin 250 $\mu\text{mol/L}$.

has been shown to be related to mitochondrial redox state and respiratory chain activity^[19]. In the present study, the result of MTT reduction could indicate a great role for mitochondrial dysfunction and cellular energy in these models of cell death. The reason seems to be that energy compromise plays a large role in the progression of PD. It is well known that the brain consumes large quantities of oxygen relative to total body mass. MPP⁺ could induce PC12 cell death by depleting cellular levels of ATP through inhibition of complex I. Low glucose levels or the inhibition of glycolysis potentiates MPP⁺ toxicity, while supplementation with fructose reduces the toxicity^[17,20]. The data in this study provided additional support for the hypothesis that MPP⁺ kill cells by inhibiting mitochondrial respiration, and that cell energy status was an important factor for MPP⁺ induced cell death. These observations could prove useful in both the formulation of an accurate cell culture model of PD-like neuro-degeneration and the elucidation of the molecular basis of MPP⁺ toxicity.

In the present study on the efficacy of melatonin to MPP⁺-treated PC12 cells in low glucose culture, melatonin increased cell viability according to the MTT and LDH release assay. Single dose treatment of PC12 cells with melatonin (250 μmol/L) induced a significant decrease in LDH release after 48 h compared with vehicle-treated cultures. TH immunocytochemistry was used to visualize catecholaminergic neurons and monitor MPP⁺-induced changes at the cellular level. As shown here, melatonin also protected PC12 cells against MPP⁺-induced morphological changes. These results indicate that melatonin possesses the remarkable ability to rescue PC12 cells from cell death in our experimental paradigms associated with MPP⁺. The present findings indicate that the protective effects of melatonin against MPP⁺ toxicity may be a result of, at least partially, its antioxidant ability and mitochondria protection. Therefore, supplemental melatonin could ameliorate the severity of neurodegenerative changes caused by free radicals and mitochondrial dysfunction. However, this remains to be confirmed with further investigation.

Our study also showed indications for susceptible neuronal populations. As nerve cells exclusively use glucose as an energy source, increasing glucose concentration in susceptible neuronal populations might be an alternative approach to treat patients with neurodegenerative diseases. Further studies of the actions of melatonin on neurons might also provide a basis for the development of new therapeutic approach to overcome neurodegenerative diseases, such as PD.

Abstract

Aim: To study the pharmacokinetics and accumulation of an *Escherichia coli*-expressed His-tag fused recombinant human endostatin (rh-endostatin) in Rhesus monkeys. **Methods:** Rh-endostatin was iv or sc injected in Rhesus monkeys, and the rh-endostatin concentration in serum samples was determined by an enzyme immunoassay (EIA) method. The serum drug concentration-time data were analyzed by compartmental analysis using the practical pharmacokinetic program 3p97. **Results:** Following iv administration at a dose rate of 1.5, 4.5, and 13.5 mg/kg in rhesus monkeys, the concentration-time curves of rh-endostatin were best fitted to a three-compartment open model. $AUC_{(0-\infty)}$ linearly increased with dose, while Cl_s exhibited no significant difference among different dose groups. The terminal half-lives (λ_3) were 8 ± 8 , 3.1 ± 1.4 , and 20 ± 14 h, respectively. After sc administration at a dose rate of 1.5 mg/kg, the concentration-time curve was best fitted to a two-compartment open model, with a terminal half-life ($T_{1/2\beta}$) of 8 ± 3 h. Bioavailability following sc injection was approximately $70\%\pm 3\%$. After consecutive iv injection of rh-endostatin at a dose rate of $1.5\text{ mg}\cdot\text{kg}^{-1}\cdot\text{d}^{-1}$ for 7 d, the $AUC_{(0-24\text{ h})}$ substantially increased from $22\pm 13\text{ mg}\cdot\text{h}\cdot\text{L}^{-1}$ (d 1) to $50\pm 29\text{ mg}\cdot\text{h}\cdot\text{L}^{-1}$ (d 7), with an accumulation factor of 2.3 ± 0.6 ($P<0.05$). **Conclusion:** The pharmacokinetic behavior of rh-endostatin in Rhesus monkeys complies with linear kinetics within the examined dose range. It tends to be accumulated in bodies after repeated administration at a dose level of $1.5\text{ mg}\cdot\text{kg}^{-1}\cdot\text{d}^{-1}$ for more than 7 consecutive days.

Introduction

Endostatin, which contains 178 amino acid residues, is a 20 kDa COOH-terminal fragment of collagen XVIII^[1]. It was firstly identified as an angiogenesis inhibitor in 1997. Endostatin specifically inhibits endothelial proliferation and potently inhibits angiogenesis and tumor growth^[2]. Subsequently, *Escherichia coli*-derived recombinant endostatin was shown to induce regression and prevent growth of experimental tumors in mice when administered in daily doses as high as $20\text{ mg}/\text{kg}$ ^[2,3]. A novel *Escherichia coli* derived rh-endostatin was developed by MedGen Ltd (Yantai City, China). Compared with the rh-endostatin reported in the literature, an additional nine-amino acid-sequence (MGGSHHHHH) was added at the N-terminal of

the protein, which resulted in the formation of a six-histidine tag (His-tag). The His-tag can be chelated with metal ions such as Ni^{2+} with a relatively high affinity, so it was utilized to simplify purification and to improve stability of the protein. The present study attempted to reveal the pharmacokinetics and the possibility of accumulation after single or multiple doses of this novel rh-endostatin in Rhesus monkeys.

Materials and methods

Drugs and reagents The rh-endostatin used in this study was provided by MedGen (lot YH0502, purity >98%). The drug was dissolved in 5 mmol/L Tris·HCl (pH 7.2) and stored at 4 °C before use.

The ACCUCYTE[®] Human Endostatin[™] enzyme immunoassay (EIA) kit was purchased from CytImmune Sciences Inc (lot 5AE002-SA, Maryland, USA). All other reagents were purchased from commercial sources and were of analytical grade.

Animals Rhesus monkeys (weighing 5.3 kg±0.8 kg, Grade I, Certificate BDW95002) were provided by the Animal Raising Center of the Academy of Military Medical Sciences, China. The animals were individually housed in stainless-steel cages and fed with a standard monkey diet. Fresh fruit was provided twice per day and water was available *ad libitum*.

Experimental design Three iv groups (at a dose rate of 1.5, 4.5, and 13.5 mg/kg body weight, respectively) were assigned to a 3×3 crossover design to perform an auto-control experiment, in which each animal received the three doses mentioned above, with an interval of 7 d between doses (washing out period). Three animals in the sc group were administered rh-endostatin at the dose rate of 1.5 mg/kg. Finally, a multiple-dose group comprising three animals was also designed, in which the monkeys received seven consecutive iv injections of rh-endostatin at the dose rate of 1.5 mg/kg, once per day.

Sample collection and assay Whole blood samples were drawn from the femoral veins of the animals using a puncture needle immediately before administration and at 2, 10 min in the iv group and 20, 40 min, 1, 1.5 h in the sc group, then at 2, 4, 8, 12, 24, 36, 48, and 72 h in all groups after a single dose and the 1st and the 7th dose in the multiple-dose group. In the multiple-dose group, samples were also collected at 2 min and 24 h after the 4th dose. The blood was kept undisturbed at room temperature, then centrifuged at 3000×g for 10 min. The serum was separated and stored at -20 °C until the assay.

The EIA kit was utilized to determine the rh-endostatin levels in the serum samples. The assay was performed according to the guidance of the procedure specified by the manufacturer. A series of calibration standards provided by Medgen was set up in each microplate. The rh-endostatin levels in the unknown samples were obtained by being calculated from the Medgen calibration standard curves on the same microplate.

Data analysis The concentration-absorbance curves were drawn with the MicroCal Origin software (ver 5.0), and then the experimental data were fitted by Logistic function according to the following formula:

$$Y = \frac{(E_{\max} - E_{\min})}{(1 + (X/EC_{50})^{\text{Slope}})} + E_{\min}$$

In which, “X” represents rh-endostatin concentration in samples, “Y” represents the absorbance at 492 nm. The E_{\max} and E_{\min} were the maximal and the minimal absorbance, respectively.

The pharmacokinetic parameters were obtained by the computer program 3p97. Statistical inference was obtained by means of Student’s *t* test or Chi-square test.

Results

Validity of the method for determination of rh-endostatin in monkey serum The ACCUCYTE[®] Human Endostatin[™] kit has been developed using rh-endostatin as the antigen for polyclonal antibody production, and is used in the kit as the assay standard. Studies have demonstrated that it has no cross-reactivity against a variety of cytokines and growth factors, including heat inactivated rh-endostatin and mouse endostatin.

Within the concentration range of 7.8–8000 µg/L, the concentration-absorbance behavior of the rh-endostatin standard provided by Medgen is presented as an inhibitory sigmoid curve that could be described by 4 parameter logistic fitting. Maximal coefficients of variation (CV%) of intra-assay and inter-assay were 13.7% and 20.8%, respectively. The limit of quantitation (LOQ) was 125 µg/L (with CV% of 6.1%). The average endogenous endostatin level observed in the rhesus monkey was 375±175 µg/L ($n=12$).

The results of the blank serum samples fortified with 2000, 500, and 125 µg/L tested rh-endostatin showed that the recovery rates were 87%±5% (81%–91%), 93%±18% (79%–114%), and 94%±4% (90%–99%), respectively ($n=5$ parallel experiments). The CV% of the intra-assay was less than 11.5%, and the CV% of the inter-assay was higher (as high as 19.7%), so it is important to calculate the rh-endostatin concentration in samples by the parameters obtained from the standard curve of the same microplate.

The validity studies demonstrated that the ACCUCYTE[®] Human Endostatin[™] kit was reliable for the determination of serum endostatin levels. The specificity, sensitivity, accuracy, and precision all met the requirements for pharmacokinetics (PK) study.

Concentration-time curves and PK following single dose of rh-endostatin Serum concentration-time profiles of rh-endostatin following iv bolus injections at doses of 1.5, 4.5, and 13.5 mg/kg were best fitted to a three-compartment open model (Figure 1). Rh-endostatin concentration in serum dramatically decreased after iv injection, with the initial half lives (λ_1) of 0.027±0.016 h, 0.04±0.03 h, and 0.10±0.04 h ($P<0.05$ vs the other two groups) following iv

Figure 1. Concentration-time curves of rh-endostatin after a single iv and sc injection in rhesus monkeys. ○, iv 1.5 mg/kg; ●, iv 4.5 mg/kg; ×, iv 13.5 mg/kg; □, sc 1.5 mg/kg. The endogenous endostatin level set at $375 \pm 175 \mu\text{g/L}$.

injection of 1.5, 4.5, and 13.5 mg/kg, respectively. The half-lives of the terminal elimination phase (λ_3) were 8 ± 8 h, 3.1 ± 1.4 h, and 20 ± 14 h, respectively. At a high dose rate of 13.5 mg/kg,

the value of λ_3 was obviously prolonged but without any statistically significant differences. Increased with dose, the mean areas under the serum concentration-time curve [$\text{AUC}_{(0-\infty)}$] of the three iv groups were $15 \pm 5 \text{ mg}\cdot\text{h}\cdot\text{L}^{-1}$, $33 \pm 7 \text{ mg}\cdot\text{h}\cdot\text{L}^{-1}$ and $93 \pm 25 \text{ mg}\cdot\text{h}\cdot\text{L}^{-1}$, respectively. With a dose ratio of 1:3:9, the ratio of $\text{AUC}_{(0-\infty)}$ in the groups was 1:2.2:6.1.

Despite the increase in $\text{AUC}_{(0-\infty)}$, the systemic clearances (Cl_s) among the iv groups were not significantly different (Table 1), indicating that the pharmacokinetic behavior of endostatin within the examined dose range is of linear profile.

The concentration-time profiles following sc administration at a dose rate of 1.5 mg/kg can be described approximately by a two-compartment model (Figure 1). After injection, rh-endostatin was absorbed rapidly, with the time to peak (T_{max}) of 1.1 ± 0.8 h. The mean peak serum concentration (C_{max}) and $\text{AUC}_{(0-\infty)}$ were $1.3 \pm 0.4 \text{ mg/L}$ and $11 \pm 4 \text{ mg}\cdot\text{h}\cdot\text{L}^{-1}$, respectively. The terminal half-life ($T_{1/2\beta}$) was 8 ± 3 h. Compared with the iv group at the same dose, rh-endostatin had a relatively high bioavailability (F) of 70% after sc administration (Table 1).

PK after multiple dosing Following repeated iv administration of rh-endostatin for a 7-d period (once daily) at a dose rate of 1.5 mg/kg, most of the rh-endostatin concentrations at the same time points following injection at d 1 and d 7 were with statistically significant difference (Figure 2). The trough level increased from $388 \pm 61 \mu\text{g/L}$ (d 1) to $623 \pm 261 \mu\text{g/L}$ (d 4) and $1008 \pm 892 \mu\text{g/L}$ (d 7), and the $\text{AUC}_{(0-24\text{h})}$ also increased from $22 \pm 13 \text{ mg}\cdot\text{h}\cdot\text{L}^{-1}$ (d 1) to $50 \pm 29 \text{ mg}\cdot\text{h}\cdot\text{L}^{-1}$ (d 7), but the difference was not significant ($P = 0.053$). The calculated accumulation factor ($\text{AUC}_{\text{d}7}/\text{AUC}_{\text{d}1}$)

Table 1. Pharmacokinetic parameters of the rh-endostatin after iv and sc injection in rhesus monkeys. $n=3$. Mean \pm SD. ^b $P < 0.05$, ^f $P < 0.001$ vs the iv 1.5 mg/kg group.

Figure 2. Concentration-time data of rh-endostatin after consecutive iv injection (q.d.×7) at a dose of 1.5 mg/kg in Rhesus monkeys. The endogenous endostatin levels set at 375±175 µg/L.

was 2.3±0.6 ($P=0.012$), indicating that the rh-endostatin had a tendency to accumulate in the body after successive iv administrations over 7 d with an interval of 24 h between doses.

Discussion

Folkman *et al* firstly described the angiogenesis inhibitor endostatin in January 1997^[2]. Although the molecular mechanisms behind the inhibition of angiogenesis have not yet been elucidated, endostatin seemed to inhibit endothelial cell migration *in vitro* and appeared to be highly effective in murine *in vivo* studies^[4]. Endostatin thought to be an ideal anticancer weapon, was quickly pushed into clinical trials^[5-8]. Thus far, however, recombinant endostatin prepared from *Escherichia coli* is insoluble after purification and therefore inappropriate for clinical settings. A soluble form of endostatin is available from a yeast system that has a relatively low yield and high cost, which has made it difficult to produce endostatin in quantities sufficient for extensive clinical evaluation^[9].

Researches attempted to solve the problems mentioned above, including using the His-tag technique^[10-12]. The rh-endostatin used in this study was His-tagged, containing a six-histidine residue sequence and an affinity tag at its N-terminal, so it could be effectively extracted by affinity chromatography based on immobilized metal ions such as Ni²⁺. In this capture step, we were able to purify 100% of the recombinant protein with more than 99% purity just as reported previously^[13]. The *in vivo* antiangiogenic and anticancer activities of this His-tag recombinant endostatin are as potent as those of the previously reported soluble form. Further, His-tag endostatin is also more convenient for analysis. In

our study, we utilized a rapid and sensitive approach, Matrix-Assisted Laser Desorption Ionization-Time of Flight-Mass Spectrometry (MALDI-TOF-MS), to analyze the proteins, which provided highly accurate the molecular weight information about the protein (data not shown).

There was a relatively high basic endostatin level in monkeys (375±175 µg/L), and it was consistent with endostatin being an endogenous protein. Moreover, to obtain an effect on tumors, the dose of endostatin in preclinical experiments and the recommended dose used in clinical trials are much higher than the dose required of most other therapeutic proteins, which reached the level of mg/kg (or mg/m²). Our PK studies showed that, although statistically not significant, λ_3 of the high dose group was obviously prolonged, suggesting that an exorbitant dose might affect the clearance of endostatin in the body. The results of the multiple dose study for 7 d continuously at the dose level of 1.5 mg/kg also suggested that rh-endostatin tended to accumulate in the body with a statistically significant accumulation factor of 2.3. Some clinical trials have shown that endostatin may cause side effects in the cardiovascular system, especially a dose-dependent toxicity in the heart. So it is best to avoid over accumulation of endostatin in the body by regulating the intervals between each administration. Furthermore, the PK study shows that differences between individuals are great, so individual monitoring during the course of treatment is also recommended in clinical trials.

Abstract

Huntington's disease (HD) is an autosomal dominant neurological disease. It is a fatal neurological disorder affecting 5–10 out of 10 000 people. While there are intensive research efforts focusing on uncovering molecular mechanisms of the pathogenesis of HD, a number of studies have begun to look for effective therapies for HD. There is a large body of encouraging news on novel therapeutic developments. The present paper reviews drugs used for symptomatic treatment of HD and experimental therapies targeting HD molecular pathology.

Introduction

Huntington's disease (HD) is a devastating neurological disorder without effective treatment. It is characterized by involuntary movement, cognition impairment, and psychological disturbance. The disease affects 5–10 out of 10 000 people in western countries. HD is a fatal neurological disorder and death usually occurs approximately 20 years after the onset of symptoms. Therefore, there is an urgent need for developing effective therapies for HD. The genetic cause of HD was uncovered in 1993^[1]. The disease is linked to an expansion of polyglutamine in the novel protein, huntingtin. Since 1993, extensive research efforts have been made to understand pathogenic mechanisms of mutant huntingtin. Multiple molecular mechanisms seem to be involved in HD pathogenesis^[2]. Researchers are actively investigating possible effective therapies based on our current understanding of the molecular pathology of HD. One approach that has been explored is high-throughput screening for small molecules affecting specific molecular targets. Potential targets for high-throughput chemical screenings include molecular chaperones, caspases, the ubiquitin/proteasome proteases, transcription factors, and the offending

polyglutamine-containing proteins themselves. Much attention has been focused on screening for drugs that prevent aggregation of huntingtin with expanded polyglutamine tract. *In vivo* screenings are also being planned or are under-way using transgenic HD mice and *Drosophila*^[3]. The other approach is to use recent advances in molecular biology of neurotrophic factors, neuronal tissue transplantation and cell engineering in HD therapeutic developments with the aim of retarding or reversing HD pathology, but without complete understanding of the molecular pathogenic mechanisms. Both approaches are moving at a fast pace and we expect new therapies will be available clinically soon. This paper reviews current treatments for clinical symptoms of HD and the development of novel therapies targeted at the molecular pathogenic mechanisms of mutant huntingtin.

Developing novel therapies aimed at mutant huntingtin

The expansion of the polyglutamine tract in huntingtin causes the "gain-of-function" mutation. Gained functions include misfolding and aggregation, abnormal protein interactions, and dysregulation of transcription conferred

on mutant huntingtin. The ideal therapy should correct these acquired properties in mutant huntingtin.

Compounds inhibit mutant huntingtin aggregation The *in vitro* aggregation of huntingtin involves a conformational change of the polyglutamine segment from a random coil to an amyloid structure, and is in some ways paralleled in cell culture by the formation of cytoplasmic aggregates and nuclear inclusions^[4-6]. Neuronal inclusions containing amino-terminal fragments have also been detected in HD brains and have become a hallmark of HD pathology. The role of huntingtin aggregates and inclusions in pathogenesis is still being debated, as they may or may not correlate to cell death^[7]. Whether the formation of huntingtin aggregates in the brain is the cause or merely the consequence of the disease is unclear. However, aggregation of mutant huntingtin has been shown to be related to HD progress. Keeping mutant huntingtin from aggregation would provide a way to prevent the progression of the disease.

Several laboratories have screened the NIH (National Institutes of Health) Small Compounds Library with *in vitro* aggregation assay using purified bacterial-expressed N-terminal huntingtin fragments or *in vivo* cell-based aggregation assay. Table 1 shows some published small compounds that directly inhibit aggregation of mutant huntingtin.

These direct aggregation inhibitors have been tested in various HD models such as cell culture, HD *Drosophila* and transgenic HD mice. Congo Red showed protective effects on survival, weight loss, and motor function even after the onset of symptoms of HD in R6/2 transgenic mice. The underlying mechanisms of Congo red include keeping mutant huntingtin fragments from aggregating and increasing the accessibility of huntingtin by proteasome^[14]. Y-27632, an inhibitor of the Rho-associated kinase p160ROCK, prevents polyglutamine protein aggregation in cultured cells and reduces neurodegeneration in an HD *Drosophila* model^[9]. Among benzothiazoles, the strongest inhibitors of mutant huntingtin aggregation, with IC₅₀ ranging from 1.2–11.0 μmol/L in the *in vitro* assay, are very toxic to the cells. But two weak inhibitors with lower IC₅₀ are nontoxic and effective in reduc-

ing the aggregation of mutant huntingtin fragments in a cell-based assay. Riluzole, a glutamate release inhibitor, showed neuroprotective effects in R6/2 transgenic HD mice by prolonging their survival and delaying progressive weight loss, but had no effect on motor coordination, locomotor activity, and the formation of neuronal intranuclear inclusions (NII)^[11]. Trehalose, a disaccharide, reduced aggregation of mutant huntingtin fragments in cells and NII in R6/2 HD transgenic mice. It was proposed that trehalose binds to expanded polyglutamines to prevent aggregation. R6/2 HD mice treated with trehalose showed improved motor function and extended lifespan^[12]. Celastrol, a natural bioactive compound, was effective in reversing the abnormal cellular localization of full-length mutant huntingtin observed in striatal cells derived from Hdh^{Q111/Q111} knock in mice^[13].

Compounds identified by cell-free aggregation assay are usually either non-effective in the cell-based aggregation assay or toxic to cells. For example, many active benzothiazoles^[10], compounds identified by cell-based assay usually reduce aggregation of mutant huntingtin fragments by indirect mechanisms, such as Y-27632^[9]. Combining both cell-free and cell-based assays would make a more reliable prediction of potential small molecules for further drug development. Most experiments used for screening and testing compounds, including *in vitro* aggregation assays, cell-based aggregation assays, HD *Drosophila* and HD transgenic mice, are based on small N-terminal huntingtin fragments with an expanded polyglutamine tract. Still uncertain is the effectiveness of these compounds in transgenic HD mice, particularly when full-length mutant huntingtin is expressed. As more and more laboratories are conducting screening and developing aggregation inhibitors, it is expected that more and more effective compounds will be identified.

In addition to direct aggregation inhibitors, inhibitors of cell toxicity caused by over-expression of N-terminal fragments with expanded polyglutamine tract were also screened from bioactive compounds^[15]. Caspase inhibitors and cannabinoids showed protective effects with EC₅₀ of 10 μmol/L and 30 μmol/L, respectively. Induction of expression of heat

Table 1. Some published small compounds inhibiting aggregation of mutant huntingtin.

Compounds	IC ₅₀ (μmol/L)	Assay system	Reference
Congo Red	0.3	<i>In vitro</i> , exon 1 fragment with 51Q	[8]
Y-27632	~5	Cell based FRET	[9]
Benzothiazoles derivatives, including riluzole	1.2–100	<i>In vitro</i> , exon 1 fragment with 51Q	[10,11]
Trehalose	Not determined	<i>In vitro</i> , a mutant myoglobin with 35Q	[12]
Celastrol and its derivatives	3.6	<i>In vitro</i> , N-terminal first 171aa with 58Q	[13]

shock proteins with geldanamycin also inhibited huntingtin aggregation and huntingtin induced cellular toxicity^[16].

Transglutaminase inhibitor It has been shown *in vitro* that transglutaminase (TGase) can use huntingtin as a substrate to cross-link huntingtin molecules^[17], and gives preference to huntingtin with polyglutamine more than 36 repeat^[18]. TGase activity was found to have increased in HD postmortem brains, and aggregated huntingtin catalyzed by TGase were found in NII^[18]. TGase provides an additional mechanism for the formation of aggregation of mutant huntingtin. This suggests that TGase might play a role in HD pathogenesis and, therefore, is a potential therapeutic target. Cystamine is an inhibitor of TGase^[19]. Treatment of R6/2 transgenic HD mice with cystamine showed a small but significant neuroprotective effect with improvement of motor function, survival and loss of bodyweight. However, whether it can reduce mutant huntingtin aggregates is not clear as contradictory results were reported^[20]. The underlying mechanism(s) is complicated as cystamine is also an antioxidant and increases transcription of certain neuroprotective chaperones, HDJ1/Hsp40^[21].

Protease inhibitors Recent findings showed that huntingtin can be cleaved by proteases, including caspases^[22,23], calpain^[24,25], and aspartyl protease^[26]. N-terminal huntingtin fragments were found in postmortem HD patients' brains^[27], and YAC transgenic mice that expressed full-length human huntingtin with expanded polyglutamine tract^[28]. Because caspase and calpain-mediated partial cleavage of mutant huntingtin promotes huntingtin aggregation and cellular toxicity, inhibitors of huntingtin partial cleavage might have therapeutic values.

The potential caspases cleavage sites are located within amino acids 513–586 and only caspases 2, 3, and 6 were found to be effective^[23]. Calpain cleaves huntingtin at amino acids 469 and 536^[25]. Aspartic endopeptidases release two distinct mHtt fragments, cp-A and cp-B, by cleaving huntingtin between amino acids 104–114. Cp-A is the major fragment that aggregates in the nucleus^[26]. In the cell based assays, caspase-resistant and calpain-resistant hHtt with expanded polyglutamine tract were reported to decrease aggregate formation and reduce cytotoxicity^[23,25]. Caspase inhibitors, z-VAD-fmk and z-DEVD-fmk, can prevent cleavage of huntingtin by caspases and reduce cytotoxicity caused by expanded polyglutamine tract^[23,29]. As N-terminal huntingtin fragments produced by caspase and calpain mediated cleavage are localized in the nucleus and prone to aggregate, this might contribute to HD pathogenesis. Protease inhibitors could reduce N-htt fragments and, in turn, prevent or delay disease progression. A few studies demonstrate that the

caspase inhibitor minocycline was able to inhibit huntingtin aggregation, retard disease progress and prolong the lifespan of HD mice^[30,31]. So far, there is no good inhibitor for calpain and aspartic endopeptidases that have been developed and tested against mutant huntingtin.

Apoptosis or programmed cell death is implicated in HD pathogenesis by the observations of the elevation of cytochrome c in the cytoplasm^[32] and activation of caspases 1, 3, 8, and 9^[32–34]. Thus, the apoptosis pathway is a reasonable target for HD therapy. In one study, intracerebroventricular administration of z-VAD-fmk, as an inhibitor of apoptosis, for 4 weeks starting at the age of 7 weeks improved survival of R6/2 mice by 24.8%^[34]. However, in another study, administration of other apoptosis inhibitors, YVAD-fmk and DEVD-fmk individually, showed no effects at all, though they can extend the lifespan of R6/2 mice by 17.2%^[30,31]. As therapeutic agents, caspase inhibitors might act on two targets: mutant huntingtin to prevent the release of toxic N-terminal fragments and apoptosis to prevent neurons from death caused by mutant huntingtin.

Histon deacetylase (HDAC) inhibitors Huntingtin interacts with several important transcription factors, including cAMP-response element binding protein (CBP), TATA box binding protein (TBP), specificity protein-1 (SP1), nuclear factor- κ B (NF- κ B)^[35–37]. Some of these are reportedly found in huntingtin aggregates. Altered gene expression was found in the R6/2 transgenic HD mice at the ages of 6 and 12 months^[38], and in full-length huntingtin transgenic mice^[39]. Abnormal transcription might be caused by direct interactions between mutant full-length huntingtin or its fragments and transcription factors, which in turn change the normal transcription mediated by these transcription factors. Mutant huntingtin can affect transcription by altered binding to transcription factors not recruiting them into aggregates. This means that altered transcription is an early event in HD pathogenesis caused by soluble mutant huntingtin, either full-length or fragmented before forming aggregates. This notion is supported by several lines of evidence: (1) no CBP, TBP, or SP1 could be found in huntingtin inclusions in several HD mouse models and they maintained normal cellular levels in these mice^[40]; (2) less SP1 was found to bind to DNA in the presence of mutant huntingtin *in vitro*^[36] and *in vivo*^[41].

Reversal of the altered transcription might be a way to retard HD progression. Inhibitors of histone deacetylase (HDAC) can increase gene transcription and have been examined as a potential therapy in both HD *Drosophila* and transgenic R6/2 HD mice. Suberoylanilide hydroxamic acid (SAHA), a selective HDAC inhibitor, reduced neurodegener-

ation in HD *Drosophila*^[42]. In R6/2 mice, SAHA increased histone acetylation and ameliorated motor deficits. However, it did not affect the aggregation and loss of brain weight^[43]. Another HDAC inhibitor, sodium butyrate, improved survival of R6/2 mice in a dose-dependent manner by up to 21.7% when administered intraperitoneally at a dose of 200–10 000 mg·kg⁻¹·d⁻¹. This treatment increased acetylation of histon 3, histon 4, and SP1, improved motor performance and bodyweight loss, and decreased atrophy of the brain and striatum. But sodium butyrate had no effect on the formation of immunoreactive huntingtin aggregates^[44].

Gene therapy Gene therapy is another potential therapeutic method for HD in addition to the small compounds described above. Intracellular antibodies (intrabodies) and RNA interference (RNAi) are 2 potential methods that could be used for gene therapy of HD. Intrabodies are a powerful tool to study protein functions *in vivo* and also a potential therapeutic approach delivered by gene therapy^[45]. This is achieved by expressing single-chain variable region fragments (svFv or sFv) of the antibody intracellularly to bind an intracellular target^[46]. One intrabody selected from a human sFv phage display library, which is specific for the first 17 amino acids of human huntingtin, dramatically reduced the aggregates formation when cotransfected with huntingtin, with expanded polyglutamine tract and a GFP tag^[47]. A recent study reported that an intrabody consisting of only a single light chain variable domain selected from a non-immune human antibody library against the first 20 N-terminal amino acids of human huntingtin and affinity matured with yeast surface display method, inhibited mutant huntingtin aggregation in both cell-free and cell-based assays^[48]. The small size of this single-domain intrabody enables it to diffuse into the nucleus readily. Given its small size and human origin, it should be a more practical approach in gene therapy. The recognition site of the intrabody determines whether the intrabody has beneficial effects. In addition to intrabodies recognizing the first 17 or 20 amino acids of huntingtin, the intrabody recognizes the polyproline domains of huntingtin inhibited aggregation and reduces the cell death caused by mutant huntingtin. However, an intrabody recognizing polyglutamine region actually promoted aggregation and apoptosis^[49].

Recently developed RNAi technology provides a powerful way to reduce target gene expression in cell cultures and in brains^[50]. To explore its potential therapeutic effects in polyglutamine diseases, double-stranded RNA (dsRNA), which induces RNA interference, was used to test against polyglutamine induced cell toxicity^[51]. dsRNA can cause sequence-specific, not allele-specific inhibition of huntingtin

translation. In mammalian cells, dsRNA reduced the toxicity and caspase-3 activation caused by expression of expanded polyglutamine tract. The outcome of a recent breakthrough in studying spinocerebella ataxia 1 (SCA1) demonstrated a bright future in using RNAi in HD^[52]. Both SCA1 and HD belong to a group of severe neurodegenerative diseases caused by expansion of the polyglutamine tract in proteins. In the study, after recombinant adeno-associate virus (AAV) vectors expressing short-hairpin RNA (shRNA) were injected into the cerebellar region of the brain of transgenic SCA1 mice expressing transgenic human disease allele (ataxin-1-Q82), the cerebellar morphology was significantly improved and ataxin-1 inclusions were reduced in Purkinje cells, while there was no effect of the RNAi vectors in wild-type mice^[52]. RNAi targets both the mutant and wild-type allele, however, it does not completely eliminate the mRNA and protein synthesis. Huntingtin plays a critical role during development as shown by the fact that huntingtin knock-out mice are embryonic lethal. However, reducing huntingtin after birth and before the onset of the disease could have minor effects on its normal function. Also, reduction of mutant huntingtin should delay the onset of disease or disease progression. Taken together, RNAi is a potential therapy for HD and will be tested in transgenic mice soon. RNAi targeting mutant huntingtin allele is also currently under development.

Neuron protection and replacement therapy

The goal of neuroprotective therapy is to preserve vulnerable neurons, restore neuronal function or replace lost neurons. These therapies do not require a full understanding of the molecular mechanisms of HD. Thus, they could be useful strategies for the present treatment of HD.

Neurotrophic factors Neurotrophic factors interact with three types of membrane receptors, named TrKA, TrkB, and TrkC. These receptors have tyrosine kinase activity. Nerve growth factor (NGF) binds to TrKA receptors, and brain derived neurotrophic factor (BDNF) and neurotrophin-4/5 (NT-4/5) bind to TrkB, whereas neurotrophin-3 (NT-3) binds preferentially to TrkC^[53]. Neurotrophic factors play critical roles in neurodevelopment and support neuronal survival and plasticity of mature neurons. In a variety of neuronal injury models, neurotrophic factors have been shown to protect neurons from death and to promote functional recovery. Thus, neurotrophic factors have long been suggested as therapeutic candidates for neurodegenerative disorders including Parkinson disease and HD.

Beneficial effects of neurotrophic factors in HD have been

demonstrated in animal models of HD. Excitotoxins and mitochondrial toxins have been used for producing animal models of HD because they induce degeneration of striatal neurons mimicking pathological features of HD. In these HD animal models, administration of neurotrophic factors reduced neuronal damage and behavioral deficits. Neurotrophins are introduced into brains by direct injection, implantation of engineered cells producing neurotrophins, or using viral expression vectors. Direct injection of neurotrophins into brains would not be clinically practical, but transplantation of neurotrophin producing cells into brains is feasible to achieve long lasting delivery of neurotrophins^[54]. To minimize immunoresponse to implanted cells, different methods of encapsulation of cells have been developed. These technologies have greatly reduced host immune response and prolonged survival of implanted cells. In a reported study, polymer-encapsulated cells secreting human NGF survived as long as one year after transplantation into rat ventricles^[55].

Instriatal administration of quinolinic acid (QA), a selective NMDA receptor agonist, causes apoptotic death of striatal projection neurons, but striatal interneurons are mostly spared^[56]. This pathology is similar to that found in HD brains. In QA-induced rodent models of HD, intrastriatal injection of adenovirus encoding BDNF protected neurons from QA-induced striatal lesions as revealed by histological examinations. Immunocytochemistry revealed that viral expression of BDNF increased survival of striatal GABAergic projection neurons^[57]. In another study, cell lines expressing BDNF, NT-3, or NT-4/5 were grafted in the adult rat striatum before QA injection. Seven days after QA injection, immunohistological examination confirmed protection of striatal projection neurons by neurotrophins. QA injection alone or in combination with the control cell line induced a selective loss of striatal projection neurons. Grafting of a BDNF-secreting cell line prevented the loss of all types of striatal projection neurons analyzed^[58]. Neuroprotective effects of transplantation of CNTF producing cells were also demonstrated in non-human primate HD models. Emerich *et al* gave Cynomolgus monkeys intrastriatal implants of polymer-encapsulated kidney fibroblasts from baby hamsters that had been genetically modified to secrete human CNTF^[59]. Human CNTF was found to exert a neuroprotective effect on striatal neurons, including GABAergic, cholinergic and diaphorase-positive neurons. Human CNTF also prevented the retrograde atrophy of layer V neurons in the motor cortex and exerted a significant protective effect on the GABAergic innervation of the two important target fields of the striatum^[59].

Another useful method for delivery of neurotrophins is

to use a viral expression vector. Introduction of viral vector into brains can achieve local production of exogenous neurotrophic factors. In 3-nitropropionic acid (3-NP)-induced rodent HD model, Jodi *et al* investigated the neuroprotective effects of glial-derived neurotrophic factor (GDNF) delivered by an AAV. Lewis rats received bilateral injections of either AAV-GDNF or AAV-green fluorescence protein into the striatum followed by chronic subcutaneous infusions of the mitochondrial toxin, 3-NP (38 mg/kg). All rats underwent 4 weeks of behavioral testing and were then killed. Following 3-NP, the motor performance of AAV-GFP-treated rats on a raised platform deteriorated, while the performance by AAV-GDNF-treated rats was near normal. Histological analysis found that 3-NP-treated rats receiving AAV-GDNF displayed 70% more NeuN-immunoreactive neurons compared to 3-NP-treated rats receiving AAV-GFP^[60]. Other studies on QA-induced rodent HD models also found that enhanced expression of BDNF or GDNF, achieved by AAV vector-mediated gene delivery, protected striatal neurons. Both AAV-BDNF and AAV-GDNF significantly reduced the loss of NeuN and calbindin-immunopositive striatal neurons 2 weeks after lesion compared to controls^[61].

Neurotrophins not only reduced neuronal loss in chemical models of HD, but also improved behavioral deficits. In rats, bilateral infusion of QA produced a significant loss of bodyweight and mortality, which was prevented by prior implantation of hCNTF-secreting cells. QA produced impairments in motor function and cognitive function. The behavioral deficits induced by QA were abolished by implantation of hCNTF-secreting cells prior to QA infusion. Consistent with behavioral improvements after implantation of hCNTF secreting cells, neurochemical examination revealed that CNTF-treated animals did not exhibit any decrease in ChAT levels and only a 10% decrease in GAD levels in the striatum, whereas in control animals QA decreased striatal ChAT levels by 35% and striatal GAD levels by 45%^[59]. Further studies in primates also showed that intracerebral delivery of low doses of CNTF at the onset of HD symptoms not only protects neurons from degeneration but also restores neostriatal functions^[62]. These results support the hypothesis that CNTF infusion into the striatum of HD patients could not only block the degeneration of neurons but also alleviate motor and cognitive symptoms associated with persistent neuronal dysfunction.

The elucidation of the genetic defect in patients with HD has allowed for the detection of individuals at risk for HD prior to the onset of symptoms. Thus “neuroprotection strategies” aimed at preventing the neuropathological and behavioral sequelae of this disease might be powerful therapeutic

tically, as they could be introduced to healthy patients before the initiation of a massive degenerative cascade principally localized to the striatum. After some issues, such as immunoresponse and long-term survival of transplanted cells, are resolved this type of therapeutic strategy could be ready for clinical testing in HD patients.

Neural cell transplantation For many years investigators have proposed the replacement of lost neurons and the restoration of functions by grafting new cells into specific brain regions. HD pathology affects multiple brain regions, but the striatum is most affected in the early stages. Now many studies have been conducted in animal models and HD patients, giving HD patients new hope for a potential novel therapy.

In early studies on a rodent HD model, intrastriatal injection of striatal neurons obtained from 14 to 15-day-old rat fetuses re-established a new striatum-like structure at the site of the ibotenic acid-induced lesions. This reduced striatal atrophy on average to approximately 50%–70% of normal control in the rats with lesions and to approximately 30%–40% in the animals with grafts. In the rats with grafts, there was a significant recovery of striatal neuronal markers after excitotoxic lesions^[63]. Both cell suspensions and tissue chunks can be implanted into the striatum. But grafts derived from cell suspensions triturated in the presence of trypsin contained larger quantities of striatal tissue within the graft and more DARPP-32-positive medium spiny neurons than grafts implanted as fragments of tissue. Afferent and efferent connectivity was also better in the trypsinized suspension graft group^[64].

The rationale for neuronal replacement as a possible therapy for HD is strengthened by showing functional recovery after cell transplantation in a primate HD model. A complete and persistent recovery was demonstrated in a frontal-type cognitive task 2 to 5 months after intrastriatal allografting. The striatal allografts also reduced the occurrence of dystonia, a major abnormal movement associated with HD^[65]. These results further support the use of neural transplantation as a potential therapy for HD. Grafted cells must establish connection with target neurons to have their functions. The establishment of a neuronal network was revealed in the experiments with transplantation of neural precursor cells into a rat model of HD. Neural precursors survived transplantation and large numbers differentiated to express neuronal markers, including DARPP-32, indicating a mature striatal phenotype had been adopted. Neuronal fibers from the grafts projected diffusely throughout the host brain, although there was no evidence that outgrowth was specifically target directed^[66]. The thalamostriatal projec-

tions to rat neostriatal grafts were studied using the Phaseolus vulgaris-leucoagglutinin (PHA-L) axonal tracing technique. Two to six months after implantation of striatal primordia into adult neostriata, PHA-L was injected into two different portions of the intralaminar nuclear complex of the thalamus and examined with an electron microscope. Some of the labeled fibers in the grafts formed dense, focal arborizations. However, the synaptic connections in grafts were different from the normal striatum. The shift of postsynaptic elements in the grafts suggests a loss of pathway specificity in the induction of dendritic spines on neostriatal neurons in grafts^[67]. In a QA-induced experimental HD model, DA-mediated electrophysiological depression was studied after fetal striatal tissue transplants were grafted. QA lesioning reduced responses to DA in the striatal neurons. The dose of DA required to inhibit striatal neuron activity in the lesioned rats was significantly increased compared to that in the non-lesioned rats. Transplantation of the fetal striatal tissue restored electrophysiological sensitivity to DA in the lesioned striatum. Tyrosine hydroxylase-positive terminals were found innervating the striatal grafts^[68]. The survival of grafts and the effects of the grafts on the development of neurological deficits in HD transgenic mice have also been examined. Hemizygote transgenic and wild-type littermate female mice received striatal grafts at the 10 weeks of age and were allowed to survive for 6 weeks. Normal healthy grafts were seen to survive and differentiate within the striatum of transgenic mice in a manner comparable to that seen in control mice. The transgenic mice exhibited a progressive decline in bodyweight from 9 weeks of age and a progressive hypoactivity in an open field test of general locomotor behavior. Although striatal grafts exerted a statistically significant influence on several indices of this impairment, all behavioral effects were small and did not exert any clinically relevant effect on the profound neurological deficiency of the transgenic mice^[69]. This could be a result of the rapid development of neurological deficits in this HD model.

The safety and therapeutic effects of neural transplantation have been tested in HD patients. The first clinical trial in HD patients was reported in 1995 by Madrazo *et al*^[70]. In their trial, homotopic fetal striatal homotransplantations were performed on two HD patients. Each patient was implanted in the ventricular wall of the right caudate nucleus with striata from a 13 week-old and a 12 week-old human fetus. After surgery both patients were kept on cyclosporine A for immunosuppression. The two patients were observed for 16–33 months post-transplantation for neurological progression of their disease. The results showed that the disease in both patients had progressed slower in relation to their pre-

operative state. The effects of fetal tissue transplantation on HD symptoms were carefully evaluated in three patients who had received surgery. Four to six months after surgery, all patients demonstrated increased scores on some measures of cognitive functions. These findings suggest that fetal striatal transplantation could improve some of the cognitive symptoms associated with HD^[71].

In a safety evaluation of three HD patients who received fetal striatal tissue transplantation for one year, MRI revealed that the grafts survived and grew within the striatum without displacing the surrounding tissue. No patients demonstrated adverse effects from the surgery or the associated cyclosporin immunosuppression, nor did any patient exhibit deterioration following the procedure^[72]. In a post-mortem examination of an HD patient, who died from cardiovascular disease 18 months after transplantation, histological analysis demonstrated surviving transplanted cells with typical morphology of the developing striatum. Selective markers of both striatal projection and interneurons showed positive transplant regions clearly innervated by host tyrosine hydroxylase fibers. Neuronal protein aggregates of mutant htt, a biohallmark of HD neuropathology, were not found within the transplanted fetal tissue^[73]. These results suggest that grafts derived from human fetal striatal tissue can survive for a relatively long time after transplantation into a patient with HD^[73]. Functional improvements were demonstrated in the Gaura *et al* report with three HD patients^[74]. They showed that the clinical changes in these three patients were associated with a reduction of the striatal and cortical hypometabolism, demonstrating that grafts were able to restore the function of striato-cortical loops. Conversely, in the two patients not improved by the grafts, striatal and cortical hypometabolism progressed over the 2-year follow-up. Finally, detailed anatomical/functional analysis of the grafted striata, enabled by the 3D fusion of MRI and metabolic images, revealed considerable heterogeneity in the anatomic and metabolic profiles of grafted tissue, both within and between HD patients.

The safety of fetal striatal tissue transplantation was demonstrated in a few clinical trials^[75–78]. All these studies reported that surgical procedures were safe and patients tolerated grafts well. The major adverse events related to the procedure were associated with immunotherapy. However, a report from Hauser *et al* raised big concerns on the safety of fetal tissue transplantation^[79]. In their clinical trial of 7 patients undergoing bilateral engraftment, there were 4 subdural haematomas (in 3 subjects), 2 requiring neurosurgical drainage. One subject died 18 months after surgery from probable cardiac arrhythmia secondary to severe atheroscle-

rotic cardiac disease. Autopsy demonstrated clearly demarcated grafts of typical developing striatal morphology, with host-derived dopaminergic fibers extending into the grafts and no evidence of immune rejection. These latter subjects might have had more advanced HD with a greater degree of brain atrophy, and this could be a contraindication to engraftment.

Other neuroprotective approaches Mitochondria dysfunction has been implicated in HD pathogenesis. The supporting evidence includes deficiency in mitochondria complex I, II and IV in HD brains and HD transgenic mice. Toxins inhibiting mitochondria complex produce striatal HD pathology. Therefore, compounds enhancing energy metabolism have been evaluated for treatment of HD. In HD patients, lactate was increased in cerebrospinal fluid and cerebral cortex. Treatment with coenzyme Q10 (CoQ10), an essential cofactor of the electron transport chain and an important antioxidant, resulted in significant decreases in cortical lactate concentrations in 18 patients. These findings provide evidence for a generalized energy defect in HD, and suggest a possible therapy^[54]. Thus, its neuroprotective effects have been investigated in a variety of animal models. These studies have demonstrated that CoQ10 can protect against striatal lesions produced by the mitochondrial toxins malonate and 3-nitropropionic acid. Oral administration of CoQ10 significantly decreased elevated lactate levels in patients with HD^[80]. CoQ10 in combination with the NMDA antagonist remacemide was examined to determine the efficacy in ameliorating the motor dysfunction and premature death of HD transgenic mice. Motor performance was specifically but transiently improved beginning 3 weeks after drug administration. Survival, however, was not prolonged^[81]. In another study in HD transgenic mice with CoQ10 and remacemide, Ferrante *et al* found that oral administration of either CoQ10 or remacemide significantly extended survival and delayed the development of motor deficits, weight loss, cerebral atrophy, and neuronal intranuclear inclusions in the R6/2 transgenic mouse model of HD. The combined treatment, using CoQ10 and remacemide, was more efficacious than either compound alone, resulting in a 32% and 17% increase in survival in the R6/2 and N171-82Q mice, respectively^[82].

Huntington *et al* completed a multicenter, parallel group, double-blind, 2×2 factorial, randomized clinical trial with CoQ10 in 2001^[83]. Research participants with early HD ($n=347$) were randomized to receive CoQ10 300 mg bid, remacemide hydrochloride 200 mg three times daily, both, or neither treatment, and were evaluated every 4 to 5 months for a total of 30 months on assigned treatment. The prespecified primary measure of efficacy was the change in total

functional capacity (TFC) between baseline and 30 months. This study, however, yielded limited beneficial results. Neither intervention significantly altered the decline in TFC. Patients treated with CoQ10 showed a trend toward slowing in TFC decline (13%) over 30 months as well as beneficial trends in some secondary measures. There were increased frequency of nausea, vomiting, and dizziness with remacemide, and an increased frequency of stomach upset with CoQ10.

Another compound having an effect on bioenergy metabolism is creatine. In HD-transgenic mice, dietary supplementation of 2% creatine significantly improved survival, slowed the development of motor symptoms, and delayed the onset of weight loss. Creatine lessened brain atrophy and the formation of intranuclear inclusions^[84]. Later studies suggested that creatine treatment started after onset of clinical symptoms in HD mice was able to significantly extend survival and improve motor performance. There was reduced brain levels in both creatine and ATP in R6/2 mice, consistent with a bioenergetic defect. Oral creatine supplementation significantly increased brain concentrations of creatine and ATP to wild-type control levels^[85]. These studies suggest that creatine might be useful in the treatment of HD. A preliminary clinical trial with creatine has been performed in 41 patients for 1 year. Creatine 5 g/d was administered. At baseline and after 6 and 12 months, the functional, neuromuscular, and cognitive status of the patients was assessed by a test battery that consisted of: (1) the Unified Huntington's Disease Rating Scale (UHDRS); (2) an exercise test on an isokinetic dynamometer to assess strength of the elbow flexor muscles; (3) a maximal exercise test on a bicycle ergometer to evaluate cardiorespiratory fitness; and (4) a test to assess bimanual coordination ability. One year of creatine intake, at a rate that can improve muscle functional capacity in healthy subjects and patients with neuromuscular disease (5 g/d), did not improve functional, neuromuscular, and cognitive status in patients with stage I to III HD^[86].

It has been suggested that excitotoxicity contributes to the pathogenesis of HD. Riluzole is a substance with glutamate antagonistic properties that is used for neuroprotective treatment in amyotrophic lateral sclerosis, and which is currently being tested in clinical trials for treatment of HD. R6/2 transgenic mice were treated with riluzole orally beginning at a presymptomatic stage until death to investigate its potential neuroprotective effects in the mouse model and it was found that survival time in the riluzole group was significantly increased in comparison to placebo-treated transgenic controls. Additionally, the progressive weight loss

was delayed and significantly reduced by riluzole treatment; behavioral testing of motor coordination and spontaneous locomotor activity, however, showed no statistically significant differences. These data suggest that riluzole is a promising candidate for neuroprotective treatment in human HD^[11].

Recently a few studies have produced interesting results on the beneficial effects of environment enrichment on HD. van Dellen *et al* housed HD mice in large standard cages that contained cardboard, paper and plastic objects, which were changed every two days, from the age of 4 weeks^[87]. They showed that exposure of these mice to a stimulating, enriched environment from an early age helps to prevent the loss of cerebral volume and delays the onset of motor disorders. In the brains of humans diagnosed with HD cannabinoid CB1 receptors are selectively lost from the basal ganglia output nuclei prior to the development of other identifiable neuropathology. In animal studies, they further showed that HD mice housed in a normal environment show a loss of cannabinoid CB1 and dopamine D1 and D2 receptors in the striatum and the corresponding output nuclei of the basal ganglia. HD mice exposed to an enriched environment showed equivalent loss of D1 and D2 receptors as their "non-enriched" counterparts; in contrast, the "enriched" mice show significantly less depletion of CB1 receptors. These results therefore show that an enhanced environment slows the rate of loss of one of the first identifiable neurochemical deficits of HD^[88]. Environment enrichment slowed a decline in RotaRod performance in R6/2 mice. Enrichment also delayed the loss of peristriatal cerebral volume in R6/2 brains^[89]. Improvement of motor functions and prevention of loss of bodyweight in HD mice were found. HD patients and transgenic mice expressing mutant human huntingtin exhibit reduced levels of BDNF, hyperglycemia, and tissue wasting. Enrichment entirely corrected these changes. BDNF levels are unaltered in HD in the anterior cortex, suggesting that enrichment might prevent HD-induced impairment of anterograde transport of this neurotrophin to the striatum^[90].

It has been shown that dietary restriction (DR) slows down the aging process and increases life expectancy. Further, the progression of neuropathological (formation of huntingtin inclusions and apoptotic protease activation), behavioral (motor dysfunction), and metabolic (glucose intolerance and tissue wasting) abnormalities in HD mice were shown to be retarded when the mice were maintained on a DR feeding regimen, which resulted in an extension of their lifespan. DR increases levels of brain-derived neurotrophic factor and the protein chaperone heat-shock protein-70 in the striatum and cortex, which are depleted in HD mice fed a

normal diet. These results suggest a dietary intervention that could suppress the disease process and increase the lifespan of humans that carry the mutant huntingtin gene^[91]. These results could provide a molecular basis for ameliorating the effects of HD by some simple yet effective approaches.

Symptomatic treatment

Movement disorder is a prominent feature of HD. The motor component of HD consists of involuntary choreiform movements and increasing difficulties with voluntary movement. Behavioral and psychological problems are the first manifested symptoms in nearly 50% of HD patients. The most common symptoms are loss of energy and initiative, poor perseverance and quality of work, impaired judgment, poor self-care, and emotional blunting. Affective symptoms such as depression, anxiety, irritability, dementia, and schizophrenia-like psychosis occur with a relatively high frequency in HD^[92,93]. At present, in the absence of a cure for HD, it is desirable to treat HD symptoms aimed at enhancing the quality of life of patients and improving overall functioning. These types of treatments should include medication, social service, and physical/occupational therapy.

Management of motor dysfunction In general, treatment of chorea is not recommended unless symptoms are disabling. Degeneration of striatal GABAergic neurons can cause hyperactivity of dopaminergic systems. Reducing dopaminergic activity might help restore the balance of neurotransmitter functions. Neuroleptics are dopamine receptor antagonists used for the treatment of psychosis. These drugs have been tried for treatment of choreiform movement in HD patients. Haloperidol is a protoform neuroleptic for the treatment of schizophrenia. Haloperidol is a dopamine D2 receptor antagonist. This drug has been tested in HD for reducing abnormal movements. Eighteen patients with Huntington's chorea were examined before and after treatment with haloperidol, pimozide and tiapride to study the effect of such treatment on hyperkinesia and motor performance. Pimozide and haloperidol improved hyperkinesia; none of the drugs significantly affected motor performance^[94]. The relationship between serum haloperidol concentration and improvement in abnormal movements was investigated in 20 adult HD patients. Serum samples and assessments of the severity of chorea were simultaneously obtained from each patient. Results showed that significant improvement of abnormal movements, greater than 30% from baseline, occurred at serum concentrations between 2 and 5 $\mu\text{g/L}$, which corresponded to doses of 1.5 to 10 mg/d^[95]. The main

adverse effect of haloperidol is the high frequency of dyskinesia. Clinically the most problematic of these are sedation, cognitive slowing, increased mobility problems, and hypotension. The inability of traditional dopamine antagonists to improve functional capacity, despite ameliorating chorea, is possibly a result of the suppression of voluntary motor activity. The antipsychotic drug risperidone was reported to be effective in the treatment of chorea and psychosis in HD patients. After initiating the treatment, the patient experienced improvement in maintaining gait and increased hand skills. It was noticed that the patient had decreased choreiform movements in the second week of the treatment^[96].

Chorea in HD and in the levodopa-induced dyskinesias of PD can be clinically indistinguishable. In PD, hyperphosphorylation of NMDA receptors expressed on striatal medium spiny neurons contributes to peak-dose dyskinesias, and drugs that block these receptors can diminish chorea severity. Because these spiny neurons are the primary target of the neurodegenerative process in HD, sensitization of NMDA receptors on residual striatal neurons might also participate in the generation of motor dysfunction in HD. Movement disorder is also treated with the NMDA receptor antagonists riluzole and amantadine. In a 6-week open-label trial of riluzole (50 mg twice a day) in eight subjects with HD, subjects were evaluated before riluzole treatment, on treatment, and off treatment, with the chorea, dystonia, and total functional capacity (TFC) scores from the Unified Huntington's Disease Rating Scale, and magnetic resonance spectroscopy measurements of occipital cortex and basal ganglia lactate levels. The chorea rating score improved by 35% on treatment and worsened after discontinuation of treatment. There was no significant effect on the dystonia or TFC score^[97]. In another open label study, riluzole was given (50 mg twice a day) to nine HD patients (clinical stages 1–3; mean age 46.4 years; mean disease duration 8 years). Patients were evaluated at baseline and after 3 and 12 months of riluzole therapy. Results demonstrated that riluzole was well tolerated. At 3 months, mean total motor scale (TMS), mean TMS chorea subscore, and mean total functional capacity scale were significantly improved compared with pre-drug baseline. At 12 months, however, this beneficial effect on motor status and overall function was not sustained. In contrast, severity and frequency of behavioral dysfunction as well as psychomotor speed assessed by the symbol digit modalities test were improved compared with baseline. These data suggest that there are transient antichoreatic effects and more sustained effects of riluzole on psychomotor speed and behavior in patients with HD^[98]. In a case report pre-

sented by Bonelli *et al*, two HD patients with severe motor dysfunction were initially treated with olanzapine (20 mg daily)^[99]. Improvement of motor performance was obtained with olanzapine in both patients. After 2 weeks of treatment with olanzapine, riluzole (50 mg twice a day) was added. A further slight improvement of motor function (especially in the fine motor tasks) was seen in the next 2 weeks without additional side-effects.

Another NMDA receptor antagonist tested for use in HD patients is amantadine. In a clinical study conducted by Verhagen *et al*, 24 patients with HD entered a double-blind placebo-controlled crossover study of amantadine with two 2-week arms^[100]. Chorea scores were lower with amantadine (usually 400 mg/d) than placebo, with a median reduction in extremity chorea at rest of 36% for all 22 patients evaluated and of 56% in the 10 individuals with the highest plasma drug levels. Improvement correlated with plasma amantadine concentrations but not CAG repeat length. The acute antidyskinetic effects of IV amantadine in HD were evaluated. A 2-h IV infusion of amantadine or placebo was given to 9 patients with HD on two different days in a double-blind, randomized crossover fashion. All patients subsequently received oral amantadine unblinded for a 1-year period. A reduction of dyskinesia scores was reported during both IV and oral amantadine treatment ($P < 0.05$)^[101].

Management of psychological disturbance There are not many studies on the treatment of the psychopathology of HD although psychological disturbance is common in HD patients. Episodic aggressive behavior in HD that responded poorly to neuroleptics was reduced by a carefully titrated dose of propranolol in 3 patients with advanced HD. The optimal doses were 180 and 30 mg/d, respectively^[102]. Lithium is a mood stabilizer used for bipolar disorder. It has been reported that 6 patients with a family history of HD chorea participated in a double blind crossover trial involving four treatments: lithium carbonate, haloperidol, lithium carbonate and haloperidol, and placebo. None of the treatments significantly affected chorea measurements. With regard to the psychological variables, the levels of irritability, the frequency of angry outbursts and depression did appear to be affected by the treatment in some patients. Three patients improved on a combination of lithium carbonate and haloperidol while the remaining three did not. It is suggested that lithium carbonate and haloperidol together should be seriously considered in the treatment of HD when patients are excessively irritable and impulsive^[103].

Atypical antipsychotic drugs have recently been found to be useful in the treatment of HD symptoms including motor dysfunction. Risperidone is a novel antipsychotic drug with

a balanced serotonin 5-HT₂ and dopamine D₂ receptor antagonism. In a case report, risperidone was introduced in combination with clozapine therapy. Risperidone was started at 0.5 mg/d and gradually increased to 6 mg/d over a 6-week period. This coincided with marked improvement in abnormal involuntary movements (AIMS score of 7) and further improvement in psychosis (BPRS score of 7). Choreiform movements of the limbs ceased almost completely, gait improved significantly, and dysarthria and facial grimacing decreased^[104]. Olanzapine is a new atypical antipsychotic drug. It is a thienodibenzodiazepine and is structurally very similar to clozapine. Olanzapine has been shown to have a high affinity for a large number of receptors including D₁, D₂, D₄, 5HT_{2A}, 5HT_{2C}, 5HT₃, α 1-adrenergic, histamine H₁, and five muscarinic receptors. Unlike clozapine it is not associated with the potentially serious side effect of agranulocytosis and therefore frequent blood monitoring is not necessary. Dipple reported the first case of using olanzapine in HD^[105]. An HD patient who had shown no improvement after using other typical anti-psychotic drugs showed a positive response in improving motor function with olanzapine. As a result, more HD patients were treated with olanzapine. In a clinical study with 11 HD patients, 9 patients were treated with olanzapine for 9.8 \pm 5.9 months. Assessment of the drug's effects was carried out using the Clinical Global Impression of Change Scale (CGIC) and the United Huntington's Disease Rating Scale behavioral (UHDRS-b) and motor (UHDRS-m) at 6-month intervals. The Mean CGIC was 2.1 \pm 0.8. UHDRS-b improved significantly and UHDRS-m did not change. It was concluded that olanzapine is a good alternative treatment in HD, mainly for psychiatric symptoms and is moderately effective for motor symptoms, possibly because of its effect on chorea^[106].

Symptomatic treatment of HD like symptoms with Chinese medicine HD diagnosis is difficult in China as autopsy and genetic testing are usually not performed. However, there are many reports describing successful treatment of choreiform movement disorders (named chorea minor) with Chinese medicine. Among these reported cases, most involve HD-like symptoms caused by other diseases. But these treatments might also be effective in relief of HD symptoms. Recent studies reported that a natural product derived from six herbs, including Ginseng and Shouwu, protected 3-nitropropionic acid induced striatal lesions and reduced behavioral deficits. This herbal product increased expression of BDNF and GDNF in the brain^[107-109].

Summary and conclusion

The therapeutic benefits of current symptomatic treat-

ments remain to be determined. The effectiveness of drug treatment usually has been evaluated only in a small number of patients, and varies in patients with different stages of HD. In order to confirm the value of these treatments in the management of symptoms of HD, more clinical trials involving a larger number of patients and better design are needed. It should be noted that improvement of chorea by typical neuroleptics might be at the expense of worsening voluntary movement. Extensive studies have greatly advanced our understanding of the molecular mechanisms of HD pathogenesis. The main challenge in finding a cure for HD is the selection of molecular targets. Multiple parallel and sequential signaling pathways are involved in cultivating ultimate neuronal dysfunction and death induced by mutant huntingtin. Identifying upstream and core molecular events could be crucial for therapeutic development. Thus far, these key issues have not been resolved. Another big challenge is an effective read-out for the assay of therapeutic effects. Many novel therapies targeting molecular pathogenesis are awaiting safe and clinical studies. With regards to fetal tissue transplantation, the resources are limited and there is still debate on the ethical issues of using this technology. The safety and rationale of tissue transplantation have also now been questioned^[110]. Compounds improving energy production are safe but their effectiveness needs to be further evaluated. At present, NMDA receptor antagonists, riluzole and amantadine, and energy production boosters, CoQ10 and creatine, might be worth testing. The use of Chinese medicine for HD treatment also needs further investigation. We have made great progress, but we still have long way to go in developing a cure for HD.

Abstract

In the present paper, we overview the discovery of new biological activities induced by ginsenoside Rg1 and Rb1 and discuss possible mechanisms of action. Both compounds could increase neural plasticity in efficacy and structure; especially Rg1, as one small molecular drug, can increase proliferation and differentiation of neural progenitor cells in dentate gyrus of hippocampus of normal adult mice and global ischemia model in gerbils. This finding has great value for treatment of Alzheimer's disease and other neurodegenerative disorders which is characterized by neurons loss. Increase of expression of brain derived neurotrophic factor, Bcl-2 and antioxidant enzyme, enhanced new synapse formation, inhibition of apoptosis and calcium overload are also important neuron protective factors. Rg1 and Rb1 have common effects, but there are some differences in pharmacology and mechanism. These differences may attribute to their different chemical structure. Rg1 is panaxtriol with two sugars, while Rb1 is panaxtriol with four sugars.

Introduction

Ginseng, the root and rhizome of *Panax ginseng* C A Meyer, has been used as a tonic remedy in Chinese traditional medicine for over 2000 years. The word panax is derived from panacea, which means cure-all and longevity. In 200 AD when this herb was described in the oldest Chinese materia medica book: Shen Nong Ben Cao Jing, the author depicted many pharmacological functions of ginseng, including both nootropic and anti-aging effects. Since then, ginseng has been widely used as a supplemental medicine. However, it is neither a tonic nor a remedy for a certain disease.

With the development of modern technology, more and more active principles have been isolated and purified from this herb, and the field of ginseng research has drawn intense attention in Asia, Europe, and the United States. Every year, there are hundreds of papers published and new uses for ginseng discovered. More than 40 ginsenosides have been isolated from several species of ginseng. Among all the active ingredients isolated from ginseng, we selected Rg1 and Rb1 for study because Rg1 and Rb1 are the repre-

sentative constituents of panax ginseng and American ginseng, respectively. Rg1 and Rb1 have different chemical structure: Rg1 is panaxtriol with 2 sugars, while Rb1 is panaxtriol with 4 sugars. The chemical structure of Rg1 and Rb1 are shown in Figure 1 and 2. Many researchers believe that they share many beneficial effects of ginseng, including alleviating learning and memory impairment, reversing pathological and physiological changes induced by stress and aging, *etc.* In the review, we take an overview of the proven anti-amnestic and anti-aging effects of both compounds and discuss their possible mechanisms in detail.

Anti-amnestic effects

Various memory-impairment models have been used to evaluate how ginseng and its active ingredients affect learning and memory. In a passive avoidance test, ginsenoside Rg1, (25–100 mg/kg) improved learning and memory's acquisition, consolidation and retrieval, which were impaired by anisodine, cycloheximide, and alcohol respectively, indicating that Rg1 can improve all stages of memory. To study the effect of Rg1 on the learning and memory induced by β -

Figure 1. The structure of ginsenoside Rg1. $R_1=OH$; $R_2=OGlc$; $R_3=OGlc$

Figure 2. The structure of ginsenoside Rb1. $R_1=OGlc(2-1)Glc$; $R_2=OGlc(6-1)Glc$

amyloid (25–35), passive avoidance and performance in Morris water maze were assayed after final treatment, and we found that Rg1 at 5–10 mg/kg significantly decreased latency and swimming distance, and improved corresponding changes in search strategies in the Morris water maze and increased step-through latency also. Rg1 significantly improved memory deficits in aged rats, ovariectomized rats, and cerebral ischemia-reperfusion rats. Results of the present study showed that ginseng extract and ginsenoside Rg1, Rb1 (25–100 mg/kg) facilitated acquisition and retrieval of memory. Moreover, they also antagonized memory loss and cognitive deficit under various pathological conditions such as cerebral ischemia and dementia. However, the nootropic effect of Rg1 was generally stronger than that of Rb1. All the beneficial effects of ginsenosides observed in the memory-impairment models have been repeated many times in different labs^[1–7].

Long-term potentiation (LTP) was first observed in 1973. Since then, it has been thoroughly investigated. Many scientists believe that LTP in the hippocampus is the key form of long-lasting synaptic plasticity and it connects the behavior of learning and memory with the plasticity of neurons. Therefore, LTP has been considered as an important index of

cognitive activities in cellular and synaptic levels. In Zhang's lab^[8,9], both total ginsenosides (25–100 mg/kg, ip) and ginsenoside Rg1 (10 and 100 nmol/L, icv) were found to improve the basic synaptic transmission and increased the amplitude of LTP induced by high-frequency-stimulation (HFS) in anesthetized rats. In contrast, although ginsenoside Rb1 (10 and 100 nmol/L, icv) administered 30 min after tetanic stimulation was found to increase population spike (PS) amplitude^[10], it exerted an inhibitory effect on LTP induced by HFS when given at the same time of stimulation and showed no influence on basic synaptic transmission. Further research suggests that nitric oxide (NO) synthesized by nitric oxide synthase (NOS), especially by nNOS, was involved in synaptic transmission improving the effect of Rg1^[11]. In order to eliminate the influence of anesthetics on synaptic transmission, rats were chronically implanted with a stimulation electrode in the perforated path and a recording electrode in the granule cell of dentate gyrus. After Rg1 was administered (10 and 30 mg/kg, ip) for 12 d, an extracellular recording technique was used to record PS. The results demonstrated that Rg1 significantly increased the sensitivity of evoking PS and the amplitude of PS in freely moving rats^[11].

Mechanisms underlying the nootropic effect of ginseng

First, ginsenoside might potentiate the cholinergic system in the central nervous system (CNS). Acetylcholine (ACh) is a very important neurotransmitter in the brain and its scarcity often leads to learning and memory impairment. In Zhang's lab, Rg1 and Rb1 were found to enhance cholinergic system's function through two different pathways: first, both ginsenosides showed the ability to increase the density of central M-cholinergic receptors, although they showed no specific binding to the receptors. Second, Rg1 and Rb1 increased the level of ACh in the CNS, which might be the result of ginsenoside-induced enhancement on choline acetyltransferase activity and inhibition on acetylcholine esterase activity^[2,12]. Meanwhile, Banishin *et al* reported that both ginsenosides facilitated cholinergic neurotransmission by increasing cholinergic metabolism in the CNS^[13].

It is very interesting to point out that according to existing theory, receptor density is directly dependent on transmitter activity in the brain. For instance, muscarinic receptor level falls in response to the administration of its agonists, while there is a rise in response to chronic administration of muscarinic antagonists. However, findings in Zhang's lab show simultaneous increases in M receptor density and ACh level, which is not in line with previous observations^[14]. So, maybe a new theory should be provided to elucidate the effects of ginseng on the cholinergic system.

First, both Rg1 and Rb1 were found to increase protein biosynthesis in the mouse brain^[12]. This finding could also explain ginseng's function on memory consolidation. In addition, the increment of M-receptor density could be one of the secondary effects of the enhancement of protein synthesis.

Second, ginsenoside may interfere with immediate early genes. The *c-fos* proto-oncogene is the prototype of the early-response class of genes and its expression can be considered as a marker of neuronal activity. Rg1 was found to significantly increase the expression of *c-fos* gene in both young and old rats^[15]. Furthermore, it had the ability to increase cyclic adenosine monophosphate (cAMP) level in rat hippocampus. This might provide another explanation for the nootropic effect of Rg1.

Third, apoptosis or programmed cell death is a process by which a cell actively commits suicide under tightly controlled circumstances. Apoptosis is required for maintenance of the homeostasis and is essential in physiological processes such as development, differentiation and aging. However, defective regulation of apoptosis might play a role in the etiology of cancer, acquired immunodeficiency syndrome, autoimmune diseases and neural degenerative disorders. Therefore, pharmacological manipulation of this process may offer new possibilities for the prevention and treatment of many illnesses. In 1997, Zhang's lab reported firstly that Rg1 at concentration of 1 $\mu\text{mol/L}$ and 10 $\mu\text{mol/L}$ inhibited apoptosis induced by withdrawing serum from the culture system of primary cortical neurons^[16]. *In vivo* study, an anti-apoptotic effect of Rg1 was seen in aged rats (24–27 month). Further study showed that mechanisms underlying Rg1's effect on apoptosis involved decreasing NO content and NOS activity, reducing intracellular calcium concentration and enhancing superoxide dismutase (SOD) activity. Researchers from the same lab also found that both NOS expression and the activity of NOS enhanced significantly in aged rats (27 months old), which leads to the increment of NO concentration in rat's cortex. This change was reversed by Rg1 administration (20 and 40 mg/kg daily for 5 d)^[17]. Taken together with previous *in vitro* results, they confirmed that NO played a role in the acceleration of senescence and that the inhibitory effect of Rg1 on NOS activity might provide an explanation for its anti-aging function.

Recently, the anti-apoptotic effect of Rg1 on neurons was further proved by both *in vivo* and *in vitro* experiments done in other labs^[18,19]. The authors of these studies suggested that this effect of Rg1 might attribute to enhancing the ratio of Bcl-2 to Bax protein and inhibiting activation of caspase-3.

Fourth, ginsenoside may modulate synaptic plasticity. Synapses are the essential structure in the CNS through which signals are transmitted, processed and integrated among neurons. The plasticity of synaptic function is also regarded as one of the most important mechanisms underlying the process of learning and memory. Interestingly, in weaning mice administered with Rg1 and Rb1 for 14 d, the thickness of cortex and density of synapses in the hippocampal CA3 region were significantly increased (Table 1)^[20]. Meanwhile, Rg1 was found to induce the sprouting of mossy fiber and the expression of the growth-associate protein (GAP-43) dose-dependently in hippocampus in adult rats (Figure 3)^[9]. Furthermore, both Rg1 and Rb1 were found to increase hippocampal synaptic density^[21]. These experiment proofs provided morphological and physiological evidence to support nootropic effect of ginseng.

Table 1. Effects of ginsenoside Rb1 and Rg1 on the number of synapses in the hippocampus CA3 region in mice. *n*=5. Mean \pm SD. ^c*P*<0.01 vs control group [Ref 20].

Finally, ginsenoside, especially Rg1 might regulate the proliferation and/or surviving ability of neural progenitor cells. A neural progenitor cell (NPC) or Neural stem cell (NSC) is a special kind of neural cell. Previous studies have shown that NPC existed in certain areas in the adult brain as well as in developing brain^[22]. Recently, several rodent stud-

Figure 4. Increase of ischemia-induced proliferation of cells by ginsenoside Rg1 in the dentate gyrus of adult gerbils. The number of bromodeoxyuridine-positive nuclei in the subgranular zone (SGZ) of animals killed 3 d ($n=4$), 7 d ($n=4$), 11 d ($n=6$), and 21 d ($n=4$) after 6 min of global ischemia. Bromodeoxyuridine (BrdU) was injected every 4 h for 12 h on the day prior to sacrifice. A: Ischemia; B: Ischemia+Rg1 (5 mg/kg); C: Ischemia+Rg1 (10 mg/kg). Each bar shows mean \pm SEM. ^b $P<0.05$ vs ischemic group^[27].

ies have suggested that the proliferation ability of NPC was reduced in association with age or diseases related cognitive decline^[23–25]. Hence, many scientists hypothesize that damage of neurogenesis may be one of the elementary reasons for function-declines in aging and neurodegenerative diseases. Recently, Shen *et al*^[26] reported that Rg1 enhanced proliferation ability of rodent hippocampal progenitor cells both *in vitro* and *in vivo*. Incubation of neural progenitor cells with Rg1 resulted in significant increase in absorbency value, [³H]thymidine incorporation and the number of proliferating progenitor cell spheres. In addition, Rg1 administered for 2 weeks (ip) led to marked enhancement of the number of dividing cells in hippocampus of adult mice. Meanwhile, the same authors found that Rg1 systemically administered not only promoted cell proliferation, but also enhanced the surviving rate of newborn cells in the dentate gyrus of adult gerbils suffered from transient global ischemia (Figure 4)^[27]. The authors suggested that influencing the NPC function might serve as one of the elementary mechanisms underlying pharmacological effects of Rg1 and ginseng on the CNS.

To summarize, the nootropic effect of ginseng and ginsenosides has been proved in both behavioral and electrophysiological studies, which is unique among existing nootropic drugs.

Anti-aging effects

Anti-stress effects Various kinds of stress, especially

chronic stress, cause many diseases and accelerate aging, so anti-stress drugs are in high demand. Ginseng has long been considered to act as an adaptogen, but the mechanisms underlying its effect are still unclear. Recently, acute, chronic, and repeated stress models were used to observe the effects of ginsenosides on stress.

Repeated hanging stress was used to observe the effect of stress on the reproduction-endocrine system. The results indicated that repeated stress reduced sexual behavior (licking, mounting, and mating), decreased plasma androgen or estrogen levels and increased corticosterone level in male and female mice. Treatment with ginsenoside Rb1 at dosage of 2.5, 5, and 10 mg/kg prior to stress prevented the decrease of sexual behavior and the increase of corticosterone. Rb1 brought the concentration of plasma sexual hormones back to normal level^[28]. Further study proved that Rb1 (2.5, 5 and 10 mg/kg, ip for 14 d) significantly improved sexual function in mice. The mechanism underlying its “zhuang yang” effects might be the activation of NO/cyclic guanosine monophosphate (cGMP) pathway in mice corpus cavernosum^[29].

Dysfunction of reproductive-endocrine system is often accompanied by the degeneration of cognitive processes in middle and late age. Therefore, the influence of chronic stress on cognitive abilities in mice was observed. The result showed that 60 consecutive days of stress caused a neuronal damage as well as cognitive impairment. Further study suggested that chronic stress decreased brain-derived neurotrophic factor and neurotrophin-3 (NT-3) protein expression throughout the brain area especially in the hippocampus. In addition, stress also induced the release of noradrenaline in the homogenates of the hippocampus and the hypothalamus. Similarly, ginsenoside Rb1 showed the ability to reverse all the pathological changes induced by stress^[30]. However, ginsenoside Rg1 had no effect on both repeated and chronic stress-related changes. Instead, it accelerated stress-induced pathological changes in mice, showing another difference between Rg1 and Rb1. Based on these results, Rb1 is believed to be the main anti-stress principle in ginseng and it might be a promising candidate for prevention and treatment of stress-related diseases.

Immunoregulatory effects It has been well documented that aging leads to a substantial decline of T cell function. The possible reasons for the decline include the inability of lymphocytes to proliferation in response to mitogenic stimulation and the decrease of interleukin-2 (IL-2) production. Rg1 given at the concentration of 20 mg/kg *in vivo* and 10 μ mol/L *in vitro* enhanced the proliferation of lymphocytes and the production of IL-2 in aged rats^[31]. However, it had

no influence on the immune function in young and adult rats. Thus, it is reasonable to consider Rg1 as an “immunoregulator” rather than an “immunopotentiating agent”. Further investigation suggested that the mechanism underlying Rg1’s effect on immune function in aged rats might be involved in increasing cAMP and cGMP levels in lymphocytes^[32].

In contrast, Rb1 had no effect on the decline of immune function in aged rats, which was the third difference found between Rg1 and Rb1.

Other effects In the previous paragraphs, we summarized the pharmacological effects of ginseng, especially ginsenoside Rg1 and Rb1, and the possible mechanisms of these actions. Recent studies have shown that ginseng saponins are a diverse group of steroidal saponins that demonstrates the ability to target a myriad of tissues and produce an array of pharmacological responses, such as anti-osteoporosis, anti-platelet aggregation, anti-arrhythmia, and anti-cancer^[7,33–39]. Furthermore, besides ginsenosides, there are also other constituents existing in ginseng, including glucoside, protein, poly-peptides, amino acids, vitamins, *etc.* Their pharmacological functions have been investigated too^[40,41].

Senescence is a physiological process and cannot be reversed. Many factors act together in this process (Figure 5). As discussed above, ginseng, especially ginsenoside Rg1 and Rb1, have the ability to interfere almost all of the pathways that accelerate aging process. Besides the effects we mentioned above, some researchers also found that both ginsenosides to some extent inhibited lipid peroxidation induced by VitC-reduced nicotinamide adenine dinucleotide phosphate and Fe²⁺-cysteine in rat liver and brain microsome; reduced the concentration of intercellular calcium; and prevented hippocampal neurons from the damage induced by excitatory amino acids^[42–46]. All those findings may prove

the anti-aging and nootropic effects of this ancient herb.

Concluding remarks

Rg1 and Rb1 are believed to be the main active principles in ginseng. As we discussed above, both Rg1 and Rb1 showed similar effects in improving learning and memory, increasing B_{max} of M-cholinergic receptors, and accelerating cerebral protein and ACh biosynthesis. However, they do behave differently in some areas. For example, Rg1, but not Rb1, enhanced basic synaptic transmission and magnitude of LTP induced by HFS, and showed immunoregulatory action in aged rats as well as an anti-osteoporosis effect in ovariectomized rats. However, Rb1 showed anti-stress effect in acute, chronic, and repeated stress models, whereas Rg1 aggravated stress-induced damage; in addition, Rb1 protected mice against low temperature damage, and Rg1 showed no such effect at the same dose. For the reason of the function differences between the two ginsenosides, some researchers hypothesize it may be due to the difference between their chemical structures (Rb1 has two more glucose as compared to Rg1).

With the application of modern scientific technology, the research of ginseng has made big progress. Ginseng is believed to be the most unique traditional medical herb because it contains the maximum numbers of active constituents, has the most extensive pharmacological effects and specific mechanism of actions in Chinese materia medica.

Chemists have already acquired nearly 40 kinds of ginsenosides from various parts of this plant and new structures continue to identified^[47–52]. Because ginsenosides and other constituents of ginseng produce different effects and a single ginsenoside initiates multiple actions in the same tissue, the overall pharmacology of ginseng is complicated. Therefore, we must investigate the effects of individual sa-

Figure 5. Sketch map of the pathophysiology of aging.

ponin and its mechanisms of actions one by one. But we still cannot synthesize any ginsenosides because of the complexity of their structures. Currently, the only way to prepare active principles from ginseng is to separate and purify them from various parts of the plant. But with the application of modern technology, the yield of some ginsenosides such as Rb1, Rg1, Rg3, and Re has reached up to 1 kg in a number of Chinese corporations. Hence, we can predict that the preparation of active constituents in ginseng has reached the level of industrial production, which makes it possible to further investigate this mysterious herb.

Ginseng and ginsenoside can increase immune function, enhance central cholinergic system function, inhibit free radical and NO generation, and promote proliferation of rodent progenitor cells *in vitro* and *in vivo* (Figure 5). These effects benefit aged people and aging-related diseases.

Abstract

Aim: To study the effects of the caspase-1 inhibitor Ac-YVAD-CHO on quinolinic acid (QA)-induced apoptosis. **Methods:** Rats were pre-treated with intrastriatal infusion of Ac-YVAD-CHO (2–8 µg) before intrastriatal injection of QA (60 nmol). Striatal total proteins, genomic DNA, and nuclear proteins were isolated. The effects of Ac-YVAD-CHO on QA-induced caspase-1 activity, internucleosomal DNA fragmentation, IκB-α degradation, NF-κB, and AP-1 activation, and increases in p53 protein levels were measured with enzyme assays, agarose gel electrophoresis, electrophoresis mobility shift assays, and Western blot analysis. **Results:** Pre-treatment with Ac-YVAD-CHO inhibited QA-induced internucleosomal DNA fragmentation. Ac-YVAD-CHO inhibited QA-induced increases in caspase-1 activity and p53 protein levels, but had no effect on QA-induced IκB-α degradation, NF-κB or AP-1 activation. **Conclusion:** Caspase-1 is involved in QA-induced p53 upregulation but not IκB-α degradation. Inhibition of caspase-1 attenuates QA-induced apoptosis in rat striatum.

Introduction

Excitotoxin-induced degeneration of striatal neurons in animals has been used as an animal model of Huntington's disease (HD). Recent studies in transgenic animal models of HD demonstrated increased response of striatal neurons to excitotoxin, supporting a role of glutamate receptors in HD^[1]. Excitotoxins acting on *N*-methyl-*D*-aspartate (NMDA) and kainic acid (KA) receptors will induce destruction of striatal GABAergic neurons by apoptotic mechanisms^[2–4]. Caspases and tumor suppresser p53 play essential roles in apoptosis in a variety of cells including neurons^[5–8]. Previous studies have reported that excitotoxin induces the activation of caspases and induces p53 expression^[9–11]. Excitotoxin also reportedly activates nuclear factor-kappaB (NF-κB), but the mechanism by which this occurs remains unknown^[12,13].

Recent studies have demonstrated that quinolinic acid (QA) induced significant increases in NF-κB binding activity in the nucleus^[14]. NF-κB nuclear translocation mediates the upregulation of p53 and c-Myc in striatal neurons exposed to excitotoxic injury^[15–17]. NMDA receptors activate NF-κB by selective degradation of an inhibitor protein, IκB-α.

Excitotoxin-induced degradation of IκB-α involves a caspase-3-dependent mechanism in rat striatum and can be blunted by a caspase-3 inhibitor and a free radical scavenger^[18,19]. In the present study we evaluated the role of caspase-1 inhibitor Ac-YVAD-CHO in QA-induced NF-κB activation, p53 induction, and apoptosis.

Materials and methods

Stereotaxic drug administration Sprague-Dawley rats (300–350 g) were obtained from the Experimental Animal Center of Soochow University (Certificate No 20020008, Grade II). Rats were anesthetized with pentobarbital sodium (50 mg/kg). Stereotaxic drug administration was performed using a Kopf stereotaxic apparatus as described by Qin *et al*^[3]. To study the effects of a caspase-1 inhibitor on QA-induced internucleosomal DNA fragmentation, rats were either pre-treated with an intrastriatal infusion of Ac-YVAD-CHO (2–8 µg) or Me₂SO (2 µL) 10 min before intrastriatal injection of QA (60 nmol) and then killed 24 h after QA administration, or pre-treated with intrastriatal infusion of Ac-YVAD-CHO (4 µg) 10 min before intrastriatal injection of QA (60 nmol) and

killed 12, 24, or 48 h after QA administration. Striatal genomic DNA was isolated and electrophoresed on a 2% agarose gel. To study the effect of a caspase-1 inhibitor on QA-induced increases in caspase-1 activity, rats were pre-treated with an intrastriatal infusion of Ac-YVAD-CHO (4 µg) or Me₂SO (2 µL) 10 min before intrastriatal injection of QA (60 nmol) and then killed 12 h after QA treatment. Striatal homogenates were used for assay of caspase-1 activity. To study the effect of a caspase-1 inhibitor on QA-induced increases in p53 proteins and NF-κB and AP-1 binding activities, rats were pre-treated with intrastriatal infusion of Ac-YVAD-CHO (4 µg) or Me₂SO (2 µL) 10 min before intrastriatal injection of QA (60 nmol) and then killed 24 h after QA treatment. Total striatal proteins were extracted for Western blot analysis. Other animals were killed 12 h after QA treatment and nuclear proteins were isolated from the striatum for an electrophoresis mobility shift assay.

Isolation of genomic DNA and electrophoresis Striatal genomic DNA was prepared as described by Qin *et al*^[3]. Briefly, striatal tissues were homogenized in a buffer containing NaCl 100 mmol/L, edetic acid 25 mmol/L, Tris-HCl 10 mmol/L (pH 8.0), 0.5% SDS, and RNase A 0.5 mg/L. Homogenates were incubated at 55 °C for 2 h. Incubation was continued overnight after 0.6 mg protease K was added to the homogenates. DNA was extracted with phenol:chloroform:isoamyl alcohol (24:25:1). DNA fragments were separated on 2% agarose gel and detected with a UV transilluminator after being stained with ethidium bromide.

Caspase-1 activity assay The caspase-1 activity assay was performed with an enzyme activity assay kit (Caspase-1/ICE Colorimetric Assay Kit, BioVision) according to the manufacturer's instructions. Each striatal tissue was homogenized in 500 µL cell lysis buffer and centrifuged for 10 min at 10 000×g. The supernatant was transferred to a fresh tube and kept on ice. Protein concentration was determined using BCA kit (Pierce, Rockford, IL). For each 100 mg protein was diluted to 50 µL with cell lysis buffer and 50 µL 2×reaction buffer (containing DTT 10 mmol/L) was added, then 5 µL of the 4 µmol/L YVAD-pNA substrate (200 µmol/L) and the mixture was incubated at 37 °C for 1 h. Read samples at 405 nm in a spectrophotometer (Bio-Rad Smart Spec 3000).

Western blot analysis Western blot analysis was performed as described previously^[16]. Striatal tissues were homogenized in a buffer containing Tris-HCl 10 mmol/L (pH 7.4), NaCl 150 mmol/L, 1% Triton X-100, 1% sodium deoxycholate, 0.1% SDS, edetic acid 5 mmol/L, PMSF 1 mmol/L, aprotinin 0.28 kU/L, leupeptin 50 mg/L, benzamidine 1 mmol/L, pepstain A 7 mg/L. Protein concentration was determined using the BCA kit. Thirty micrograms of protein from each

sample was subjected to electrophoresis on a 12% SDS-PAGE gel using a constant current. Proteins were transferred to nitrocellulose membranes and incubated with anti-p53 antibody (p53, p240, Santa Cruz, CA) in Tris buffered saline containing 0.2% Tween-20 (TBST) and 3% nonfat dry milk for 3 h. Membranes were washed and incubated with horseradish peroxidase-conjugated second antibody in TBST containing 3% nonfat dry milk for 1 h. Immunoreactivity was measured with enhanced chemoluminescent autoradiography (ECL kit, Amersham, Arlington Heights, IL) according to the manufacturer's instructions.

Electrophoresis mobility shift assay Striatal nuclear proteins were prepared as described by Qin *et al*^[14]. Protein concentration was determined with the BCA kit (Pierce, Rockford, IL). Synthetic double-stranded NF-κB and AP-1 oligonucleotidyl probes were purchased from Promega (Madison, WI) and labeled with [³²P]ATP using T4 polynucleotide kinase (Promega). Nuclear proteins (6–14 µg) were incubated with [³²P]labeled probes (40 000 c/min) for 15 min at room temperature in the binding buffer (Promega). Reaction mixtures were electrophoresed on a 4.5% non-denaturing polyacrylamide gel, then dried and exposed to x-ray film at –80 °C with intensifying screens for 24 to 48 h. The results were quantitatively analyzed using an image analyzer (SigmaPlot Pro 4).

Results

Effects of Ac-YVAD-CHO on QA-induced internucleosomal DNA fragmentation To evaluate the consequences of caspase-1 inhibition on apoptosis, we studied the effect of Ac-YVAD-CHO on QA-induced internucleosomal DNA fragmentation. The results showed that QA (60 nmol) induced intense internucleosomal DNA fragmentation 24 h after drug administration. The DNA fragments were generally multimers of 180–200 base pairs, indicating internucleosomal DNA digestion by an endonuclease. QA-induced DNA fragmentation was strongly attenuated by Ac-YVAD-CHO in a dose-dependent manner (Figure 1A). The results also showed that Ac-YVAD-CHO (4 µg) inhibited QA-induced DNA fragmentation at all time points examined (12, 24, and 48 h after QA administration; Figure 1B).

Effects of Ac-YVAD-CHO on a QA-induced increase in caspase-1 activity QA injection significantly activated caspase-1 activity in comparison with saline injected animals ($P < 0.05$, $n = 6$). The increase in caspase-1 activity induced by QA was significantly inhibited by Ac-YVAD-CHO ($P < 0.05$, $n = 6$); however, pre-treatment with Me₂SO had no effect on the QA-induced activation of caspase-1 (Figure 2).

Figure 1. Effects of Ac-YVAD-CHO on QA-induced internucleosomal DNA fragmentation. (A): Rats were pre-treated with intrastriatal injection of Ac-YVAD-CHO (2–8 μ g) or Me₂SO (2 μ L) 10 min before intrastriatal injection of QA (60 nmol) and then killed 24 h after QA treatment. Genomic DNA from the injected striatum was isolated and electrophoresed on a 2% agarose gel. Lane 1:100-base pair DNA ladder; 2: QA+Vehicle; 3: QA+Ac-YVAD-CHO (2 μ g); 4: QA+Ac-YVAD-CHO (4 μ g); 5: QA+Ac-YVAD-CHO (8 μ g). (B): Rats were pre-treated with Ac-YVAD-CHO (4 μ g) and QA (60 nmol) as described above. Lane 1: 100-base pair DNA ladder; 2: QA+Vehicle, 12 h; 3: QA+Ac-YVAD-CHO, 12 h; 4: QA+Vehicle, 24 h; 5: QA+Ac-YVAD-CHO, 24 h; 6: QA+Vehicle, 48 h; 7: QA+Ac-YVAD-CHO, 48 h.

Figure 2. Effects of Ac-YVAD-CHO on the QA-induced increase in caspase-1 activity. The results were expressed as a percentage of control (saline injection) after using statistical analysis. Statistical analysis was carried out with Student's *t*-test. $n=6$. Mean \pm SD. ^b $P<0.05$ vs NS; ^c $P<0.05$ vs QA-treated group.

Effect of Ac-YVAD-CHO on QA-induced p53 induction

QA induced significant increases in p53 protein levels by approximately 100%, which was significantly inhibited by Ac-YVAD-CHO ($P<0.05$, $n=6$, Figure 3).

Figure 3. Effects of Ac-YVAD-CHO on QA-induced increase in p53 proteins expression. The results from 4 animals in each group were analyzed with an image analyzer and were expressed as percent of control (untreated animals). Statistical comparisons were carried out with ANOVA followed by Dunnett *t*-test. $n=4$. Mean \pm SD. ^b $P<0.05$ vs QA+Me₂SO group.

Effects of Ac-YVAD-CHO on QA-induced degradation of I κ B- α

QA treatment significantly reduced protein levels of I κ B- α , indicating that I κ B- α was degraded after QA treatment. Pre-treatment with various doses of Ac-YVAD-CHO (2–8 mg) had no significant effect on QA-induced degradation of I κ B- α (Figure 4).

Effect of Ac-YVAD-CHO on the QA-induced activation of NF- κ B and AP-1

Changes in NF- κ B and AP-1 binding in nuclear extracts were measured by using an electrophoresis mobility shift assay. QA induced dramatic increases in NF- κ B binding activity in nuclei. However, Ac-YVAD-CHO (4 mg) had no significant effect on QA-induced NF- κ B activation (Figure 5A). Similarly, AP-1 binding activity was increased markedly after QA administration and Ac-YVAD-CHO failed to inhibit the QA-induced activation of AP-1 (Figure 5B).

Discussion

Apoptotic mechanisms are involved in the degeneration of strial neurons induced by the glutamate receptor agonist QA. In the present study, the role of caspase-1 in QA-induced p53 upregulation and NF- κ B activation was investigated using the selective cell-permeable caspase-1 inhibitor

Figure 4. Effect of Ac-YVAD-CHO on the QA-induced degradation of IκB-α. The results from 5-6 animals in each group were analyzed with an image analyzer and expressed as percentage of control (untreated animals). Statistical comparisons were carried out using ANOVA analysis. Mean±SD.

Ac-YVAD-CHO. The results of the study showed that pretreatment with Ac-YVAD-CHO dose-dependently inhibited QA-induced internucleosomal DNA fragmentation. Ac-YVAD-CHO had no significant effect on the QA-induced IκB-α degradation and NF-κB activation. However, Ac-YVAD-CHO partially inhibited QA-induced increase in p53 protein levels. These results suggest that caspase-1 plays a role in QA-induced p53 upregulation but not QA-induced IκB-α degradation.

It has been reported that glutamate receptor agonists activate NF-κB via the degradation of IκB-α^[15,16]. Previous studies have further suggested that caspase-3, like protease, is involved in NMDA receptor-stimulated degradation of IκB-α^[18,19]. Activation of NF-κB upregulates c-Myc and p53, indicating that NF-κB contributes to excitotoxin-induced apoptosis via the induction of cell cycle regulators^[16,17,20]. p53 plays a critical role in cell death and survival. Its level is usually regulated by the rate of its degradation^[21]. Now studies show that the levels of p53 can be regulated by NF-κB^[16,17,22]. In the present study, caspase-1 inhibitor Ac-YVAD-CHO had no effect on either QA-induced IκB-α degradation or NF-κB activation. In contrast, Ac-YVAD-CHO significantly attenuated QA-induced increases in p53 pro-

Figure 5. Effect of Ac-YVAD-CHO on QA-induced NF-κB activation. Vertical bars represent mean±SD. *n*=6. Statistical comparisons were carried out with ANOVA analysis. A: Effect of Ac-YVAD-CHO on the QA-induced NF-κB activation. B: Effect of Ac-YVAD-CHO on AP-1 activation.

tein levels and apoptosis. This study indicated that both NF-κB dependent and independent mechanisms are involved

in the QA-induced upregulation of p53 and apoptosis.

In conclusion, we found that the caspase-1 inhibitor Ac-YVAD-CHO inhibited the QA-induced increase in p53 protein levels and internucleosomal DNA fragmentation, but had no effect on QA-induced I κ B- α degradation and NF- κ B activation. These results suggest that caspase-1 plays an important role in QA-induced p53 induction and apoptosis, but caspase-1 does not contribute to the QA-induced degradation of I κ B- α or NF- κ B activation.

Abstract

Aim: To investigate the effects of orexin A on release of histamine, norepinephrine, and serotonin in the frontal cortex of mice. **Methods:** Samples for measuring histamine, norepinephrine, and serotonin contents were collected by *in vivo* microdialysis of the frontal cortex of anesthetized mice. The histamine, noradrenaline, and serotonin content in dialysates were measured by HPLC techniques. **Results:** Intracerebroventricular injection of orexin A at doses of 12.5, 50, and 200 pmol per mouse promoted histamine release from the frontal cortex in a dose-dependent manner. At the highest dose given, 200 pmol, orexin A significantly induced histamine release, with the maximal magnitude being 230% over the mean basal release. The enhanced histamine release was sustained for 140 min, and then gradually returned to the basal level. However, no change in norepinephrine or serotonin release was observed under application of the same dose of orexin A. **Conclusion:** These results suggest that the arousal effect of orexin A is mainly mediated by histamine, not by norepinephrine or serotonin.

Introduction

The neuropeptides orexin A and B (also called hypocretins 1 and 2) have recently been isolated from rat hypothalamic extracts, and have been reported to be involved in sleep-wake regulation^[1–3]. Intracerebroventricular (icv) application of orexin A strongly enhances arousal in rats and mice^[4–6]. Furthermore, c-fos expression in orexin neurons and prepro-orexin mRNA levels show a diurnal variation, with the strongest expression being observed during waking^[7,8]. Mice lacking either the orexin gene (*preproorexin* knock-out mice) or orexin neurons (*orexin/ataxin-3* transgenic mice) have phenotypes remarkably similar to the human sleep disorder narcolepsy^[9–11], a disabling neurological disorder characterized by symptoms including excessive daytime sleepiness, sleep attacks, sleep fragmentation, cataplexy, and sleep-onset periods of rapid eye movement^[12]. Lesions of the lateral hypothalamus by orexin-2-saporin produce narcoleptic-like sleep behavior in rats^[13]. Consistent with these findings, recent reports suggest that human narcolepsy is accompanied by a

loss of orexin neuropeptide production and specific destruction of orexin neurons^[14–17]. These results suggest that the orexinergic system is involved in sleep-wake regulation and mainly contributes to arousal.

Orexin neurons are located specifically in the lateral hypothalamic area and project to almost all parts of the brain except the cerebellum^[2,10,18]. Particularly dense projections of these neurons are observed in monoaminergic nuclei, such as the noradrenergic locus ceruleus (LC), serotonergic raphe nuclei (DRN), and histaminergic tuberomammillary nucleus (TMN). These monoaminergic nuclei expressing orexin receptors (OX1R and/or OX2R)^[19] play important roles in the promotion of wakefulness. Electro-physiological studies have revealed that orexins had mainly excitatory effects on all monoaminergic neurons *in vitro*^[20–24], suggesting that the arousal effect of orexins is mediated by these monoaminergic systems. However, which type(s) of these monoaminergic systems is involved in orexin-induced arousal remains to be elucidated.

In the present study, we investigated the effects of orexin A on the release of the monoaminergic neurotransmitters histamine, norepinephrine (NE), and serotonin (5-HT) in the frontal cortex (FrCx) of mice by using *in vivo* microdialysis to further clarify the mechanism underlying the arousal effects of orexin A.

Materials and methods

Animals Male C57BL/6 mice (Shizuoka Laboratory Animal Center, Shizuoka, Japan) weighing 24–28 g (11–13 weeks old) were housed at a constant temperature (24 ± 0.5 °C) and relative humidity ($60\%\pm 2\%$), an automatically controlled 12:12 h light/dark cycle (light on at 8 AM), and *ad libitum* access to food and water. All animal experiments used in this study were approved by the Animal Care Committee of Osaka Bioscience Institute.

Microdialysis procedure The microdialysis was performed as previously described^[5]. As shown in Figure 1, under urethane anesthesia (1.8 g/kg, ip), a micro-dialysis probe (CUP7, membrane length of 2-mm; Carnegie Medicin, Stockholm, Sweden) was inserted in the FrCx of mice at a position 1.8 mm anterior and 0.8 mm lateral to the bregma and 2.3 mm depth from the dura. One stainless steel cannula (outer diameter, 0.2 mm) was stereotaxically placed at the site of 2.0 mm lateral to the bregma and inserted to a depth of 2.2 mm from the surface of the cortex at an angle of 25° from the midsagittal plane according to the atlas of Franklin and Paxinos^[25]. The microdialysis probe was perfused with Ringer's solution (NaCl 147 mmol/L, KCl 4.0 mmol/L, and CaCl_2 2.3 mmol/L; pH 7.3) at a flow rate of 2 $\mu\text{L}/\text{min}$ to stabi-

lize the release of histamine, NE, and 5-HT. Two hours after insertion of the microdialysis probe, dialysates were continuously collected from the FrCx at 20-min interval (40 μL each) for 1 h as the basal value before the orexin A injection, and until 4 h after administration of the peptide.

Determination of histamine, NE, and 5-HT levels by HPLC The histamine levels in the dialysates were measured by using a fluorometric HPLC system^[26], and NE and 5-HT levels were determined by using HPLC with electrochemical detection^[27]. Since the absolute basal release of histamine, NE, and 5-HT varied between subjects, the mean of the first 3 fractions before administration of orexin A was defined as the mean basal release, and subsequent fractions were expressed as a percentage of the mean basal release.

Drugs Orexin A (Peptide Institute, Osaka, Japan) was diluted in saline to the concentrations needed and was injected into the lateral ventricle of mice from the cannula at doses of 200, 50, or 12.5 pmol per mouse in 2 μL of saline at a speed of 2 $\mu\text{L}/\text{min}$. Fluoxetine (Sigma-Aldrich, St Louis, MO, USA), a 5-HT reuptake inhibitor which has been reported to also increase NE release through activation of postsynaptic 5-HT_{1A} receptors by increased 5-HT^[28,29], was dissolved in saline and injected ip (20 mg/kg).

Statistical analysis Data were expressed as mean \pm SD. Differences between groups were analyzed by analysis of variance (ANOVA) followed by the *post-hoc* Newman-Keuls test. The significant level of difference was set at $P<0.05$.

Results

Effect of orexin A on histamine release The mean basal release of histamine was 0.06 ± 0.01 pmol per 20 min. Compared with the control, orexin A at doses of 12.5 and 50 pmol produced a rapid and significant elevation of histamine release, with the maximal magnitude being 150% and 175% over the mean basal release, respectively; and these higher levels maintained for approximately 1 and 2 h (Figure 2A), respectively. At the highest dose (200 pmol) tested, orexin A markedly promoted histamine release, and the release reached its maximal level of 230% over the mean basal level. The significant increase lasted 140 min.

For comparison of the differences between different dosage groups, we calculated the total amount of histamine released over a 3-h period after the administration of orexin A. The total amounts of histamine released were 0.55 ± 0.08 , 0.74 ± 0.09 , and 0.79 ± 0.11 pmol per 3 h in the groups treated with orexin A at doses of 12.5, 50, and 200 pmol, respectively. In the latter 2 groups the release was significantly higher than that of the control (0.43 ± 0.05 pmol per 3 h, $P<0.05$) (Figure

Figure 1. Schematic representation of the implantation sites for the microdialysis probe in the FrCx and the stainless steel cannula in the lateral ventricle of mice. Orexin A was infused into the lateral ventricle through the stainless steel cannula; and dialysate samples for monitoring histamine, NE, or 5-HT levels were collected from the microdialysis probe. FrCx, frontal cortex.

Figure 2. Effect of orexin A on histamine release in the FrCx of anesthetized mice. Time-courses of histamine release (A) and the total amounts of histamine released over 3 h after the administration of orexin A (B) in the FrCx are shown. *n*=5–6 mice. Mean±SD. ^b*P*<0.05, ^c*P*<0.01 vs the control.

2B). These results indicated that orexin A induced histamine release in a dose-dependent manner.

Effects of orexin A on NE and 5-HT release The mean basal release of NE and 5-HT was 1.75±0.21 and 16.9±2.33 pg per 20 min, respectively. No difference was observed in NE or 5-HT release between the group treated with orexin A (200 pmol) and the control. As the positive control, fluoxetine, significantly elevated the extracellular levels of NE and 5-HT, with the maximal magnitude being approximately 200% over the mean basal release at approximately 1.5 h and 1 h after administration (20 mg/kg, ip), respectively. Compared with the control, the increase in NE and 5-HT lasted about 180 and 160 min, respectively (Figure 3).

Discussion

In the present study we found that orexin A activated a histaminergic system in mice. An increasing body of evidence indicates the interaction between the orexinergic and histaminergic systems. For example, with respect to neuro-

Figure 3. Effects of orexin A on 5-HT and NE release in the FrCx of anesthetized mice. Time-courses of 5-HT and NE release in the FrCx are shown. The arrow stands for the time point of administration. *n*=5–6 mice. Mean±SD. ^b*P*<0.05, ^c*P*<0.01 vs the control.

anatomy, orexin cells densely innervate the histaminergic TMN^[18,30], a nucleus enriched in orexin 2 receptors^[19]. Most human narcolepsy is caused by a loss of orexin neurons^[16] and a consequent reduction in orexin levels^[15,31]. Gliosis accompanies this loss of orexin neurons and is most intense in the posterior hypothalamus where the histaminergic TMN is located^[16,17], suggesting that the orexinergic terminals are lost in this region and that the consequent loss of orexinergic innervation of histaminergic cells is an important component of the pathology of narcolepsy. Based on neurochemical studies, Nishino *et al*^[31] reported that the histamine content was markedly decreased in the cortex of orexin-2 receptor-mutated narcoleptic Dobermans and that the decrease was due to a lack of excitatory input of orexin neurons caused by a loss of function of orexin-2 receptors in histaminergic TMN cell groups. Furthermore, Lin *et al*^[32] found that orexin A and B contents were significantly lower in histamine H₁ receptor knockout mice. These results indicate that there exist functional connections between histaminergic and orexinergic systems.

The FrCx is a brain region that has higher EEG frequency during waking^[33], and which receives projections of monoaminergic neurons such as the noradrenergic, serotonergic, and histaminergic neurons that originate from the LC, DRN, and TMN, respectively. Microdialysis studies have revealed that extracellular levels of histamine and 5-HT in the FrCx showed typical changes across the sleep-wake cycle, with their highest levels during the waking period^[34-37]. Thus, orexin-activated release of these neurotransmitters in the FrCx reflects their contributions to the arousal effect of orexin. In the present study, we found that orexin A significantly promoted histamine release in the FrCx in a dose-dependent manner, but not release of NE or 5-HT, although orexin A excites noradrenergic and serotonergic neurons *in vitro*^[20-22]. We previously reported that a prostaglandin E₂ receptor subtype EP₄ agonist enhanced histaminergic neuron activity with an increase in histamine release in the FrCx to produce arousal^[38]. Together with our previous observations that orexin induced wakefulness in wild-type mice but not all in histamine H₁ receptor knockout mice^[5], these findings suggest that the arousal effect of orexin is largely mediated by histaminergic systems and activation of H₁ receptors. In contrast to the histaminergic activity linked to the maintenance of wakefulness, John *et al*^[39] found that noradrenergic and serotonergic neurons were more tightly coupled to the maintenance of muscle tone during wakefulness and its loss during rapid eye movement sleep and cataplexy.

Taken these findings together, we conclude that the arousal effect of orexin A is mainly mediated by the activation of histaminergic systems.

Abstract

Aim: To study the modulating effect of adenosine deaminase (ADA) on the adenosine A₁ receptor (A₁R) in HEK293 cells stably expressing the human A₁R. **Methods:** cDNA was amplified by RT-PCR using total RNA from human embryo brain tissue as the template. The PCR products were subcloned into the plasmid pcDNA3 and cloned into the plasmid pcDNA3.1. The cloned A₁R cDNA was sequenced and stably expressed in HEK293 cells. The modulating effect of adenosine deaminase on A₁R was studied by using [³H]DPCPX binding assay and an intracellular calcium assay. **Results:** HEK293 cells stably expressing human A₁R were obtained. Saturation studies showed that the K_D value and B_{max} value of [³H]DPCPX were 1.6±0.2 nmol/L and 1.819±0.215 nmol/g of protein respectively, in the absence of ecto-ADA respectively, and 1.3±0.2 nmol/L and 1.992±0.130 nmol/g of protein in the presence of ecto-ADA respectively, suggesting that the K_D value and B_{max} value of [³H]DPCPX were unaffected by ecto-ADA. In the case of [³H]DPCPX competition curves obtained from intact cells or membranes, A₁R agonist CCPA/[³H]DPCPX competition curve could be fitted well to a one-site model in the absence of ecto-ADA and a two-site model in the presence of ecto-ADA with a K_H value of 0.74 (0.11–4.8) nmol/L (intact cells) or 1.8 (0.25–10) nmol/L (membrane) and a K_L value of 0.94 (0.62–1.41) μmol/L (intact cells) or 0.77 (0.29–0.99) μmol/L (membrane). The K_L value is not significantly different from the IC₅₀ value of 0.84 (0.57–1.23) μmol/L (intact cells) or 0.84 (0.63–1.12) μmol/L (membrane) obtained in the absence of ecto-ADA. Similar results were obtained from the CPA/[³H]DPCPX competition curve in the absence or presence of ecto-ADA on intact cells or membranes. Intracellular calcium assay demonstrated that the EC₅₀ value of CPA were 10 (5–29) nmol/L and 94 (38–229) nmol/L in the presence or absence of ecto-ADA, respectively. **Conclusion:** A₁R stably expressed in the HEK293 cells display a low affinity for agonists in the absence of ADA and high and low affinities for agonists in the presence of ADA. The presence of ADA may promote the signaling through the adenosine A₁ receptor in HEK293 cells.

Introduction

Adenosine is a ubiquitous physiological regulator and neuromodulator capable of multiple physiological actions in various systems^[1]. Adenosine receptors are members of the G-protein-coupled receptor superfamily, and comprise A₁,

A_{2a}, A_{2b}, and A₃ adenosine receptors, identified by convergent data from molecular, biochemical, and pharmacological studies^[2]. A₁R is widely expressed in the brain, adipose tissue, the testis, and the spinal cord^[3]. Via A₁R, adenosine reduces heart rate^[4], glomerular filtration rate, and renin release in the kidney^[5], induces bronchoconstriction^[6,7] and inhibits

lipolysis. A₁R can be coupled to different pertussis toxin-sensitive G proteins^[8-10], which mediate the inhibition of adenylyl cyclase^[11] and regulate Ca²⁺ and K⁺ channels and inositol phosphate metabolism^[12]. A₁R present two different affinities for agonists, which have classically been attributed to a different coupling to heterotrimeric G proteins^[13], coupled receptor-G protein complexes display high affinity for A₁R agonists, whereas uncoupled receptors display low affinity^[13,14].

Adenosine deaminase (ADA, E.C.3.5.4.4) is an enzyme which catalyzes the hydrolytic deamination of adenosine to inosine. ADA is located both in the cytosol and on the cell membrane. Recent evidence suggest that ecto-ADA had extra-enzymatic and co-stimulatory functional roles. ADA modulates ligand binding and signaling through A₁R on DDT₁MF-2 cells, a smooth muscle cell line^[15]. ADA seems to be necessary for the high affinity binding of agonists to A₁R^[16,17]. In the present study, the effect of ADA on the ligand-mediated regulation of A₁R in HEK293 cells stably expressing human A₁R has been studied.

Materials and methods

Materials High glucose Dulbecco's modified Eagle's medium (DMEM), fetal calf serum, G418, benzylpenicillin and streptomycin were obtained from Gibco. Restricted enzyme (*Hind*III, *Eco*RI, *Xho*I), T4 DNA ligase, reverse transcriptase enzyme and buffer were purchased from Promega (USA). Pyrobest DNA polymerase and PCR buffer were obtained from TaKaRa (Dalian, China). N⁶-cyclopentyladenosine (CPA), 8-cyclopentyl-1,3-dipropylxanthine (DPCPX), and 2-Chloro-N⁶-cyclopentyladenosine (CCPA) were obtained from RBI (Natick, MA, USA). Adenosine deaminase was obtained from Roche Biochemicals (Mannheim, Germany). Fluo-3/AM, *p*-(dipropylsulfamoyl)benzoic acid, pluronic F-127, HEPES, Triton X-100, bovine serum albumin, leupeptin, pepstatin A, aprotinin and PMSF were purchased from Sigma (USA). [³H]DPCPX was purchased from Amersham (USA). Plas-

mids pcDNA3, pcDNA3.1(+), and Lipofectamine²⁰⁰⁰ were purchased from Invitrogen (USA). Human embryo brain tissue was donated by Huashan Hospital (Shanghai, China). PCR primers were synthesized by Shenyou (Shanghai, China).

Cloning of the human A₁R cDNA Human brain total RNA was obtained from human embryo brain tissue. The total RNA was reverse-transcribed using oligo-dT18 as a primer. With the cDNA, PCR was carried out using the primers A₁R-1SE and A₁R-1AS (Table 1). Gel-purified PCR product was treated with *Eco*RI/*Xho*I and subcloned into the *Eco*RI/*Xho*I site of the mammalian expression vector pcDNA3. With the subcloned A₁R-pcDNA3 plasmid as template, PCR was carried out using the primers A₁R-2SE and A₁R-2AS (Table 2), which resulted in full length codon sequence cDNA. Gel-purified PCR product was treated with *Hind*III/*Eco*RI and cloned into the *Hind*III/*Eco*RI site of the mammalian expression vector pcDNA3.1(+).

Production of HEK293 cell lines stably expressing human A₁R HEK293 Cells were transfected with the A₁R-pcDNA3.1(+) expression vector, using the Lipofectamine2000 reagent. Cells were treated with selection medium containing G418 (1 g/L) for 3 weeks to select stably transfected cells displaying neomycin resistance. Between 2 and 3 weeks in the selection process, resistant cells began to appear. They were sought out by serial dilutions and allowed to grow from single cells. Receptor expression of single cell-derived colonies was tested by radioligand binding assay.

Table 2. Representative competition inhibition experiments of CCPA and CPA versus the A₁R antagonist [³H]DPCPX in intact cells and membrane preparations from A₁R cells. R_H is expressed as a mean. K_H and K_I/IC₅₀ are expressed as a mean with 95% confidence intervals.

		ADA	R _H (%)	K _H (nmol/L)	K _I /IC ₅₀ (μmol/L)

Cell culture Human embryonic kidney (HEK293) cells were cultured in DMEM containing streptomycin (100 mg/L), benzylpenicillin (1000 kU/L) and fetal bovine serum (10%). Cells were incubated at 37 °C in 5% CO₂. Stably transfected HEK293 cell lines were cultured in DMEM high glucose medium containing streptomycin (100 mg/L), benzylpenicillin (1000 kU/L), G-418 (200 mg/L), and fetal bovine serum (10%). Cells were incubated at 37 °C in 5% CO₂. For passaging, the cells were detached from the cell culture flask by washing with phosphate-buffered saline (PBS) and brief incubation with trypsin (0.5 g/L)/EDTA (0.2 g/L). The cells were passaged every 3 d.

Membrane preparation The A₁R cells (HEK293 cells stably expressing human A₁R) were lifted from Petri dishes with a cell scraper. Harvested cells were washed twice with ice-cold PBS and centrifuged at 420×g for 5 min at 4 °C. The cell pellet was resuspended with hyponic buffer (Tris-HCl 5 mmol/L, EDTA 2 mmol/L, pH 7.4, leupeptin 1 mg/L, pepstatin A 1 mg/L, aprotinin 1 mg/L, PMSF 1 mmol/L) and sonicated (18 s) three times on ice. The homogenate was centrifuged at 960×g for 10 min at 4 °C. The precipitated nucleic fraction was discarded and the supernatant was centrifuged at 40 000×g for 30 min at 4 °C. The pellet was washed with 50 mmol/L Tris-HCl buffer (pH 7.4) and centrifuged again under the same conditions. Finally, the pellet was resuspended in the same buffer, and protein concentration was determined by using the BCA Kit (Pierce) as described previously^[18].

[³H]DPCPX binding assays in intact cells and membranes Binding assays in intact cells were performed in a reaction tube at a density of 2.0×10⁵ cells per tube, using [³H]DPCPX as a radioligand. Cells were resuspended in 50 mmol/L Tris-HCl (pH 7.4) and treated with ADA 65 nmol/L at 4 °C for 30 min^[17]. After this treatment, cells were incubated for 1 h at 37 °C with [³H]DPCPX 0.5 nmol/L for competition assays. Different concentrations of the A₁R agonist CCPA or CPA were used in the competition curves.

Membranes (30–50 μg proteins) from A₁R cells were resuspended in Tris-Cl 50 mmol/L (pH 7.4) and treated with ADA 65 nmol/L at 4 °C for 30 min. Saturation assays were performed at different concentrations of [³H]DPCPX (0.05–10 nmol/L) using unlabeled DPCPX (20 μmol/L) to obtain nonspecific binding. Competition curves were carried out by using [³H]DPCPX 0.5 nmol/L and different concentrations of A₁R agonists CCPA or CPA.

After incubation for 1 h, the binding assays were stopped by rapid filtration through Whatman GF/B filters, and the filters were immediately washed three times with ice-cold buffer. Filters were then transferred to Eppendoff tubes, and scintillation liquid was added to measure the radioactivity.

Intracellular Ca²⁺ measurements Ca²⁺ fluorescence measurements were performed using a NOVOstar plate reader with a pipettor system (BMG labtechnologies, Offenburg, Germany). A₁ cells were harvested with 0.05% trypsin/0.02% EDTA and rinsed with high glucose DMEM containing 10% fetal bovine serum, streptomycin 100 mg/L, and benzylpenicillin 1000 kU/L. Pelleted cells were resuspended in fresh medium and kept under 5% CO₂ at 37 °C for 1 h and vortexed every 15 min. After two washes with Krebs-HEPES buffer, cells were loaded with Fluo-3/AM 5 μmol/L for 30 min containing 1% pluronic F-127 and *p*-(dipropylsulfamoyl)benzoic acid 2.5 mmol/L. Then cells were rinsed 3 times with Krebs-HEPES buffer containing 0.5% bovine serum albumin, the diluted, and evenly plated into 96-well plates at a density of 1×10⁴ cells/well. Microplates were kept at 37 °C for 15 min^[19,20]. Buffer alone or different concentrations of CPA were then injected sequentially into separate wells, and fluorescence intensity was measured at 520 nm for 50 s at 0.2 s intervals. The excitation wavelength was 485 nm.

[Ca²⁺]_i was calculated as follows: $[Ca^{2+}]_i = K_d (F - F_{min}) / (F_{max} - F)$. F_{max} refers to fluorescence intensity measured after permeabilization of the cells with 1% Triton X-100. Ten mmol/L EDTA was added to chelate Ca²⁺ and minimum fluorescence intensity was obtained (F_{min}). A K_d value of 324 nmol/L was used for Fluo-3.

Data analysis Experiments were performed in triplicate. All data were expressed as mean±SD and data were analyzed with the GraphPad Prism 4.0 program (GraphPad Software, San Diego, CA, USA). Student's *t*-test was used for statistical analysis.

Results

Cloning of the human adenosine A₁R cDNA To obtain the cDNA with the full length codon sequence of human A₁R, a reverse transcription reaction was carried out using the total RNA extracted from human embryo brain tissue. Using cDNA with full length codon sequence of A₁R, a PCR product (1332 bp) was obtained using primers described previously. The PCR product subcloned into a pcDNA3 plasmid and cDNA (981 bp) containing the full A₁R codon sequence was obtained using this subcloned vector as a template. The cDNA was then cloned into the mammalian expression vector pcDNA3.1. Sequence analysis demonstrated that the sequence of the constructed A₁R-pcDNA3.1 expression vector was identical to that of human A₁R cDNA in the gene bank.

Selection of cell clones Colonies of the selected stable

integrants were initially analyzed for human A₁R expression by using a receptor binding assay using [³H]DPCPX. From the transfected HEK293 cell clones, one cell line was obtained with specific [³H]DPCPX binding.

Saturation experiments with the adenosine A₁ receptor antagonist [³H]DPCPX As Figure 1 shown, no significant difference was found between the A₁R cells in the absence and presence of ADA with respect to the B_{max} and K_D values for the A₁R binding sites labeled with [³H]DPCPX. The B_{max} values for the A₁R cells were 1.819±0.215 and 1.992±0.130 nmol/g of protein (n=3) in the absence and presence of ADA, respectively. The K_D values for the A₁R cells were 1.6±0.2 and 1.3±0.2 nmol/L (n=3) in the absence and presence of ADA, respectively. The non-specific binding was <5% of the total binding.

Competition experiments of A₁R agonist CCPA or CPA versus the A₁R antagonist [³H]DPCPX Competition experiments with CCPA versus the A₁R antagonist [³H]DPCPX in intact A₁R cells or membrane preparations from A₁R cells incubated previously with ADA showed a significantly better fit with the 2 binding sites model than that with the 1 binding site model (F test, P<0.05). Similar K_H and K_L values were obtained in intact cells or membrane preparations from A₁R cells incubated previously with ADA, and the proportions of the A₁R in the high affinity state (R_H values) were

18%±3% and 20%±5% , respectively (Figure 2 and Table 2). In intact A₁R cells or membrane preparations from A₁R cells in the absence of ADA, a significant better fit for one binding site (R_H=0) was obtained, with the IC₅₀ values very similar to the K_L value obtained in intact cells or membrane preparations previously treated with ADA. Similar results were obtained from competition experiments with CPA versus the adenosine A₁R antagonist [³H]DPCPX in intact A₁R cells or membrane preparations from A₁ cells in the absence of ADA (Figure 3, Table 2).

Effects of A₁R agonist CPA on intracellular calcium level in the presence or absence of ADA An increase in intracellular Ca²⁺ appears to be a universal second messenger signal for a majority of recombinant GPCRs^[20]. A₁R agonists evoked a concentration-dependent and reproducible Ca²⁺ signal at A₁R^[22]. To assess the effect of the presence of ADA on A₁R signal transduction, we performed an intracellular calcium assay. A significant difference was found between the A₁R cells in the absence and presence of ADA with respect to the EC₅₀ values of A₁R agonist CPA. A₁R agonist CPA induced an intracellular [Ca²⁺] increase. The EC₅₀ values for the A₁R cells in the absence and presence of ADA were 94 (38–229) and 10 (5–29) nmol/L, respectively. CPA appears more potent at the A₁ cells in the presence of ADA compared with the A₁R cells in the absence of ADA (Figure 4).

Figure 1. Saturation curve of [³H]DPCPX binding to adenosine A₁R in plasma membrane isolated from A₁R cells untreated (A, B) and treated (C, D) with ADA. Binding assays were performed as described in Methods, using A₁R antagonist [³H]DPCPX as radioligand in a concentration range from 0.05 to 10 nmol/L. A and C: Saturation curve of [³H]DPCPX binding to adenosine A₁ receptors. B and D: Scatchard plot of these data and analysis gave the K_D and B_{max} values indicated in Results. Data are mean±SD and were obtained from three independent experiments performed in triplicate.

Figure 2. Representative competitive inhibition curve of A₁R agonist CCPA versus the A₁R antagonist [³H]DPCPX in intact cells (A) and membrane preparations (B) from A₁R cells untreated and treated with ADA. Competition assays were done at 0.5 nmol/L [³H]DPCPX and increasing concentrations of CCPA. IC₅₀ values are means (95% confidence intervals) obtained from three independent experiments performed in triplicate.

Discussion

Recently, several evidences demonstrated that cell-surface ADA interacted with A₁ receptors in brain cortex and DDT₁MF-2 cells and that the enzyme was able to modulate ligand binding and signaling through A₁R^[16,21-23]. By immunoprecipitation and affinity chromatography, it was found that ADA and A₁R interacted in pig brain cortical membranes. By means of this interaction ADA led to the appearance of the high-affinity site of the receptor. Thus, it seems that ADA is necessary for coupling A₁R to heterotrimeric G proteins^[16]. In Chinese hamster ovary (CHO) cells, stably transfected with the human adenosine A₁R, it was found that in the presence of ADA, the [³H]DPCPX/cyclohexyladenosine competition curve could be analysed by a two-site model with 93% of the sites having high affinity and the remainder having low affinity. In the absence of ADA, the [³H]DPCPX/cyclohexyladenosine competition curve was well described by a two-site model. Under these conditions, 70% of the

Figure 3. Representative competitive inhibition curve of A₁R agonist CPA versus the A₁R antagonist [³H]DPCPX in intact cells (A) and membrane preparations (B) from A₁R cells untreated and treated with ADA. Competition assays were done at 0.5 nmol/L [³H]DPCPX and increasing concentrations of CPA. IC₅₀ values are means (95% confidence intervals) obtained from three independent experiments performed in triplicate.

Figure 4. Concentration-response curves for the effect of A₁R agonist CPA on intracellular [Ca²⁺]_i in A₁R cells untreated and treated with ADA. Mean±SD. *n*=3. EC₅₀ values is mean (95% confidence intervals) obtained from three independent experiments performed in triplicate.

binding of [³H]DPCPX was associated with a high-affinity site with the remaining sites having low affinity. Thus there is a clear difference in the potency of cyclohexyladenosine

at the high-affinity state^[24]. In the present study, human adenosine A₁R were cloned and stably expressed in the HEK293 cells and the effects of ecto-ADA on adenosine A₁R were studied. By using competitive inhibition assay of adenosine A₁R agonists CCPA or CPA against [³H]DPCPX, we found that A₁R displayed two different affinities for agonists in the presence of ADA. However, A₁R only displayed a low affinity for agonists in the absence of ADA, suggesting that most of the binding of [³H]DPCPX was associated with the low-affinity site under these conditions and that the interaction of ADA with A₁ adenosine receptors led to the appearance of the high-affinity site of the receptor.

To further demonstrate possible interaction between A₁R and ADA, intracellular calcium assay was carried out in the present studies. The results demonstrated that the EC₅₀ value of CPA for inducing increase of intracellular calcium level was lower in the presence of ADA than that in the absence of ADA, suggesting that the presence of ADA may promote signaling through A₁ receptors in the stably transfected HEK293 cells. Our results further support the notion that ADA may promote the signaling through A₁ receptors.

Abstract

Aim: To investigate whether the amlodipine derivatives, CJX1 and CJX2, have a modulative effect on P-glycoprotein (P-gp) function in rat brain microvessel endothelial cells (RBMEC). **Methods:** Isolated RBMEC were cultured in DMEM/F12 (1:1) medium. The amount of intracellular rhodamine (Rh123) was determined, using a fluorescence spectrophotometer, to evaluate the function of P-gp. **Results:** The accumulation of Rh123 in RBMEC was potentiated in a concentration-dependent manner after incubation with CJX1 and CJX2 at 1, 2.5, 5, and 10 $\mu\text{mol/L}$ ($P < 0.01$), but no accumulation of Rh123 was observed in human umbilical vein endothelial cells after incubation with CJX1 and CJX2 10 $\mu\text{mol/L}$ ($P > 0.05$). Accumulation of intracellular Rh123 was increased and efflux of intracellular Rh123 was decreased in a time-dependent manner from 0–100 min after CJX1 and CJX2 at 10 $\mu\text{mol/L}$ treatment. The inhibitory effect of CJX1 and CJX2 on P-gp function was reversible and remained even at 120 min after removal of CJX1 and CJX2 at 2.5 $\mu\text{mol/L}$ from the medium. **Conclusion:** CJX1 and CJX2 exhibited a potent effect in the inhibition of P-gp function *in vitro*.

Introduction

The treatment of cancer with chemotherapeutic drugs is frequently impaired or ineffective as a result of acquired resistance of tumor cells. This phenomenon is termed as multi-drug resistance (MDR) and characterized by the over-expression of P-glycoprotein (P-gp) at the surface of cancer cells. As a 170 kDa protein, P-gp is encoded by MDR gene and belongs to a membrane transporter of the ABC superfamily. It acts as an energy-dependent drug efflux pump preventing adequate intracellular accumulation of a broad range of cytotoxic drugs including anthracyclines, *Vinca* alkaloids, epipodophyllotoxins, and taxanes^[1–3]. P-gp is also expressed in normal tissues such as the endothelial cells of the blood brain barrier (BBB) capillaries^[4]. The capillary endothelial cells protect the brain against many exogenous toxin injuries and sudden fluctuation in the levels of systemic substances. The hydrophobic agents, such as vinblastine and doxorubicin and lipid-soluble compounds, such as cyclosporin A, cannot accumulate in the brain^[5–7]. P-gp expression in the BBB capillaries is responsible for the extru-

sion of these compounds from the endothelial cells, and thereby attenuates the accumulation of the drugs in the brain leading to the failure of therapy for the brain disease. There are a variety of agents, such as verapamil (Ver) and cyclosporine A for overcoming MDR^[8,9]. However, verapamil and cyclosporine A, are used as anti-arrhythmic agents and immunosuppressants, respectively. Therefore, they will cause side effects when used as MDR-reversing agents. In light of these findings, the development of compounds specially inhibiting P-gp function in cancer cells or BBB may contribute to the treatment of cancers and central nervous system diseases. Amlodipine, a calcium channel antagonist, belongs to dihydropyridines family and is currently applied in the treatment of hypertension^[10]. A previous report has revealed that amlodipine has an inhibitory effect on P-gp-mediated transport of dauxorubicin and digoxin^[11]. CJX1 and CJX2, the amlodipine derivatives, were synthesized by substituting the hydrogen of the amino group on amlodipine with 4,5-dihydro-imidazole and 4,5-dihydro-thiazole, respectively. The aim of this study was to investigate the

effects of CJX1 and CJX2 on the P-gp function in rat brain microvessel endothelial cells (RBMEC).

Figure 1. The chemical structure of amlodipine, CJX1, and CJX2.

Materials and methods

Materials The cell line of human umbilical vein endothelial cells (HUVEC) was a gift from Prof Zhuang ZHANG (Beijing University of Chinese Medicine); CJX1 (M_r 471) and CJX2 (M_r 488) were obtained from Dr Yun-gen XU (Novel Drug Research Centre, China Pharmaceutical University). Rhodamine123 (Rh123) and verapamil were purchased from Sigma Co (St Louis, USA). Fetal calf serum and DMEM/F12 (1:1) medium were purchased from GIBCO (USA). All other chemicals used in the experiments were commercial products of reagent grade.

Culture of RBMEC RBMEC were isolated according to the method of Abbott *et al*^[12] with minor modification. Isolated cortex from ten rats was placed in ice-cold phosphate-buffered saline (PBS). After removal of surface ves-

sels and meninges, cortex gray matter was minced and incubated at 37 °C for 25 min in D-Hanks' solution containing 0.05% trypsin. The samples were filtered through a 150- μ m nylon mesh. After centrifugation at 800 \times g for 5 min, the pellet was re-suspended in PBS containing 20% bovine serum albumin (BSA) and centrifuged at 2000 \times g at 37 °C for 5 min. After removal of fat, cell debris, and myelin floating on BSA, the pellet containing microvessels was resuspended and incubated in PBS containing 0.1% collagenase II at 37 °C for 30 min. The microvessels were finally collected by centrifugation at 800 \times g for 5 min, then the pellet was washed twice with PBS and cultured in DMEM/F12 (1:1) medium supplemented with 20% fetal bovine serum at 37 °C in a 5% CO₂ humidified atmosphere.

Intracellular Rh123 accumulation assay RBMEC were seeded at a density of 5 \times 10⁷/L in 24-well plates. After reaching confluence, cell monolayers were exposed to Rh123 5 μ mol/L in serum-free DMEM/F12 medium containing CJX1 and CJX2 at 1, 2.5, 5, and 10 μ mol/L at 37 °C for 90 min, respectively. Verapamil was used as a positive control for an P-gp inhibitor. After incubation, the medium was removed, and all monolayers were washed three times with ice-cold PBS and then dissolved in 1% Triton X-100. Fluorescence of Rh123 was measured using fluorescence spectrophotometer and concentration of Rh123 was calculated from the fluorescence value on the Rh123 standard curve. The amount of Rh123 in cell samples was normalized with the amount of protein in each sample as described previously^[13,14].

Rh123 uptake assay RBMEC were seeded at a density of 5 \times 10⁷/L in 24-well plates, and then incubated in DMEM/F12 (1:1) medium containing Rh123 at 5 μ mol/L in the presence or absence of CJX1 or CJX2 10 μ mol/L at 37 °C in a humidified atmosphere of 5% CO₂ for 10, 25, 45, 60, and 90 min, respectively. After removal of the medium, the cell monolayers were washed three times in ice-cold PBS and dissolved in 1% Triton X-100. The amount of Rh123 was determined as described in the accumulation assay. The uptake constant (k_{up}) was obtained by fitting the data to $F_t = F_{ss}(1 - e^{-k_{up}t})$, where F_t is the amount of Rh123 at time t , F_{ss} is the amount of Rh123 at 90 min. The amount of intracellular Rh123 was plotted against time.

Rh123 efflux assay The RBMEC were incubated in the medium containing Rh123 5 μ mol/L at 37 °C in a humidified atmosphere of 5% CO₂ for 90 min. After washing three times in ice-cold PBS, RBMEC were incubated in the presence or absence of CJX1 and CJX2 1-10 μ mol/L or verapamil 10 μ mol/L at 37 °C for 5, 10, 25, 30, 60, and 90 min, respectively. The amount of intracellular Rh123 was determined

as described in the accumulation assay. The efflux constant (k_e) of CJX1 and CJX2 10 $\mu\text{mol/L}$ was obtained by fitting the data to $F_t = F_0 e^{-k_e t}$, where F_t is the amount of Rh123 at time t . The amount of intracellular Rh123 was plotted against time.

Persistence of CJX1 and CJX2 activity The RBMEC were incubated in the medium containing Rh123 5 $\mu\text{mol/L}$ in the presence or absence of CJX1 and CJX2 2.5 $\mu\text{mol/L}$ or verapamil 2.5 $\mu\text{mol/L}$ in the humidified atmosphere of 5% CO_2 for 90 min at 37 $^\circ\text{C}$, respectively. After washing three times in rhodamine-free and drug-free medium, the amount of intracellular Rh123 was measured after 10, 30, 60, 90, and 120 min, respectively. The amount of Rh123 in cell samples at different time points was determined as described in the accumulation assay. T_0 represents the amount of Rh123 which was monitored immediately after incubation with CJX1, CJX2 or verapamil.

Data analysis All data were expressed as mean \pm SD and analyzed by t -test.

Results

Effect of CJX1 and CJX2 on intracellular accumulation of Rh123 After RBMEC were incubated with Rh123 for 90 min in the presence of CJX1 and CJX2 1-10 $\mu\text{mol/L}$, the amount of intracellular Rh123 was greatly increased in a concentration-dependent manner compared with the control group ($P < 0.01$). Accumulation of Rh123 was not increased in HUVEC. The amount of intracellular Rh123 in CJX1 10 $\mu\text{mol/L}$ -treated group was comparable to that of the verapamil 10 $\mu\text{mol/L}$ -treated group (Table 1).

Effect of CJX1 and CJX2 on uptake of Rh123 After the RBMEC were incubated in the presence of CJX1 and CJX2 10 $\mu\text{mol/L}$, Rh123 was accumulated in a time-dependent manner from 0-100 min. The rate constants (k_{up}) of the uptake in CJX1 and CJX2-treated group was 0.0508 and 0.0495 respectively, and higher than those of control group (0.0264) and verapamil-treated group (0.044) (Figure 2).

Effect of CJX1 and CJX2 on Rh123 efflux CJX1 and CJX2 1-10 $\mu\text{mol/L}$ inhibited the efflux of Rh123 from RBMEC from 0 to 100 min (Figure 3). The inhibitory effects remained even at 120 min after removal of CJX1 or CJX2 2.5 $\mu\text{mol/L}$ from the medium (Figure 4). This amount suggested that the inhibitory effects of CJX1 and CJX2 on P-gp function was reversible and that the inhibitory effects of CJX1 on P-gp persisted longer compared with verapamil. The efflux constants in CJX1 and CJX2 10 $\mu\text{mol/L}$ -treated groups was 0.0097 and 0.0127, respectively, and was lower than those in control group (0.0312) and verapamil-treated group (0.0131).

Discussion

Beaulieu *et al* showed that P-gp was localized in the luminal membranes of RBMEC^[15]. RBMEC was a valuable tool for the study of BBB permeability *in vitro*^[13]; however, HUVEC was often used as a negative control and had no detectable P-gp expressions^[16,17]. The efflux of fluorescent dye Rh123 was known to be P-gp-dependent and consequently was used extensively to determine the efflux rate from the cells expressing P-gp and to screen novel effective P-gp reversal agents^[18].

The present study showed that before the RBMEC and HUVEC were exposed to Rh123, the amount of intracellular Rh123 in RBMEC was lower than that in HUVEC. After CJX1 and CJX2 treatment, intracellular accumulation of Rh123 was elevated greatly in RBMEC in a concentration-

Figure 3. Effect of CJX1 (A) and CJX2 (B) on the efflux of Rh123 in rat brain microvessel endothelial cells. *n*=3 experiments (each 4 wells). Mean±SD.

dependent manner. But no increase was observed in HUVEC. The intracellular amounts of Rh123 in the CJX1 10 μmol/L-treated group were higher than those in the verapamil 10 μmol/L-treated group. CJX1 and CJX2 significantly enhanced the uptake of Rh123 over the uptake phase. The uptake of Rh123 by RBMEC was more rapid in the CJX1- and CJX2-treated group compared with verapamil-treated group. In contrast, CJX1 and CJX2 significantly reduced the efflux of Rh123. The efflux of Rh123 were slower in the CJX1- and CJX2-treated groups than in the verapamil-treated group. All the results indicated that CJX1 had more potent effect in inhibiting the P-gp-mediated transport of Rh123.

The amount of Rh123 was decreased and returned to the control level after washout of CJX1 and CJX2 at different

Figure 4. Persistence of activity of CJX1 and CJX2. *n*=3 experiments (each 4 wells). Mean±SD.

time points. This suggested that P-gp function recovered and the inhibitory effect of CJX1 and CJX2 on P-gp was reversible. The amount of Rh123 was less than 40% of baseline at 60 min after washout of verapamil and CJX2. But in the CJX1-treated group, there was about 40% Rh123 in RBMEC at 90 min after washout of CJX1. This result showed that the inhibitory effect of CJX1 persisted longer than that of verapamil.

The inhibitory effect of CJX1 and CJX2 on P-gp function in RBMEC indicated that the two compounds may be able to reverse MDR mediated by P-gp. This study has been performed on doxorubicin-resistant human myelogenous leukemia (K562/DOX) cells in our laboratory and the results will be published. The effect of CJX1 and CJX2 on P-gp function *in vivo* will be observed in our laboratory in the near future.

In conclusion, CJX1 and CJX2 exhibited a potent effect on the inhibition of P-gp function *in vitro*. They may become candidates of the effective P-gp reversal agents.

Abstract

Aim: To investigate the mechanism of the action of estrogen, which stimulates the release of secreted amyloid precursor protein α (sAPP α) and decreases the generation of amyloid- β protein (A β), a dominant component in senile plaques in the brains of Alzheimer's disease patients. **Methods:** Experiments were carried out in primary rat cortical neurons, and Western blot was used to detect sAPP α in a culture medium and the total amount of cellular amyloid precursor protein (APP) in neurons. **Results:** 17 β -Estradiol (but not 17 α -estradiol) and β -estradiol 6-(*O*-carboxymethyl) oxime: BSA increased the secretion of sAPP α and this effect was blocked by protein kinase C (PKC) inhibitor calphostin C, but not by the classical estrogen receptor antagonist ICI 182,780. Meanwhile, 17 β -estradiol did not alter the synthesis of cellular APP. **Conclusion:** The effect of 17 β -estradiol on sAPP α secretion is likely mediated through the membrane binding sites, and needs molecular configuration specificity of the ligand. Furthermore, the action of the PKC-dependent pathway might be involved in estrogen-induced sAPP α secretion.

Introduction

Alzheimer's disease (AD) is characterized by two major pathological lesions in the brain: intracellular neurofibrillary tangles and extracellular deposition of senile plaques composed mainly of amyloid- β protein (A β)^[1]. Efforts have been made to explore the relative contribution of plaques and tangles to the pathogenesis of AD. In recent years, the amyloid hypothesis has been accepted by many researchers, who regard accumulation of A β in the brain as the primary factor driving AD pathogenesis^[2,3]. A β is derived from a larger ubiquitous transmembrane protein, amyloid precursor protein (APP). APP is cleaved through at least two different pathways: α -secretase pathway and β -secretase pathway. Through the β -secretase pathway, which involves β -secretase and γ -secretase, APP is cleaved into two fragments: sAPP β and A β . Alternatively, through the α -secretase pathway, which involves α -secretase and γ -secretase, APP is cleaved within the domain of amyloidogenic A β , thus precluding the generation of A β and producing non-

amyloidogenic secreted APP (sAPP α) and p3 (A β 17-40/42). Several studies demonstrated that the increased activity of the α -secretase pathway led to a decrease in the activity of the β -secretase pathway^[4].

Estrogen is considered as a neurotropic and neuro-protective agent^[5]. Estrogen replacement therapy (ERT) in postmenopausal women is related with a reduced risk and delayed onset of AD^[6]. It is therefore worthwhile investigating whether estrogen produces its neuroprotective effect through the regulation of APP processing^[7].

There are several lines of evidence supporting this hypothesis. In cell culture, the addition of estrogen resulted in increase in the production of sAPP α and a decrease in A β ^[8,9]. In animal models, estrogen treatment prevented the accumulation of A β in the brain of guinea pigs and transgenic mutant APP/PS1-expressing mice^[10,11]. It was suggested that the increased release of sAPP α by estrogen was mediated through the phosphorylation of extracellular-regulated kinase 1 and 2 (ERK1/2)^[12]. However, the precise mechanism of the neuroprotective effects of estrogen remains to be fur-

ther investigated. The purposes of the present study are to explore: (1) whether the effect of estrogen on sAPP α release is mediated through the membrane sites or the nuclear receptors; (2) whether the effect of estrogen depends on its molecular configuration specificity; (3) whether protein kinase C (PKC) is involved in the regulation of APP processing; and (4) whether classical estrogen receptor antagonist ICI 182 780 blocks the sAPP α secretion induced by estrogen.

Materials and methods

Cells and cell culture procedures Cortical neurons from 1-d postnatal Sprague-Dawley female or male rats were prepared as described previously^[13]. Cells were plated in DMEM (Life Technologies, Gaithersburg, Germany) containing 10% fetal bovine serum (GIBCO) in poly-*L*-lysine-coated (0.1 g/L; Sigma, St Louis, USA) 100-mm dishes (approximately 1.8×10^7 cells per dish) under standard conditions (37 °C, 5% CO₂). On the following day, the medium was replaced with phenol red-free Neurobasal Medium (GIBCO), supplemented with B27 (GIBCO), which produced cultures with >99% neuronal composition^[14]. The medium was replaced every 3 d. On the ninth day, the medium was replaced with phenol red-free Neurobasal Medium, supplemented with N₂ (10% volume as described in guideline, GIBCO, Rockville, USA). Estrogen and/or other chemicals were added to the dishes. The chemicals used were 17 β -estradiol (Sigma) dissolved in dimethyl sulfoxide (Me₂SO), 17 β -estradiol (Sigma) dissolved in Me₂SO; β -estradiol 6-(*O*-carboxymethyl) oxime: BSA (Sigma) dissolved in PBS, β -estradiol 17-hemisuccinate: BSA (Sigma, St Louis, USA) dissolved in PBS, ICI 182, 780 (TOCRIS) dissolved in Me₂SO, and PKC inhibitor calphostin C (Calbiochem, La Jolla, USA) dissolved in Me₂SO. After a 12-h incubation, the medium was collected for measurement of sAPP α . The medium was then centrifuged at 4000 \times g for 10 min to remove the cellular debris. The cleared supernatant was concentrated with 30 kDa pore size Amicon Ultra (Millipore Co, Billerica, USA) for analysis. Cell monolayers were washed three times with ice-cold PBS and lysed in 1 \times SDS loading buffer with protease inhibitors for 10 min on ice. The cell lysates were boiled for 5 min and then centrifuged for 10 min at 14 000 \times g. The proteins were stored at -20 °C.

Western blot analysis The protein concentrations were determined by BCA protein quantitative analysis kit (Shenergy Biocolor BioScience & Technology Company). An equal amount of protein from the medium was subjected to 7%–10% gradient SDS-poly-acrylamide gel electrophoresis (PAGE) (Amresco). After electrophoretic separation, proteins were transferred onto a PVDF membrane and the polyclonal antibody Rat A Beta (1:1000, Signet), which is

specific for Ab 3-16, was used to detect sAPP α . The efficiency of transfer was confirmed by staining the membrane with Ponceau S. The Ponceau S stain was then removed from the membrane by washing in PBST. Cellular APP was detected using monoclonal antibody 22C11 (1:200, Roche), which is specific for the amino terminus of APP. The amount of β -actin on the same membrane, which was determined by polyclonal antibody β -actin (1:1000, Santa Cruz), was taken as control. Antibody binding was detected by counter-staining with horseradish peroxidase-conjugated antibodies (1:1000, Calbiochem) and visualized using an ECL-detection kit (Pierce). The relative intensity of immunoreactive bands on the exposed film was quantified by a computer-assisted densitometry program (Smart view, Life Science Research Products and System Engineering).

Statistics Data from sAPP α measurement were analyzed by one-way ANOVA followed by Tukey *post hoc* test (SPSS software). Student's *t*-test was used to analyze the data of cellular APP content. $P < 0.05$ was considered to be statistically significant. Each experiment was repeated three to four times to verify the reproducibility of the results.

Results

Effect of 17 β -estradiol on sAPP α secretion and cellular APP content Primary cortical neurons were treated with 10, 100, and 1000 nmol/L 17 β -estradiol. Figure 1 shows that a 12-h treatment with increasing concentrations of 17 β -estradiol

Figure 1. Effect of 17 β -estradiol on sAPP α secretion from the rat cortical neurons. (A) Effect of 17 β -estradiol of various concentrations. $n=3$. Mean \pm SD. ^b $P < 0.05$, ^c $P < 0.01$ vs control. (B) Electrophoresis results from a representative experiment. (1) Control; (2) 10 nmol/L 17 β -estradiol; (3) 100 nmol/L 17 β -estradiol; (4) 1000 nmol/L 17 β -estradiol.

resulted in a significant dose-dependent increase in sAPP α release into the medium as compared with the sAPP α level in the control. 17 β -Estradiol (100 nmol/L) did not alter the total cellular APP content in cultured cortical neurons (Figure 2).

Figure 2. Effect of 17 β -estradiol on total cellular APP content in the cultured rat cortical neurons. (A) Cellular APP content with or without 17 β -estradiol administration. $n=3$. Mean \pm SD. (B) Results from a representative experiment for total cellular APP. (C) β -actin on the same film as (B).

Effect of β -estradiol 6-(*O*-carboxymethyl) oxime: BSA on the release of sAPP α To investigate whether the membrane-impermeable estradiol-BSA conjugates, β -estradiol 6-(*O*-carboxymethyl) oxime: BSA and β -estradiol 17-hemisuccinate: BSA, exerted similar actions on sAPP α secretion as 17 β -estradiol, neurons were incubated with these two agents. After a 12-h incubation, the supernatant was collected for measurement of sAPP α . β -Estradiol 6-(*O*-carboxymethyl) oxime:BSA (1000 nmol/L) increased sAPP α secretion, although the magnitude of the effect was smaller than that of 1000 nmol/L 17 β -estradiol. Estradiol 17-hemisuccinate: BSA (1000 nmol/L) also stimulated sAPP α secretion, but the difference was not statistically significant (Figure 3).

Effect of 17 α -estradiol on the release of sAPP α In order to investigate whether estradiol stimulates sAPP α secretion depending on its configuration specificity, we treated the neurons with 100 nmol/L, 1000 nmol/L 17 α -estradiol and 100 nmol/L 17 β -estradiol. Twelve hours later, the supernatant was collected and concentrated for Western blot analysis.

Figure 3. (A) Effects of 17 β -estradiol(E2), β -estradiol 6-(*O*-carboxymethyl) oxime:BSA(E2-6:BSA), and β -estradiol 17-hemisuccinate:BSA (E2-17:BSA), respectively, on the release of sAPP α . $n=4$. Mean \pm SD. ^b $P<0.05$, ^c $P<0.01$ vs control. (B) Electrophoresis results from a representative experiment. (1) Control; (2) 17 β -estradiol; (3) β -estradiol 6-(*O*-carboxymethyl) oxime:BSA; (4) β -estradiol 17-hemisuccinate:BSA.

Figure 4. Effect of 17 α -estradiol on sAPP α release from rat cortical neurons. (A) Effects of 100, 1000 nmol/L 17 α -estradiol and 100 nmol/L 17 β -estradiol on the release of sAPP α . $n=3$. Mean \pm SD. ^b $P<0.05$, ^c $P<0.01$ vs control.

The results showed that, in contrast to 17 β -estradiol, 17 α -estradiol did not alter sAPP α secretion (Figure 4).

Effect of PKC inhibitor on 17 β -estradiol-induced sAPP α secretion Calphostin C, a PKC inhibitor, was used to investigate the role of PKC on 17 β -estradiol-induced secretion of

sAPP α . Incubation with calphostin C (250 nmol/L) alone for 12 h did not change the sAPP α secretion. However, when the neurons were co-treated with calphostin C (250 nmol/L) and 17 β -estradiol (100 nmol/L) for 12 h, the stimulatory

Figure 5. Involvement of PKC in 17 β -estradiol effect on sAPP α secretion. (A) Effects of 17 β -estradiol, calphostin C, and 17 β -estradiol+calphostin C on the release of sAPP α , respectively. $n=3$. Mean \pm SD. ^c $P<0.01$ vs control. ^e $P<0.05$ vs E2. effect of 17 β -estradiol on sAPP α secretion disappeared (Figure 5).

Effect of estrogen receptor antagonist on the 17 β -estradiol-induced sAPP α secretion To explore whether activation of the classical estrogen receptors is involved in 17 β -estradiol stimulating sAPP α secretion, rat cortical neurons were treated with 17 β -estradiol (100 nmol/L), estrogen receptor antagonist ICI 182 780 (1 μ mol/L) alone, and 17 β -estradiol (100 nmol/L) together with ICI 182 780 (1 μ mol/L). The results showed that ICI 182 780 alone produced no alteration in sAPP α secretion, while simultaneous administration of ICI 182 780 and 17 β -estradiol resulted in a significant increase in sAPP α secretion, similar to the effect of 17 β -estradiol (Figure 6).

Discussion

It appears that ERT prevents the onset of AD, but is not an effective treatment for AD^[6]. However, recent clinical studies revealed that ERT brought beneficial as well as adverse effects^[15]. Therefore, it is important to elucidate the mechanisms of the neuronal action of estrogen and to develop new drugs that retain the beneficial effects, but do not have the side effects of estrogen^[16]. It is generally accepted

Figure 6. No antagonism by ICI 182 780 against the 17 β -estradiol-induced sAPP α secretion. (A) Effects of 100 nmol/L 17 β -estradiol, 1 μ mol/L ICI 182 780 alone, and 100 nmol/L 17 β -estradiol+1 μ mol/L ICI 182 780 on the release of sAPP α . $n=3$. that the effect of estrogen in preventing AD is mediated through regulating APP processing^[2,7]. Our study provides evidence that estrogen increases sAPP α release without changing the total cellular APP content in cultured rat cortical neurons. Because the up-regulation of the α -secretase pathway mediating sAPP α production occurs within the same time course as down-regulation of the β -secretase pathway^[4], it is reasonable to suggest that estrogen could reduce the generation of A β secondary to increases in sAPP α secretion and, in turn, exert its neuroprotective functions.

In addition to classical intracellular estrogen receptor, estrogen binding sites are also present on the cell membrane^[5]. The actions of estrogen on its target tissues include a long-term “genomic” action mediated by intracellular estrogen receptors, and a rapid action through membrane binding sites that modulate a diversity of intracellular signal transduction pathways^[17]. Therefore, it is interesting to know whether the estradiol-induced release of sAPP α is brought about through the mediation of nuclear or membrane binding sites. Our data clearly demonstrated that β -estradiol 6-(*O*-carboxymethyl) oxime: BSA, a membrane-impermeable estradiol conjugate^[18,19], produced a similar effect like estrogen to increase the release of sAPP α , suggesting the involvement of the membrane binding sites. Furthermore, the estrogen receptor antagonist ICI 182 780 did not affect the effect of estrogen, suggesting that the classical estrogen receptors ER α or ER β

were not involved in the above-mentioned estradiol effect. The role of classical estrogen receptors in the neuronal effect of estrogen is controversial. Some studies showed that the estrogen-induced rapid intracellular signal transduction cascades were unaffected by the classical estrogen receptor antagonists^[18,20,21], such as tamoxifen and ICI 182 780, in cell lines that did or did not express estrogen receptors ER α and ER β ; while other studies showed that the rapid intracellular signal transduction was blocked by the classical estrogen receptor antagonists^[13,22–24]. The reason for the difference in these studies is unknown, but it is probably a result of the different cells the researchers used and different parameters chosen for study, which appear through different membrane binding sites. The results of the present study suggest that the structure of the membrane binding sites responsible for the estradiol-induced sAPP α secretion is probably different from that of the classical estrogen receptors.

In present study, 17 β -estradiol and its two BSA conjugates produced effects with different potencies. One of the possible explanations is that the combination of BSA alters the dimensional configuration of estradiol and thus changes its affinity for the membrane binding sites. In β -estradiol 6-(*O*-carboxymethyl) oxime: BSA, BSA attaches to estradiol at position 6, that is, on the “bottom” of the structure of estradiol, making the “top” (the C and D rings) of estradiol accessible. In contrast, in β -estradiol 17-hemisuccinate: BSA, BSA attaches to position 17 on the “top” of estradiol, making the “bottom” (the A and B rings) of the estradiol accessible. The difference in the configuration between the two conjugates can change the binding ability to the membrane sites and therefore change the effect in regulating sAPP α secretion. It is possible that a small amount of estradiol might dissociate from the conjugates, however, some studies reported that a very small amount of estradiol that dissociated from the conjugates did not exert effects on estrogen receptors^[25].

Behl *et al* indicated that both 17 β -estradiol and its isomer 17 α -estradiol exhibited neuroprotective actions against oxidative stress^[26]. 17 α -estradiol does not bind to the nuclear ER, but 17 α -estradiol was reported to stimulate phosphorylation of ERK1/2 in immature rat neurons^[27]. Our present study showed that 17 α -estradiol was unable to regulate the APP processing. Therefore, the mechanism for anti-oxidation effects of estrogens might be different from those of regulating APP metabolism.

Estrogen stimulates a rapid Ca²⁺ release from the intracellular calcium stores^[28]. Yeon *et al* indicated that PKC ϵ played an important role in modulating APP and that overexpression of the PKC ϵ V1 region, which specifically binds to the recep-

tor for activated C-kinase (RACK), blocked the phorbol ester-induced enhancement of sAPP α secretion^[29]. Recently, Beyer *et al* reported that estrogen activated G-protein-coupled phospholipase C, leading to the release of Ca²⁺ from intracellular stores and the activation of PKC^[30]. In the present study, we demonstrated that calphostin C prevented the increase of sAPP α secretion induced by 17 β -estradiol, indicating the involvement of PKC.

In summary, our data indicate that, in cultured rat cortical neurons, estrogen stimulates sAPP α secretion through mechanisms involving membrane binding sites and the activation of PKC. The effects of estradiol are not mediated by classical ER. The details of the estrogen membrane binding sites and the related signaling pathways remain to be further studied.

Abstract

Aim: To examine the basic expression levels of *N*-methyl-*D*-aspartate (NMDA) receptor NR1 and NR2B subunits in six brain regions of Sprague-Dawley (SD) rats with different visual recognition memory. **Methods:** Rats were tested by a novel-object-recognition model and grouped into the high and the low visual recognition memory groups. The expression levels of NR1 and NR2B subunits in the cortex, hippocampus, striatum, amygdala, diencephalon, and olfactory bulb were measured by semiquantitative immunoblotting. **Results:** The NR1 and NR2B subunit protein levels in the hippocampus of the high visual recognition memory group were 35.9% ($P < 0.01$) and 53.4% ($P < 0.05$) higher respectively than those in the low group. In addition, the NR2B level in the striatum in the high visual recognition memory group was 25.0% ($P < 0.05$) higher than that in the low one. However, no significant difference was found in the levels of the subunits between the two groups in other brain regions. **Conclusion:** The visual recognition memory in rats is related to the basic expression level of NMDA receptor NR1/NR2B subtype in the hippocampus and striatum.

Introduction

N-Methyl-*D*-aspartate (NMDA) receptors, the major ionotropic glutamate receptors in the central nervous system, play key roles in excitatory synaptic transmission and plasticity, and are involved in many physiological and pathological processes^[1,2]. NMDA receptors are mainly composed of NR1 subunit and NR2A, NR2B, NR2C, or NR2D subunit, respectively, and the different subunit combinations form different NMDA receptor subtypes with distinct functional properties^[3,4].

It has been demonstrated that NMDA receptors are involved in long-term synaptic plasticity and certain forms of learning and memory^[5-8]. For example, numerous data indicate that NMDA receptor activity and NMDA receptor-dependent synaptic plasticity in the hippocampus are crucial for spatial recognition memory^[7,8]. However, there have been a few reports about the role of NMDA receptors in visual recognition memory^[9-12], and there are some discrepant or even contradictory results in the visual recognition memory with regard to different doses of NMDA receptors antagonist,

and animal species. Furthermore, most of those findings were mainly obtained from animals with specific brain region injuries, pharmacological manipulated animals or transgenic mice with one of NMDA receptor subunits abnormally expressed. Little is known whether the basic expression levels of NMDA receptors is related to different visual recognition memory in normal adult rats.

Therefore, the objective of our studies was to examine the relationship between the basic expression levels of NR1 and NR2B subunits in six specific regions (cortex, hippocampus, striatum, amygdala, diencephalons, and olfactory bulb) and visual recognition memory in rats.

Materials and methods

Animals All experiments were carried out in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animal. The animals used in this study were 6-week old male Sprague-Dawley (SD) rats, weighing 175–190 g (Grade II, Certificate No 22-9601018, Experimental Animal Center, Zhejiang University, China), maintained in

an air-conditioned room with controlled temperature (22–26 °C) and humidity (40%–70%), housed in cages with a 12-h light/dark cycle (lights on from 8:00 AM–20:00 PM) with food and water available. Experiments were carried out each day between 10:00 AM–17:00 PM.

Novel object recognition task Rat was individually habituated to an open-field box (50 cm×50 cm×30 cm high) for 3 d. During training sessions, two novel objects were placed into the open field and the animal was allowed to explore for 5 min. The time spent for exploring each object was recorded. During retention tests, the animal was placed back into the same box after a 24-h delay, in which one of the objects used during training was replaced by a novel object, and allowed to explore freely for 5 min. Behaviour was considered exploratory when an animal was touching or directed towards the object at a distance ≤ 2 cm with its nose; while behaviour was not considered exploratory when an animal was turning around or sitting on the object. To avoid interference effect of the olfactory cue due to scent traces left, after each experiment, both the objects and the arena were scraped by 10% ethanol. The preference index, a ratio of the amount of time spent exploring any one of the two objects (training session) or the novel one (retention session) over the total time spent exploring both objects, was used to measure recognition memory. All 40 male SD rats were ranked by the preference index. From these, eight superior and eight inferior rats were used as high visual recognition memory group and low visual recognition memory group, respectively, in the present study.

Preparation of tissue The rats were killed by decapitation and the brains were quickly removed. The brains were dissected on ice into six specific regions (cortex, hippocampus, striatum, amygdala, diencephalon, and olfactory bulb), and homogenized twice in 100 volumes (100×wet weight) of ice-cold 10 mmol/L Tris-HCl (pH 7.4) containing 320 mmol/L sucrose with a TissueMizer (Heidolph DIA×900) at speed 5 for 10 s with a 20 s interval between bursts. The tissue homogenate was centrifuged at 700×g for 10 min at 4 °C. The supernatant was collected and centrifuged at 37 000×g for 40 min at 4 °C. This high-speed pellet was resuspended in 10 mmol/L Tris-HCl (pH 7.4). Protein concentrations were determined using Folin phenol reagent with bovine serum albumin as a standard.

Semiquantitative Western blot Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and transfer of proteins to nitrocellulose membranes were performed according to conventional methods. The denatured membrane proteins were separated on 7.5% polyacrylamide gels and transferred to nitrocellulose membranes in transfer

buffer (Tris 25 mmol/L, glycine 192 mmol/L, 20% methanol and 0.05 % SDS, pH 8.3). The membranes were incubated with a blocking buffer of 5% non-fat dry milk in TBST (Tris-HCl 20 mmol/L, NaCl 140 mmol/L, 0.1% Tween-20, pH 7.4) at room temperature for 1 h. The membranes were then incubated with anti-NR1, and anti-NR2B antibodies (1 g/L) in blocking buffer overnight at 4 °C. After several washes with TBST, the membranes were incubated with horseradish peroxidase-conjugated secondary antibody in blocking buffer for 1 h at room temperature. Following washes for 20 min with four intermediate changes with TBST, proteins were visualized with enhanced chemiluminescence. The resulting film was scanned and analyzed using a laser densitometer and GelScan XL software (Pharmacia LKB). In order to make different gel samples evaluable, every gel was run with three lanes of the same cortex proteins as a standard^[13,14].

Statistical analysis All results were expressed as mean±SD. Differences were analyzed by group comparisons *t*-test with Mann-Whitney Test by SPSS 11.0 software. $P < 0.05$ was considered statistically significant.

Results

Novel object recognition task The preference indexes for the high visual recognition memory group and the low visual recognition memory group were summarized in Figure 1. During the training sessions, no significant difference was found in the exploratory preference between the two groups (0.43 ± 0.12 vs 0.49 ± 0.11 , $P > 0.05$). During the retention sessions, the exploratory preference of the high visual recognition memory group was significantly higher than that of the low one ($P < 0.01$).

Figure 1. Exploratory preference of rats with different visual recognition memory during the training session and the retention session in the novel-object-recognition task. $n=8$. Mean±SD. ^a $P > 0.05$ vs the training session of the group with low visual recognition memory. ^f $P < 0.01$ vs the retention session of the group with low visual recognition memory.

Relationship between the basic expression level of NR1 subunit and visual recognition memory in rats The protein level of NR1 subunit in the hippocampus in the high visual recognition memory group was 35.9% higher than that in the low group (1.89 ± 0.18 vs 1.39 ± 0.39 , $P < 0.01$). However, no significant difference was found in the protein levels of NR1 subunit in the cortex, striatum, amygdala, diencephalon and olfactory bulb of rats between the two groups (Figure 2).

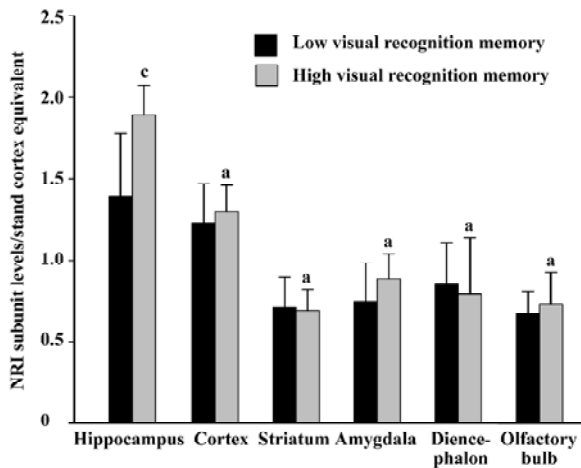

Figure 2. Relative expression levels of NR1 subunits in six brain regions in rats with different visual recognition memory. $n=8$. Mean \pm SD. ^a $P > 0.05$, ^c $P < 0.01$ vs the group with low visual recognition memory.

Relationship between basic expression level of NR2B subunit and visual recognition memory in rats As shown in Figure 3, the protein level of NR2B subunit in the hippocampus in the high visual recognition memory group was 53.3% higher than that in the low group (2.04 ± 0.22 vs 1.33 ± 0.57 , $P < 0.05$). In addition, the NR2B level in the high one was 25.0% higher than that in the low group in the striatum ($P < 0.05$). While, no significant difference was found in the protein levels of NR2B subunit in other brain regions between the two groups ($P > 0.05$).

Discussion

In the present study, we observed that both NR1 and NR2B subunits in the hippocampus in the high visual recognition memory group were remarkably higher than those in the low group. So the NMDA receptor NR1/NR2B subtype is higher in the high visual recognition memory group, although it is unclear whether there is any difference in the basic expression levels of the other subtypes of NMDA

Figure 3. Relative expression levels of NR2B subunits in six brain regions in rats with different visual recognition memory. $n=8$. Mean \pm SD. ^a $P > 0.05$, ^b $P < 0.05$ vs the group with low visual recognition memory.

receptors. The result is consistent with the previous studies, which found that the transgenic mice overexpressing NR2B subunit in the forebrains exhibited an enhancement of novel-object-recognition memory^[10], and the CA1-specific NR1 subunit knockout mice exhibited impairment in object recognition^[15]. Therefore, our data provided more evidence *in vivo* to support the concept that NMDA receptors in the hippocampus are involved in visual recognition memory.

Previous studies showed that lesions to the perirhinal, postrhinal cortex and associated structures induced deficits in the ability to recognize single objects^[16,17], and that NMDA receptor blockade in the perirhinal cortex impaired object discrimination in rats^[18]. It seems that NMDA receptors in the cortex are related to visual recognition memory. However, in our study, no change in the basic expression levels of NR1 and NR2B subunits in the cortex was found between the groups with different visual recognition memory. Quinlan *et al* also reported that the NR2B subunit level in the visual cortex remained unchanged by visual experience^[19]. The explanation for these converse results might be that the cortical coding of object recognition decays quickly and is not sufficient for maintaining information about objects across longer retention intervals (eg 24 h)^[20]. It is also possible that the NMDA receptor NR2B subunit in some sub-regions of the cortex is related to visual memory. So our results at least suggest that the basic expression levels of NR1 and NR2B subunits in the cortex correlated less with visual recognition memory when a 24 h retention interval was imposed.

The striatum is a brain region involved in procedural

memory and diverse forms of implicit memory^[21,22]. It is well known that glutamatergic input from the cortex to the striatum is critical for striatal learning^[23] and NR2B subunit in the striatum is correlated with water maze performance in the inferior group of the aged rats^[24]. Our results here provided more evidences that the basic expression level of NR2B subunit in the striatum was also correlated with visual recognition memory.

The novel-object-recognition task was used in this study, which is based on the spontaneous preference that animals display for novel objects. This task is considered to need only “familiarity judgment” as to whether the objects presented in the choice phase are novel or familiar to the animals^[25]. The advantage of this method is that performance does not depend on the retention of a rule, and it is not influenced by changes in response to reward, which can provide a relatively pure measure of “working memory”^[26].

In conclusion, the main finding of the present study is that the basic expression level of the NMDA receptor NR1/NR2B subtype in the hippocampus and striatum is related to visual recognition memory.

Abstract

Aim: To investigate the antinociceptive effect of adenosine agonist R-phenylisopropyl-adenosine (R-PIA) given to conscious rats by intracerebroventricular (ICV) and intrathecal (IT), and identify the effect of R-PIA on minimum alveolar concentration (MAC) of halothane with pretreatment of A₁ receptor antagonist 8-cyclopentyl-1,3-dipropylxanthine (DPCPX) or K⁺ channel blocker 4-aminopyridine (4-AP). **Methods:** Sprague-Dawley rats were implanted with 24-gauge stainless steel guide cannula using stereotaxic apparatus and ICV method, and an IT catheter (PE-10, 8.5 cm) was inserted into the lumbar subarachnoid space, while the rats were under pentobarbital anesthesia. After one week of recovery from surgery, rats were randomly assigned to one of the following protocols: MAC of halothane, or tail-flick latency. All measurements were performed after R-PIA (0.8–2.0 μg) microinjection into ICV and IT with or without pretreatment of DPCPX or 4-AP. **Results:** Microinjection of adenosine agonist R-PIA in doses of 0.8–2.0 μg into ICV and IT produced a significant dose- and time-dependent antinociceptive action as reflected by increasing latency times and ICV administration of adenosine agonist R-PIA (0.8 μg) reducing halothane anesthetic requirements (by 29%). The antinociception and reducing halothane requirements effected by adenosine agonist R-PIA was abolished by DPCPX and 4-AP. **Conclusion:** ICV and IT administration of adenosine agonist R-PIA produced an antinociceptive effect in a dose-dependent manner and decreased halothane MAC with painful stimulation through activation of A₁ receptor subtype, and the underlying mechanism involves K⁺ channel activation.

Introduction

Adenosine, a purine nucleotide, is present in the brain in concentrations sufficient to be important in the regulation of central nervous system (CNS) function^[1]. The compound adenosine has various modulatory effects in the peripheral and central nervous system, mediated through specific cell-surface associated receptors^[2]. For example, in addition to the antinociceptive action of adenosine in animal models^[3], adenosine is used to treat the symptoms of paroxysmal supraventricular tachycardias, and to produce controlled hypotension during some surgical procedures, and in the diag-

nosis of coronary artery disease^[4]. The current view is that adenosine receptors of the A₁ subtype are associated with a modulatory effect on pain transmission at brain and spinal cord level. Animal studies have repeatedly demonstrated that adenosine-mediated inhibitory influences presumed nociceptive reflex responses^[5]. These examinations on rodents have tested acute pain models involving tactile, pressure and heat stimulations. More recently, animal lesion models, presumably reflecting chronic pain, have shown that adenosine analogue can suppress nociceptive behavior both by systemic and intrathecal administration^[6]. Consequently, there are substantial evidence that adenosine can modulate

nociceptive input. The general thinking about the mechanism of analgesic-anesthetic action of adenosine is that adenosine interacts with G-protein-coupled adenosine receptor and activates K^+ channel in CNS. However the roles of K^+ channel activation by adenosine in the antinociceptive action of adenosine in CNS and spinal cord has not been well demonstrated. Thus, in the present study we investigated whether adenosine agonist R-phenylisopropyl-adenosine (R-PIA) administered through intracerebroventricular (ICV) or intrathecal (IT) methods will produce an antinociceptive effect and enhance the halothane-anesthetized state.

Materials and methods

Animal preparation With approval of the Animal Care and Use Committee of our institution, studies were performed on 70 male Sprague-Dawley rats weighing 300 ± 20 g (9 weeks old). Rats were housed individually in a temperature-controlled (21 ± 1 °C) room with a 12-h light/dark cycle, and they were given free access to water and food. All experimental measurements were performed between 10:00 AM and 5:00 PM. Each rat was assigned to only one of the following protocols: minimum alveolar concentration (MAC) of halothane ($n=30$), or tail-flick latency (IT injection, $n=20$; ICV injection, $n=20$). Each animal was studied two to four times in an experimental series with an interval of at least 5 d.

Surgical preparation For the ICV cannular placement, as previously described by Ma *et al*^[7], animals were anesthetized with pentobarbital (50 mg/kg), and positioned in a stereotaxic apparatus (Narishige, Tokyo, Japan). A 24-gauge stainless steel guide cannula was unilaterally implanted 1 mm above the lateral ventricle using the following stereotaxic coordinates: 1.5 mm lateral to the midline, 1.0 mm posterior to bregma, 2.5 mm ventral to dura. The guide cannula was then fixed to the skull with two steel screws and dental cement. The IT catheter was implanted as previously described by Zeng *et al*^[8], and animals were placed in a stereotaxic head holder with the head fixed forward. At the site of occipital a midline incision was made till the escape of cerebrospinal fluid. Intrathecal catheter was inserted at a length of 8.5 cm to the lumbar intrathecal level. The catheter's external arm was tunneled subcutaneously to emerge at the neck. After the surgery the rats were allowed to recover for one week before the experiments began. Only animals exhibiting no motor deficits as a result of surgery were used.

Minimum alveolar concentration measurement Anesthesia was induced through inhalation of halothane in a transparent container. The rat's trachea was intubated with a 16-

gauge cannula, and the lungs were mechanically ventilated with 1.0% halothane in oxygen and air ($F_{I}O_2$ 0.3–0.5). End-tidal carbon dioxide pressure was maintained at 35 to 40 mmHg. Rectal temperature was continuously monitored and maintained at 37.5 °C with a heating pad. Fifteen minutes after the initiation of halothane anesthesia, saline or 4-aminopyridine (4-AP) 2 mg/kg was injected intraperitoneally, then a 30-gauge stainless steel internal cannula connected to polyethylene tubing was inserted into the guide cannula and positioned 1.0 mm beyond the tip. R-PIA at the dose of 0.8 μ g, 1.0 μ g, and 2.0 μ g, or combined with A_1 antagonist 8-cyclopentyl-1,3-dipropylxanthine (DPCPX) 5.0 μ g was injected into the lateral cerebral ventricle at a volume of 5.0 μ L over 90 s using a microinjection pump. Five minutes after the drug or vehicle injection, MAC was determined using the up and down technique^[9]. Briefly, the administration of halothane was adjusted in steps of 0.1%, and a stable end-tidal concentration for 15 min was obtained before stimulation. Noxious stimulation was applied with a 6-inch hemostat to the middle third of the tail for 60 s at the first ratchet position. The criteria for positive movements included purposeful movements of either the head or the four extremities. When animal had a positive response, the halothane concentration was increased; when there was no response, the concentration was decreased until movement was observed. When the interval was bracketed by positive and negative responses, the midpoint of the interval was then the MAC of halothane. End-tidal gas samples were obtained with an airtight glass syringe through a 26-gauge needle inserted to a tracheal tube during 15 expirations. Halothane concentrations were analyzed using an infrared analyzer (M1025B; Hewlett Packard). Calibration with the standard gas was performed before study. All chemicals were purchased from Sigma Chemical (St Louis, MO, USA).

Measurements of antinociception The antinociceptive effect was measured by the tail-flick (TF) latency response. A high-intensity light was focused on the dorsal surface of the rat tail; the time for the rat to move its tail out of the light beam was automatically recorded (Thermal Analgesimeter KN-205E, Natume, Tokyo, Japan). A different patch of the middle one-third portion of the tail was exposed to the light beam on each trial to minimize the risk of tissue damage during the experiment. A cut-off time of 10 s was predetermined, at which time the trial was terminated if no response occurred. TF latency was determined 5, 10, 15, 20, 30, 40, 50, and 60 min after ICV or IT administration of R-PIA (0.8 μ g, 1.0 μ g, and 2.0 μ g), with or without pretreatment of DPCPX 5.0 μ g or 4-AP 2 mg/kg. Each TF latency data point consisted of a mean of three trials on an individual animal.

Histology examination At the end of the experiments, bromophenol blue (5.0 μ L) was microinjected to label the site of ICV injection. The rat was then killed with an overdose of pentobarbital. The brain was removed and fixed in 10% neutral buffered formalin. Dye spots were localized from 0.3–0.5 mm serial coronal sections and identified on diagrams from the atlas of Paxinos and Watson^[10]. Bromophenol blue (10 μ L) was used to confirm the position of the intrathecal catheter and likely spread of the injectate.

Statistical analysis All data were presented as mean \pm SEM. In MAC measurements statistical testing were performed with a Student's *t*-test. Because a cut-off value was used in the TF latency test, data were converted to the percentages of the maximum possible effect (% MPE). Where % MPE=(postdrug TF latency-baseline TF latency)/(cut-off time-baseline TF latency) \times 100. The cut-off time was defined as a stimulus time of 10 s. For the effect of drugs on TF latency, statistical differences were analyzed using a two-way analysis of variance (ANOVA), followed by Fisher's test for *post hoc* analysis of means. *P*<0.05 was considered to be statistically significant.

Results

Effect of ICV R-PIA injection on the MAC of halothane with pretreatment 4-AP or DPCPX The MAC of halothane was significantly reduced by direct application of adenosine agonist R-PIA in doses of 0.8 μ g, 1.0 μ g, and 2.0 μ g. The MAC of halothane in the control group (saline injection) was 0.95% \pm 0.05% (Figure 1), which corresponds with our previously reported MAC values^[9]. R-PIA 0.8 μ g decreased MAC of halothane by 29%. Pretreatment of 4-AP 2 mg/kg intraperitoneal injection or ICV injection DPCPX 5 μ g inhibited the effect of R-PIA 0.8 μ g, whereas the dose of 4-AP or DPCPX itself did not affect the MAC of halothane (Figure 2).

ICV and IT administration of R-PIA on antinociception Time courses were determined for adenosine agonists R-PIA in the TF latency test. IT administration of R-PIA in doses of 0.8–2.0 μ g induced antinociception as reflected by the increase in latency times compared with the control animals. The antinociceptive action reached maximal effect within 10 min and lasted over 60 min, and showed a dose-dependent manner (Figure 3). The ICV administration of adenosine agonist R-PIA (0.8–2.0 μ g) produced the antinociceptive effect as reflected by increasing the TF latency (Figure 4). The peak effect of antinociception of R-PIA was within 5 min and showed a dose-dependent manner. The intraperitoneal injection of 4-AP or ICV injection of DPCPX had no effect on the baseline of TF latency, but its pretreatment produced a significant reverse effect elicited

by the ICV or IT administration of R-PIA (Figure 3, 4). The experiment dose of R-PIA did not show any detectable effect on motor function or general behavior during the observation period (60 min).

Discussion

The present data demonstrated that adenosine agonist R-PIA injection by ICV and IT, produced antinociceptive effect in a dose-related manner and enhanced halothane anesthesia. Because such effects of R-PIA were attenuated with pretreatment of DPCPX, an A₁ receptor antagonist, and 4-AP, a voltage-gated K⁺ channel blocker, the action of R-PIA is mediated via A₁ receptor subtype activation and its

mechanisms are likely to be involved in, at least in part, K⁺ channel activation.

Adenosine and its analogues were shown to produce antinociception in the tail flick and hot plate tests following both IT and central administration^[5,6]. Such antinociception has been diminished by methylxanthines, such as caffeine and theophylline, suggesting the involvement of specific adenosine receptor^[11]. In the present study, we administered R-PIA through IT method to induce dose-dependent

antinociception. Pretreatment A₁ antagonist DPCPX reversed this effect. The results indicate that R-PIA inhibits nociceptive responses by acting on A₁ receptors. By using selective adenosine agonist on the evoked potential record of the rat spinal cord, the adenosine A₁ receptor agonist obviously inhibited the slow ventral root potential, which is the C-fiber-evoked excitatory response associated with nociceptive information^[2]. In the present study, ICV administration of R-PIA produced a very short period (15 min) of antinociception. Systemically administered adenosine analogue R-PIA did not affect synaptic neurotransmission in the hippocampus, which are enriched in A₁-type adenosine receptors, because they failed to reach the appropriate receptors^[11]. Thus, it is likely with the tail flick test that the site of action of R-PIA is probably at the spinal cord, because ICV injection of R-PIA only produced fewer responses in the tail flick test, although it has previously been reported that activity in the hot-plate test was observed^[12]. In the hot-plate test, the potential for an additional supraspinal action would need to be considered.

Adenosine modulation of anesthesia has been extensively studied in the past^[13]. The standard for determining anesthetic requirements is the MAC of an inhaled agent that prevents gross purposeful movement in response to a supramaximal painful stimulus. Because of its simplicity and reproducibility, the MAC concept has remained an important tool for studying anesthetic action. Previous studies have shown that on a halothane anesthetized rat the effect of adenosine in decreasing the halothane MAC was probably related to an adenosine-induced decrease in CNS noradrenergic transmission because noradrenergic neurotransmission was decreased following R-PIA administration in all brain regions^[13]. The present results provided evidence that into R-PIA injection significantly reduced MAC of halothane by 29%, and this reduction in MAC of halothane was inhibited with pretreatment of A₁ antagonist DPCPX suggests that R-PIA increased the effects of anesthetic suppression was directly mediated A₁ receptor. However, ICV injection of R-PIA also exhibited antinociceptive action, and the relationships between neurotransmitter and adenosine decrease MAC of halothane are not very clear. It is important that the behavioral responses consist of nociception, motor responses and central processing were measured with MAC. We are still unable to dissect which element(s) are affected by the central action of R-PIA.

Agonists of adenosine A₁ receptors (including R-PIA) have activation action on K⁺ channels in neurons of the CNS. ATP-sensitive K⁺ channel blocker could inhibit the antinociception of adenosine in mice^[14]. Other responses

induced by adenosine A₁ receptor agonist also appear to be linked to the opening of K⁺ channels. Adenosine A₁ receptors in cardiac and vascular muscle cells are coupled to ATP-sensitive K⁺ channels^[4]. In the present study, the effect of R-PIA on reducing the MAC of halothane and antinociception were antagonized by pretreatment with voltage-gated K⁺ channel blocker 4-AP. The apparent involvement of voltage-gated K⁺ channels in R-PIA-induced effect, as our results suggest, was not unexpected because 4-AP, as a potent voltage-gated K⁺ channel blocker, blocks outward conducting potassium channels, thereby lowering the threshold for initiation of action potentials as well as prolonging action potential duration in excitable membrane. In addition, the antinociceptive effect of GABA_B receptor agonist baclofen and [*D*-ala²]-deltorphin II was also antagonized by 4-AP^[15]. K⁺ channel opener could potentiate the analgesic effect of morphine^[16], and the spinal antinociceptive action of morphine was caused by the release of adenosine and subsequent activation of adenosine receptors within the spinal cord^[6]. Taken together, it is possible that adenosine affected the A₁ receptor, resulted in increased K⁺ conductance preventing pain signal transmission to produce spinal antinociception and ICV methods reducing the requirement of halothane. Thus voltage-gated K⁺ channels play a key role in the R-PIA-induced effect both by IT and ICV administration.

In summary, the results provide implications for the use of adenosine analog in anesthetic settings and pain management. As evidenced from our data, the use of an adenosine analog during painful stimuli and halothane anesthesia profoundly decreased the response to nociception and increased the anesthetic depression through the A₁ receptor subtype, and its mechanisms involves K⁺ channel activation. This observation pertains during other forms of volatile anesthesia and other types of pain treatment although definitive conclusions require further investigation.

Abstract

Aim: To investigate the relationship between spinal cord norepinephrine, α_1 and α_2 adrenergic receptors and antinociception of propofol in mice. **Methods:** Kunming mice were used. Antinociceptive tests were investigated with the tail-immersion test and the acetic acid-induced writhing test. The effects of subcutaneous (sc), intrathecal (ith) and intracerebroventricular (icv) injection propofol on pain threshold were observed. The influences of pretreatment with ith 6-hydroxydopamine, α_1 R antagonist prazosin, or α_2 R antagonist yohimbine on the antinociception of propofol were studied. **Results:** Significant antinociception was produced by propofol (25, 50 mg/kg, sc) and propofol (20, 40 μ g, ith) in tail-immersion test and acetic the acid-induced writhing test ($P < 0.05$ or $P < 0.01$). Icv propofol (10, 20, and 40 μ g) did not produce any effect on pain threshold in mice ($P > 0.05$). The 6-hydroxydopamine (5 and 10 μ g), prazosin (5 and 10 μ g), or yohimbine (5 and 10 μ g) ith alone did not affect basal tai-flick latency (TFL) in conscious mice, but significantly reduced the TFL as measured by tail-immersion test in propofol (50 mg/kg, sc)-treated mice, compared with basal TFL and vehicle groups ($P < 0.05$ or $P < 0.01$). **Conclusion:** The spinal cord is a target of propofol antinociception. In mice propofol antinociception is partly mediated by spinal norepinephrine, α_1 R and α_2 R.

Introduction

Propofol (2,6-diisopropylphenol, Diprivan) is widely used in the clinical setting as an iv anesthetic. Its antinociceptive effect results from an excitation of spinal GABA_A receptors^[1] and an inhibition of spinal NMDA, AMPA receptors^[2], *etc.* A study by Antognini *et al* also suggested that propofol has a direct depressant effect on dorsal horn neuronal responses to noxious stimulation^[3]. Therefore, these studies suggested a spinal mediation of propofol-induced antinociception. However there was also a study that concluded that propofol could control pain and this action might be centrally modulated through the opioid system rather than at the level of the spinal cord^[4]. Therefore the contribution of supraspinal sites versus spinal sites to the antinociception of propofol is still unclear.

The mechanism whereby stimulation of opiate receptors

in supraspinal regions produced analgesia has been extensively investigated and appeared, in part, to involve a descending noradrenergic pathway^[5,6]. Norepinephrine (NE) is a major neurotransmitter in the descending inhibition of nociceptive transmission. Available evidence suggests that at the level of the spinal cord, there appear to be at least two neuronal systems that are involved. The first is the direct presynaptic inhibition of the nociception of the primary afferent neurons or postsynaptic inhibition of the second order neurons through activation of α_2 adrenergic receptor (α_2 Rs)^[7,8]. The second is the indirect activation of the inhibitory interneurons through α_1 Rs located on these neurons^[8,9].

Based on these observations, in the present study, we injected propofol systemically, intrathecally, or intracerebroventricularly to further examine the role of spinal and supraspinal sites in mediating the antinociception of propofol.

We sought evidences of the involvement of spinal NE, α_1R , and α_2R in the antinociception induced by sc propofol in mice.

Materials and methods

Animals With the approve of the Committee of Animal Research of Xuzhou Medical College, we conducted experiments on Kunming mice (22±3 g, Grade II, Certificate No SCXK-SU-2002-0022) of both sexes, obtained from the Laboratory Animal Center of Xuzhou Medical College, housed individually in a temperature-controlled 22±2 °C room with a 12-h light-dark cycle and given free access to food and water. Each animal was used in only one experiment.

Chemicals Propofol and vehicle (10% intralipid) were supplied by the AstraZeneca Company. Prazosin, yohimbine and 6-hydroxydopamine (6-OHDA) were purchased from Sigma-Alexis (USA). Ice acetic acid was produced by Beijing Chemical Factory. All drugs were all freshly prepared. Prazosin was first dissolved in 50% dimethyl sulfoxide (Me₂SO) in normal saline (NS) and the solution was diluted with NS. Yohimbine was dissolved in NS. 6-OHDA was dissolved in a saline vehicle (0.02% ascorbic acid in 0.9% saline). Systemic drug administration was sc performed in a single volume of 0.01 L/kg.

Intracerebroventricular injection in conscious mice^[10] A 25-gauge needle was inserted in the left lateral ventricle of the brain with the following coordinates: left 2 mm of sagittal suture on the linking line of ears, and 2 mm down the skull surface. Volume of icv injections was 5 µL. The proper position of the icv localization was verified at the end of each protocol by injection of methylene blue staining with the same coordinates.

Intrathecal injection in conscious mice^[2] A 25-gauge needle was inserted at L₅–L₆ intrathecal space. Ith placement was confirmed by a sudden lateral movement of the tail. All mice were injected with a 5-µL volume of drugs or vehicles and, after allowing 5 s for the injectant to disperse, the needle was slowly withdrawn. While developing this technique we injected 5 µL of 2% lidocaine ith in 10 mice, which consistently caused a transient hind-paw paralysis.

Tail-immersion test^[11] The caudal 1/3 of tails of mice were immersed in 48±0.5 °C water. The time for the mice to remove their tails from the water was expressed as the tail-flick latency (TFL). All mice were tested twice at a 5-min interval and the mean value was considered as the basal pain threshold. A cut-off time of 60 s was used to minimize damage to the skin of the tail. The influences of sc propofol (12.5, 25, and 50 mg/kg, *n*=10) alone on the TFL and the

effects of pretreatment with ith prazosin and yohimbine 10 min before propofol (50 mg/kg, sc, *n*=10) injection on the TFL were investigated, respectively. To demonstrate the sc propofol-induced prolongation of TFL was not caused by its hypnotic effect, the time courses for the development of propofol-induced hypnosis were established. The loss of righting reflex was assessed by placing the mice on their backs and determining if the animals could right themselves within 30 s.

In a separate study, groups of mice were pretreated intrathecally with 6-OHDA (5, 10, and 20 µg) for 3 d (one injection in all). The dosing scheme of 6-OHDA was chosen according to the study by Hung *et al*^[12] with minor modification. The tail-immersion test was performed on d 4 and the effect of propofol (50 mg/kg, sc, *n*=10) on TFL was observed.

Acetic acid-induced writhing test^[2] Mice were administered NS, intralipid or propofol 30 min before ip injection of 0.9% ice acetic acid in a volume of 10 mL/kg. The number, latency and times of writhing mice were recorded within 15 min after the last injection.

Statistical analysis All data were present as mean±SD. Statistical comparisons in each group were performed by one-way analysis of variance (ANOVA) followed by *t*-test. Difference was considered to be significant at *P*<0.05.

Results

Hypnotic and antinociceptive effects of propofol were temporarily uncoupled Propofol 12.5, 25 mg/kg sc had no appreciable effect on the general behavior in mice. After 2–5 min treatment of propofol (50 mg/kg, sc), mice showed slight sedation. The sedative effect reached maximum after 5 min of propofol injection, and 20% mice (2/10) developed a loss of righting reflex; however, after this time there was no significant increase in TFL. In contrast, sc propofol resulted in a significant increase in TFL 10–30 min after its injection with the peak effect at 10 min (*P*<0.01, Table 1), but after 30 min, all mice remained righting reflex and there was no appreciable effect on general behavior. Neither propofol ith nor icv resulted in any appreciable abnormal behavior.

Effects of propofol on pain threshold in tail-immersion test and acetic acid-induced writhing test in mice There was no significant change of TFL before and after sc, ith, or icv injection of 10% intralipid compared with the NS (sc, ith, or icv) group, respectively in tail-immersion test (*P*>0.05, Table 1). Propofol (12.5 mg/kg, sc) and propofol (5 µg, ith) showed no effect on TFL. However, propofol (25 and 50 mg/kg, sc) and propofol (10, 20 µg, ith) increased

the TFL in a dose- and time-dependent manner 10–30 min after its injection ($P<0.05$ or $P<0.01$ vs NS, Table 1).

No significant difference existed in the number of writhing mice, writhing latency writhing times before and after sc, ith, or icv injection of 10% intralipid. Propofol (12.5 mg/kg, sc) and propofol (5 μ g, ith) showed no anti-nociceptive effect in acetic acid-induced writhing test. But propofol (25 and 50 mg/kg, sc) and propofol (10 and 20 μ g, ith) significantly reduced the writhing times in a dose-dependent way (sc or ith) group ($P<0.05$ or $P<0.01$ vs NS, Table 2). Icv propofol (10, 20, and 40 μ g) did not produce any antinociceptive effects in the tail-immersion test and acetic acid-induced writhing test ($P>0.05$, Table 1, 2).

Effects of intrathecal prazosin and yohimbine on TFL in conscious mice in tail-immersion test No significant difference existed in the TFL between NS group and Me₂SO group ($P>0.05$, Table 3). Ith prazosin (5 and 10 μ g) or yohimbine (5 and 10 μ g) alone had no effect on the general behavior and TFL. However, mice in prazosin (20 μ g) and yohimbine (20 μ g) groups exhibited less movement and the muscle strength of hindlimbs decreased at least for 1 h followed by a full recovery. The TFL in prazosin 20 μ g and yohimbine 20 μ g groups was significantly shortened, compared with its own baseline and NS group ($P<0.05$, Table 3). Therefore, prazosin (5 and 10 μ g) and yohimbine (5 and 10 μ g) were used in the subsequent antinociceptive studies of propofol.

with NS, Me₂SO, prazosin, or yohimbine at different doses 10 min before sc propofol. No significant differences existed in the TFL between NS group and Me₂SO group. Pretreatment with ith prazosin (5, 10 µg) and yohimbine (5, 10 µg) significantly decreased the TFL 10-30 min after propofol injection with the doses of prazosin and yohimbine increasing (*P*<0.05 vs NS, Table 5).

Effects of pretreatment with 6-OHDA on TFL in conscious mice and propofol (50 mg/kg, sc)-treated mice in tail-immersion test Mice in the 6-OHDA (20 µg) alone group exhibited biting and scratching behavior and the TFL significantly decreased in comparison with its own baseline and the NS group (*P*<0.05, Table 4). No change in behavior and TFL was observed after treatment with ith NS, vehicle or 6-OHDA (5, 10 µg) in conscious mice. However, pretreatment with ith 6-OHDA (5, 10 µg) significantly decreased the TFL 10–30 min after propofol treatment with the dose of 6-OHDA increasing (*P*<0.05 vs NS, Figure 1).

Discussion

In attempting to elucidate the mechanisms for the antinociceptive effect of propofol, it is important to obviate sedation that can exert on the antinociceptive assay. In the present study, we found that the hypnotic and antinociceptive effects of propofol were temporarily uncoupled. In addition, the anesthetic on awareness was clearly supraspinal. Ith 6-OHDA, prazosin, or yohimbine significantly inhibited the antinociception of propofol but not consciousness of animals. Furthermore, we used the heat tail-flick assay, which measures the latency of a spinal withdraw reflex to noxious heat, which is independent of hypnotic-induced decrement in purposeful movement. These results indicated that propofol-induced prolongation of TFL observed in the present study was a result of antinociception but not sedation.

Propofol (50 mg/kg, sc) produced a motor block 2–5 min after injection, but there was no significant increase in TFL. Furthermore, Kerz T *et al* have suggested that immobility

during propofol anesthesia was not caused by a depression of spinal motoneuron circuit excitability^[13]. In addition, pretreatment with ith 6-OHDA, prazosin, or yohimbine inhibited the antinociception of propofol but not propofol-induced motor impairment. Therefore, it is not probable that motor nerve conduction block affects TFL nonspecifically.

In the present study, propofol (25 and 50 mg/kg, sc) caused no noticeable sedation 30 min after its injection, but dose-dependently decreased the writhing times in the acetic-acid writhing test on mice. Therefore, these results suggested that systemic propofol also inhibited the chemical stimulation. The same results were shown in a previous study^[2]. However, propofol had no effect on the writhing latency, which suggested that the antinociceptive effect of propofol at subanesthesia doses on inflammatory pain might be not very strong.

In the present study, systemic propofol (25 and 50 mg/kg, sc) and propofol (10 and 20 μ g, ith) displayed a dose- and time-dependent antinociceptive effect. However, icv propofol did not produce any antinociceptive effects. Taken together, these results suggest that propofol produced antinociception at the spinal level but not at the supraspinal sites.

Ith 6-OHDA (20 μ g) treatment for 3 d, which markedly depleted NE contents by more than 90% but not serotonin in the spinal cord study^[12], significantly shortened the basal TFL in conscious mice in our study. Additionally, α_1 R antagonist prazosin (20 μ g, ith) or α_2 R antagonist yohimbine (20 μ g, ith) alone significantly shortened the basal TFL. These results supported the previous finding that noradrenergic synaptic transmission was important in pain sensory processing in the spinal dorsal horn. The effect of ith high dose of yohimbine on tail response was consistent with the conclusion that NE mediated the inhibition of nociception by α_2 R_s in the spinal cord. The reduction of TFL after ith higher dose of prazosin suggested that spinal α_1 R_s also contributed to the pain sensory modulation, which agrees with the purpose that NE mediated the inhibition of nociception by activation of α_1 R_s located on inhibitory interneurons^[8,9]. This possibility is supported by several studies which demonstrated that ith α_1 R agonist activated dorsal horn to produce antinociception. For example ith selective α_1 R agonists, such as methoxamine^[14,15] and phenylephrine^[16] produced antinociception that could be reduced by pretreatment with ith α_1 R antagonist prazosin^[14,15].

Pretreatment with ith 6-OHDA (5 and 10 μ g), which markedly depleted NE contents in the spinal cord, significantly attenuated the antinociception of propofol. Furthermore, pretreatment with ith α_1 R antagonist prazosin or α_2 R antagonist yohimbine significantly inhibited the

antinociception of sc propofol in tail-immersion test. Therefore, these results strongly indicated that spinal noradrenergic system had a significant modulatory role in propofol antinociception. However, with 6-OHDA, prazosin and yohimbine did not completely reverse the antinociception of propofol. This suggested that other mechanisms, such as an excitation of spinal GABA_A receptors^[1] and an inhibition of spinal NMDA, AMPA receptors^[2], contributed to antinociception of propofol. In the present study, we used only α_1 R and α_2 R antagonists; therefore it was unclear whether propofol could bind directly with α_1 Rs or α_2 Rs in the spinal cord.

Taken together, our data suggest that systemic propofol activates the central noradrenergic system to produce antinociception, which increases the spinal release of NE and results in an antinociceptive effect via α_1 Rs and α_2 Rs in the spinal cord. To further prove this speculation, a direct measurement of the spinal release of NE induced by propofol will be necessary in the near future.

Abstract

Aim: To investigate the effects of complete Freund's adjuvant (CFA) on inflammatory hyperalgesia and morphological change of the coexistence of interleukin-1 beta (IL-1 β) and type I IL-1 receptor (IL-1RI) in neurons and glia cells of rat dorsal root ganglion (DRG). **Methods:** The pain-related parameters and the expression of IL-1RI and IL-1 β positive neurons and glia cells of DRG in normal saline (NS) and adjuvant-induced arthritic (AA) group were examined with pain behavior assessment methods and immunohistochemical assay, respectively. **Results:** Five hours, 1 d, and 2 d after intra-articular injection of 50 μ L CFA, tactile hyperalgesia induced by CFA was observed in the foot flexion and extension scores of the ipsilateral hindpaw of AA group. Three days after injection, the distribution of IL-1RI/IL-1 β double-stained coexisted neurons and glia cells were observed in ipsilateral DRG of both groups. The number of IL-1 β positive neurons, IL-1RI positive neurons, IL-1 β /IL-1RI double-stained neurons, and IL-1RI positive glia cells in ipsilateral DRG of the AA group were higher than that of NS group ($P < 0.05$ or $P < 0.01$). **Conclusion:** The coexistence of IL-1 β and IL-1RI in neurons and nonneuronal cells suggests an as yet unknown autocrine and/or paracrine function of IL-1 β in the DRG. The function was enhanced in articular arthritis induced by CFA and could play an important role in hyperalgesia under inflammatory conditions.

Introduction

Interleukin-1 beta (IL-1 β) is a bioactive polypeptide cytokine that is produced by a large variety of cells, including macrophages, fibroblasts, keratinocytes, synovocytes, mast cells, glial cells, and neurons; and has various immune roles responding to antigens, malignant cells, inflammatory stimuli, and tissue injury^[1]. IL-1 β also has proinflammatory cytokine activity and induces hyperalgesia after subcutaneous injection into the rat paw^[2] or after intrathecal administration in rats and mice^[3,4]. This means administration of exogenous IL-1 β can produce hyperalgesia. However, inflammation can also induce the release of endogenous IL-1 β which was responsible for hyperalgesia as well. A previous study showed that intraplantar injection of complete

Freund's adjuvant (CFA) in adult rats resulted in a significant elevation in IL-1 β and nerve growth factor (NGF) levels in the inflamed tissue^[5-6]. IL-1 β exerts its effects through high-affinity receptors on target cells, of which two types have been identified: IL-1RI and IL-1RII^[7]. IL-1 receptor antagonist (IL-1Ra), has been shown conclusively to block the effects of IL-1 β ^[8]. Targeted deletion of the IL-1 receptor type I or the IL-1 receptor accessory protein, and transgenic over-expression of IL-1R α within the brain and spinal cord significantly lowered thermal and mechanical pain sensitivity in mice^[9].

The major cellular source of IL-1 β production in the central nervous system are from glial cells, predominantly microglia. However, several studies have provided evidence for the neuronal expression of IL-1 β in the peripheral ner-

vous system: sensory neurons in the dorsal root ganglia (DRG) as well as sympathetic neurons^[10]. Moreover, cytokines released in the periphery by sensory and by sympathetic neurons have an established role in regulating immune cell activation, connective tissue and vascular responses, and nociception in peripheral inflammatory processes. Among the cytokines produced and released by both sensory and sympathetic neurons are transforming growth factor- β (TGF- β), tumor necrosis factor- α (TNF- α), and interferon-gamma (IFN- γ)^[11,12]. Sympathetic neurons have also been demonstrated to express IL-1 β ^[13,14]. IL-1 β appears to be an important mediator in nociception and has been shown to induce the release of substance P from nociceptive sensory neurons^[15]. The expression of IL-1 β as well as the type I IL-1 receptor in sensory neurons in rat DRG has been investigated using nonradioactive *in situ* hybridization and immunohistochemistry^[16]. However, there is no morphological evidence for the coexistence of IL-1 β and IL-1RI of neurons and glia cells in DRG and the effects of articular injection of CFA.

In the present study, we investigated the effects of CFA on inflammatory hyperalgesia and the morphological changes of IL-1 β and IL-1RI coexistence in neurons and glia cells of rat DRG.

Materials and methods

Animals Experiments were carried out on male adult Sprague-Dawley rats (180–200 g), purchased from the Experimental Animals Center of Tongji Medical College of Huazhong University of Science and Technology (Grade II, Certificate No 19-053). The rats were housed individually in cages with a 12-h light/dark cycle, and had free access to food and water for a week before experiments began. They were randomly divided into two groups: (1) normal saline (NS) group ($n=7$), the rats were pretreated with an intra-articular injection of 50 μ L normal saline into the left (ipsilateral) tibio-tarsal joint under light anesthesia with 10% chlorhydrate (300 mg/kg, ip) injection; (2) adjuvant-induced arthritic (AA) group ($n=7$), the rats were pretreated with an intra-articular injection of 50 μ L complete Freund's adjuvant (CFA, Sigma) into the left tibio-tarsal joint under the same light anesthesia^[17,18].

Preclinical tests The following parameters were measured: (1) weight; (2) mobility score^[19] (0=the rat only lies down; 1=the rat only crawls; 2=the rat walks with difficulty; 3=the rat walks and runs with difficulty; 4=the rat walks and runs normally); (3) diameter of the tibiotarsal joint, detected with vernier caliper.

Pain behavioral parameters The following pain parameters were measured using two tests in the following sequence^[20]: (1) flexion scores: mean scores of rats was evaluated by flexion of one hind paw. Under these conditions a squeak or leg-withdrawal could be elicited. Five such stimuli were repeated at 5-s intervals, and a rating of 1 or 0 was respectively given depending on whether the animal emitted a squeak or leg-withdrawal. Thus for each animal the total scores of squeak and leg-withdrawal ranged from 0 to 10; (2) extension scores: mean scores of rats as evaluated by extension of one hind paw (identical rating used as for flexion score).

Each group animals were tested before injection to obtain baseline value and continued to be detected in 5 h, 1 d, and 2 d post-injection.

Tissue preparation On d 3 post-injection, all animals were deeply anesthetized with 20% urethane (1 g/kg) by abdominal injection, cleared with 200 mL of saline solution and perfused with 300 mL of 4% phosphate-buffered paraformaldehyde (pH 7.4) through left ventricle. After perfusion, the L4-L5 ipsilateral DRG was removed and post-fixed for 8–10 h. They were then soaked in 20% sucrose phosphate-buffered solution at 4 °C overnight prior to freezing and subsequent cryosectioning. Sections (10 μ m) were cut on a cryostat.

The sections were put in 0.01 mol/L PBS buffered solution. Sections were selected randomly to do experiments with double immunofluorescence staining of IL-1RI/IL-1 β , or IL-1RI immunohistochemistry single staining procedure.

Double immunofluorescence staining procedure We used the following steps: (1) sections were incubated with 0.25% Triton X-100 for 30 min at 37 °C; (2) after being rinsed by 0.01 mol/L PBS, sections were incubated with 15% normal goat serum for 30 min at 37 °C; (3) sections were then incubated for 48 h at 4 °C in a mixture of the two primary antibodies (rabbit anti-rat IL-1RI, 1:100, Santa Cruz; mouse anti-rat IL-1 β , 1:100, Serotec); (4) after being rinsed in PBS, sections were incubated for 3 h at room temperature in a mixture of the two secondary antibodies, Cy3-conjugated anti-rabbit IgG (Sigma, 1:200) and FITC-conjugated anti-mouse IgG (Sigma, 1:200); (5) the sections were picked and mounted on slides with glycerin-PBS buffered solution (1:9).

Omission of the primary antibody and incubation in IL-1 β or IL-1RI pre-absorbed antibody served as negative controls. Laser scanning confocal microscope (Lesia, German) was used to take photos and fluorescent microscope (Olympus, Japan) was used to capture images and count positive cells.

IL-1RI immunohistochemistry procedure We used fol-

lowing steps: steps (1) and (2) were the same as above double immunofluorescence stain procedure; (3) sections were then incubated for 48 h at 4 °C in the primary antibodies (rabbit anti-rat IL-1RI, Santa Cruz, 1:200). (4) after being rinsed in PBS, sections were incubated for 30 min at room temperature of the secondary antibodies, biotinylated goat anti-rabbit IgG (Santa Cruz, 1:200); (5) after being thoroughly washed in PBS, the sections were incubated in a streptavidine-peroxidase conjugate (Santa Cruz, 1:200) for 30 min at room temperature; (6) after being rinsed with 0.05 mol/L Tris-buffered saline, the immunoreaction product was revealed by a freshly prepared solution containing 0.04% 3,3-diamino-benzidine and 0.01% H₂O₂. The sections were picked up and mounted on slides with glutin. They were dehydrated with graded alcohol and transparentized with xylene, then covered with neutral gum. Each experiment had set up blank antitheses as described before.

Statistic analysis Seven rats per group were used for analysis. Digital images were captured in four sections per animal and 10 squares (38.4 mm² each) per section of immunofluorescence or immunohistochemistry respectively, using an Olympus microscope (objective×20; eyepiece×10) and a 3CC immunohistochemistry-D color video camera (Sony). The number of immunofluorescence-stained IL-1RI/IL-1β positive neurons or immunohistochemistry-stained IL-1RI positive glia cells in each image were counted by a blinded experimenter with a computer-assisted image analyzer (Image Pro-plus Kodak, USA). The number of positive DRG large-, medium-, and small-sized neurons were calculated. As reported previously, the primary sensory neurons in the DRG have been classified into large type A neurons (diameter over 30 μm), medium diameter neurons type B, and small type C neurons (diameter under 20 μm)^[21]. For large neurons were regarded as medium sized ones when they were not cut through their nucleus. In our study we calculated the total of medium and large neurons of immunofluorescence-stained IL-1RI/IL-1β positive neurons. The SPSS software (SPSS 11.0) was used for data analysis. The data was expressed as mean±SD, and analysis of variance (ANOVA) was used to compare the difference among different groups.

Results

Preclinical and behavioral studies After 5 h, 1 d, and 2 d of intra-articular injection of 50 μL CFA, the weight of the rats was unchanged ($P>0.05$, data not shown). The rats of the AA group developed inflammation which was confined to the inoculated articular characterized by edema of ipsilateral tibiotarsal joint (Table 1). There was a dramatic decrease observed in the mobility scores of rats of the AA group

Table 1. Diameter of the ipsilateral tibiotarsal joint of rats in NS group and AA group. $n=7$. Mean±SD. ^b $P<0.05$, ^c $P<0.01$ vs NS group.

Group	Diameter of the ipsilateral tibiotarsal joint/mm			
	Before injection	5 h after injection	1 d after injection	2 d after injection
NS	4.32±0.02	5.33±0.11	5.46±0.40	4.86±0.08
AA	4.52±0.07	6.34±0.15 ^c	6.37±0.24 ^b	5.86±0.40 ^b

compared with the NS group ($P<0.05$, $P<0.01$, Table 2). In other words, the inoculated rats are impaired in their ambulatory activities.

Table 2. Mobility score of rats in NS group and AA group. $n=7$. Mean±SD. ^b $P<0.05$, ^c $P<0.01$ vs NS group.

Group	Mobility score of rats in NS group and AA			
	Before injection	5 h after injection	1 d after injection	2 d after injection
NS	4	3.71±0.18	3.43±0.20	3.71±0.18
AA	4	2.57±0.20 ^c	2.71±0.29 ^b	2.86±0.14 ^c

Effects of CFA on the pain behavioral parameters of rats

Five hours, 1d, and 2 d after intra-articular injection of 50 μL CFA, tactile hyperalgesia induced by CFA was observed in the foot flexion and extension scores of ipsilateral hindpaw of AA group (Table 3, 4), while the pain scores of the contralateral hindpaw of both groups were close to 0 and had no significant difference ($P>0.05$, data not shown).

Table 3. Ipsilateral flexion score of rats in NS group and AA group. $n=7$. Mean±SD. ^b $P<0.05$, ^c $P<0.01$ vs NS group.

Group	Ipsilateral flexion score			
	Before injection	5 h after injection	1 d after injection	2 d after injection
NS	0	3.86±1.50	3.43±1.70	2.86±1.10
AA	0.43±0.30	7.43±1.34 ^b	7.71±1.41 ^b	7.57±1.32 ^c

Effects of CFA on double immunofluorescence staining of IL-1β and IL-1RI of ipsilateral DRG

Three days after

Table 4. Ipsilateral extension score of rats in NS group and AA group. *n*=7. Mean±SD. ^b*P*<0.05, ^c*P*<0.01 vs NS group.

Group	Ipsilateral extension score			
	Before injection	5 h after injection	1 d after injection	2 d after injection
NS	0.29±0.18	1.14±0.26	2.57±0.75	2.29±0.97
AA	0.29±0.18	7.57±1.23 ^c	6.14±1.55 ^b	5.86±0.91 ^b

injection, IL-1β and IL-1RI positive products were detected in the same neurons as well as in some glial-like cell types. IL-1β/IL-1RI immunoreactivity positive products were mainly located in the cytoplasm and nucleus of the positive neurons of NS group (Figure 1), while immunoreactivity positive products were distributed in the membrane and nucleus of the positive neurons of the AA group (Figure 2). There were still a few neurons presented no IL-1β or IL-1RI immunoreactivity in the DRG of the NS group, but most neurons in the DRG of AA group presented IL-1β or IL-1RI immunoreactivity (Figure 1C, 2C).

With statistic analysis, it was found that the number of IL-1RI single stained neurons, IL-1β/IL-1RI double-stained

neurons, and the percentages of the number of double-stained neurons to the number of IL-1β positive neurons of small neurons in DRG of AA group were higher than that of NS group (*P*<0.05 or *P*<0.01, Table 5). The number of IL-1RI single stained neurons, IL-1β/IL-1RI double-stained neurons of large and medium neurons in DRG of AA group were higher than that of NS group (*P*<0.05, Table 6). The percentage of double-stained neurons to IL-1β or IL-1RI positive neurons of large and medium neurons in DRG presented no significant difference between the two groups (*P*>0.05, Table 6).

Effects of CFA on single immunohistochemistry staining of IL-1RI of ipsilateral DRG Three days after injection, the IL-1RI in DRG was expressed in glial-like cell types as well as in sensory neurons using a microscope under normal light. Some of the glial-like cells were satellite cells ensheathing the large sensory cell bodies, some sparsely distributed in the connective tissues between neurons of DRG. The IL-1RI immunoreactivity positive products were stained as brown and mainly located in the membrane and cytoplasm of glia cells. The stained color of glia cells in DRG of AA group was deeper than that of the NS group (Figure 3, 4). The number of glia cells of DRG of AA group was 13.45±2.35/38.4 mm², which was higher than that of NS group (5.31±1.58/38.4mm²) (*P*<0.01).

Table 5. The percentage of IL-1β/IL-1RI double-stained small neurons to IL-1β or IL-1RI single-stained small neurons of DRG. *n*=7. Mean±SD. ^b*P*<0.05, ^c*P*<0.01 vs NS group.

Discussion

IL-1 β is one of the cytokines synthesized and released from immunocytes and considered to be an important mediator during inflammation and hyperalgesia. Indeed, the injection of IL-1 β into animals has been shown to produce hyperalgesia in response to mechanical and thermal stimuli^[2-4,22]. There are several lines of evidence indicating that IL-1 β al-

ters primary afferent neural activity or sensitivity in mice and rats^[10,23-25]. Nociceptive primary afferent neurons contain neuropeptides such as SP, neurokinin A, and calcitonin gene-related peptide that are released on stimulation of these afferent fibers. A previous study of cellular culture experiment demonstrated that IL-1 β can induce SP to release from cultured DRG by activating the COX-2 system. IL-1R antago-

nist can block this access, which suggests an IL-1 β exerted effect by combine with IL-1R on DRG^[15]. Using RT-PCR with *in situ* hybridization, it was found that type I IL-1R, not type II, expressed on the DRG of normal rats^[26]. However, there is no study on the coexistence of IL-1RI and IL-1 β in neurons and glia cells of DRG and the influence of adjuvant-induced arthritic on it.

In the present study, we demonstrated that both IL-1RI and IL-1 β coexisted in the sensory neurons and glia cells of normal saline injected rats. The combined expression of IL-1 β and the type I IL-1 receptor suggests autocrine or paracrine IL-1 β signaling in sensory neurons.

Meanwhile a significant increase in the IL-1RI and IL-1 β double stained neurons in ipsilateral DRG were observed in the AA group than in the NS group, and IL-1RI mainly distributed in the membrane of the AA group than in the cytoplasm of NS group. This morphological change also paralleled to the pain behaviour scores. It indicated that the inflammation resulted in the up-regulation of the expression of IL-1RI on the membrane of neurons in ipsilateral DRG, and the increase of IL-1 β sythesis as well.

It has been found that intraplantar injection of CFA increased the concentration of IL-1 β and NGF accompanied by elevation of the level of substance P and calcitonin gene-related peptide (CGRP) in the L4 dorsal root ganglion 48 h post CFA injection^[5]. The author demonstrated that IL-1 β could alter neuropeptide expression in primary sensory neurons secondary to an increase of NGF levels as NGF has well known actions on the regulation of both SP and CGRP in adult rat DRG neurons^[6]. It has been recently proved that IL-1 β increases SP synthesis by enhancing the expression of preprotachykinin mRNA encoding for SP and other tachykinins in the DRG^[27]. Our results showed that IL-1 β could be synthesized in neurons of DRG, as wells as in the inflamed tissue from previous study, it indicated that more IL-1 β was able to release by neurons of DRG and excite more IL-1RI, which presumably brought about more SP synthesis and release in the central and peripheral terminals of neurons in the DRG, which in turn led to hyperalgesia.

We also found that the number of glia cells in ipsilateral DRG, which express IL-1RI, increased after CFA injection. The expression of type I IL-1 receptor in non-neuronal cells in the DRG might mediate another possible function of IL-1 β synthesized by the sensory neurons. It has been reported that IL-1 β enhances neurite outgrowth in DRG^[28], which would contribute to tactile hypersensitivity of articular arthritis. This effect of IL-1 β seems to be indirect and presumably involves an IL-1 β -induced increased in release of neurotrophins from nonneuronal cells^[29]. It could be that,

under inflammatory condition sensory neurons regulate their own maintenance by releasing more IL-1 β and thus stimulating their environment to release neurotrophins to induce hyperalgesia.

Our study showed that IL-1 β /IL-1RI doubled stained immunoreactivity positive products were located in the nucleus as well as the cytoplasm or membrane of positive neurons in ipsilateral DRG of both groups. This is consistent with the results of immunoelectron microscopy, which found that GSSP-intensified IL-1 β immunoreaction products were found dispersed in small aggregates throughout the cytoplasm and a few small immuno-aggregates of IL-1 β were also found in the nucleus of neurons in DRG. The functional significance of intranuclear IL-1 β /IL-1RI is as yet unclear, but might suggest involvement in transcriptional regulation^[16].

In conclusion, we found coexistence of IL-1 β and IL-1RI in sensory neurons and glia cells of DRG. The presence of the type I IL-1 receptor in neurons and non-neuronal cells suggests an as yet unknown autocrine and/or paracrine function of IL-1 β in the DRG. The function was enhanced in the articular arthritis induced by CFA and might play an important role in hyperalgesia under the inflammatory condition.

Abstract

Aim: In our previous observations, adenosine triphosphate (ATP) was found to evoke immediate elevations in intracellular free calcium concentration ($[Ca^{2+}]_i$) in HT4 neuroblastoma cells of mice. We tried to see if a brief pretreatment of glucocorticoids could inhibit the Ca^{2+} response and reveal the underlying signaling mechanism. **Methods:** Measurement of $[Ca^{2+}]_i$ was carried out using the dual-wavelength fluorescence method with Fura-2 as the indicator. **Results:** Preincubation of HT4 cells for 5 min with corticosterone (B) or bovine serum albumin conjugated corticosterone (B-BSA) inhibited the peak $[Ca^{2+}]_i$ increments in a concentration-dependent manner. Cortisol and dexamethasone had a similar action, while deoxycorticosterone and cholesterol were ineffective. Both extracellular Ca^{2+} influx and internal Ca^{2+} release contributed to ATP-induced $[Ca^{2+}]_i$ elevation. The brief treatment with only B attenuated Ca^{2+} influx. Furthermore, the $[Ca^{2+}]_i$ elevation induced by the P2X receptor agonist adenosine 5'-(β,γ -methylene) triphosphate (β,γ -meATP) was also suppressed. The rapid inhibitory effect of B can be reproduced by forskolin 1 mmol/L and blocked by H89 20 mmol/L. Neither nuclear glucocorticoid receptor antagonist mifepristone nor protein kinase C inhibitors influenced the rapid action of B. **Conclusion:** Our results suggest that glucocorticoids modulate P2X receptor-mediated Ca^{2+} influx through a membrane-initiated, non-genomic and PKA-dependent pathway in HT4 cells.

Introduction

Glucocorticoids (GC) play an important role in the developmental organization and ongoing activities of the nervous system^[1]. At cellular level, they work in a diverse manner. A genomic mechanism where the complex of GC and their receptors acts as nuclear transcription factor has been well elucidated over the past 30 years, and accounts for the long-latency effects of most GC. However, some of their actions take place so rapidly (onset in seconds or minutes) that they do not fit into the paradigm of the genomic mechanism^[2,3]. There are many examples in which GC act through the rapid, non-genomic way in the nervous system, ranging from the regulation of neuronal excitability to the modulation of neurotransmitter secretion and uptake^[1,2].

The HT4 neuroblastoma cell line was derived from the

hippocampal neurons of mice^[4]. In our previous observations, we found an ATP-induced transient in $[Ca^{2+}]_i$ within the cells^[5]. The Ca^{2+} response was decreased by the activation of protein kinase A (PKA) or protein kinase C (PKC) (unpublished data). As it is already known that some of the rapid actions of GC are mediated by protein kinases^[6,7], we wonder whether there is a similar signaling pathway for GC in HT4 cells, which may result in fast modification of the ATP-induced Ca^{2+} response. We provide evidence showing that ATP-induced Ca^{2+} response can be rapidly modified by GC through a membrane-initiated, nongenomic pathway that is PKA dependent.

Materials and methods

Materials ATP, β,γ -meATP, bovine serum albumin con-

jugated corticosterone (B-BSA), cholesterol, corticosterone (B), cortisol, deoxycorticosterone, dexamethasone, egtazic acid, *N*-[2-hydroxyethyl] piperazine-*N'*-[2-ethanesulfonic acid] (HEPES), ionomycin, pluronic F-127, phorbol 12-myristate 13-acetate (PMA), and thapsigargin (TG) were obtained from Sigma (St Louis, MO, USA). Forskolin, H-89, GF-109203X, and Ro31-8220 were obtained from Calbiochem-Novabiochem (San Diego, CA). DMEM and *L*-glutamine used for cell culture from Life Technologies (Gaithersburg, MD, Germany). Trypsin from Amresco Inc (Solon, OH, USA). Fura-2 acetoxyethyl (AM) ester from Molecular Probes (Eugene, OR, USA). Newborn calf serum was from Sijiqing Co (Hangzhou, China). All other chemicals used were of analytical grade.

Cell culture HT4 cells, a kind gift from Dr B AMES (University of California at Berkeley), were maintained in DMEM containing 10% newborn calf serum and 4 mmol/L *L*-glutamine in a humidified atmosphere of 95% air and 5% CO₂ at 37 °C. No antibiotic was added to the media. For [Ca²⁺]_i measurements, cells were seeded on glass coverslips and used within 3–4 d.

Fura-2 loading In the present study, fluorescent dye Fura-2 was used to indicate the [Ca²⁺]_i. The cells on the coverslips were loaded *in situ* at 37 °C for 30–60 min in HEPES-buffered saline (in mmol/L: NaCl 140, KCl 5, MgCl₂ 1, CaCl₂ 2.5, glucose 11.5, HEPES 10, pH 7.2–7.4) containing Fura-2 AM 2 μmol/L and 0.04% pluronic F-127. The Fura-2-loaded cells were then rinsed three times with saline and mounted in a perfusion chamber for immediate [Ca²⁺]_i measurements. Alternatively, they were kept in dark conditions at room temperature for up to 2 h. Fura-2 loading was uniform over the cytoplasm, and compartmentalization of the dye was seldom observed.

[Ca²⁺]_i measurements Measurement of [Ca²⁺]_i was carried out by the dual-wavelength fluorescence method as described previously^[8] with some modifications. Fura-2-loaded cells were mounted in a perfusion chamber and placed under an inverted microscope (IX70, Olympus). Light emitted from a 75-W xenon arc lamp (AH2-RX, Olympus) passed through an excitation filter set (Chroma) to generate ultraviolet monochromatic waves of 340 and 380 nm. With the aid of a computerized filter wheel (Lambda 10-2, Sutter Instruments), the cells in the chamber were alternately exposed to the two waves through an Olympus objective (UAp0/340, 40×/0.90). The resulting fluorescent emission from the Ca²⁺-sensitive dye was collected through a 510 nm-long pass filter (Chroma) with a cooled charge-coupled device camera (MicroMax 5 MHz system, Princeton Instruments). All image acquisition was computer-controlled by

MetaFluor Imaging program (v.4.01, Universal Imaging Corporation). Images were acquired at 3-s intervals to reduce photobleaching. All measurements were made at 22–25 °C.

Images acquired were corrected for background fluorescence and shading across the field of view. Conversion of the ratio to [Ca²⁺]_i was carried out using the equation: [Ca²⁺]_i = $K_d \times [(R - R_{\min}) / (R_{\max} - R)] \times (F_{\min}^{380} / F_{\max}^{380})^{[8]}$, where R_{\max} and R_{\min} are the maximum and minimum ratio obtained by the addition of ionomycin (10 μmol/L) and egtazic acid (10 mmol/L) respectively, $F_{\min}^{380} / F_{\max}^{380}$ is the ratio of Ca²⁺-free and Ca²⁺-saturated fluorescence signals at the excitation wavelength of 380 nm, and K_d is the dissociation constant of the Fura-2/Ca²⁺ complex (224 nmol/L). R is the acquired ratio value at each time point.

Perfusion chamber and drug applications The custom-built chamber, with a coverglass at the bottom, was continuously perfused with HEPES-buffered saline during measurements. The perfusion rate was set at 2 mL/min to aid drug removal. All drugs were diluted in saline from their stock solutions immediately before the experiments and applied directly to the cells using a computer/manual operated 7-barrel local superfusion system for desired lengths of time. The tip (100 μm inside diameter) of the outlet was placed approximately 200 μm away from the cells, and the gravity force was adjusted to achieve rapid drug application while avoiding any mechanical disturbance of the cells. The time delay for arrival of drugs at the cells was less than 100 ms (data not shown).

Data analysis [Ca²⁺]_i values were expressed as means ± SD. Statistical analysis was performed using *t*-test or analysis of variance (ANOVA) depending on data types. $P < 0.05$ was considered to be significant.

Results

Inhibition of ATP-induced [Ca²⁺]_i increase by GCs In HT 4 cells, the basal level of [Ca²⁺]_i was 54 ± 8 nmol/L^[5]. ATP 100 μmol/L induced an immediate rise in [Ca²⁺]_i, which was significantly attenuated by pre-incubation with B (1 μmol/L) for 5 min (Figure 1A). The original Ca²⁺ response recovered 5–10 min after B was washed out (data not shown). The inhibitory effect was concentration-dependent (0.1–100 μmol/L). B-BSA was also effective in suppressing the Ca²⁺ response with a similar potency compared to B (Figure 1B), while BSA had no effect on either basal or stimulated [Ca²⁺]_i levels (data not shown). To further elucidate the rapid action of B, we studied the effect of mifepristone (a GR antagonist) on the response. Pretreatment with mifepristone (1 μmol/L) for 30 min did not influence the inhibitory effect

Figure 1. Inhibition of ATP-induced $[\text{Ca}^{2+}]_i$ increase by GCs in HT4 cells. (A) the $[\text{Ca}^{2+}]_i$ increase elicited by 100 $\mu\text{mol/L}$ ATP in HEPES-buffered saline was measured after a 5-min pre-incubation with or without 1 $\mu\text{mol/L}$ B. Traces from representative cells are shown and superimposed for ease of comparison (continuous trace: ATP only, dotted trace: B pretreated). The horizontal bar represents drug application. (B) Dose-response relationships of the B and B-BSA induced inhibition. (C) $[\text{Ca}^{2+}]_i$ increases elicited by 100 $\mu\text{mol/L}$ ATP were measured after a 5-min pre-incubation with cortisol (F), dexamethasone (Dex), deoxycorticosterone (Doc), and cholesterol (Cho), respectively. All steroids were at 1 $\mu\text{mol/L}$ in concentration. $n=3$ determinations. Mean \pm SD. ^b $P<0.05$ vs control (100 $\mu\text{mol/L}$ ATP only).

of B (1 $\mu\text{mol/L}$) (data not shown). Thus, the findings above imply that the action of B in HT4 cells is initiated at the plasma membrane and may not involve the nuclear receptors.

Other GCs or analogs, such as cortisol and dexamethasone, were also tested and shown to be effective using the same experimental protocol. However, deoxycorticosterone and cholesterol were not effective (Figure 1C).

P2X receptor-mediated Ca^{2+} influx was affected by B

In the absence of extracellular Ca^{2+} , ATP (100 $\mu\text{mol/L}$) was also capable of elevating $[\text{Ca}^{2+}]_i$ but with smaller amplitude. The $[\text{Ca}^{2+}]_i$ level dropped gradually to baseline even if ATP was not withdrawn. The subsequent introduction from the local superfusion system of 2.5 mmol/L Ca^{2+} -containing ATP solution to the same cells gave rise to a secondary calcium elevation (Figure 2A). These results suggest the generation of both Ca^{2+} influx across plasma membrane and Ca^{2+} release from intracellular stores upon ATP treatment. Using this experimental protocol, we investigated which component of the Ca^{2+} response was affected by the brief treatment of B. As shown in Figure 2A, the Ca^{2+} release evoked by ATP was not affected while the $[\text{Ca}^{2+}]_i$ increment during Ca^{2+} influx was significantly smaller after the pre-incubation of B (1 $\mu\text{mol/L}$). β, γ -meATP is a specific agonist for P2X receptors that has little effect on P2Y receptors^[9]. The $[\text{Ca}^{2+}]_i$ increase induced by β, γ -meATP 10 $\mu\text{mol/L}$ in HT4 cells was also inhibited by the pre-incubation of B (1 $\mu\text{mol/L}$) (Figure 2B and 2C). Taken together, the above results suggest that Ca^{2+} influx through P2X receptors was affected by B.

Effect of B on Ca^{2+} influx through SOC

As shown earlier, ATP increases Ca^{2+} release from intracellular stores in HT4 cells. The depletion of the Ca^{2+} stores has been reported to trigger the opening of store-operated channels (SOC)^[10,11]. We therefore examined whether B might exert its inhibitory effect by reducing Ca^{2+} influx through SOC. Thapsigargin (TG), a specific inhibitor of endoplasmic reticulum Ca^{2+} -ATPase, is widely used to activate SOC by depleting Ca^{2+} stores. In HT4 cells, exposure of TG (1 $\mu\text{mol/L}$) caused an initial spike followed by a sustained elevation at lower level that was indicative of the activation of SOC. Our results showed that the TG-induced plateau was insensitive to treatment of B (1 $\mu\text{mol/L}$), while ATP-induced further increase in $[\text{Ca}^{2+}]_i$ at this stage was still attenuated by B (Figure 3).

Rapid action of B was PKA-dependent

Our previous observation found that ATP-induced $[\text{Ca}^{2+}]_i$ increase was negatively modulated by PKA or PKC in HT-4 cells^[5]. Therefore we examined whether PKA or PKC related signaling pathways were involved in the rapid action of B. Effects of forskolin (1 $\mu\text{mol/L}$), PMA (0.5 $\mu\text{mol/L}$) on the $[\text{Ca}^{2+}]_i$ increase were studied and compared with that of B (1 $\mu\text{mol/L}$). There was no significant difference in the degrees of inhibition among groups pretreated with forskolin or B, or both, while the effect of a combination of PMA and B was addi-

Figure 2. P2X receptor-mediated Ca²⁺ influx was affected by B. (A) using a Ca²⁺-free and Ca²⁺-reintroduction protocol, the ATP-evoked Ca²⁺-influx was found to be suppressed by 5-min pretreatment of B (1 μmol/L). n=3 determinations. Mean±SD. ^bP<0.05 vs control (10 μmol/L β,γ-meATP only). (B) β,γ-meATP (10 μmol/L) caused a rapid increase in [Ca²⁺]_i (continuous trace), which was inhibited by pretreatment of the cells for 5 min with 1 μmol/L B (dotted trace). The horizontal bar represents drug application. (C) n=3 determinations. Mean±SD. ^cP<0.05 vs AMP-PCP group.

tive (Figure 4). These results imply that the forskolin-activated pathway is involved in the signaling of B-induced inhibition. However, PMA and B exerted their modulatory effects through distinct pathways. PKA inhibitor H89 (20 μmol/L), when applied 20 min before B, completely abrogated the inhibitory effect of B (1 μmol/L), while PKC inhibitors Ro31-8220 (0.5 μmol/L) and GF-109203X (0.5 μmol/L) had little influence (Figure 4). None of the drugs changed the basal [Ca²⁺]_i level in HT4 cells (data not shown).

Figure 3. Effect of B on ATP-induced [Ca²⁺]_i increase after TG treatment. HT-4 cells were first exposed to TG (1 μmol/L) and subsequently stimulated with ATP (100 μmol/L) 25 min later. B (1 μmol/L) was applied 20 min after TG when the [Ca²⁺]_i levels reached a plateau. (A) a representative trace is presented to show the experimental protocol. (B) Δ[Ca²⁺]_i values recorded immediately before ATP application represents the plateau phase Ca²⁺ levels. n=3–4 determinations. Mean±SD. ^bP<0.05 vs control (100 μmol/L ATP after TG treatment).

Discussion

Pre-incubation with B inhibited the ATP-induced [Ca²⁺]_i increase in HT4 cells in a concentration-dependent manner. The minimum effective dose was 100 μmol/L, which falls below the peak-free B concentration (750 μmol/L) in serum during stress^[12]. The pre-incubation time for B adopted in most of our experiments was 5 min. However, a 3-min pretreatment was found to be enough for B to take effect (data not shown). The very short latency is consistent with the criteria to define a rapid effect of steroid hormones^[11]. Moreover, the rapid action was insensitive to treatment with nuclear receptor antagonist, further supporting the notion that this is a nongenomic effect of B.

Being large and predominantly hydrophilic molecules, steroid-BSA conjugates are thought to be membrane impermeable within 30 min^[13]. However, they are biologically active and can reproduce the actions of free steroids^[14]. In our study, B-BSA was found to be effective in inhibiting

Figure 4. Rapid action of B was PKA-dependent. (A) before ATP (100 $\mu\text{mol/L}$) stimulation, HT4 cells were pretreated with B (1 $\mu\text{mol/L}$) for 5 min or forskolin (FK, 1 $\mu\text{mol/L}$) for 10 min or in combination. In experiments using H89 (20 $\mu\text{mol/L}$), the drug was applied 20 min before the addition of B. (B) before ATP (100 $\mu\text{mol/L}$) stimulation, HT4 cells were pretreated with PMA (0.5 $\mu\text{mol/L}$) for 5 min alone or in combination with B. In experiments using Ro31-8220 (Ro, 0.5 $\mu\text{mol/L}$) or GF109203X (GF, 0.5 $\mu\text{mol/L}$), the drugs were applied 20 min before the addition of B. $n=3-4$ determinations. Mean \pm SD. ^b $P<0.05$ vs control (100 $\mu\text{mol/L}$ ATP only). ^d $P>0.05$, ^e $P<0.05$ vs B+ATP group.

ATP-induced $[\text{Ca}^{2+}]_i$ increase, suggesting its action at the plasma membrane, where a signal was generated and transduced into the cells. Until now, several specific membrane proteins have been reported as the receptors that mediate the rapid actions of GC^[15,16]. It is interesting to note that they are different not only in molecular weight, but also in genetic identity. Being a splice variant of the nuclear GR, one membrane receptor has been reported to have cross-antigenicity with its nuclear counterpart, while others do not^[17]. The identity of the membrane target in HT4 cells is not clear and needs to be elucidated.

The potency of B-BSA in this experimental model is almost the same as that of B. Previous work in our lab has revealed that both B and B-BSA activate PKC in PC12 cells, but the dose-dependence curve of the latter shifts rightward (ie, with lower potency)^[6]. The reason for the difference is also unclear.

ATP, being a normal metabolite, exists in all living cells.

In the nervous system, it is an important signaling molecule belonging to a class of fast excitatory transmitter in the brain^[18,19]. Its signaling is mediated through the metabotropic P2Y and ionotropic P2X receptors^[9]. In our experiment, the stable ATP analog $\beta,\gamma\text{-meATP}$ was shown to be a potent agonist in HT4 cells. This result strongly implies actions at P2X receptors. Modulation of P2X purinoceptor-mediated Ca^{2+} responses by protein kinases has been well investigated^[10,20-22]. In PC12 cells, for example, ATP-induced Ca^{2+} influx through P2X receptors is inhibited when PKC activity is enhanced^[10].

It has been reported that PKA is involved in the GC rapid, nongenomic actions in many cell models^[2]. It is interesting to note that the models are all pituitary-originated, such as rat pituitary cells in culture^[23], cichlid fish pituitary *in vitro*^[24], and mouse corticotroph tumor cell line AtT20^[25]. In contrast, studies on rat brain synaptosomes, rat hippocampal neurons, PC12 cells, and glial cell lines reveal an alternative PKC pathway^[2,26]. This prompted us to speculate that the protein kinases involved in GC rapid action could be predicted by cell type^[2]. However, the present data we found in HT4 cells, a mouse hippocampus-derived cell line, show that such generalization is premature and open to further consideration.

Acknowledgment

We are grateful to Dr Zhuan ZHOU (Institute of Neuroscience, Chinese Academy of Sciences) for providing us the local superfusion apparatus from which our experiments greatly benefited.

Abstract

Aim: To investigate the effects of onychin on the proliferation of cultured rat artery vascular smooth muscle cells (VSMCs) in the presence of 10% new-born calf serum (NCS). **Methods:** Rat VSMCs were incubated with onychin 1–50 μmol/L or genistein 10 μmol/L in the presence of 10% NCS for 24 h. The proliferation of VSMCs was measured by cell counting and MTS/PMS colorimetric assays. Cell cycle progression was evaluated by flow cytometry. Retinoblastoma (Rb) phosphorylation, and expression of cyclin D₁ and cyclin E were measured by Western blot assays. The tyrosine phosphorylation of ERK1/2 was examined by immunoprecipitation techniques using anti-phospho-tyrosine antibodies. **Results:** The proliferation of VSMCs was accelerated significantly in the presence of 10% NCS. Onychin reduced the metabolic rate of MTS and the cell number of VSMCs in the presence of 10% NCS in a dose-dependent manner. Flow cytometry analysis revealed that the G₁-phase fraction ratio in the onychin group was higher than that in the 10% NCS group (85.2% vs 70.0%, $P < 0.01$), while the S-phase fraction ratio in the onychin group was lower than that in 10% NCS group (4.3% vs 16.4%, $P < 0.01$). Western blot analysis showed that onychin inhibited Rb phosphorylation and reduced the expression of cyclin D₁ and cyclin E. The effects of onychin on proliferation, the cell cycle and the expression of cyclins in VSMCs were similar to those of genistein, an inhibitor of tyrosine kinase. Furthermore immunoprecipitation studies showed that both onychin and genistein markedly inhibited the tyrosine phosphorylation of ERK1/2 induced by 10% NCS. **Conclusion:** Onychin inhibits the proliferation of VSMCs through G₁ phase cell cycle arrest by decreasing the tyrosine phosphorylation of ERK1/2, and the expression of cyclin D₁ and cyclin E, and sequentially inhibiting Rb phosphorylation.

Introduction

Alterations in vascular smooth muscle cell (VSMC) proliferation plays an important role in the development of the pathological process that underlies restenosis, atherosclerosis, and vascular graft occlusion^[1]. Despite intense efforts, no widely effective therapy exists for the prevention of such vascular diseases. Recently some agents have been shown to have potential value by virtue of their abilities to attenuate the proliferation of VSMCs^[2–4]. Among them, genistein (4,5,7-trihydroxyisoflavone), a soybean-derived isoflavone, has been shown to inhibit platelet derived growth

factor (PDGF)-induced proliferation and DNA synthesis of aortic smooth muscle cells in stroke-prone spontaneously hypertensive rats^[5]. Moreover, epidemiological studies indicate that genistein has beneficial effects on cardiovascular disease^[6,7], such as lowering total and low density lipoprotein (LDL)-cholesterol levels. More recently, onychin, a new component extracted from *Onychin lucidum* of sinopteridaceae, has attracted our interest because its structure is similar to genistein^[8]. Interestingly, our previous results have shown that onychin protects the endothelium-dependent relaxation in rabbit aortic rings and inhibits oxidative stress-

induced apoptosis of endothelial cells, which is mediated by increasing NO release, regulating expression of caveolin-1 and activation of mitogen-activated protein kinases (MAPK)^[9-13]. In the present study, we extend our investigation to the effects of onychin on the proliferation of rat VSMCs induced by 10% NCS.

Materials and methods

Materials Male Sprague-Dawley rats were obtained from the Experimental Animal Center of Nanhua University (Hengyang, China). Genistein, elastase, and monoclonal antibodies for α -actins of smooth muscle cells were obtained from Sigma (St Louis, USA). Dulbecco's modified Eagle's medium (DMEM) and NCS were from GibcoBRL (Maryland, USA). The Cell Titer 96 Aqueous Non-Radioactive Cell Proliferation Assay Kit (MTS/PMS) was purchased from Promega (WI, USA). Monoclonal mouse anti-ERK1/2, -pTyr, -cyclin D₁, -cyclin E, and polyclonal mouse anti-Rb were from Santa Cruz Biotechnology (Santa Cruz, USA).

Cell culture The thoracic aortas were isolated from the 150–200 g male Sprague-Dawley rats and cultured by using a novel enzymatic dispersion method^[14]. Briefly, rat aortas were in sterile conditions removed from left subclavian origin to the point of diaphragmatic insertion. The vascular media was digested, and the cells were centrifuged and plated down in prepared flasks. VSMCs were cultivated in DMEM (containing 10% NCS) and in a 5% CO₂ humidified-atmosphere incubator until they displayed as a typical "hill and valley" morphology. The immunohistochemistry staining with a monoclonal antibody against α -actins showed that there were no co-cultured fibroblast cells. VSMCs from 5 to 15 passages were used for experimentation. Before mitogenic stimulation, subconfluent cells were arrested in a quiescent state with DMEM containing 0.1% NCS for 48 h.

Cell count VSMCs (2.5×10^4) were plated into a 24-well plate and grown in DMEM supplemented with 10% NCS for 24 h. In some experiments cells were growth-arrested by incubation in DMEM containing 0.1% NCS for 48 h and then exposed to different concentrations of onychin before treatment with 10% NCS for 24 h or 48 h. Genistein (10 μ mol/L) was used as the positive control. The cells were then washed with phosphate-buffered saline (PBS), trypsinized, and diluted with isotonic solution. Cells were stained with Trypan blue and the viable cells were counted using a coulter counter.

MTS assay Cell growth was measured by using MTS assay according to the manufacture's instructions. Briefly,

3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2*H*-tetrazolium (MTS) and phenazine methosulfate (PMS) were mixed at a ratio of 20:1 immediately before being added to the samples. The MTS/PMS solution (20 μ L) was added to each well of the 96-well plate and the plates were incubated at 37 °C in a humidified 5% CO₂ atmosphere for 90 min. Absorbance was read at 490 nm using Bio-Tek's Power Wave X reader-assay system (BIO-TEK Instruments, USA). Each sample was read in triplicate.

Flow cytometry Cells were suspended in phosphate-buffered saline (PBS, pH 7.4), and fixed with 70% (v/v) ethanol at -20 °C for 30 min. After the ethanol was removed, the cells were incubated with PBS containing RNase (172 MU/L) at 37 °C for 30 min and then stained for 30 min with 0.005% propidium iodide. Fluorescence was measured by using Epics Altra Flow Cytometer (Beckman Coulter Co, USA).

Western blot analysis After treatment, VSMCs were washed twice with cold (4 °C) PBS (pH 7.4) and harvested on ice in buffer A containing HEPES 20 mmol/L (pH 7.4), EDTA 2 mmol/L, glycerophosphate 50 mmol/L, dithiothreitol 1 mmol/L, Na₃VO₄ 1 mmol/L, 1% Triton, 10% glycerol, leupeptin 1 mg/L, aprotinin 1 mg/L, and phenylmethylsulfonyl fluoride 100 μ mol/L. The suspension was incubated on ice for 20 min and vortexed every 5 min. Cell lysates were then centrifuged at 13 000 r/min (Eppendorf centrifuge, Osterode, Germany) for 30 min at 4 °C. The supernatants were collected, and protein concentration was measured by using the Bio-Rad assay. Forty micrograms of protein (40 μ g) was electrophoresed onto a 12% SDS-PAGE gel and transferred to a polyvinylidene difluoride membrane. The membrane was incubated for 1 h with primary antibodies followed by incubation with second antibodies (horseradish peroxidase-conjugated). Immunoactive bands were visualized using chemiluminescence (Amersham-Pharmacia Biotech, Piscataway, USA) and densitometric analysis was carried out using an imager and densitometer^[15].

Immunoprecipitation Growth-arrested VSMCs were exposed to 0.1% NCS, 10% NCS, 10% NCS+10 μ mol/L onychin, or 10% NCS+10 μ mol/L genistein for 20 min. Cell lysates were prepared for immunoprecipitation as described previously^[16]. Briefly, equal amounts of protein (500 μ g) were immunoprecipitated with anti-ERK1/2 polyclonal antibodies overnight at 4 °C. Immune complexes were collected by incubation with protein A-Sepharose beads for 2 h at 4 °C. Immunoprecipitates were separated by using SDS-PAGE, and proteins were detected by immunoblotting as described above using anti-pTyr monoclonal antibodies.

Statistical analysis All values are expressed as mean±SD. Statistical significance was determined by one-way ANOVA. $P < 0.05$ was considered significant.

Results

Effect of onychin on the proliferation of VSMCs Both cell counting and the MTS assay showed that onychin treatment for 24 h or 48 h significantly inhibited VSMC proliferation induced by 10% NCS. The inhibition was concentration-dependent with peak at 10 μmol/L (Table 1). The efficiency of 10 μmol/L onychin treatment for 24 h was similar to that of 10 μmol/L genistein. Therefore we chose 10 μmol/L onychin treating cells for 24 h in the following experiments.

Changes in the VSMC cycle induced by onychin treatment The percentages of G₀/G₁ or S phase cells in the 10% NCS-stimulated group were 70.0% and 16.4% respectively. In contrast, 10 μmol/L onychin and 10 μmol/L genistein treatments for 24 h led to a significant inhibition of DNA synthesis as evidenced by the fact that the percentages of G₀/G₁ phase cells increased to 85.2% and S phase cells decreased to 4.3% in the onychin group (Figure 1).

Decreased Rb phosphorylation induced by onychin treatment The cell cycle progression from G₁ to S phase is usually accompanied by Rb phosphorylation in the late G₁ phase. We therefore examined Rb phosphorylation in VSMCs by using Western blotting with anti-phospho Rb antibody. NCS (10%) stimulated Rb phosphorylation markedly and onychin and genistein inhibited Rb phosphorylation by 70.1% and 58.8%, respectively (Figure 2).

Onychin lowers the expression of cyclin D₁ and cyclin E To further explore the mechanism by which onychin inhibited Rb, we examined the expression of cyclin D₁ and cyclin E by Western blotting. Results showed that 10% NCS treatment significantly increased both expressions of cyclin D₁ and cyclin E and that pretreatment with onychin 10 μmol/L and genistein 10 μmol/L decreased the NCS-induced expression of these two proteins (Figure 3, 4).

Effect of onychin on the tyrosine phosphorylation of ERK1/2 ERK1/2 activation is at upstream of cyclins. It has been reported that the protein tyrosine inhibitor genistein is able to inactivate ERK1/2. To investigate whether the inhibitory effect of onychin on ERK1/2 is mediated by tyrosine kinase inhibition, we observed the phosphorylation of the tyrosine residue in ERK1/2. When growth-arrested VSMCs were treated with 10% NCS, a marked time-dependent tyrosine phosphorylation of ERK1/2 was observed, with peak at 20 min (data not shown). Pretreatment with genistein, as well as onychin, significantly inhibited the 10% NCS-induced

Figure 1. Effect of onychin 10 μmol/L on cell cycle progression induced by 10% NCS for 24 h in cultured vascular smooth muscle cells (VSMCs). Growth-arrested VSMCs were exposed to 0.1% NCS, 10% NCS, 10% NCS+10 μmol/L onychin or 10% NCS+10 μmol/L genistein for 24 h. Then cells were fixed with ethanol and incubated with PBS containing Rnase followed by staining with propidium iodide. Fluorescence was determined by using a flow cytometer.

tyrosine phosphorylation of ERK1/2, suggesting that onychin might be a potential inhibitor of tyrosine kinase (Figure 5).

Discussion

VSMC proliferation contributes to the remodeling of blood vessels and has been implicated in the pathogenesis of atherosclerosis. Phytoestrogens such as genistein can inhibit the proliferation of VSMC and have been implicated in the suppression of VSMC proliferation in neo-intima formation *in vivo*. Onychin, which has a similar structure to genistein, has been considered as a candidate for providing

**Figure 3.** Inhibitory effect of onychin on cyclin D₁ expression in cultured VSMCs. A) Growth-arrested VSMCs were exposed to 0.1% NCS, 10% NCS, 10% NCS+10 μ mol/L onychin, or 10% NCS+10 μ mol/L genistein for 24 h. Cells were harvested, and lysates were analyzed for cyclin D₁ by using Western blotting. B) The relative expression of cyclin D₁ was measured by using densitometry of autoradiograms in the linear range of film development. The results of each experiment were normalized to the density of the control (0.1% NCS) sample, which was arbitrarily adjusted to 1.0. The response to 10% NCS, and 10% NCS+10 μ mol/L onychin, 10% NCS+10 μ mol/L genistein was then determined on a relative basis. $n=3$ experiments. several cardiovascular protective effects^[9-13]. To further investigate its actions in vascular biology, in the present study we studied the effect of onychin on the proliferation of rat VSMC induced by 10% NCS. The results showed that 1–50 μ mol/L onychin inhibited the proliferation of VSMCs in a concentration-dependent manner, with a peak at 10 μ mol/L.

Proliferating cells pass through several cell cycle checkpoints, mainly the G₁ to S and G₂ to M transitions. The former checkpoint is considered to be the most important one in the replication of DNA and mitosis. We thus

logically speculate that onychin affects VSMC proliferation via alterations in the cell cycle progression. Indeed our data show that onychin blocks cell cycle progression at the G_1 transition and stops VSMCs entering the S phase from G_0/G_1 , consequently inhibiting the replication of DNA and the growth of VSMCs.

Rb is a key modulator of cell-cycle transit because of its ability to control the G_1/S -phase transition^[17]. Rb activity is related to its ability to modulate the activation of the E_2F family, which are required for S-phase progression^[18]. Cell cycle progression from G_1 to S phase is usually accompanied by Rb phosphorylation, which is induced by the cyclin D_1 -CDK₄ and the cyclin E-CDK₂ complexes in the late G_1 phase. Rb phosphorylation leads to E_2F release. Conversely, hypophosphorylated Rb sequesters E_2F and prevents transcription of the E_2F target genes. Recent evidence indicates that phosphorylated Rb (pRb) inactivation is a key molecular event leading to S-phase commitment at the G_1 restriction point in the cell cycle^[19]. Therefore, deregulating pRb inactivation in the G_1 phase becomes a universal mechanism underlying cellular transformation. Recently, Chang *et al.* showed that a nonphosphorylatable, constitutive active form of murine Rb inhibited VSMC proliferation and reduced neointima formation in injured rat carotid arteries and porcine femoral artery models^[20]. Growth factors such as platelet-derived growth factor, epidermal growth factor, and fibroblast growth factor have been shown to induce Rb phosphorylation in quiescent cells entering into the cell cycle^[21]. In light of this broad spectrum of activity, Rb is a strong candidate for use as an anti-proliferative agent in a number of disorders that are characterized by inappropriate proliferate responses. To test the possible effects of onychin on Rb phosphorylation, we observed the relative amounts of hypophosphorylated and phosphorylated forms of Rb in VSMCs by using Western blotting. The results showed that onychin decreased the phosphorylation levels of Rb.

Progression through the mammalian mitotic cycle is coordinated by expression and/or activation of multiple holoenzymes composed of a catalytic cyclin-dependent kinase (CDK) and a cyclin-regulatory subunit^[22]. Different cyclin/CDK complexes are temporally activated at specific phases of the cell cycle. Progression through the first gap phase (G_1) requires cyclin D-dependent kinase (CDK₄ and CDK₆) and cyclin E/CDK₂ activity^[22,23], which results in Rb hyperphosphorylation. The association of CDK₄ or CDK₆ with D-type cyclins is critical for G_1 phase progression, whereas the CDK₂-cyclin E complex is important for initiation of the S phase. It has been reported that administration

of genistein in rats with an acute renal injury decreases ERK activation and cyclin D₁ expression^[24]. It has been reported that exposure of VSMC to 10% FCS causes a time-dependent increase in cyclin D1 and cyclin E^[25]. In the present study, we also found that 10% FCS up-regulated the expression of cyclin D₁ and cyclin E, and onychin treatment inhibited the effects of NCS.

The MAPK family constitutes a major ubiquitous intracellular signaling system involved in the regulation of cell growth, differentiation, and survival^[26]. To date, at least three distinct mammalian MAPKs have been characterized: the extracellular-regulated kinases (ERKs), Jun N-terminal kinases/stress-activated protein kinase (JNK/SAPK) and p38. Among of them, the mammalian ERKs (ERK1/p44 and ERK2/p42) are generally thought to play a role in cell proliferation and differentiation. ERK1/2 is serine/threonine kinase, which is activated by phosphorylation at both threonine and tyrosine residues. Evidence indicates that phosphorylation of the residues Thr 202/Tyr 204 (for human ERK, or Thr 185/Tyr 187 for bovine ERK) in the conserved Thr/Glu/Tyr ERK sequences is necessary and sufficient for full activation of these enzymes and serves as an indicator of their activation status^[27]. In our experiments, we observed an obvious tyrosine phosphorylation of ERK1/2 in the 10% NCS group. Onychin, like genistein, markedly declined the phosphorylation level of tyrosine of ERK1/2.

In summary, onychin inhibits the proliferation of VSMCs through G₁ phase cell cycle arrest by decreasing the tyrosine phosphorylation of ERK1/2, decreasing the expression of cyclin D₁ and cyclin E, and sequentially inhibiting Rb phosphorylation.

Abstract

Aim: To investigate the effect of mifepristone (RU486) as a single dose on pinopodes expression in the endometrial surface of mice at the time of implantation.

Methods: Pregnant mice in the treated four groups received mifepristone subcutaneously (0.1 mg) between 07:00 and 08:00 AM on Pd (day of pregnancy) 1, Pd2, Pd3, and Pd4. Pregnant mice in the non-treated group were used as controls. The uterine horns were collected randomly from two mice in each group between 21:30 and 22:00 PM on Pd4, and from another two mice of the same group between 09:30 and 10:00 AM on Pd5. The specimens were examined by scanning electron microscopy for the detection of pinopodes. **Results:** When mifepristone was given on Pd1, developing and fully developed pinopodes were observed, but the expression was markedly reduced compared to the control group. When mifepristone was administered on Pd2, only a few developing pinopodes were present. When mifepristone was administered on Pd3, developing pinopodes were observed. When mifepristone was administered on Pd4, different development stage pinopodes were present in specimens collected between 21:30 and 22:00 PM on Pd4, but no pinopodes was observed in specimens taken between 09:30 and 10:00 AM on Pd5. **Conclusion:** These findings suggest that administration of a single dose of RU486 subcutaneously on Pd1, Pd2, Pd3, and Pd4 might play a role in inhibiting development and maturation of endometrium, hence affecting embryo implantation in mice.

Introduction

Mifepristone (RU486), a progesterone antagonist steroid, has been largely used for both planned and emergency contraception^[1], as well as for termination of pregnancy^[2]. Although the effect of RU486 for contraception has been described previously, its mechanism has not been completely elucidated. Anovulation, inhibition of fertilization and transportation of embryo through the Fallopian tube, and embryo implantation dysfunction have all been postulated. Recent data sustain the hypothesis that mifepristone reduces perivascular decidual haemostasis and increases extracellular matrix-degrading protease activity^[3].

It is now well established that the cross-talk between the

implanting embryo and the endometrial epithelium is a versatile and dynamic process, which requires a series of rather complicated and synchronous morphological and biochemical changes. Large and smooth membrane protrusions with pinocytotic function, known as pinopodes, have been observed in the endometrial surface during the window of implantation^[4,5]. The formation and appearance of pinopodes appears to advance or regress, depending on hormonal milieu and other physiological modifications throughout the menstrual cycle^[6]. Furthermore, a positive correlation between the pinopodes number and blastocyst implantation has been reported^[7]. Fully developed pinopodes have been considered as the characteristic morphologic markers to assess endometrial receptivity and to locate the implantation win-

dow^[8,9].

The aim of this experimental study was to investigate the timing of pinopodes expression in the endometrial surface epithelium of mice following a single dose administration of RU486.

Materials and methods

Animals and reagents Seventy female (weight: 28–30 g) and 15 male (weight: 40–45 g) adult Kunming mice (age 8–12 weeks) were provided by Sanitary Epidemic-Prevention Station of Hubei Province, China (Certificated No 19-082, China). Mifepristone tablets (Third Pharmaceutical Factory of Beijing, China) were ground carefully and dissolved in propylene glycol.

Animal treatment Female and male mice in a ratio of 2:1 were kept overnight in a cage for mating. The following morning, the display of a vaginal plug in female mice was designated as day 1 of pregnancy (Pd1). The pregnant mice were divided into five groups, as follows: a) non-treated group; b) treated group 1; c) treated group 2; d) treated group 3; and e) treated group 4. The non-treated group was considered the control. All mice in the treated groups received mifepristone subcutaneously (0.1 mL solution containing 0.1 mg mifepristone) between 07:00 and 08:00 AM on Pd1, Pd2, Pd3, and Pd4, respectively.

Scanning electron microscopy Two mice selected randomly from each group were killed by cervical dislocation between 21:30 and 22:00 PM on Pd4, and another two mice in the same group were killed between 09:30 and 10:00 AM on Pd5. All remaining mice were killed on Pd7 in order to observe the pregnancy and the average number of implanted embryos.

The murine uterine horns were excised and then cut open along the longitudinal axis. The endometrial tissue was rinsed in saline solution, fixed in 2.5% (w/v) glutaraldehyde solution in a sodium cacodylate buffer (0.15 mol/L, pH 7.3) and post-fixed in a 1% (w/v) osmium tetroxide solution in a sodium cacodylate buffer (0.15 mol/L, pH 7.3) containing sucrose (75 mmol/L). The specimens were dehydrated in a graded series of acetone, then dried in a critical-point drier with carbon dioxide, mounted on the specimen holder, coated with gold palladium, and observed by scanning electron microscopy (SEM) (S-520, Hitachi, Tokyo, Japan).

To avoid inter-observer bias, all specimens were analyzed by the same observer. Based on development stage and abundance, pinopodes were scored as developing, fully developed, or regressing, and then as few (<20%), moderate (20%–50%), or abundant (>50%), respectively. If different development stages were observed in the same specimen, only the commonest pattern was reported^[6].

Statistical analysis Data were expressed as mean±SD. Unpaired *t*-test and χ^2 -test were used. Software SPSS 11.0 for Windows was used. *P*<0.05 was considered to be statistically significant.

Results

Pregnancy rate and average implanted embryos No mice in treated groups 1, 2, or 3 conceived. In contrast, one mouse in group 4 achieved a pregnancy. Number of pregnant mice and average number of implanted embryos was significantly lower in treated group 4 as compared with controls (1 vs 9, *P*<0.01; 6 vs 14.67±1.35, *P*<0.01, respectively).

Pinopodes expression in endometrial surface In the control group, specimens collected between 21:30 and 22:00 PM on Pd4 showed abundant membrane projections widely distributed in the endometrial luminal surface. Clear, smooth, and slender projections were covered by short microvilli (developing pinopodes) (Figure 1). In specimens collected between 09:30 and 10:00 AM on Pd5, the endometrial surface was covered by membranous structures protruding and folding maximally (fully developed pinopodes). No microvilli were observed (Figure 2).

In treated group 1, the specimens collected between 21:30 and 22:00 PM on Pd4 showed smooth membrane projections. These structures, resembling developing pinopodes, were smaller, less abundant, and slightly lagged behind those present in controls (Figure 3). In specimens collected between 09:30 and 10:00 AM on Pd5, mainly fully developed pinopodes and developing pinopodes were present. Fully developed pinopodes were observed exclusively in epithelial cell depressions, while the neighboring surface was covered with short tips of microvilli (Figure 4).

In treated group 2, the specimens taken between 21:30 and 22:00 PM on Pd4 showed endometrial surface covered by scanty membrane projections. The endometrial luminal surface was relatively smooth with few and slender membranous projections (developing pinopodes) (Figure 5). These structures appeared slightly more pronounced in specimens collected between 09:30 and 10:00 AM on Pd5, but no fully developed pinopode was observed (Figure 6).

In treated group 3, no membrane projections were present in the endometrial surface of specimens collected between 21:30 and 22:00 PM on Pd4. The epithelial cells lining the luminal surface were rather smooth and covered by small tips of microvilli (Figure 7). The specimens taken between 09:30 and 10:00 AM on Pd5 showed smooth endometrial surface covered by normal epithelial cells and short microvilli in one case, while in the other there were slender membranous projections (developing pinopodes) which were much smaller

Figure 1. Pinopode expression in control group between 21:30 and 22:00 PM on Pd4. Smooth and slender membrane projections covered with short microvilli, almost the same shape and size, distributed over the whole endometrial luminal surface. (developing pinopodes: white arrow) (SEM, A×1500, B×3000).

Figure 2. Pinopode expression in control group between 09:30 and 10:00 AM on Pd5. The endometrial surface was extensively covered with projections protruding and folding maximally (fully developed pinopodes: black arrow). No microvilli were observed. (SEM, A×1500, B×3000).

than those expressed in controls between 21:30 and 22:00 PM on Pd4 and between 09:30 and 10:00 AM on Pd5 (Figure 8).

Finally, in treated group 4, no synchronously developed structure was expressed in all specimens collected between 21:30 and 22:00 h on Pd4. Few pinopodes in different development stages were present. The majority of endometrial

surface expressed no membrane projections and was covered by epithelial cells with short and thick microvilli. The boundaries of epithelial cells were not clear (Figure 9). Specimens collected between 09:30 and 10:00 AM on Pd5 had no pinopodes, but abundant microvilli and clear boundaries on the epithelial cells (Figure 10).

Figure 3. Pinopode expression in treated group 1 between 21:30 and 22:00 PM on Pd4. The specimens showed a lot of smooth membrane projections (developing pinopodes: white arrow) which were smaller, less abundant, and slightly lagged behind those in control group. (SEM, A×1500, B×3000).

Figure 4. Pinopode expression in treated group 1 between 09:30 and 10:00 h on Pd5. Fully developed pinopodes (solid arrow) with many folds like a flower were observed in one specimen (SEM, A×3000), whereas another was mainly covered by abundant developing pinopodes (empty arrow) (SEM, B×1500).

Discussion

The use of mifepristone for emergency contraception has been widely accepted^[1,3], however, a large number of prospec-

tive, randomized, double-blind studies are still in progress. Several clinical trials have shown that a single dose of mifepristone (10 mg) is effective for emergency contraception when given within 120 h from unprotected coitus, causing mild or

Figure 5. Pinopode expression in treated group 2 between 21:30 and 22:00 PM on Pd4. The endometrial luminal surfaces were relatively smooth with few and slender membranous projections (developing pinopodes: white arrow). (SEM, A×1500, B×3000).

Figure 6. Pinopode expression in treated group 2 between 09:30 and 10:00 AM on Pd5. These membrane projections (white arrow) appeared a little more pronounced in specimens, but no fully developed pinopodes were observed. (SEM, ×1500).

no side-effects^[10,11]. However the biological mechanism of RU486 remains a matter of much debate.

Wang *et al*^[12] investigated the effects of a single dose of mifepristone (10 mg) on the endometrial expressions of HOXA-11, progesterone receptors (PR), and leukaemia inhibitory factor (LIF). They found that following oral adminis-

tration of mifepristone on d 2 post-ovulation (LH+2) the development of endometrium was quite delayed. In the glandular epithelium, the expressions of HOXA-11 and PR increased significantly and that of LIF decreased. Conversely, in the stromal epithelium, the expressions of these markers remained unchanged.

More recently, it has been proved that mifepristone could inhibit the establishment of uterine receptivity in some animals^[13,14]. Marions *et al*^[15] reported that following mifepristone administration during early luteal phase in fertile women, down-regulation of PR was inhibited and no significant modifications of the remaining markers of endometrial receptivity, such as pinopodes, integrin dimmers α_4 and β_3 , cyclooxygenase-1 and -2 were found. These authors^[15] have also observed that the endometrial changes happened irrespective of embryo; however, its influence on implantation could not be ignored. Furthermore, they observed the influence of RU486 on endometrium only after RU486 was given on LH+2 whereas RU486 is effective for emergency contraception when given within 120 h from unprotected coitus.

A large consensus of opinion sustains that fully developed pinopodes represent specific morphological markers of endometrial receptivity^[6,8,9]. The appearance and disappearance of fully developed pinopodes coincide with the nidation window both in humans and animals. Synchronous expressions of fully developed pinopodes and other markers of uterine receptivity such as integrins ($\alpha_v\beta_3$)^[16], heparin-binding epidermal growth factor (HB-EGF)^[17], LIF and

Figure 7. Pinopode expression in treated group 3 between 21:30 and 22:00 PM on Pd4. No membrane projections appeared. The epithelial cells (grey arrow) lining the luminal surface were rather smooth and covered by small tips of microvilli. (SEM, A×1500 B×3000).

Figure 8. Pinopode expression in treated group 3 between 09:30 and 10:00 AM on Pd5. Smooth endometrial surface was covered by normal epithelial cells (grey arrow) and short microvilli in one case (SEM, A×1500), while in the other there were very slender membranous projections (developing pinopodes: white arrow) (SEM, B×1500).

LIF-receptor^[18] have been noted. Therefore, it is plausible that morphological and biochemical changes during the menstrual cycle may be reliable in evaluating endometrial function and receptivity.

In this study, mifepristone as a single dose was administered straight away after the murine successful coitus was

confirmed. When RU486 was given on Pd4, only one mouse conceived and the number of implanted embryos was significantly lower compared to controls ($P < 0.01$). No mice conceived when RU486 was given on Pd1, Pd2, and Pd3. These data show that a single dose of RU486 is effective when given on Pd1, Pd2, Pd3, and Pd4.

Figure 9. Pinopode expression in treated group 4 between 21:30 and 22:00 PM on Pd4. No synchronously developed structures were expressed in the samples. The pinopodes (white arrow) were few and with different development stages (SEM, A \times 1000). The majority of endometrial surface expressed no membrane projections and was covered by epithelial cells with short and thick microvilli. (SEM, B \times 1500).

Figure 10. Pinopode expression in treated group 4 between 09:30 and 10:00 AM on Pd5. Specimens had no pinopodes, but abundant microvilli and clear boundaries on the epithelial cells (grey arrow) (SEM, \times 1500).

When RU486 was administered on Pd1, developing and fully developed pinopodes were observed in the endometrial surface, but its expression was reduced compared to that of controls. It is therefore likely that mifepristone administration on Pd1 inhibits zygote development or embryo transportation through the Fallopian tube rather than hav-

ing an effect on the endometrial surface. When mifepristone was given on Pd2, the uterine receptivity was significantly impaired, hence elucidating the effects of this antiprogesterone steroid on the endometrium and its rationale for contraception. Likewise, administration of RU486 on Pd3 and Pd4 appeared to impair development and maturation

tion of pinopodes, so affecting endometrial receptivity and embryo implantation.

The effect of RU486 on the endometrium on Pd3 is stronger than that on Pd2 and Pd4. Conversely, the effect is relatively weak when this compound is given on Pd1. To our knowledge, this is the first report in the literature assessing pinopode expression as morphological marker of implantation window in mice following administration of mifepristone. Therefore, comparison with other data is not possible.

In conclusion, these findings suggest that mifepristone might inhibit endometrial receptivity and, to some extent, prevent embryo implantation as a result of morphological modifications of the luminal epithelial cells. Since the establishment of endometrial receptivity includes morphological immunological changes, further studies exploring the effects of RU486 on the expressions of cytokines, adhesion molecules and other immunological factors during the implantation window would provide new insights and improve our knowledge of implantation and early pregnancy.

Introduction

Peroxisome proliferator-activated receptor (PPAR) is a ligand-binding transcriptional regulatory factor, which belongs to the nuclear receptor superfamily and regulates the expression of a group of genes involving glucose and lipid metabolism. There are three PPAR subtypes, commonly designated as PPAR α , PPAR β (δ), and PPAR γ ^[1,2]. The functions of these PPAR isoforms, after activation by drugs (anti-inflammatory agents, fibric acids) and fatty acid derivatives (including prostaglandins and plasticizers), include an increase in lipid and cholesterol metabolism, adipocyte differentiation, and an improvement in insulin sensitivity^[1,3,4]. PPAR γ is the most extensively studied PPAR subtype. It has been demonstrated that PPAR γ is the receptor of the thiazolidinedione (TZD) class ligands^[5]. Among the TZD

Abstract

Aim: To search the peroxisome proliferator-activated receptor γ (PPAR γ) agonists from *Swietenia mahagony* extract (*SmE*) and observe the possible ameliorative effects of *SmE* on diabetic *db/db* mice. **Methods:** The PPAR γ agonistic activity of *SmE* was screened by yeast-two hybrid system. The blood glucose levels of diabetic *db/db* mice were measured using a blood glucose level monitor and the data were statistically analyzed by NDST8.8W software. **Results:** By using the clinical drug rosiglitazone as a positive control, it was found that the PPAR γ agonistic activity of *SmE* at a concentration of 50 $\mu\text{g/L}$ was approximately half that of 35.7 $\mu\text{g/L}$ (0.1 $\mu\text{mol/L}$) of rosiglitazone. At the dose of 1000 mg/kg, *SmE* remarkably decreased the blood glucose concentration of *db/db* mice from (15.26 \pm 2.98) to (7.58 \pm 2.20) mmol/L, and reduced the blood glucose levels by 55.49% compared with the control group ($P < 0.01$). **Conclusion:** *SmE* shows agonistic activity to PPAR γ and can ameliorate the blood glucose levels of diabetic *db/db* mice. *SmE* may be thus used as a potential agent for diabetes therapy.

type antidiabetic drugs, rosiglitazone and troglitazone are potent adipocyte-differentiating agents, which activate *ap2* gene expression in a PPAR γ -dependent manner^[6]. As PPAR γ ligands may regulate the adipogenesis, they can be designed and modified for the treatment of cardiovascular disease and diabetes mellitus^[1,7], and PPAR γ has been an attractive target for new drug discovery. To date, several types of PPAR γ agonist with new structures have been developed, as though few can be clinically used^[8]. In fact, the search for new PPAR γ agonists has long been an alluring project.

Nature remains as a source for organic structures with unparalleled diversity, and the enormous importance of natural product is obvious. In recent years, there has been growing interest in alternative therapies and the therapeutic use of natural products, especially those derived from plants. In fact, natural products, containing inherently more structural

diversity than synthetic compounds, have been the major resources of bioactive agents and will continue to play an important role in the discovery of new drugs^[9]. Encouraged by these facts, we have recently focused on finding of PPAR γ agonist on the basis of natural resource exploration. This present study was to test the PPAR γ agonistic activity of *SmE* and observe the ameliorative effects of *Smietenia mahagony* extract (*SmE*) on diabetic *db/db* mice.

Materials and methods

Materials The plant material was purchased from Indonesia and the specimen (No 20030601) was deposited in Shanghai Institute of Materia Medica. OneTouch^R Ultra used for measuring the blood glucose level of diabetic *db/db* mice was purchased from Shanghai Qiangsheng Medical Treatment Equipment Ltd, Shanghai, China.

Animals The *db/db* mice were supplied by Shanghai BK Corporation. The male mice, 40–50 g, were sanitary, and allowed free access to water during the experiment.

Extract of *Swietenia mahagony* Powdered *Smahagony* seeds (0.8 kg) was refluxed with EtOH (95%, 2 L) for 2 h three times, then filtered. The combined filtrate was concentrated under reduced pressure and partitioned by EtOAc to obtain EtOAc fraction (40 g).

PPAR γ agonists assay Yeast liquid synthetic dropout medium without leucine and tryptophan (T-L-) was prepared referring to Yeast Protocol Handbook^[10]. *SmE* (50 μ g/L) and rosiglitazone (0.1 μ mol/L) were dissolved in Me₂SO for assay use.

The yeast two-hybrid system was established for identifying PPAR γ agonist by our laboratory^[11]. The yeast strain AH109 named p1c2, harboring the expression plasmid pGADT7-CBP and PGBKT7-PPAR γ LBD, was used for PPAR γ agonist screening^[12].

Yeast clone p1c2 was inoculated into 2 mL T-L-liquid medium from a plate, then incubated at 30 °C overnight (16–18 h) with shaking (250 r/min). After vortexing and recording OD₆₀₀, the cell culture was diluted with T-L-liquid medium until its OD₆₀₀ reached about 0.05. Subsequently 5 μ L of Me₂SO or drug was added to 495 μ L of diluted yeast culture, test cultures were incubated at 30 °C overnight (14–16 h), and then α -Galactosidase Assay was performed^[10].

Blood glucose level measurement The basal blood glucose levels of 40 male *db/db* diabetic mice were measured everyday for 7 d, and 24 mice showing comparatively steady blood glucose level were screened out. These mice were divided into three groups ($n=8$) according to the blood glucose level. The mice were given 0.5% CMC-Na (10 mL/kg) in the control group, *SmE* (1000 mg/kg) or rosiglitazone (10 mg/

kg) in the treated group by ig everyday for 2 weeks. The blood glucose concentrations were measured using a blood glucose level monitor (OneTouch^R Ultra, Shanghai) every other day. Data were analyzed using the NDST8.8W analysis program.

Statistical analysis The results were expressed as mean \pm SD and analyzed by unpaired *t*-test.

Results

PPAR γ ligand-binding activity of *SmE* *SmE* exhibited moderate agonistic activity to PPAR γ , and its relative α -galactosidase intensity from the yeast two-hybrid assay was 2.13 at the concentration of 50 μ g/L, which was approximately half that of rosiglitazone 35.7 μ g/L (0.1 μ mol/L), a potent synthetic PPAR γ agonist (Figure 1), whose relative α -galactosidase intensity is around 4.29.

Figure 1. PPAR γ agonistic activity was measured using a yeast two-hybrid system. All samples were dissolved in Me₂SO and the PPAR γ agonistic activity was expressed as the relative α -galactosidase intensity. Data are means of three experiments performed in triplicate.

Effect of *SmE* on diabetic *db/db* mice After 14 d of feeding, the blood glucose levels decreased markedly in the both *SmE*- and rosiglitazone-treated groups compared with the control group. The blood glucose concentration of *db/db* mice in the control group was 17.03 mmol/L, yet in the treated groups 7.58 mmol/L and 6.98 mmol/L respectively (Table 1). In comparison with the control group, the blood glucose levels decreased 55.49% ($P<0.01$) in the *SmE*-treated group and 59% ($P<0.01$) in the rosiglitazone-treated group.

Discussion

Swietenia mahagony is a large, medicinally and economically important timber tree native to the West Indies. The seeds of this plant are used for the treatment of hypertension and malaria as a folk medicine in Indonesia^[13]. In the present study, we tested the effect of *Smahagony* on the

PPAR γ agonistic activity and the amelioration of the blood glucose level in type-II diabetic mice, a representative insulin resistance syndrome. With the help of the yeast two-hybrid system assay, the possible anti-diabetic mechanism of *Swietenia mahagoni* was proposed. The results *in vivo* showed that *SmE* exhibited moderate effects on decreasing the blood glucose levels of the diabetic *db/db* mice. These results may give us a new hint that *SmE* might be used as a potential agent for diabetic therapy with its PPAR γ transcriptional regulatory function as one of the *in vivo* mechanisms even though there may be existed other efficient components in *SmE* against other targets for diabetic therapy.

Abstract

Aim: To investigate the effects of triptolide, a diterpenoid triepoxide from *Tripterygium wilfordii* Hook F (TWHF), on the co-stimulatory molecule expression and interleukin-12 (IL-12) production from THP-1 cells. **Methods:** THP-1 cells were differentiated into macrophage-like cells by Me₂SO, and then cultured with IFN- γ (500 kU/L) and lipopolysaccharide (LPS) (1 mg/L) with or without triptolide. The surface molecule expressions were analyzed on a FACScan flow cytometer. IL-12p40, IL-12p70 were assayed by ELISA. **Results:** Triptolide suppressed CD80 and CD86 expressions on IFN- γ (500 kU/L) and LPS (1 mg/L) activated THP-1 cells at nontoxic dosages of 2.5–0.625 μ g/L. Furthermore, the production of IL-12p40 and IL-12p70 were also significantly reduced in THP-1 cells exposed to triptolide. **Conclusion:** Triptolide impairs the antigen-presenting function by inhibiting CD80 and CD86 expressions and decreased IL-12p40 and IL-12p70 (bioactive form) productions from the activated THP-1 cells.

Introduction

Human cells of monocytic lineage, including monocytes, macrophages, and monocyte-derived dendritic cells, play an essential role in initiating and maintaining immune responses by acting as antigen-presenting cells (APC). They process and present antigenic peptides via the major histocompatibility complex (MHC) molecules and the expression of costimulatory molecules^[1,2]. The best-characterized costimulatory molecules to date are two structurally related proteins, CD80 and CD86. Both provide costimulation to T-cells, leading to their proliferation, cytokine production, and development^[2,3]. *In vivo* studies using anti-CD80 and anti-CD86 monoclonal antibodies or genetically manipulated animals have demonstrated that a blockade of CD80/CD86 costimulatory molecules can prolong allograft survival and reduce the severity of autoimmune diseases^[4,5]. Preliminary clinical studies in human subjects also support this concept^[6]. Therefore, pharmacological intervention in the upregulation of CD80/CD86 may therefore be useful in the treatment of autoimmune diseases or in transplantation.

Tripterygium wilfordii Hook F (TWHF) is a herb used in traditional Chinese medicine for the treatment of rheumatoid arthritis and other autoimmune diseases^[7,8]. Triptolide, a highly oxygenated diterpenoid triepoxide, is the major component responsible for the immunosuppressive and anti-inflammatory effects of TWHF^[9]. It is effective for the treatment of autoimmune diseases, prevention of allograft rejection, and graft-versus-host disease in animal experiments^[10–13]. The inhibitory effect of triptolide on T-cell activation is stronger than cyclosporine^[14] and FK-506^[15] *in vitro*. Furthermore, it can induce activated T-cell apoptosis^[16]. Thus, T-cells are considered to be the main target for triptolide. Recently, Hong *et al*^[17] and Li *et al*^[18] demonstrated that triptolide inhibited upregulation of B7 on activated human proximal tubular epithelial cells. These results suggest that triptolide may have suppressive effects on APC. In a further analysis of this theory, we used a human monocytic leukemia cell line (THP-1) that had been differentiated into macrophage-like cells by treatment with Me₂SO. The macrophage-like THP-1 cells were used to examine the influences of triptolide on the expression of CD80 and CD86 molecules and the production

of IL-12, an important cytokine that biases CD4⁺ T-cells toward Th1 differentiation^[19].

Materials and methods

Reagents Triptolide was provided by the Department of Chemistry, Shanghai Institute of Materia Medica. Lipopolysaccharide (LPS, Escherichia coli 055: B5), 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyl-tetrazolium bromide (MTT), and 3,3',5,5'-tetramethylbenzidine (TMB) were from Sigma (St Louis, MO, USA). Recombined human IFN- γ was purchased from Shanghai Clonbiotech (Shanghai, China). PE-conjugated mAbs were used to detect cell surface expression of CD14, HLA-ABC, HLA-DR, CD80 and CD86 by flow cytometry, as well as isotype-matched mAbs, which were purchased from PharMingen (San Jose, CA, USA).

Cells The human monocytic THP-1 line (ATCC, Manassas, VA, USA) was maintained in suspension culture in RPMI1640 medium, supplemented with 10% FBS. Cultures were maintained at 37 °C in a humidified atmosphere of 5% CO₂ and were subcultured at 1/10 dilution every 5–6 d. Cells were used to differentiate when seeded at a density of 5 × 10⁸ cells/L in a 10-cm² culture dish for 24 h.

Flow cytometry analysis THP-1 cells were cultured in a screw cap container 2.4 × 10⁶ cells in 4 mL of RPMI1640 medium with 10% FBS per-well. Cells were differentiated with 1.2% Me₂SO for 24 h, then pre-treated with IFN- γ (500 kU/L) for 16 h and stimulated by LPS (1 mg/L) for another 24 h. Various concentrations of triptolide were added at the initiation of the culture. Cells were collected and washed in an ice cold staining buffer (PBS containing 0.1% w/v sodium azide, 1% FBS, pH 7.2). Cells were then resuspended at 4.0–5.0 × 10⁹/L in an ice-cold staining buffer. Optimal concentrations of each fluorochrome-labeled antibody were added. Cells were incubated at 4 °C for 30 min, then washed twice and analyzed by flow cytometry using FACSCalibur (Becton Dickinson, San Jose, CA, USA). Data were illustrated by CELLQuest.

Cytokine analysis THP-1 cells were cultured in 24-well plates at 6.0 × 10⁵ cells in 2 mL of RPMI1640 medium with 10% FBS and other treatments were the same as in the surface molecules analysis. Culture supernatants were harvested and stored at -20 °C. Human IL-12p70 and IL-12p40 productions were measured using ELISA kits (PharMingen) according to the manufacturer's instructions.

MTT assay Cytotoxicity was assessed by MTT assay^[20]. Me₂SO-differentiated THP-1 cells were incubated in a 96-well plate at 5.4 × 10⁴ cells in 180 μ L of RPMI1640 medium with 10% FBS per-well for 72 h with and without various concentrations of triptolide. MTT (5 g/L) 18 μ L was added 5 h prior

to the end of the culture, and then 90 μ L solvent (10% SDS, 50% *N,N*-dimethyl formamide, pH 7.2) was added. The cells were then incubated for another 7 h and value was measured at 570 nm by a microplate reader (Bio-Rad Model 550, Japan).

Statistical analysis Results were expressed as mean \pm SD. An independent two-tailed *t*-test was performed and *P* < 0.05 was considered to be statistically significant.

Results

Triptolide influenced the surface molecule expressions on Me₂SO-differentiated THP-1 cells THP-1 cells are known to be activated by LPS stimulation and have been used as a surrogate for investigation of human monocytes^[21]. When THP-1 cells are treated with Me₂SO, the cells differentiate into macrophage-like cells and proliferation is profoundly inhibited. IFN- γ pretreatment and LPS stimulation enhanced the expression of a variety of surface molecules such as HLA-ABC, HLA-DR, and B7 molecules on THP-1 cells. Triptolide could suppress CD80 and CD86 expressions on IFN- γ (500 kU/L) and LPS (1 mg/L)-activated THP-1 cells at 2.5–0.625 μ g/L (Figure 1). Triptolide also weakly down-regulated the HLA-ABC expression, but it did not change the expressions of HLA-DR and CD14 on THP-1 cells.

Triptolide inhibited IL-12 production of Me₂SO-differentiated THP-1 cells IFN- γ pretreatment and LPS stimulation induced IL-12p40 and IL-12p70 production from Me₂SO-differentiated THP-1 cells. The productions of IL-12p40 and IL-12p70 in response to IFN- γ (500 kU/L) and LPS (1 mg/L) induction were significantly reduced in THP-1 cells exposed to triptolide in the concentration of 2.5–0.625 μ g/L (Figure 2). IL-10 production was too low to be detected in this experimental system.

Cytotoxicity of triptolide on Me₂SO-differentiated THP-1 cells We examined whether the above suppressive effects of triptolide were due to its cytotoxicity to THP-1 cells. When Me₂SO-differentiated THP-1 cells were cultured with and without different concentrations of triptolide for 72 h, the cytotoxicity was monitored by MTT assay. As shown in Figure 3, triptolide did not exert any cytotoxic effect on the THP-1 cells from 2.5 μ g/L to 0.625 μ g/L in the present study.

Discussion

The immunosuppressive and therapeutic activity of triptolide upon systemic administration has been demonstrated in animal models for human-like diseases, such as in experimental autoimmune uveitis^[22], collagen-induced arthritis^[11], diabetes^[12], nephrotic syndrome^[13]. It also improves

Figure 1. Suppressive effects of triptolide on the expression of CD80 and CD86 in THP-1 cells. Dotted line represents cells incubated with isotype-matched antibodies and solid line represents cells incubated with specific antibodies. Results were obtained from one of the three experiments performed.

the survival rate of the heart^[23] and kidney^[24] allograft in the rat transplantation model and graft-versus-host disease in a murine allogeneic bone marrow transplantation model^[25]. However the immunosuppressive mechanism of triptolide has not been completely delineated^[26]. In the present study, we demonstrated a new finding that triptolide, an active component of TWHF, directly down-regulates the costimulation

Figure 3. Cytotoxicity of triptolide on THP-1 cells. THP-1 cells ($6.0\times 10^8/\text{L}$) were differentiated with 1.2% Me_2SO . Compounds were added at the initiation of culture. Mean \pm SD. ^c $P<0.01$ vs control. Results were obtained from one of the three experiments performed.

molecule CD80 and CD86 expressions on macrophages-like cells (Me_2SO -differentiated THP-1 cells), and inhibits the bioactive form of IL-12p70 production from Me_2SO -differentiated THP-1 cells by a dose-dependent manner.

CD80 and CD86 on APC delivered the critical costimulatory signals for optimal T-cell activation^[3]. Blockade of CD80 and CD86 signaling resulted in ineffective T-cell activation. The implication is that reduced and blocked CD80/CD86 costimulations can prevent the induction of pathogenic T-cell responses in autoimmune disease and allow for prolonged acceptance of allografts in organ transplantation^[4-6]. In addition to the processing and presentation of antigenic peptides via MHC molecules and the expression of costimulatory molecules, APC played a central role in driving CD4^+ T helper cell differentiation through the

production of critical cytokines, such as IL-12, IL-10, TGF- β and possibly IL-4. The production of bioactive form IL-12p70 by host antigen-presenting cells was a primary determinant in the differentiation of naive CD4⁺ T cells into Th1 effector cells^[19]. These suppressive effects of triptolide on CD80 and CD86 expressions, and IL12p70 production suggest an important therapeutic implication for multiple sclerosis and other abnormal immune response mediated diseases associated with the increased expression of CD80/CD86 and the production of IL-12^[27].

Triptolide has been proven to be a potent immunosuppressive agent, although information on the molecular mechanism of triptolide is scarce. Recent studies have shown that triptolide inhibits T-cell activation and early cytokine gene transcription in T-cell at the purine-box/ARRE/NF-AT and NF- κ B target sequence after specific DNA binding^[28,29]. NF- κ B is a family of transcription factors central to immunity and inflammation. It regulates expression of a number of genes, including cytokines, costimulatory molecules, nitric oxide, and susceptibility to apoptosis^[30]. Therefore, the suppressive effects of triptolide on the co-stimulatory molecular expression and IL-12 production from THP-1 cells can result from the inhibition of NF- κ B transcriptional activation.

In conclusion, we have demonstrated that triptolide down-regulates the levels of CD80 and CD86 expressions in THP-1 cells. Production of bioactive form IL-12p70 in THP-1 cells was effectively inhibited by triptolide. These immunosuppressive activities of triptolide contribute, at least in part, to the therapeutic effect and mechanism of triptolide in the treatment of autoimmune diseases.

Abstract

Aim: To evaluate a new plasmid mediated RNA interference (RNAi) system and investigate whether knock-down of *bcl-xL* by short hairpin RNA (shRNA) can induce apoptosis of human nasopharyngeal carcinoma (NPC) cell line CNE-2Z *in vitro*. **Methods:** The plasmid containing mU6 promoter was subcloned to yield the pmU6 plasmid, recombinant plasmid expressing shRNA targeting *bcl-xL* gene was designed and constructed, and were co-transfected cells with green fluorescence protein expressing plasmid. Flow cytometry was used to evaluate transfection efficiency, and RT-PCR and Western blot were applied to analyze *bcl-xL* mRNA and protein levels, respectively. **Results:** The shRNA expressed by the recombinant plasmid efficiently suppressed *bcl-xL* gene expression and induced apoptosis of NPC cells *in vitro*. **Conclusion:** The recombinant plasmid can sufficiently mediate RNAi in CNE-2Z cells, and knock-down of the *bcl-xL* expression by shRNA significantly induced apoptosis in CNE-2Z cells. The results suggest this new system, mediated RNAi can be used as a tool for the study of gene function and gene therapy.

Introduction

RNA interference (RNAi) is a ubiquitous mechanism of eukaryotic gene regulation that can be exploited for specific gene silencing. In 1998, Fire and his colleagues firstly named these phenomena as RNAi^[1]. Recently, RNAi has emerged as a powerful reverse genetic tool to silence gene expression in multiple organisms including plants, *Caenorhabditis elegans*, and *Drosophila*^[2].

The specificity of RNAi is determined by 21- to 23-nt RNA duplexes, referred to as micro-RNAs (miRNA) or small interfering RNAs (siRNA). miRNAs are generated from endogenous precursors, which form hairpin structures with stretches of double-stranded RNA (dsRNA). They are cleaved by the ribonuclease Dicer to produce mature miRNA. After unwinding, one of the strands becomes incorporated into the RNA-induced silencing complex (RISC) and guides the destruction or repression of complementary mRNA. siRNA arise from viral or other exogenous dsRNA, but they use the same mechanism to effect mRNA degradation^[3].

Nasopharyngeal carcinoma (NPC) is a gene-related malignancy that threatens many people's lives in Southern China. Since its discovery, many people have lost their lives to this malignancy because of the lack of ideal therapeutics. Presently, overexpression of *bcl-xL* is widely considered as a poor prognosis in this cancer. In recent years, we have done much work to investigate its ideal therapeutics, including antisense gene therapy strategy. We found a favorable selectivity and high specificity of antisense RNA to treat NPC *in vivo*; however, the quick degradation of antisense RNA in cells and the unspecific toxicity limit its applications. RNA interference, a tool for inhibiting the overexpression of specific oncogenes, has been included in therapeutic studies of cancers in recent years^[4].

One obstacle to achieve RNAi in mammals is that dsRNA longer than 30 nt will provoke an antiviral response, leading to the non-specific degradation of RNA transcripts and a global shutdown of host cell protein translation, known as a strong cytotoxic response. As a result, the long dsRNA

does not produce RNAi activity as expected. This obstacle has recently been solved by Elbashir *et al* who found that gene specific suppression in mammalian cells can be achieved by *vitro*-synthesized siRNA that are 21 nt in length, long enough to induce gene-specific suppression, but short enough to evade the host interferon response^[2,5]. However, this gene-specific suppression is transient, which severely restricts its applications. To overcome this restriction, various kinds of vectors have been designed to express siRNA or hairpin RNA transcripts to suppress expression of endogenous genes in mammalian cells^[6-8].

In this article, we constructed a plasmid to achieve RNAi in mammalian cells. With this plasmid, shRNA are predicted to be synthesized from a DNA template under the control of mU6 promoter (a kind of eukaryotic RNA polymerase III promoter) in transfected cells. This construction has two *BbsI* cloning sites under mU6 promoter to ensure the coding sequences for shRNA insert in the right direction and direct the synthesis of shRNA in cells. Also, this plasmid containing a neomycin resistance gene (*neo^r*) can be used for positive screening. These properties make it possible to use DNA templates to synthesize shRNA *in vivo* and produce RNAi activity to trigger silencing of homologous gene expression. Using this plasmid, we found that *bcl-xL* in NPC cells can be efficiently inhibited and then induce apoptosis in NPC cells.

Materials and methods

Construction of plasmid containing DNA template for synthesis of shRNA under the control of mU6 promoter mU6 promoter was obtained by cutting mU6pro (gift of Li-ping LI, Guangdong Medical College, Zhanjiang, China) with *BbsI* and cloned into pcDNA3 instead of its CMV promoter to generate the plasmid pmU6. A general strategy for constructing an RNAi plasmid involved cloning an inverted repeat into pmU6 at the *BbsI* site. The selection of the coding sequences for siRNA were empirically determined but were analyzed by BLAST search to ensure that they did not have significant sequence homology with other genes. To generate the pmU6 *bcl-xL* RNAi plasmid, a 21-nt oligo corresponding to nucleotides (605–625) of the *bcl-xL* coding region was designed together with the 9-nt spacer, five Ts and two *BbsI* sites. They were then inserted into the pmU6 vector digested with *BbsI* to generate pmU6 *bcl-xL* RNAi plasmid. This oligonucleotide sequence encoding shRNA for the targeted gene *bcl-xL* coding region was taken from GenBank accession Z23115 L20121, GI-510900 (nucleotides 605–625)^[9,10]. Primitive oligo is 5'-GGAGATGCAGGTATTG-

GTGAG-3' (forward) and 5'-CTCACCAATACCTGCATCTCC-3' (reverse). Modified oligos are primitive oligos plus the 9-nt spacer, five Ts and two *BbsI* sites, Modified oligo is 5' TTTGGGAGATGCAGGTATTGGTGAGTTCAAGAGACTCACCAATA-CCTGCATCTCCTTTTT 3' (forward) and 5' GCTAAAAA-AGGAGATGCAGGTATTGGTGA-GTCTCTTGAACCTCAC-CAATACCTGCATCTCC 3' (reverse).

Cell culture and transfections NPC cell line CNE-2Z cells were cultured in RPMI-1640 (GIBCO, NY, USA) complete culture medium which supplemented with 10% of heat-inactivated FBS (GIBCO, NY, USA), benzylpenicillin (100 kU/L) and streptomycin (100 mg/L) at 37 °C in an incubator in a humidified atmosphere, with 5% CO₂ in air. The cells were routinely passaged every 1 or 2 d^[11]. For transfection, 0.5 × 10⁵ cells mixed with 500 μL RPMI-1640 (Invitrogen, Carlsbad, CA, USA, supplemented with 10% of heat-inactivated FBS, without any antibiotic) were seeded into a well of a 24-well plate and incubated at 37 °C for 24 h. pmU6-RNAi plasmid and pTR-UF5 plasmid (gift of Dr Muzyczka, Florida University, USA) harboring green fluorescence protein (GFP) reporter gene were co-transfected using a Lipofectamine 2000 (Invitrogen, Carlsbad, CA, USA)-mediated method according to the manufacturer's protocol. Nearly confluent cells in 24-well plates were transfected with 2.0 μg of pmU6-RNAi plasmid and 0.2 μg of pTR-UF5 per well, the final concentration of plasmid was 0.4 μg/mL; the ratio of plasmid to lipofectamine was 1:1. After a 6 h-transfection, the medium was replaced by complete culture medium. Cells were continuously cultured until harvest for analysis.

Transfection efficiency assay The procedure of transfection was the same as described above. Cells were harvested after 24 h by centrifugation for 5 min at 200 × g, to remove cell debris and washed three times with phosphate buffered saline (PBS) by centrifugation for 5 min at 1000 × g to remove culture medium. Cells were then suspended again in PBS again for analysis by flow cytometry (Coulter, Becton Dickinson, USA). For each samples, at least 1 × 10⁴ cells were analyzed by flow cytometry. Results were presented as the number of green fluorescence cells versus the total cells detected by flow cytometry and repeated for at least 3 times^[12] and analyzed by Student's *t*-test.

Hoechst 33258 fluorescence staining CNE-2Z cells (1 × 10⁵) were seeded in a T-10 cm² cell culture plate and cultured in RPMI-1640 supplemented with 10% heat-inactivated FBS without antibiotic. After an incubation at 37 °C for 24 h, cells were transfected with 4.0 μg of pmU6-RNAi plasmid alone per plate. After a transfection for 6 h, the medium was changed to complete culture medium. Cells were collected

12 to 24 h after the transfection and centrifuged for 5 min at $200\times g$ to remove cell debris, and cells were washed three times with 0.9% saline after a centrifugation for 5 min at $1000\times g$ to remove culture medium. And then 10 μL of cell suspensions were treated with 10 μL of 10 mg/L Hoechst 33258 for 30 min in the dark. Ten μL of the stained cell suspensions were taken out and dripped on the slides and covered with a cover slip. The morphological changes of nuclei in CNE-2Z cells were observed by fluorescence microscope ($\times 400$) to discriminate native cells, apoptotic cells and necrotic cells. Cells were photographed and processed by Adobe PHOTOSHOP software.

Quantitative RT-PCR Cells were collected 12 to 48 h after transfection and washed with PBS (pH 7.3), homogenized once and centrifuged at $1000\times g$ for 5 min to remove culture medium. One mL TRIzol (Gibco, NY, USA) was added to the cell pellets, total RNA was extracted from with or without pmU6-RNAi plasmid transfected CNE-2Z cells according to a single step method (One-Step RT-PCR Kit, Applied QIAGEN Inc, USA). After centrifugation, the supernatant was extracted once with 0.2 mL chloroform and 0.5 mL isopropanol respectively, then total RNA was precipitated with 75% ice-cold ethanol (diluted with DEPC water). The precipitate was centrifuged and dissolved with 100 μL RNase-free water, after purification by a LiCl precipitating method, UV spectrophotometer analysis at 260 nm and electrophoresis detection showed good quality of purified RNA^[13]. The upstream primer of *bcl-xL* (amplified products were 448 bp) was 5'-CCCAGA AAG GAT ACA GCT GG-3', the downstream primer was 5'-GCG ATC CGA CTC ACC AAT AC-3'. The expression of house keeping gene, β -actin mRNA, was used as an internal standard^[14]. The upstream primer of β -actin (amplified products were 235 bp) is 5'-GGGAGC CAA AAG GGT CAT CAT CT-3', the downstream primer was 5'-GAG GGG CCA TCCACAGTCTTC T-3' (primers were commercially available). PCR were run 30 cycles for *bcl-xL* and β -actin in Eppendorf Mastercycler. Denaturing, annealing, and extension reactions were performed at 94 °C for 45 s, 55 °C for 1 min, and 72 °C for 1 min. The PCR products were electrophoresed on 1% agarose gel, stained with ethidium bromide, and detected by UV irradiation. The levels of *bcl-xL* mRNA were expressed as the ratio of *bcl-xL* to β -actin.

Western blotting The cells were washed three times with PBS and collected by scraping and were lysed in 150 μL of ice-cold Tris buffer (50 mmol/L, pH 7.5) containing edetic acid 5 mmol/L, NaCl 150 mmol/L, 0.1% NP-40, 0.1% SDS, 2.0 g/L aprotinin, 0.02% NaN_3 , PMSF 0.2 mmol/L, and antiprotease mixture, sonicated, and centrifuged at $12\,000\times g$ for 15 min and the concentration of protein in each lysate

was determined with Coomassie brilliant blue G-250. Loading buffer was added to each lysate, which was subsequently boiled for 3 min and then electrophoresed on a SDS-PAGE^[15]. Before electrophoresis, the proteins were mixed with 2 \times loading buffer (containing Tris-HCl 100 mmol pH 6.8, 20% Glycerin, 4% SDS, tetrabromophenol-sulfonphthalein 0.05 g/L and 10% 2- β -mercaptoethanol) by the same volume. Proteins were transferred onto nitrocellulose and incubated with antibody and then with peroxidase-conjugated secondary antibody in the second reaction (The anti-*bcl-xL* antibody was used at a 1:500 dilution, the anti- β -actin antibody was used at a 1:400 dilution, the anti-HA mAb was used at a 1:2500 dilution, all antibodies was obtained from Peking Zhongshan Biotechnology, Beijing, China). Detection was performed with enhanced chemiluminescence agent. The electrochemiluminescence (ECL) Test Kit-based detection was performed with Chemiluminescence Reagent (Sigma Life Science) according to the manufacturer's instructions. The results of Western blot analysis represented the average of three individual experiments.

Results analysis and statistics The electrophoregram of RT-PCR and Western blotting were scanned by Scanner and the optical density scores of bands were calculated to analyze the relative content of *bcl-xL* to β -actin. Differences between individual groups were analyzed by One-Way ANOVA with SPSS10.0 software, and the results was expressed as mean \pm SD.

Results

Analysis of transfection efficiency The expression of GFP in cells was detected by flow cytometry 24 h after co-transfection. Transfection efficiency was the rate of GFP expressing cells to the totally assayed cells; fluorescence index (FI) reflects the expression efficiency of the GFP gene^[16]. The transfection efficiency of the untreated control group and pTR-UF5 group was (0.4 \pm 0.4)% and (50.7 \pm 4.4)% respectively, implying lipofectamine-2000 can efficiently introduce plasmid into cancer cells. The FI of the control group and pTR-UF5 group was negative (-) and 13.0 \pm 0.3 ($P < 0.01$ vs control), respectively, showing GFP had a higher expression in NPC cells after introducing pTR-UF5 into cancer cells by lipofectamine-2000 (Figure 1).

Morphology of fluorescence staining cells Hoechst 33258 is a specific fluorescent stain. A small quantity of Hoechst 33258 will be allowed to enter normal cells because of its natural characteristics. Cell membrane permeability will be enhanced during apoptosis, which makes more Hoechst 33258 enter apoptotic cells than natural cells to bind

Figure 1. The fluorescence index of CNE-2Z cells transfected with lip-mediated plasmid of pTR-UF5. One of the three representatives.

with base regions of DNA. At disposal of Hoechst 33258, the apoptotic body or fragments of nuclei were stained a deep blue color, normal cells a light blue color, and the delimitation between cytoplasm and nuclei of necrotic cells became unclear for organelle swelling and lysis through fluorescence microscope. From the photographs (Figure 2), apoptotic cells were nearly invisible from the untreated group and the empty pmU6 group, whereas the pmU6-RNAi groups (12 h, 24 h, and 48 h after transfection) had more apoptotic cells compared to the above mentioned groups. These results showed that the pmU6-RNAi plasmid efficiently induced apoptosis in CNE-2Z cells by expressing shRNA.

Quantitative RT-PCR The reduction of mRNA was in a time-dependent manner (Figure 3) apart from the untreated and the pmU6 treated group. The mRNA was reduced by 90% to 99% 12 to 48 h after transfection with pmU6-RNAi, respectively (Figure 4). The results indicate that the shRNA expressed by the pmU6-RNAi plasmid in cells could efficiently suppress *bcl-xL* gene expression.

Western Blotting Western blot was used for the analysis of *bcl-xL* protein level. Compared with control, the pmU6-RNAi showed great capacities of inhibition at a protein level, and we also detected dramatic differences in the *Bcl-xL* protein levels between 24 h and 48 h after transfection, *Bcl-xL* protein was hardly measured after 48 h transfection (Figure 5, 6). This result suggested *bcl-xL* shRNA expressed by pmU6-RNAi could efficiently downregulate the protein level of *Bcl-xL*. Associated with the corresponding transfection time of *bcl-xL* mRNA levels and protein data, we found that *bcl-xL* shRNA could suppress *bcl-xL* gene expression, not only in transcript levels but also in protein levels.

Discussion

The expression level of some oncogenes such as *bcl-2/*

bcl-xL, *survivin*, and *caspase* is significantly related to the prognosis of NPC. Particularly, overexpression of *bcl-xL* is widely considered as a poor prognosis following a tumor resection and might be associated with increased resistance to cancer chemotherapy^[17,18]. Presently, radiotherapeutics and chemotherapeutics are the main therapies for this malignancy, and usually result in a favorable clinical response and a dramatic regression of NPC. But they have various kinds of unwanted side effects and locally advanced or metastatic NPC severely affect the prognosis in these patients and these therapies also fail to deliver a significant improvement in 5 year survival. It has been shown that specific suppression of over-expressed *bcl-xL* genes might result in an improvement in the therapy for this cancer. RNA interference, an useful tool for inhibiting the overexpression of specific oncogenes, was involved in the study of therapies for NPC in our study.

The *Bcl-2* family of proteins play major role in regulating apoptosis and include both anti- and pro-apoptotic members^[19]. The *bcl-xL* is an important anti-apoptotic member of the *bcl-2* family and it has 44% homology to *bcl-2*. Its function is similar to *bcl-2* in anti-apoptosis. Expression of this protein is significantly higher in NPC where it might play a pivotal role in tumor initiation, progression, and resistance to chemotherapy and radiotherapy^[20,21]. In the present study, we constructed a plasmid expressing *bcl-xL* shRNA that could suppress *bcl-xL* gene expression in cells, and results indicated that *bcl-xL* shRNA could efficiently inhibit the expression of the target genes. According to the morphology of Hoechst 33258 staining cells, more apoptotic cells could be seen from the pmU6-RNAi transfected group than the empty plasmid group and the untreated group. RT-PCR analysis and Western-blot assay further indicated *bcl-xL* shRNA expressed by pmU6-RNAi had silenced the target gene and induced apoptosis in NPC cells.

Our results showed an obvious difference of time course between inducing of apoptotic cells by Hoechst 33258 analysis and decrease of *bcl-xL* mRNA by quantitative RT-PCR analysis (compare Figure 2 to Figure 3). The change at the mRNA level in pmU6-RNAi (12 h) transfected cells was obvious, whereas apoptotic cells were observed until 24 h after transfection. This strongly suggested that down regulation of *bcl-xL* mRNA and protein, thereafter, by shRNA was the reason for apoptosis in NPC cells. The apoptosis occurred approximately 12 h after diminution of *bcl-xL* mRNA and finally the protein, to a definitive threshold.

Quantitative RT-PCR analysis of mRNA extracted from pmU6-RNAi transfected CNE-2Z cells was used to compare mRNA levels of *bcl-xL* with the corresponding protein data.

Figure 2. Fluorescence micrographs of Hoechst 33258 stained CNE-2Z cells after transfection with pmU6-RNAi for 12 h, 24 h, and 48 h, respectively. The arrows point to apoptotic cells. ($\times 400$). (A) Untreated group; (B) pmU6; (C) pmU6-RNAi (12 h); (D) pmU6-RNAi (24 h); (E) pmU6-RNAi (48 h).

From the analysis of RT-PCR, it showed that the *bcl-xL* mRNA levels between the empty plasmid group and the untreated group had no significant difference, and the results of quantitative RT-PCR analysis of *bcl-xL* revealed mRNA variations generally correlated with the Western blot data in our study. Another more interesting discovery was that pmU6-RNAi plasmid reduced *bcl-xL* mRNA levels by nearly 9.5-fold 12 h after transfection, almost equal to the decrease in the mRNA levels 24 h after transfection, despite significant and consistent changes were not always equal between mRNA and protein^[22]. The tendency for variations between them was a common coincidence in our present study. For example, pmU6-RNAi treated for 24 h reduced mRNA levels by nearly

9.5-fold, and the reduction at the protein level was 8.5-fold. In another example, we detected a >9.9 -fold decrease in the mRNA level by pmU6-RNAi (48 h) treated group, whereas the corresponding Western blots showed a 9.4-fold diminution in *bcl-xL* protein (compare Figure 4 to Figure 6). According to the above analysis, we presumed that there were similar changes between the protein level and the corresponding mRNA level of *bcl-xL* in pmU6-RNAi (12 h) treated group.

Based on the RNAi-mediated *bcl-xL* gene silencing in NPC cell line described above, we underlined the effects of *bcl-xL* shRNA to suppress *bcl-xL* gene expression. Taken together, these issues will have a profound influence on the use of RNAi technology, on a large scale, for functional

Abstract

Aim: To study the degrees of influence of changing side ester chains at position C20 of camptothecin on the anti-tumor activity of the molecules. **Methods:** The esterification reaction of camptothecin 1 and 9-nitrocamptothecin 2 with crotonic anhydride in pyridine gave the corresponding esters 3 and 4, respectively. The acylation of 1 and 2 with cinnamoyl chloride gave products 7 and 8. Epoxidation reaction of 3 and 4 with *m*-chloroperoxybenzoic acid in benzene solvent gave the products 5 and 6. Esters 3, 4, and 5 were tested for anti-tumor activity against 14 human cancer cell lines. **Results:** Both *in vitro* and *in vivo* anti-tumor activity studies for these esters were conducted and the data demonstrated positive results, that is, these esters were active against the tested tumor lines. **Conclusion:** Alkenyl esters 3 and 4 showed strong anti-tumor activity *in vitro* against 14 different cancer cell lines. Ester 3 was active against human breast carcinoma in mice and the toxicity of the agent was not observed in mice during the treatment, implying that this agent is effective for treatment with low toxicity.

Introduction

Camptothecin, a pentacyclic alkaloid derived from a Chinese tree *Camptotheca acuminata*, showed good anti-tumor activity against the mouse leukemia L1210 system^[1]. Camptothecin itself is water-insoluble. The sodium form of this compound was prepared and used in early clinical trials. Unfortunately, this carboxylate form of the molecule did not show the inherent anti-tumor activity, but severe toxicity^[2-6], which caused the discontinuation of human clinical trials in the 1970s. Pharmacology and activity studies conducted since then have demonstrated that the lactone form and the 20-S-OH group of the compound are the most important structural requirements for anti-cancer activity. For example, the carboxylate sodium salt form showed only one-tenth the potency of the lactone form in an anti-tumor assay (P388 rodent leukemia) conducted by Wani *et al*^[7]. In order to increase the stability of the lactone form of the molecule, we previously reported the preparation of alkyl camptothecin esters (Scheme 1)^[8]. These alkyl camptothecin esters substantially increase the stability of the lactone form of the drug in mouse and human plasmas, and also the biological

life of the active form of the drug in body. Zhao *et al* also reports that the 20-acylation of camptothecin brings lactone stabilization^[9]. It is established that the 20-acylation of camptothecin is an effective method of increasing the lactone stability of the molecule.

Our structure-activity relationship (SAR) studies of alkyl camptothecin esters indicated that the anti-tumor activity of alkyl camptothecin esters A depends on the geometric shape of their side alkyl chains. For example, of all alkyl camptothecin esters tested, the compound with a C₂ straight alkyl chain (R₁=CH₂CH₃) shows good anti-tumor activity^[10,11]. The compound is less active when R₁ group in structure A becomes longer (C₃, or C₄), or bulkier (isopropyl group, or cyclic propyl group). The compound is inactive when the R₁ group in structure A becomes larger (C₅, C₆, etc). Based on these SAR studies we propose that the introduction of an unsaturated functional group such as a double-bond or an epoxy group into the side ester chain in structure A would have an effect on anti-tumor activity. We now wish to report the preparation of alkenyl camptothecin esters 3, 4, 7, and 8 and the corresponding epoxy derivatives 5-6 together with the pre-

Scheme 1.

liminary results of biological studies with these new compounds.

Materials and methods

General Dry nitrogen was routinely used as the reaction atmosphere in all reactions. All glassware was baked at 70 ± 10 °C for a minimum of 2 h before being used. Melting points were obtained with a MEL-TEMP melting point apparatus and were uncorrected. The ^1H NMR spectrums of approximately 10 % (w/v) solution in CDCl_3 were obtained at 270.05 MHz with a JEOL GX-270 WB NMR spectrometer. Chemical shifts are reported in parts per million (δ scale), employing tetramethylsilane as an internal standard. In reporting the NMR data, we have used the following abbreviations: coupling constants in Hertz (J), singlet (s), doublet (d), triplet (t), multiplet (m), and *etc.* Mass Spectra were recorded using a VG ZAB-SEQ mass spectrometer (VG Analytical Co, England) with a resolution of 10 000. Routinely used solvents such as THF and methylene chloride were dried and freshly distilled. Silica gel (230–400 mesh, Aldrich) for column chromatography was used for all product separations. TLC sheets (Silica gel with fluorescent indicator on polyethylene) employed in TLC (Thin-layer Chromatography) operations were purchased from Aldrich Chemical Co (Aldrich, Milwaukee, WI). The numbering system used in reporting NMR data were shown in Scheme 2. Camptothecin was purchased from China and purified before being used. Nine-nitrocamptothecin was prepared in our laboratory by using an established procedure^[14].

Preparation of camptothecin-20-O-crotonate 3 Crotonic anhydride (40 mL) and pyridine (30 mL) were mixed in a 100 mL round-bottomed flask equipped with a magnetic stirrer. To this solution, 8 g (0.0230 mol) of the starting camptothecin 1 was added. The mixture was stirred at 110 ± 10 °C with a sand bath for 15 h. After cooling to room temperature, the reaction mixture was poured onto 1000 mL petroleum ether while stirring. The crude products precipitated from petroleum

ether were collected by filtration and then separated by column chromatography with THF- CH_2Cl_2 (1:15) as eluent. Pure product 3 (3 g) was obtained as white powder after precipitation from 300 mL of petroleum ether, mp $218\text{--}220$ °C (deformed at 155 °C), yield 31%, purity 99% (HPLC); ^1H NMR: δ : 1.00 (3H, t, J 7.51, C19-methyl protons), 1.94 (3H, dd, $J_{\text{H}_{25}\text{-H}_{24}}$ 6.96, $J_{\text{H}_{25}\text{-H}_{23}}$ 1.89 Hz, C25-methyl protons), 2.15–2.35 (2H, m, C18-methylene protons), 5.28 (2H, s, C5-methylene protons), 5.38–5.74 (2H, dd, J 17.22, 17.22, C17-methylene protons), 5.99 (1H, d, J 13.92, C23-H), 7.05–7.14 (1H, dq, $J_{\text{H}_{24}\text{-H}_{23}}$ 15.38, $J_{\text{H}_{24}\text{-H}_{25}}$ 6.96, C24-H), 7.24 (1H, s, C14-H), 7.67 (1H, t, J 6.96, C10-H), 7.83 (1H, t, J 6.96, C11-H), 7.94 (1H, d, J 7.70, C9-H), 8.21 (1H, d, J 8.43, C12-H), 8.39 (1H, s, C7-H); m/z (relative intensity) 416 (M^+ , 20), 330 [$\text{M}-86$ ($\text{CH}_3\text{CH}=\text{CHCOOH}$), 100], 315 [$\text{M}-101$ ($\text{CH}_3\text{CH}=\text{CHCOOH}+\text{CH}_3$), 40], 302 [$\text{M}-114$ ($\text{CH}_3\text{CH}=\text{CHCOOH}+\text{CO}$), 73], 287 [$\text{M}-129$ ($\text{CH}_3\text{CH}=\text{CHCOOH}+\text{CO}_2+\text{H}$), 30], 274 (10), 259 (9), 246 (9), 234 (3), 218 (5), 205 (4), 191 (3). HMRS ($\text{C}_{24}\text{H}_{20}\text{N}_2\text{O}_5$): Found: 416.137, required, 416.137.

Preparation of 9-Nitrocamptothecin-20-O-crotonate 4 Using 3.0 g (0.0076 mol) of 9-nitrocamptothecin 2 as the starting material, the reaction was carried out in the same manner as when preparing 3. Pure product 4 (2.5 g) was obtained as yellow powder, mp $224\text{--}225$ °C (deformed twice at 180 °C and 203 °C respectively), yield 71%, purity 99% (HPLC); ^1H NMR: δ : 1.01 (3H, t, J 7.48, C19-methyl protons), 1.94 (3H, dd, $J_{\text{H}_{25}\text{-H}_{24}}$ 7.00, $J_{\text{H}_{25}\text{-H}_{23}}$ 1.83, C25-methyl protons), 2.15–2.33 (2H, m, C18-methylene protons), 5.36 (2H, s, C5-methylene protons), 5.40–5.73 (2H, dd, J 7.20 and 17.20, C17-methylene protons), 6.01 (1H, d, J 13.93, C23-H), 7.08–7.24 (1H, dq, $J_{\text{H}_{24}\text{-H}_{23}}$ 15.35, $J_{\text{H}_{24}\text{-H}_{25}}$ 6.98, C24-H), 7.26 (1H, s, C14-H), 7.92 (1H, t, J 6.98, C11-H), 8.47–8.53 (2H, m, C10-H and C12-H), 9.26 (1H, s, C7-H); m/z (relative intensity) 461 (M^+ , 15), 375 [$\text{M}-86$ ($\text{C}+\text{H}_3\text{CH}=\text{CHCOOH}$), 100], 360 [$\text{M}-101$ ($\text{CH}_3\text{CH}=\text{CHCOOH}+\text{CH}_3$), 32], 347 [$\text{M}-114$ ($\text{CH}_3\text{CH}=\text{CHCOOH}+\text{CO}$), 74], 332 [$\text{M}-129$ ($\text{CH}_3\text{CH}=\text{CHCOOH}+\text{CO}+\text{CH}_3$), 32], 319 (10), 302 (10), 286 (13), 274 (8), 216 (7). HMRS ($\text{C}_{24}\text{H}_{19}\text{N}_3\text{O}_7$): Found, 461.122, required, 461.122.

Scheme 2.

Preparation of camptothecin 20-O-(2',3'-epoxy)-butyrate

5 To 50 mL benzene in a 100-mL round-bottomed flask equipped with a magnetic stirrer 0.16 g (~0.0004 mol) of ester 3 and 150 mg of *m*-chloroperoxybenzoic acid (57%–86%, Aldrich Chemical) were added. The mixture was stirred at room temperature for a week. The solvent was removed by a rotary evaporator. The residue was chromatographically separated with THF-methylene chloride (1:10) as eluent. Pure product 5 (0.12 g) was obtained as white powder after precipitation from 100 mL of petroleum ether, mp 210–213 °C (decomposition, the crystals deformed at 175 °C), yield 72%, purity 99% (HPLC); ¹H NMR: δ; 0.99 (3H, t, *J* 7.51, C19-methyl protons), 1.90–1.94 (3H, dd, *J*_{H25-H24} 6.96, *J*_{H25-H23} 1.84, C25-methyl protons), 2.07–2.33 (2H, m, C18-methylene protons), 5.30 (2H, s, C5-methylene protons), 5.38–5.72 (2H, dd, *J* 17.59 and 17.95, C17-methylene protons), 5.95–6.02 (1H, dq, *J*_{H23-H24} 15.75, *J*_{H23-H25} 1.83, C23-H), 7.04–7.12 (1H, dq, *J*_{H24-H25} 6.59, *J*_{H24-H23} 15.38, C24-H), 7.22 (1H, s, C14-H), 7.75–8.01 (4H, m, C9–C12 aromatic protons), 8.78 (1H, s, 7-H); *m/z* (relative intensity) 432 (M⁺, 28), 416 [M-16(O), 12], 346 [M-86(C₄H₆O₂), 100], 331 [M-101(C₄H₅O₃), 53], 318 [M-114(C₄H₆O₂+CO), 75], 303 [M-129(C₄H₅O₃+CO), 54], 287 [M-145(C₄H₅O₃+CO₂), 27], 275 (15), 259 (7), 246 (8), 231 (5), 218 (8), 205 (10), 191 (5).

HRMS (C₂₄H₂₀N₂O₆): Found, 432.132, required, 432.132.

Preparation of 9-Nitrocamptothecin-20-O-(2',3'-epoxy)-butyrate 6 Using 0.9 g (~0.0020 mol) of 4 as starting material, the reaction was carried out in the same manner as when preparing 5. Pure product 6 (0.10 g) was obtained as yellow powders after precipitation from 100 mL of petroleum ether, mp 216–218 °C (decomposition, deformed at ~196 °C), yield 10%, purity 99% (HPLC); ¹H NMR: δ; 1.00 (3H, t, *J* 7.50, C19-methyl protons), 1.91–1.95 (3H, dd, *J*_{H25-H24} 6.97, *J*_{H25-H23} 1.85, C25-methyl protons), 2.05–2.31 (2H, m, C18-methylene protons), 5.31 (2H, s, C5-methylene protons), 5.39–5.74 (2H, dd, *J* 17.60 and 17.94, C17-methylene protons), 5.97–6.04 (1H, dq, *J*_{H23-H24} 15.77, *J*_{H23-H25} 1.81, C23-H), 7.02–7.14 (1H, dq, *J*_{H24-H23} 15.40, *J*_{H24-H25} 6.61, C24-H), 7.24 (1H, s, C14-H), 7.78–8.10 (3H, m, C10-H, C11-H, and C12-H), 9.25 (1H, s, C7-H); *m/z* (relative intensity) 477 (M⁺, 30), 461 [M-16(O), 10], 391 [M-86(C₄H₆O₂), 100], 376 [M-101(C₄H₆O₃), 55], 363 [M-114(C₄H₆O₂+CO), 73], 348 [M-29(C₄H₆O₃+CO), 51], 332 [M-145(C₄H₆O₃+CO₂), 26], 320 (13), 314 (6), 301 (7), 286 (5), 273 (7), 268 (9), 254 (4). HRMS (C₂₄H₁₈N₃O₈): Found, 477.122, required, 477.121.

Preparation of camptothecin-20-O-cinnamate 7 Camptothecin 4.0 g (0.0115 mol) was added to 23 g (in excess) of cinnamoyl chloride in a 100 mL round-bottomed flask

equipped with a magnetic stirrer and a sand bath. The mixture was stirred at $110\pm 10^\circ\text{C}$ for 24 h. After cooling to 50°C , the reaction mixture was poured onto 400 mL petroleum ether portion by portion while stirring. The crude product was collected by filtration after precipitation from petroleum ether. The crude product was then added to 300 mL of acetone-petroleum ether mixture (100 mL acetone, 200 mL petroleum ether) and was refluxed for 1 h. The pure product was obtained as pale yellow crystals after precipitation from the acetone-petroleum ether solvent system, mp 268°C (deformed at 250°C), yield 80%, purity 99% (HPLC); $^1\text{H NMR}$ ($\text{Me}_2\text{SO}-d_6$): δ ; 0.97 (3H, t, J 7.325, C19-methyl protons), 2.09–2.26 (2H, m, C18-methylene protons), 5.27 (1H, s, C5-methylene protons), 5.53 (2H, s, C17-methylene protons), 6.86 (1H, d, J 16.381, C23-H), 7.04 (1H, s, C14-H), 7.442–7.813 (8H, m, C10-H, C11-14, C24-C30-Hs), 8.09 (2H, t (d+d), J 8.545 and 9.156, C9H and C12-H), 8.66 (1H, s, C7-H); $^{13}\text{C NMR}$ ($\text{Me}_2\text{SO}-d_6$): δ ; 7.68 (C19), 30.35 (C18), 50.30 (C5), 66.37 (C17), 75.87 (C20), 94.70 (C23), 116.64 (C14), 118.96, 127.75, 128.01, 128.53, 128.82, 128.92, 129.05, 129.84, 120.43, 131.09, 131.68, 133.69, 145.49, 146.04, 146.95, 147.81, 152.26, 156.63 (C2, C3, C6-C16a, C24-C30), 165.00, 167.32 (C21, C22); m/z (relative intensity) 478 (M^+ , 26), 330 [M-148 ($\text{C}_6\text{H}_5\text{CH}=\text{CHCOOH}$), 100], 315 (42), 302 (63), 287 (12), 259 (8), 246 (7), 234 (5); HRMS ($\text{C}_{29}\text{H}_{22}\text{N}_2\text{O}_3$): Found: 478.138, required, 478.137.

Preparation of 9-nitrocamptothecin-20-O-cinnamate 8

Nine-nitrocamptothecin 1.4 g (50% pure, prepared in our laboratory) was added all in once to 6.0 g of cinnamoyl chloride in a 100 mL round-bottomed flask equipped with a magnetic stirrer and a sand bath. The mixture was stirred at $110\pm 10^\circ\text{C}$ for 24 h. After cooling to 50°C , the reaction mixture was poured onto 100 mL petroleum ether while stirring. The crude products were precipitated from the solvent. After filtration the crude products were chromatographically separated with THF-methylene chloride (1:15) as an eluent. The pure product was obtained as yellow powders after precipitation from petroleum ether, mp 282°C , yield 21%, purity 99% (HPLC); $^1\text{H NMR}$: δ ; 1.04 (3H, t, J 7.325, C19-methyl protons), 2.156–2.40 (2H, m, C18-methylene protons), 5.36 (2H, s, C5-methylene protons), 5.42–5.75 (2H, dd, J 17.09 and 17.70, C17-methylene protons), 6.57 (1H, d, J 5.87, C23-H), 7.25 (1H, s, C14-H), 7.40–7.55 (5H, m, C10-H, C11-H, C12-H, C27-H, and C29-H), 7.74 (1H, d, J 16.47, C24-H), 7.87 (1H, t, J 7.94, C28-H), 8.44–8.48 (2H, m, C26-H, C30-H), 9.245 (1H, s, C7-H); $^{13}\text{C NMR}$: δ ; 7.64 (C19), 31.91 (C18), 50.20 (C5), 67.07 (C17), 75.80 (C20), 97.08 (C23), 116.12 (C14), 120.90, 121.56, 125.80, 127.37, 128.38, 128.54, 128.90, 130.94, 131.48, 133.85, 136.48, 144.50, 145.96, 147.46, 157.60 (C2, C3, C6-C16a, C25-C30), 167.323 (C21 or C22, one of them not found); m/z (relative

intensity) 523 (M^+ , 12), 375 [M-148 ($\text{C}_6\text{H}_5\text{CH}=\text{CHCOOH}$), 100], 360 (30), 347 (71), 332 (30); HRMS ($\text{C}_{29}\text{H}_{21}\text{N}_3\text{O}_7$): Found, 523.124, required, 523.123.

Growth inhibition assay To assess the anti-proliferative activity of the various esters, identical cell cultures received equimolar concentrations of these esters and the cell number per ml was counted using the Trypan blue exclusion method. Cells were seeded at a concentration of 2.5×10^4 cells per well in a 48-microwell plate. Three such plates were seeded for end-point observation of cytotoxicity after 3, 5, and 7 d of treatment. Two concentrations of each test compound were used, one which was equal to the known cytotoxic level of the parent compound and one which was four times that amount. Stocks consisted of fine suspensions of esters in polyethylene glycol (PEG-400; Aldrich). Control cultures received only the carrier. The cell number was counted at time points of 72, 120, and 168 h, respectively. The targeted cells included 14 human malignant cell lines: CLO breast carcinoma, MDA 231 breast carcinoma, BRO melanoma, SCH melanoma, MiaPaCa2 pancreatic carcinoma, panc1 pancreatic carcinoma, HT 29 colon carcinoma, MCCN colon carcinoma, EFO27 ovarian carcinoma, 2774 ovarian carcinoma, DU145 prostate carcinoma, PC3 prostate carcinoma, DOY lung carcinoma, and SPA lung carcinoma.

HPLC procedure for purity analysis The purities of the ester products were determined by HPLC analysis. The procedure was previously reported^[12].

In vivo toxicity and anti-tumor activity All the animal experiments were performed on nude Swiss mice of the NIH, high-fertility strain. They were bred and raised in our laboratory under strict pathogen-free conditions. For the *in vivo* toxicity and anti-tumor activity determination, a tumor xenograft growing in a nude mouse, approximately 1 cm^3 in size, was surgically removed under sterile conditions, finely minced with iridectomy scissors, and suspended in cell culture medium at the ratio 1:10, v/v. One half of 1 mL of this suspension, containing about 50 mg of wet-weight tumor mince was subcutaneously inoculated on the upper half of the dorsal thorax of the mouse. Groups of four or five animals were used. The drug was finely suspended in cottonseed oil and then injected into the stomach cavity of the mouse through the anterior abdominal wall using a 26-gauge needle. The weekly schedule previously established for intragastric injection of 9NC was once a day, 5 on, and 2 off. This schedule was employed throughout all the animal experiments. Treatment was initiated when the tumor had reached a volume of approximately 200 mm^3 , well-vascularized, measurable, and growing exponentially. Tumors growing in animals were checked and measured with a

caliper once a week.

Statistical analysis Data were expressed as mean±SD and compared with *t*-test.

Results and discussion

Chemistry A number of published reports have shown the methodologies for 20-OH acylation of camptothecins. Wall *et al* successfully prepared Camptothecin acetate by using the straight acylation reaction of camptothecin with acetic anhydride in pyridine^[1]. This compound was also prepared by two other different methods, one using acetic acid (rather than the reactive anhydride) as acylating agent with nitronium tetrafluoroborate as the catalyst, and one using trichloroethane as acylating agent with concentrate sulfuric acid as the reaction solvent^[12,13]. We used crotonic anhydride as acylating reagent to prepare alkenyl camptothecin esters 3 and 4. Camptothecin 1 and 9-nitrocamptothecin 2 were allowed to react with a largely excessive amount of crotonic anhydride in pyridine to give the corresponding products 3 (31% yield) and 4 (71% yield), respectively. The reaction mixture was heated with a sand bath at 110±10 °C for 15 h. The products 3 and 4 were obtained respectively as white crystals (3) and yellow crystals (4) after separation by column and precipitation from petroleum ether. The subsequent epoxidation of 3 and 4 with *m*-chloroperoxybenzoic acid in benzene solvent gave the corresponding products 5 and 6 in yields of 70% and 10%, respectively (Scheme 2). Esters 7 and 8 were obtained in yields of 80% and 21%, respectively by heating the starting 1 or 2 in cinnamoyl chloride. The proton NMR spectra showed characteristic peaks at

1.00±0.05 ppm for C19-methyl protons of compounds. The C18-methylene protons of these compounds absorbed in the 2.05 to 2.35 ppm region with a multiplet peaks. The C25-methyl protons showed characteristic double doublets at 1.90±1.94 ppm for compounds 3–6. The alkenyl C23 proton of ester 3 and 4 showed characteristic peaks at 6.00±0.01 ppm; the other alkenyl C24 proton absorbed in the 7.04 to 7.24 ppm region. Esters 7 and 8 absorbed at 6.72±0.15 ppm for C23 proton. The C23 proton of esters 5 and 6 absorbed in the 5.95 to 6.04 ppm region with dq peaks because of the remote coupling between C23-proton and C25-methyl protons; the C24 proton of these two epoxy derivatives absorbed in the 7.02 to 7.14 ppm region. The mass spectra of these esters showed characteristic fragmentation pathway as depicted in Scheme 3.

Biological studies Cytotoxicity of these esters was observed *in vitro* by microwell plate screening as a first means of determining whether or not a compound warrants further evaluation. Standard microscopic observation of toxicity includes changes in morphology and the percent of cells remaining after specified amount of time in treated versus untreated cells. These esters were tested *in vitro* against 14 human malignant cell lines for anti-tumor activity. The experimental results were shown in Table 1. Table 2 showed the comparison of IC₅₀ values of esters 3 and 4 to the commercially available camptothecin analogues, irinotecan (CPT-11) and topotecan. Figure 1 showed the anti-tumor activity of ester 3 against human breast carcinoma growing in nude mice as xenografts. Figure 2 showed the corresponding toxicity of ester 3 in mice. All esters tested in this study

Scheme 3.

showed anti-tumor activity. However, larger doses were needed for these compounds in order to show the same strength of anti-tumor activity of their parent compounds, implying these esters are prodrugs. It is apparent from Table 1 that esters 3 and 4 are active against the tested cell lines and have almost the same strengths. It is also clear that from these tests that the activity of ester 5 is slightly higher than esters 3 and 4. Finally, the data in Table 1 showed that esters 6, 7, and 8 were only slightly active against those tested cell lines when comparing them to the control. We chose esters 3 and 4 for the further IC₅₀ comparison studies because of the availability of the substances due to their easier syntheses. Irinotecan and topotecan are two camptothecin derivatives approved by FDA for treating cancer patients.

Number 4.00 represents the highest level of confluent cells at a given time point. A rating of 4.00 would be given to healthy dividing cells as seen in a control group and in a group treated with a drug which has no apparent cytotoxic effect. Number 3.00 represents 75% of the cells remain as compared to level 4.00; and accordingly, numbers 2.00 and 1.00 represent 50% and 25%, respectively, of the cells remain as compared to level 4.00. The numbers represent the growth inhibition. The smaller the number, the greater the inhibition.

The IC₅₀ values of esters 3 and 4 are compared to the IC₅₀ values of two marketed camptothecin analogues as shown in Table 2. In terms of IC₅₀ values, ester 3 is 3 to 12 folds more potent than irinotecan against all testing cell lines and 1.3 to 3 folds more potent than topotecan against almost every testing cell line except for cell line McCain; ester 4 is 4 to 27 folds more potent than irinotecan and 1 to 4 folds more potent than topotecan against all testing cell lines. We also found that the anti-tumor activity of these new esters is same as or slightly higher than the corresponding alkyl derivatives when comparing the data in Table 1 to the data we previously reported for the corresponding alkyl ester compounds^[10,11]. Thus, the introduction of an unsaturated double bond into the side ester chain of the molecule does not significantly alter the anti-tumor activity. We also chose ester 3 for the *in vivo* evaluation because of the availability of the

Table 2. Comparison of IC₅₀ values of esters 3 and 4 to commercially available anticancer agents irinotecan and topotecan. *n*=3. Mean±SD.

HT-29 and McCain: human colon cell lines; T47D and Kielty: human breast cell lines; DU-145: human prostate cell line; MPC2: Human pancrea cell line; DOY: human lung cell line; SchC11 and BRO: human melanoma cell lines.

larger scale synthesis of the molecule. Figure 1 shows the anti-tumor activity of ester 3 at a dose of 8 mg/kg against human breast carcinoma growing as xenografts in nude mice, and Figure 2 shows the corresponding toxicity of 3 at same dose level in mice. It is apparent from these *in vivo* studies that compound 3 completely inhibits the growth of human breast tumor in mice with no signs of toxicity as the bodyweight of mice increased slightly during the treatment.

Figure 1. Anti-tumor activity of ester 3 against human breast cancer in mice. *n*=8.

Figure 2. Toxicity of ester 3 in mice. *n*=8.

In conclusion, alkenyl camptothecin esters 3 and 4 can be obtained by the straight esterification of the corresponding starting mother compounds with crotonic anhydride. These two compounds are more potent than the commercially available camptothecin analogues, irinotecan and topotecan, in terms of IC_{50} values. Furthermore, compound 3 shows strong *in vivo* anti-tumor activity against human breast carcinoma in mice with no signs of toxicity. Thus, these alkenyl camptothecin esters have great potential to be developed for human treatment.

Abstract

Aim: To study the *in vitro* release of recombinant human tumor necrosis factor- α (rHuTNF- α) encapsulated in poly (methoxypolyethyleneglycol cyanoacrylate-co-*n*-hexadecyl cyanoacrylate) (PEG-PHDCA) nanoparticles, and investigate the influence of methoxypolyethyleneglycol (MePEG) molecular weight and particle size. **Methods:** Three sizes (approximately 80, 170, and 240 nm) of PEG-PHDCA nanoparticles loading rHuTNF- α were prepared at different MePEG molecular weights (M_r =2000, 5000, and 10 000) using the double emulsion method. The *in vitro* rHuTNF- α release was studied in PBS and rat plasma. **Results:** A higher burst-release and cumulative-release rate were observed for nanoparticles with higher MePEG molecular weight or smaller particle size. A decreased cumulative release of rHuTNF- α following the initial burst effect was found in PBS, while the particle sizes remained constant and MePEG liberated. In contrast, in rat plasma, slowly increased cumulative-release profiles were obtained after the burst effect. During a 5-h incubation in rat plasma, more than 50% of the PEG-PHDCA nanoparticles degraded. **Conclusion:** The MePEG molecular weight and particle size had an obvious influence on rHuTNF- α release. rHuTNF- α released from PEG-PHDCA nanoparticles in a diffusion-based pattern in PBS, but in a diffusion and erosion-controlled manner in rat plasma.

Introduction

The rapid removal of colloidal drug carrier systems in blood by the mononuclear phagocytic system (MPS), which is comprised mainly of Kupffer cells of the liver and macrophages of the spleen, has been identified as major obstacle in the efficient targeting of colloidal particles in sites such as solid tumors and inflammatory regions^[1,2]. Recently, a great deal of work has been devoted to developing “stealth” particles that are “invisible” to macrophages. Stealth nanoparticles (NP) are characterized by a prolonged half-life in the blood compartment that allows them to extravasate and accumulate more in pathological sites, such as tumors with leaky vasculature caused by the “enhanced permeability and retention effect”^[3,4]. In our previous study, higher intratumoral drug accumulation and antitumor potency were achieved for recombinant human tumor necrosis factor- α (rHuTNF- α)-loaded stealth poly (methoxypolye-

thyleneglycol cyanoacrylate-co-*n*-hexadecyl cyanoacrylate) (PEG-PHDCA) NP with sizes of approximately 150 nm and methoxypolyethyleneglycol (MePEG) molecular weight of 5000^[5].

It is known that surface properties, particle size, and drug release behavior are the key for the biological fate of stealth NP. However, no previous study has focused on the relationship between these characteristics and their ability to accumulate in tumors and antitumor efficacy. The aim of the present study is to investigate the influence of MePEG molecular weight and particle size on their long-circulating properties, tumor targeting, and antitumor efficacy. In this article, rHuTNF- α -loaded PEG-PHDCA NP with various MePEG molecular weights and particle sizes were elaborated. The particle physicochemical characteristics, drug release behaviors and mechanisms in PBS and rat plasma were determined. This work on the *in vitro* characteristics of

stealth NP might contribute to further understanding of their *in vivo* biological fate and tumor targeting properties.

Materials and methods

Reagents and drugs rHuTNF- α ($M_r=17\ 000$) was supplied by Shanghai Research Center of Biotechnology, Chinese Academy of Sciences (Shanghai, China). MePEG ($M_r=2000, 5000$), human serum albumin (HSA), and Na¹²⁵I were obtained from Sigma Chemical (St Louis, MO, USA). MePEG ($M_r=10\ 000$) was donated by the Department of Polymer Material and Science of Fudan University. Cyanoacetic acid, 1,3-dicyclohexyl carbodiimide, 4-(dimethylamino)pyridine, and poly (vinylalcohol) (PVA) ($M_r=16\ 000$, 98% hydrolyzed) were purchased from Acros Organics (Geel, Belgium). All other reagents and solvents were of analytical grade.

Preparation and measurement of PEG-PHDCA polymers PEG-PHDCA was synthesized as described^[6] in a previous study at an MePEG to *n*-hexadecyl ratio of 1:5 with appropriate modifications. The poly (*n*-hexadecyl cyanoacrylate) (PHDCA) was synthesized and used as a control.

¹H-NMR and ¹³C-NMR spectra were recorded in CDCl₃ on a Mercury Plus 400 MHz spectrometer. Recognition of methyl, methylene, methane and quaternary carbon nuclei in ¹³C-NMR spectra rested on the BB and DEPT-135. FTIR spectra (Avatar 360ESP) were obtained from a neat film cast from the chloroform copolymer solution between KBr tablets. GPC of polymers was performed in tetrahydrofuran with a Waters Associates Model ALC/GPC 244 apparatus. Molecular weight and molecular weight distribution of polymers were calculated by using polystyrene as the standard.

Preparation of rHuTNF- α -loaded nanoparticles rHuTNF- α was labeled with ¹²⁵I using the IODO-GEN procedure. Briefly, 100 μ g of protein in 60 μ L of potassium phosphate buffer (0.1 mol/L, pH 7.4) was layered over a freshly prepared film of IODO-GEN (100 μ g) and incubated at 4 °C for 10 min with 2 mCi of carrier-free Na¹²⁵I. The reaction mixture was made up to 0.5 mL volume with PBS, and the unreacted iodine was removed by gel filtration chromatography on a Sephadex G-25 PD10 column equilibrated with PBS. The specific radioactivity of the product was assessed in an autogamma (Packard Instruments, CT, Meriden, USA).

NP were prepared by an adjustment of the double emulsion ($w_1/o/w_2$) procedure as described in a previous study^[7]. A w_1/o emulsion was prepared by sonicating 0.1 mL of a rHuTNF- α solution (w_1) containing HSA (2%, w/v) with a PEG-PHDCA or PHDCA solution in methylene chloride in an ice bath. The first emulsion was then poured into a PVA

solution and sonicated in an ice bath. The double emulsion ($w_1/o/w_2$) obtained was diluted in 150 mL PVA solution (0.1%, w/v) and the organic solvent was evaporated at room temperature under reduced pressure. Finally, the NP were isolated and collected by two cycles of ultracentrifugation at 21 000 \times g for 40 min and washed three times with water.

Particle size and zeta potential measurement Particle size was determined in double distilled water by dynamic light scattering using Nicomp 380ZLS (NICOMP Particle Sizing Systems, Santa Barbara, CA, USA). Determinations were carried out at 23 °C at a fixed angle of 90°. He-Ne laser was operated at 632.8 nm as light source.

Zeta potential of the NP was determined in double distilled water using electrophoretic light scattering technique on a Nicomp 380ZLS instrument.

Determination of entrapment efficiency and drug loading The NP containing rHuTNF- α and [¹²⁵I]-iodinated rHuTNF- α with HSA (2.0%) were centrifuged, washed and the supernatants were assessed for gamma emission. The amount of rHuTNF- α encapsulated in the NPs was calculated by the difference between the total amount used to prepare the NP and the amount of rHuTNF- α present in the aqueous phase. The rHuTNF- α loading of the NP, given as a percentage, indicates the amount of protein encapsulated per 100 mg of NP.

rHuTNF- α release and MePEG liberation in PBS *In vitro* release studies were performed in triplicate in 25 mL of phosphate buffered saline (PBS, 0.05 mol/L, pH 7.4) containing 0.2% (w/v) sodium azide. The NP suspensions were continuously stirred in a thermoshake (60 r/min) at 37 °C in dark. At predetermined time intervals, 1 mL samples were withdrawn, centrifuged at 21 000 \times g for 40 min, and replaced by fresh release medium. The 0.5 mL supernatant was removed for measurement of the released rHuTNF- α fraction, by radioactivity counting.

For PEG-PHDCA NP, MePEG liberated during drug release in PBS was assayed using an iodine complexation method^[8]. At preselected times, 0.8 mL of supernatant was collected by centrifugation of NP suspensions at 21 000 \times g for 40 min, diluted with 1.2 mL double-distilled water and then mixed with 50 μ L of iodine solution composed of I₂ (10 g/L) and KI (20 g/L). After 5 min of incubation at room temperature in dark, the absorbance at 525 nm was read against a blank. In order to assay the total amount of MePEG in NP, the NP suspensions were digested by NaOH (2 mol/L) at 50 °C for 5 d. The method was linear in the range of MePEG concentrations measured (1–25 mg/L).

rHuTNF- α release and nanoparticle degradation in rat plasma A total of 0.5 mL of each NP suspension was

incubated with equal volumes of fresh rat plasma in a water bath at 37 °C in dark. At 0.5, 1, 2, 3, 4, and 5 h, the NP were separated from release medium by centrifugation at 21 000×*g* for 40 min. The drug release (%) was determined at each time point from the ratio of radioactivity associated with the pellet and the supernatant^[9].

The degradation of the NP in rat plasma was performed by spectrophotometric measurements using a UV/VIS spectrophotometer (Shimadzu 2401) as described in a previous study^[10]. The reduction in light transmission at 450 nm was recorded for evaluating the degradation of NP.

rHuTNF- α adsorption on PHDCA nanoparticles Blank PHDCA NP (approximately 25 mg of NPs in 25 mL of 0.05 mol/L phosphate buffer, pH 7.4, stabilized with 0.2% (w/v) sodium azide) were incubated at 37 °C in a thermoshake (60 r/min) with an aqueous solution of rHuTNF- α (10 mg/L). At fixed time intervals, 1 mL of samples were centrifuged at 21 000×*g* for 40 min, and the amount of free rHuTNF- α in the supernatant was determined by radioactivity measurement. The amount of rHuTNF- α adsorbed on NP was determined using difference between the initial amount and the amount remaining in the supernatant.

Statistical analysis Physicochemical characteristics and *in vitro* release of NP were evaluated for statistical significance with analysis of variance (ANOVA) and Dunnett *t*-test.

Results

Characterization of PEG-PHDCA and PHDCA The ¹H-NMR, ¹³C-NMR, and FTIR spectra were consistent with the structures of polymers (figures not shown). GPC showed that all polymers had narrow size distribution with an index of polydispersity less than 1.1 (Table 1).

Physicochemical characteristics of nanoparticles The basic characteristics of the eight types of NP formulations are summarized in Table 2.

rHuTNF- α release and MePEG liberation in PBS The

influence of MePEG molecular weight on the protein release in PBS is shown in Figure 1. For each formulation, an initial burst release followed by a slow reduction of rHuTNF- α cumulative release was observed. More than 40% of rHuTNF- α released from the PEG-PHDCA NP during the first 1 h, but less than 10% of the drug released from the PHDCA NP during the same time. At d 8, PEG-PHDCA NP had a remarkably higher cumulative release ratio than PHDCA ($P<0.01$). As a whole, the cumulative release ratio increased with the increase of MePEG molecular weight ($P<0.05$). The effect of particle size on the rHuTNF- α release is compared in Figure 2. Each formulation showed burst effect followed by decreased rHuTNF- α cumulative release. For both PEG₅₀₀₀-PHDCA and PHDCA NP, the NP of the smallest size showed the largest burst effect and highest cumulative release ratio ($P<0.05$).

In the study of rHuTNF- α release in PBS, MePEG detachment from PEG-PHDCA NP was observed (Figure 3). In 8 d, about 35% (w/w) of MePEG liberated. The evolution of the mean diameters of the NP during the 8-d *in vitro* release period was studied. The initial size of all the NP formulations remained constant and no new larger or smaller size populations were observed until the end of this study.

rHuTNF- α release and nanoparticle degradation in rat plasma All NP formulations showed a greater burst effect in rat plasma than in PBS ($P<0.05$) (Figure 4). The amount of drug released increased with the increase of incubation time. The burst release amount depended on both the particle size and the MePEG molecular weight. It significantly varied in the following series: PEG₅₀₀₀-PHDCA NP (80.0 nm)>PEG₅₀₀₀-PHDCA NP (170.9 nm)>PEG₅₀₀₀-PHDCA NP (242.9 nm) ($P<0.01$); PHDCA NP (85.2 nm)>PHDCA NP (173.1 nm)>PHDCA NP (242.3 nm) ($P<0.01$); PEG₁₀₀₀₀-PHDCA NP (168.8 nm)>PEG₅₀₀₀-PHDCA NP (170.9 nm)>PEG₂₀₀₀-PHDCA NP (172.4 nm) ($P<0.01$).

In rat plasma, more than 50% of PEG-PHDCA NP were degraded in 5 h of incubation, while no degradation occurred

to PHDCA NP during the same time (Figure 5). For PEG-PHDCA NP, the degradation rate increased with the increase of MePEG molecular weight ($P<0.01$).

Evaluation of rHuTNF- α adsorption on PHDCA nanoparticles The aim of the present study was to shed light on the adsorption of rHuTNF- α on the hydrophobic blank PHDCA NP surface and to better understand what happens during its release from NP. The adsorption was studied for 8 d (Figure 6). The adsorption of rHuTNF- α on PHDCA NP was very rapid, depending on the particle size. It was shown that the adsorption capacity varies in the series: 85.2 nm>173.1 nm>242.3 nm ($P<0.05$). The adsorption plateau was reached after approximately 1 to 2 d.

Discussion

Both particle size and MePEG coating influenced the zeta potential (Table 2). In the same size range, the significant lower negative potentials were obtained for PEG-PHDCA

NP compared to PHDCA NP ($P<0.01$). This might be related to a shift of the hydrodynamic phase of shear to greater distance from the particle surface. The surface negative charge of PEG-PHDCA NP dramatically decreased with the increase of MePEG molecular weight. As for PEG₅₀₀₀-PHDCA NP, the surface charge notably increased when the particle size increased ($P<0.05$), and the reason is now under investigation.

In the same size range, PEG-PHDCA NP showed lower entrapment efficiency compared with PHDCA NP ($P<0.01$). The same results were obtained in the comparison made of PEG-PLA and PLA^[11] and those made of PEG-PLGA and PLGA NP^[12]. The difference might come from the presence of MePEG in the PHDCA chains, but the mechanism was indistinct. For PEG-PHDCA NP, entrapment efficiency increased with the increase of MePEG molecular weight ($P<0.05$), and the influence of particle size on the entrapment efficiency was irregular. No regular change with re-

spect to drug loading was found. And the differences of drug loading among PHDCA and PEG-PHDCA NP were not remarkable ($P>0.05$).

The burst release depended on MePEG molecular weight (Figure 1). It was shown that the higher the MePEG molecular weight, the more the rHuTNF- α burst release. It was reported that the faster release of tetanus toxoid from PLA-PEG microspheres than PLA could be related to their different inner structure and reduced protein-polymer interactions^[11]. Similarly, the MePEG chains in NP orient not only towards the external aqueous medium but also towards the inner aqueous phase^[13,14]. Thus the protein reservoirs are theoretically surrounded by a MePEG barrier, which reduces the interaction of rHuTNF- α with the PHDCA matrix^[7]. The different burst effect might result from the differ-

ent intensity of this interaction between rHuTNF- α and PHDCA. It is supposed that the longest chain (MePEG of 10 000) hindered the interaction between rHuTNF- α and PHDCA, and PEG₁₀₀₀₀-PHDCA NP had the highest burst effect. Higher burst release of small size NP than middle and large NP could be related to their larger surface areas (Figure 2).

For PEG-PHDCA NP, a reduction of rHuTNF- α release percentage following burst effect was observed in PBS. This same phenomenon in the process of protein release from NP was reported in other articles^[8,15]. MePEG chains can create a steric barrier around NP and repel proteins to some degree, in which the density of MePEG "brush" is of great importance^[16]. MePEG chains are highly hydrophilic and can facilitate the penetration of incubation medium, and hydroly-

Figure 5. Degradation profiles of rHuTNF- α -loaded NP in rat plasma. $n=3$. Mean \pm SD.

sis of the ester bonds associated to them^[10] (Figure 3). After partial MePEG detachment, the density of MePEG “brush” was not sufficient to repel proteins and rHuTNF- α was re-absorbed on the particle surface, which resulted in a decreased cumulative release ratio. The readsorption phenomenon is evidenced in the study of rHuTNF- α adsorption on blank PHDCA NP (Figure 6).

There might be competition between protein release from NPs and protein readsorption onto the NP surface^[15]. It is reasonable that the amount of rHuTNF- α detected in the supernatant was the result of rHuTNF- α release and rHuTNF- α readsorption onto the NP surface, each process having its

own rate that depended on the rHuTNF- α concentrations in NP and in release medium. After a certain time, the release plateau was reached, indicating that equilibrium was established between the release and readsorption of rHuTNF- α . Noticeably, the readsorption phenomenon in the present study did not occur in a previous study in our lab^[7]. We hypothesized that the loading of the NP used here was lower than that of the PEG₅₀₀₀-PHDCA NP (approximately 150 nm) prepared previously and relatively lower rHuTNF- α concentrations in NP were obtained in this study. Therefore it is possible that after a significant burst release, the rHuTNF- α concentration in NP is lower than that in the release medium and that a slow readsorption happened till the release plateau was reached. This could also be used to explain the readsorption of PHDCA NP.

The mean diameters of the eight types of NP remained constant during the 8-d release at 37 °C in PBS. The ratios of particle size after incubation to its initial size for each NP formulation were all in the range of 1.0 \pm 0.3, indicating no significant aggregation or degradation occurred^[17]. In summary, rHuTNF- α release was accompanied with constant particle size evolution and MePEG detachment from PEG-PHDCA NP in PBS. Combined with the known fact that polyalkylcyanoacrylate (PACA) polymer could be degraded mainly by enzymatic degradation^[10], and PACA NP degraded mainly by surface erosion^[18], it is hypothesized that rHuTNF- α release in PBS from PEG-PHDCA NP might follow a diffusion-based model.

Figure 5 showed that the presence of the MePEG chain greatly increased the degradation of PHDCA in rat plasma.

Figure 6. Adsorption kinetics of rHuTNF- α on blank PHDCA NP. (A) rHuTNF- α adsorption over 8 d; (B) a close up of the first 3 h. $n=3$. Mean \pm SD.

This might be a result of the enhanced penetration of the plasma and the esterase hydrolysis caused by the highly hydrophilic MePEG moieties in the polymer structure.

The influence of particle size and MePEG molecular weight on the release of rHuTNF- α in rat plasma was similar to that in PBS. But no decreased cumulative release profiles was observed. We supposed that a competitive readsorption existed between rHuTNF- α and the proteins in rat plasma. Relatively small amounts of rHuTNF- α in the supernatant could hardly be reabsorbed onto the NP surface with a great amount of plasma proteins. Thus, a slightly increased cumulative release percentage was obtained under this condition. The burst release of PEG-PHDCA NP was greater than that of PHDCA NP. This could be a result of PEG-PHDCA degradation and the hindrance of interaction between protein and PHDCA by MePEG chains. Combined with the NP degradation behavior in rat plasma, it can be expected that rHuTNF- α released in rat plasma in a diffusion-controlled pattern for PHDCA NP, but in a diffusion and erosion-controlled manner for PEG-PHDCA NP.

Compared with PHDCA NP, PEG-PHDCA NP had a much higher cumulative release ratio, but their burst effects were a bit larger, which was a disadvantage when designing a stealth delivery system. However, compared to the free drug, a markedly extended circulating time was still obtained for stealth NP with high burst release^[19]. And it was reported that *in vitro* release behavior did not always coincide with *in vivo* circulation time of NP, which represented the more complex nature of the *in vivo* system^[20]. Therefore, for the validation of the “stealth” property of NP, pharmacokinetic studies *in vivo* are necessary. In view of the lower burst release possessed by PHDCA NPs, we supposed NP made with a proper ratio of PEG-PHDCA: PHDCA might have a lower burst effect as well as satisfactory cumulative release characteristics. This needs to be studied further.

In summary, a higher MePEG molecular weight offered higher entrapment efficiency, lower zeta potential, faster rHuTNF- α release rate and a larger cumulative release ratio. Larger particle size provided relatively higher surface charge, slower drug release rate and a smaller cumulative release ratio. rHuTNF- α release from PEG-PHDCA NP follows a diffusion-based model in PBS while a diffusion and erosion-controlled pattern in rat plasma. The present results implied that these NP might have different biological fates. The relationship between their *in vitro* characteristics and *in vivo* intratumoral drug accumulation and antitumor potency is now under investigation.

Abstract

Aim: To study the pharmacokinetics and tissue distribution of 5-fluorouracil encapsulated by galactosylceramide liposomes (5-Fu-GCL) in mice. **Methods:** The concentration of 5-fluorouracil (5-Fu) in serum was detected by high performance liquid chromatography after 5-Fu-GCL (80, 40, 20 mg/kg) and free 5-Fu (40 mg/kg) were injected intravenously into mice. The tissue distribution of 5-Fu-GCL (40 mg/kg) and free 5-Fu (40 mg/kg) was investigated, and concentration-time profile of the two preparations in the liver were studied. Data were analyzed by 3p97 program. **Results:** Serum concentration-time curves of 5-Fu-GCL and free 5-Fu conformed to one compartment model of first order absorption. 5-Fu-GCL at 80, 40, and 20 mg/kg had $T_{1/2Ke}$ of 25.8±4.2, 27.3±4.4, and 28.2±5.6 min; C_0 of 24.9±4.9, 17.7±3.6, and 11.5±2.7 mg/L; and AUC of 990.0±45.2, 622.5±38.3, and 340.4±25.6 mg·min·L⁻¹, respectively. In contrast free 5-Fu at 40 mg/kg had $T_{1/2Ke}$ of 15.8±2.2 min, C_0 of 35.8±6.2 mg/L, AUC of 639.0±35.9 mg·min·L⁻¹. The tissue distribution of 5-Fu-GCL in the liver and immune organs was significantly increased, while in heart and kidney it was remarkably decreased. The AUC of 5-Fu-GCL in the liver was 3 times higher than that of free 5-Fu. **Conclusion:** The pharmacokinetics and tissue distribution of 5-Fu-GCL appears to be linear-related and dose-dependent, and exhibits sustained-release and hepatic target characteristics.

Introduction

5-Fluorouracil (5-Fu) is a chemotherapeutic drug that is used widely for the treatment of malignant cancers, and is usually the first choice of drug for the treatment of hepatic cellular cancer. High doses of this drug are currently administered, mostly by continuous infusion, over 5 to 21 d^[1]. But its use has been limited by its systemic toxicities, which have severe gastrointestinal toxicities, hematologic side effects, and severe disturbance in bone marrow^[2]. Moreover, 5-Fu has a serum half-life of only 15 min, further limiting its usefulness^[3]. Several studies have reported a relationship between 5-Fu plasma levels and its toxicity, and the response to treatment. 5-Fu is often monitored in serum by pharmacokinetic follow-up with liquid chromatography^[4].

In order to maximize the therapeutic effect of 5-Fu and minimize its adverse effects, microsphere, liposome,

implants, and nanoparticles were made^[5–8]. But they were all passive for targeting preparations. Galactosylceramide (GC), as a novel membrane material, was adopted to envelop 5-Fu and form liposomes. This kind of 5-Fu preparation has not been previously reported. The purpose of this study was to measure the pharmacokinetic parameters and tissue distribution of 5-Fu-GCL in mice, which should supply evidence for its long effect and active targeting.

Materials and methods

Drugs and reagents 5-Fluorouracil encapsulated by galactosylceramide liposomes (5-Fu-GCL) (Batch No 20020318, enveloped rate: 52%), was made in the Institute of Clinical Pharmacology, Anhui Medical University. Free 5-Fu (Batch No 20020318, purity >99.3%), was obtained from Ji-nan Pharmaceutical Co (Ji-nan, China). Acetonitrile,

para-aminobenzoic acid and ethyl acetate was of analytical grade.

Apparatus Shimadzu LC-10A HPLC equipment consisted of LC-10A pumps, SCL-6A system controller, SPD-6AV ultraviolet spectrophotometric detector, ODS-C18 column (150 mm×4.6 mm) (Shimadzu Co, Japan), and V4.0⁺ software on a computer.

Animals Balb/c mice (male and female, 18–22 g) in the study were provided by the Experimental Animal Center of Anhui Medical University (certificate No 001). All animals were maintained at a controlled temperature (22±2 °C), and a regular light/dark cycle (7:00 AM to 19:00 PM, light), and all animals had free access to food and water. All experimental protocols described in this study were approved by the Ethics Review Committee for Animal Experimentation of Anhui Medical University.

Liposome preparation 5-Fu was encapsulated in liposomes made of galactocerebroside, Lecithin Granules and cholesterol in a molar ratio of 6:3:1. Liposomes were prepared by combined calcium-induced fusion with reverse evaporation method. In brief, phospholipids were dissolved in 0.7 mL of carbinol and chloroform compound with 2:1 volume and subjected to rotary evaporation until the lipid membrane formed. Then 1.5 mL of chloroform, 250 µL of 5-Fu (10 g/L) and 250 µL of ultrasonic buffer were added to the dried phospholipids, to which ultrasonic vibrations and rotary evaporation were carried out to wipe off organic solvent until the gel formed. Ultrasonic buffer 1.5 mL was added and the compounds were rotated at room temperature after which 125 µL of calcium liquor was added to 0.5 mL of liposomes prepared through reverse-phase evaporation. After incubation at 37 °C for 60 min, 12.5 µL of edetic acid (EDTA) was added to the compounds and shaken acutely, followed by incubation at 37 °C for 15 min and at room temperature for another 30 min. Using an initial drug-to-lipid molar ratio of 5:1, the enveloped rate was 52%. After being stored at 4 °C for 6 months, its permeability rate was less than 5%, which indicated the stability of 5-Fu-GCL was high. The recovery of 5-Fu-GCL was between 95.3% and 98.7%.

Pharmacokinetics of 5-Fu-GCL Two hundred and eighty-eight mice were randomly divided into four groups. Each group, which consisted of 36 males and 36 females, was injected with 5-Fu-GCL 20, 40, and 80 mg/kg or free 5-Fu 40 mg/kg through the tail vein. Before each injection and 2, 5, 10, 15, 20, 30, 45, 60, 90, 120, and 180 min later, 6 mice were anesthetized by diethyl ether, after which their eyeballs were excised and exsanguinated. Blood samples were centrifuged at 1400×g for 10 min to obtain 0.2 mL of serum each. Finally, mice were killed by dislocation of the

cervical vertebra^[9].

Tissue distribution of 5-Fu-GCL Twenty mice were stratified into two groups. Both groups including 5 males and 5 females were injected with 5-Fu-GCL 40 mg/kg and free 5-Fu 40 mg/kg through the caudal veins. Twenty minutes later, the mice were killed and the hearts, livers, spleens, lungs, kidneys, brains, lymph, thymuses, and marrow were removed, washed (except marrow), weighed, and homogenized using a tissue blender in 2 mL PBS solution. After extraction, concentrations in different tissues were detected by HPLC to study whether there were differences in distributions between the two groups^[10].

Concentration-time course of 5-Fu-GCL in liver The livers from mice untreated and treated with 5-Fu-GCL 40 mg/kg or free 5-Fu 40 mg/kg at 2, 5, 10, 15, 20, 30, 45, 60, 90, 120, and 180 min were removed, washed, weighed, and homogenized using a tissue blender in 2 mL PBS solution. The sample was extracted and detected by HPLC.

Analytical method The drug concentration in serum and tissues were analyzed by HPLC. The mobile phase components were water and acetonitrile (99:1). Ultraviolet wavelength was 205 nm. The flow-rate was 1 mL/min^[11,12].

The ratio of the peak area of 5-Fu to that of internal standard was plotted versus the concentration of the 5-Fu. Values of unknown serum drug concentrations were determined from calibration curve.

Standard solutions 5-Fu was dissolved in acetonitrile, then different amounts of this solution were added into blank 5-mL glass tubes and evaporated to dryness by nitrogen. The residues were dissolved with 0.2 mL mice serum or tissues to make 5-Fu of 0.313, 0.625, 1.25, 2.5, 5.0, 10.0, 20.0, and 40.0 mg/L, respectively, as serum standard solutions. The extraction of serum standard solutions was described in "Serum extraction procedure."

Sample extraction procedure Serum or tissue samples (0.2 mL) were added with 150 µL para-amino-benzoic acid (15 mg/L) as internal standard, distilled water (0.2 mL), and ethyl acetate (4 mL). They were then vortex-mixed in a 10-mL glass tube for 1 min. After centrifugation at 700×g for 20 min, the organic phase was aspirated. The remainder was extracted by addition of 4 mL ethyl acetate as described above. The two organic phases were mixed and evaporated until dry under a gentle stream of nitrogen at 35 °C in a water bath. The residues were reconstituted with 200 µL ethanol, and 50 µL of extracted samples were injected into the chromatography of liquid. On account of its character of being collapsed by ethyl acetate, 5-Fu-GCL could be detected as free 5-Fu. Both 5-Fu-GCL and free 5-Fu were detected by HPLC in the study.

Recovery, accuracy, and precision of 5-Fu Different 5-Fu standards were added into blank glass tubes and evaporated to dryness by nitrogen. The residues were dissolved with 0.2 mL serum or tissues to make concentrations of 0.313, 1.25, 5, and 20 mg/L. The samples were handled referring to the “serum extraction procedure.”

Five extracted samples of each concentration were determined. The recovery of 5-Fu in serum or tissues was assayed, and expressed as the percentage of detected concentrations to nominal concentration of standard (recovery). The accuracy of 5-Fu in serum or tissues was assayed, and expressed as the percentage of detected concentration to nominal concentration of serum or tissues (accuracy). Meanwhile, the inter-day and intra-day coefficient of variation of samples of different concentrations were measured 5 times on a single day and daily for a consecutive 5 d respectively (precision).

Pharmacokinetics calculations Pharmacokinetic parameters were calculated by 3p97 program.

Statistical analysis Data were presented as mean±SD. Statistical analysis of the data was performed using the *t*-test. *P*<0.05 was considered statistically significant.

Results

Method validation In the conditions described above, no significant interfering peak was observed. The retention time of 5-Fu was 7.7 min (Figure 1). The calibration curve of 5-fluorouracil in serum or tissue was in good linearity over the concentration range of 0.313–40.000 mg/L, and the coefficient of correlation was 0.9992–0.9996. The regression equation was: $A=0.10+2.18C$ (serum); $A=0.11+2.17C$ (heart); $A=0.11+2.19C$ (liver); $A=0.09+2.18C$ (spleen); $A=0.13+2.19C$ (lung); $A=0.10+2.17C$ (kidney);

$A=0.11+2.18C$ (brain); $A=0.13+2.21C$ (thymus); $A=0.12+2.20C$ (lymph); $A=0.12+2.19C$ (marrow). *A*: ratio of 5-Fu peak area to internal standard peak area; *C*: 5-Fu concentration. The limit of detection was 15.6 ng. The average recovery of 5-Fu was over the range of (80±3)%–(97±7)% (Table 1, 2) and the accuracy of 5-Fu was over the range of (93±4)%–(103±7)% (Table 3, 4). The inter-day and intra-day reproducibility of 5-Fu is shown in Table 5, 6, and the coefficient of variation was all below 10%. Meanwhile, the average recovery of internal standard was over the range of (88±4)%–(93±5)%. And the stability of internal standard was high because the deviation of it were all below 15%.

Pharmacokinetic parameters of 5-Fu-GCL in serum

Data of drug serum concentrations at different time points in three 5-Fu-GCL groups (80, 40, and 20 mg/kg) and free 5-Fu group (40 mg/kg) are shown in Figure 2.

Pharmacokinetic parameters were calculated by 3p97 program. Drug serum concentration-time course of 5-Fu-GCL groups (80, 40, and 20 mg/kg) and free 5-Fu group (40 mg/kg) conformed to one compartment model of the first

order absorption. Pharmacokinetic parameters of groups are shown in Table 7.

The results demonstrated that 5-Fu-GCL, in contrast to free 5-Fu, had delayed characteristics.

Concentration of 5-Fu-GCL in different tissue Distribution results showed that drug concentrations of 5-Fu-GCL in immune organs, which include the spleen, thymus, and lymph, but especially in the liver were remarkably higher than those of free 5-Fu at the same dose (40 mg/kg). Drug concentrations of 5-Fu-GCL in the heart and kidney were significant lower than that of free 5-Fu. In the brain, drug

mg·min·kg $^{-1}$).

Discussion

In drug delivery^[13], liposomes could congregate drugs in

certain tissues, decrease poisonous effects and increase the curative effect. Lecithoid material is the primary liposome in common use.

As GC is a cerebroside containing galactose, liposomes made of GC also possess galactose. As a result, this kind of

Figure 4. Liver concentration-time profile of 5-Fu after a single dose of 5-Fu-GCL or free 5-fluorouracil. *n*=6. Mean±SD.

liposome has a special bonding ability to salivary acid protein receptor located on the membrane of mammal^[14,15]. Compared with lecithoid^[16], GC has several advantages such as the stable chemical characters, the long retention in blood, the anti-oxide ability, and the unique directional trait. It could be developed to be a new kind of medicine carrier.

5-Fu is a dissoluble chemical with small molecules so it is difficult to achieve a highly enveloped rate. In a recent study, we applied combined calcium-induced fusion with reverse evaporation method to envelop 5-Fu, and the enveloped rate reached 52%.

Pharmacokinetic results showed that serum drug concentration curves of 5-Fu-GCL in single intravenous administration at 20, 40, and 80 mg/kg conformed to one compartment model of the first order absorption. Mean serum $T_{1/2Ke}$ of three dosage groups was similar. The pharmacokinetics of 5-Fu-GCL appeared to be linear over the doses. Both C_0 and AUC were enhanced as the dose increased. $T_{1/2Ke}$ of 5-Fu-GCL was much longer and the C_0 was strongly lower than those of free 5-Fu. All these results indicated that 5-Fu-GCL could be released much slower.

Because 5-Fu-GCL was injected through the vein and exhibited first order kinetic characteristics, it had no absorption or distribution phase and had only the elimination phase. For the study of tissue distribution one time point needed to be chosen. Tissue distribution results elucidated that the concentrations of 5-Fu-GCL in immune organs, especially in the liver, were remarkably higher than those of free 5-Fu with the same dose. Concentration-time course of 5-Fu-GCL in the liver showed that the AUC of 5-Fu-GCL was 3 times higher than that of free 5-Fu. This suggests that 5-Fu-GCL had a high selectivity to liver. In contrast, drug concentrations of 5-Fu-GCL in the heart and kidneys were significantly reduced, so we proposed that the toxicity of 5-Fu-GCL in the heart and kidneys were lower than that of free 5-Fu. Drug

concentrations of both 5-Fu-GCL and free 5-Fu were not detected in the brain. The data indicate that they did not cross the blood brain barrier.

Previous studies showed that LD_{50} of 5-Fu-GCL was higher than that of free 5-Fu, indicating that toxicity of 5-Fu-GCL was lower than that of free 5-Fu. We, therefore conclude that 5-Fu-GCL could prospectively be used to develop a novel preparation for liver cancer therapy with long efficacy, low toxicity, and directional peculiarity.

In this issue of *Acta Pharmacologica Sinica*, we are proud to present to our readers and colleagues a series of review articles from several Chinese-American university laboratories in USA^[1–6]. These reviews are a collection of the proceedings from the 8th Chinese Cardiovascular Pharmacology Conference held on July 23–26, 2004 in Urumchi, Xinjiang. As the first of its kind at any Chinese Pharmacological Society meeting, a half-day research symposium in English was held on the first day of this conference (an official meeting of the society held every three years for Chinese cardiovascular pharmacologists worldwide). The symposium was co-sponsored by the Cardiovascular Pharmacology Division of the Chinese Pharmacological Society and the Academy of Cardiovascular Research Excellence (ACRE), a non-profit academic organization in USA that includes many of prominent American faculties from mainland China in the field of cardiovascular research.

Like many other biomedical research areas in China, cardiovascular pharmacology research has experienced significant growth in recent years. The Cardiovascular Pharmacology Division is the largest division of the Chinese Pharmacological Society with the most registered members. Similarly, of all the original research articles published in *Acta Pharmacologica Sinica*, the premier pharmacology journal in China, the total number of cardiovascular pharmacology articles currently ranked first. An increasing number of cardiovascular pharmacology laboratories in China have recently begun to publish their original research findings in international journals, including some in the top-tier journals of cardiovascular research in the world^[7,8]. More and more principal investigators have also developed research collabora-

tions with a number of overseas laboratories. The aforementioned phenomena represent a promising trend towards a modernizing era of Chinese cardiovascular pharmacology in the early 21st century.

Despite the significant progress and growth, biomedical research in China still faces a number of major challenges as highlighted in two unprecedented “China voices” supplements recently published in *Nature*^[9,10]. Among these problems, a major issue is a lack of impact in scientific publications. Although the total publications from China ranked the ninth in the world between the years 1997–2001, the citations per paper from China ranked only the nineteenth with a rate of 1.56 according to a most recent study based on the ISI Essential Science Indicators^[11]. A prominent overseas Chinese-American scientist pointed out that as “measured by the number of original research papers published in internationally refereed high-impact journals”, a productive scientist should have “published at least eight highly cited research papers in the past ten years ... in a journal with an impact factor of at least two ... and at least one should be published in a journal with an impact factor of five or above”^[12]. If such a “not overly demanding standard”^[12] would be used to judge research productivity, concrete efforts must be made by a majority of Chinese cardiovascular pharmacologists to meet it.

Chinese pharmacologists worldwide are eager and determined to make a significant contribution to the success of the 15th World Congress of Pharmacology (IUPHAR) to be hosted by the Chinese Pharmacological Society in Beijing on July 2–7, 2006. The primary authors of this review collection all grew up in China and now have all established their

independent research laboratories in several major universities across the United States. The research work they presented in these reviews spans from molecular cardiovascular biology to integrated physiology and pharmacology. As an internationally refereed pharmacology journal with increasing impact, *Acta Pharmacologica Sinica* would like to showcase the research of these overseas Chinese cardiovascular pharmacologists in this issue, and by doing so hopes to enhance not only the research exchange and collaboration between Chinese pharmacologists at home and overseas, but also the quality and impact of Chinese pharmacology research in the world.

Abstract

Wound healing impairment represents a particularly challenging clinical problem to which no efficacious treatment regimens currently exist. The factors ensuring appropriate intercellular communication during wound repair are not completely understood. Although protein-type mediators are well-established players in this process, emerging evidence from both animal and human studies indicates that nitric oxide (NO) plays a key role in wound repair. The beneficial effects of NO on wound repair may be attributed to its functional influences on angiogenesis, inflammation, cell proliferation, matrix deposition, and remodeling. Recent findings from *in vitro* and *in vivo* studies of NO on wound repair are summarized in this review. The unveiled novel mechanisms support the use of NO-containing agents and/or NO synthase gene therapy as new therapeutic regimens for impaired wound healing.

Introduction

Wound repair is a well orchestrated and highly coordinated process that includes a series of overlapping phases: inflammation, cell proliferation, matrix deposition, and tissue remodeling. This involves a complex, dynamic series of events including clotting, inflammation, granulation tissue formation, epithelialization, neovascularization, collagen synthesis, and wound contraction^[1]. Loss of a functional healing process could lead to severe disabilities. Accordingly, chronic, non-healing wound conditions represent a situation of major clinical importance. The series of pathological changes associated with several diseases ultimately leads to severely disturbed wound healing conditions^[2]. Among those, the most prominent chronic wound impairments include decubitus or pressure ulcers, venous ulcers, and diabetic ulcers. The advent of molecular and cellular biology and the use of different modeling systems, most notably genetically engineered animals, have greatly extended our knowledge of wound repair. Inflammation, re-epithelialization, and granulation tissue formation are driven in part by a complex mixture of growth factors and cytokines, which are released coordinately into the wounds^[1,2]. Besides these protein-type factors and mitogens, evidence is emerging for the important role of small diffusible molecules such as nitric

oxide (NO) in wound repair^[3]. In this review, we summarize the current knowledge of the modulating functions of NO on wound repair.

Chemistry and biosynthesis of nitric oxide

NO is a highly diffusible intercellular signaling molecule implicated in a wide range of biological effects. It is generated by the enzyme nitric oxide synthase (NOS), which catalyzes the conversion of *L*-arginine to *L*-citrulline^[4]. Three NOS isoforms have been characterized, each encoded by different chromosomes. Two enzyme isoforms are constitutively expressed (endothelial and neuronal NOS), whereas one isoform is an inducible enzyme (iNOS), initially found in macrophages. All three NOS isoforms exist in their active form of homodimers of two domains: a C-terminal reductase domain, and an N-terminal oxygenase domain with molecular masses of approximately 135 kDa (eNOS), 150–160 kDa (nNOS), and 130 kDa (iNOS)^[4]. The reductase domain contains binding sites for one molecule each of nicotinamide adenine dinucleotide phosphate (NADPH), flavin mononucleotide (FMN), and flavin dinucleotide (FAD), in close homology with cytochrome P-450 reductase, whereas the oxygen domain binds heme, the essential cofactor tetrahydrobiopterin (BH₄), and the substrate *L*-arginine^[4].

Between these two regions lies the calmodulin (CaM) binding site, which plays a key role in both the structure and function of the enzyme. The constitutive isoforms (eNOS and nNOS) are permanently active, generating low concentrations of NO (in nmol/L range). Their enzymatic activities are regulated by intracellular calcium fluxes or exogenous calmodulin. The expression, transcription, and function of the iNOS is induced by a variety of cytokines, growth factors, and inflammatory stimuli on target cells which lead to the release of much higher levels of NO (in $\mu\text{mol/L}$ range), which is involved in host immune response.

All three NOS isoforms are expressed in skin tissue^[3]. Expression of nNOS has been observed in keratinocytes and melanocytes; eNOS can be detected in keratinocytes of the basal epidermal layer, dermal fibroblasts, endothelial capillaries, and eccrine glands; and iNOS can be induced in keratinocytes, fibroblasts, Langerhans, and endothelial cells. Accordingly, NO participates in the regulation of skin homeostatic functions such as circulation, sunburn erythema, and maintenance of the protective barrier against microorganisms.

Nitric oxide and wound healing

L-Arginine, the substrate for NOS, was first noted to enhance wound healing in 1978^[5]. Subsequently, dietary *L*-arginine intake has been shown to improve collagen deposition and wound strength in both animals and humans^[6-8]. This effect of *L*-arginine may be due in part to its conversion to *L*-ornithine through the action of arginase, an enzyme that may compete with NOS for *L*-arginine and thereby help regulate NO production during wound healing^[9]. However, the finding that *L*-arginine intake does not improve collagen deposition in iNOS-deficient mice to the same extent as in wild-type littermates implicates that part of *L*-arginine's effect involves NO directly^[10].

Accumulating evidence indicates that NO plays a key role in normal wound repair (Figure 1)^[11-18]. Production of nitrite (NO_2) and nitrate (NO_3), the stable NO metabolites, are elevated early in the fluid of subcutaneous wounds^[11], and urinary nitrate excretion increases in a sustained manner after excisional wounding^[12]. Furthermore, the presence of nitrite and nitrate is directly correlated with collagen deposition within the wound and in dermal fibroblasts, suggesting that NO synthesis is critical for wound collagen accumulation and acquisition of mechanical strength^[11,13,14]. All three NOS isozymes are involved in the wound healing process. Both iNOS and nNOS mRNA and protein expression are increased in cutaneous wounds^[15,16]. Our recent findings dem-

onstrate that there is a significant increase of cutaneous eNOS protein expression as well as constitutive NOS enzymatic activity after excisional wounding in normal mice^[17]. Consequently, an NO deficiency directly contributes to wound healing impairment. Inhibition of NOS by competitive inhibitors, either applied to the wound surface^[18] or given systemically^[11], decreases collagen deposition and breaking strength of incisional wounds and impairs the healing.

Consistent with these findings, studies with targeted disruption of NOS genes have revealed that the excisional wound closure is delayed by 30% in both eNOS and iNOS knockout mice compared to their wild-type littermates^[19,20]. Conversely, adenoviral vector-mediated gene transfer of iNOS to the wound site of iNOS knockout mice completely reversed the delayed healing^[20].

Finally, there are strong correlations between reduced cutaneous NO levels and impaired wound healing under disease conditions such as diabetes^[11,14,17,21], malnutrition^[13], and chronic steroid treatment^[18]. Diabetic wound healing impairment is one of the most well-known chronic wound situations. Studies of ours and others demonstrate that cutaneous eNOS expression, constitutive NOS activity, and/or NO levels are significantly decreased in streptozotocin (STZ)-induced type 1 diabetic animals^[11,14,17,21]. In fact, our findings indicate that the augmented cutaneous eNOS protein expression and constitutive NOS activity observed in normal animals in the healing process are absent in the type 1 diabetic mice^[17]. These findings suggest that impairment of wound-induced endogenous NOS expression and NOS activity is responsible for reduced cutaneous NO bioavailability in type 1 diabetic animals (Figure 1). In agreement with the above notion, cutaneous gene therapy of eNOS or manganese superoxide dismutase (MnSOD) restored eNOS protein and NO levels and accelerated the wound healing rate in STZ-induced diabetic mice^[17]. Similarly, the NO donor molsidomine (*N*-ethoxycarbonyl-3-morpholinyl-sidnonimine) or NO releasing poly (vinyl alcohol) hydrogel dressings are also shown to partially restore such healing impairment in STZ-induced diabetic rats^[22,23]. Collectively, impairment of skin NO function represents an important factor for delayed wound healing in diabetes and strategies aimed at restoring cutaneous NO bioavailability with NO donors or NOS gene therapy may serve as effective means for diabetic wound healing.

Mechanisms of nitric oxide on wound healing

NO and angiogenesis Angiogenesis, the process of forming new microvessels, is an important component of normal

Figure 1. Nitric oxide (NO) as a signaling molecule accelerates wound healing. Abbreviations: eNOS, endothelial nitric oxide synthase; iNOS, inducible nitric oxide synthase; MnSOD, manganese superoxide dismutase; VEGF, vascular endothelium growth factor.

wound repair. NO plays a central role in this process^[24] as it increases angiogenesis in ischemic murine tissues^[25]. Conversely, NOS inhibitors impair angiogenesis in granulation tissue during gastric ulcer healing^[26] and suppress capillary organization *in vitro*^[27].

NO is also vital to the activity of pro-angiogenic cytokines. Vascular endothelial growth factor (VEGF) is a potent angiogenic factor which involves the modulation of NO generation^[28]. VEGF increases NO production via upregulation of eNOS^[29,30]. Conversely, the angiogenic effect of VEGF also depends on NO as pharmacological blockade of NOS prevent both VEGF-induced endothelial cell proliferation and mitogen-activated protein (MAP) kinase^[31]. VEGF-stimulated endothelial cell migration, decreased adhesion, and organization are also dependent on NO^[32,33]. Keratinocytes are the major source of VEGF expression upon cytokine stimulation^[34], which is blocked by iNOS inhibitors both *in vitro* and *in vivo*^[35]. NO has also been shown to downregulate protein kinase C (PKC)-induced VEGF expression in smooth muscle cells by interfering with the binding of AP-1^[36] and to participate in the conversion of VEGF from an inert to an angiogenic form^[37]. Interestingly, NO is also involved in VEGF-independent angiogenesis mechanisms. Evidence includes the role of NO in monocyte-induced angiogenesis induced by monocytes^[38], substance P^[39], and transforming growth factor (TGF)- β 1^[40]. Taken together, these studies suggest a vital role of NO in post-wound

angiogenesis.

NO and inflammation NO has been shown to modulate chemoattractant cytokines that initiate post-wound inflammation, including interleukin (IL)-8^[41], TGF- β 1^[42], monocytes, and neutrophils^[43] that contribute to wound chemoattraction. Once monocytes and neutrophils are attracted to the site of a wound, they are activated and begin to produce TNF- α and IL-1, both of which are implicated in wound healing^[33]. Because IL-1 is a potent chemoattractant for keratinocytes, the modulation of IL-1 by NO may usher keratinocyte recruitment, proliferation, and differentiation. Taken together, NO modulation of inflammation-associated cytokines may affect the inflammatory phase of wound healing.

NO and cell proliferation, differentiation, and apoptosis NO affects proliferation, differentiation, and apoptosis in a number of cell types involved in wound healing. The iNOS inhibitor *N*^o-imino ethyl *L*-lysine (*L*-NIL) has been found to decrease proliferation in keratinocytes at the wound edge^[44]. Indeed, treatment of murine wounds with *L*-NIL leads to delayed re-epithelialization with atrophied hyperproliferative epithelium seen at the wound edge^[45]. Conversely, the NO donor sodium nitroprusside (SNP) significantly increases fetal bovine serum-induced thymidine incorporation into the DNA of human dermal fibroblasts and enhances fibroblast growth factor- or platelet-derived growth factor-induced DNA synthesis^[46]. Furthermore, low levels of NO increase keratinocyte proliferation *in vitro*^[44], an effect that is mimicked by 8-bromo-cGMP^[33], an analog of NO second messenger cGMP. NO also modulates keratinocyte apoptosis induced by irradiation of keratinocytes with ultraviolet B light as addition of NOS inhibitors to irradiated keratinocytes increases apoptosis, an effect that is reversed by the NO donor *S*-nitroso-penicillamine^[47]. It appears that both inducible and constitutive NOS are involved in this process. Furthermore, NO has been shown to stimulate the proliferation of endothelial cells, protect endothelial cells from apoptosis, and mediate VEGF production^[34]. These effects of NO on endothelial cells may also be related to another facet of wound healing, namely angiogenesis. In contrast, NO may also affect fibroblast proliferation. For instance, NO donor SNAP has been reported to decrease the proliferation of normal dermal fibroblasts in rats^[48] while increase their proliferation in mice^[49], even though the reasons for such discrepancy are not clear. Altogether, the above studies suggest that NO affect the proliferative phase of wound healing.

NO and matrix deposition and remodeling The final phases of healing require increased collagen synthesis and

deposition, and a link between NO and collagen deposition has been described^[11]. In most studies, treatment with NO donors, dietary *L*-arginine, or iNOS overexpression via gene therapy increased the collagen content of experimental wounds^[10,11,50,51]. Indeed, treatment with a NO donor has been shown to increase collagen formation in fibroblasts derived from both normal and wound skin, which was decreased following NOS inhibition^[51]. The effect of NO may primarily be due to the posttranslational enhancement of collagen synthesis rather than *de novo* transcription of the relevant collagen genes^[51].

Mechanisms of wound nitric oxide dysfunction

Although impaired NO function contributes to delayed wound healing in diabetes, the mechanisms of cutaneous NO dysfunction in this setting is unclear. In diabetes, causative factors for hyperglycemia-induced organ damage include the activation of the polyol pathway, nonenzymatic glycation, activation of PKC pathway, and increased hexosamine pathway flux^[52]. However, previously there was no apparent common element linking these mechanisms. Recent studies suggest that these different mechanisms may be linked by a single cellular process: an overproduction of superoxide induced by sustained hyperglycemia^[53]. Sustained hyperglycemia is known to increase vascular superoxide levels, resulting in cardiovascular dysfunction^[54]. Superoxide produced in the vasculature rapidly inactivates NO and thus reduces its bioavailability in diabetic vasculature^[55]. Independent strategies aimed at reducing superoxide levels have been shown to prevent high glucose-induced PKC activation, formation of advanced glycation end-products (AGEs), sorbitol accumulation, and NF κ B activation, resulting in improvement of endothelium-dependent NO-mediated vasodilation^[53,54]. These results indicate that increased superoxide levels are a key factor in vascular NO dysfunction in diabetes. However, whether sustained hyperglycemia increases cutaneous O₂⁻ levels and the mechanisms by which cutaneous NO levels are decreased in diabetes is unknown. Our recent studies demonstrate that glucose concentration-dependently increases superoxide levels in normal mouse skin and there is a marked increase of cutaneous superoxide levels in streptozotocin-induced type 1 diabetic mice^[17]. Furthermore, cutaneous gene therapy of MnSOD significantly reduced superoxide and increased NO levels, resulting in accelerated wound healing in this model. These results provide the direct evidence that increased cutaneous superoxide contributes to reduced NO bioavailability and wound healing impairment in diabetes (Figure 2).

Figure 2. The proposed mechanism by which superoxide contributes to decreased NO bioavailability and wound healing impairment in diabetes.

Future directions

Although a central role for several protein-type growth factors and mitogens on wound repair has been well-established for many years, the application of these factors in the treatment of wound healing has not provided a breakthrough in the clinical arena^[1,2]. One possible reason for the failure of markedly accelerating closure of chronic wounds may be due to increased protease activities in the wound fluids, which may impair the ability of endogenous and exogenously applied growth factor proteins to stimulate healing. In contrast, NO may represent a novel target molecule to circumvent these difficulties. Because NO is a short-lived gas molecule, maintaining an effective level of NO at the wound site is an obvious problem for clinical therapy. In recent studies we have demonstrated that gene therapy of NOS or SOD is effective in restoring cutaneous NO levels and accelerating wound healing in diabetic mice^[17]. Gene therapy strategies aimed at increasing NO or reducing superoxide levels may represent an effective means of reversing cutaneous NO deficiency at the wound site for healing refractory wounds in diabetes and other diseases. Future preclinical studies are warranted to optimize the designs and regimens before clinical trials can be conducted and the ultimate translation of basic science to the clinical settings for human gene therapy.

Abstract

In comparison to cation (K^+ , Na^+ , and Ca^{2+}) channels, much less is currently known about the functional role of anion (Cl^-) channels in cardiovascular physiology and pathophysiology. Over the past 15 years, various types of Cl^- currents have been recorded in cardiac cells from different species including humans. All cardiac Cl^- channels described to date may be encoded by five different Cl^- channel genes: the PKA- and PKC-activated cystic fibrosis transmembrane conductance regulator (*CFTR*), the volume-regulated *CIC-2* and *CIC-3*, and the Ca^{2+} -activated *CLCA* or *Bestrophin*. Recent studies using multiple approaches to examine the functional role of Cl^- channels in the context of health and disease have demonstrated that Cl^- channels might contribute to: 1) arrhythmogenesis in myocardial injury; 2) cardiac ischemic preconditioning; and 3) the adaptive remodeling of the heart during myocardial hypertrophy and heart failure. Therefore, anion channels represent very attractive novel targets for therapeutic approaches to the treatment of heart diseases. Recent evidence suggests that Cl^- channels, like cation channels, might function as a multiprotein complex or functional module. In the post-genome era, the emergence of functional proteomics has necessitated a new paradigm shift to the structural and functional assessment of integrated Cl^- channel multiprotein complexes in the heart, which could provide new insight into our understanding of the underlying mechanisms responsible for heart disease and protection.

Introduction

Abnormalities of cardiac ion channels have been linked to a variety of inherited and acquired cardiac diseases including myocardial ischemia, hypertrophy, heart failure, and arrhythmias^[1–5]. In addition, ion channels may also be mediators of the cardioprotective effects of ischemic preconditioning (IPC)^[6,7]. While cation (K^+ , Na^+ , and Ca^{2+}) channels have received the most attention in the past four decades, the role of anion channels in the cardiovascular system has been largely ignored. Within the last 15 years, a re-surgence of interest in Cl^- channels in the cardiovascular system has led to the discovery of at least seven different types of Cl^- currents in cardiac cells from different regions of the heart and in different species^[8]. Intensive efforts have been given to characterize the properties of these anion channels at the

cellular and molecular levels. More details about the biophysical, pharmacological, and molecular properties of Cl^- channels in the heart can be found in several recent excellent review articles^[8–11]. It has also been demonstrated in recent studies that Cl^- channels may be involved in the regulation of a large repertoire of cellular functions, including cellular excitability, cell volume homeostasis, intracellular organelles acidification, cell migration, proliferation and differentiation, and apoptosis^[8,9,12]. With the recent identification of molecular entities responsible for cardiac Cl^- channels^[8] and the genes mapped to specific human chromosomal locations^[13], gene targeting and transgenic techniques have been used to delineate the functional role of Cl^- channels in the context of health and disease. It has been reported that Cl^- channels could contribute to: 1) arrhythmogenesis in myo-

cardial injury; 2) the adaptive remodeling of the heart during myocardial hypertrophy and heart failure; and 3) IPC. Therefore, anion channels represent very attractive novel targets for therapeutic approaches to the treatment of heart diseases. In this review, we will briefly summarize the major findings and recent advances in the study of functional role of anion channels in the heart.

Anion channels in the heart

Since the independent discovery of a cAMP-activated Cl⁻ current in the guinea pig heart by Bainski *et al*, Harvey and Hume in 1989^[14,15], intensive efforts have been made to characterize Cl⁻ channels in the cardiovascular system at both the cellular and molecular levels. These have been

Figure 1. Schematic representation of anion channels in cardiac myocytes. Anion channels and their corresponding molecular entities or candidates are indicated in parentheses. $I_{Cl,PKA}$, Cl⁻ current regulated by adenylyl cyclase-cAMP-protein kinase A pathway; CFTR, cystic fibrosis transmembrane conductance regulator; M1-6, CFTR transmembrane spanning segments 1-6; M7-12, CFTR transmembrane spanning segments 7-12; NBD1, nucleotide binding domain 1; NBD2, nucleotide binding domain 2; R, regulatory subunit; P, phosphorylation sites for protein kinase A (PKA) and protein kinase C (PKC); PP, serine-threonine protein phosphatases; Gi, heterodimeric inhibitory G protein; A₁R, adenosine type I receptor; M₂R, muscarinic type II receptor; AC, adenylyl cyclase; H₂R, histamine type II receptor; G_s, heterodimeric stimulatory G protein; β-AR, β-adrenergic receptor; P₂R, purinergic type 2 receptor; $I_{Cl,vol}$, Cl⁻ current regulated by cell volume; CIC-3, member of voltage-gated CIC Cl⁻ channel family; $I_{Cl,Ca}$, Cl⁻ current regulated by intracellular Ca²⁺ concentration ([Ca²⁺]_i); CLCA1, member of a Ca²⁺-sensitive Cl⁻ channel family (CLCA); *Bestrophin*: the *Bestrophin* gene family; $I_{Cl,r}$, inward rectifying Cl⁻ current; CIC-2, member of voltage-gated CIC Cl⁻ channel family. Membrane topology models (α-helices A-X) for CIC-2 and CIC-3 are modified from Dutzler *et al*^[125].

recently reviewed and thoroughly described elsewhere^[8-11] and will not be repeated in this review. Briefly, at the molecular level, all cardiac Cl⁻ channels described so far may fall into the following Cl⁻ channel gene families (Figure 1): 1) the cystic fibrosis transmembrane conductance regulator (CFTR), which is a member of the adenosine triphosphate-binding cassette (ABC) superfamily and may be responsible for the Cl⁻ currents activated by protein kinase A (PKA) (I_{ClPKA})^[14-16], protein kinase C (PKC) (I_{ClPKC})^[17,18], and extracellular ATP (I_{ClATP}) in the heart^[19-21]; 2) CIC voltage-gated Cl⁻ channel superfamily: a) *CIC-2*, which is responsible for the hyperpolarization- and cell swelling-activated inwardly rectifying Cl⁻ current (I_{Clir})^[22-24]; b) *CIC-3*, which is responsible for the volume regulated outwardly rectifying Cl⁻ current (I_{Clvol}), including the basally-activated (I_{Clb})^[25] and swelling-activated ($I_{Clswell}$) components^[25-34]; 3) *CLCA-1*, which was thought to be responsible for the Ca²⁺-activated Cl⁻ current (I_{ClCa})^[35-38]; and 4) *Bestrophin*, a new candidate for I_{ClCa} ^[39-42]. Further studies on the molecular and functional properties of these Cl⁻ channel genes are necessary to define the structure of the channel proteins and to elucidate the physiological and clinical significance of these channels.

Functional role of Cl⁻ channels in cardiac diseases

Theoretically, Cl⁻ channels could be involved in the regulation of cellular excitability, cell volume homeostasis, intracellular organelles acidification, cell proliferation and differentiation, and apoptosis^[12]. Thus, they may have important physiological and pathological significance in cardiac function under normal and pathological (hypoxia, ischemia, myocardial infarction, hypertrophy, and heart failure) conditions. Mutations in several Cl⁻ channels have been known to result in human inherited diseases^[13]. But the exact role of Cl⁻ channels in human cardiovascular physiology and pathophysiology is still unclear^[8]. The ability to examine the exact role of Cl⁻ channels in human cardiovascular physiology and pathology has been hampered by the lack of specific pharmacological and molecular tools. With the recent identification of the molecular entities responsible for Cl⁻ channels in the heart^[8] and the genes mapped to specific human chromosomal locations^[13], it is now possible to overcome these obstacles by use of gene targeting and transgenic animals. We have been using a multitude of approaches from traditional methodologies including biophysics, biochemistry, electrophysiology, and pharmacology to state-of-the-art technologies including telemetry system, echocardiography, genomics, and proteomics to ef-

fectively and accurately define the role of each Cl⁻ channel in heart function in the context of health and disease.

Functional role in electrophysiology and arrhythmogenesis

Estimates of intracellular Cl⁻ activity (a_{Cl}^i) in cardiac myocytes from ion-selective microelectrode studies indicate the equilibrium potential for Cl⁻ (E_{Cl}) be more positive than the resting membrane potential under normal physiological conditions with an extracellular Cl⁻ concentration ($[Cl^-]_o$) of 145 mmol/L and an intracellular Cl⁻ concentration ($[Cl^-]_i$) of 10 to 20 mmol/L^[43-46]. Because the E_{Cl} is within a membrane potential range (usually -65 to -40 mV) that can be either negative or positive to the actual membrane potential during the normal cardiac cycle, activation of cardiac Cl⁻ channels can generate both inward and outward currents (Figure 2). Thus, compared with cationic channels, Cl⁻ channels have the unique ability to cause both depolarization as well as repolarization during the action potential and produce significant effects on cardiac pacemaker activity and action potential characteristics.

The degree to which activation of Cl⁻ currents depolarizes the resting membrane or accelerates the repolarization of action potential depends critically on the actual value of E_{Cl} and the magnitude of the Cl⁻ conductance relative to the total membrane conductance. Under physiological conditions the transmembrane Cl⁻ gradient is asymmetrical. Thus, the activation of CFTR and CIC-3 Cl⁻ channels in the heart will result in outwardly rectifying currents. This will have more significant effects at positive potentials to accelerate repolarization and shortening of the action potential duration compared with smaller depolarizing effects at negative potentials near the resting membrane potential (Figure 2). The ability of Cl⁻ current activation to depolarize cardiac cells is also opposed by the presence of a large background K⁺ conductance that normally controls the resting membrane potential. Both abbreviation of APD and depolarization of E_m upon activation of Cl⁻ channels may play a role in rhythm disturbance and likely contribute to arrhythmogenesis under pathological conditions.

CFTR and arrhythmogenesis CFTR channels are closed under basal conditions but can be open under conditions where intracellular PKA- and PKC-dependent phosphorylation activity is increased. A major physiological role of activation of CFTR channels may be to minimize (oppose) the significant action potential prolongation associated with β -adrenergic stimulation of I_{Ca} . This is expected to contribute to action potential shortening during strong adrenergic stimu-

Figure 2. Modulation of cardiac electrical activity by sarcolemmal anion channels in cardiac myocytes. Changes in action potentials (top) and membrane currents (bottom) caused by activation of cystic fibrosis transmembrane conductance regulator (CFTR) and volume-regulated CIC-3 Cl⁻ channels (A), Ca²⁺-activated Cl⁻ channels (B), CIC-2 channels (C) are depicted. $I_{Cl,CFTR}$ can be activated by stimulation of protein kinase A (PKA), protein kinase C (PKC), or purinergic receptors; $I_{Cl,Vol}$ is activated by cell swelling induced by exposure to hypotonic extracellular solutions or possibly membrane stretch; $I_{Cl,Ca}$ is activated by elevation of localized [Ca²⁺]_i. $I_{Cl,ir}$ is activated by hyperpolarization, cell swelling, acidosis. Range of estimates for normal physiological values for Cl⁻ equilibrium potential (E_{Cl}) is indicated in green in top panels in A–C; range of zero-current values corresponding to E_{Cl} is shown in green in bottom panels. Numbers in top panels of A–C illustrate conventional phases of a prototype ventricular action potential under control conditions (black) and after activation of I_{Cl} (red). In A, activation of I_{Cl} induces larger membrane depolarization and induction of early afterdepolarizations (EAD) under conditions where resting K⁺ conductance is reduced (dashed red lines); in B, activation of $I_{Cl,Ca}$ during [Ca²⁺]_i overload results in oscillatory transient inward current (I_{Tn}) and induction of delayed afterdepolarization (DAD); in C, activation of $I_{Cl,ir}$ during hyperpolarization causes acceleration of phase 4 depolarization and automaticity (dashed red lines, left panel) and shortening of action potential duration, membrane depolarization and/or phase 4 depolarization and induction of abnormal electrical impulse (trigger activity) and automaticity (right panel).

lation and faster heart rates. Therefore, activation of CFTR channels may prevent excessive prolongation of APD and protect the heart against the development of early after depolarizations (EAD) and triggered activity caused by activa-

tion of Ca²⁺ channels in the presence of β-adrenergic stimulation. EAD arising from phase 2 and 3 underlie focal triggered tachyarrhythmias and repolarization abnormalities, which contribute to cardiac sudden death^[47]. It is well-

established that APD prolongation favors EAD by allowing recovery of inward currents and, conversely, shortening of APD makes it more difficult to induce EAD. Therefore, activation of CFTR channels should protect against focal triggered arrhythmias. However, when background K^+ conductance is reduced in the case of myocardial hypokalemia, activation of CFTR channels will cause significant membrane depolarization and induce abnormal automaticity leading to the development of EAD (dotted red lines in Figure 2A). These predicted effects of CFTR channel activation on APD and automaticity have been verified experimentally by manipulations of the Cl^- gradient or the use of Cl^- channel blockers^[11,48-51]. Histamine was found to activate CFTR channels in ventricular myocytes and induce oscillatory activity and abnormal impulses in the heart, although the contribution of CFTR channels to these arrhythmogenic activities has not been further explored. It has been shown that activation of CFTR channels contributes to hypoxia-induced shortening in APD^[52]. Activation of CFTR channels may accelerate the development of reentry because of the shortening of APD and refractoriness and a decrease in conduction velocity caused by a slight depolarization of diastolic potential leading to Na^+ channel inactivation.

CIC-3 and arrhythmogenesis The current through CIC-3 channels under basal or isotonic conditions is small, but can be further activated by stretching of the cell membrane by inflation and/or cell swelling induced by exposure to hypotonic solutions. Activation of CIC-3 channels is expected to induce a similar effect on cardiac action potentials as that of activation of CFTR channels (Figure 2A) because both Cl^- currents through both channels are relatively time- and voltage-independent over the physiological range of membrane potentials^[53,54]. Activation of CIC-3 channels might produce more significant action potential shortening than CFTR channels because of its stronger outwardly rectifying property. Because myocardial cells swell during hypoxia and ischemia, and the washout of hyperosmotic extracellular fluid after reperfusion induces further cell swelling, activation of CIC-3 channels may also contribute to hypoxia, ischemia and reperfusion induced shortening in APD and arrhythmias^[9,53,54]. Abbreviation of APD and, therefore, the effective refractory period reduces the length of the conducting pathway needed to sustain reentry (wavelength). In principle, this favors the development of atrial or ventricular fibrillation, which depends on the presence of multiple reentrant circuits or rotating spiral waves. $I_{Cl,swell}$ also may slow or enhance the conduction of early extrasystoles, depending on the timing. In the case of myocardial hypertrophy and heart failure, ionic remodeling is one of the major

features of pathophysiological changes^[55]. It has been found that the current densities and molecular expression of several major repolarizing K^+ channels (such as $Kv4x$) are significantly reduced, which may be responsible for the prolongation of APD and development of EAD^[55]. However, under these conditions, $I_{Cl,vol}$ is constitutively active^[56]. The persistent activation of $I_{Cl,vol}$ may limit the APD prolongation and make it more difficult to elicit EAD. Indeed, as shown in Figure 3, in myocytes from hearts in failure, block of $I_{Cl,vol}$ by tamoxifen significantly prolonged APD and decreased the depolarizing current required to elicit EAD by about 50% (Figure 4B) and hyperosmotic cell shrinkage, which also inhibits $I_{Cl,vol}$, was almost equivalent to tamoxifen in causing EAD in these myocytes (Figure 4C)^[9]. Therefore, the consequences of activation of $I_{Cl,vol}$ are very complex. It may be detrimental, beneficial, or simultaneously both in different parts of the heart.

Figure 3. Activation of $I_{Cl,vol}$ shortened APD and increased threshold for inducing early afterdepolarizations (EAD) in canine ventricular myocytes isolated from infarction and peri-infarction zones 30 days after left anterior descending artery ligation (MI). EAD were elicited with depolarizing pulses (20–200 pA) and current-voltage relationships were obtained from the same cells (not shown). Threshold for inducing EAD was 120 pA in a post-MI ventricular myocyte in 1T. Tamoxifen (10 μ mol/L) reduced the threshold for induction of EAD in isotonic (1 T) solutions from 120 to 60 pA. Hyperosmotic shrinkage (in 1.5 T solutions), which also inhibits $I_{Cl,vol}$, reduced threshold for eliciting EAD to 40 pA. All panels from same cell under perforated patch conditions. (From Baumgarten and Cleme^[9] with permission from Elsevier Science).

It has been shown that mechanical stretching or dilation of the atrial myocardium is able to cause arrhythmias. Since $I_{Cl,swell}$ was also found in sino-atrial (S-A) nodal cells, CIC-3 channels may serve as a mediator of mechanotransduction and play a significant role in the pacemaker function if they act as the stretch activated channels in these cells^[9,57]. Baumgarten's laboratory has recently demonstrated that $I_{Cl,swell}$ in ventricular myocytes could be directly activated by

Figure 4. Contribution of I_{CLCa} to delayed afterdepolarization in ventricular and Purkinje myocytes. (A) Ventricular action potentials were recorded during control (●), 38 (1), and 45 (2) seconds after application of norepinephrine. Norepinephrine elevated the plateau and prolonged the action potential duration (1) and eventually caused delayed afterdepolarization (DAD) accompanied by transient repolarizations during the plateau (arrows). (B) Purkinje action potentials were recorded during control (●), 49 (1), and 52 (2) seconds after application of norepinephrine. Both action potentials recorded in the presence of norepinephrine were accompanied by DAD, but only the action potential recorded at (2) shows a transient repolarization (arrow) as well. (C) Membrane currents in ventricular myocyte activated by voltage steps from -53 mV to potentials between -23 and +37 mV in the presence of norepinephrine (1 mmol/L). Depolarization to -23 mV induced a large Ca^{2+} current which is superimposed with a transient outward current. This became more pronounced with stronger depolarization (From Verkerk *et al*^[64] with permission from American Heart Association).

mechanical stretch through selectively stretching $\beta 1$ -integrins with mAb-coated magnetic bead^[19,58,59]. Although it has been suggested that stretch and swelling activate the same anion channel in some non-cardiac cells, further study is needed to determine whether this is true in cardiac myocytes.

Ca^{2+} -activated Cl^{-} channel and arrhythmogenesis As illustrated in Figure 2B, the activation of I_{CLCa} will have considerably different effects on cardiac action potentials and resting membrane potential from those of CFTR and CIC-3 channels, even though I_{CLCa} is also expected to be outwardly rectifying under physiological conditions. This is because

the kinetic behavior of I_{CLCa} is significantly determined by the time course of the $[Ca^{2+}]_i$ transient^[60]. Normally, I_{CLCa} will have insignificant effects on the diastolic membrane potential, as resting $[Ca^{2+}]_i$ is low. When $[Ca^{2+}]_i$ is substantially increased above the physiological resting level, however, I_{CLCa} carries a significant amount of transient outward current. I_{CLCa} will be activated early during the action potential in response to an increase in $[Ca^{2+}]_i$ associated with Ca^{2+} -induced Ca^{2+} release (CICR). The time course of decline of the $[Ca^{2+}]_i$ transient will determine the extent to which I_{CLCa} contributes to early repolarization during phase 1 (Figure 2B). In the rabbit left ventricle, I_{CLCa} contributes to APD shortening in subendocardial myocytes but not in subepicardial myocytes. These differences in functional expression of I_{CLCa} may reduce the electrical heterogeneity in the left ventricle^[61]. In Ca^{2+} -overloaded cardiac preparations, I_{CLCa} can contribute to the arrhythmogenic transient inward current (I_{Ti} , Figure 2B)^[62]. I_{Ti} produces delayed afterdepolarization (DAD)^[63] and induces triggered activity (red dotted line in Figure 2B), which is an important mechanism for abnormal impulse formation. In sheep Purkinje and ventricular myocytes, activation of I_{CLCa} was found to induce DAD and plateau transient repolarization (Figure 4)^[64]. Therefore, blockade of I_{CLCa} may be potentially antiarrhythmic by reducing DAD amplitude and triggered activity based on DAD. However, the role of I_{CLCa} in phase 1 repolarization and the generation of EAD and DAD of either normal or failing human heart seem very limited^[65-67]. Therefore, the clinical relevance of I_{CLCa} blockers remains to be determined.

CIC-2 and arrhythmogenesis CIC-2 channels are activated by hyperpolarization, cell swelling, and acidosis and have an inwardly rectifying $I-V$ relationship. During the cardiac action potential, therefore, the CIC-2 channel will conduct a mainly inward current as a result of Cl^{-} efflux at negative membrane potentials and cause a depolarization of the resting membrane potential of cardiac cells. At membrane potentials more positive than E_{Cl} , CIC-2 may conduct a small outward current as a result of Cl^{-} influx and may accelerate repolarization of the action potential. It is also possible that, in a manner analogous to the role and tissue distribution pattern of the cationic pacemaker channels (I_f), Cl_{ir} channels normally play a much more prominent role in the SA or AV nodal regions of the heart (Figure 2C). The hyperpolarization-activated inward rectifying Cl^{-} current (I_{Clx}) through CIC-2 channels under basal or isotonic conditions is small, but can be further activated by hypotonic cell swelling^[22] and acidosis^[23,24]. The volume-sensitivity of the channel also suggests its role in cell volume regulation. The sensitivity of CIC-2 to $[H^{+}]_o$ and cell volume may be of pathologi-

cal importance during hypoxia- or ischemia-induced acidosis or cell swelling. Therefore, it may be possible that the significance of $I_{Cl_{ir}}$ in the heart becomes more prominent under some pathological conditions (ischemia or hypoxia)^[68]. As a matter of fact, ischemia and acidosis have consistently been shown to depolarize the resting membrane potential of cardiac myocytes, increase automaticity and cause lethal arrhythmias, although the mechanism has remained obscure^[1,11]. It is reasonable to suggest that an increase in CIC-2 conductance could be responsible for these phenomena and be pro-arrhythmic. Drugs targeting CIC-2 channels could be anti-arrhythmic. Therefore, the CIC-2 channels could have important clinical significance for such cardiac diseases as arrhythmias, ischemia and reperfusion, and congestive heart failure. Activation of CIC-2 current should mainly cause a depolarization of the RMP and it is suggested that the acidosis-induced increase in $I_{Cl_{ir}}$ might underlay the depolarization of the resting membrane potential during acidosis or hypoxia^[23,24].

It should be pointed out that prediction of the consequences of activation of Cl^- channels is complex. Most studies that have examined the contribution of Cl^- currents to the cardiac action potential and arrhythmias have relied on anion antagonist and substitution experiments. The pharmacological specificity of many of these anion channel antagonists can be problematic, and anion substitution, in addition to altering anion movement through channels, can have other unpredictable side effects on other transport proteins and signaling pathways^[69,70]. With the recent identification of the molecular entities responsible for Cl^- channels in the heart, it is now possible to combine electrophysiological, molecular biological, and especially gene-targeting techniques in the study of cardiac Cl^- channels to effectively and accurately define the role of each Cl^- channel in heart function. However, as the distribution of various Cl^- channels in the heart varies among cell types and regions^[8], activation of these channels may increase the dispersion of the electrophysiological properties and provide substrates for heart diseases involving cardiac arrhythmias and myocardial remodeling.

Functional role of Cl^- channels in cardiac IPC

Ischemia causes myocardial damage and leads to infarction through apoptosis (programmed cell death) and necrosis. IPC is a phenomenon in which brief ischemic episodes elicit protection of the heart against sustained ischemia. It has been suggested that both sarcolemmal and mitochondrial ATP-sensitive potassium channels (sarc- K_{ATP} and mito- K_{ATP} , respectively) may serve as triggers or end-effectors. PKC

may link cellular signal events during ischemia to the activation of end-effectors, which will somehow prevent or delay apoptosis and protect the cardiac myocytes. The precise mechanism of IPC, however, remains to be elucidated. Several recent studies have pointed to a potential role of Cl^- channels in IPC.

$I_{Cl_{swell}}$ and CIC-3 in IPC It has been reported that the block of $I_{Cl_{swell}}$ in rabbit cardiac myocytes inhibits preconditioning by brief ischemia, hypoosmotic stress^[71,72] and adenosine receptor agonists^[73]. These studies are solely based on the use of several Cl^- channel blockers, such as anthracene-9-carboxylic acid (9-AC) and 4-acetamide-4'-isothiocyanato-stilbene-2,2'-disulfonic acid (SITS). As mentioned above, these pharmacological tools lack specificity to a particular Cl^- channel in the heart and may also act on other ion channels or transporters. Therefore it has been very difficult to confirm the causal role of $I_{Cl_{swell}}$ in IPC^[74]. The exact role of $I_{Cl_{swell}}$ in IPC needs to be further determined adequately using more specific approaches. To specifically test whether the volume-regulated Cl^- channels are indeed involved in IPC, we have recently established *in vitro* and *in vivo* IPC models in CIC-3 knockout mice ($ClCn3^{-/-}$). Our preliminary results indicate that targeted inactivation of CIC-3 gene prevented protective effects of late IPC but not of early IPC, suggesting that $I_{Cl_{swell}}$ may contribute differently to early and late IPC^[75]. The underlying mechanisms for these differential effects are currently unknown. Recent reports, however, suggest that $I_{Cl_{swell}}$ and CIC-3 might play an important role in apoptosis. Cl^- channel blockers 4,4'-diisothiocyanato-stilbene-2,2'-disulphonate (DIDS) and 5-nitro-2-(3-phenylpropylamino)-benzoic acid (NPPB) were as potent as a broad-spectrum caspase inhibitor in preventing apoptosis and elevation of caspase-3 activity and improved cardiac contractile function after ischemia and *in vivo* reperfusion^[76]. Transgenic mice overexpressing Bcl-2 in the heart had significantly smaller infarct size and reduced apoptosis of myocytes after ischemia and reperfusion^[77]. It has been shown that Bcl-2 induces up-regulation of $I_{Cl_{vol}}$ by enhancing CIC-3 expression in human prostate cancer epithelial cells^[78]. Cell shrinkage is an integral part of apoptosis, suggesting that $I_{Cl_{vol}}$ and CIC-3 might be intimately linked to apoptotic events through regulation of cell volume homeostasis^[78,79].

CFTR channels and IPC Several lines of evidence suggest that CFTR channels could be involved in IPC including: (1) sarc- K_{ATP} blockers, such as glibenclamide, which suppress IPC protection, also block CFTR channels in noncardiac^[80,81] and cardiac cells^[19,82]; (2) PKC and PKA, two essential second messengers in IPC^[83,84] can activate CFTR

channels^[8,19,85]; and (3) triggers of IPC (nitric oxide, opioids, and adenosine *etc*) can all regulate CFTR channel function^[8]. We have directly tested whether activation of CFTR channels is involved in IPC by studying hemodynamics and tissue injury of hearts isolated from WT and two strains of *CFTR* knockout (*CFTR*^{-/-}) mice subjected to ischemia and reperfusion. In isolated mouse heart perfused in the Langendorff or working heart mode, we have recently found that targeted inactivation of *CFTR* gene prevented protection on cardiac function and myocardium injury against sustained ischemia by ischemic preconditioning (Figure 5)^[86]. Our *in vivo* studies using both wild type and *CFTR* knockout mice also demonstrated that CFTR was an important mediator in both early and late ischemic preconditioning in the heart^[87]. Several mechanisms may be responsible for a functional role of CFTR channels in mouse heart IPC: (1) It has

been demonstrated that cardiac CFTR plays a role in early action potential shortening during hypoxia and ischemia^[52]. Activation of CFTR will also decrease resting membrane potential and action potential duration, thereby limiting intracellular Ca²⁺ overload and cell damage^[8]; (2) The CFTR channel is an important transporter of sphingosine 1-phosphate (S-1-P)^[88], which has recently emerged as an important lipid messenger involved in IPC^[89]; (3) CFTR is permeable not only to Cl⁻, but also to larger organic ions, as well as reduced and oxidized forms of glutathione (GSH)^[90]. Therefore CFTR may contribute to the control of oxygen stress-induced apoptosis and the regulation of inflammation and the immune responses; (4) CFTR might decrease intracellular pH and modulate apoptosis^[91]; (5) CFTR functions as a regulator of volume-dependent homeostatic cell mechanisms in cell proliferation and apoptosis^[92]. We are currently in the

Figure 5. Effects of cystic fibrosis transmembrane conductance regulator (CFTR) gene knockout (FABPCFTR) on ischemic preconditioning (IPC) in isolated working mouse heart. (A) Experimental protocol. (B–D) Recovery of left ventricular contractile (B,C) and relaxation (D) function of WT (FVB/NJ), *CFTR*^{+/+} and *CFTR*^{-/-} (FABPCFTR) mice after 45 min of ischemia and 40 min of reperfusion. (E,F) IPC on infarct size of ventricles. (E) Representative ventricle transverse slices after ischemia (Isch) or IPC. (F) Mean infarct size measured from age-matched WT, *CFTR*^{+/+}, or *CFTR*^{-/-} mouse heart after ischemia (Isch) or IPC (*n*=6 for each group). **P*<0.05, ***P*<0.01, ****P*<0.001. process of investigating these potential mechanisms and the relative role of CFTR in early and late preconditioning.

$I_{Cl,Ca}$ in IPC It has been well known that ischemia/reperfusion usually causes a cytosolic overload of Ca^{2+} in cardiac myocytes^[93,94]. Therefore, it is very possible that $I_{Cl,Ca}$ may be activated during ischemia and reperfusion^[38,62,64,95-98]. But, no information for the possible involvement of $I_{Cl,Ca}$ in IPC is currently available.

Functional role of Cl^- channels in myocardial hypertrophy and heart failure Myocardial hypertrophy and its progression to dilated cardiomyopathy or heart failure are characterized by not only structural remodeling, including hypertrophic growth of cardiac myocytes (changes in cell volume) and changes in the cytoskeleton and extracellular matrix (ECM)^[99,100] but also ionic remodeling, that is, changes in expression and activity of many ion channels. It should be pointed out that ionic remodeling during the progression of hypertrophy to heart failure provides not only substrates for arrhythmias but also cellular mechanisms for structural remodeling. During the remodeling process, multiple neurohormonal and intracellular signaling cascades, including tyrosine kinases, PKA, PKC, protein phosphatases, MAP kinases, and endothelin, are activated^[101]. These second messengers are well-known effective regulators of various ion channels. Indeed, it has been found that several cation channels, such as K^+ channels, Ca^{2+} channels, and stretch-activated non-selective channels, undergo significant changes. Recent evidence also supports possible involvement of anion channels in the remodeling process.

$I_{Cl,swell}$ and $ClC-3$ in myocardial hypertrophy and heart failure $I_{Cl,swell}$ is persistently activated in ventricular myocytes from a canine pacing-induced dilated cardiomyopathy model^[102]. Using the perforated patch-clamp technique, Clemo *et al* found that, even in isotonic solutions, a large 9-AC-sensitive, outwardly rectifying Cl^- current was recorded in heart failure myocytes but not in normal myocytes. Graded hypotonic cell swelling (90%–60% hypotonic) failed to activate additional current while graded hypertonic cell shrinkage caused an inhibition of the “basal” Cl^- current in failure myocytes. Moreover, the maximum current density of the $I_{Cl,swell}$ in failure myocytes was about 40% greater than that in osmotically swollen normal myocytes. Constitutive activation of $I_{Cl,swell}$ is also observed in several other animal models of heart failure, such as a rabbit aortic regurgitation model of dilated cardiomyopathy^[103,104] and a dog model of heart failure caused by myocardial infarction^[105]. In human atrial myocytes obtained from patients with right atrial enlargement and/or elevated left ventricular end-diastolic pressure, a tamoxifen sensitive $I_{Cl,swell}$ was also found to be persistently

activated^[106]. It is not known at this time whether $I_{Cl,swell}$ is also persistently activated in hypertrophied non-failure (or non-dilated) myocytes in the above described models or in the human heart. In a rat aortic constriction model, however, a 9-AC-sensitive Cl^- current is present in hypertrophied ventricular myocytes but not in control myocytes, and this hypertrophy-activated Cl^- current seems to contribute to the shortening of APD in the hypertrophied cells^[107]. It is not known, however, whether this hypertrophy-activated Cl^- current is the same as $I_{Cl,swell}$ because the volume-sensitivity of this Cl^- current was not assessed. Nevertheless, it is possible that persistent activation of $I_{Cl,swell}$ is a common response of cardiac myocytes to hypertrophy or heart failure-induced remodeling. The mechanism for this phenomenon is still not clear. Perhaps the cell volume increase caused by hypertrophy and cell membrane stretch caused by dilation, are both involved in the activation of $I_{Cl,swell}$. Alternatively, the persistent activation of $I_{Cl,swell}$ may be caused by signaling cascades activated during hypertrophy and heart failure independent of changes in cell length and volume, or both. $I_{Cl,swell}$ could be activated by direct stretching of $\beta 1$ -integrin through focal adhesion kinase (FAK) and/or Src^[58]. Mechanical stretch of myocytes also releases angiotensin II (AngII), which binds to AT1 receptors (AT1R) and stimulates FAK and Src in an autocrine-paracrine loop. A recent study by Browe and Baumgarten suggests that the stretch of $\beta 1$ -integrin in cardiac myocytes activates $I_{Cl,swell}$ by activating AT1R and NADPH oxidase and, thereby, producing reactive oxygen species. In addition, NADPH oxidase may be intimately coupled to the channel responsible for $I_{Cl,swell}$, providing a second regulatory pathway for this channel through membrane stretch or oxidative stress^[59]. This finding is very important for further understanding of the mechanism for hypertrophy activation of $I_{Cl,swell}$ and $ClC-3$ channels and their relationship to hypertrophy and heart failure as it is very well known that Ang II plays a crucial role in myocardial hypertrophy and heart failure^[108].

The functional and clinical significance of $I_{Cl,swell}$ in the hypertrophied and dilated heart is currently unknown. Using a mouse aortic banding model of myocardial hypertrophy, we have recently found that targeted disruption of $ClC-3$ gene ($ClCn3^{-/-}$) accelerated the development of myocardial hypertrophy and the discompensatory process^[109], suggesting that activation of $I_{Cl,swell}$ might be important in the adaptive remodeling of the heart during pressure overload. Further studies on the mechanism for the $ClC-3$ channels' effects on hypertrophy and heart failure are in progress in our laboratory. It is well accepted that in most cells activation of $I_{Cl,vol}$ represents one important trigger to initiate regula-

tory volume decrease (RVD) when cells swell^[112]. Cell volume homeostasis, therefore, could be an important function of $I_{Cl_{swell}}$ activation in the heart. Activation of Cl^- conductance causes significant changes in APD and intracellular Ca^{2+} concentration, and should also affect excitation-contraction (E-C) coupling, contractility, and other hemodynamic functions of the heart^[8,11]. Recent studies suggest that $I_{Cl_{swell}}$ and $ClC-3$ channels play important roles in cell proliferation^[110], differentiation^[111], migration^[112], and apoptosis^[78,79]. All of these have been demonstrated as important cellular processes in myocardial remodeling during hypertrophy and heart failure^[113].

CFTR in myocardial hypertrophy and heart failure

Remodeling of CFTR channels has been observed in myocardial hypertrophy and heart failure. Using *in situ* mRNA hybridization in a combined pressure and volume overload model of heart failure in the rabbit, Wong *et al* found that the normal epicardial to endocardial gradient of CFTR mRNA expression is reversed due to a significant decrease in epicardial expression of CFTR mRNA in the rabbit left ventricle^[114]. A post-translational change in the CFTR expression could be responsible for this phenomenon^[115]. The loss of the normal transmural gradient of repolarising ion channels is likely to contribute to instability of repolarisation in the hypertrophied heart and hence increased risk of cardiac arrhythmias in patients with heart failure. The exact functional and clinical significance of the changes in CFTR expression during hypertrophy and heart failure is currently not clear and merits further study.

$I_{Cl_{Ca}}$ in myocardial hypertrophy and heart failure The critical role of Ca^{2+} in cardiac development, function, and disease is undisputable. Despite the heterogeneous etiology and overt manifestations of heart failure, abnormalities in Ca^{2+} handling are prominent, and alterations in Ca^{2+} homeostasis are a hallmark of myocardial hypertrophy and heart failure^[116]. Ca^{2+} transients in failing cardiac myocytes, for example, are characterized by diminished amplitude, elevated diastolic Ca^{2+} levels, and prolonged decay of the Ca^{2+} transients. In non-cardiac cells, $I_{Cl_{Ca}}$ could be an important mediator of apoptosis^[117]. But, information on the possible involvement of $I_{Cl_{Ca}}$ in heart failure is currently very limited. It is reported that $I_{Cl_{Ca}}$ may play little, if any, role in the electrical remodeling of human end-stage failing heart^[66,67,118].

Conclusions and future directions

Although the field of anion channels in cardiac physiology and pathophysiology lags significantly behind that of cation channels, the gap can now be narrowed with the recent identification of molecular entities responsible for car-

diac Cl^- channels^[8], their genes mapped to specific human chromosomal locations^[13] and the use of gene targeting and transgenic animals. Recent efforts not only at the cellular and molecular levels but also the isolated organ and whole animal levels have provided strong evidence that Cl^- channels may play an important role in cardiac diseases, including arrhythmias, myocardial ischemia, hypertrophy, and congestive heart failure. Anion channels in the heart, therefore, may represent important novel targets for therapeutic agents against heart diseases.

Despite these exciting developments, further investigations of the cellular and molecular mechanisms by which the Cl^- channel proteins function to impart a physiological or a pathophysiological phenotype may require a multitude of approaches for the assessment of the Cl^- channel functions in healthy and diseased hearts. Although global knockout mice are invaluable experimental models and functional genomics remains a powerful approach to understanding the function of cardiac Cl^- channels, several theoretical and practical problems should be considered. First, homologous recombination gene targeting is based on the assumption that targeting will result in specific loss of the gene's product and will not directly affect the expression of other genes. In reality, however, even though the loss of the gene's product can be verified, the upregulation of another gene in the vicinity of the targeting can occur^[119] and may readily escape detection. Such upregulation could have an important effect on the observed phenotype. Second, a knockout may not always be a knockout^[120] such as when the targeted gene is widely or ubiquitously expressed, when alternative splicing variants of the gene exist^[121], and when functional channels are actually heteromultimeric and the structure might be associated with modulatory subunits, such as Barttin for ClC channels^[122]. Accessory proteins may be involved in the determination of the stability of the channel complex in the membrane and in the modulation of biophysical, pharmacological, and regulatory properties of the channel. Recent evidence suggests that Cl^- channels, like cation channels^[52,123,124], may function as a multiprotein complex or functional module. A functional anion channel module may be a complex composed of the following: (a) pore forming subunit for ion transportation; (b) auxiliary subunits for modulating pore gating; and (c) proteins as second messengers tightly coupled to channel function. These proteins might be intimately linked to certain physiological functions and belong to the same subproteome. Manipulation of one gene in the subproteome may cause changes in other proteins of the same subproteome. Therefore, the functional consequences of disrupting the specific gene are very difficult to

predict unless the changes in the entire subproteome are examined. Similar phenotypes can be attained from alternative protein pathways within cellular networks, which are influenced by disease, environmental, internal, and biochemical stimuli. Therefore, caution should be taken when conventional global gene knockout animals are used in functional studies. Alternatively, tissue-specific conditional or inducible knockout or knockin animal models may be more valuable in the phenotypic studies of specific genes by limiting the effect of upregulation or developmental compensation on the phenotype of manipulated genes. Many phenotypic changes may actually be a result of posttranslational changes caused by protein modifications such as phosphorylation or dephosphorylation. Therefore, it is clear that conventional functional genomics may provide only limited information on the functional module of multiprotein complexes. We are now facing the challenge of a major paradigm shift in the study of integrated anion channel functions. In the postgenomic era, the recent advances in the genome resources including genome-wide microarray profiling together with advancement in the application of functional proteomics and bioinformatics will certainly facilitate our understanding of the functions of anion channels in the cardiovascular system. It is feasible that anion channels may become novel targets for therapeutic approaches to the treatment of cardiovascular diseases.

Abstract

RhoA and Rho-kinase (ROCK) participate in a wide variety of cell signal functions such as cell growth, smooth and cardiac muscle contraction, cytoskeleton rearrangement, cell migration and proliferation. In vascular smooth muscle cells, RhoA and ROCK play an important role in Ca²⁺ sensitization and regulate vascular smooth muscle tone. In the heart, RhoA and ROCK mediate hypertrophic response leading to cardiac hypertrophy. Recent cellular and molecular biology studies using ROCK inhibitors such as Y-27632 and fasudil have indicated a pivotal role of the RhoA-ROCK cascade in many aspects of cardiovascular function such as cardiac hypertrophy and ventricular remodeling following myocardial infarction. Inhibition of the RhoA-ROCK signaling pathway may be a suitable target for a number of cardiovascular diseases including hypertension, atherosclerosis, diabetes and hypertrophic heart failure. This review focuses on the current understanding of the RhoA-ROCK signal pathway in heart diseases and discusses the use of ROCK inhibitors as therapeutic agents for heart diseases ranging from hypertensive cardiomyopathy to heart failure.

Introduction

RhoA, along with RhoB, RhoC, Rac1, Rac2, Cdc42, RhoG, and TC10, belongs to the Ras family of small GTP-binding proteins. RhoA and Rho-kinase (ROCK), a downstream target protein of small GTP-binding protein Rho, are known to regulate a wide variety of cellular processes such as changes in cell morphology, cell motility, focal adhesions, light chain phosphorylation, and cytokinesis^[1,2]. Inhibition of the RhoA/ROCK cascade has been demonstrated to elicit beneficial effects on function of both heart tissues and vasculature. RhoA is believed to play a key role in cell growth, myofibrillar assembly, cardiac hypertrophy, hypertension, vascular smooth muscle cell proliferation and migration in response to heterotrimeric G protein receptor stimulation and to mechanical strain or tyrosine kinase growth factors^[3–8]. ROCK has been implicated to mediate the angiotensin II (Ang II)-induced hypertrophic responses of vascular smooth muscle cells and hypertensive vascular diseases in hypertension^[9,10]. In addition to cardiovascular diseases, RhoA and ROCK also participate in normal physiological processes such as preg-

nancy and early heart development. The mRNA expression of RhoA and two types of ROCK (α and β) was found to be elevated in the pregnant myometrium^[11], which may be responsible for the augmented myometrial contractility during pregnancy. Using the small interfering RNAs (siRNA) technique, it was reported that disruption of RhoA expression resulted in absence of heart tube fusion and abnormal head development in chick embryos, indicating the importance of RhoA for normal embryogenesis and early heart development^[12]. Recent studies have indicated that inhibition of the RhoA-ROCK signal pathway may be a potential target for a number of cardiovascular diseases including hypertension, atherosclerosis, diabetes and hypertrophic heart failure^[13]. This review will summarize the role of RhoA and ROCK in heart morphology and function, with a special focus on the pathogenesis of heart diseases associated with abnormal RhoA and ROCK signaling. As certain factors such as peripheral vascular resistance may affect cardiac afterload and subsequently cardiac contractile function, the effect of RhoA-ROCK on cardiac morphology and function appears to be more complex than originally thought and requires more

intensive research.

Role of RhoA in cardiac hypertrophy Cardiac hypertrophy is a cardiac physiological adaptation in response to pressure or volume overload. However, after a prolonged period of time, this initial adaptive response becomes maladaptive, thus switching the heart from a compensated to a decompensated state and ultimately increased cardiac mortality and morbidity. The Gq-RhoA-ROCK pathway, which may be activated by several neurohormonal factors such as angiotensin II, is believed to function as an important signaling pathway for cardiac hypertrophy or transition from left ventricular hypertrophy to heart failure. Activation of RhoA is essential for sensing externally applied force, subsequently relaying onto the actin cytoskeleton leading to translocation of extracellular signal-regulated kinase (ERK) *en route* to cardiac hypertrophy^[14,15]. It is believed that hypertrophy-related gene expression in response to RhoA activation is mediated through cross-talk with β 1 integrin signal pathway via an organized actin cytoskeleton^[14,15]. In addition, transcription factor GATA-4, a key regulator of cardiac genes, may also be a nuclear mediator of RhoA participating in sarcomere assembly in cardiomyocytes. Both RhoA and GATA-4 are necessary for sarcomeric reorganization in response to hypertrophic stimuli. It has been demonstrated that overexpression of either protein alone is sufficient to trigger sarcomeric reorganization^[16].

In a recent study of heart failure model in Dahl salt-sensitive rats fed an 8% NaCl diet from 8 weeks with or without the ROCK inhibitor Y-27632, Satoh and colleagues reported elevated left ventricular mass, cardiac myocyte cross-sectional area, interstitial fibrosis, and contractile dysfunction shown as reduced left ventricular ejection fraction and fractional shortening, as well as prolongation in contraction/relaxation duration associated with increased protein expression of Galphaq and ROCK in the Dahl salt-sensitive, salt intake Y-27632-untreated group. Interestingly, the degree of myocardial hypertrophy was significantly reduced in conjunction with improved contractile function but no change in interstitial fibrosis following Y-27632 treatment in Dahl salt-sensitive, salt intake rats^[17]. These results suggest the possibility that the Gq-ROCK signal pathway plays an important role in the process of hypertension-induced left ventricular hypertrophy leading to contractile dysfunction. The notion of a key role for RhoA-ROCK in cardiac hypertrophy received convincing support from transgenic studies using mice overexpressing RhoA or a constitutively-activated RhoA mutant in atria and ventricles^[18]. Heterozygotes displayed high premature mortality, ventricular dilatation (without change in mass) and dysfunction, changes in ex-

pression of hypertrophic index gene, increases in atrial mass, marked conduction abnormalities, and other signs of heart failure^[18]. Nevertheless, the phenotype of cardiac anomalies in these transgenic mice is different from those commonly seen in compensated hypertrophy, thus precluding any firm conclusion to be drawn regarding the role of RhoA in cardiac hypertrophy. The possible role of RhoA in cardiac hypertrophy also received indirect evidence from the work related to 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, or statins. Statins have been shown to inhibit cardiac hypertrophy by cholesterol-independent mechanisms including inhibition of activation of RhoA and Rac1^[19]. Since Rac1 is a crucial component of reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, which is a main source for reactive oxygen species (ROS) in the hearts, the fact that statins inhibit Rac1-mediated oxidative stress may contribute to their inhibitory effects on cardiac hypertrophy^[19].

RhoA and cardiac electromechanical function Although there have been some indications that inhibition of RhoA-ROCK may benefit cardiac dysfunction under conditions such as heart failure or ischemia-reperfusion cardiac injury^[20], the precise role of RhoA-ROCK on cardiac contractile function remains unclear. Using the Dahl salt-sensitive heart failure model, it was demonstrated that inhibition of ROCK with Y-27632 significantly improved cardiac contractile dysfunction in Dahl salt-sensitive high salt intake heart failure model including reconciling reduced in left ventricular ejection fraction and fractional shortening, prolonged duration of contraction and relaxation, associated with lessened cardiac hypertrophy. These authors also found that the upregulated proto-oncogene *c-fos* gene expression, but not that of ERK and p70S6 kinase phosphorylation, under heart failure rats was decreased by inhibiting ROCK, suggesting a differential activation of the Rho-ROCK and the ERK-p70S6 kinase pathways in the failing hearts of Dahl salt-sensitive hypertensive rats^[20]. The observation that ROCK inhibition rescues cardiac contractile defects (reduced contractility and prolonged duration of contraction/relaxation) is supported by cardiac function assessment obtained from the RhoA transgenic mice. Cardiac-specific overexpression of RhoA triggered prolongation of action potential duration and reduction in ventricular contractility^[18]. In a separate study, cardiac-specific inhibition of ROCK was achieved by expressing Rho GDI α , an endogenous specific GDP dissociation inhibitor for Rho family proteins, using the α -myosin heavy chain (α -MHC) promoter. Increased expression of Rho GDI α preserved the left ventricular systolic and diastolic function both before and after the development of cardiac hypertrophy,

indicating that Rho GTPases may not be required for maintenance of ventricular contractile function under basal physiological conditions^[21]. The RhoA-ROCK also participates in the function of cardiac conducting system. Electrocardiography and intracardiac electrophysiological evidence suggest first- and second-degree atrioventricular (AV) block in cardiac-specific Rho GDI α (which inhibits Rho GTPase) transgenic hearts at 1 and 4 weeks of age, respectively, prior to the development of cardiac hypertrophy^[21]. These results suggest that the RhoA-ROCK signal cascade is necessary for cardiac electrical conduction under normal physiological conditions. Further examination revealed that expression of connexin 40 was significantly decreased from 1 to 4 weeks of age in the Rho GDI α transgenic heart, which may contribute, at least in part, to the conduction defects in the Rho GDI α transgenic mice^[21].

RhoA, hypertension, and cardiac afterload Regulation of vascular smooth muscle cell contractile state is critical for the maintenance of vascular tone. The RhoA-ROCK signal cascade may affect heart function indirectly through regulation of peripheral vascular resistance. The RhoA-ROCK pathway has been demonstrated to play an important role in a wide variety of cell functions in the vasculature including actin cytoskeleton organization and vascular smooth muscle contraction. The RhoA-ROCK pathway is constitutively active in a number of organs including vascular smooth muscle under physiological and pathophysiological conditions^[22]. It is believed that upregulated RhoA-ROCK signal cascade promotes cytosolic Ca²⁺ sensitization and vascular tension in smooth muscles, leading to enhanced peripheral vascular resistance, vascular tone and subsequently hypertension^[22,23]. Myosin phosphatase is the key enzyme responsible for myosin light chain (MLC) dephosphorylation that regulates smooth muscle cell contraction. Vasoconstrictors and vasodilators are expected to inhibit or promote the activity of myosin phosphatase, respectively. It was indicated that G-protein-coupled receptor agonists might inhibit the activity of myosin phosphatase leading to vasoconstriction through activation of RhoA-ROCK. However, nitric oxide (NO) may activate myosin phosphatase, leading to vasorelaxation through cGMP-dependent protein kinase. It has been postulated that RhoA regulates vascular smooth muscle contraction through interaction with myosin phosphatase-Rho interacting protein, a likely new member of the myosin phosphatase controlling myosin light chain dephosphorylation^[24].

In addition to the peripheral effect, blockade of the RhoA-ROCK signal pathway in nucleus tractus solitarius (NTS) of brain stem decreased blood pressure, heart rate, and renal

sympathetic nerve activity in both Wistar-Kyoto (WKY) rats and spontaneously hypertensive rats (SHR), suggesting a role of the RhoA-ROCK signal cascade in central regulation of blood pressure^[7]. Interestingly, the magnitude of blood pressure, heart rate, and renal sympathetic nerve activity drop was much greater in SHR than in WKY rats. Furthermore, membrane RhoA expression and ROCK activity in NTS were enhanced in SHR compared with WKY rats, confirming the contribution of the NTS RhoA-ROCK pathway to blood pressure regulation via sympathetic nervous system^[7]. Additional work from the same group suggested that activation of the RhoA-ROCK signal pathway might contribute to neurogenic hypertensive mechanisms caused by chronic inhibition of NO synthesis^[8]. Chronic inhibition of NO synthesis by the NO synthase (NOS) inhibitor *N*^o-nitro-*L*-arginine methyl ester (*L*-NAME) is known to trigger the onset of hypertension, which was alleviated by the ROCK inhibitor, Y-27632. Expression of membranous RhoA and phosphorylation of the target proteins of ROCK, the ERM (ezrin, radixin, moesin) family members, was significantly greater in the *L*-NAME-treated group than control group, indicating that activation of the RhoA-ROCK signal pathway contributes to neurogenic hypertension triggered by chronic NOS inhibition^[8].

RhoA and diabetic cardiovascular complications Prolonged contraction and relaxation are hallmarks of diabetic cardiomyopathy, one of the most devastating complications in diabetes^[25,26]. Studies from our laboratory depicted prolonged duration of contraction and relaxation associated with normal contractility and maximal rate of contraction and relaxation in diabetes^[25-27]. Although several mechanisms have been postulated for the diabetes-related mechanical defects such as diabetes-induced myosin isozyme switch (from the fast type V₁ to the slow type V₃), impaired function of sarco (endo) plasmic reticulum Ca²⁺-ATPase (SERCA) and Na⁺/Ca²⁺ exchanger, as well as reduced myofilament Ca²⁺ sensitivity^[26,28-30], the signaling mechanisms responsible for these cellular alterations remain poorly defined. Recently, we reported up-regulation of cardiac RhoA signaling in diabetic hearts^[27]. RhoA expression has been demonstrated to be up-regulated in arteries from aged, hypertensive, or diabetic rats^[27,31-33]. The dynamics of RhoA gene expression is sparsely documented although binding of transcription factor cAMP-responsive element binding (CREB) protein/activating transcription factor-1 (ATF-1) has been shown to increase the RhoA promoter activity^[34]. Hyperglycemia and reactive oxygen species, which often accompany hyperglycemia, have been shown to increase nuclear CREB activity through a p38 MAP kinase-dependent pathway^[35,36]. Elevated oxidative stress in diabetic heart and enhanced p38

MAP kinase activation were observed in a preliminary study (Ren and colleagues, unpublished data), which may be related to enhanced expression of RhoA and activity of ROCK. Although there is little evidence depicting a direct regulation of RhoA signaling in cardiac excitation-contraction coupling, activation of ROCK, the Rho-dependent serine-threonine kinase, has been shown to regulate cardiac contractility and gene expression, probably mediated through the MAP kinase super-family^[6,18,20]. One of the likely scenarios that RhoA may participate cardiac excitation-contraction coupling is speculated to be mediated through regulation of K⁺ channel and action potential duration. Cardiac-specific overexpression of RhoA was reported to prolong action potential duration and to diminish ventricular contractility^[18]. The RhoA-induced prolongation of action potential may be related to its ability to interrupt certain voltage-dependent K⁺ channel(s)^[37]. These speculations are supported by our recent observation of concurrent up-regulation of RhoA mRNA/protein and diminished Kv1.2 protein expression in diabetic hearts (Ren and colleagues, unpublished data). Depressed expression and function of voltage-

dependent K⁺ channels have also been implicated in prolonged phase 3 of action potential repolarization and thus lengthened relaxation duration in diabetic hearts^[38]. The involvement of RhoA signaling in diabetic heart dysfunction was supported by our finding using the ROCK inhibitor Y27632. Incubation of Y-27632 with high extracellular glucose (25.5 mmol/L) for 12 h significantly reduced the compromised cardiac mechanical function elicited by high glucose toxicity (Figure 1), suggesting that RhoA-ROCK activation may be a permissive step in the development of cardiac mechanical defects in response to high extracellular glucose or diabetic environments.

Our recent study revealed that IGF-1 transgene protected diabetes-induced mechanical dysfunctions in cardiac myocytes^[39] in parallel to its action on STZ-induced elevation of RhoA mRNA and protein expression, down-regulation of Kv1.2 channels and activation of p38 MAP kinase (Ren and colleagues, unpublished data). Our results did not favor any involvement of another MAP kinase signal molecule ERK1/2 in diabetes-induced cardiomyocyte dysfunction or the cardiac protective effect of IGF-1 (Ren and

Figure 1. Effect of the ROCK-specific inhibitor Y27632 (10 μmol/L) on glucose toxicity (25.5 mmol/L)-induced mechanical defects in rat ventricular myocytes. Myocytes from normal adult male rats (225–250 g) were isolated and maintained under normal (NG, 5.5 mmol/L) or high (HG, 25.5 mmol/L) glucose medium for 12 h in the presence or absence of A27632. (A) Peak shortening (normalized to resting cell length); (B) Maximal velocity of shortening/relengthening ($\pm dL/dt$); (C) Duration of contraction: time-to-peak shortening (TPS); (D) Duration of relaxation time to 90% relengthening (TR_{90}). $n=60-62$ cells/group. Mean \pm SEM. ^b $P<0.05$ vs NG group.

colleagues, unpublished data). Collectively, these data suggest that up-regulation of the RhoA-ROCK signal cascade may suppress the expression or function of voltage-dependent K^+ channel and p38 MAP kinase, an route to mechanical dysfunction in diabetes manifested as prolonged duration of contraction and relaxation, as well as reduced contractility. It is possible that the beneficial effects of IGF-1 on cardiac mechanical defects diabetes may be elicited through suppression of activation of the RhoA-ROCK signal cascade^[40,41].

Results from our study suggested likely additional signaling mechanisms from RhoA and p38 MAP kinase (Ren and colleagues, unpublished data). Activation of p38 MAP kinase has been speculated to be down-stream of the ROCK signaling pathway^[35]. However, current data failed to display that an enhanced ROCK I/II mRNA expression in diabetic groups, indicating that the activity rather than mRNA expression of ROCK I/II may be involved. Nevertheless, IGF-1 transgene reduced ROCK I/II mRNA, consistent with the notion that IGF-1 may inactivate RhoA signal cascade. The lack of effect on ERK1/2 phosphorylation in response to either diabetes or IGF-1 is somewhat consistent with our earlier report using the high glucose culture system^[42].

RhoA and other cardiovascular complications Ample of evidence has demonstrated that the RhoA-ROCK mediated signaling pathway plays an important role in other cardiovascular complications such as ischemia/reperfusion heart injury and ventricular remodeling following myocardial infarction. It was reported that fasudil, a potent ROCK inhibitor, prevented occurrence of myocardial ischemia in patients with microvascular angina^[43]. It was found that ischemia/reperfusion upregulated RhoA expression in ischemic myocardium and increased ROCK activity. Inhibition of ROCK with selective ROCK inhibitors protected the heart against ischemia injury and enhanced post-ischemia cardiac function. This cardioprotective effect may be attributed to an anti-apoptotic mechanism of ROCK inhibition since ROCK inhibitors may significantly attenuate the downregulation of Bcl-2 expression induced by ischemia/reperfusion injury. An alternative explanation for such cardioprotective property of the ROCK inhibitors may be associated with their ability to suppress ischemia/reperfusion-induced elevation in serum levels of proinflammatory cytokines^[44]. Further studies have shown that RhoA may be a novel mediator of adenosine-induced cardiac protection against ischemia. The adenosine A_3 receptor mediated anti-ischemic function in the heart appeared to signal selectively through RhoA since overexpression the RhoA-noninteracting mutant caused significant reduction of A_3 agonist-induced anti-ischemic effect.

It was suggested that RhoA was an important cardioprotective signaling molecule that interacted directly to phospholipase D (PLD) in cardiac myocytes^[45]. Inhibition of ROCK attenuates production of superoxide, reduces generation of monocyte chemoattractant protein-1 or plasminogen activator inhibitor-1 (PAI-1), and inhibits activation of macrophages, neutrophils, and platelets, all of which are considered essential for inhibition of stress-induced regional inflammatory responses and diminished myocardial ischemia-reperfusion injury^[46]. Furthermore, RhoA was found to mitigate the reperfusion-induced change in the shape of cardiac capillary endothelial cells *in situ* and thereby ameliorate the reperfusion injury^[47].

Apart from cardiac ischemia/reperfusion injury, RhoA-ROCK has also been demonstrated to be involved in the process of myocardial infarction. It is generally accepted that inhibition of ROCK directly relaxes vascular smooth muscle and therefore increases regional myocardial blood flow at sites of major coronary artery stenosis by dilating abnormally narrowed or occulted artery. However, a recent study revealed that the infarct-limiting mechanism which involved ROCK inhibition could be independent of either a change in systemic hemodynamics or recruitment of collateral blood flow. Transient accumulation of cAMP was demonstrated in myocardium during ischemic preconditioning and may play a role to limit the size of infarction^[48]. Other mechanisms such as down-regulating inflammatory responses mediated by cytokines and chemokines may also be involved in limiting the growth of infarct size^[49] although further study is warranted to elucidate the therapeutic value of ROCK inhibitors in the management of myocardial infarction.

Summary and conclusion During the past few years, considerable progress has been made toward understanding the signaling pathways and the function of RhoA-ROCK in cardiovascular systems. These studies have convincingly revealed that RhoA-ROCK are versatile signaling molecules regulating diverse cellular functions including cytoskeletal rearrangement^[50], Ca^{2+} sensitization^[51], cytokinesis^[52] and lineage commitment as well as fate of stem cells^[53]. However, much remains to be learned about the detailed regulation mechanisms of RhoA-ROCK as well as its downstream signaling targets. It is imperative that future efforts be directed toward better defining and characterizing the signal pathways regulated by RhoA-ROCK in cardiovascular systems. Such efforts will likely yield new molecular targets for the RhoA-ROCK signal cascade and ultimately more effective therapies for preventing or ameliorating cardiovascular diseases such as cardiac hypertrophy, hypertension, diabetes

and atherosclerosis through either pharmacologically or genetic modulation of RhoA-ROCK regulated signaling.

Abstract

Mammalian transient receptor potential (TRP) channels consist of six related protein sub-families that are involved in a variety of pathophysiological function, and disease development. The TRPV1 channel, a member of the TRPV sub-family, is identified by expression cloning using the “hot” pepper-derived vanilloid compound capsaicin as a ligand. Therefore, TRPV1 is also referred as the vanilloid receptor (VR1) or the capsaicin receptor. VR1 is mainly expressed in a subpopulation of primary afferent neurons that project to cardiovascular and renal tissues. These capsaicin-sensitive primary afferent neurons are not only involved in the perception of somatic and visceral pain, but also have a “sensory-effector” function. Regarding the latter, these neurons release stored neuropeptides through a calcium-dependent mechanism via the binding of capsaicin to VR1. The most studied sensory neuropeptides are calcitonin gene-related peptide (CGRP) and substance P (SP), which are potent vasodilators and natriuretic/diuretic factors. Recent evidence using the model of neonatal degeneration of capsaicin-sensitive sensory nerves revealed novel mechanisms that underlie increased salt sensitivity and several experimental models of hypertension. These mechanisms include insufficient suppression of plasma renin activity and plasma aldosterone levels subsequent to salt loading, enhancement of sympathoexcitatory response in the face of a salt challenge, activation of the endothelin-1 receptor, and impaired natriuretic response to salt loading in capsaicin-pretreated rats. These data indicate that sensory nerves counterbalance the prohypertensive effects of several neurohormonal systems to maintain normal blood pressure when challenged with salt loading. The therapeutic utilities of vanilloid compounds, endogenous agonists, and sensory neuropeptides are also discussed.

Introduction

Mammalian transient receptor potential (TRP) channels consist of six related protein sub-families known as TRPV, TRPC, TRPM, TRPP, TRPML, and TRPA^[1]. These channels are widely distributed and involved in sensing local stimuli ranging from changes in hemodynamics to pH and osmolarity. The TRPV1 channel, a member of the TRPV sub-family, was identified by expression cloning using the “hot” pepper-derived vanilloid compound capsaicin as a ligand. TRPV1 is therefore referred as the vanilloid receptor (VR1) or the capsaicin receptor. Capsaicin as well as other closely related vanilloid substances are principal constituents in the

hot chilli peppers and responsible for the pungency of these spices^[2].

Over the last several centuries, knowledge about the physiological actions of capsaicin has grown and capsaicin has become a powerful tool, as will be described, for studying mechanisms underlying hypertension. Ever since its isolation in the mid-nineteenth century, capsaicin has been documented to act on sensory fibers with neuroselectivity^[3,4]. Nelson elucidated the structure of capsaicin, reporting it as 8-methyl-vannillyl-6-noneamide, an acylamide derivative of homovanillic acid^[5]. The compound consists of three functional moieties: vanylyl, acylamide, and alkyl^[2]. Jancso later showed that capsaicin-sensitive nerve endings could be

stimulated as well as destroyed by a sufficiently high dose of capsaicin^[6]. The neurotoxicity effect of capsaicin is of paramount importance, for reasons that will become clear, to neurobiologists using capsaicin sensitive-sensory nerve degeneration to study blood pressure regulation. The review that follows outlines the advances that have been made since Jancso's publications, with regard to mechanisms of capsaicin's action, cardiovascular effects of select neuropeptides released by a subset of capsaicin-sensitive primary afferent neurons (CSPAN) innervating cardiovascular and renal tissues, and pathophysiologic mechanisms of hypertension elucidated by capsaicin sensitive sensory-nerve degeneration. Capsaicin pharmacology and the nature of capsaicin-sensitive sensory nerves are discussed in greater detail in a number of other excellent scholarly reviews^[7-9]. This review is restricted to a discussion of the effects of capsaicin on the cardiovascular system. Other authors have reviewed the effects of capsaicin on the somatosensory, respiratory, thermoregulatory, and gastrointestinal systems^[10-14].

VR1 positive sensory neurons

VR1-positive sensory neurons refer to a subset of primary afferent neurons that express the VR1 receptors which can be activated by capsaicin. The pharmacological property of sensitivity to capsaicin distinguishes these afferent neurons, mostly having unmyelinated (C fibers) or thinly myelinated axons (A δ fibers), from other afferent neurons^[15].

Maggi^[15] has described the functional anatomy of the VR1-positive primary afferent neuron by identifying four sites from which neurotransmitter release may occur: (i) central terminals of the afferent neuron in contact with second-order neurons in the CNS; (ii) terminals distributed in the prevertebral ganglia; (iii) peripheral terminals distinct from the terminal at which the sensory stimulus is applied; and (iv) the same peripheral terminal at which the sensory stimulus is applied. Neurotransmitter release at sites (i) and (ii) accounts for the sensory function of CSPAN and is central to perception of somatic and visceral pain. In contrast, and as implied by neuropeptide release from peripheral terminals (iii) and (iv), CSPAN nerve endings not only serve as sensory receptors, but also as effector sites from which neurotransmitters are released. Thus, neurotransmitter release from sites (iii) and (iv) accounts for the "sensory-efferent" function of CSPAN, with release from site (iv) not even requiring neuronal conduction^[15]. Accordingly, Maggi and Meli^[11] have termed release from site (iv) the "sensory receptor potential-coupled efferent response." Local sensory

stimuli that may induce neurotransmitter release are varied and include nerve growth factor^[16], vascular wall tension^[17], the sympathetic nervous system^[18], bradykinin^[19], and endothelin^[20].

Efferent function of VR1-positive sensory neurons

VR1-positive sensory neurons have a dual function: sensory perception and sensory efferent function. Binding of capsaicin and capsaicin agonists to VR-1 leads to neuropeptide release from a subpopulation of neuropeptide-containing primary afferent neurons^[15]. Binding to this receptor opens a receptor-operated permeable cation channel^[21-25] that ultimately results in the influx of sodium and calcium ions. Sodium influx is sufficient for afferent impulse conduction. In sharp contrast, calcium influx, and thus extracellular calcium, is prerequisite for neuropeptide release. Without extracellular calcium, sensory neuropeptides are no longer released from sensory nerve endings when these endings are depolarized^[15].

Given that the neuroselectivity of capsaicin is a reflection of the selective expression of the VR1 on a subpopulation of primary afferent neurons, a closer look at the VR1 is warranted. Initial evidence supporting a capsaicin-binding site on a subset of primary afferent neurons came from observations that capsaicin analogues are able to exert similar functional changes^[26,27]. Additional support came from experimentation with resiniferatoxin, a phorbol ester derivative that has been shown to exhibit structural similarity^[28,29] and desensitizing and excitatory properties homologous to those exhibited by capsaicin, albeit at 1000-fold lower doses^[28-30]. Definitive support for the presence of a chemical moiety capable of binding to capsaicin and related agonists came with the development of capsazepine, experimentally shown to act as a competitive antagonist of vanilloid binding and activity^[31]. The VR-1 has been reviewed in greater detail in an authoritative review by Caterina and Julius^[32].

Concerning the nature of transmitters released from VR1-positive sensory neurons, Maggi and Meli^[15] have reported that at least the following 12 different types of transmitters are present in capsaicin-sensitive sensory neurons: substance P (SP), neurokinin A, neuropeptide K, eledoisin-like peptide, somatostatin, vasoactive intestinal polypeptide, cholecystokinin-octapeptide, calcitonin gene-related peptide (CGRP), galanin, corticotrophin-releasing factor, arginin vasopressin, bombesin-like peptides. These authors also report that multiple neuropeptides can be simultaneously released from VR1-positive sensory nerve endings. However,

different neuropeptides may be preferentially released as a function of stimulus intensity^[33].

It has been shown that plasma concentrations of CGRP rise transiently after administration of capsaicin in adult rats^[3,4]. Given that capsaicin exerts its action through release of neuropeptides, acute administration of capsaicin produces functional changes related to the activity of the released neuropeptides^[35]. In contrast, and of significance to elucidating mechanisms underlying hypertension, capsaicin administered systemically at a dose of 50 mg/kg of body weight to neonatal rats or mice leads to an irreversible loss of more than 80% of small-diameter sensory neuron cell bodies^[36-41]. These observations indicate that high doses of capsaicin lead to neurotoxic effects including substantial depletion of stores of neuropeptides within VR-1 positive sensory neuron.

Innervation of cardiovascular tissue by VR1-positive sensory nerves

VR1-positive sensory nerves are found around blood vessels in virtually all vascular beds. CGRP, often co-localized with SP, is found in nerve endings of a subset of these sensory nerves^[42-46]. Synthesis of these neuropeptides occurs in the dorsal root ganglia which contain cell bodies of the capsaicin-sensitive sensory nerves. CGRP, co-localized with SP, is also found in a subpopulation of VR1-positive sensory nerves innervating the hearts of rats, guinea pigs, and humans, though in a much lower density than around blood vessels^[43].

CGRP is a potent vasodilator that also has positive chronotropic and ionotropic effects^[43]. The coronary vasculature is a particularly susceptible target of the vasodilatory action of CGRP^[47,48]. Of significance to understanding the pathogenesis of hypertension, systemic administration of CGRP decreases blood pressure in normotensive animals, normotensive humans, and spontaneously hypertensive rats^[43,44]. This decrease is produced via peripheral arterial dilation mediated through nitric oxide-dependent and nitric oxide-independent mechanisms^[43]. The fact that bolus injection of CGRP₈₋₃₇, a CGRP receptor antagonist, produces dose-dependent increases in mean arterial pressure in deoxycorticosterone-salt hypertensive rats indicates that CGRP-induced vasodilation may play a compensatory role in this model^[49].

VR1-positive sensory nerves and established models of hypertension

At least two hypertensive models have been used for

defining the role of VR1-positive sensory nerves. One is the one-kidney wrap (1K-WRAP) hypertensive model and the other the deoxycorticosterone (DOCA)-salt hypertensive model. Intrathecal administration of capsaicin to adult rats was used to deplete SP and CGRP within central processes of afferent renal nerves (ARN) within selective laminae of the dorsal horn for determining whether SP and/or CGRP localized in ARN play a role in the development of 1K-WRAP hypertension or DOCA-salt hypertension^[50]. Capsaicin treatment enhanced the development of 1K-WRAP hypertension, considering that systolic blood pressure was greater in 1K-WRAP rats pretreated with capsaicin compared with vehicle-treated 1K-WRAP rats^[50]. However, capsaicin pretreatment had no effect on systolic blood pressure in DOCA-salt rats, suggesting that the depletion of sensory neurotransmitters from ARN by capsaicin does not exacerbate DOCA-salt hypertension. Indeed, these authors concluded that "ARN did not play a major role in the development of DOCA-salt hypertension."^[50]

Manzini and Bacciarelli^[51] performed a similar study in which the effect of neonatal degeneration of VR1-positive sensory nerves on the development of DOCA-salt hypertension was investigated. As expected by the degeneration of sensory neurons in capsaicin-pretreated animals, substance P-like immunoreactivity was virtually undetectable in capsaicin-pretreated animals and blood pressure was much less responsive to acute administration to capsaicin as compared to control animals. DOCA-salt induced-hypertension was of quicker onset and of greater magnitude in the animals pretreated with capsaicin. Hypertensive rats pretreated with capsaicin also had a greater incidence of cardiac necrosis. These authors, in contrast to Burg *et al*, concluded that capsaicin-sensitive sensory fibers may underlie antihypertensive mechanisms and play a protective role in preventing the development of DOCA-salt hypertension^[51].

VR1-positive sensory nerves and increased salt sensitivity

Though studies by Burg *et al*^[50] and Manzini and Bacciarelli^[51] have shown that VR1-positive sensory nerves are implicated in blood pressure regulation, these investigations have not shown whether impairment of the sensory nervous system is sufficient to produce hypertension. We showed for the first time in 1998 that neonatal degeneration of VR1-sensitive sensory nerves rendered an adult rat salt-sensitive^[52]. We administered 50 mg/kg capsaicin or vehicle subcutaneously to newborn Wistar rats on the first and second days of life, and a high or normal sodium diet was given

immediately following the weaning period. We found that neonatal treatment with capsaicin led to elevation of blood pressure in rats fed a high sodium diet, but not in those fed a normal sodium diet. High salt intake increased urine volume and sodium excretion in both vehicle and capsaicin treated rats. However, these parameters were significantly lower in capsaicin treated rats fed a high-salt diet compared to vehicle treated rats fed a high-salt diet. These results suggest that capsaicin neonatal treatment might impair renal function when rats are loaded with salt.

Role of the renin-angiotensin-aldosterone system (RAAS) To define the molecular mechanisms underlying sensory nerve function involved in the pathogenesis of salt-sensitive hypertension, we^[53] subsequently explored the role of the RAAS in the aforementioned salt-sensitive hypertensive model induced by sensory denervation. Capsaicin plus high-salt-treated rats were given losartan (a type I angiotensin II receptor blocker), prazosin (a selective α_1 -adrenoceptor blocker), or hydralazine (a nonspecific vasodilator). Both tail-cuff systolic blood pressure and mean arterial blood pressure were higher in capsaicin-treated rats fed a high-salt diet and capsaicin treated rats fed a high-salt diet plus prazosin when compared to capsaicin treated-rats fed a high-salt diet plus losartan or hydralazine, the vehicle-treated rats fed a high-salt diet, or capsaicin-treated rats fed a normal salt diet. These results suggest that losartan and hydralazine, but not prazosin, are able to prevent the development of salt-induced hypertension in capsaicin-pretreated animals. Of significance to understanding the pathophysiology of salt-sensitive hypertension, these results revealed that there was an interaction between the sensory nervous system and the RAAS in a manner that prevents the development of salt-induced hypertension in sensory-intact rats. This study also confirmed that capsaicin might impair the natriuretic response to a high salt intake, as rats pretreated with capsaicin and fed a high-salt diet have decreased urinary volume and sodium excretion. Interestingly, losartan and hydralazine did not protect against the impaired natriuretic response, even though these agents did prevent the development of hypertension in salt-loaded capsaicin pretreated rats. These results indicate that intact sensory innervation is essential for the normal natriuretic response to sodium loading and that the antihypertensive effects of losartan and hydralazine may be mediated by mechanisms for example, vasodilatory mechanism, other than those that protect against the impairment of urinary sodium and water excretion in this model.

To further investigate the roles of the type 1 (AT1) and 2 (AT2) angiotensin II (AII) receptors in the development of salt-induced hypertension in capsaicin-pretreated rats,

we^[54] treated capsaicin-pretreated rats fed a high-salt diet with candesartan (a selective blocker of the AT1 receptor), PD 123319 (a selective blocker of the AT2 receptor), or a combination of these two drugs. Development of hypertension in capsaicin treated rats fed a high-salt diet was prevented or attenuated by candesartan and PD 123319, respectively, indicating that both of these antagonists were protective and effective in lowering increased blood pressure induced by a salt challenge in capsaicin-pretreated animals. The antihypertensive effect of PD 123319 is unexpected and the underlying mechanisms remain to be defined. Plasma renin activity (PRA) was suppressed by high salt intake in both vehicle- or capsaicin-treated rats, but it was significantly less suppressed in the latter than in the former. This observation suggests that PRA may be insufficiently suppressed in capsaicin-pretreated animals, likely contributing to hypertension in these animals.

We next studied aldosterone and its interaction with the sensory nervous system in the induction of salt-sensitive hypertension, in light of the aforementioned finding that PRA is insufficiently suppressed in neonatally capsaicin-pretreated rats challenged with a salt load^[54,55]. Both vehicle- and capsaicin-treated rats fed a high-salt diet was given spironolactone, an aldosterone receptor antagonist for 3 weeks. We found that chronic spironolactone treatment appeared to restore renal functional impairment and prevented the development of hypertension in neonatally capsaicin-pretreated rats fed a high-salt diet^[55]. This is in contrast to our previous report with losartan and hydralazine, which have been shown to attenuate elevated blood pressure in capsaicin pretreated rats challenged with a salt load, but not able to improve renal functional impairment^[53]. These results indicate that the antihypertensive effect of spironolactone in this model is mediated by improving renal function, consistent with the role of aldosterone receptors in the kidney that cause sodium and water retention.

Albeit markedly suppressed by salt loading, plasma aldosterone levels (PAL) and PRA were significantly higher in capsaicin-pretreated rats challenged with salt load than sensory-nerve-intact rats fed the same high-salt diet^[55]. This suggests PRA and PAL are insufficiently suppressed in sensory-denervated rats, contributing to increased salt sensitivity and renal functional impairment in these animals. Insufficiently suppressed PAL in response to salt loading can be attributed to one or both of the following: (i) increased circulating and/or tissue AII levels; and/or (ii) upregulation of the AII type I receptor in the zona glomerulosa of the adrenal gland, a receptor to which binding of AII increases aldosterone synthesis and secretion. We^[55] found that the

AT1 receptor content in the adrenal gland was not altered in any of the experimental groups, strongly suggesting that insufficiently suppressed PAL is a reflection of insufficiently suppressed circulating and/or tissue AII levels.

In contrast to above mentioned studies that define the role of the RAAS in the development of hypertension in capsaicin treated rats fed a high-salt diet, we studied the role of sensory nerves in attenuating the development of hypertension induced by AII infusion^[56]. AII or vehicle-infused rats were pretreated with capsaicin or vehicle. Mean arterial pressure was higher in rats infused with AII, and it was higher in AII-infused rats pretreated with capsaicin compared to rats infused with AII alone. Northern blot analysis revealed that AII-infused rats had an increase in the level of CGRP mRNA in the dorsal root ganglia, suggesting that subpressor infusion of AII either stimulates the synthesis of CGRP mRNA or retards its degradation. Taken together, these data suggest that neuropeptides released by sensory nerves attenuate elevated blood pressure induced by AII infusion and that the increase in CGRP synthesis appears to be a compensatory response to diminish increased blood pressure induced by AII infusion. Furthermore, 24-h urinary and sodium excretions were lower in AII-infused rats pretreated with capsaicin than they were in rats infused with AII alone. These results are consistent with the finding that degeneration of VR1 positive sensory nerves impairs the natriuretic response to a salt load^[52-55].

Role of the sympathetic nervous system Defining the interaction between the sympathetic and sensory nervous systems, we found that sympathectomy produced by administration of guanethidine subcutaneously prevented the development of salt-sensitive hypertension induced by sensory nerve degeneration^[57]. This finding suggests that: (i) enhanced sympathoexcitatory response occurs in capsaicin-pretreated rats fed a high-salt diet, which may contribute to increased salt sensitivity in these animals; and (ii) there is a balance between antihypertensive effects of sensory nerves and prohypertensive effects of the sympathetic nervous system in a normal rat. This balance is disrupted following capsaicin-pretreatment and consequential sensory nerve degeneration, such that the animal is salt-sensitive. Sympathectomy may also result in less renin release by withdrawing the stimulation of the α_1 -adrenergic receptors.

These findings appear to be in contrast to our previous results in which prazosin is not able to prevent the development of salt-induced hypertension in capsaicin-pretreated animals^[53]. To reconcile this finding about prazosin with the antihypertensive effect of sympathectomy, one should keep in mind the following considerations: (i) the dose of prazosin

may not have been high enough to decrease blood pressure in neonatally capsaicin-pretreated rats challenged with a salt load, even though the same dose resulted in reduction in blood pressure in spontaneously hypertensive rats^[58]; (ii) α_1 -adrenoreceptors are necessary for preventing salt-induced hypertension, an idea supported by findings by Osborn *et al*^[59] who have shown that blockade of the α_1 -adrenoreceptor with prazosin renders the rat salt-sensitive and leads to the development of salt-sensitive hypertension; and (iii) the sympathetic nervous system may contribute to the development of salt-induced hypertension in neonatally capsaicin-pretreated rats via a non- α_1 -adrenoreceptor mechanism.

Role of the endothelin system We investigated the role of endothelin-1 (ET-1) and its receptors in sensory-dependent salt-sensitive hypertension, in light of the finding that AII is a stimulus for ET-1 production^[60-63]. We found that plasma ET-1 levels and blood pressure were elevated in sensory-denervated rats fed a high-salt diet. Moreover, development of salt-sensitive hypertension in these rats can be prevented by blockade of the ET_A receptor, just as it can be prevented with losartan^[53] and candesartan^[54], hydralazine^[53], sympathectomy^[57], and spironolactone^[55]. Unlike chronic treatment with spironolactone^[55], however, blockade of the ET_A receptor is not able to alleviate renal functional impairment in capsaicin-pretreated rats fed a high-sodium diet.

Furthermore, elevated plasma ET-1 levels may reflect one or both of the following: (i) decreased internalization by ET_B receptors, which have been shown to act as clearance receptors for ET-1^[64-65]; or (ii) increased production. Because we observed that plasma ET-1 levels in sensory denervated rats that were salt loaded were unaffected by blockade of the ET_B clearance receptor^[60], it is clear that elevated plasma ET-1 levels are indeed the result of increased production, consistent with the possibility of increased synthesis and release of ET-1 secondary to insufficiently suppressed PRA in these capsaicin-pretreated animals^[54,55].

VR1-positive sensory nerves and pulmonary hypertension

The role of neuropeptides released by sensory nerves in hypoxic pulmonary hypertension have been studied^[66,67]. Tjen-A-Looi revealed that rats pretreated with capsaicin and subsequently placed in hypobaric hypoxia (10% O₂, 16 d) had increased pulmonary artery pressure and right ventricular hypertrophy compared to sensory-nerve-intact rats subjected to the same hypoxia^[66]. These investigators concluded that depleted stores of CGRP secondary to capsaicin

administration exacerbated hypoxic pulmonary hypertension. Interestingly, these authors reported that depletion of SP did not exacerbate pulmonary artery pressure and right ventricular hypertrophy. Regarding the latter observation, it follows that endogenous CGRP may indeed modulate pulmonary vascular tone and counterbalance hypoxic pulmonary vasoconstriction, reducing elevated pulmonary artery pressure and right ventricular hypertrophy in pulmonary hypertension.

In contrast to the protective effect of CGRP on pulmonary artery pressure observed by Tjen-A-Looi^[66], Zhou and Lai^[67] found that SP was implicated in pulmonary hypertension. Zhou and Lai induced ventilatory dysfunction and pulmonary hypertension in Sprague-Dawley rats by administering monocrotaline (MCT). SP levels were elevated 1–2 weeks after the administration of MCT. Compared to rats given MCT alone, rats given MCT plus capsaicin showed attenuated increases in pulmonary arterial pressure and the weight ratio of right ventricle/(left ventricle+septum). These data suggest that MCT produces pneumotoxicity that may be mediated or at least accompanied by elevated SP levels. Because capsaicin treatment depletes this neuropeptide, capsaicin attenuates MCT-induced pneumotoxicity^[67].

Clinical and therapeutic implications

Given that excitation of VR1-positive sensory nerves is followed by a refractory state, capsaicin has been found to have therapeutic potential in the treatment of neuropathic pain^[68]. But, and as has been suggested within this review, capsaicin has implications beyond the treatment of pain as an agent capable of acting on the cardiovascular system. The observation that capsaicin (an agonist of the VR1) is able to produce a hypotensive effect in SHR is an indication that activation of the VR1 may be an efficacious means of preventing the development of hypertension – a prospect with far-reaching therapeutic implications^[69].

Of growing interest is the compelling evidence that vanilloid receptors on sensory nerves may mediate the vasodilator action of anandamide^[70–74], which was originally isolated from the brain as an endogenous cannabinoid receptor ligand^[75]. Indeed, our recent data indicate that administration of methanandamide caused a greater hypotensive effect in SHR rats as compared with control animals, suggesting that anandamide may serve as an endogenous compound able to stimulate VR1 and consequently produce a decrease in blood pressure^[69]. It follows that changes in circulating or tissue anandamide levels under particular pathophysiological conditions may alter VR1 function and

thereby regulate blood pressure. The search for endogenous VR1 activators and inhibitors is certainly motivated by the implications that such vanilloid therapy may treat hypertension.

In addition to vanilloid therapy, there are broad implications for the clinical application of neuropeptides stored in the endings of VR1-positive sensory nerves. In particular, the clinical utility of CGRP receptor agonists in the treatment of cardiovascular disorders is discussed below and in greater detail in a review by Feuerstein *et al*^[76].

Considering its potent vasodilatory action, CGRP has been evaluated in the treatment of subarachnoid hemorrhage and shown to relax severely constricted vessels in animal models of this disorder^[77]. However, the European CGRP in Subarachnoid Hemorrhage Study Group^[78] was not able to produce definitive evidence supporting the use of this neuropeptide in the treatment of subarachnoid hemorrhage. Their study was complicated by almost two-thirds of patients in the treatment group not being able to complete the course of the trial because of frequent episodes of CGRP-induced hypotension. Perhaps this adverse systemic side effect could be minimized by intrathecal administration of CGRP.

Other studies have shown that CGRP has potential beneficial hemodynamic effects in congestive heart failure^[79–80]. Shekhar *et al* observed that CGRP infusion over 8 h increased cardiac output by 72% while reducing right atrial and pulmonary wedge pressure^[80]. Unfortunately, these favorable hemodynamic responses returned to pre-infusion levels once CGRP delivery was withdrawn. The need for continuous infusion of CGRP thus diminishes its clinical utility in the treatment of congestive heart failure.

Similarly, CGRP has been evaluated in the treatment of coronary heart disease. Indeed, it has been shown to improve exercise tolerance in patients with chronic stable angina^[81]. But, specificity for CGRP or related agonists for the coronary vasculature has not been demonstrated and CGRP infusion for the treatment of coronary heart disease would thus be expected to produce systemic side effects, as it does in the treatment of heart failure.

As another example of the possible clinical utility of CGRP, it has been demonstrated that patients with Raynaud's disease are deficient in cutaneous CGRP-containing nerve fibers^[82]. However, CGRP has not been shown to be useful in the treatment of this peripheral vascular disease.

Conclusion remarks

It is estimated that 50 million individuals in the United

States suffer from hypertension. The detrimental consequences of this disease involve myocardial infarction, congestive heart failure, stroke, and renal failure. Despite intensive research in this field, the molecular basis underlying human essential hypertension is largely unknown and pharmacologic prevention of end organ damage induced by hypertension is a challenge. Defining how sensory nerves sense changes in the environment, alter their afferent and efferent activities, and cross-talk with other systems to modulate cardiovascular and renal function and blood pressure may provide valuable new insight into the interactions that lead to hypertension and increased salt sensitivity. Such insight may unveil novel pharmacologic approaches to tackle hypertension and end organ damage. The study of abnormalities in VR1 expression, VR1-induced release of sensory neurotransmitters, and post-signaling pathways may also have significant impact in our understanding of the pathogenesis of hypertension and have far-reaching clinical and therapeutic implications.

Abstract

Hypertension and related cardiovascular diseases are the leading causes of death in many countries. The etiology of human essential hypertension is largely unknown. It is highly likely that hypertension is a complex and multifactorial disease resulting from the interaction of multiple genetic and environmental factors. Animal models of hypertension have been proved to be useful to study the pathogenesis of, and to find a new therapy for, hypertension. The aim of this article is to briefly review the most widely used rodent models of experimental hypertension, including history and recent advances. These models are classified as genetically-induced, environmentally-induced, pharmacologically-induced, and renal-induced hypertension according to the way of induction; the typical representatives of each of these major types of experimental hypertension are spontaneous hypertension, cold-induced hypertension, DOCA-salt-induced hypertension, and renal-induced hypertension, respectively. The processes of induction of hypertension, possible pathogenesis, characteristics, advantages, and limitations of these animal models are reviewed. In addition, the clinical implications of the above experimental models of hypertension are addressed.

Introduction

Hypertension is the prevalent cause of cardiovascular disease that leads to heart failure, stroke, renal failure, and, ultimately, to death. In the USA, approximately 50 million people have hypertension, according to Phase I estimates of the National Health and Nutrition Examination Survey III (NHANES III), from 1988 to 1991^[1]. The prevalence is about 20%. According to a report^[2], about 40% of white people and more than 50% of black people aged 65 or older suffer from some form of high blood pressure in the USA. Epidemiological surveys have demonstrated an increasing prevalence of hypertension in China, from 5.11% in 1958 to 7.73% in 1980 and 11.89% in 1991^[3,4]. Although this incidence is lower than that in many developed countries such as the USA (20%)^[1] and Canada^[5], it represents 50 million people in 1980 and 90 million people in 1991 due to the size of the Chinese population. According to relevant reports^[4,6], cardiovascular diseases are the leading causes of death in Chi-

nese society.

The syndrome of hypertension is more than just an elevation of arterial pressure, although it is this aspect that the general public is most familiar with. Hypertension when fully developed is characterized by an increase in vascular resistance to blood flow, cardiac hypertrophy, often an increase in cardiac output, an increased output of sympathetic nervous system (SNS), changes within the vascular smooth muscles, often atherosclerosis, and abnormalities in renal function. Increased vascular resistance is due to constriction of the vascular smooth muscle, primarily in the high resistance vessels. The etiology of essential hypertension is not known and the causes of it may be multifactorial. It is generally believed that both genetic and environmental factors and their interactions play a critical role in the pathogenesis of hypertension and other cardiovascular diseases. Since hypertension and associated cardiovascular diseases are the leading causes of death of human beings, medical scientists are dedicated to elucidate the mechanism of and

explore the treatment for hypertension.

It is noticed that animal models of human disease have been widely used to study etiology and pathogenesis of human disease, to prevent disease or to find a therapy and identify risk factors contributing to the disease. This literature reviews briefly advances in the most widely used rodent models of hypertension, including advantages and limitations. Hopefully, this will be useful to those in choosing appropriate animal models of hypertension for their researches. This comprehensive review may help physicians and scientists understand the pathogenesis of hypertension and therefore optimize therapeutic approaches. It is our expectation that the creation and utilization of novel animal models of hypertension will fundamentally advance the fields of cardiovascular medicine and physiology.

The major animal models of hypertension

Basically, animal models of hypertension comprise primary and secondary hypertension according to hypertension etiology (Figure 1). The primary hypertension includes genetically-induced and environmentally-induced hypertension and the secondary hypertension includes pharmacologically-induced and renal-induced hypertension by the way of induction.

Figure 1. The classification of major animal models of hypertension.

Genetically-induced hypertension Animals that have undergone artificial genetic manipulation are predestined to become hypertensive. Some investigators believe that genetically hypertensive rats comprise the most popular models to study essential hypertension^[7]. One example is the spontaneously hypertensive rat (SHR), originally inbred from Wistar stock by Okamoto and Aoki, and their WKY inbred nonhypertensive controls. These rats develop hypertension at about 4–6 weeks of age, largely independent of dietary levels of either Na⁺ or Cl⁻. Another model is the Dahl salt-sensitive rats, originally derived from Sprague-Dawley

stock by Dahl on the basis of developing hypertension with high NaCl diet. When fed with normal salt diets, these rats become hypertensive, indicating that this is a genetic model of hypertension with the feature of salt sensitivity. O'Dowd and Rapp^[8] have refined the genetic background of the original Dahl stock, and their salt-sensitive/Jr line is now preferred (along with their salt-resistant/Jr controls). Genetic analysis revealed linkage with loci close to the angiotensin converting enzyme (ACE) and guanylyl cyclase A (GCA)/atrial natriuretic factor (ANF) receptor genes in Dahl salt-sensitive rats^[9]. It was found that certain alleles at the GCA and ACE loci (or at loci closely linked to them) had a significant impact on blood pressure response to high salt in Dahl salt-sensitive rats.

The SHR was generated by inbreeding Wistar rats with the highest blood pressure^[7]. The SHR develop many features of hypertensive end-organ damages including cardiac hypertrophy, heart failure, and renal dysfunction. According to relevant reports^[11,12], the SHR is the most commonly used genetic model although the mechanisms for producing the hypertension are not clear. Overactivity of the brain renin-angiotensin system (RAS) appears to be involved in initiating the development of spontaneous hypertension based on the finding that central injections of angiotensin II (AngII) receptor antagonists cause greater reductions in systolic blood pressure in SHR than in normotensives^[13,14]. However, DePasquale and colleagues^[15] reported that central administration of AT₁ receptor blocker losartan (DuP 537) did not lower blood pressure in SHR. Thus, the above hypothesis needs further confirmation. Interestingly, some hemodynamic alterations which occur during the development of the disease are similar to human essential hypertension (ie, a high cardiac output early, and in the adult, a normal cardiac output and an increased vascular resistance)^[16]. In this model, there is also an increase in the activity of the sympathetic nervous system as evidenced by increased renal sympathetic activity^[16]. The renal blood flow and glomerular filtration rate are normal^[17] and renal vascular resistance is increased^[22]. The SHR stroke prone (SHR-SP) is a further developed sub-strain with even higher levels of blood pressure and a strong tendency to die from stroke^[18]. The SHR has been used to evaluate genetic factors involved in hypertension. Although a wide variety of genes seems to cosegregate in various crosses^[12], neither of these genes is confirmed to be the etiological gene for hypertension. The advantage of this model is that its pathophysiological changes are similar to those found in human essential hypertension^[16,19]. A major drawback of this model is the lack of an appropriate control, which has been genetically altered

yet is free from the disease and the complexity of the genetic mutations which have affected not only blood pressure but many other regulatory systems as well.

Transgenic hypertension models can be generated by over-expressing a specific gene. This type of genetic model usually has a relatively good normotensive control, the same strain of animals without genetic alteration. It is an excellent model to study the role of a specific gene in the pathogenesis of hypertension. However, the transgenic model may not mimic human essential hypertension as well as the SHR does in terms of pathophysiology. A representative of this type of hypertension is the TGR (mREN2)27 transgenic rats^[10]. In this genetic model, the introduction and overexpression of the mouse Ren-2 gene in Sprague-Dawley rats leads to severe hypertension^[10]. The appropriate control is the age-, body weight-, and sex-matched normotensive Sprague-Dawley rats without renin transgene.

Environmentally-induced hypertension In recent years, the important role of environmental factors in the disease process has received great attention from scientists and physicians. The primary interest is focused on the area of cardiovascular disorders, particularly hypertension. To understand better the ways in which the environmental factors affect the cardiovascular functions, researchers have tried to produce experimental hypertension in animals by exposing them to different experimental paradigms.

Stress-induced hypertension Epidemiologists and clinicians have long suspected that stressful life events can be a sufficient trigger for the expression of hypertension in some individuals^[20]. Attempts to induce hypertension in animals using sensory stimulation have generally employed loud noises, flashing lights, and oscillating cages, either separately or together. For example, in one early study rats were subjected to 20 weeks of randomized flashing lights, motion, and loud noises^[21]. After 12 weeks on this schedule, systolic blood pressure (SBP) values reached approximately 150–160 mmHg. Perhaps a better example of this type of experiment is found in a study by Lin and Li^[22]. Stressed rats developed hypertension within two weeks after irregular foot electric-shocks combined with buzzing noise. It is accepted that activation of sympathetic nervous system^[23] and the RAS^[24] play a role in the initiation of stress-induced hypertension. Li^[25] found that increased activity of the cholinergic system in the rostral ventrolateral medulla (rVLM) was also involved in the development of stress-induced hypertension. Plasma catecholamine, corticosterone, angiotensin II, glucose, and lipids were found to be increased during stress. In this model, about 40%–50% of stressed rats failed to develop hypertension^[26].

Diet-induced hypertension It is known that long-term exposure to a special diet (high salt, fat, or sugar) results in dietary hypertension in some animals or humans. For example, chronic fructose treatment in rats repeatedly has been shown to elevate blood pressure associated with insulin resistance and hyperinsulinemia^[27,28]. Hyperactivity of the SNS and the RAS, vascular hypertrophy, and sodium retention by the kidney tubules have been proposed to be some of the mechanisms by which fructose induces hypertension. By degeneration of capsaicin-sensitive nerves, Wang and colleagues^[29,30] developed a salt-sensitive model of hypertension. In this model, the increased salt sensitivity is mediated by the enhancement of the SNS^[29].

Cold-induced hypertension: Fregly^[31] and Sun^[32–36] found that chronic exposure of rats to mild cold (41 °F or 5 °C) induced hypertension including cardiac hypertrophy within 3 weeks. This is presently the only “naturally-occurring” form of experimentally-induced hypertension that is induced without surgical intervention, administration of excessive doses of drugs or hormones, or genetic manipulation. It is interesting that the elevated blood pressure of rats after 7 weeks of exposure to cold does not return to pre-cold exposure level during the 4 weeks after removal from cold. Thus, an elevation of blood pressure induced by a longer period of cold exposure might not be reversible after return to thermoneutral temperature. Intermittent exposure of rats to cold also induces hypertension, with a sigmoid relationship between the hours per day exposed to cold and systolic blood pressure.

Cold-induced hypertension (CIH) is also demonstrable in humans. Epidemiological surveys and clinical observations have established that people who live and work in cold areas have a high incidence of hypertension and related cardiovascular diseases^[37–39]. Cold temperature (weather) makes hypertension more severe in hypertensive patients^[39,40]. The cold winter season has the highest mortality and morbidity of cardiovascular diseases in a year^[39–42]. Donaldson^[38], after studying the relationship between outdoor temperature and blood pressure in men in central London between 1986 and 1992, reported that cold exposure of normal life in winter is sufficient to induce significant and prolonged hypertension in the general population.

It was originally assumed that cold-induced elevation of blood pressure was a direct vasoconstrictive effect of sympathetic nervous system (SNS). Indeed, the SNS is activated by chronic cold exposure and the plasma and urine levels of catecholamines are increased significantly in cold-exposed rats^[32–34,43]. However, the *in vitro* vascular contractile response to α_1 -adrenoceptor agonist, phenylephrine, is

decreased significantly in cold-exposed rats^[44]. The *in vivo* pressor response to phenylephrine is significantly reduced by chronic cold exposure^[45]. Thus, the vascular α_1 -adrenoceptors are down-regulated during cold exposure. Several studies^[32,34,36,46] have shown that blockade of the RAS at different sites could attenuate or prevent the cold-induced elevation of blood pressure. Antisense oligodeoxynucleotides to angiotensinogen mRNA or AT₁-receptor mRNA reduce elevated blood pressure of cold-exposed rats^[47]. Angiotensinogen gene knockout delays and attenuates CIH^[48]. It has been therefore suggested elsewhere^[32-34,36,48] that the hyperactivity of the SNS initiates CIH probably via activation of the RAS. Indeed, plasma renin activity (PRA) is increased during exposure to cold and abolishment of the rise in PRA by renal denervation prevents the development of CIH^[32]. Cold-exposed rats had an elevation of blood pressure that was proportional to the concentration of NaCl in the diet^[49], suggesting that CIH is sodium-dependent hypertension.

CIH is a prototypic model of environmentally-induced hypertension, which is similar in many ways to human hypertension. Induction of CIH requires a climate-controlled chamber, with a strict requirement of temperature and humidity. Perhaps, this is the limitation of this model.

Pharmacologically-induced hypertension The DOCA-salt-induced model of hypertension is a typical representative of pharmacologically-induced hypertension. A very high dose of deoxycorticosterone acetate (DOCA) ranging from about 300 to 1000 mg·kg⁻¹·d⁻¹ (sc) is required to induce hypertension in rats. Isotonic saline is the sole drinking fluid. This is an important co-factor because it expedites the development of hypertension and makes it more severe. Thus, this model is salt-dependent in its initiation. It often needs surgical reduction of renal mass or unilateral nephrectomy. The combination of DOCA-salt and unilateral nephrectomy results in hypertension, cardiac and renal hypertrophy, and nephrosclerosis^[50]. DOCA-salt hypertension is a low renin and volume overloaded form of hypertension. There is evidence that arginine vasopressin (AVP) plays a role in both the development and maintenance of DOCA-salt hypertension^[51,52]. It is believed that AVP is involved as a vasopressor hormone in the pathogenesis of malignant DOCA-salt hypertension^[53]. The SNS also appears to be involved in the development of DOCA-salt hypertension^[54]. The increased activity of the SNS may affect renal function through the renal nerve, as denervation of the kidneys delays the onset and decreases the severity of the disease^[54,55]. Further studies^[56] indicated that AngII receptor binding sites were increased in the brain, suggesting an up-regulation of

AngII receptors. However, AngI converting enzyme inhibitors and AngII receptor blocker are ineffective in reducing blood pressure in low-renin, DOCA-salt hypertension^[57,58]. In contrast, aldosterone receptor blockers and diuretics are effective in reducing blood pressure in this model^[59]. Most recent studies indicate that the endothelin system plays an important role in the pathogenesis of DOCA-salt hypertension^[60-65]. Oxidative stress may also be involved in DOCA-salt hypertension^[65,66]. The major limitations of the DOCA-salt model are: 1) the pharmacological (large) doses of drug required; 2) requirement for surgical reduction of renal mass; and 3) ingestion of a large amount of NaCl required. The major advantage of this model is the potential to investigate the role of sodium in the developmental stages of hypertension.

Renal-induced hypertension The physiological function of the kidney includes maintenance of electrolyte and fluid balance and secretion of renin, an important component of the RAS. Thus, its involvement in the regulation of blood pressure and its important role in the development of hypertension are well accepted. Since 1934, when Goldblatt and his co-workers^[67] induced an elevation of blood pressure by partial constriction of the renal artery of the dog, many renal-induced models of hypertension have been successfully established in rats, rabbits, sheep, and cats^[68]. Generally, renal-induced experimental hypertension includes two-kidney Goldblatt hypertension (constriction of one renal artery while the contralateral kidney is left intact) and one-kidney Goldblatt hypertension (one renal artery is constricted and the contralateral kidney is removed).

In the rat, by clipping one renal artery (leaving the contralateral kidney untouched) with a clip which induced a severe hypertension, a biphasic course in the plasma renin activity was found. In the initial phase, sodium retention occurred and was associated with a transient increase in plasma renin activity returning to control levels within a week^[69,70]. Thus, it has been suggested that the RAS plays a role in the development of two-kidney Goldblatt hypertension^[69-71]. The sustained elevation of blood pressure may still be AngII-dependent since a sub-pressor dose of AngII would result in an elevation of blood pressure due to a shift in the dose-response curve of AngII^[72]. This suggests, but does not prove, that AngII receptors are upregulated in this model of hypertension. The initial elevation of blood pressure in the one-kidney Goldblatt model is also AngII-mediated^[73]. Due to the absence of the other normal kidney, no compensatory increase in sodium and water excretion can occur, and hence, fluid volume is retained^[74]. This model is thus a sodium-fluid volume-dependent model. This would

be an ideal model for studying the role of volume expansion in the development of hypertension.

During the early developmental stage of these two renal-dependent models, when the clip is removed, arterial blood pressure returns to normal^[70,75]. Thus, renal-induced hypertension is reversible and reproducible. Furthermore, these models provide a unique opportunity to investigate the changes which occur specifically at the level of the kidney, as well as the role of the kidney in the long-term blood pressure control. If the reversal of hypertension is time-dependent, it would suggest that relevant changes, perhaps structural, have developed.

Clinical implications of animal models of hypertension

It should be mentioned that each of the above models of experimental hypertension studies a specific aspect of hypertension. Neither of them encompasses all traits of human essential hypertension. Due to the unknown etiologies of hypertension, the use of various research models, each of which induces the disease by a different mechanism yet with the same end result, is advantageous. By using different types of experimental hypertension, scientists could identify and evaluate potential risk factors contributing to hypertension and related cardiovascular diseases. This would allow new and effective measures to be adopted for preventions and therapies. Usually, animal studies are essential to the success of clinical trials. It is noted that remarkable advances in cardiovascular medicine have been originated from experimental hypertension. Therefore, animal models of hypertension are very important approaches to the study of human hypertension.

Physicians and scientists could learn the developmental process and pathogenesis of hypertension from these animal models that are designed to mimic those of human hypertension. The induction of hypertension in animals could help understand the etiological factors that may be involved in essential hypertension. For example, hypertension and cardiovascular diseases (CVD) may have genetic predeterminants. There is a predisposition to hypertension and CVD in those patients with a positive family history. The notion of genetic predisposition for the development of hypertension has been strengthened by the development of genetic or spontaneous models of hypertension. The pathophysiological changes of spontaneous hypertension in animals are very similar to those of human essential hypertension. Also, transgenic models of hypertension induced by targeting different genes are excellent tools to study genes rel-

evant to hypertension. An animal model of DOCA-induced hypertension is an ideal model for evaluating the role of sodium in hypertension. Studies from DOCA-induced hypertension have provided a strong basis for using spironolactone (aldosterone receptor blocker) to treat clinical hypertension. Because some special diets (high salt, fat, or sugar) could result in dietary hypertension, restriction of these diets has been suggested by clinicians for preventive and therapeutic purposes. The cause of hypertension varies with hypertensive patients. Thus, it is important to identify the potential cause of hypertension prior to treatment; which guarantees appropriate and effective treatment. For example, stenosis of the renal artery could cause hypertension as learned from an animal model of renal-induced hypertension. In this case, surgical correction of the stenosis of the renal artery may be more important than treatment with antihypertensive drugs. In addition, research findings from experimental hypertension may have clinical implications. For example, the RAS has been found to play a critical role in the pathogenesis of CIH in rats. This has led to a clinical trial which proves that the ACE inhibitor (captopril) or AT₁ receptor blocker (losartan) can control hypertension appropriately and effectively in hypertensive patients in winter. This also could help to control the high incidence of myocardial infarction and stroke during the cold season. In contrast, the use of animal models of hypertension would allow scientists to test new pharmacological treatments and gene therapy for hypertension and related CVD. Thus, what is learned from animal hypertension may reveal new insights into both preventive strategies and optimization of therapeutic approaches. It should be emphasized that any experimental data from animal models of hypertension must be tested and further validated in humans before they can be applied in hypertensive patients.

Abstract

Polymerases with a proofreading function in their internal 3' to 5' exonuclease possess high fidelity for DNA replication both *in vivo* and *in vitro*. The obstacle facing Exo⁺ polymerases for single nucleotide polymorphism (SNP) detection could be bypassed by using primer-3'-termini modification. This hypothesis has been well tested using three types of modified allele specific primers with: 3' labeling, 3' to 5' exonuclease resistance, and 3' dehydroxylation. Accordingly, three new SNP assaying methods have been developed to carry out genome-wide genotyping, taking advantage of the enzymatic properties of Exo⁺ polymerases. These new mutation detection assays are widely adaptable to a variety of platforms, including multi-well plate and microarray technologies. Application of Exo⁺ polymerases to genetic analysis, including genotyping that is mostly relevant to pharmacogenetics, high-fidelity gene expression profiling, rare mutation detection and mutation load assay, will help to accelerate the pace of personalized medicine. In this review paper, we will first introduce three new assays that we have recently developed, and then describe a number of their applications in pharmacogenetics and in other biomedical studies.

High-fidelity DNA polymerases mediate genotyping

3' Terminal-labeled primer extension Terminal-labeled primer extension is a single nucleotide polymorphism (SNP) assay consisting of 3' terminal-labeled, allele-specific primers and DNA polymerases with proofreading activity. Both 3' terminal [³H]-labeled and fluorescent-labeled primers have been successfully applied in genotyping analyses. The 3' terminal mismatched nucleotide that bears the signal to be detected was removed by the proofreading function, whereas the label was retained when the primer and template were perfectly matched. The terminal-labeled primer extension approach has several advantages over current SNP assays. The most significant advantage is that it greatly decreases false positive results by a direct consequence of the proofreading activity of Exo⁺ polymerases. The second advantage of terminal-labeled primer extension is its high sensitivity.

Terminally labeled primer extension harnesses the power of polymerase chain reaction (PCR) to improve the efficiency of genetic analysis^[1-7].

SNP-triggered on/off switch Exo⁺ polymerases together with 3' phosphorothioate-modified mismatched primers work as an off switch in DNA polymerization. Phosphorothioate modification renders oligonucleotides nuclease-resistant, which blocks mismatch excision, a strategy widely used in antisense technology as well as in single base extension. For 3' allele-specific primers with phosphorothioate modification, a perfectly matched primer turns on DNA polymerization, whereas mismatched primers turn it off, resulting in no product. This breakthrough observation of an on/off switch action has been repeatedly confirmed using either short artificial amplicons or natural genomic DNA templates. The off switch directly resulted from 3' exonuclease activity and has been well supported by comparisons of a variety of DNA polymerases in both linear and expo-

nential amplification with phosphorothioate-modified, allele-specific primers^[3-13].

The crucial structural components of the on/off switch are: (i) allele-specific primers with 3' terminal exonuclease-resistant modification; and (ii) DNA polymerases possessing 3' exonuclease activity. In recent studies by Di Giusto *et al*^[6,7,14], four types of DNA polymerases, T4⁺, T7⁺, KF⁺ and Vent, were tested and similar off switches were observed when the polymerases were combined with 3' phosphorothioate-modified primers. Based on the new model of this proofreading mechanism (Figure 1), polymerases with 3' exonuclease function should have a higher base discrimination ability over *exo*-polymerases regardless of the properties of the substrates used. In addition to comparing nine different DNA polymerases, Di Giusto *et al*^[6,7,14] evaluated the effect of dNTP (2'-deoxynucleotide-5'-triphosphate), ddNTP (2',3'-dideoxynucleotide-5'-triphosphate), and acyNTP (acyclo-2'-deoxynucleotide-5'-triphosphate) on the accuracy of primer extension. The maintenance of high fidelity with ddNTP and acyNTP allows the *Exo*⁺ polymerases to be applied in both exponential and linear primer extensions in SNP analysis. The latter was tested using MALDI-TOF MS (Matrix Assisted Laser Desorption/Ionization Time of Flight Mass Spectrometry) and is compatible with many other detection formats.

Figure 1. Mismatch primer extension model using *Exo*⁺ polymerases based on results from phosphorothioate (PTO)-modified primers.

SNP-triggered reversed on/off switch or off/on switch The SNP triggered reversed on/off switch works in a way complementary to proofreading 3' exonuclease-resistant or 3' labeled primers. With the introduction of inert allele-specific primers or proprimers, matched amplicons turn off and mismatched amplicons turn on DNA polymerization. Inert primers of a perfectly matched amplicon are not processed by the 3'*Exo* domain of the high-fidelity DNA polymerases. In this circumstance, inert primers remain inactive and no DNA polymerization occurs. In contrast, the

inert primers of mismatched amplicons trigger the 3' exonuclease excision process by which the mismatched 3' terminal is removed and subsequent processes activate the 3' hydroxyl group for DNA polymerization. One of the benefits of the reversed on/off switch is that positive results can screen all three mismatched nucleotides other than the complementary one, and this is a powerful tool in mutation detection.

To date two types of 3' dehydroxylated primers, 3' phosphorylated and 3' hydrogenized, have been evaluated for use in the SNP-triggered reversed on/off switch. The 3' phosphorylated primers can always be extended regardless of whether low-fidelity or high-fidelity polymerases are used. Fortunately, the 3' hydrogenized primer works well as an inert primer that can not be extended without activation through removal of the 3' terminal nucleotide residue. The SNP-operated reversed on/off switch is not a simple candidate method in mutation detection. One particularly important feature of the previously developed on/off switch and this new reversed on/off switch is the identical reaction conditions of the two types of *Exo*⁺ DNA polymerases mediated by the primer extension. In large-scale SNP scanning, the application of two complementary assays within one platform, such as multi-well plates or microarrays, will help to minimize wrongly genotyped SNP sites resulting from special local sequence contents. With the application of the reversed on/off switch using the inert primers and the on/off switch using the 3' exonuclease-resistant primers, their complementary effect will help to increase assay sensitivity and reliability in genetic analysis. The on/off switch provides assays for precise detection of the location and type of mutation, whereas the reversed on/off switch serves as a very powerful and efficient assay in unknown mutation scanning^[11]. The reversed on/off switch was first described in 1998 as a proofreading PCR by Bi and Stambrook^[15].

Genomapping applications other than SNP assay

The high-fidelity features of the *Exo*⁺ polymerases mediated on/off and off/on switch can be widely used in a variety of genetic analysis, other than SNP assays. These include both genotyping and gene expression profiling. Genotyping focuses on the sequencing context and gene expression profiling evaluates both the sequence context and the functional levels of any specific isoforms of a given gene product. The *Exo*⁺ polymerases mediated assays provide methods useful for these two types of genetic assays simultaneously, an advantage favor to pharmacogenetic studies. To simplify the terminology, we refer the combination of genotyping

and gene expression profiling as genomapping analysis.

Analysis of mutations with short deletion/insertion Most of the currently available SNP assays, such as the single base extension assay, can not discriminate between wild-type alleles and mutants with small insertions or deletions. The aforementioned data illustrates the powerful mutation detection ability of the novel on/off switch, indicating its potential in the analysis of both SNP and other types of mutations. Except for the deletion or insertion of identical short repeats, the application of this on/off switch provides an efficient and high throughput compatible assay for mutation analysis^[4-11,16].

Detection of rare alleles using the novel on/off switch

The novel SNP-operated on/off switch is more sensitive than many conventional mutation analysis methods, including preferential amplification of the mutant allele, preferential destruction of the wild-type allele and spatial separation of mutant from wild-type alleles, by virtue of its use of Exo⁺ high-fidelity DNA polymerases. This breakthrough observation of an on/off switch action was repeatedly confirmed using either short artificial amplicons or natural genomic DNA templates^[11]. Another outstanding feature of the novel on/off switch is its flexibility and its ability to apply double switches in a single reaction (for example both the forward and the reverse primers are 3'-phosphorothioate modified and allele specific). The double-switch approach does not compromise sensitivity as is the case in most other primer-extension-based SNP assays.

Allele frequency estimation in pooled DNA samples The application of pooled DNA samples in initial studies can help to identify significant divergence in allele frequencies between case and control populations for further, more extensive association studies or for haplotype analysis. Invader technology, Bi-PAP (double directions-pyrophosphorolysis activated polymerization), and the SNP-operated on/off switch can all be used in allele frequency estimation. Among these three assays, the on/off switch has the advantage of simplicity, sensitivity, and accuracy. The application of the novel on/off switch in allele frequency estimation is expected to lower the cost and increase the accuracy of allele estimation using pooled DNA samples. Because the analysis of pooled samples requires only a handful of reactions per SNP, low assay development cost becomes of paramount importance.

High-fidelity gene expression profiling with the novel on/off switch

In our SNP and mutation detection assays, we have shown that the on/off switch can recognize a single mis-

match in six nucleotides upstream of the 3' terminus. In most circumstances, Exo⁺ DNA polymerases can discriminate single mismatched nucleotides several bases upstream of the primer-3'-termini, but this varies according to the amplicons and the enzymes^[3].

In the early stage of gene expression analysis, mRNA is the target material. Such methods include Northern blotting and ribonuclease protection assays. Although these methods could be compatible with high throughput scalability, the ribonuclease protection assay is still, to date, the most reliable method in gene expression profiling. Microarray technology has solved the high throughput issue for genome-wide gene expression profiling. However, cDNA is an indirect target because it cannot completely represent the type and abundance of mRNA. False positives are particularly high when post reverse transcription amplification by *Taq* polymerases is used. To minimize the errors introduced by *Taq* polymerase-mediated amplification, high-fidelity DNA polymerases have recently been used in genome-wide gene expression profiling. Because proofreading polymerases display up to two orders of magnitude better amplification fidelity, the application of high-fidelity polymerases has great potential in improving the reliability of microarray-based gene expression profiling.

In general, false positives in gene expression profiling arise from three sources: mismatched incorporation in reverse transcription, mismatched priming, and mismatched incorporation during primer extension. Although the high-fidelity gene expression assay described in the present study has nothing to do with the errors introduced from reverse transcription, it eliminated the mismatched priming error and greatly minimized the mismatched incorporation during primer extension. Increased fidelity in gene expression profiling not only benefits assay sensitivity and reliability, it also provides new applications in genetic analysis. The differential amplification of the on/off switch allows for the profiling of very rare abundant transcripts in normal tissues or cancer tissues. It also offers simple and convenient methods for comparing isoforms, inter-species or intra-species.

Suggested strategies for somatic mutation load assay

It was almost impossible to analyze rare mutations or mutation loads before the development of highly sensitive genotyping methods. The false positives recorded in conventional assay methods, in both hybridization-based and enzyme-based assays, are higher than the mutation rate. Theoretically, our recently developed Exo⁺ polymerase-mediated on/off switch is a good method for examining rare

mutations because it almost eliminates false positives. However, assay sensitivity is another obstacle facing the detection of rare mutations. For example, for single-copy genes, 1 mg genomic DNA only contains 3×10^5 molecules of relevant genes. Theoretically, to detect a single mutant out of 1×10^9 – 1×10^{10} wild-type molecules (based on the mutation rate in human somatic cells per generation), at least mg scale genomic DNA is needed. These results in two immediate problems: technical difficulties in obtaining the large amount of human genomic DNA required, and the inhibitory effect of large amounts of DNA on PCR reactions.

An alternative approach in somatic mutation load analysis is to use genetic elements with high-copy numbers in the genome. As spontaneous mutation rates vary among genes and tissues, interspersed repeats might be a better choice than tandem repeats. A combination of highly sensitive SNP genotyping methods and a high-copy number of interspersed repeats may provide a practical and useful strategy for somatic mutation load assays at the genome level.

Selection of interspersed repeats for somatic mutation load analysis Short, interspersed nucleotide element (SINE) repeats, such as Alu elements with a high incidence of CpG dinucleotides in new Alu inserts, predisposes a higher mutation rate than long, interspersed nucleotide elements (LINE). Approximately half of the SNP in young Alu elements fall in the region of CpG dinucleotides. For somatic mutation load analysis, it appears that the targeting nucleotides to be chosen need to be carefully sorted. If too many targets are CpG dinucleotides, the overall estimated somatic mutation load might be biased and higher than the actual load.

In the case of this example, 1 ng of genomic DNA used in a somatic mutation load assay with a high-copy number repeat sequence will have the same power as approximately 1 mg of genomic DNA when targeting single-copy genes. Another issue regarding our strategies for somatic mutation load analysis is validation using genomic DNA samples that have different somatic mutations as expected, such as DNA from cancer tissue versus DNA from normal tissue, or DNA from cells in their early passages versus that from late passages.

Alternative opportunities from mitochondrial DNA The large number of mitochondria present in every mammalian cell (1000–10 000) makes this extra-nuclear genetic material very useful in somatic mutation analyses. Furthermore, studies have reported that mitochondrial DNA (mtDNA) has a mutation rate of one base mutation per 1500–3000 years of evolution, which is believed to be a higher rate than chromosomal DNA. The existence of homoplasmy and heteroplasmy in mitochondria mutation and their close relationship with

the development of disease strongly suggests the value of testing the mutation load of mtDNA in future studies of personalized medicine. Some mtDNA somatic mutation showed a dose-dependent pattern in causing diseases^[17,18]

One technical advantage of sequence comparisons is the very-low copy numbers of well-matched regions between mitochondrial and chromosomal DNA. This is especially true for mitochondrial tRNA genes, which are never observed in more than five copies in chromosomal DNA. This feature allows somatic mutation load assays to be separately designed for chromosomal and mitochondrial DNA without preparing separate DNA samples.

Target simplification by using *in vitro* amplified DNA Genomic DNA can be easily simplified and amplified using routine PCR technology. From a technical point of view, a combination of the PCR amplification of target DNA and a subsequent mutation load detection using one of the mutation quantitative analysis methods outlined can be viewed as a type of nested PCR. An advantage of this nested strategy is that any chromosomal region can be used as the target in somatic mutation load analysis.

In addition, many types of RNA are transcribed at highly abundant levels. Therefore, cDNA obtained immediately from *in vitro* reverse transcription or with a low-cycle-number PCR amplification can be a useful target in somatic mutation load analysis. A potential drawback of using RNA as the target in somatic mutation load analyses is that most mutated RNA are not as stable as their wild-type partners, which may decrease the opportunity for accurately detecting mutations. Therefore, RNA can act as one of the targets, but can not be used as the sole target in practical somatic mutation load analyses when a global approximate of the mutation load is required.

Conclusion

Significant advances after the completion of the Human Genome Project, including bioinformatic algorithms and highly sensitive SNP genotyping technologies, have provided great possibilities for studies relating genotype with phenotype. High-fidelity DNA polymerases have been approved for use as new and very attractive members among a variety of enzymes in genetic analysis. The three types of new methods mediated by proofreading polymerases provide sensitive and reliable tools for genomapping analyses consisting of genotyping, gene expression profiling, and mutation load assay. Genotyping, including SNP screening, is now widely used in pharmacogenetic studies. The most immediate tasks in somatic mutation load analysis are the selection of the genetic sequence set as representative tar-

gets for mutation assay, and the validation of these representative sequences using one or more of the three mutation analysis methods discussed. It is reasonable to expect that somatic mutation load analysis, especially the mitochondrial somatic mutation load, will have an important impact on both basic research and clinical practice.

Abstract

Aim: To investigate differential gene expression and the pharmacological mechanism of baicalin and gardenin in focal cerebral ischemia in rats with high-density cDNA microarray. **Methods:** Rat left middle cerebral arteries were occluded and treated with either baicalin or gardenin. The pharmacological effects were investigated using the difference in infarction areas before and after treatment, which were determined by 2,3,5-triphenyltetrazolium chloride (TTC) staining. Gene expression was demonstrated using a "Biostar40S" gene microarray. Semiquantitative reverse transcription-polymerase chain reaction (RT-PCR) was used to verify the result of the selected genes. **Results:** Both baicalin and gardenin reduced the infarction areas in focal cerebral ischemia rats ($P < 0.05$). The differential genes were 211, 177, and 70 (upregulated or downregulated) in the model group, baicalin, and gardenin treatment groups compared with the sham-operated group, respectively. Gene expression of Rpl19 and Csnk2 underwent an approximately 1.9 and 2.1-fold increase, respectively, verified by semiquantitative RT-PCR, which was the same trend as the cDNA microarray. **Conclusion:** Differential gene expression with respect to the pharmacological effects of baicalin and gardenin on focal cerebral ischemia by cDNA microarray revealed a number of clues with respect to the therapeutic mechanisms of Chinese traditional medicine. In addition, the present study provided theoretical and experimental evidence that will aid future studies examining cerebral ischemia.

Introduction

Stroke, mostly caused by cerebral ischemia, is a multifactorial disease involving the activation of myriads of death inducers, which leads to injury of neurons by eliciting cascades of signal transduction pathways^[1]. The Qing Kai Ling injection (QKLI) is a modified preparation of the "An Gong Niu Huang" pill, a famous traditional Chinese medicament. In recent studies, QKLI showed strong therapeutic effects on stroke in clinical usage. However, this preparation is a compound comprising of many components. Its therapeutic mechanism is very complex, with regard to both individual and integrative effects. Baicalin and gardenin are two effective compounds of QKLI. Baicalin, known as an antioxidant flavonoid *in vitro*, functions as a biological response modi-

fier^[2,3], and has been investigated for its neuroprotective effects against glutamate/*N*-methyl-*D*-aspartate (Glu/NMDA) stimulation and glucose deprivation in primary cultured rat brain neurons. Baicalin was found to significantly reduce Glu/NMDA-increased lactate dehydrogenase (LDH) release^[4]. Baicalin is also a potent inhibitor of endothelial cell proliferation, migration, and differentiation^[5]. Gardenin can significantly decrease the content of transcription factor monocyte chemoattractant protein-1 (MCP-1) in rat brains suffering focal ischemia^[6]. cDNA microarray possesses the ability to analyze the expression changes of hundreds, thousands, or even tens of thousands of genes simultaneously. Several waves of gene expression have been observed after focal cerebral ischemia^[7]; however, a comparative study examin-

ing the pharmacological mechanisms of different drugs has not been reported in the literature. Results from the present study suggest that baicalin and gardenin play a pharmacological role in focal cerebral ischemia by regulating gene expression.

Materials and methods

Cerebral ischemia Forty-four Sprague-Dawley rats (250–280 g, supplied by Beijing Weitong-Lihua Experimental Animal Center, Beijing, China) were randomly divided into four groups: model, baicalin-treatment, gardenin-treatment, and sham-operated group, respectively. Under isofurane anesthesia, rats were subjected to occlusion of the left middle cerebral artery (MCAO) using an intraluminal filament as described by Haruo *et al*^[8]. After 24 h of focal cerebral ischemia, the rats were deeply re-anesthetized using halothane and the left half of the brain was removed for total RNA isolation. In the sham-operated rats, all procedures except for MCAO were carried out. Baicalin or gardenin (National Institute for the Control of Pharmaceutical and Biological Products, Beijing, China) was given orally (40 mg/kg) 2 h after MCAO.

Measurement of cerebral infarction areas Eight rats from each group were used to calculate the infarction ratio. In brief, the cerebrum was removed and cut into five slices on the coronal section at the location from which the distance to the prefrontal is 1, 3, 5, and 7 mm, respectively. The slices were stained in 4% 2,3,5-triphenyltetrazolium chloride (TTC) solution for 10 min^[9]. Images of the slices were captured using a digital camera (Color CCD camera TP-6001A, Topica Inc, Japan). We calculated the areas of the infarction region using a Pathology Image Analysis System (Topica Inc, Japan). The ratio of the infarction area to the total slice area was calculated.

Total RNA isolation The left half of the brain from the remaining three rats in each group was carefully dissected out from the re-anesthetized rats under RNAase-free conditions. The total RNA in each sample was extracted with Trizol reagent (Invitrogen, San Diego, CA, USA) using the procedure outlined in the manufacturer's protocol.

Microarrays Hybridization was carried out on the rat "Biostar40S" gene microarray (BioStar Genechip Incorporated, Shanghai, China), which contained 4096 elements. The array provided a broad overview of the rat genome, which was added to the high-quality array cDNA libraries, and the sequence information, maps, and expression data were placed into the public domain (NCBI, Nucleotide). All clones used for production of the microarrays

were sequence verified. Three pieces of total RNA from the same group were pooled following transcription into cDNA and were labeled with Cy5 and Cy3, respectively, and hybridized on the array. Image files were processed using the Axon GenePix 4000B scanner (Axon, USA) and datasets were prepared according to the routine procedures using Genepix 4.0 software (Axon, USA).

Data analysis Data sheets derived from the results of the Genepix 4.0 analysis were further evaluated using Excel software (Microsoft, USA). The microarrays were hybridized in triplicate and each measurement containing the extracted total RNA from each group was used to analyze each gene, which had three data points of relative changes. Thus, a balance coefficient was calculated to correct variations resulting from unequal amounts of fluorescent dye fade; the average signal from all elements in the Cy3 channel was divided by the average signal from all elements in the Cy5 channel, which resulted in the balance coefficient. The Cy5 signal for each element was then multiplied by the balance coefficient, prior to calculating the expression ratio (Cy3/Cy5). A fold value of =2.0 or =-2.0 indicated that differences in the Cy3: Cy5 ratio were detected at a 99% confidence level (information provided by Incyte, USA). All probes fulfilling the criterion (=2.0 or =-2.0) were compiled^[10–13].

Semiquantitative RT-PCR The procedures for isolating total RNA using Trizol reagent (Invitrogen, Life Technology, Incorporated, New York, NY, USA) and synthesizing first strand cDNA were exactly as previously described^[14]. The optimal polymerase chain reaction (PCR) amplification conditions and cycle number were determined experimentally to ensure specific signal generation. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was considered to be stably expressed after focal cerebral ischemia acted as an interference gene. All amplifications were carried out on a Gradient PCR System (Biometra, USA). cDNA synthesis was carried out using 200 ng of mRNA with 5×10^5 U/L reverse transcriptase (TaKaRa, Japan) in a total 100 μ L reaction mixture and incubated for 60 min at 48 °C. The primer pairs were for ribosomal protein L19 (Rpl19): AACAGATCA GGAAGC TGA TCA AGA; AGT CTT GAT GAT CTC CTC CTT CTT (NM 031103); casein kinase II beta subunit (Csnk2b): CGG ACATAAAGATGAGTAGCTCTGA; GTG GTG CCTAGA GGA CTT GGG TGT G (NM 031021); GAPDH: ACC ACA GTC CAT GCC ATC AC; TCC ACC ACC CTG TTG CTG TA (NM 008084.1). After heating to 95 °C for 5 min, each RT reaction mixture was used for PCR amplification. The PCR mixture started with in an initial step of 5 min at 95 °C followed by 35 cycles of 30 s at 95 °C and an annealing temperature of 1 min at 64.5 °C for Csnk2b mRNA, at 57.4 °C for

Rpl19 mRNA and GAPDH, followed by 72 °C for 10 min. Products of 5 μL from each PCR mixture were dyed with 1 μL SYBR Green I Nucleic Acid Gel stain (Cambrex Bio Science Rockland Incorporated, USA) and loaded on 2.5% agarose gels, which were evaluated according to the intensity differences of image electrophoresis using Gel Analyzing Imager (FuRi, Shanghai, China).

Results

TTC staining Both baicalin and gardenin reduced the infarction areas in cerebral ischemia rats by 6%–7% compared with the model group. The ratio of differences was tested using the Student *t*-test (Figure 1, Table 1).

Figure 1. Cross-sections showing cerebral infarction areas (in white) of a number of samples stained with 2,3,5-triphenyltetrazolium chloride.

Table 1. Cerebral infarction areas from a number of samples stained with 2,3,5-triphenyltetrazolium chloride. *n*=8. Mean±SD. ^b*P*<0.05 vs the model group.

Group	Percentage of infarcted area to cerebral area/%
Model	24.7±5.6
Baicalin	14.7±3.0 ^b
Gardenin	15.4±3.2 ^b

Changes in gene expression after MCAO occlusion

Genes were classified into 12 categories by the International General Principle (www.geneontology.org). One hundred and ninety-nine genes were significantly upregulated which are involved in metabolism, signal transduction, cell organization, response to stress, cell adhesion, transport, apoptosis, and a variety of other processes. Another 12 genes showed downregulated expression under the same conditions (Table 2).

Metabolism The largest increases in gene expression were shown by genes involved in protein synthesis: the ribosomal proteins L10, S5, S3a, S24, S6, S11, and L19, glyco-

protein 38, eukaryotic translation elongation factor 1 alpha and actin-related protein complex 1b. The expression of genes related to cell metabolism changed with increased expression of coenzyme A dehydrogenase, procollagen-lysine, lactate dehydrogenase and ubiquinone oxidoreductase subunit B13.

Cell organization and adhesion Cell organization and adhesion genes also showed prominent changes in expression. These included Fibronectin 1, Integrin, H2A histone family member and apolipoprotein M.

Signal transduction Increases in expression were shown by genes involved in cellular signal transduction: CDK5, pyruvate kinase 3, phosphatidylinositol 4-kinase, and casein kinase II. In addition, the G protein pathway suppressor showed decreased expression over this interval.

Response to stress Several “stress” genes involved in cellular responses to inflammation and injury were induced, including Cd63 antigen, MRC OX-45 surface antigen and immunoglobulin superfamily member. Another induced gene, glutathione peroxidase 1, was also upregulated after focal cerebral ischemia.

Apoptotic genes The expression of several apoptotic effector genes was altered. These included programmed-cell-death-8, Urmodulin, and tumor protein translationally controlled genes.

Effect of baicalin on gene expression Increases in gene expression were observed in 89 genes. These included genes involved in metabolism, signal transduction, cell organization, responses to stress, and transcription regulators. In addition to the induced genes, 88 genes simultaneously showed decreased expression (Table 3).

Metabolism Metabolism-related genes showed prominent changes in expression. These included ADP-ribosylation factor, enolase, adenine phosphoribosyltransferase, and palmitoyl-protein thioesterase. In addition, histamine *N*-methyltransferase simultaneously showed decreased expression.

Signal transduction The largest increases in expression were shown by genes involved in protein tyrosine phosphatase receptor type D and receptor type A. S100 calcium-binding protein A9 also showed prominent changes. In addition, the expression of protein kinase C-binding protein Zeta and surfactant-associated protein decreased. Protein kinase is controlled by specific binding proteins, which are believed to sequester each type of kinase to the region of a neuron, such as the postsynaptic specialization or cell nucleus, that requires its function^[15]. The protein kinase C-binding protein Zeta is one of these proteins. Arachidonic acid epoxygenase, an adapter protein of the prostaglandin

and leukotriene family of intracellular messengers, also appears to play an important role in the regulation of signal transduction in the brain and elsewhere^[14].

Cell organization The expression of nucleolar phosphoprotein p130, an adapter protein that participates in nucleolar disassembly and cell cycle, decreased after MCAO. In addition, peroxisomal membrane protein showed increased expression over this interval.

Transcription regulator Two genes related to the transcription regulator were altered. These were spliceosome-associated protein and DNA primase.

Effect of gardenin on gene expression Increases in gene expression were observed for 68 genes. These included genes involved in metabolism, signal transduction, cell organization, response to stress, cell cycle, and cell mobility. In addition, two genes showed decreased expression over this interval (Table 4).

Metabolism The expression of several genes involved in protein synthesis and cell metabolism was altered. These included ADP-ribosylation factor, HS-glycoprotein and deoxyribose-phosphate aldolase.

Signal transduction Changes in the expression of genes indirectly related to signal transduction were observed, and consisted of increased expression in nuclear receptor,

adapter-related protein complex and retinoid-inducible serine carbopeptidase precursor.

Response to stress Several "stress" genes involved in cellular responses to oxidation were induced. The most striking was the increased expression of glutathione-S-transferase.

Cell mobility Myosin heavy chain and tropomyosin beta chain genes that participate in cell mobility and cell cycle were also induced.

Semiquantitative RT-PCR The outcome of this study showed that the expression of ribosomal protein RpL19 mRNA and Csnk2 mRNA were consistently upregulated in the individual samples from MCAO rats relative to sham-operated rats. Expression increased by 1.9- and 2.1-fold, respectively, and showed the same trend as the results of the microarray. The outcome of RT-PCR indicated that broad, array-based gene expression measurements were reliable for determining gene expression patterns in the brain (Figure 2).

Discussion

Messenger RNA is only an intermediate on the way to the production of the eventual protein products. In the present study we explored the potential role of cDNA

microarrays for gene expression analysis after focal brain ischemia and examined the differences in gene expression after the action of different compounds of QKLI. An ischemia period of 24 h was used because this is the maximum period of cerebral ischemia that is compatible with neuroprotection^[16-18]. To select results from microarray ex-

periments with reliably altered ratios, we filtered the results using two criteria^[10-13]: minimal fold-change values, and ratios reproducibly different from unity. The hybridization ratio had to be at least two-fold higher or lower than the control groups. Of these filters, the two-fold ratio filter was by far the most restrictive and there was no uniform standard across the different platforms of the arrays. We have listed the information of differential gene expression according to the functional classification of genes. In brief, baicalin and gardenin appear to have a profound influence on the model by regulating the expression of different genes or by acting on different metabolic pathways. The genes related to cell metabolism presented striking changes, and showed increased expression in both model and baicalin-treatment groups in contrast to the gardenin-treatment group. Baicalin appears to have a more prominent action on signal transduction in cells than gardenin, including activation of ion channels, regulation of kinase and phosphorylation of receptor proteins. In contrast, the effects of gardenin in stress responses and anti-oxidation appear to be more significant

Figure 2. Some strongly regulated Rpl19 and Csnk2 genes are confirmed with RT-PCR. Size of the internal control is 550 bp, and that of the target genes are 350 and 320 bp. Ratios indicate the signal intensity of examined gene vs that of glyceraldehyde-3-phosphate dehydrogenase (GAPDH) at different groups. The bottom panel in each graph is a representative gel of the PCR products of three independent repeats.

than those of baicalin.

Changes in gene expression after MCAO Prominent changes were recorded in the ribosomal proteins S6, L6, S3a, S24, L5, L10, L19, and S11 on the microarray^[19]. In general, this finding supports previous studies^[20], perhaps reflecting recovery from an early postischemic transcriptional defect. Integrin is a transmembrane protein, and the adhesion effects between leucocytes and cerebral microvessel cells mediated by integrin participated in the injury and destruction of inflammation factors to tissues. The increased expression of integrin after MCAO is, in general, in line with a preceding report^[21]. The increased expression of protein kinase (PK) is mostly caused by the large amount of PK released as a result of metabolic dysfunction, necrosis, ischemia and hypoxia of cells, which occurs in acute cerebrovascular diseases, and this finding was in accordance with the clinical diagnosis. The increased expression of genes in the G protein pathway suppressor 1 may have contributed to the adaptive modulation of the body. In general, G protein plays a role in signal amplification and in switching the molecule on and off in the

course of signal transduction. G protein pathway suppressor was upregulated after focal cerebral ischemia, which might occur in compensation for stress and signal transduction regulation in the body^[22,23]. Casein kinase II is a necessary substance for cell survival, and increased expression of casein kinase II is correlated with hyperplasia and the proliferation of cells after cerebral ischemia. Cyclin-dependent kinase 5 (CDK5) mRNA was found to be downregulated after focal brain ischemia, whereas variable changes were noted at the protein level in focal ischemia^[24]. Downregulation of phosphatases was noted, which would alter the balance of protein phosphorylation in several cellular signaling pathways; much more information is needed before any suggestions regarding functional effects can be made. As the oxidation of glutathione peroxidase might offer a new modulating mechanism of cellular signal transduction^[25], it was suggested that its increased expression could provide a sign in response to stress in the body.

Effect of baicalin on gene expression Programmed-cell-death-8 was upregulated after MCAO with baicalin treatment.

Furthermore, novel mediators of cerebral ischemia inducing neuronal death have also been found using cDNA microarrays. All these studies reinforce the idea that common cell death pathways are activated in response to neuron death inducers, which promise to serve as potential therapeutic targets for modulation to achieve neuroprotection^[26]. The expression of the protein kinase C-binding protein Zeta was downregulated in rats treated with baicalin, which resulted in a decrease in the activity of protein kinase C (PKC). Aronowski *et al*^[27] observed that the activity of PKC in the brain cortex and hippocampus decreased significantly after ischemia and this decrease could be alleviated by the pre-treatment of the NMDA receptor antagonist. Further studies need to examine whether baicalin acts as an antagonist to the NMDA receptor. After all, the relationship between the changing activity of PKC and neuron injury has not been elucidated completely in many key pathophysiological procedures of ischemia, such as increment of fermentation, acidosis, and deficiency of ATP production. The prominent differential genes involved in protein tyrosine phosphatase receptor type D and A are central to the course of signal transduction, which has been implicated both in the regulation of cell growth and the rearrangement of actin that is mediated by several receptor tyrosine kinases. Differential gene expression showed that baicalin played an important role in cell signal transduction and protein phosphorylation after MCAO, and might act as a neuroprotectant.

Effect of gardenin on gene expression The differential genes in the gardenin-treatment group showed extreme variation compared with the baicalin-treatment group. Several genes encoding anti-oxidation were upregulated. For example, an increase in Mu2 suggested that Mu2 played an activation role in anti-oxidation responses, and was regarded as one of the markers of internal anti-injury because of its anti-oxidative and antidotal effects^[25]. According to the actions of Mu2, the anti-oxidative and antidotal effects of gardenin might be one of the mechanisms of cerebral protection after MCAO.

The most interesting phenomenon observed was that there was no overlap in the genes showing differential expression in the three groups despite the similar trends in expression. The results suggest that there are considerable differences in the pharmacological effects of baicalin and gardenin at the molecular level after MCAO. Compared with the role of gardenin and bacalin, which are components of QKLI, it appears that QKLI plays an integral role and has important therapeutic effects requiring further investigation.

In conclusion, the cDNA microarray study not only confirmed that changes in many genes contributed to cerebral

ischemia, but also suggested several potential targets for further investigation. Of course, global expression of genes measured at the levels of mRNA transcription obtained using microarray analysis should be viewed from two different standpoints. Looking from mRNA towards protein, one would ultimately like to test the increased production of the proteins encoded by the upregulated mRNA or demonstrate a loss of protein encoded by downregulated mRNA. Thus, it may be rewarding to reconstruct the networks of regulation in response to ischemia and, by inference, to hypoxia, using bioinformatic strategies^[28]. Understanding such regulatory networks and the therapeutic mechanisms of QKLI for ischemia-hypoxia responsive gene expression in neurons may extend the relevance of these studies.

Abstract

Aim: To investigate the role of inducible nitric oxide synthase (iNOS)-derived nitric oxide (NO) in the cardioprotection of intermittent hypoxia (IH) against ischemia/reperfusion (I/R) injury. **Methods:** Langendorff-perfused isolated rat hearts were used to measure variables of left ventricular function during baseline perfusion, ischemia, and reperfusion period. Nitrate plus nitrite (NOx) content in myocardium was measured using a biochemical method. iNOS mRNA and protein expression in rat left ventricles were detected using reverse transcription polymerase chain reaction (RT-PCR) and Western blot, respectively. **Results:** Myocardial function recovered better in IH rat hearts than in normoxic control hearts. The iNOS-selective inhibitor aminoguanidine (AG) (100 μmol/L) significantly inhibited the protective effects of IH, but had no influence on normoxic rat hearts. The baseline content of NOx in IH hearts was higher than that in normoxic hearts. After 30 min ischemia, the NOx level in normoxic hearts increased compared to the corresponding baseline level, whereas there was no significant change in IH hearts. However, the NOx level in IH hearts was still higher than that of normoxic hearts during ischemia and reperfusion period. AG 100 μmol/L significantly diminished the NOx content in IH and normoxic hearts during ischemia and reperfusion period. The baseline levels of iNOS mRNA and protein in IH hearts were higher than those of normoxic hearts. Compared to the corresponding baseline level, iNOS mRNA and protein levels in normoxic rat hearts increased and those in IH rat hearts decreased after reperfusion. The addition of AG 100 μmol/L significantly decreased iNOS mRNA and protein expression in IH rat hearts after I/R. **Conclusion:** IH upregulated the baseline level of iNOS mRNA and protein expression leading to an increase in NO production, which may play an important role in the cardiac protection of IH against I/R injury.

Introduction

Intermittent hypoxia, or periodic exposure to hypoxia interrupted by a return to normoxia or less hypoxic conditions, is encountered more frequently in life than sustained hypoxia^[1,2]. Many studies have shown that intermittent hypoxia adaptation might have cardioprotective effects similar to those observed in ischemic preconditioning

(IPC)^[3-6]. To date, several potential factors have been proposed to be involved in the protective mechanisms afforded by IH^[4-10]; however, the precise mechanisms in which IH increases resistance to myocardial ischemia remain far from clear.

Beall *et al* reported that exhalation of nitric oxide (NO) by chronically hypoxic populations of Tibetans and Bolivian Aymara is unexpectedly increased compared with low-alti-

tude populations^[11]. The similar response of these two geographically separate high-altitude populations underlines the importance of NO for life under hypoxic stress. Beall *et al* speculated that one possible adaptation to maintaining high-output NO synthesis under hypoxia included increased expression of the synthase enzymes themselves. Nitric oxide synthase (NOS) are a family of three isozymes responsible for the production of NO: the constitutive endothelial (eNOS) and neuronal (nNOS) isozymes and the inducible isozyme. It is known that iNOS is expressed in a wide variety of cell types, including cardiac myocytes. iNOS is usually expressed in response to various physiological and pathophysiological stimuli, such as intense exercise and hypoxia. Recent studies have shown that NO plays an important role in protecting myocardium from I/R injury^[12-14]. In addition, studies have indicated that the cardioprotective effects of late preconditioning observed after 24 h resulted from the upregulation of NOS and, more specifically, of iNOS^[15,16]. Neckar *et al*^[17] reported that the cardioprotective effects of chronic hypoxia and IPC were not additive, suggesting that the mechanisms of protection conferred by chronic hypoxia and preconditioning may share some common signaling pathways. At present, little is known about the role of iNOS-derived NO in the cardioprotection of IH and there is no evidence about the changes in iNOS mRNA and protein in IH rat hearts subjected to ischemia and reperfusion. The aim of the present study was to evaluate: (i) the effect of aminoguanidine (AG) on the post-ischemic recovery of left ventricular function in IH rat hearts, thereby determining the role of iNOS-derived NO in the cardioprotection afforded by IH; and (ii) the effect of IH on iNOS mRNA and protein expression in rat hearts during baseline perfusion, ischemia and reperfusion period.

Materials and methods

Animal preparation Adult male Sprague-Dawley rats (Clean grade, Shanghai Experimental Animal Center, Chinese Academy of Sciences, Shanghai, China), initially weighing 100–130 g and finally weighing 280–330 g, were exposed to intermittent high-altitude hypoxia of 5000 m in a hypobaric chamber for 6 h/day. Barometric pressure (p_B) was lowered to the level equivalent to an altitude of 5000 m ($p_B=54$ kPa; $p_{O_2}=11.3$ kPa). The total number of exposures was 42-day. The temperature in the chamber was maintained at 22–24 °C. The animals were examined the day after the last hypoxic exposure. The control group of animals was kept under normoxic environmental conditions. All animals were maintained with a natural light-dark cycle (12 h Light:

12 h Dark).

Isolated rat heart perfusion The rats were anesthetized with sodium pentobarbital (60 mg/kg, ip) as previously described^[9]. Hearts were quickly excised and mounted on a Langendorff apparatus for a retrograde perfusion with Krebs–Henseleit solution (K-H buffer solution) at a constant pressure of 80 mmHg. K-H buffer solution contains (mmol/L): NaCl 118.0, KCl 4.7, CaCl₂ 2.5, MgSO₄ 1.2, NaHCO₃ 25.0, KH₂PO₄ 1.2, glucose 11.0, and sodium pyruvate 2.0. The medium was continuously gassed with 95% O₂ and 5% CO₂ (pH 7.4) and maintained at 37 °C. A water-filled latex balloon connected to a pressure transducer (Gould P23Db) was introduced into the left ventricle via the mitral valve to record isovolumic left ventricular pressure. The balloon volume was adjusted to achieve a stable left ventricular end-diastolic pressure (LVEDP) of 5–10 mmHg during the initial equilibration. Heart rate (HR), left ventricular peak systolic pressure (LVPS), LVEDP, left ventricular developed pressure (LVDP), coronary flow (CF), and the peak rate of pressure developed ($\pm dp/dt_{max}$) were monitored using a PowerLab system (AD Instrument Ltd, Castle Hill, Australia). LVDP=LVPSP–LVEDP. Pressure-rate product (PRP) was calculated, PRP = HR×LVDP.

Experimental protocol and groups We chose AG, an iNOS-specific inhibitor^[18], to detect its effect on the cardioprotection of IH. Rats were divided into four groups: (1) corresponding control (CON) group; (2) CON+AG group; (3) IH group; and (4) IH+AG group. In the present study, we used 20 min baseline perfusion, 30 min no-flow global ischemia, followed by 30 min reperfusion protocol. The hearts of rats in the drug group were treated with AG 100 μ mol/L for 5 min before ischemia and maintained during 30 min ischemia, followed by 30 min reperfusion with K-H buffer solution. To obtain samples for biochemical, RT-PCR, and Western-blot experiments, each group was further divided into three subgroups: (1) baseline perfusion group: 20 min baseline perfusion; (2) ischemia group: 20 min baseline perfusion followed by 30 min no-flow global ischemia; and (3) ischemia/reperfusion group: 20 min baseline perfusion, 30 min no-flow global ischemia, followed by 30 min reperfusion. At the end of baseline perfusion, ischemia, and reperfusion, respectively, the hearts were dissected into left and right ventricles, frozen in liquid nitrogen, and stored at –80 °C.

Nitrate plus nitrite (NOx) measurement NOx, the stable end product of NO, was assessed as nitrite concentration after conversion of nitrate to nitrite with nitrate reductase and measured using a commercial kit (Nanjing Jiancheng Bioengineering Institute, Nanjing, China). NOx was designated as μ mol/g protein. Its concentration was determined

at an optical density of 550 nm in a spectrophotometric method. Protein determination was carried out according to the Bradford method using bovine serum albumin as the standard.

RNA isolation and semi-quantitative determination of iNOS using RT-PCR Total RNA was extracted from frozen ventricular tissue with Trizol reagent and quantified by absorption at 260 nm. Reverse transcription from 0.5 µg total RNA was incubated in a 20-µL mixture containing 40 U reverse transcriptase, 500 µmol/L of each dNTP, 500 ng oligo(dT) and reaction buffer at 42 °C for 50 min. The sequences of the iNOS primers were 5'-ACTGCTGGTGGTGA-CAAG-3' (forward) and 5'-CGTTGGAAGTGTA-GCGTT-3' (reverse), allowing the amplification of a 333-bp fragment; the sequences of the M28S primers were 5' AGCAGCCGACTTAGAACTGG-3' (forward) and 5'-TAGGGACAGTGGGATCTCG-3' (reverse), allowing the amplification of a 250-bp fragment. The PCR contained 0.1 µmol/L of each primer, 200 µmol/L of each dNTP, 2.5 mmol/L MgCl₂ reaction buffer and 1 U *Taq* DNA polymerase in a final reaction volume of 20 µL. The reaction mixture was incubated in a thermocycler (Eppendorf Mastercycler gradient, Germany) programmed to predenature at 94 °C for 5 min, denature at 94 °C for 40 s, anneal at 60 °C for 40 s, and extend at 72 °C for 40 s for a total of 38 cycles. The last cycle was followed by a final elongation at 72 °C for 5 min and cooled to 4 °C. A pilot experiment had shown that this cycle number allowed product detection within the linear phase of amplification.

The amplified products were electrophoresced on a 1.0 % agarose gel stained with ethidium bromide, visualized under ultraviolet light, and scanned using Gel doc 2000 (Bio-Rad, Richmond, CA, USA). The results were expressed as the relative intensity of bands for iNOS PCR product normalized by the intensity of the band for M28S.

Preparation of protein extracts and Western blot analysis of iNOS isozyme The protein extracts were prepared by homogenizing the left ventricles in isotonic sucrose buffer A (mmol/L): Tris-HCl 20.0, sucrose 250.0, Na₃VO₄ 0.03, MgCl₂ 2.0, edetic acid 2.0, egtazic acid 0.5, PMSF 2.0, DTT 1.0, protease inhibitor cocktail 0.02 % (v/v), pH 7.4. The homogenates were centrifuged at 100 000×g for 60 min at 4 °C to separate the particulate fraction from the cytosolic fraction. The supernatant containing soluble NOS, designated as cytosol, was used for the Western blot analysis of iNOS.

After boiling for 10 min, equivalent amounts of cytosolic protein (40 µg) were separated by 8% denaturing sodium dodecyl sulfate (SDS)-polyacrylamide gel electrophoresis (PAGE), electroblotted onto a nitrocellulose membrane and

immunoreacted with iNOS primary antibody (Santa Cruz Biotech, Santa Cruz, CA, USA) overnight at 4 °C, followed by a 2-h incubation at room temperature with the second antibody (goat anti-rabbit IgG, Sigma Chemical Company, St Louis, MO, USA) conjugated with horseradish peroxidase. The iNOS isozyme was detected using enhanced chemiluminescence (ECL, Amersham Biosciences, UK) as 130-kDa bands. Each iNOS isozyme signal was normalized to the standard signal of the normoxic control heart. The scanned image was imported into Adobe Photoshop software; scanning densitometry was used for quantitative analysis of the data.

Materials and reagents AG was purchased from the Sigma Chemical Company; Trizol isolation reagent was from Invitrogen Life Technologies (San Diego, CA, USA); primers of iNOS and M28S were synthesized by Sangon Bioengineering Company (Shanghai, China); and the reverse transcription system was obtained from Promega (Madison, WI, USA).

Statistical analysis All data are expressed as mean±SD. Statistical analysis were carried out using one-way ANOVA or Student's *t* tests when appropriate. Differences were considered significant at *P*<0.05.

Results

Effects of AG on recovery of CF and ventricular function after I/R in IH and normoxic rats Our previous study showed that the ratio of whole ventricle weight to body weight of rats in IH groups was not significantly different from normoxic control animals, which meant that intermittent hypoxia in this experimental condition did not result in heart hypertrophy^[6,19]. The present study demonstrated that CF was slightly but significantly higher in IH hearts during baseline perfusion (Table 1). CF dramatically decreased during reperfusion in all groups, but the improvement of CF during reperfusion was greater in the IH group compared with the normoxic control group. The addition of AG 100 µmol/L did not significantly change either pre-ischemic CF or LVDP, but inhibited pre-ischemic $\pm dp/dt_{\max}$ in normoxic and IH hearts (data not shown). The addition of AG 100 µmol/L inhibited the improvement of CF during reperfusion in the IH group, but had no influence on normoxic hearts.

As shown in Table 1, HR did not change in any group and was not affected by AG 100 µmol/L. Baseline values of ventricular function variables did not differ in any group during baseline perfusion, except for CF, but the values of LVDP, $\pm dp/dt_{\max}$, and PRP were greatly decreased, whereas LVDP significantly increased during reperfusion. During

CF, coronary flow; LVPSP, left ventricular peak systolic pressure; LVEDP, left ventricular end-diastolic pressure; HR, heart rate; $\pm dp/dt_{\text{max}}$, peak rate of pressure developed; PRP, pressure-rate product.

reperfusion, values of $\pm dp/dt_{\text{max}}$, LVEDP, and PRP in the IH group were superior to the normoxic group, suggesting that left ventricular functional recovery was modestly facilitated by IH adaptation. AG significantly inhibited the recovery of IH hearts, whereas it had no effect on normoxic hearts during reperfusion (Figure 1).

Effects of AG on the nitrate/nitrite content of IH and normoxic rat hearts The biochemical experiment demonstrated that the baseline content of NO_x in IH hearts was 30.4% higher than that in normoxic hearts ($P<0.01$). After 30 min ischemia, the NO_x level in normoxic heart tissue increased from 0.608 \pm 0.060 to 0.747 \pm 0.062 $\mu\text{mol/g}$ protein, whereas in IH heart tissue there was no significant change ($P>0.05$, 0.793 \pm 0.075 vs 0.837 \pm 0.054 $\mu\text{mol/g}$ protein). The addition of AG 100 $\mu\text{mol/L}$ significantly diminished the content of NO_x in IH hearts from 0.837 \pm 0.054 to 0.606 \pm 0.070 $\mu\text{mol/g}$ protein and from 0.747 \pm 0.062 to 0.541 \pm 0.062 $\mu\text{mol/g}$ protein in normoxic hearts during the ischemia period. AG also significantly decreased the content of NO_x in IH hearts from 0.742 \pm 0.062 to 0.535 \pm 0.072 $\mu\text{mol/g}$ protein and from 0.617 \pm 0.072 to 0.519 \pm 0.059 $\mu\text{mol/g}$ protein in normoxic hearts during the reperfusion period (Figure 2).

Effects of AG on iNOS mRNA expression in IH and normoxic rat hearts The expression of iNOS mRNA is shown in Figure 3A,3B. The baseline level of iNOS mRNA in

IH hearts was higher than that in normoxic hearts by 50.2% ($P<0.01$). After reperfusion, iNOS mRNA level in normoxic hearts increased from 0.470 \pm 0.051 to 0.590 \pm 0.092 ($P<0.05$); however, the iNOS mRNA level in IH hearts decreased from 0.706 \pm 0.061 to 0.549 \pm 0.066 after reperfusion ($P<0.05$). The addition of 100 $\mu\text{mol/L}$ AG significantly diminished iNOS mRNA level in normoxic and IH hearts after reperfusion; however, the reduced extent of IH hearts was higher than that of normoxic hearts ($P<0.01$).

Effects of AG on iNOS protein expression in IH and normoxic rat hearts The expression of iNOS protein is demonstrated in Figure 4A, 4B. In accordance with the changes at mRNA level, the baseline level of iNOS protein in IH hearts was 33.8% higher than that of normoxic hearts ($P<0.05$). After reperfusion, iNOS protein level in the normoxic hearts increased by 18.4% (from 100% \pm 0.0% to 118.4% \pm 8.4%, $P<0.05$); however, iNOS protein level in IH hearts decreased by 31.9% (from 133.8% \pm 16.6% to 91.1% \pm 7.0%, $P<0.01$). After reperfusion, the level of iNOS protein between normoxic and IH hearts was significantly different ($P<0.05$). The addition of 100 $\mu\text{mol/L}$ AG significantly decreased iNOS protein level in IH hearts; however, AG had no influence on iNOS protein expression in normoxic hearts after reperfusion. Ischemia significantly decreased iNOS protein expression in the different groups ($P<0.05$).

Figure 1. Original recording of left ventricular developed pressure in isolated Langendorff-perfused rat hearts in different groups during 20 min baseline perfusion, 30 min ischemia, and 30 min reperfusion. The arrow indicates the times of the different treatments. (A) normoxic control heart; (B) intermittent hypoxia (IH) heart; (C) normoxic heart pretreated with aminoguanidine (AG) 100 μ mol/L for 5 min before ischemia and during ischemia; and (D) IH heart pretreated with AG 100 μ mol/L for 5 min before ischemia and during ischemia.

Discussion

The present study showed that IH increased the tolerance of hearts to I/R injury, determined by improved recovery of post-ischemic ventricular function. This protective effect was abolished by AG, suggesting that iNOS-derived NO may participate in the cardioprotection of IH. Our results also showed that the baseline level and the recovery of CF after ischemia were higher in IH hearts compared with normoxic hearts. Zhong *et al*'s study revealed that capillary densities were increased in IH hearts, which contributed to better functional recovery when isolated rat hearts were sub-

jected to an I/R injury^[6]. The recovery of post-ischemic CF in IH hearts was abolished by AG, suggesting that iNOS-derived NO may be involved in the improvement of CF by IH.

The level of NOS expression relates directly to the quantity of NO_x production. To examine the effect of IH on iNOS expression, we investigated NO_x content, iNOS mRNA, and protein expression in normoxic and IH rat hearts during baseline perfusion. Providing important additional insights into IH against I/R injury, we also examined NO_x content, iNOS mRNA and protein expression in IH and normoxic rat

hearts subjected to ischemia/reperfusion. This may help us to understand why IH could improve the post-ischemic recovery of left ventricular function. Our results showed that iNOS mRNA and protein were unregulated and that NO_x content increased after IH adaptation in rat hearts. Palmer *et al* showed that hypoxia induced iNOS expression in cardiac myocytes and vascular endothelial cells^[20,21]. Rouet-Benzineb *et al* also indicated that after 15 days of hypoxia there was a two-fold increase in iNOS protein abundance in rat left ventricles^[22]. However, Baker *et al* demonstrated that

increased tolerance to ischemia in rabbit hearts adapted to chronic hypoxia was associated with increased expression of eNOS isozymes, which led to an increase in myocardial nitrite/nitrate content and cGMP level^[23]. The signaling functions of NO begin with its binding to protein receptors, such as guanylyl cyclase, which generates cGMP. In the present study, the elevated expression of myocardial iNOS in IH hearts compared to control hearts was also consistent with Zhong *et al's* report^[6], which showed that the myocardial cGMP level in IH rats increased compared to normoxia control rats. Baker *et al* suggested that a small increase in NO levels appears to be cardioprotective, whereas a large increase in NO production may be detrimental, resulting in vasodilation, decreased blood pressure and, perhaps, vascular leakage^[23]. Importantly, in our study the magnitude of iNOS upregulation caused by IH was mild. This quantitative induction of iNOS may be critical in explaining the protective effects of iNOS following IH adaptation. The discrepancies between Baker *et al's* study and ours lie in the age of the animals (adult vs neonatal), the species (rabbit vs rat), the experimental model, and the training duration and/or intensity.

In the present study, iNOS-derived NO was assessed by measuring the AG-inhibitable nitrite/nitrate content in IH and normoxia rat hearts. The addition of 100 $\mu\text{mol/L}$ AG significantly decreased NO_x content, iNOS mRNA and protein levels in IH hearts after reperfusion and abolished the protective effect of IH; AG also decreased NO_x content and

iNOS mRNA expression in normoxic hearts; however, the inhibitory extent was lower in normoxic hearts compared with IH hearts. This result suggests that iNOS is tonically higher in IH hearts compared with normoxic hearts and that iNOS may play an important role in the cardioprotection of IH.

Studies examining the role of NO in modulating ischemia/reperfusion injury are complicated. There are conflicting reports about the changes in NO content during ischemia/reperfusion period. A number of studies have demonstrated that NO content increased in hearts subjected to ischemia^[24,25]. Studies have also shown that short-term ischemia leads to an increase in iNOS activity and expression; however, iNOS activity and expression decreased with prolonged ischemia. This may be related to a deficiency in essential co-factors for protein synthesis and stability (eg, haem, FAD, FMN, calmodulin). In addition to NO production by specific NOS, Zweier *et al* also demonstrated that NO could be generated in tissues by either direct disproportionation or reduction of nitrite to NO under the acidic and highly reduced conditions that occur in disease states, such as ischemia^[26]. Thus, we considered that the basal level of nitrite and nitrate was a better index of nitric oxide production from the aerobically perfused heart.

In addition, we found that iNOS mRNA and protein level in normoxic hearts increased after reperfusion; however, iNOS mRNA and protein level decreased in IH hearts. The results from Zingarelli *et al*'s study differed from our result in that iNOS mRNA in wild-type mice was significantly increased after 30 min reperfusion compared to the basal level^[27]. In the present study, the level of iNOS protein in normoxic hearts was higher than the level in IH hearts after I/R. It is known that induction of high-output iNOS usually occurs in an oxidative environment, and thus high levels of NO have the opportunity to react with superoxide anion (O_2^-) leading to peroxynitrite ($ONOO^-$) formation and cell toxicity^[28]. The generation of $ONOO^-$ can account for the toxicity of NO in biological systems. Yasmin *et al* and Wang and Zweier's studies indicated that generation of $ONOO^-$ at reperfusion contributed to the I/R injury in isolated rat hearts^[29,30]. In general, O_2^- formation increases during the early period of reperfusion and reacts with NO to form $ONOO^-$, which results in amino acid nitration and cellular injury^[30]. Our previous study suggested that an increase in antioxidant capacity might play an important role in the effect of IH reducing I/R injury^[5]. Based on the above investigations, we propose that during reperfusion, normoxic hearts may be predisposed to produce more O_2^- and $ONOO^-$ than IH hearts, and thus produce more potent toxicity than IH hearts. Our results also suggest that during reperfusion after sustained ischemia,

NO may have bidirectional effects on myocardium because of the coexistence of NO and O_2^- . AG significantly diminished NOx content, iNOS mRNA and protein level in IH hearts after reperfusion and led to the inhibitory effect of AG on the recovery of left ventricular function of IH rat hearts. As far as we know, NO is considered to play a pivotal role in numerous physiological and pathophysiological processes, with effects arising from both a lack and a surfeit of this chemically reactive molecule. This seemingly paradoxical behavior may be explained by the amount of NO generated, temporal-spatial intracellular compartmentalization of NO, and the intracellular redox environment.

The mechanisms leading to upregulation of iNOS after IH adaptation and the mechanism whereby iNOS-derived NO plays a role in the protection of IH have not been clarified and need to be further investigated. Mechanisms by which hypoxia induces gene expression include transcriptional and posttranscriptional regulation. The molecular mechanisms of hypoxia adaptations are centered on the activation of hypoxia-inducible factor 1 (HIF-1). During hypoxia, however, HIF-1 α is stabilized, leading to accumulation of the active HIF-1 α , HIF-1 β heterodimer, which binds to specific recognition elements within promoter/enhancer regions of many target genes, the induction of which generates this cytoprotective process. The set of genes induced in this manner include iNOS^[20,21], which drives cytoprotective events mediated by NO. At the same time, complex mechanisms may exist and interplay in the regulation of iNOS expression in the heart.

NO is an important endogenous regulatory molecule involved in a variety of biological functions. For example, it maintains coronary vasodilator tone, inhibits platelet aggregation and the adhesion of neutrophils to vascular endothelium^[31]. It can also regulate myocardial contractile function. Studies have suggested that NO could also regulate oxygen demand and the delivery of oxygen^[32]. Therefore, moderate increases in NO during intermittent hypoxia might be involved in the regulation of the above effects.

We concluded that IH upregulated the baseline level of iNOS mRNA and protein expression leading to an increase in NO production, which may play an important role in the cardiac protection of IH against I/R injury.

Abstract

Aim: To determine whether Ca²⁺/calcineurin mediated the inhibitory effects of nitric oxide /cGMP-dependent protein kinase (NO/PKG) on the proliferation of vascular smooth muscle cells (VSMC). **Methods:** Proliferation and viability of primary VSMC from rat aorta were measured using [3-(4,5-dimethyl thiazol-2-yl)-2,5-diphenyl tetrazolium bromide] (MTT) assay and acridine orange and ethidium bromide staining, respectively. Cytosolic Ca²⁺ was determined by Fluo-3/AM. Calcineurin protein and its activity were assayed using immunoblotting and free inorganic phosphate analysis, respectively. **Results:** (±)-*S*-nitroso-*N*-acetylpenicillamine (SNAP) and Sp-8-(4-chlorophenylthio)-guanosine-3',5'-cyclic monophosphorothioate (Sp-8-pCPT-cGMPS) decreased phenylephrine (PE)-induced proliferation of VSMC by 27.3% and 36.6%, respectively, but Rp-8-[(4-chlorophenyl)thio]-guanosine-3',5'-cyclic monophosphorothioate (Rp-8-pCPT-cGMPS) increased PE-induced proliferation of VSMC. SNAP, Sp-8-pCPT-cGMPS, and Rp-8-pCPT-cGMPS did not affect the viability of VSMC. Calcineurin protein was decreased by 63.1% and its activity was decreased by 59.7% in smooth muscle cells (SMC) pretreated with verapamil (Ver) and then stimulated by PE. In SMC pretreated with Ver, the absorbance of cells stimulated by PE decreased by 22.0% and was further inhibited by the additional treatment of SNAP and Sp-8-pCPT-cGMPS. In SMC pretreated with cyclosporin A (CsA), the absorbance of cells stimulated by PE decreased by 36.7%, but could not be further altered by the additional treatment of SNAP, Sp-8-pCPT-cGMPS, and Rp-8-pCPT-cGMPS. In addition, Ver inhibited PE-induced intracellular Ca²⁺ variations, which could be further inhibited by SNAP and Sp-8-pCPT-cGMPS, but not by Rp-8-pCPT-cGMPS. Moreover, the increase in calcineurin activity induced by PE was inhibited by SNAP and Sp-8-pCPT-cGMPS, but was promoted by Rp-8-pCPT-cGMPS. **Conclusion:** NO/PKG regulates calcineurin activity via the modulation of intracellular Ca²⁺ concentration, and thus partially inhibits the proliferation of VSMC without affecting their viability.

Introduction

Injuries to vascular endothelium induce the migration, hypertrophy, and proliferation of vascular smooth muscle cells (VSMC)^[1]. Compelling evidence indicates that nitric oxide (NO) negatively regulates the proliferation of VSMC via the pathways of guanosine-3',5'-cyclic monophosphate (cGMP) and cGMP-dependent protein kinase (PKG). Ca²⁺/

calcineurin is involved in smooth muscle-specific transcription, and may be a potential target of smooth muscle cell proliferation^[2–4]. However, the mechanisms by which NO/PKG inhibits VSMC proliferation remain unknown.

Therefore, it is proposed that NO/PKG can inhibit VSMC proliferation via modulation of Ca²⁺/calcineurin. NO donor SNAP inhibited the intracellular Ca²⁺ response of SMC to acetylcholine (ACh). Caffeine^[5] and cGMP can modulate

Ca²⁺ spark activity^[6]. PKG regulates intracellular Ca²⁺ variations at multiple levels^[7]. Inhibition of nuclear factors of activated T cells (NFAT) by NO-cGMP-PKG I is responsible for cardiac hypertrophy after α 1-adrenoceptor stimulation^[8]. However, whether or not NO/PKG inhibits the proliferation of VSMC via the modulation of Ca²⁺/calcineurin is unclear. In the present study, we used VSMC from rat aorta and studied the activities of NO/PKG, intracellular Ca²⁺, and calcineurin in VSMC proliferation.

Materials and methods

Materials NO donor (\pm)-*S*-nitroso-*N*-acetylpenicillamine (SNAP), phenylephrine (PE), cyclosporin A (CsA), and verapamil (Ver) were purchased from Sigma-Aldrich Corp. (St Louis, MO, USA). The PKG-selective cGMP analog Sp8-pCPT-cGMPS and PKG antagonist Rp-8-[(4-chlorophenyl)thio]-guanosine-3',5'-cyclic monophospho-thioate (Rp-8-pCPT-cGMPS) were from BioMol Company (Plymouth Meeting, PA, USA). Fluo-3/AM ester was obtained from Biotium Inc (Hayward, CA, USA). Rabbit anti-calcineurin A α affinity-purified polyclonal antibody was from Chemicon Incorporated (Temecula, CA, USA). The biotinylated protein ladder detection pack was from Cell Signaling Technology, Inc (Beverly, MA, USA). The calcineurin assay kit was from Nanjing Jiancheng Bioengineering Institute (NJBI) (Nanjing, China). Dulbecco's modified Eagle's medium (DMEM) and fetal bovine serum (FBS) were obtained from Gibco/Life Technologies (Grand Island, NY, USA).

Culture of VSMC The medial layer of the thoracic aorta from 7-day-old Wistar rats was explanted and cultured in DMEM containing 5% FBS at 37 °C in 5% CO₂ atmosphere. The cells were spread onto six-well plates or 35-mm dishes and cultured to a near confluent condition. Primary VSMC (<4 passage) were used.

Intracellular Ca²⁺ by Fluo-3/AM staining The experiment was carried out at room temperature in a darkroom. Intracellular Ca²⁺ concentration in VSMC was monitored using the fluorescent Ca²⁺ indicator, Fluo-3/AM. In brief, cells growing in a special 35-mm culture dish were loaded with Fluo-3/AM 10 μ mol/L (acetoxymethyl esters) in Krebs-Ringer solution (in mmol/L: NaCl 140, KCl 5, MgCl₂ 0.5, HEPES 5.5, glucose 10, CaCl₂ 1.2, pH 7.4) containing 0.05% pluronic acid at 37 °C for 60 min. After being washed twice with Krebs-Ringer solution to remove unhydrolyzed indicator, the dish was transferred to a chamber to which the drugs were added. Fluorescence in cells was measured using a confocal microscope. The excitation wavelength was 488 nm, and the emission wavelength was 522 nm. Change in fluorescence was expressed as F/F_0 , where F represents

the fluorescence intensity (F) of each pixel in the original fluorescence image and F_0 is defined as the intensity at the beginning of the images when the cell was assumed to be in the resting state.

Calcineurin protein expression Protein was separated by 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and transferred to nitrocellulose membranes, and the membranes were incubated with rabbit anti-calcineurin A α affinity-purified polyclonal antibody directed against the major calcineurin catalytic subunit, calcineurin A (CnA)- α . Additional procedures followed the methods of Hammes *et al*^[9]. The blotted antibody was visualized using chemiluminescence, and a densitometric scanner determined the density of the band.

Calcineurin enzymatic activity The activity of calcineurin was determined using a calcineurin activity assay kit as described in the manufacturer's protocol. The RII-phosphopeptide (BioMol) was used as a highly specific substrate for calcineurin. The detection of free inorganic phosphate released from RII by calcineurin was based on the malachite green dye reaction. Reactions were terminated after 30 min, and absorption was read on an ultraviolet spectroscope at 660 nm. The activity was corrected for protein concentration. Calcineurin activity was expressed as a percentage compared with the control group.

Cell proliferation assay After VSMC were incubated at 37 °C for 48 h, stock [3-(4,5-dimethyl thiazol-2-yl)-2,5-diphenyl tetrazolium bromide] (MTT) solution was added and incubated with the cells for 4 h. The medium was then removed as completely as possible without disturbing the formazan crystals that had formed within the cells. After the addition of Me₂SO (Merck, Darmstadt, Germany) into the wells the plate was shaken for a short time, and optical density was measured at 570 nm.

Cell viability VSMC were cultured to 1 \times 10⁴ cells/well in six-well dishes and then incubated in the absence (control) or presence of PE 10 μ mol/L, SNAP 250 μ mol/L, Sp-8-pCPT-cGMPS 500 μ mol/L, and Rp-8-pCPT-cGMPS 100 μ mol/L, or various combinations for 48 h. At the end of the incubation, nucleic acid-binding fluorescent dyes, acridine orange and ethidium bromide (10 mg/L each per well), were added. Using fluorescent microscopy, viable cells with green fluorescent nuclei and non-viable cells with red or orange fluorescent nuclei were counted, and at least 200 cells were counted for each sample. Cell viability (%) = 100 \times (number of viable cells)/(number of cells counted).

Statistical analysis Data were expressed as mean \pm SEM and statistical analysis were carried out using ANOVA followed by *Bonferroni* or *Dunn post-hoc* tests. $P < 0.05$ was

considered significant.

Results

Effect of NO/PKG on the proliferation and viability of VSMC SNAP (250 μmol/L) and Sp-8-pCPT-cGMPS (500 μmol/L) decreased PE 10 μmol/L-induced proliferation of VSMC by 27.3% and 36.6%, respectively, and Rp-8-pCPT-cGMPS (100 μmol/L) increased PE-induced proliferation of VSMC. However, SNAP, Sp-8-pCPT-cGMPS, and Rp-8-pCPT-cGMPS did not affect the viability of VSMC compared with the control group (Figure 1).

Figure 1. Effects of NO/PKG on PE-induced proliferation and the viability of vascular smooth muscle cells (VSMC). VSMC were stimulated in the absence (control) or presence of PE (10 μmol/L), SNAP (250 μmol/L), Sp-8-pCPT-cGMPS (500 μmol/L), and Rp-8-pCPT-cGMPS (100 μmol/L), or various combinations for 48 h. *n* = 5 experiments. Mean ± SEM. ^b*P* < 0.05 vs control. ^e*P* < 0.05 vs PE.

Effect of Ver on calcineurin protein expression and activity in VSMC After VSMC were pretreated with Ver (8 μmol/L) for 24 h and then incubated with PE (10 μmol/L) for another 24 h, calcineurin protein expression and its activity were decreased by 63.1% (Figure 2A) and 59.7% (Figure 2B) compared with the control group, respectively.

Effect of Ver and CsA on the downregulation of VSMC proliferation by NO/ PKG VSMC were pretreated with Ver (8 μmol/L) or CsA (500 μg/L) for 24 h to inhibit Ca²⁺ influx or calcineurin activity, respectively. The VSMC were then treated with SNAP (250 μmol/L), Sp-8-pCPT-cGMPS (500 μmol/L), or Rp-8-pCPT-cGMPS (100 μmol/L) for 12 h. Finally they were incubated with PE (10 μmol/L) for 12 h.

Pretreatment with Ver decreased PE-induced VSMC proliferation by 22.0% compared with the control group. Additional treatment with SNAP and Sp-8-pCPT-cGMPS further inhibited VSMC proliferation compared with the Ver pretreat-

Figure 2. Effect of verapamil on the proliferation of vascular smooth muscle cells (VSMC) induced by PE. VSMC were pretreated in the absence (control) or presence of PE (10 μmol/L), Ver (8 μmol/L) or Ver and PE. *n* = 5 experiments. Mean ± SEM. ^b*P* < 0.05 vs control.

ment group (*P* < 0.05, Figure 3A).

Pretreatment with CsA decreased PE-induced VSMC proliferation by 36.7% compared with the control group. Additional treatment with SNAP, Sp-8-pCPT-cGMPS, or Rp-8-pCPT-cGMPS did not further affect VSMC proliferation compared with the CsA pretreatment group (*P* > 0.05, Figure 3B).

Effects of Ver and NO/PKG on variations in intracellular Ca²⁺ induced by PE in VSMC VSMC were pretreated with Ver (8 μmol/L) for 30 min and then incubated with SNAP (250 μmol/L), Sp-8-pCPT-cGMPS (500 μmol/L), or Rp-8-pCPT-cGMPS (100 μmol/L) for 30 min. Finally the VSMC were stimulated with PE (10 μmol/L). Intracellular Ca²⁺ variation was inhibited by Ver. Additional treatment with SNAP and Sp-8-pCPT-cGMPS after Ver pretreatment further inhibited intracellular Ca²⁺ variation, but additional treatment with Rp-8-pCPT-cGMPS did not (Figure 4).

Effect of NO/PKG on calcineurin expression and activity in VSMC The increase in calcineurin protein expression and its activity induced by PE (10 μmol/L) for 24 h were inhibited by a 24-h pretreatment with SNAP (250 μmol/L) or Sp-8-pCPT-cGMPS (500 μmol/L), and was slightly promoted by a 24-h pretreatment with Rp-8-pCPT-cGMPS (100 μmol/L) (Figure 5).

Figure 3. Role of Ca²⁺/calcineurin in the regulation of vascular smooth muscle cells (VSMC) proliferation by NO/ PKG. VSMC were pretreated with Ver (8 μmol/L, A) or CsA (500 μg/L, B) for 24 h, and then incubated with SNAP (250 μmol/L), Sp-8-pCPT-cGMPS (500 μmol/L), and Rp-8-pCPT-cGMPS (100 μmol/L) for 12 h, respectively. PE was finally added to stimulate the VSMC for 12 h. *n*=5 experiments. Mean±SEM. ^b*P*<0.05 vs control. ^e*P*<0.05 vs Ver+PE group.

Discussion

NO inhibits the proliferation of VSMC via the pathways of cGMP and PKG. NO/PKG modulates a large variety of physiological functions including vascular tone, platelet aggregation, apoptosis, and proliferation. However, the mechanisms by which NO/PKG inhibits VSMC proliferation are still unclear. The present study investigated the activities of NO/PKG, intracellular Ca²⁺, and calcineurin in the proliferation of VSMC.

PE, a stimulator for Ca²⁺ oscillations and cell growth^[10,11], is used to induce intracellular Ca²⁺ variations and the proliferation of VSMC. Our results show that the addition of SNAP and Sp-8-pCPT-cGMPS decreases cell proliferation in cells pre-stimulated with PE by 27.3% and 36.6%, respectively,

Figure 4. PE-induced intracellular Ca²⁺ variations by NO/PKG in vascular smooth muscle cells (VSMC). VSMC were first stimulated by Ver for 30 min, and then incubated with SNAP (250 μmol/L), Sp-8-pCPT-cGMPS (500 μmol/L), and Rp-8-pCPT-cGMPS (100 μmol/L) for 30 min, respectively. Finally PE (10 μmol/L) was added to the superfusion buffer (indicated by the arrow). *n*=5 experiments.

Figure 5. Effect of NO/PKG on calcineurin protein expression and activity in vascular smooth muscle cell (VSMC) proliferation. VSMC were stimulated in the absence (control) or presence of PE (10 μmol/L), SNAP (250 μmol/L), Sp-8-pCPT-cGMPS (500 μmol/L) and Rp-8-pCPT-cGMPS (100 μmol/L), or various combinations as indicated. *n*=5 experiments. Mean±SEM. ^b*P*<0.05 vs control. ^e*P*<0.05 vs PE.

whereas the addition of Rp-8-pCPT-cGMPS increases cell

proliferation. No significant changes in VSMC viability were found between the experimental groups. These results suggest that NO/PKG is involved in the inhibitory effects on SMC proliferation, but has no marked effects on SMC viability.

Ca²⁺ is an essential regulator of the cell cycle. The Ca²⁺ response control gene was expressed in various cell types^[12]. In VSMC, when intracellular [Ca²⁺]_i level increases, calcineurin is activated. Its de-phosphorylated transcription factors, NFAT, in turn promote nuclear translocation of NFAT. The NFAT transcription factors then cooperate with nuclear transcription factors and stimulate the transcriptional activation of various genes that are involved in VSMC proliferation^[13]. Our results confirm that intracellular Ca²⁺ variations play an important role in regulating VSMC proliferation.

Recent studies have shown that NO/PKG can regulate intracellular Ca²⁺ variations. NO reduces the intracellular Ca²⁺ concentration in SMC by inhibiting sarcoplasmic reticulum (SR). Ca²⁺ release through both IP₃R and RyR^[5], and Ca²⁺ influx through N-channel gating via cGMP and PKG^[14]. cGMP can modulate Ca²⁺ spark activity by decreasing myofibrillar Ca²⁺ sensitivity and increasing Ca²⁺ uptake by the SR^[6]. PKG has been proposed to regulate [Ca²⁺]_i variations in different cell types by different mechanisms^[7]. For example, PKG can inhibit intracellular Ca²⁺ release from the endoplasmic reticulum by inhibition of IP₃ formation^[15] and Ca²⁺ entry through plasma membrane Ca²⁺ channels^[16,17] or stimulate its efflux across the membrane by activation of a Na⁺/Ca²⁺ exchanger^[18]. Bonnevier and Arner^[19] reported that signals downstream of cGMP/PKG could reverse PKC-mediated Ca²⁺ sensitization in smooth muscle. However, whether or not NO/PKG inhibits VSMC proliferation via the regulation of intracellular Ca²⁺ movement has not been revealed. We found that Ver inhibited PE-stimulated intracellular Ca²⁺ variations, which could be further inhibited by SNAP and Sp-8-pCPT-cGMPS. These results suggest that NO/PKG can regulate PE-induced intracellular Ca²⁺ variations in VSMC, which is possibly achieved via regulation of Ca²⁺ release, Ca²⁺ efflux, and Ca²⁺ influx by NO/PKG. The definite mechanisms by which NO/PKG modulates intracellular Ca²⁺ variations of SMC will be studied in the future. For these reasons, we conclude that NO/PKG inhibits VSMC proliferation via modulation of intracellular Ca²⁺ variations.

Calcineurin is a heterodimer consisting of a 59-kDa subunit, CnA, and a 19-kDa subunit with calcineurin B (CnB) tightly bound to CnA. CnA consists of a catalytic and a regulatory domain. The regulatory domain contains the CnB binding domain, the calmodulin binding domain, and an autoinhibitory domain at the C-terminus. Ca²⁺ binds to both

calmodulin and CnB displacing the inhibitory C-terminal peptide from the active site of CnA, thus activating phosphatase function^[20]. So CnB acts as a sensor for changes in intracellular Ca²⁺. Calcineurin is a downstream target of intracellular Ca²⁺. Increase in intracellular Ca²⁺ concentration will activate calcineurin, thus inducing proliferation-related gene transcription. Our results further demonstrate that intracellular Ca²⁺ variation plays an important role in regulating the expression and activity of calcineurin in VSMC, and that calcineurin is a potential target for treatment of diseases related to SMC proliferation. However, it remains to be determined whether NO/PKG decreases the proliferation of VSMC via calcineurin. Our study shows that the pre-addition of CsA decreases PE-induced proliferation by 36.7% compared with controls. CsA had no influence on the inhibitory effects of SNAP, Sp-8-pCPT-cGMP, and Rp-8-pCPT-cGMPS. These results suggest that NO/PKG inhibits VSMC proliferation via calcineurin. Furthermore, our study demonstrates that SNAP and Sp-8-pCPT-cGMPS reduced, but Rp-8-pCPT-cGMPS increased, calcineurin protein expression and its activity in SMC stimulated by PE. Therefore, we conclude that NO/PKG inhibits VSMC proliferation by regulating calcineurin expression and its activity.

In addition, Sp-8-pCPT-cGMPS has the ability to stimulate both PKG and cAMP-dependent protein kinase (PKA) with similar potency. cAMP/PKA is able to induce Ca²⁺ desensitization by inhibition of the muscarinic receptor signaling upstream from Rho activation and preferentially reverse PKC-mediated Ca²⁺ sensitization in SMC^[21]. It is possible that PKA is partially involved in the regulation of calcineurin by changing intracellular Ca²⁺ variations in SMC proliferation.

In conclusion, NO/PKG partially inhibits the proliferation of VSMC without affecting their viability. It is associated with the regulation of calcineurin activity by modulating intracellular Ca²⁺ concentration.

Abstract

Aim: To explore the effects of cariporide, a selective sodium-hydrogen antiporter inhibitor, on endothelial dysfunction induced by high glucose. **Methods:** Acetylcholine (ACh)-induced endothelium-dependent relaxation (EDR), sodium nitroprusside (SNP)-induced endothelium-independent relaxation and biochemical parameters including malondialdehyde (MDA), superoxide dismutase (SOD), and nitric oxide (NO) were measured in rat isolated aorta. **Results:** A 6-h incubation of aortic rings with high glucose (44 mmol/L) resulted in a significant inhibition of EDR, but had no effects on endothelium-independent relaxation. After the 6-h incubation of aortic rings in the co-presence of cariporide (0.01, 0.1, and 1 μ mol/L) with high glucose, cariporide prevented the inhibition of EDR caused by high glucose in concentration-dependent manners. Similarly, high glucose decreased SOD activity and contents of NO, and increased MDA concentration in aortic tissue. Cariporide (1 μ mol/L) significantly resisted the decrease of NO content and SOD activity, and elevation of MDA concentration caused by high glucose in aortic tissues. Mannitol (44 mmol/L) or cariporide (1 μ mol/L) alone had no effect on EDR, endothelium-independent relaxation and biochemical parameters. **Conclusion:** Cariporide significantly prevented endothelial dysfunction induced by high glucose. The mechanisms of endothelial dysfunction induced by high glucose may involve the activation of sodium-hydrogen antiporter and the generation of oxygen-free radicals, but it is not related to the change of osmolarity.

Introduction

The relation between diabetes and premature vascular disease has been well established^[1]. One of the defects involves endothelial dysfunction characterized by impaired endothelium-dependent relaxation responses. Many metabolic disturbances of diabetes, hyperglycemia have been suggested to be the main cause of endothelial dysfunction. High glucose *in vitro* or *in vivo* has been reported to inhibit acetylcholine (ACh)-induced endothelium-dependent relaxation^[2] responses, to impair the biological synthesis pathway of nitric oxide (NO)^[3], and to generate reactive oxygen species^[4].

It has been demonstrated that hyperactivity of sodium-hydrogen exchange subtype 1 (NHE-1) has been implicated

in the vascular injury in diabetes mellitus^[5]. Ganz *et al*^[6] found that the activity and expression of NHE-1 significantly increased in mesangial cells after exposure to high glucose. Our previous experiments have demonstrated that the benzoylguanidine compound cariporide (4-isopropyl-3-methylsulfonyl-benzoylguanidine methanesulfonate), which is a selective NHE-1 inhibitor, protected against injuries of endothelial functions induced by high lipid diet in rabbits^[7]. However, it is not known whether NHE-1 inhibitor protects against endothelial function affected by high glucose. The aim of this study is to explore the effect of cariporide against endothelial dysfunction of isolated rat aortic rings induced by high glucose and to investigate its mechanisms.

Chemical structure of cariporide

Materials and methods

Drugs and chemicals Cariporide was obtained from Hoechst Company (Frankfurt, Germany). SNP, ACh, and phenylephrine (Phe) were purchased from Sigma Chemical Co (Saint Louis, Mo, USA). The kits for measurement of nitrite/nitrate (NO), MDA, and SOD activity were purchased from Nanjing Jiancheng Bioengineering Institute (Jiangsu, China).

Animal Male Sprague-Dawley rats (No. SCXK2003-0003; Grade II) weighing 180–200 g, supplied by the Animal Center of Xiangya Medical College (Central South University, China) were used.

Preparation of rat thoracic aorta rings The rats were killed by exsanguinations after an intraperitoneal anesthesia with pentobarbital sodium 30 mg/kg and intravenous anticoagulation with heparin sodium 150 U/kg. The descending thoracic aorta was rapidly dissected from the rats and immersed in Krebs' solution, composed of (mmol/L): NaCl, 118.3; KCl, 4.7; MgSO₄·7H₂O, 1.2; KH₂PO₄, 1.2; CaCl₂, 2.5; NaHCO₃, 24.0; glucose, 11; and Na₂-EDTA, 0.026; and bubbled with 95% O₂+5% CO₂ (pH 7.4). After the perivascular tissue was carefully removed, the aortic rings (which were approximately 4 mm in length), were prepared.

Bioassay of vasoreactivity^[8] For isometric force recording, the aortic rings were mounted between two stainless steel hooks and suspended in a 10 mL organ bath containing above Krebs' solution at 37 °C bubbled with 95% O₂+5% CO₂ gas mixture (pH 7.4). An initial load of 2.0 g was applied, and the tension of the aortic ring was monitored by a force transducer and recorded on a polygraph (Model YL-1, Chengdu Instruments, China). After a 90-min equilibration period, the ring was precontracted by Phe 1 μmol/L. When the development tension attained its peak value, the ring was relaxed by ACh or SNP, respectively. Accumulative concentration-response curves to ACh (0.003, 0.01, 0.03, 0.1, 0.3, 1, and 3 μmol/L) or SNP (0.001–1 μmol/L) were recorded.

Determination of MDA concentration After a 6-h incubation of aortic segments, the aortic segments were blot-

ted dry and weighed, then made into 5% tissue homogenate in ice-cold 0.9% NaCl solution. A supernatant was obtained from tissue homogenate by centrifugation (1000×g, 4 °C, 10 min). The MDA concentration (thiobarbituric acid reactive substances, TBARS) in the supernatant was measured. Briefly, 1.0 mL of 20% trichloroacetic acid and 1.0 mL of 1% TBARS reagent were added to 100 μL supernatant, then mixed and incubated at 100 °C for 80 min. After cooling on ice, samples were centrifuged at 1000×g for 20 min and the absorbance of the supernatant was read at 532 nm. TBARS results were expressed as MDA equivalents using tetraethoxypropane as standard.

Assay of SOD activity in aortic rings The supernatant of tissue homogenate of the aortic rings were obtained as described earlier. A competitive inhibition assay was performed by using xanthine/xanthine oxidase reaction-generated superoxide radicals to reduce nitro blue tetrazolium (NBT) quantitatively to blue formazan. Conversion of superoxide radicals to hydrogen peroxide by superoxide dismutase inhibited dye formation and served as a measure of superoxide dismutase activity. Briefly, the supernatant of 0.5 mL with xanthine 50 μmol/L and xanthine oxidase 2.5 μmol/L in potassium phosphate buffer 50 mmol/L (pH 7.8, 37 °C) were incubated for 40 min and NBT was added. Blue formazan was then monitored spectrophotometrically at 550 nm. The amount of protein that inhibited NBT reduction to 50% maximum was defined as 1 nitrite unit (NU) of SOD activity.

Assay of NO concentration of incubation medium The incubation medium of the aortic artery was centrifuged (1000×g, 15 min, 4 °C) and the supernatant was used for NO measurement. NO was assayed by the Griess method. Because NO is a compound with a short half life and is rapidly converted to the stable end products nitrate (NO₃⁻) and nitrite (NO₂⁻), the principle of the assay is the conversion of nitrate into nitrite by cadmium and followed by color development with Griess reagent (sulfanilamide and *N*-naphthyl ethylenediamine) in acidic medium. The total nitrite was measured by Griess reaction. The absorbance was determined at 540 nm with a spectrophotometer.

Protocol of experiment The first series of experiments were designed in order to evaluate the protective effects of cariporide against ACh-induced endothelium-dependent and SNP-induced endothelium-independent relaxing response of isolating rat aortic rings affected by high glucose. The experiment was divided into 7 groups with 8 aortic rings from 8 rats in each group. First, a normal control bioassay of vasoreactivity was formed in normal Krebs' solution. The rings, of which a percentage of relaxation induced by ACh

3 $\mu\text{mol/L}$ to the contraction elicited by Phe 1 $\mu\text{mol/L}$ is more than 80%, were considered as intact endothelium and used in the study. The aortic rings of each group were then continually incubated for 6 h in the following medium: (1) control group: glucose 11 mmol/L in Krebs' solution^[9]; (2) high glucose group: glucose 44 mmol/L in Krebs' solution^[9]; (3)–(5) cariporide-treated groups: cariporide 0.01, 0.1, and 1 $\mu\text{mol/L}$ in Krebs' solution with glucose 44 mmol/L, respectively; (6) cariporide alone group: cariporide 1 $\mu\text{mol/L}$ in Krebs' solution; (7) mannitol group: mannitol 44 mmol/L in Krebs' solution. The incubation mediums were changed every 30 min and cariporide was present throughout the incubation. After a 6-h incubation of aortic rings, the perfusion solution was changed to Krebs' solution, and bioassay of vasoreactivity was performed.

The second series of experiments were designed to assay the effects of high glucose on SOD activity, MDA concentration, NO and the effects of cariporide on the biochemical parameters in rat aortic rings. The experiment was divided into 5 groups with 8 aortic segments of 2 cm from 8 rats in each group; control group, high glucose group, mannitol group, cariporide-treated group, and cariporide-alone group. The components of incubation medium were the same as described earlier except that cariporide only had a dose of 1 $\mu\text{mol/L}$. The incubations media were changed every 30 min. Cariporide was added throughout incubation. After a 6-h incubation, the segments were transferred to 1 mL normal Krebs' solution which contained ACh 1 $\mu\text{mol/L}$ for 30 min. The aortic segments and the medium were then collected and frozen at $-70\text{ }^{\circ}\text{C}$ until analyzed.

Data analysis The ACh (3 $\mu\text{mol/L}$) or SNP (1 $\mu\text{mol/L}$)-induced maximal relaxation (E_{max}) in aortic rings was calculated as a percentage of the contraction to Phe (1 $\mu\text{mol/L}$). The half maximum effective concentration (EC_{50}) was defined as a concentration of the ACh that induced 50% of maximum relaxation response to contraction elicited by Phe (1 $\mu\text{mol/L}$) and calculated from the concentration-response curve generated by linear regression analysis. All data were expressed as mean \pm SD. Statistical comparisons were made using one-way ANOVA followed by Newman–Keuls test. $P < 0.05$ was statistically significant.

Results

Effects of high glucose on EDR and endothelium-independent relaxation in aortic rings There were no significant differences in ACh-induced relaxation responses of rat isolated aortic rings before the 6-h incubation among various groups (data not shown). After a 6-h incubation of aortic rings in control glucose (11 mmol/L) buffer, ACh (0.003–3

$\mu\text{mol/L}$) still evoked a normal concentration-dependent relaxation (Figure 1), the E_{max} of aortic rings reached $88.4\% \pm 12.3\%$, and the EC_{50} value was $94.5 \pm 10.8\text{ nmol/L}$. After the 6-h incubation of the aortic rings and exposure to high glucose (44 mmol/L), the E_{max} fell to $43.7\% \pm 16.1\%$ and the EC_{50} value increased to $154.8 \pm 22.9\text{ nmol/L}$ ($P < 0.01$ vs control group, $n=8$). However, no significant changes of E_{max} and EC_{50} were shown in the rings incubated in the cariporide (1 $\mu\text{mol/L}$)-alone group or mannitol (44 mmol/L) group, compared with the control group (Figure 1).

Figure 1. EDR induced by ACh in rat isolated aortic rings. After a 6-h incubation of aortic rings in control glucose (11 mmol/L), high glucose (44 mmol/L), mannitol (44 mmol/L), or cariporide (1 $\mu\text{mol/L}$) in Krebs' solution, the ACh (0.003–3 $\mu\text{mol/L}$)-induced EDR was measured and calculated as a percentage of the contraction to Phe (1 $\mu\text{mol/L}$). $n=8$. Mean \pm SD. ^b $P < 0.05$, ^c $P < 0.01$ vs control group.

The endothelium-independent relaxation induced by SNP (0.001–1 $\mu\text{mol/L}$) was not significantly different between the different treated groups (data not shown).

Effects of cariporide on the impairment of EDR induced by high glucose Treatment with cariporide in different concentration (0.01, 0.1, and 1 $\mu\text{mol/L}$, $n=8$, respectively) significantly prevented inhibition of EDR induced by high glucose (Figure 2). The E_{max} were $61.7\% \pm 10.5\%$, $76.0\% \pm 10.5\%$, and $83.4\% \pm 10.1\%$, and the EC_{50} value was $131.5 \pm 15.9\text{ nmol/L}$, $117.1 \pm 13.7\text{ nmol/L}$, and $109.6 \pm 10.5\text{ nmol/L}$, respectively. There was a significant difference ($P < 0.05$ or $P < 0.01$), compared with those in the high glucose group (Figure 2).

Effects of cariporide on biochemical index in aortic segments A 6-h incubation of isolated aortic segments in high glucose resulted in an elevation of MDA content, decrease of SOD activity in aortic tissue, and reduction of NO

Figure 2. Effects of cariporide (0.01, 0.1, and 1 $\mu\text{mol/L}$) on EDR impaired by high glucose (44 mmol/L). After a 6-h incubation, ACh (0.003–3 $\mu\text{mol/L}$)-induced EDR were measured and calculated as a percentage of the contraction to Phe (1 $\mu\text{mol/L}$). $n=8$. Mean \pm SD. ^b $P<0.05$, ^c $P<0.01$ vs HG group.

releasing from aortic segments. Treatment with cariporide (1 $\mu\text{mol/L}$) in the high glucose (44 mmol/L) group significantly prevented the increase of MDA content, and protected the activity of SOD and release of NO in aortic segments (Table 1). Mannitol (44 mmol/L) or cariporide (1 $\mu\text{mol/L}$) alone had no effects on MDA, SOD, and NO, compared with the control group (Table 1).

Discussion

Diabetes mellitus is characterized by chronic hyperglycemia and associated with significant morbidity as a result of long-term complications, including diabetic nephropathy, atherosclerosis, and hypertension. High glucose had a lot of toxicity effects in endothelial cells, such as impairment of endothelial dependent relaxation^[10], decrease of NO release, generation of free radicals, and increase in apoptosis^[11]. The endothelial dysfunction has been thought to be the major cause of vascular disease due to hyperglycemia condition.

It was reported that hyperglycemia resulted in an increase of NHE-1 activity in diabetes^[12,13]. In addition, high glucose may induce the activation of NHE-1 and increase NHE-1 mRNA expression *in vitro* smooth muscle cells or myocytes^[14,15]. However, there are no reports as to whether NHE-1 inhibitor is able to protect against the impairment of endothelial functions caused by high glucose. The present study explores the effects of cariporide against high glucose-induced endothelial dysfunction of rat isolated aorta and discusses its mechanisms.

In the present study, we employed a mimic pronounced hyperglycemia model in which the rat isolated aortic rings were exposed to high glucose for 6 h. High glucose significantly inhibited EDR and the release of NO in rat isolated aortic rings, but did not affect vasodilatation induced by SNP, a NO donor. It has been demonstrated that endothelium dysfunction induced by high glucose related to the release of NO from endothelial cells. The same concentration of mannitol had no effect on EDR of aortic rings, which showed that the damage of EDR of aortic rings induced by high glucose was not due to a hyperosmotic effect. These results in the present study were consistent with a previous study^[2]. We also found that cariporide in dose-dependent manners prevented the inhibition of EDR induced by high glucose in rat isolated thoracic aorta (Figure 1), and simultaneously maintained SOD activity and NO release and decreased MDA concentration caused by high glucose in rat aortic segments (Table 1). It was reported that cariporide significantly inhibited the injuries of mitochondrial and pulmonary endothelial cells, and protected cardiac ischaemia and reperfusion *in vitro* by reducing intracellular pH and inhibiting NHE-1 activation, which simultaneously attenuated oxidant production^[16–18]. The Na^+/H^+ exchanger inhibitor, amiloride, significantly reduced oxidant production of hepatic stellate cells including intracellular hydroperoxides and MDA induced by oxidant^[19]. Accordingly, it is believed that the protective effects of cariporide against endothelial dysfunctions induced by high glucose may partly be due to anti-oxidation and pro-

Table 1. MDA concentration, SOD activity and NO content of isolated aortic segments in the different treated groups. $n=8$. Mean \pm SD. ^b $P<0.05$, ^c $P<0.01$ vs control glucose group. ^e $P<0.05$, ^f $P<0.01$ vs high glucose group.

tective activity of anti-oxidative enzymes.

In the resting state, NHE-1 is relatively quiescent. When intracellular pH falls, the NHE-1 is activated, and the rate of H⁺ efflux mediated by NHE-1 increases and causes intracellular alkalinization and Na⁺ overload, which leads to intracellular Ca²⁺ overload through a mechanism of reverse Na⁺-Ca²⁺ exchange. It is presumed that during high glucose condition, there is a metabolic mismatch between glycolysis and glucose oxidation that results in the accumulation of hydrogen ions, which, in turn, activates NHE-1, leading to intracellular alkalinization and Ca²⁺ overload. Therefore, we hypothesized that, in the present study, the mechanisms of cariporide against high glucose-induced endothelial dysfunction of rat isolated aortas might be also related to decreasing intracellular alkalinization and Ca²⁺ overload. Although intracellular pH and intracellular Ca²⁺ concentration were not assayed in the study, it has been reported that cariporide could protect from releasing NO in vascular endothelium through inhibiting activity of NHE-1, decreasing intracellular alkalinization and Ca²⁺ overload^[17,20].

In conclusion, this study demonstrates that cariporide significantly prevents endothelial dysfunction, decreases NO release, elevates MDA concentration and reduces SOD activity induced by high glucose in rat isolated thoracic aorta. The mechanisms of protective effects of cariporide may be related to the inhibition of NHE-1 and the decrease of oxidative stress injury. These results provide a potential new target for intervention in the prevention of diabetic complications.

Abstract

Aim: To investigate the mechanism of action of a potent analgesic, (\pm)-meptazinol. **Methods:** The structures of meptazinol enantiomers were compared with opioid pharmacophore and tramadol. **Results:** Neither enantiomer of meptazinol fitted any patterns among the opioid pharmacophore and tramadol, although they did share some structural and pharmacological similarities. However, the structure superpositions implied that both enantiomers of meptazinol might share some similar analgesic mechanisms with typical opiate analgesics. **Conclusion:** Meptazinol should have a different mechanism of action to known analgesics, which would be helpful in further investigations of meptazinol in the search for non-addictive analgesics.

Introduction

(\pm)-Meptazinol (Figure 1), with one chiral center in the structure, is a potent analgesic similar to pethidine. Included in the British Pharmacopoeia in 1998^[1], (\pm)-meptazinol was recommended by Hoskin and Hanks as one of six widely used agonist–antagonist analgesics^[2]. However, to date its analgesic mechanism remains unknown. For example, we are still unsure if it is an agonist, an antagonist, or even a mixed agonist–antagonist, and whether it acts on one target or multiple targets.

During the early stages of development, meptazinol was regarded as a mixed agonist–antagonist opioid analgesic based on the following experimental evidence^[3]: (i) the chemi-

cal structure of meptazinol is similar to that of morphine (Figure 1); (ii) meptazinol-induced analgesia is almost completely reversed by the opioid antagonist naloxone, although higher doses are required to reverse meptazinol compared to morphine; (iii) meptazinol is believed to be a selective μ opioid agonist^[4]; and (iv) meptazinol reverses the signs of acute morphine overdose in animals and precipitates abstinence in animals rendered physically dependent on morphine.

However, unlike typical opiates whose notorious side-effects include respiratory depression and addiction, meptazinol induces little respiratory depression and has low addictive potential^[5,6]. These properties make meptazinol

Figure 1. The structure of meptazinol, morphine, and tramadol.

quite similar to another analgesic, tramadol^[7] (Figure 1), which is believed to have multiple analgesic mechanisms. Recent studies have also revealed that both tramadol and meptazinol differ from opioid analgesics in the lack of sensitization related to a low propensity to induce addiction, which might greatly reduce the possibility of their abuse^[8]. Furthermore, tramadol was found to induce its anti-nociceptive effects through monoamine neurotransmitters, whereas there was a cholinergic component in the action of meptazinol^[9]. For example, the (–)-enantiomer of meptazinol was shown to be an inhibitor of acetylcholinesterase *in vitro* with potency 100-fold less than that of physostigmine^[10]. All this evidence implies that there would be a unique analgesic mechanism for meptazinol.

Therefore, we are very interested in exploring the analgesic mechanism of meptazinol. Because the three-dimensional structures of opioid receptors are not available yet, as a first step of exploration we focused on structural comparisons of meptazinol with typical opiates and with tramadol. Our results will help elucidate the analgesic mechanism of meptazinol and will benefit the search for non-addictive analgesics.

Materials and methods

All calculations were carried out on a R14000 SGI Fuel workstation using the molecular modeling software package SYBYL version 6.9 (Tripos, St Louis, MO, USA).

Material preparation Both enantiomers of meptazinol were synthesized in our laboratory. Their analgesic activities were determined by observing the wrenching body reaction of mice after oral administration at the Shanghai Institute of Materia Medica, Chinese Academy of Sciences. Their absolute configurations were determined using x-ray crystallography, co-crystallizing with dibenzoyl tartaric acid (DBTA), in our previous work^[11], which was used as a starting point for this study. For each enantiomer of meptazinol, a random search was carried out on the seven-member ring to ensure a stable ring conformation. Then, all of the other rotatable bonds (except bonds within the seven-member ring) were selected for a systematic search with an interval of 30° for each bond to obtain the lowest energy conformation. After the initial simple energy minimization, the lowest energy conformation of meptazinol was further optimized using a quantum chemical calculation [semi-empirical Austin Model 1 (AM1) method^[12] available in SYBYL]. This final optimized geometry of meptazinol was used in the subsequent structural comparisons.

Nine typical opiates, including agonists, antagonists and partial agonists, were selected to generate the opioid

pharmacophore according to previous literature^[13]. The initial atomic coordinates for seven of these opiates (ie morphine^[14], 3-*O*-methyletorphine^[15], azidomorphine^[16], *N*-allylnormetazocine^[17], cyclazocine^[18], naloxone^[19], and nalbuphine^[20]) were obtained from published x-ray crystallographic data and modeled using the CRYGIN tool of SYBYL. The other two opiates, codeine and 6-hydroxylevalorphan, were constructed based on their analogues, the crystal structures of which were available in SYBYL.

The initial structure of (*R,R*)-tramadol, the active isomer of tramadol, was retrieved from the MDL Drug Data Report-3D database (MDDR-3D), and underwent a similar optimizing treatment to meptazinol with one exception. All the rotatable bonds of tramadol (except bonds within the six-member ring) underwent a genetic algorithm conformational search to find the corresponding lowest energy conformation.

All structures were energy minimized for 1000 steps using the Tripos force field and POWELL method and the termination setting was 0.001 kcal/(mol×Å).

Analgesic pharmacophore generation The analgesic pharmacophore is defined in Figure 2. For comparison, related values were obtained from the literature^[13] in which the pharmacophore was composed of four distances and two torsion angles. We extracted the common structures of nine opiates composed of a tyramine fragment considered to be the key pharmacophore according to the average values of the nine opiates. As shown in Figure 2, it should be noted that the hydroxyl group was located in the *para*-position of the phenyl ring in the opiates, but in the *meta*-position of the phenyl ring in meptazinol and tramadol (methoxyl instead of hydroxyl group in tramadol). Thus, we manually removed the two carbons between the nitrogen atom and the phenyl ring from the pharmacophore structure. The pharmacophore are composed of one protonated nitrogen atom and a phenol fragment. We superimposed all opiates to the pharmacophore template separately and calculated the average standard deviation value as shown in Table 1. In addition, we defined the pharmacophore for meptazinol and tramadol. One more torsion angle was defined in tramadol because the interval distance between the nitrogen atom and the phenyl ring is three carbon atoms in tramadol compared with two in the other compounds.

Structural superposition The method used to determine superposition was the database alignment facility in SYBYL, in which some or all of the molecules in the database were aligned with a template molecule also in the database. A common substructure was provided to evaluate the best “fit”. Only rigid-body rotations and translations were supported.

For the comparison of meptazinol with the opioid pharmacophore, the generated pharmacophore were set as the common substructure for alignment. Both enantiomers of meptazinol were superimposed on each other first, and then superimposed with the other opiates separately.

Using the same pharmacophore, both meptazinol enantiomers and tramadol were superimposed onto the template.

Results and Discussion

The analgesic activities were determined as ED₅₀ values for the two enantiomers of meptazinol, 14.583 μmol/kg for (+)-enantiomer and 31.333 μmol/kg for the (–)-enantiomer. The (+)-enantiomer is more potent than the (–)-enantiomer, although the difference between them was not significant.

Because the structures of morphine and its derivatives and analogs are fairly rigid, it is reasonable to assume that their x-ray structures are the same as the active conformations binding to opioid receptors. Therefore, our pharmacophore model was based on these rigid structures. According to the analgesic pharmacophore defined in Figure 2, we built this pharmacophore using the mean values of the nine opiates as the common substructure for superposition in SYBYL. For reasons mentioned above, we removed the two carbon atoms from the pharmacophore. We also mea-

sured the torsions of our pharmacophore structures without the removal of the carbon atoms to make our pharmacophore resemble the original one in the literature (Table 1).

The crystal structures of the meptazinol enantiomers were treated with a series of methods to determine the lowest energy conformer for each enantiomer. According to the systematic search results for both meptazinol enantiomers, we found the lowest energy conformations to be very similar. The lowest energy conformation was selected as the low energy conformer followed by semi-empirical AM1 geometry optimization.

Using the opiate pharmacophore as the overlap template we first superimposed both enantiomers of meptazinol onto each other. As illustrated in Figure 3, the pharmacophore elements of the meptazinol enantiomers superimposed well onto each other. Thus, both meptazinol enantiomers may induce a similar analgesic mechanism, at least in part. An experiment using electrical stimulation of guinea pig isolated ileum indicated that both enantiomers of meptazinol were μ-selective opioid receptor agonists^[21]. And the similar pharmacology results from observing the mice wrenching body reaction of meptazinol enantiomers also supports this conclusion, although for the (–)-enantiomer there is another cholinergic component in the participating antinociceptive effect^[10].

Table 1. Molecular parameters for the x-ray-determined crystals of opiates, meptazinol and tramadol (MDDR-3D).

	A (Å)	B (Å)	C (Å)	D (Å)	τ_1	τ'	τ_2

(–)-Meptazinol·(–),(–)DBTA	6.380	5.158	0.750	5.103	50.8°		169.0°
(+)-Meptazinol·(+),(+)DBTA	6.378	5.178	0.723	5.123	148.4°		–173.5°
(<i>R,R</i>)-Tramadol	4.510	2.960	2.581	1.449	62.1°	60.0°	–65.9°

DBTA, dibenzoyl tartaric acid; (*R,R*)-tramadol, the active isomer of tramadol. The molecular parameters are defined in Figure 2.

Figure 2. Diagrammatic illustration of the pharmacophores. (A) Distance between the N atom and the O atom; (B) Distance between the N atom and the center of the phenyl ring; (C) Vertical distance of the N atom to the plane of the phenyl ring; (D) Horizontal distance of the N atom to the center of the phenyl ring. Torsion angle definitions: τ_1 : C₁-C₁₁-C₁₀-C₉, τ_2 : C₁₁-C₁₀-C₉-N for opiates; τ_1 : C₂-C₁-C₃-C₂, τ_2 : C₁-C₃-C₂-N for meptazinol; τ_1 : C₂-C₁-C₁-C₂, τ_2 : C₁-C₂-C₇-N, τ' : C₁-C₁-C₂-C₇ for tramadol.

Figure 3. Superimposition of (-)-meptazinol (in thin sticks) and (+)-meptazinol (in thick sticks) based on the opiate pharmacophore.

However, as demonstrated in Figure 4, the meptazinol pharmacophore differed from the opiate pharmacophore, particularly in the position of the nitrogen atom. The overlap of (+)-meptazinol to the opiate pharmacophore is a little better than (-)-meptazinol in the region of the phenol fragment, which may account for the minor increase in analgesic effect of (+)-meptazinol. These differences were also reflected in related molecular parameters. From Table 1, we can see that distance A in the pharmacophore of meptazinol was about 0.6 Å shorter than that in the opiates examined. The nitrogen atom actually becomes further away (>0.7 Å) from the phenol fragment in meptazinol than in the opiates, which was confirmed by the increased B and D values in meptazinol. Both enantiomers of meptazinol did not fit the skeletons of the opiates particularly well. The azepane ring of meptazinol did not match the corresponding alkyl chain between the nitrogen atom and the phenol fragment in the opiates (Figure 4). Whether or not the azepane ring contributes to analgesic potency needs further investigation.

In addition, we compared meptazinol with tramadol be-

cause they share more common pharmacological effects with each other than with other opiates. It should be noted that we still used the pharmacophore model generated from the opiate structures because their pharmacology may be mediated by a similar mechanism. To determine the active conformation of (*R,R*)-tramadol, a series of methods were carried out. Twenty-four minimum energy conformations of tramadol were analyzed and found to be very similar to each other. Therefore, the lowest energy conformation was selected and geometrically optimized further using the quantum chemical calculation method AM1, which resulted in the active conformation of tramadol. The related molecular parameters of tramadol are also listed in Table 1, and the superposition of tramadol with meptazinol is shown in Figure 5. Although the pharmacophore of meptazinol enantiomers and tramadol occupied a similar region, poor overlap occurred between meptazinol enantiomers and tramadol in the phenol fragment and the protonated nitrogen atom. Although (*R,R*)-tramadol shares some similar pharmacological effects with meptazinol, our studies revealed that their pharmacophores might be different.

Conclusion

In summary, from the structural comparisons conducted in the present study we learned that both enantiomers of meptazinol differed from typical opiates and from (*R,R*)-tramadol. However, the pharmacophore of both enantiomers of meptazinol might be similar to each other, and this result is consistent with previous studies^[21]. Therefore, we suggest that meptazinol has a unique analgesic mechanism that is different from known analgesics (ie meptazinol may not target opioid receptors only, and one of its enantiomers might

Figure 4. Superimposition of the nine opiates (in thin lines) with (+)- and (-)-meptazinol (in thick lines).

Figure 5. Superimposition of (+) or (-) meptazinol (thick lines) with (*R, R*)-tramadol (thin lines).

act on other targets in the cholinergic system). The antinociceptive targets and mechanism of meptazinol enantiomers needs to be investigated further.

Abstract

Aim: To develop a complex high-throughput screening (HTS) assay based on scintillation proximity assay (SPA) technology for identification of novel peroxisome proliferator-activated receptor gamma (PPAR γ) modulators. **Methods:** Full-length PPAR γ and retinoid X receptor alpha (RXR α), biotinylated PPAR response element (PPRE), [³H]BRL49653 and streptavidin-coated FlashPlate or microbead were used to develop an HTS assay based on SPA technology. This ‘ABCDE’ method was validated against conventional hydroxyapatite (HA) assay and applied to large-scale screening of 16 000 synthetic compounds and natural product extracts. **Results:** (1) IC₅₀ values of positive control compounds (BRL49653 and troglitazone) obtained from the ‘ABCDE’ method and HA assay were comparable and consistent with those reported elsewhere; (2) Approximately 178 compounds, showing more than 70% competitive inhibition on BRL49653 binding to PPAR γ , were identified initially by the ‘ABCDE’ method (microbead); (3) Secondary screening using FlashPlate and cross-reactivity studies with RAR α , β , γ and RXR α , β , γ confirmed that 12 compounds possessed specific PPAR γ binding properties including 2 with IC₅₀ values less than 0.5 μ mol/L and novel chemical structures. **Conclusions:** The ‘ABCDE’ method using either FlashPlate or microbead, is a highly efficient, automatable, and robust tool to screen potential PPAR γ modulators in HTS setting. Its application may be expanded to other nuclear receptors that form heterodimers upon activation.

Introduction

Nuclear receptors (NRs) are a superfamily of ligand activated transcription factors that modulate specific gene expression. To date, more than 100 NRs have been identified including class I (ligand-dependent), class II (ligand-independent), and orphan receptors. A common feature of NRs is that they all contain a DNA binding domain that interacts with respective target genes to exert physiological functions^[1]. Peroxisome proliferator-activated receptors (PPARs) with three isoforms (α , β , and γ) regulate gene transcription in response to small, lipophilic ligands^[2-5]. PPAR α is present in the liver, kidney, and heart, PPAR β (also known as PPAR δ) is expressed ubiquitously, and PPAR γ is mainly found in the adipose tissue and muscle. Upon ligand binding, PPARs release relevant co-repressors and form heterodimers

with retinoid X receptors (RXRs)^[6]. The heterodimers bind to peroxisome proliferator response elements (PPREs)^[7,8] and recruit co-activators to initiate transcription of target genes. It is known that PPAR γ is activated by fatty acids and prostaglandin J2 derivatives, although the identities of its physiologically relevant activators are not certain^[9,10].

Because PPAR γ activation can cause insulin sensitization, its synthetic agonists have been used in the treatment of type 2 diabetes^[11,12]. Recently discovered liabilities of such therapy, namely, weight gain and edema, led to regulatory concerns on the long-term administration of drugs acting through PPAR γ ^[13,14]. The elimination of such adverse effects may depend on the discovery of novel compounds with improved tissue selectivity while retaining insulin-sensitizing property.

Conventional methods to study and characterize NRs include non-homogeneous hydroxyapatite (HA) and gel shift assays which require a laborious separation procedure and thus, are not suitable for high-throughput screening (HTS). Scintillation proximity assay (SPA)^[15] technology, however, provides a homogeneous screening approach that does not involve post-reaction liquid handling steps and is well-suited to automation and HTS. In the SPA system, an isotope (eg, ^3H) is brought very close to a scintillant-impregnated microbead or FlashPlate by binding to its surface. Because the emitted β particles or auger electrons can only travel short distances in the bulk solution, the microbead or FlashPlate preferentially captures electrons from the bound radiolabeled ligand. Therefore, the amount of light emitted from the scintillant in the microbead or FlashPlate is directly proportional to the amount of bound radiolabeled ligand (Figure 1). Several SPA-based NR competitive binding assays were developed and applied to HTS using biotinylated receptor ligand binding domains (LBDs; ‘ABC’ method)^[16,17]. In this paper, we describe a more complex SPA-based assay system which includes the full-length PPAR γ and RXR α , biotinylated PPRE, [^3H]BRL49653 and streptavidin-coated FlashPlate or microbead in a homogeneous setting. This ‘ABCDE’ approach was fully validated and applied to HTS of a sizable compound library. A series of structurally diversified ‘hits’ were found, and subsequent characterization led to the discovery of two novel PPAR γ binders with sub-micromolar potency and high specificity.

Figure 1. Principle of SPA: PPAR γ forms a heterodimer with RXR α upon activation by BRL49653. The heterodimer binds to biotinylated PPRE via streptavidin-coated microbead. Because the distance between [^3H]BRL49653 and scintillant is short enough, the latter can be stimulated by [^3H] to release $h\nu$. In the case of FlashPlate, biotinylated PPRE, streptavidin and scintillant were immobilized on the surface of each well.

Materials and methods

Reagents Potassium chloride, sodium phosphate

monobasic anhydrous, and magnesium chloride hexahydrate were purchased from Shanghai Chemical Co, Ltd. Edetic acid was purchased from Sigma-Aldrich (USA). BRL49653 and troglitazone were purchased from Cayman Chemical Co (USA). 3-[(3-Cholamidopropyl)dimethylammonio]-1-propane sulfonate (CHAPS) was purchased from Boehringer Mannheim GmbH (Germany). Dithiothreitol (DTT) was purchased from BioBasic Inc (Canada) and hydroxyapatite was obtained from Bio-Rad Laboratories (USA). Aprotinin and leupeptin were purchased from Merck KGaA (Germany). [^3H]BRL49653 (53 Ci/mmol) was obtained from American Radiolabeled Chemicals, Inc (USA), FlashPlate and flat-bottom IsoplateTM was obtained from PerkinElmer, Inc (USA), and streptavidin-coated microbead was obtained from Amersham Biosciences UK Ltd (England). The plasmids of human NRs used in this study were from Dr Shen X of Shanghai Institute of Materia Medica, Chinese Academy of Sciences and Dr Chen SJ of Shanghai Institute of Hematology. Full-length PPAR γ , RAR α , β , γ , and RXR α , β , γ were produced with a baculovirus expression system using IPLB-Sf-21 cells^[18]. The stock solutions for PPAR γ , RAR α , β , γ and RXR α , β , γ extract proteins were at 7, 12–15, and 7–13 g/L, respectively. Double-strand 5'-biotinylated-PPRE (CCTT-TGACCTATTGAACTATTACCT) was synthesized by Shanghai Sangon Biological Engineering Technology & Service Co, Ltd.

HA assay The assay buffer consists of 10% glycerol (v/v), NaH_2PO_4 25 mmol/L, MgCl_2 0.5 mmol/L, DTT 1 mmol/L, edetic acid 1 mmol/L, CHAPS 5 mmol/L, aprotinin 2 mg/L and leupeptin 100 $\mu\text{mol/L}$. PPAR γ 1 μL extract protein (70 mg/L) was loaded into each well of IsoplateTM containing the assay buffer, followed by [^3H]BRL49653 (1.2 μL , 10 nmol/L) and various concentrations of BRL49653 or troglitazone (2.5 μL), to give a final volume of 100 μL per well. The plates were sealed and incubated overnight at 4 $^\circ\text{C}$. HA (25%, v/v) 25 mL was added to each well the next morning and the plates were gently agitated twice for 5 min each. Following centrifugation at 1200 $\times g$ for 3 min, the supernatant was decanted and 100 μL assay buffer was added to each well. This washing procedure was repeated twice before adding 150 μL scintillation liquid (PerkinElmer), the plates were gently agitated to resuspend HA and counting was measured by a MicroBeta counter (PerkinElmer).

FlashPlate based SPA assay Biotinylated-PPRE (4 μL from a stock solution of 10 g/L) was mixed with the above assay buffer (20 mL) containing fish sperm DNA (Sangon; 20 μL from a 10 g/L stock solution), loaded to streptavidin-coated FlashPlate (200 $\mu\text{L/well}$) and incubated overnight at 4 $^\circ\text{C}$. It was then washed three times with the assay buffer,

200 μ L reaction solution containing 14 μ g PPAR γ extract protein (70 mg/L), 0.94 mg RXR α extract protein (4.7 mg/L), 10 nmol/L [3 H]BRL49653 and various concentrations of BRL49653 or troglitazone were added to each well. Following incubation at 4 $^{\circ}$ C for 4 h, the plates were counted by the MicroBeta counter. For validation purpose, various concentrations of PPAR γ and RXR α extract proteins, as well as different reaction time lengths, were studied to determine an optimal assay condition.

Microbead based SPA assay Biotinylated-PPRE (2 μ L from a stock solution of 10 g/L) was mixed with the assay buffer (10 mL) containing fish sperm DNA (Sangon; 10 μ L from a 10 g/L stock solution) and 4 mg streptavidin-coated microbead in a conical polypropylene centrifuge tube (Corning Inc, USA) and incubated overnight at 4 $^{\circ}$ C. The mixture was centrifuged for 10 min at 1500 \times g. The supernatant was then removed and washed three times with the 10-mL assay buffer. Reaction solution 10 mL containing 700 μ g PPAR γ extract protein (70 mg/L), 47 μ g RXR α extract protein (4.7 mg/L), 10 nmol/L [3 H]BRL49653 and various concentrations of BRL49653 or troglitazone were distributed to each well of a IsoplateTM (100 μ L/well) and incubated at 4 $^{\circ}$ C for 4 h before counting by the MicroBeta counter. For validation purposes, various amounts of microbead were used to determine an optimal assay condition.

HTS studies The compound library used for screening consists of 16 000 pure synthetic compounds and extracts of natural products. A 10-compound pool per well mix was applied to the primary screening (microbead based SPA assay), with an average concentration of 7 μ mol/L for each compound dissolved in 100% Me₂SO solution. This matrix system maximizes the advantage of HTS and allows duplicate screening of each compound^[19]. In each 96-well IsoplateTM, 16 wells were used as positive control (BRL-49653) and samples showing greater than 70% inhibition were considered 'hits'. Positive compounds were re-screened with FlashPlate based SPA assay and confirmed 'hits' studied for their binding cross-reactivities with RAR α , β , γ and RXR α , β , γ using respective HA assay.

Results

Assay validation In the present study, we first assessed the kinetics of the signal strength generated by FlashPlate assay. Time-course experiment suggested that the equilibrium reached after 3.5 h of incubation at 4 $^{\circ}$ C and prolongation of the reaction time did not improve the assay efficiency (Figure 2A). Various concentrations of PPAR γ and RXR α were used to establish the optimal assay condition. In the

absence of unlabeled BRL49653, a maximum signal was detected with a combination of 140 mg/L (1:50 of the stock solution) PPAR γ extract protein and 7 mg/L (1:1000 of the stock solution) RXR α (Figure 2B). The fully optimized assay possessed a signal to background ratio of 5. Thus, optimal receptor concentrations were determined for PPAR γ (70 mg/L; 1:100) and RXR α (4.7 mg/L; 1:1500), respectively. Under this assay condition, IC₅₀ values for the two PPAR γ agonists, BRL49653 and troglitazone were measured (Figure 2C), and found to be comparable to those calculated from the HA assay (Figure 2D). Since the principle of microbead-based SPA assay is similar to that of FlashPlate, identical receptor concentrations were used with a reduced assay volume (100 μ L/well). When different concentrations of microbead were used, a saturation reached between 2 and 4 g/L (Figure 3A) with a signal-to-background ratio equal to 5. The IC₅₀ values for BRL49653 and troglitazone determined by this assay were within the range described earlier (Figure 3B).

Assay parameters In order to apply the microbead-based SPA assay to HTS, both non-specific binding (NSB; using 22.5 mmol/L BRL49653) and maximum binding (MB; using 0 mmol/L BRL49653) were studied. Coefficient of variation (CV) values were 8.5% for NSB and 6.2% for MB, respectively (Figure 3C). The Z' factor, which estimates the suitability to HTS^[20], was calculated to be 0.71.

High-throughput screening Of the 16 000 samples initially screened, 178 'hits' (1.11%) showing greater than 70% competitive inhibition on BRL49653 binding to PPAR γ were discovered (all synthetic compounds; Figure 4A). Secondary (single compound per well) screening confirmed that 24 of the above 'hits' displayed consistent inhibitory effects with IC₅₀ values between 0.2 and 28.5 μ mol/L. Cross-reactivity studies with RAR α , β , γ and RXR α , β , γ revealed that 12 of these compounds possess specific PPAR γ binding properties including 2 with IC₅₀ values less than 0.5 μ mol/L (Table 1). In this HTS campaign, the signal-to-noise ratio (10-to-15-fold), CV (5%–8%) (Figure 4B) and Z' factor (0.66–0.75) are of high quality nature.

Discussion

Three receptor binding assays were employed and compared side-by-side in the present study to measure specific binding properties of two known PPAR γ agonists, namely, BRL49653 and troglitazone. Conventional HA assay is a non-homogeneous method widely used to assess competitive interaction between a testing agent and receptor in the presence of radiolabeled ligand. For PPAR γ , such interaction involves additional components such as RXR α and

Figure 2. (A) Time-course study of FlashPlate assay. Equilibrium of PPAR γ , RXR α , [3 H]BRL49653, unlabeled BRL49653, PPRE and streptavidin-coated FlashPlate was reached at 4 h. (B) Effects of different receptor concentrations on FlashPlate assay signal strength (the stock solution concentration is 7 g/L for both PPAR γ and RXR α). (C) Dose-response curves of BRL49653 and troglitazone measured by FlashPlate assay from which IC $_{50}$ values were calculated. (D) Dose-response curves of BRL49653 and troglitazone measured by HA assay. Data shown are duplicate samples with mean \pm SEM from at least two experiments.

PPRE. Therefore, the ‘ABCDE’ method utilizing either FlashPlate or microbead based on SPA technology was developed and validated to include both RXR α and PPRE in the assay system. The final readout is fully dependent upon specific binding of biotinylated PPRE to streptavidin-coated FlashPlate or microbead as addition of free biotin was able to block this interaction completely^[16]. Although the IC $_{50}$ values of BRL49653 and troglitazone generated by these three approaches were very similar and comparable to those reported previously with a relatively simple ‘ABC’ SPA method (BRL49653: $K_d=26$ nmol/L, IC $_{50}=36$ nmol/L; troglitazone: $K_d=310$ nmol/L, IC $_{50}=320$ nmol/L)^[16], the ‘ABCDE’ model is obviously superior in terms of physiologic mimicry, easy to use, robustness and efficiency, largely due to its inclusiveness and homogenous nature.

We found that both FlashPlate and microbead-based SPA methods could be readily adapted to automated HTS. However, the cost of FlashPlate, including assay volume (200

μ L), associated reagent consumption, and compound depletion, *etc.*, is approximately 5 times greater than that of microbead (100 μ L). This may constitute a major concern when implementing a large HTS campaign. All the key assay parameters, such as CV and Z’ factor, obtained from our microbead-based SPA validation experiments, indicate that it is well suited to HTS^[20]. Indeed, when employed in HTS of potential PPAR γ modulators, this assay system demonstrated a consistently high quality in terms of the signal-to-noise ratio, CV and Z’ factor in all the 40 pooled compound matrix plates. One implication of this is that microbead-based SPA technology may be expanded to other NRs that form heterodimers upon activation.

Following the initial screening of 16 000 samples, a ‘hit’ rate of 1.11% was achieved, of which, only 13.5% of the ‘hits’ could be confirmed by secondary screening. They were further tested for cross-reactivities with both RARs and RXRs (defined as IC $_{50}$ less than 70 μ mol/L), and 12 compounds

Figure 3. (A) Effects of different microbead concentrations on SPA assay signal strength. Saturation reached between 2 and 4 g/L. showed high specificity for PPAR γ with IC₅₀ values ranging from 0.2 to 28.5 μ mol/L. The IC₅₀ for one thiazolidinedione-like compound is 0.2 μ mol/L, better than several currently marketed PPAR γ agonists. The other compound with an IC₅₀

Abstract

Aim: To examine the effects of *Astragalus* polysaccharide (APS), a component of an aqueous extract of *Astragalus membranaceus* roots, on protein tyrosine phosphatase 1B (PTP1B), a negative regulator of insulin-receptor (IR) signal transduction, and its potential role in the amelioration of insulin resistance. **Methods:** Ten-week-old fat-fed streptozotocin (STZ)-treated rats, an animal model of type II diabetes mellitus (TIIDM), were treated with APS (400 mg/kg *po*) for 5 weeks. Insulin sensitivity was identified by the insulin-tolerance test. Further analyses on the possible changes in insulin signaling occurring in skeletal muscle and liver were performed by immunoprecipitation or Western blotting. PTP1B activity was measured by an assay kit. **Results:** The diabetic rats responded to APS with a significant decrease in body weight, plasma glucose, and improved insulin sensitivity. The activity and expression of PTP1B were elevated in the skeletal muscle and liver of TIIDM rats. Thus the insulin signaling in target tissues was diminished. APS reduced both PTP1B protein level and activity in the muscle, but not in the liver of TIIDM rats. Insulin-induced tyrosine phosphorylation of the IR β -subunit and insulin receptor substrate-1 (IRS-1) were increased in the muscle, but not in the liver of APS-treated TIIDM rats. There was no change in the activity or expression of PTP1B in APS-treated normal rats, and blood insulin levels did not change in TIIDM rats after treatment with APS. **Conclusion:** APS enables insulin-sensitizing and hypoglycemic activity at least in part by decreasing the elevated expression and activity of PTP1B in the skeletal muscles of TIIDM rats.

Introduction

Diabetes mellitus (DM) is a chronic disease characterized by high blood glucose levels. It can be broadly categorized into type I and type II. The former develops as a result of insulin deficiency and the latter is due to defects in pancreatic secretion of insulin and insulin action^[1], and insulin resistance in target tissues, mainly muscle and liver. The biological effect of insulin is initiated with insulin binding to the α -subunit of insulin receptor (IR) and activating the intrinsic tyrosine kinase activity of the β -subunit of the receptor^[2]. Activated IR results in the subsequent phosphorylation of intracellular substrates including insulin receptor substrates (IRSs) such as IRS-1 and -2, phosphatidylinositol (PI) 3-kinase, and protein kinase B (PKB)^[3,4]. Normal insu-

lin action leads to increased glycogen synthesis, glucose transport, and lipogenesis, and decreased gluconeogenesis, glycogenolysis, and lipolysis^[5-7]. The net effect on glucose metabolism is that hepatic glucose production is reduced, whereas use of peripheral glucose is increased^[6,7].

An exquisite balance is required between kinases, which are involved in transmitting signals to the downstream targets necessary for the processes described above, and phosphatases, which are required to shut down this signaling to prevent excessive or, in some cases, insufficient activation^[8]. Insulin resistance and diabetes represent states in which the regulation of the signaling pathways is altered so that the intracellular actions of insulin are absent or reduced^[9]. Overactivation of phosphatases is one possible means of

blocking the insulin signaling. One key phosphatase, protein tyrosine phosphatase 1B (PTP1B), which dephosphorylates the activated insulin receptor and IRS-1, has been shown to play a major role in insulin resistance and type II diabetes^[10]. Recently, it was shown that PTP1B-knock-out mice become more insulin sensitive and fail to gain weight despite being fed with a fat-rich diet^[11]. Moreover, the role for certain PTPs, including PTP1B, in the insulin resistance associated with diabetes and obesity, has been suggested by some clinical studies in which correlations between the levels of PTP1B expression in muscle and adipose tissue and insulin resistant states were found^[12,13]. Therefore, PTP1B might be an attractive therapeutic target in the treatment of type II diabetes and obesity.

Plants have always been usable sources of drugs, and many currently available drugs are directly or indirectly derived from plants. Currently available therapies for diabetes include insulin and various oral anti-diabetic agents, such as sulfonylureas, metformin, α -glucosidase inhibitors, and rosiglitazone. These drugs are used as monotherapies or in combination to achieve better glycemic control. Each of these oral agents suffers from implication in a number of serious adverse effects^[14]. Therefore, it is important to investigate the hypoglycemic actions of plants that were originally used in traditional medicine^[15,16]. The biologically active components of plants with hypoglycemic actions include flavonoids, alkaloids glycosides, polysaccharides, and peptidoglycans^[17,18]. *Astragalus* polysaccharides (APS) are one of the main efficacious principles of *Radix Astragali* (*Astragalus membranaceus*), which is reported to have antioxidant, anti-diabetic, anti-hypertensive, and immunomodulatory activities^[19].

To study natural products with anti-diabetes activity, we screened our extract bank for inhibitors of PTP1B enzyme and found that a fraction from an aqueous extract of the roots of *A membranaceus* showed strong inhibitory bioactivity against PTP1B with IC_{50} equaling 7.50 $\mu\text{mol/L}$ (positive control sodium orthovanadate $IC_{50}=10 \mu\text{mol/L}$). This study was to investigate the effects of APS on the activity and expression of PTP1B in the livers and skeletal muscles of non-diabetic rats and rats with high-fat streptozotocin-induced diabetes. The effects of APS on insulin sensitivity and insulin-induced tyrosine phosphorylation of IR β -subunit and IRS-1 in non-diabetic and diabetic rats were also studied in an effort to establish the mechanisms of its hypoglycemic actions.

Materials and methods

Plant materials and preparation of APS *Astragalus*

membranaceus (Fisch) Bunge var *mongholicus* (Bunge) Hsiao was purchased from Shanghai Medicinal Materials Co (Shanghai, China), and identified by the Department of Authentication of Chinese Medicine, Hubei College of Chinese Traditional Medicine (Wuhan, China). A representative specimen has been kept in our laboratory for future reference.

APS were extracted with optimized techniques using direct water decoction, as described previously^[20]. The yield of APS was 2.0%, and the total polysaccharide content was 38.5%. Three subtypes of APS are defined by phytochemical screening: APSI, II, and III (1.47:1.21:1). APSI consists of *D*-glucose, *D*-galactose, and *L*-arabinose in molar ratios of 1.75:1.63:1 and has an average molecular weight of 36 300. Both APSII and APSIII are dextrans, the linkage mode of which is mainly α -(1 \rightarrow 4) linkages, and in which α -(1 \rightarrow 6) linkages are exiguous.

APS is a *hazel*-colored and water-soluble powder. It was diluted to 20 g/L in distilled water before use.

Materials and chemicals The reagents for sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) and immunoblotting were obtained from BioVision (Palo Alto, CA, USA) and the apparatus from Bio-Rad (Richmond, CA, USA). Streptozotocin (STZ), Tris, Nonidet P-40, porcine insulin, and nitrocellulose (NC) membranes were obtained from Sigma Chemical Co (St Louis, MO, USA). Protein A–Sepharose 6 MB was from Pharmacia (Uppsala, Sweden). The monoclonal anti-phosphotyrosine antibody (α PY, PY99) was purchased from Santa Cruz Biotechnology, Inc (Santa Cruz, CA, USA). Rabbit polyclonal anti-insulin receptor β -subunit (IR β) antibody was purchased from Upstate Biotechnology Inc (Lake Placid, NY, USA). The anti-rat carboxy-terminal IRS-1 antibody (clone 8–63) was from NeoMarkers (Fremont, CA, USA). α -PTP1B polyclonal antibody was purchased from Upstate Biotechnology Inc. Enhanced chemiluminescence (ECL) detection reagents were from Kirkegaard & Perry Laboratories (Gaithersburg, MA, USA). All other chemicals were of the highest analytical grade.

Type II diabetic (TIIDM) rat model and treatment protocol Male Sprague–Dawley rats [from the experimental animal center of Wuhan University, certificate No SCXK (Hubei) 2003-0003], 8 weeks of age and weighing approximately 200 g, were used for all studies. All procedures were in accordance with the Institute Ethical Committee for the Experimental Use of Animals of Wuhan University. Rats were housed five per cage in a room with a 12:12 hour light:dark cycle and an ambient temperature of 22–25 °C. Animals were fed either a normal chow diet consisting (as a percentage of total kcal) of 12% fat, 60% carbohydrate, and

28% protein, or a high-fat diet (HFD) consisting of 41% fat, 41% carbohydrate, and 18% protein. After 2 weeks on either diet, animals (with the exception of noninjected controls) were anesthetized with ketamine (65 mg/kg) and xylazine (7 mg/kg) after an overnight fast and injected with STZ (30 mg/kg in 0.1 mol/L citrate-buffered saline, pH 4.5) into the tail vein via a temporary indwelling 24-gauge catheter. Animals had free access to food and water after the STZ injection, and both STZ-injected and noninjected animals continued on their original diets (chow or fat) for the duration of the study. After a 12-h fast, animals showing fasting glucose levels >6.7 mmol/L at 72 h after STZ injection were considered diabetic. The control rats were fasted in an identical manner and had a volume of citrate-buffered saline, equal to that of the STZ solution, injected by the same route.

The control and diabetic groups were then further subdivided into treated and untreated groups: control ($n=10$); control treated with APS (Control+APS, $n=10$); TIIDM ($n=12$); and TIIDM treated with oral APS (400 mg/kg) (TIIDM+APS, $n=12$). Treatment was given daily for 5 weeks. The control group received an equal volume of vehicle (saline). At the end of each week, individual body weights were recorded, and glucose and insulin levels were determined under fasting and nonfasting conditions. Glycemia was assessed on blood collected from the tail vein using an OneTouch Ultra blood glucose meter (LifeScan, Milpitas, CA, USA). Insulin levels were determined by radio-immunoassay (RIA) with a kit from Beifang Biotech Research Center (Beijing, China). Before necropsy, saline- and APS-treated animals were intraperitoneally administered insulin (5 U/kg) in saline with 0.1% bovine serum albumin (BSA) or vehicle (saline with 0.1% BSA) after a 10-h fast. Tissue samples from livers and soleus muscles were taken (10 min after treatment) from both vehicle- and insulin-treated animals and snap frozen in liquid nitrogen.

Insulin sensitivity Peripheral insulin resistance was assessed with an insulin-tolerance test (ITT)^[21] that measured insulin sensitivity using K_{ITT} as an index of insulin-mediated glucose metabolism. Rats were fasted for 15 h before insulin challenge. Neutral insulin injections were diluted with 0.9% saline to a final concentration of 2 kU/L, and then administered at a dose of 2 U/kg body weight by slow intravenous injection through the tail vein. Blood samples were collected at 0, 10, 20, 30, and 60 min after the administration of insulin. Serum was separated and subjected to glucose estimation. Serum glucose concentrations were determined using a commercial assay kit (Sigma Diagnostics, St Louis, MO, USA) and 10 μ L of serum was used for each

assay. K_{ITT} was determined from the slope of a linear portion of the regression line of the natural logarithm of glucose versus time^[21], and calculated using the formula^[22]: $K_{ITT} = (0.693/t_{1/2}) \times 100$, where $t_{1/2}$ represents the half-life of plasma glucose decay, which was estimated by plotting plasma glucose concentration versus time on semilogarithmic graph paper. Lower insulin-sensitivity index (K_{ITT}) scores mean higher degrees of insulin resistance.

Lysate preparation and protein assays Frozen liver tissue (50 mg) was sonicated in 1 mL of lysis buffer (buffer A) containing Tris-HCl 20 mmol/L (pH 7.4), 1% Triton X-100, 10% glycerol, NaCl 150 mmol/L, edetic acid 2 mmol/L, β -glycerophosphate 25 mmol/L, sodium fluoride 20 mmol/L, sodium orthovanadate 1 mmol/L, sodium pyrophosphate 2 mmol/L, leupeptin 10 mg/L, benzamidine 1 mmol/L, 4-(2-aminoethyl) benzenesulfonyl fluoride hydrochloride 1 mmol/L, and microcystin 1 mmol/L, and rocked for 40 min at 4 °C. Detergent-insoluble material was sedimented by centrifugation at 12 000 $\times g$ at 4 °C for 10 min. Muscle samples (50 mg) were homogenized and centrifuged at 1000 000 $\times g$ for 1 h in ice-cold Hepes buffer 50 mmol/L (pH 7.4) containing NaCl 150 mmol/L, sodium pyrophosphate 10 mmol/L, Na_3VO_4 2 mmol/L, NaF 10 mmol/L, edetic acid 2 mmol/L, phenylmethylsulfonyl fluoride (PMSF) 2 mmol/L, leupeptin 5 mg/L, 1% Nonidet P-40, and 10% glycerol (buffer B).

Supernatants were collected, and protein concentrations were measured with Bradford protein assay reagent (Bio-Rad), using BSA as the standard.

Western blotting Aliquots (50 μ g) of muscle or liver homogenates were subjected to SDS-PAGE (7.5% gel) and transferred electrophoretically onto nitrocellulose (NC) membranes for 5 h. NC membranes were then blocked for 2 h at room temperature with block solution provided in the ECL kits. This step was followed by overnight incubation at 4 °C with anti- α -PTP1B polyclonal antibody or anti-phosphotyrosine (PY99) as the primary antibodies, as described in the figure legends. The NC membranes were then washed for 30 min with wash solution (ECL kits), followed by a 1-h incubation with either anti-mouse or anti-rabbit IgG conjugated with horseradish-peroxidase in block solution. The NC membranes were washed for 30 min in wash solution, and the immunoreactive bands were detected with an enhanced chemiluminescence method.

Tyrosine phosphorylation of IR-subunit and IRS-1 Muscle or liver lysates (1 mg of protein) were immunoprecipitated overnight at 4 °C with 2 μ g of anti-IR β or anti-IRS-1 coupled to protein A-Sepharose. The immune complex was washed three times in phosphate-buffered saline (PBS) (pH 7.4) containing 1% Nonidet P-40 and Na_3VO_4

2 mmol/L, resuspended in Laemmli buffer, and boiled for 5 min. Proteins were resolved on SDS-PAGE (7.5% gel), then electrotransferred from the gel to nitrocellulose membranes. The nitrocellulose filters were incubated at 4 °C overnight with 1 mg/L PY99. Subsequent steps were performed as described above.

PTP1B protein levels and activity The tissue homogenate was assayed in a microtiter plate at 27 °C. The PTP1B assay kit was obtained from Upstate Biotechnology Inc. The protocol outlined by the manufacturer was followed rigidly. PTP1B protein levels were assessed by immunoblotting using polyclonal antibodies directed against PTP1B, as described above.

Statistical analysis All values are expressed as mean±SEM. Statistical significance was determined using analysis of variance (ANOVA) followed by Tukey's test. $P<0.05$ was considered statistically significant.

Results

Characteristics of experimental animals The glucose levels of both fasting and fed rats were significantly higher ($P<0.05$) in HFD/STZ rats (TIIDM) than in normal control rats (Control) (Table 1). The levels of glucose in fasting and fed TIIDM rats were significantly reduced ($P<0.05$) after treatment with APS at a dose of 400 mg/kg *po* per day for 5 weeks (TIIDM+APS). It should be noted that insulin concentrations in type II diabetic rats were similar to values of control rats. Treatment with APS did not affect insulin levels in control or type II diabetic rats. HFD/STZ diabetic rats weighed 20 g more than the normal chow-fed controls ($P<0.05$). APS treatment could significantly reduce body weights in diabetic rats and had no effects on those of control rats. All data are mean±SEM calculated from 10 rats.

Table 1. Characteristics of the experimental animals. $n=10$. Mean±SEM. ^b $P<0.05$ vs control group. ^c $P<0.05$ vs TIIDM group.

	Control	Control+APS	TIIDM	TIIDM+APS
Plasma glucose (fasting)(mmol/L)	4.3±0.2	4.1±0.2	10.3±0.8 ^b	6.8±0.5 ^c
Plasma glucose (fed) (mmol/L)	6.6±0.5	6.2±0.3	15.6±1.2 ^b	9.8±0.7 ^c
Insulin (pmol/L)	162±13	168±15	178±20	171±18
Body weight (g)	200±2	202±2	220±5 ^b	205±3 ^c

Insulin sensitivity Insulin sensitivity in the TIIDM rats was significantly lower than that in the control group. The impaired insulin sensitivity in the TIIDM rats was improved following APS treatment (Figure 1).

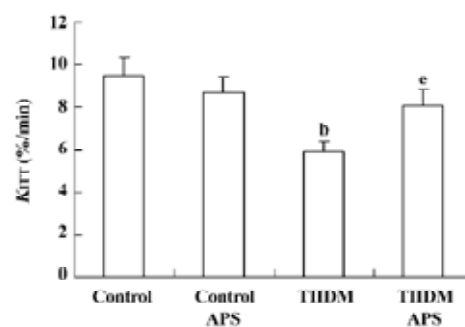

Figure 1. Effect of APS on insulin sensitivity in TIIDM rats. $n=5-8$. Mean±SEM. ^b $P<0.05$ vs control. ^c $P<0.05$ vs TIIDM group.

Effects of APS on PTP1B expression in muscles and livers of control and TIIDM rats PTP1B protein levels in the skeletal muscles of TIIDM rats were significantly increased (1.6-fold, $P<0.05$) compared with those of controls. In TIIDM rats, the level of PTP1B after treatment with APS was reduced by 30% ($P<0.05$), compared with that of the TIIDM rats (Figure 2A and C). PTP1B protein levels in the livers of TIIDM rats were also significantly increased (1.7-fold, $P<0.05$) compared with those of control rats. However, treatment with APS did not affect PTP1B protein levels in the livers of TIIDM rats (Figure 2B and D). PTP1B levels in the muscles and livers of normal control rats were not affected by APS treatment.

Effects of APS on PTP1B activity in muscles and livers of control and TIIDM rats There was a two-fold ($P<0.01$) increase in the activity of PTP1B in the skeletal muscles of TIIDM rats. APS reduced the activity of PTP1B by 25% ($P<0.05$) in APS-treated TIIDM rats (Figure 3A). PTP1B activity in the livers of TIIDM rats was significantly elevated (1.8-fold, $P<0.01$) compared with that of the controls. Treatment with APS did not change PTP1B activity in the livers of TIIDM rats (Figure 3B). Nor did APS affect the activity of PTP1B in the skeletal muscles or livers of APS-treated control rats.

Effects of APS on insulin-induced tyrosine phosphorylation of IR β -subunit In each group of animals, the administration of insulin resulted in an increase in the tyrosine phosphorylation of the IR β -subunit (Figure 4). However, the levels of IR β tyrosine phosphorylation in the skeletal muscles and livers of TIIDM rats after stimulation with insulin were reduced by 47% ($P<0.05$) and 41% ($P<0.05$), respectively, compared with those of the control rats (Figure 4). Treatment with APS significantly increased the level of IR β tyrosine phosphorylation stimulated by insulin in the skeletal muscles of TIIDM rats, but did not affect that in the livers of TIIDM rats. APS also did not affect the IR β ty-

rosine phosphorylation stimulated by insulin in the skeletal muscles or livers of APS-treated control rats, as evaluated by scanning densitometry.

Effects of APS on insulin-induced tyrosine phosphorylation of IRS-1 Insulin administration resulted in an increase in IRS-1 tyrosine phosphorylation in each group of animals (Figure 5). TIIDM rats exhibited a reduced response to insulin, and the levels of tyrosine phosphorylation of IRS-1 after insulin stimulation in skeletal muscles and livers were reduced by 37% and 35% ($P<0.05$), respectively, compared with the values measured in control rats (Figure 5). APS treatment did not increase the level of tyrosine phosphorylation of IRS-1 induced by insulin in the liver tissues of TIIDM rats, but significantly improved that in skeletal muscles ($P<0.05$) in TIIDM rats. APS had no effect on the tyrosine phosphorylation of IRS-1 stimulated by insulin in the skeletal muscles or livers of APS-treated control rats.

Discussion

In the present study, we developed an animal model for type II diabetes, the HFD/STZ rat. These rats constitute a relatively inexpensive and easily accessible rodent model that is not extremely obese and simulates the natural history and metabolic characteristics of patients with type II diabetes^[23]. Recent reports^[24] have indicated that insulin resis-

tance may be caused by an excess nutrient supply. Both excess glucose and excess fat can cause insulin resistance in muscle and fat tissues, whereas excess fat can cause impaired suppression of endogenous glucose production. The present animal model was based on the rationale described above. At first, we used high-fat diets to induce insulin resistance in Sprague-Dawley rats. Plasma glucose concentrations were similar in chow-fed and HFD rats after two weeks of the high-fat diet, whereas insulin concentrations in the HFD rats were significantly higher than those in the chow-fed controls (HFD: 338 ± 25 vs Control: 162 ± 13 pmol/L, $P<0.05$). The association of normoglycemia and hyperinsulinemia suggested that the HFD rats were insulin-resistant. Conversion of pre-diabetes to frank hyperglycemia in patients with type II diabetes is associated with a decline in the secretory capacity of the pancreatic β -cells^[25,26]. However, this failure in β -cell compensation is relative, not absolute^[23]. We attempted to simulate this evolution from a state of insulin resistance and absolute hyperinsulinemia to a state of "relative" hypoinsulinemia by injecting insulin-resistant HFD rats with a moderate amount of STZ, which partly damaged β -cell and reduced the serum insulin concentration to a relatively lower level (178 ± 20 pmol/L), which is approximately that of normal chow-fed rats. Comparison of the data in Table 1 indicates that we were successful in this attempt.

The signaling pathways affected by the inhibition of

PTP1B, particularly in a diabetic model, have been characterized. In this study, we observed increased PTP1B activity in skeletal muscle and liver tissues of HFD/STZ rats when *para*-nitrophenyl phosphate (*p*NPP) was used as substrate. These changes were similar to those in PTP1B protein levels in the tissues. Corresponding to these results, insulin-induced tyrosine phosphorylation of the IR β -subunit and IRS-1 were significantly decreased in muscle and liver tissues. This is the first study to demonstrate the *in vivo* effects of changes in PTP1B activity and expression on insulin signaling molecules in the skeletal muscles and livers of HFD/STZ rats.

Using reduced carboxymethylated-maleylated (RCM)-lysozyme as a substrate, Seiichi Tagami^[27] and McGuire *et al*^[28] found increases in PTP1B activity in the skeletal muscles of insulin-resistant Otsuka Long-Evans Tokushima fatty (OLETF) rats and insulin-resistant human subjects, relative to the activity in the corresponding control groups. Muscle PTP1B activity, measured with myelin basic protein and the insulin-receptor cytoplasmic domain as substrates, was also increased in an animal model of insulin-resistant obesity and DM^[10]. Those findings accord with our results. It is reasonable to postulate that increased PTP1B activity in the muscle and liver contributes to insulin resistance and type II diabetes in HFD/STZ rats because PTP1B inhibits tyrosine phosphorylation of the insulin receptor and its substrates, including IRS-1.

Our own earlier ethnopharmacological studies of an aqueous extract of *Astragalus* confirm the data reported for the plant *A membranaceus*, which is traditionally used as an infusion of (mainly) roots by the Chinese population to treat type II diabetes. Most important of all, *A membranaceus* is an important component of the majority of traditional herbal blend prescriptions used to cure type II diabetes in traditional Chinese medicine. The unique nature of the *A membranaceus* extract inspired us to work towards the isolation of the active ingredient from the crude extract. When subjected to sequential extraction, maximum activity was found in APS. In the present study, we found that APS significantly reduced both PTP1B protein levels and activity in the skeletal muscles, but not in the livers of HFD/STZ rats. Consistent with this change, the insulin-induced tyrosine phosphorylation of the IR β -subunit and IRS-1 increased in the skeletal muscles, but not in the livers of APS-treated TIIDM rats. Furthermore, blood glucose levels were controlled and insulin sensitivity was apparently improved in APS-treated TIIDM rats when K_{ITT} was used as an index of glucose metabolism. This is a simple, reasonably accurate, and rapid method for screening insulin resistance^[29], and in-

dicates the net resistance to insulin at the target level, including receptor and post-receptor defects. The data collected in this study indicate that blood insulin levels are not altered by treatment with APS in TIIDM rats, suggesting that the hypoglycemic effects of APS are not mediated through insulin secretion. In addition, HFD/STZ rats had a higher body weight than that of normal rats. The effect of STZ injection plus high fat diet on body weight gain is in accordance with the earlier findings^[23,30]. APS could decrease body weight in diabetic rats. It has been suggested that PTP1B can act as a negative regulator of leptin signaling by dephosphorylating the leptin receptor associated kinase Jak2^[31,32]. So one can postulate that the obesity resistance effect of APS be associated with enhanced leptin sensitivity induced by its inhibitory action on PTP1B.

PTP1B is a well-established drug target in the treatment of TIIDM and obesity^[33]. However, the PTP family of enzymes is large, and all are highly specific for charged phosphotyrosine residues. Finding a selective small-molecule inhibitor of PTP1B is therefore proving difficult. Numerous PTP1B-inhibiting candidates are undergoing trials, but significant success has yet to be achieved^[34]. Our study showed that protein levels of PTP1B changed in parallel with changes in its activities in skeletal muscle and liver. The alterations in PTP1B activities may be partly due to changes in its protein levels. Therefore, we postulate that the inhibitory effect of APS on PTP1B activity is most likely mediated by the inhibition of PTP1B protein expression. Detailed studies are in progress in our laboratory to clarify the mechanism underlying the inhibitory action of APS on PTP1B. In the present study, our data suggest that APS induces normalization of PTP1B activity in the muscles, leading to an improvement in insulin sensitivity. However, changes in PTP1B activity alone may not account for the complete insulin-sensitizing effect of APS. Other possible mechanisms cannot be excluded.

In conclusion, we have presented evidence to substantiate the anti-diabetic and insulin-sensitizing effects of the *A membranaceus* extract, APS. The insulin-enhancing effects of APS are at least partially exerted through its effects on PTP1B in skeletal muscle. The results of this study support this hypothesis, at least in this animal model.

Abstract

Aim: To explore the change of 5-lipoxygenase (5-LO) pathway expression and proinflammatory mediators level of lung tissue and cerebral cortex, and the possible regulatory mechanism through central nervous 5-LO pathways to pulmonary inflammatory status in antigen repeated challenged rats. **Methods:** Four groups of rats were treated as control, asthma model, asthma model treatment with dexamethasone (DXM, 0.5 mg/kg, ip) and ketotifen (5 mg/kg, ig). Tumor necrosis factor (TNF)- α , interleukin (IL)-4, interferon (IFN)- γ , and nitric oxide (NO) were detected by ELISA kits. The mRNA expression of 5-LO and LTA₄-hydrolase (LTA₄-H) was analyzed by reverse transcription-polymerase chain reaction (RT-PCR), and the protein content of 5-LO was measured by Western blot. **Results:** Increase of TNF- α , IL-4, NO level, and decrease of IFN- γ level in bronchoalveolar lavage fluid (BALF) and cerebral cortex in sensitized rats were shown after repeated antigen challenge. The expression of 5-LO and LTA₄-H mRNA, and 5-LO protein levels were increased in lung tissue and cerebral cortex in asthma rats. In comparison with the asthma model, DXM significantly inhibited the increase of cytokine levels and the expression of 5-LO pathway enzyme ($P < 0.05$). Ketotifen also inhibited the increase of TNF- α level and 5-LO pathway enzyme expression in lung and cerebral cortex, but had no effect on the level of NO, IL-4, and IFN- γ . **Conclusion:** The correlative increase of 5-LO pathway enzyme expression and proinflammatory mediators of brain may have a regulatory effect on pulmonary inflammation in asthma.

Introduction

The interaction between central nervous-immune pathways or neuroendocrine-immune (NEI) networks in various disease states is affected by various pathophysiologic status. In the pathogenesis of allergic diseases, the abnormalities in immune function are mediated by the NEI network through overproduction of allergic mediators^[1]. Undoubtedly, leukotrienes (LTs), the metabolites of 5-lipoxygenase (5-LO) pathways are thought to play crucial roles in the inflammatory network. Up to now, it is unclear how the metabolites of 5-LO pathways in the central nervous system regulate inflammation in lung tissue of asthma rats. From previous work, we found that the change of Th1/Th2 paradigm (ratio

of interferon (IFN)- γ /interleukin (IL)-4 decreased and the content of LTB₄ in the cerebral cortex increased correspondent to that in bronchoalveolar lavage fluid (BALF) or lung tissue in inflammatory status of asthma rats^[2,3]. These findings indicate that there is an interactive response of LTs and proinflammatory cytokines in the central nervous system, and the changes of these proinflammatory mediators in the central nervous system may have pathophysiologic effects in asthma rats. To explore these hypotheses and get a clearer understanding of the central nervous system changes of 5-LO pathway, Tumor necrosis factor (TNF)- α , IL-4, IFN- γ , and nitric oxide (NO) in asthma rats, we have further investigated the correlative alterations of proinflammatory mediators and the expression of 5-LO pathway enzyme in lung

tissue and cerebral cortex.

Materials and methods

Animal and reagent Sprague–Dawley rats of either sex weighing 180 g±20 g were purchased from the Laboratory Animal Center of Medical School of Zhejiang University (Grade II, Certificate No 220010014), and maintained on a regular 12-h daylight cycle with water and food available *ad libitum*. Dexamethasone sodium phosphate (DXM, Suzhou Sixth Pharmaceutical Factory, Suzhou), ketotifen (Shanghai Pharmaceutical Factory, Shanghai), egg albumin Grade V (Sigma, St Louis, USA), heparin sodium (Xuzhou Biochemical Pharmaceutical Factory, Xuzhou), IFN- γ , TNF- α , NO, and IL-4 ELISA kit (Jinmei Biotech Co Ltd, Shenzhen, China) were commercially available. TRIzol reagent, SuperScript II reverse transcriptase, and Taq DNA polymerase were obtained from GIBCO BRL (Paisley, Scotland, UK).

Sensitization, treatment, and challenge regimens The sensitization procedure to induce IgE-mediated asthma response is as earlier described^[3]. At d 14 after sensitization, the rats were placed in a 45 cm×45 cm×15 cm plastic box and challenged by exposure to an aerosol of ovalbumin (10 g/L in saline) which was generated in a jet nebulizer (partical size 1-5 μ m; BARI, MASTER, Germany) for 20 min, and repeated daily for 6 d. Control rats were similarly exposed to an aerosol of saline. One hour before antigen challenge, the rats in the treatment groups were administered with DXM (0.5 mg/kg, ip) and ketotifen (5 mg/kg, ig), respectively. The rats in the control and model groups were administered with saline (ip). All the animals were studied on d 21 after the first sensitization.

BALF Bronchoalveolar lavage (BAL) was performed by flushing the airways with saline 5 mL containing 1% bovine serum albumin and 1 kU/L heparin sodium through the tracheal cannula three times. BAL fluid (BALF) were pooled and centrifuged (Eppendorf Centrifuge 5804R, Germany) at 500×g for 10 min at 4 °C. The supernatant was collected and stored at -70 °C for assaying IFN- γ , TNF- α , NO, and IL-4 level.

Brain homogenates preparation Blood cells in systemic circulation were removed by perfused with D-Hanks' liquid through ascending aorta cannula. The left cerebral cortex was then cut into 1 mm³, homogenated (DY89-I Homogenater, Linbo Xinzhi SCI-TETH research Institute, Ningbo) in ice-cold Hanks' buffer (pH 7.5). Thereafter, the homogenates were centrifuged at 3000×g at 4 °C for 10 min. The supernatant was collected and stored at -70 °C for assaying IFN- γ , TNF- α , NO, and IL-4 level.

Assay of IFN- γ , TNF- α , NO, and IL-4 The IFN- γ , TNF- α , NO, and IL-4 levels in the BALF and cerebral cortex homogenates were measured according to the ELISA kit description. All measurements were carried out in duplicate.

Reverse transcription-polymerase chain reaction (RT-PCR) assay Total RNA was isolated from the cerebral cortex and lung tissue. Trizol 1 mL was added per 100 mg tissue and was homogenized; samples were left at 18–21 °C for 3 min. Chloroform 0.2 mL was added to the homogenizer and mixed. After 10 min at 18–21 °C, the samples were centrifuged at 15 000×g in a microcentrifuge at 4 °C for 15 min. The upper phase was transferred to new tubes and the same volume isopropanol was added. RNA was allowed to precipitate at 18–21 °C for 10 min and collected by centrifugation at 15 000×g at 4 °C for 10 min. After washing precipitates in 75% ethanol and drying for 10 min, the RNA was dissolved in DEPC-treated water and quantified by the measurement of ultraviolet absorption at 260 nm (Eppendorf Biophotometer, Germany). All samples were kept at -70 °C until use.

For the synthesis of the single-stranded cDNA (Eppendorf Mastercycler gradient, Germany), total RNA (4 μ g) from each sample was reverse-transcribed using an antisense specific primer and 200 U of SuperScript II RT. Sequences of the PCR primers for 5-LO, LTA₄-H, and glyceraldehydes-3-phosphate dehydrogenase (GAPDH) were derived from published sequences as follows: 5-LO: sense 5' AGG CTG CAG TGA GAA GCA TC 3', antisense 5' GCC AGT GGT TCT TGA CTC TC 3', designed to amplify a fragment corresponding to nucleotides 181–770^[4]; LTA₄-H: sense 5' CAG TCA CAG GAG GAT AAT 3', antisense 5' GGA GTG AGC CAC TGA AGG 3', designed to amplify a fragment corresponding to nucleotides 131–363^[5]; GAPDH: sense 5' ACC ACC ATG GAG AAG GCT GG 3', antisense 5' CTC AGT GTA GCC CAG GAT GC 3', designed to amplify a fragment corresponding to nucleotides 372–899. All amplified segments extended over at least 1 intron boundary of the genomic DNA. The reactants were cycled at 94 °C 30 s, 59 °C 20 s, 72 °C 10 s for LTA₄-H, and 94 °C 45 s, 58 °C 30 s, 72 °C 90 s for 5-LO and GAPDH. Reaction products were separated by electrophoresis using 1.5% standard agarose gel. Amplification of GAPDH was performed as a control. PCR products were analyzed by electrophoresis (CLP, USA), visualized by ultraviolet transillumination of ethidium bromide-stained gels, and the intensity of each band was measured by the UVP Image Analyzer (UVP, Inc Upland, CA). The expression of 5-LO and LTA₄-H were normalized to that of GAPDH.

5-LO Western immunoblotting The cerebral cortex and lung tissue were dissected and homogenized in homogeniz-

ing buffer, containing Tris-HCl 20 mmol/L, egtazic acid 2 mmol/L, edetic acid 5 mmol/L, pepstatin 1.5 mmol/L, leupeptin 2 mmol/L, phenylmethylsulfonyl fluoride 0.5 mmol/L, aprotinin 0.2 kU/L, and dithiothreitol 2 mmol/L, using a Polytron. The homogenates were centrifuged at 100 000×g at 4 °C for 60 min . The resulting supernatant was a portion of the cytosol (S1) fraction, and the pellet was resuspended in the homogenizing buffer and centrifuged again at 100 000×g at 4 °C for 60 min. The resulting supernatant (S2) was combined with the S1 fraction, and the combination was used for analyses as the “cytosol” fraction. The concentration of protein in these two fractions was determined using the procedure of Lowry *et al*.

Equal volumes of protein samples (40 mg of protein) and gel loading solution (Tris-HCl 50 mmol/L pH 6.8, β-mercaptoethanol 4%, sodium dodecyl sulfate 1%, glycerol 40%, and a trace amount of bromphenol blue) were mixed, and the samples were boiled for 3 min and kept on ice for 10 min. The samples were placed onto 12.5% (w/v) acrylamide gel using the Mini Protean gel apparatus (CLP, USA). The gels were electrophoresed using Tris base 25 mmol/L, glycine 192 mmol/L, and sodium dodecyl sulfate 0.1% (w/v) at 150 V. The proteins were subsequently transferred electrophoretically to an ECL nitrocellulose membrane (Amersham) using the CLP semi-dry Electrobloetter (CLP, USA) at 150 mA constant current. Membranes were washed with TBST buffer (Tris base 10 mmol/L, NaCl 0.15 mol/L, and Tween-20 0.05%) for 10 min.

The blots were blocked by incubating them with 5% (wt/vol) powdered non-fat milk in TBST buffer, Nonidet P-40 2 mL, and sodium dodecyl sulfate 0.02% (wt/vol) (pH 8.0). Thereafter, the blots were incubated overnight with the primary anti-5-LO antibody (rabbit polyclonal; cayman chemical, Ann Arbor, MI, USA) at a dilution of 1:1000. The blots were then washed with TBST buffer, incubated with horseradish peroxidase-linked secondary antibody (anti-rabbit IgG; 1:3000) for 4 h at room temperature, and processed

with the ECL kit. The blots were then washed with TBST and exposed to ECL film. The UVP Image Analyzer was used to measure and analyze the band intensity.

Statistical analysis Data were presented as mean±SD. Statistical difference was determined using one-way analysis of variance followed by the Student-Newman-Keuls method for multiple comparisons between groups. All statistical calculations were performed using a Sigmapstat statistical package.

Results

Antigen-induced changes of IL-4 and IFN-γ, TNF-α, and NO in BALF and cerebral cortex homogenate

Amounts of IL-4, TNF-α, and NO from BALF and cerebral cortex homogenates in antigen-challenged rats were markedly higher compared with samples from normal rats (*P*<0.05). In contrast, amounts of IFN-γ in antigen-challenged rats were less (BALF *P*<0.05, cerebral cortex homogenates *P*<0.01). Therefore, the IFN-γ/IL-4 ratio was lowered. DXM-treated rats had less IL-4, TNF-α, and NO amounts in cerebral cortex homogenates and higher IFN-γ amounts compared with that of model rats. The down-regulation of IFN-γ/IL-4 ratio in antigen-challenged rats was recovered by DXM (BALF *P*<0.05 and cerebral cortex homogenates *P*<0.01). Ketotifen had no effect on the amount of IL-4, IFN-γ, and NO in BALF and cerebral cortex homogenates, but inhibited the TNF-α both in BALF and cerebral cortex homogenates in model rats (*P*<0.05) (Table 1).

5-LO and LTA₄-H mRNA expression in lung tissue and cerebral cortex

Using GAPDH as the internal control, the band intensity of 5-LO and LTA₄-H mRNA is shown in Figures 1, 2. The expression of 5-LO and LTA₄-H mRNA in asthma rats were significantly higher than that in the control rats (*P*<0.05). Both DXM and ketotifen inhibited the 5-LO and LTA₄-H mRNA expression of lung and cerebral cortex in the asthma rats (Figures 1, 2).

5-LO protein content Both 5-LO mRNA expression and the amount of cytosol 5-LO-immunoreactive protein in both cerebral cortex and lung tissue increased in the asthma rats compared with the control rats ($P<0.05$ and $P<0.01$ respectively; Figure 3). Both DXM and ketotifen significantly decreased the 5-LO protein level in cytosol of asthma rats ($P<0.05$).

Discussion

The first step in the production of all LTs, the oxygenation of arachidonic acid (AA) to form 5-hydroperoxyeicosatetraenoic acid and the immediate dehydration of this unstable intermediate to LTA₄, is carried out by 5-LO. Metabolism of LTA₄ by LTA₄ hydrolase (LTA₄-H) results in the production of the potent chemoattractant LTB₄. Alternatively, LTA₄ can be conjugated with glutathione by LTC₄ synthase (LTC₄-S) to produce LTC₄ and its metabolites LTD₄ and E₄, collectively

referred to as the cysteinyl LTs^[6].

The actions of 5-LO metabolites and Th1/Th2 paradigm in the pathogenesis of asthma and allergic disease have been understood^[7,8]. In the present research, IL-4 level, the expression of 5-LO and LTA₄-H mRNA, and 5-LO protein are simultaneously increased in BALF and the cerebral cortex in asthma rats. We postulate that the increased expression of 5-LO pathway enzymes is partly due to the overproduction of proinflammatory cytokines, as heterogeneous profiles of eicosanoid generation would be determined by the absence or presence of additional local factors, particularly the Th2 cytokines that associate with mucosal surfaces in allergic diseases. Previous literature has shown that Th2 cytokines, thought to favor asthma and allergic diseases, upregulated LT synthesis. Recent findings showed that IL-4, IL-5, and IL-13 also upregulated cysteinyl LT1 receptor expression^[9]. IL-4 priming dramatically induced the steady-state expression of LTC₄-S^[10], and IL-5 supported the localization of 5-LO to the nucleus of human mast cells *in vivo*^[11]. With immunologic disorders, inflammatory mediators interacted with one another, creating upregulatory cascades by various feedback mechanisms^[12]. Conversely, the regulation of cytokine expression by LTs has also been explored:

cysteinyl LTs upregulated Th2 cytokine expression and decreased Th1 cytokine expression, favoring an allergic phenotype^[13]. LTB₄ stimulated monocytes and T cell to produce IL-1, TNF- α , and IL-5^[14]. However, it is unclear how it influences pulmonary function during the increase of expression of 5-LO, LTA₄-H mRNA, and LTB₄ level in the cerebral cortex. Recently, our group found exogenous LTB₄, by intercerebro-ventricularly injection, inhibited antigen-induced increase of lung resistance and decreased lung compliance in sensitized rats, and reduced antigen-induced eosinophils infiltration of airway in the sensitized mice (unpublished data). The results suggest the increase of 5-LO mRNA expression and metabolites in inflammatory status of asthma may be a negative feedback to relieve asthmatic inflammation.

Glucocorticoids are the most effective drugs to inhibit inflammatory reaction in asthma, but whether they are also able to inhibit the 5-LO pathway enzyme expression in sensitized rats after antigen challenge is still unclear. In our previous experiment, the effect of DXM in decreasing LTB₄ and IL-4 content was found to decrease the number of inflammatory cells in cerebral cortex and lung tissue of sensitized rats^[2,3]. In this study, administration of DXM (0.5 mg/kg, ip) before each challenge fully inhibited the 5-LO and LTA₄-H mRNA expression. Conversely, Uz *et al*^[15] found that DXM stimulated 5-LO mRNA expression in the brain of normal rats. These data suggest that glucocorticoid may be at least partly effective in regulating the metabolites of 5-LO pathways in the brain.

It is known that TNF- α is released in allergic responses from both mast cells and macrophages via IgE-dependent mechanisms, and elevated levels have been demonstrated in the BALF of asthmatic subjects undergoing allergen challenge^[16]. In the present research, we found a coincidental increase of TNF- α between the cerebral cortex and lung tissue in asthma rats, which could be inhibited by DXM and ketotifen. Ketotifen, as the mast cell membrane stabilizer and H₁ receptor antagonist, can inhibit the release of mediators from inflammatory cells. Our previous study demonstrated that ketotifen inhibited the increase of LTB₄ level in the cerebral cortex and BALF in asthma rats^[3]. In this study, ketotifen did not inhibit the downregulation of IFN- γ and upregulation of IL-4 but decreased 5-LO and LTA₄-H mRNA expression and TNF- α level in asthma rats. Canetti *et al*^[17] found that using a neutralizing anti-TNF- α antibody could block IL-18 induced LTB₄ production, and Spanbroek *et al*^[18] found granulocyte-macrophage colony-stimulating factor plus TNF- α promoted dendritic cells differentiation and induced a strong rise in 5-LO expression. The results suggest

that ketotifen may not influence the Th1/Th2 paradigm but inhibits the release of mediators from mast cells. TNF- α may be also one of the proinflammatory mediators of regulating 5-LO and LTA₄-H mRNA expression.

NO can inhibit the secretion of IL-2 and IFN- γ by Th1 cells but has no effect on IL-4 production by Th2 cells. Thus, NO seems to exert a self-regulatory effect on Th1 cells implicated in immunopathology. NO derived from airway epithelial cells, macrophages, and Th1 cells plays an important role in amplifying and perpetuating the Th2 cell-mediated inflammatory response, both in allergic and non-allergic asthma^[19]. Low concentrations of reactive oxygen intermediates in combination with NO were additive in suppressing 5-LO enzyme activity, possibly through peroxynitrite generation. The ability of peroxynitrite to suppress LT synthesis is associated with its ability to cause nitrotyrosination and S-nitrosylation of the 5-LO enzyme^[20]. Contrary to the inhibitory effect of DXM on NO content in this research, ketotifen did not inhibit the increased NO level in the asthma rats. Therefore, the regulatory effect of NO on 5-LO and LTA₄-H requires elucidating.

In the present research, the correlative increase of 5-LO pathway and proinflammatory mediators between cerebral cortex and lung tissue were shown in sensitized rats after repeated antigen challenge. We postulate that an increase of 5-LO pathway expression and pro-inflammatory mediators of the brain may have regulatory effects on pulmonary inflammation of asthma.

Abstract

Aim: To investigate the biological activity of human lens epithelial cells (HLEC) in producing inducible nitric oxide synthase (iNOS) and nitric oxide (NO), and to assess the effect of diethyldithiocarbamate (DDC) on iNOS mRNA levels and expression of NOS. **Methods:** The human lens epithelial cell line SRA 01/04 was used in this experiment. Semi-quantitative reverse transcription polymerase chain reaction (RT-PCR) and Western blotting were used to detect, respectively, iNOS mRNA expression and protein production. **Results:** A costimulation by interferon gamma (IFN- γ) and lipopolysaccharide (LPS) was necessary for iNOS expression in HLEC. The expression of iNOS was significantly reduced in a dose-dependent manner by adding DDC from 10 μ mol/L to 1 mmol/L. **Conclusion:** The expression of iNOS in HLEC needs co-stimulation with IFN- γ and LPS and it is inhibited by DDC.

Introduction

Cataracts are still the most important cause of blindness in the world and are a significant and increasing global problem. The mechanism of cataract development is complicated and involves many factors. For many years, we have been involved in the development of anti-cataract treatments and investigating the mechanisms of cataract development. Our previous studies on selenite-induced rat cataracts demonstrated that the NO concentration in ocular tissue was significantly higher than in normal rats. Inducible nitric oxide synthase (iNOS or NOS2) is thought to play a role in the initiation of cataracts, and the development of cataracts is prevented by NOS inhibitors^[1]. We researched whether NO was produced by the ocular tissues or comes from other parts of the body, so we selected human lens epithelial cells (HLEC) for further study.

Inducible NOS, one of the three isoforms of NOS, catalyses the oxidization of *L*-arginine and generates large amounts of NO^[2]; it does not require elevated intracellular Ca²⁺ levels for activation. In addition, its function lasts for a longer period than that of constitutive NOSs (endothelial NOS, eNOS; neural NOS, nNOS). Inducible NOS can be

produced by treatment with agents, such as cytokines, interferons and bacterial lipopolysaccharide (LPS), in a wide variety of cell types such as macrophages, hepatocytes, keratinocytes, endothelial cells, and epithelial cells^[3-7]. In the eye, eNOS and nNOS are localized in the retina, ciliary body and conjunctiva, and are thought to be involved in neurotransmission, regulation of intraocular pressure and vasodilation, while iNOS is involved in endotoxin-induced uveitis and inflammation of the anterior segment of the eye, and inhibits the cellular proliferation of retinal pigment epithelial cells^[8,9]. Therefore, the purpose of this study is to investigate the biological activity of HLEC in iNOS expression and NO production.

Diethyldithiocarbamate (DDC), a potent free radical scavenger, has been found to prevent selenite-induced opacity in cultured rat lenses^[10]. This was thought to be related to its anti-oxidant effect. It has been reported that both NO and its derivative peroxynitrite (ONOO⁻) inhibit mitochondrial respiration and may increase oxygen radical production by mitochondria. Large or persistent levels of NO promote mitochondrial oxidant formation, and inhibit the respiratory chain complexes, probably by nitrosylating or oxidizing protein thiols and removing iron from the iron-sulphur centres.

Peroxynitrite causes irreversible inhibition of mitochondrial respiration and damage to a variety of mitochondrial components via oxidizing reactions, most notably at complexes I and II of the electron transport chain, ATPase, aconitases, and Mn-superoxide dismutase^[11,12]. These damages lead to deficient energy metabolism. Usually, in the initiation of cataractogenesis, deficient energy metabolism occurs with mitochondria function disorder. Thus, the effect of DDC for the prevention of NO overproduction was also investigated in this study.

Materials and methods

Materials DDC and bovine serum albumin (BSA) were purchased from Wako Pure Chemical Industries Ltd (Osaka, Japan). Dulbecco's modified Eagle's medium (low glucose) (DMEM), fetal bovine serum (FBS), 0.05% trypsin-EDTA solution and phosphate buffered saline (PBS) were purchased from GIBCO™ Invitrogen Co (Tokyo, Japan). Gentamicin reagent solution (10 g/L) was obtained from GIBCO BRL Life Technologies (Japan). Interferon- γ (IFN- γ) was purchased from PeproTech EC Ltd (London, UK). LPS purified from *Escherichia coli* was obtained from Sigma-Aldrich Co (St Louis, MO, USA). Protease inhibitor cocktail tablets were obtained from Complete Roche Applied Science (Japan). All the primers used were synthesized by Sigma Genosys (Sigma Genosys, Japan, KK). Alkaline phosphatase (AP)-conjugated anti-rabbit IgG and ProtoBlot II AP System with Stabilized Substrate (BCIP/NBT) were obtained from Promega Co. All other chemicals used, except where indicated, were of analytical grade.

Cell culture and treatments The human lens epithelial cell line SRA 01/04 was provided by Ibaraki Medical University, and maintained in DMEM supplemented with 10% (v/v) heat-inactivated FBS and 10 mg/L gentamicin at 37 °C in a humidified CO₂ incubator (ESPEC BNA-111, TABAI ESPEC CORP, Japan) with 5% CO₂. Culture medium was changed every other day. The confluent cells were separated and trypsinized with 0.05% trypsin-EDTA to produce single cells, after which they were seeded at 4×10⁴ cm⁻² and allowed to form subcultures. Cell viability was assessed by Trypan blue exclusion assay. Each treatment was carried out on d 3 after seeding, when the cells were 80% confluent. The culture medium was changed every other day for routine culture, and then 1 h before each experiment. All cultures were carried out in duplicate.

Semiquantitative reverse transcription-polymerase chain reaction (RT-PCR) for iNOS mRNA evaluation Total cellular RNA was extracted and purified from HLEC

with the RNeasy Mini Kit and RNase-Free DNase Set (QIAGEN KK, Tokyo, Japan) according to the manufacturer's instructions. The RNA level was quantified by measuring the absorbance at 260 nm. The samples with a ratio of 260/280 nm greater than 1.8 were used. RT-PCR was performed using the RNA PCR Kit (AWV Ver 2.1, TAKARA BIO INC, Tokyo, Japan). As a control for calibrating an equivalent amount of input cDNA, the mRNA level of constitutively expressed G3PDH was determined in parallel aliquots of cDNA to control any differences in cDNA synthesis efficiency. In general, total RNA 1 μ g was added to a 20 μ L volume of reaction medium for reverse transcription, and all PCR procedures were performed using a volume of 50 μ L according to the manufacturer's instructions. The primers used in this study were as follows: iNOS (sense, 5'-CCAGT GACAC AGGAT GACCT TCAG-3' and antisense, 5'-TGCCA TTGTT GGTGG AGTAA CG-3'), and human G3PDH (sense, 5'-CATCA CCATC TTCCA GGAGC GAGA-3' and antisense, 5'-CCACC ACCCT GTTGC TGTAG CCA-3'). The cycling conditions were: 35 cycles for iNOS and 20 cycles for G3PDH at 94 °C for 30 s, 65 °C for 30 s, and 72 °C for 1 min for amplifying 603 bp and 752 bp products, respectively. Finally, the extension of products was performed at 72 °C for 10 min. PCR-amplified samples were run on 1.5% agarose gel and visualized using ethidium bromide, and then photographed (ImageMaster VDS-CL, Amersham Biosciences) under UV light.

Western blotting for determination of iNOS protein At the end of the treatment, cells were washed with ice-cold phosphate buffer and removed from plates by a cell scraper and centrifuged at 200×g for 5 min. The cell pellets were then suspended in 200 μ L lysis buffer (Tris-HCl 50 mmol/L, pH 7.6, protease inhibitor cocktail tablet in PBS 150 mmol/L, Triton X-100 0.5%) and lysed for 30 min on ice. The cell debris was removed by centrifugation at 12 000×g at 4 °C for 20 min. The protein concentration was determined using a protein assay kit (Bio-Rad Laboratories, CA, USA) with BSA as the standard. A sample of total protein (20 μ g) was separated on an 8% polyacrylamide sodium dodecyl sulfate (SDS) gel. The proteins were then transferred to polyvinylidene difluoride (PVDF) membranes (BIO-RAD, CA, USA), using a semi-dry transfer cell (TRans-Blot SD Semi-Dry Electrophoretic Transfer Cell, BIO-RAD, CA, USA). The transfer buffer used in the system contained Tris-HCl 25 mmol/L, glycine 192 mmol/L, methanol 20%, and SDS 0.0375%. After transfer, nonspecific sites on the membranes were blocked with 5% non-fat dry milk in PBS. The blots were probed with 1 mg/L rabbit anti-human iNOS polyclonal antibody (Santa Cruz Biotechnology Inc, CA, USA) overnight at

4 °C followed by washing several times with PBS-0.1% Tween 20 (PBST). A secondary alkaline-phosphatase conjugated anti-rabbit IgG (1:7500 dilutions) was added, and incubated for 1 h at room temperature. After washing several times in PBST, iNOS proteins were visualized by BCIP/NBT kit.

Results

Induction of iNOS mRNA The expression of iNOS has been studied in most detail in murine macrophages where maximum expression can be induced by a combination of IFN- γ and LPS^[16]. Figure 1 showed that non-stimulated HLEC had undetectable levels of iNOS mRNA (lane 1). Stimulation with LPS or IFN- γ alone for 3 h had a negligible effect on iNOS mRNA induction (lanes 2 and 3). HLEC, pretreated with IFN- γ for 3 h, then washed twice with PBS, followed by an incubation with LPS for 3 h, had a very thin band (lane 4), whereas, cells treated with IFN- γ for 3 h followed by co-incubation with LPS and IFN- γ , produced a substantial amount of iNOS mRNA (lane 5).

Figure 1. Transcription of iNOS mRNA in HLEC treated with/without IFN- γ and LPS. Representative results of the 3 independent experiments are shown.

Increasing the amount of LPS from 1 $\mu\text{g}/\text{L}$ to 1 mg/L resulted in a corresponding increase of iNOS mRNA levels (Figure 2A). With the co-incubation time increase, the intensity of the iNOS bands tended to increase (Figure 2B). On the contrary, extending the pretreatment time of IFN- γ from 1 d to 2 d did not produce a stronger iNOS band (Figure 2C, lane 5 *vs* 3).

Inhibitory effect of DDC on iNOS expression Figure 3 shows the effect of DDC on iNOS mRNA expression. Incubation with LPS, IFN- γ , or DDC alone failed to produce iNOS mRNA or protein, while the combination of LPS and IFN- γ resulted in the expression of iNOS (lane 4), and the expression was inhibited by adding DDC to the culture medium (lane 5). However, the induction of iNOS by LPS and

Figure 2. Transcription of iNOS mRNA in HLEC. HLEC were pretreated with IFN- γ for 3 h followed by co-incubation (A) with LPS at different concentrations, (B) with LPS for indicated time intervals, and (C) pretreated with IFN- γ for 1 day or 2 day followed by a co-incubation with/without LPS for another 3 h. Representative results of the 3 independent experiments are shown.

Figure 3. Inhibitory effect of DDC on iNOS mRNA transcription and protein production. HLEC were pretreated with/without IFN- γ in the presence/absence of DDC for 3 h, followed by a 24-h co-incubation with/without LPS. Representative results of the 3 independent experiments are shown.

IFN- γ was attenuated in HLEC that had been loaded with DDC. In addition, the inhibitory effect was enhanced at increased DDC concentrations from 10 $\mu\text{mol}/\text{L}$ to 1 mmol/L (Figure 4).

Figure 4. Relationship between DDC concentrations and inhibitory effect on iNOS mRNA transcription. HLEC were treated with/without IFN- γ in the presence/absence of DDC for 3 h, followed by a 24-h coincubation with/without LPS. Representative results of the 3 independent experiments are shown.

Discussion

The present research reports the expression of iNOS mRNA in HLEC stimulated with LPS and IFN- γ . The co-incubation of both factors is needed for a quick cellular response and large amount of iNOS mRNA production, compared with stimulation with LPS or IFN- γ alone or successively. The synergistic effect between LPS and IFN- γ , as far as the transcription of iNOS mRNA is concerned, has been extensively investigated in mouse macrophages^[15-17]. LPS is a common initiator of inflammation, triggering tyrosine phosphorylation and activation of mitogen-activated protein kinases (MAPKs)^[18]. MAPKs phosphorylate and regulate a variety of transcription factors, leading to inflammatory gene expression^[19]. In several cell types, LPS also activates transcription nuclear factor kappa B (NF- κ B) and regulates iNOS gene expression^[20]. The synthesis of iNOS is mainly regulated at the transcriptional level. The promoter region of the iNOS gene from different species has been reported to contain binding sites for several transcription factors. Those known to be active include κ B sites located both in the enhancer and basal promoter^[20,21], two juxtaposed enhancer-linked IFN-stimulated response elements (ISREs), the distal one of which is a strong activator^[20,21], while the proximal one is a weak activator of transcription^[22], and an octamer element in the basal promoter^[21]. An IFN- γ activated site (GAS) is necessary for full expression of the mouse iNOS gene in response to IFN- γ and LPS. The binding of Stat1 α to the GAS of the iNOS promoter is required for optimal induction of the iNOS gene by IFN- γ and LPS^[23]. Also, iNOS gene expression appears to require the simultaneous presence of all transcription factors binding to their enhancers. When all are present, transcription is enhanced; when any one of them is absent, the transcription level is reduced or completely stopped. In the case of humans, transcriptional regulation is a crucial factor in the initiation of cytokine-

stimulated NO production by human iNOS^[24]. The two activator protein-1 sites, as well as the upstream NF- κ B site, are important for LPS and IFN- γ stimulation of human iNOS induction.

Activation of NF- κ B seems to be an essential step for iNOS induction in most cell types, and the inhibitory effect of DDC on the transcriptional activity of the iNOS gene may be due to an effect on the activation of transcription factor NF- κ B, which regulates the expression of a variety of genes essential for cellular immune response, inflammation, growth, and development. Because dithiocarbamates are well-known antioxidants and NF- κ B inhibitors^[25,26], and DDC, a dithiocarbamate analogue, exhibits concentration-dependent biphasic effects in inhibiting NF- κ B activation in cerebral endothelial cells^[27], that is, it inhibits NF- κ B activation at low but not high concentrations (>500 μ mol/L). The present studies investigated the inhibitory effect of DDC at concentrations ranging from 10 μ mol/L to 1 mmol/L, and no biphasic effect was observed. If a biphasic effect does exist in HLEC, the "high concentration" should be more than 1 mmol/L. Our previous studies on the ocular bioavailability of disulfiram (DSF), which is a dimer of DDC and quickly converted into DDC by catalysis of the protein mercapto group in the cornea and aqueous humor, demonstrated that the concentration of DDC in the aqueous humor was not more than 100 μ mol/L after topical administration. Thus, if DSF is used as an anticataract agent for the prevention and treatment of cataracts, the main problem we need to consider is how to enhance the corneal permeability and bioavailability of DSF preparations. Whether the anticataract effect of DDC is due to its inhibition of NF- κ B or not, the signal transduction pathway linking stimulation of iNOS mRNA in HLEC needs to be clarified by further investigations.

In conclusion, the present study reports the expression of iNOS in HLEC, which shows that co-stimulation of IFN- γ and LPS is required, while the expression is inhibited by DDC.

Acknowledgment

We are most grateful to Dr David JACK for comments and suggestions on our manuscript.

Abstract

Aim: To investigate the effect of antisense oligodeoxynucleotides (ASODN) targeting Pim-2 on cell proliferation of DU-145 cells. **Methods:** Three ASODN targeting Pim-2 were designed and synthesized. After transfection with ASODN, cell proliferation was analyzed using an MTS [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium, inner salt] assay. In addition, Pim-2 mRNA, protein levels, and cell cycles were examined. **Results:** The ASODN designed and synthesized by our laboratory significantly reduced Pim-2 mRNA level and protein content in DU-145 cells. After transfection with ASODN for 48 h, a marked reduction in cell viability was observed in DU-145 cells in a dose-dependent manner. No remarkable apoptosis occurred in cells treated with ASODN compared with control cells. However, it should be noted that G₁ phase arrest was clearly observed in ASODN-treated cells. **Conclusion:** ASODN targeting Pim-2 resulted in a marked reduction in DU-145 cell proliferation, and induction of G₁ phase cell cycle arrest is one of the important mechanisms for ASODN to reduce cell growth. Moreover, antisense inhibition of Pim-2 expression provides a new promising therapy target for prostate cancer.

Introduction

Prostate cancer is the most frequent non-cutaneous malignancy and the second leading cause of cancer death among males in the western world. It has long been recognized that cancer arises as a result of somatic mutations; and a concept dramatically reinforced by the demonstration that a cellular “proto-oncogene” is mutationally involved in prostate cancer formation. To date a number of the genes associated with prostate cancer formation and progression have been identified, which are deregulated or abnormally over-expressed contributing to tumor formation. Recent technological developments have paved the way for the identification of the genes PRC17, Stat3, and Pim^[1–5]. Identification of these genes provides a new target for prostate cancer therapy.

The Pim serine/threonine kinase family was first identified as a common proviral insertion site in T and B-cell lymphomas in mice^[6]. To date, three family members have been identified: Pim-1, Pim-2, and Pim-3. These related enzymes

show substantial homology, but differ in their tissue expression^[7]. It is unknown to what extent the various family members differ in their biochemical effects. The Pim-2 gene encodes a cytoplasmic serine/threonine kinase whose expression is regulated by hematopoietic cytokines^[8,9]. There are multiple isoforms of Pim-2 protein resulting from the use of the alternative translation start codon, CTG^[10]. Among these isoforms, the short Pim-2 (34 kDa) form is the most active at enhancing survival of FDCEP1 cells after cytokine withdrawal. The Pim-2 transgene induces lymphoid tumors, and exhibits potent synergy with *c-myc*^[9]. Recent studies have indicated that Pim-2 kinase could phosphorylate the pro-apoptotic protein Bard on serine 112, and thus inhibit cell apoptosis^[11]. Although the contribution of Pim-2 to cancer formation and progress is relatively unknown, Pim-2 has been recognized as a proto-oncogene, and proto-oncogenes are associated with many types of cancer formation.

At present, more and more patients are being diagnosed with early stage prostate cancer because of improvements in

diagnostic techniques. Although surgery and chemotherapy are effective on patients with localized tumors, the prognosis of patients with advanced or metastatic tumors is not ideal. It is clear that novel treatment approaches to prostate cancer are urgently needed. It is now accepted that antisense oligodeoxynucleotides have sequences that are complementary to specific strands of RNA. Once delivered into a target cell, the oligodeoxynucleotides hybridise with its RNA complement and inhibit expression of the corresponding disease-relevant protein. More and more data demonstrate that antisense therapy for cancer is a very promising strategy. Consequently, the aim of our paper is to investigate whether inhibition of Pim-2 expression using antisense oligodeoxynucleotides can reduce proliferation of DU-145 cells.

Materials and methods

Antisense oligodeoxynucleotides The antisense sequences used in these experiments were designed using a computational neural network model^[12]. BLAST confirmed that they were specific for the Pim-2 gene. Eicosomer ASODN were synthesized in our laboratory using an Applied Biosystems 391 DNA synthesizer and purified by OPC (Oligonucleotide Purification Cartridge) (Perkin-Elmer, Foster City, CA, USA). Table 1 shows the sequence of ASODN.

Table 1. The sequence of antisense oligodeoxynucleotides (ASODN).

No	Position	Sequence (5'-3')
ASODN 1	4-23	CGCCGCGGCTCGTGCCGAA
ASODN 2	123-142	CCTCGAACGCTTCCCGATCC
ASODN 3	344-363	TGGCCACCTGGAGTCGATCT

Cell line and culture Human prostate cancer cell lines, DU-145, were obtained from the Chinese Academy of Medical Sciences (Beijing, China). Cells were cultured in RPMI-1640 medium (Invitrogen, San Diego, CA, USA) supplemented with 10% fetal bovine serum (GIBCO BRL, Grand Island, NY, USA), 100 kU/L benzylpenicillin and 100 mg/L streptomycin. All cultures were incubated at 37 °C in a 5% CO₂ atmosphere.

Cell viability The effects of ASODN on cellular viability were determined using an MTS [3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulphophenyl)-2H-tetrazolium, inner salt] assay. In brief, 3×10³ cells were seeded in 96-well microtiter plate and allowed to attach overnight. Cells were then transfected with different concentrations

(0.1 μmol/L, 0.2 μmol/L, 0.4 μmol/L, 0.8 μmol/L) of ASODN. After 48 h of incubation, 20 mL of MTS (Sigma Chemical Company, St Louis, MO, USA) was added to each well. The 96-well microtiter plate was incubated for 2 h at 37 °C, and a 490 nm absorbance value was determined using an MR 600 Microplate reader (Wallac, Turku, Finland). Each assay was carried out in quadruplicate. Cellular proliferation inhibition rate is calculated as: $(A_{\text{control}} - A_{\text{sample}}) / (A_{\text{control}} - A_{\text{blank}}) \times 100\%$.

Lip-mediated transfection of antisense oligodeoxynucleotides Cells were plated in six-well plates at a density of 1×10⁵ cells per well. Transfections were carried out after plating for 24 h, when cells reached a confluence of (50–80)%. Lipofectamine 2000 (Invitrogen) was used for transfection in this experiment and transfection was carried out according to the manufacturer's instructions. ASODN concentrations were selected as 0.1 μmol/L, 0.2 μmol/L, 0.4 μmol/L, 0.8 μmol/L, respectively. After transfection (incubation for 6 h at 37 °C), the cells were washed with phosphate-buffered saline (PBS) and incubated in fresh culture medium.

Reverse transcription-polymerase chain reaction (RT-PCR) After transfection for 48 h, total RNA was extracted using TRIzol (Invitrogen) by a single-step phenol extraction. Subsequent RT-PCR was carried out using a reverse transcription system (RT-PCR kit, Promega, Madison, WI, USA). In brief, first strand cDNA was synthesized using an Oligo (dT)₁₅ primer at 42 °C for 30 min. The PCR reaction for Pim-2 and β-actin was carried out in a single reaction of 20 mL volume. The latter served as a control following 32 cycles of denaturing at 95 °C for 45 s, annealing at 55 °C for 40s, and extending at 72 °C for 40 s. Under this reaction condition, the amplification showed linearity (data not shown). PCR products were run on a 3.0% agarose gel and visualized using ethidium bromide staining, and the intensities were measured by scanning the gel with Gel Doc 1000 (Bio-Rad, Hercules, CA, USA). Inhibition of Pim-2 mRNA was calculated according to the following formula:

$$\text{Inhibition percentage (\%)} = \left(\frac{1 - A_{\text{sample}} \times A_{0\text{control}}}{A_{\text{control}} \times A_{0\text{sample}}} \right) \times 100$$

where A_{sample} is the intensity of Pim-2 PCR product in cells transfected with ASODN and lipofectamine, $A_{0\text{sample}}$ is the intensity of Pim-2 PCR product in cells transfected with lipofectamine alone, A_{control} is the intensity of β-actin product in cells transfected with ASODN and lipofectamine, and $A_{0\text{control}}$ is the intensity of β-actin product in cells transfected with lipofectamine alone.

Western blot analysis After 72 h of transfection with

ASODN, cells were lysed in RIPA buffer [10 mmol Tris-HCL (pH 7.4), 1% deoxycholate, 1% NP40, 150 mmol NaCl, 0.1% SDS, 0.2 mmol phenylmethyl sulfonyl fluoride, 1 mg/L aprotinin and 1 mg/L leupeptin] for 30 min on ice. The lysates were centrifuged at 12000×g for 15 min to remove debris. Protein samples (30 μg) were separated using 12% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) gel and transferred onto hybond-polyvinylidene difluoride (PVDF) membranes (Schleicher & Schuell Biosciences, Inc, Keene N H, USA). Pim-2 protein was identified using anti-Pim-2 primary and peroxidase-conjugated secondary antibody (Santa Cruz Biotechnology, Santa Cruz, CA, USA). Finally, the reactive band was visualized using an ECL-plus Detection Kit (Amersham Biosciences) and scanned by Gel Doc 1000 (Bio-Rad).

Cell cycle and apoptosis analysis Cell cycle assays were carried out as described previously^[13]. In brief, cells were harvested after transfection with 0.4 μmol/L ASODN for 48 h, and fixed with 70% ethanol at -20 °C overnight. Fixed cells were washed twice again with PBS, and stained with 50 mg/L propidium iodide (PI) in the presence of RNase A. The stained cells were analyzed for DNA content by fluorescence-activated cell sorting (FACS) in a FACScan (SOBR model, Becton-Dickinson, San Jose, CA, USA). Cell cycle fractions were quantified with CellQuest (Becton Dickinson), and apoptosis was estimated using the fraction of sub-G₁ phase cells.

Statistics Data were expressed as mean±SD. Statistical analysis were carried out using Student's *t*-tests (two-tailed). $P < 0.05$ indicates statistical significance.

Results

Effects of ASODN on Pim-2 expression After transfection of ASODN targeting Pim-2, semi-quantitative RT-PCR was used to determine the inhibitory effects on Pim-2 mRNA transcription. ASODN 1–3 examined in the present study exerted different inhibitory effects on mRNA transcription (Figure 1A). The Pim-2 transcription level was decreased by 64.5%, 56.8%, and 55.2% ($P < 0.05$) in DU-145 cells by ASODN1-3, respectively (Figure 1B). In addition, the Pim-2 protein amount was diminished by treatment with ASODN compared with the control (Figure 2).

Effects of ASODN on cell viability As shown in Figure 3, all of the ASODN targeting Pim-2 gene treatment significantly decreased cell viability, and the inhibition rate was dose-dependent.

Effects of ASODN on DU-145 cell growth arrest and apoptosis Flow cytometry was used to quantify changes in

Figure 1. Effects of antisense oligodeoxynucleotides (ASODN) on mRNA level of Pim-2 in DU-145 cells. (A) Electrophoresis of reverse transcription-polymerase chain reaction products of the Pim-2 gene and β-actin gene in DU-145 cells transfected with ASODN1, 2 and 3. (B) Quantification of the data presented in (A). Data are expressed as mean±SD from four independent experiments. $P < 0.05$ vs the cells transfected with lipofectamine alone.

Figure 2. Inhibition of Pim-2 protein expression in DU-145 cells after transfection with antisense oligodeoxynucleotides (ASODN) 1, 2, and 3. (A) Cell extracts were separated using sodium dodecyl sulfate gel electrophoresis, transferred to a membrane and blotted with anti-Pim-2 goat polyclonal antibody. Anti-β-actin rabbit polyclonal antibodies were used as loading control. (B) Quantification of the data presented in (A). Data are expressed as mean±SD from four independent experiments. $P < 0.05$ vs the cells (CK) transfected with lipofectamine alone.

Figure 3. Effects of antisense oligodeoxynucleotides (ASODN) on the proliferation of DU-145 cells. Data are expressed as mean±SD from four independent experiments.

cell cycle and apoptosis 48 h after treatment with Pim-2 ASODN. All of the ASODN targeting Pim-2 increased the fraction of cells undergoing growth arrest at G₀/G₁ in DU-145 cells, and the inhibitory effect of ASODN1 was greater than the others (Table 2). It should be noted that no apparent apoptosis occurred in cells after treatment with any of the ASODN (Figure 4).

Table 2. Cell cycle distribution of DU-145 cells (%) treated with antisense oligodeoxynucleotides (ASODN). ^bP<0.05 vs the control group.

Cell cycle (phase)	ASODN1	ASODN2	ASODN3	Control
G ₀ /G ₁	71.68 ^b	69.78 ^b	65.72 ^b	51.76
G ₂ /M	7.06	8.13	8.26	9.26
S	21.26 ^b	22.09 ^b	26.02 ^b	38.98

Discussion

The balance between cell death and cell proliferation determines cells survive or die. Although the detailed mechanism and function of Pim-2 in cells are still unknown, research suggests that Pim-2 acts as an important factor to mediate cell survival. Consequently, ASODN against Pim-2 are anticipated to restrain cell proliferation. In this experiment, three ASODN targeting Pim-2 were designed and synthesized by our laboratory. Results indicated that all three ASODN could specifically reduce the mRNA transcription and protein expression level of Pim-2 in DU-145 cells

Figure 4. Analysis of cell apoptosis after transfection with antisense oligodeoxynucleotides (ASODN) in DU-145 cells. Cells transfected with lipofectamine alone were used as a control.

(Figures 1, 2).

Prostate cancer is the most frequently diagnosed cancer in men. The incidence of prostate cancer rose in the late 1980s and early 1990s as a result of increased life expectancy, earlier and more accurate diagnosis, and increased public awareness of the disease. Nowadays, prostate cancer is believed to be the second leading cause of cancer related death in men. Thus, there is an urgent need to develop efficient therapy approaches to prostate cancer. Data presented here indicate that our ASODN could repress DU-145 cells growth to varying extents, and inhibitory effects were dose-dependent (Figure 3).

Despite extensive investigation, the physiological substrates of the Pim-2 kinase remain unknown. However, ASODN against Pim-2 induced marked G₁ phase cell cycle arrest in DU-145 prostate cancer cells (Table 2). This result implies that a number of proteins that are associated with cell cycle control are substrates of Pim-2 kinase. Similarly, Pim-1, its homological gene, was found to phosphorylate the cell cycle inhibitor p21Cip1/WAF1 and abrogate G₁ phase cell cycle arrest^[14]. Taken together, these results offer evidence that the Pim serine/threonine kinase family show substantial homology, which can mediate the activity of a number of cell cycle related proteins. This experiment, implies that, in DU-145 cells, Pim-2 kinase is not the essential factor determining cell survival. In addition, abrogation of G₁ phase cell cycle arrest by Pim-2 serine/threonine kinase may be an important mechanism for prostate cell proliferation.

Antisense therapeutics for cancer are, after decades of difficulties, finally close to fulfilling their promise in the clinic.

Antisense compounds targeting certain genes, such as HER-2, VEGF, IGF-IR, and protein kinase C, were reported to efficiently inhibit target gene expression^[15-18]. Advances in defining molecular abnormalities in prostate cancer offer the hope of improving both the diagnosis and therapy of the disease. It is now well established that the progression of epithelial cells in the prostate from normal to dysplastic or adenomatous epithelium to carcinoma *in situ* and finally to invasive carcinoma is the result of the sequential accumulation of genetic abnormalities involving oncogenes and tumor suppressor genes. A number of genetic mutations are found in prostate cancer, including activating mutations of the Pim-2 oncogene and loss of the tumor suppressor gene P₅₃^[1-5]. In the present study, our antisense compounds could downregulate the expression of target mRNA level *in vitro*, as well as display certain antitumor activity. It is possible that antisense or other small molecule approaches to inhibit Pim-2 signaling may play a role in the treatment of patients with prostate cancer. In addition, a significant fraction of non-prostate tumors, including many colon, gastric, and testis carcinomas express elevated Pim-2 levels^[19,20]. Whether or not antisense ODN targeting Pim-2 can also show antitumor activity against such neoplasm requires further study.

In summary, ASODN designed and synthesized by our laboratory against Pim-2 can efficiently suppress target gene expression and inhibit the growth of DU-145 cells, providing a new promising therapy target for prostate cancer.

Abstract

Aim: To examine the effect of venom from the spider *Macrothele raven* on cell proliferation and cytotoxicity in human cervical carcinoma, HeLa cells. **Methods:** Morphological and biochemical signs of apoptosis appeared using acridine orange-ethidium bromide (AO/EB) staining. Marked morphological changes in HeLa cells after treatment with spider venom were observed using scanning electron microscopy (SEM) and transmission electron microscopy (TEM). Cell proliferation and cytotoxicity were determined by [*methyl*-³H] thymidine assay (³H]TdR) and lactate dehydrogenase (LDH) release, respectively. DNA fragmentation and cell cycle distribution were monitored using flow cytometry. In addition, Western blot analysis was used to evaluate the level of caspase-3 expression. *In vivo* examination of the inhibition of the size of tumors in nude mice treated with spider venom was measured. **Results:** Marked morphological changes were observed using AO/EB staining, SEM and TEM assay. Spider venom at concentrations of 10–40 mg/L caused dose- and time-dependent inhibition of HeLa cell proliferation. The ratio of apoptosis and necrosis increased. The activity of caspase-3 was upregulated after spider venom treatment. *In vivo* study of tumor size revealed that tumors significantly decreased in size from controls to tumors treated for 3 weeks with spider venom (*P*<0.05). **Conclusion:** The inhibition of HeLa cells by the venom of the spider *Macrothele raveni* was carried out in three ways: induction of apoptosis, necrosis of toxicity damage and direct lysis. Spider venom is a novel anti-tumor material both *in vitro* and *in vivo*.

Introduction

Spider venoms are biochemically and biologically well studied world-wide and we know as much about spider venoms as we know about other animal venoms, such as snake venoms, bee venoms, and scorpion venoms. In general, the main toxin components of most spider venoms have been well identified as a complex mixture of proteins, polypeptides, polyamine neurotoxins, nucleic acids, free amino acids, monoamines, and inorganic salts that cause a wide range of effects in both vertebrates and invertebrates^[1–3].

As far as the pharmacology and biochemistry of spider

venom is concerned, spider venom represents a wide variety of ion channel toxins, novel non-neurotoxins, enzymes and low molecular weight compounds^[4].

A number of studies have examined the anti-tumor substances found in snake venom^[5–9], bee venom^[10–12], and scorpion venom^[13]. Many toxins isolated from spider venom have been invaluable in helping to determine the role and diversity of neuronal ion channels and the process of exocytosis^[14–16]. Six peptide toxins (Magi 1–6) were isolated from the Hexathelidae spider, *Macrothele gigas*, dealing with sodium channel (Magi 1–5) and high toxicity in lepidoptera larvae of 3.1 nmol/g (Magi 6)^[17]. Toxicological assays

showed diverse lethal or paralytic activities of Magi 7–16 in mice and/or insects^[18]. The spider *Macrothele raveni* was identified as a new species in the genus *Macrothele*^[19]. There have been two papers published about raven toxin tests in mice in which the toxins acted as a neurotoxic peptide and blocked neuromuscular transmission^[20,21]. To date there has been no study examining the venom of the spider *Macrothele raveni*. In the present study, the effects of *M raveni* spider venom on HeLa cells and possible mechanisms of action were evaluated.

Materials and methods

Reagents RPMI-1640 (Gibco Laboratories, Grand Island, NY, USA) dissolved in double distilled water with the pH value adjusted to 7.0 using NaHCO₃, was disinfected and stored at -20 °C. Fetal calf serum was purchased from Sijiqing Biological Engineering Company (Hangzhou, China), sterilized, and stored at -20 °C. [³H]TdR was purchased from the Atomic Energy Institute of China (Beijing, China). Verapamil, streptomycin, penicillin and 0.5% hydrocortisone were purchased from North China Pharmaceutical Company (Shijiazhuang, China). Propidium iodide (PI), bovine serum albumin (BSA), and Triton X-100 were purchased from Sigma Company (St Louis, MO, USA). The rabbit polyclonal antibody against caspase-3 and rodamine-labeled secondary antibody were purchased from Santa Cruz Biotech (Santa Cruz, CA, USA).

Spider venom Pure spider *Macrothele raveni* venom was collected by electrical stimulation of 15 spiders *M raveni* (the weight of each spider was approximately 60 g)^[22]. Spider venom was dissolved in phosphate buffered saline (PBS) and centrifuged at 8000×g for 10 min to remove insoluble materials. The concentration of spider venom was adjusted to 0 (control group), 10, 20, 40 mg/L. The spider venom was freeze-dried and stored at -80 °C until required.

Cell culture The human cervical carcinoma cell line HeLa was obtained from the Cellular Biology Institute of the Chinese Academy of Sciences (Shanghai, China). The frozen cells were defrosted, transferred into the culture medium RPMI-1640 supplemented with 10% fetal calf serum, 100 kU/L streptomycin, and 100 kU/L benzyl penicillin. The cells were grown at 37 °C under a humidified atmosphere of 5% CO₂.

Determination of apoptosis Morphological evidence of apoptosis was obtained using acridine orange-ethidium bromide (AO/EB) staining. Monolayer cell cultures in 96-well plates were used for these studies. After removal of the incubation medium, the cells were rinsed and treated with a solution composed of AO/EB (100 mg/L PBS of each dye).

Cells were examined using fluorescence microscopy and photographed (Olympus, Tokyo, Japan). Viable cells were colored green with intact nuclei. Non-viable cells had bright orange chromatin. Apoptosis was demonstrated by the appearance of cell shrinkage with condensation and fragmentation of nuclei. Apoptotic cells were easily distinguished from necrotic cells because the latter appeared orange with a normal nuclear structure. This procedure was used to quantify the number of apoptotic cells after treatment with spider venom. Apoptosis was also quantified using an enzyme-linked immunosorbent assay (ELISA) kit (Bindazyme; the Binding Site, Birmingham, UK) that measured the amounts of mono- and oligo-nucleosomes produced in the cytoplasmic fraction of lysed cells as a consequence of DNA fragmentation^[23]. After treatment with spider venom, cells were collected and lysed according to the manufacturer's instructions. After centrifugation at 11 000×g for 15 min, equal amounts (0.3 μg of protein) of the cytosolic fractions were used for the assays.

Specimens for electron microscopy HeLa cells in the exponential phase were used and cultivated with various concentrations of spider venom for 24 h. The cells were harvested and fixed with 25 mL/L glutaraldehyde in 0.1 mol/L phosphate buffer (pH 7.4) for 2 h at 4 °C. For scanning electron microscopy (SEM) examination, the specimens were postfixed for 1 h in 2% OsO₄, dehydrated by adding a series of graded ethanol solutions to the filtration system and then slowly dried over the course of 24 h by evaporation. The filter was removed from the filtration apparatus and mounted on an aluminum stub, after which the cells were gold sputter coated. Specimens were examined with a STEREOSCAN 260 SEM at 25 kV. For transmission electron microscopy (TEM) examination, cells corresponding to each population were collected in Haemoline (BioChem Pharma, Allentown, PA, USA), transferred to microcentrifuge tubes, pelleted, and fixed in 1% OsO₄ (in distilled H₂O). A total of 4×10⁷ cells were sorted to collect 2×10⁶ cells representative of each of the individual populations. After dehydration through a series of graded alcohol and propylene oxide solutions, the cells were infiltrated with Epon (epoxy resin) and polymerized. Ultra-thin sections were cut, recovered on Formvar-coated copper grids, stained with uranyl acetate and lead citrate, and then examined with a 100 CXII transmission electron microscope (Jeol, Tokyo, Japan) operated at 80 kV.

Cell proliferation assay The inhibition of [³H]TdR incorporation into DNA was examined using the pulse-labeling method. Proliferating HeLa cells were seeded onto 96-well plates and incubated for 16 h. HeLa cells were treated with different concentrations of spider venom (0, 10, 20, and

40 mg/L) for the next 24, 48, or 72 h. [³H]TdR (37 MBq/L) was added and HeLa cells were exposed to [³H]TdR for 16 h. The cells were then washed three times with PBS, lysed with 1 mol NaOH. After that the cells were harvested onto glass fiber filters with an automatic harvester. Filters were dried and radioactivity was quantified using liquid scintillation counter (Beckman LS6500, Fullerton, CA, USA). Results were expressed as the percent of specific lysis. Percent of specific lysis = $100 \times [\text{percent released from the target in the presence of effectors (experimental release)} - \text{percent released from the target in the presence of medium only (spontaneous release)}] / (\text{maximal release} - \text{spontaneous release})$.

Cell cytotoxicity assay Lactate dehydrogenase (LDH) release from cells was used as an index of cytotoxicity or necrosis. The quantity of LDH released by the cells into the medium was measured by the decrease in the absorbance at 340 nm for NADH disappearance within 5 min^[13]. After incubation with various concentrations of spider venom (0, 10, 20, and 40 mg/L) for 24 h, the cell culture supernatant and medium (100 mL) were mixed with 900 mL PBS and 20 mg/L BSA. The percentage of LDH release ($n=6$) was equal to LDH activity in the medium divided by activity in both the cell culture supernatant and the medium $\times 100\%$.

Cell cycle distribution using flow cytometry Bivariant flow cytometry was carried out on cells grown in the presence (control group) or absence of spider venom (10, 20, and 40 mg/L) after 24 h. Cells were collected and washed in cold PBS twice and resuspended in 100 mL of binding buffer (HEPES containing 2.5 mmol/L CaCl₂). Fluorescein-labeled annexin V and PI were added to the cell suspension. Cells were then analyzed using flow cytometry (Becton Dickinson, Mountain View, CA, USA). The DNA content of the cells was determined by staining with PI. The cells were incubated in 100 mL of fixing solution (PBS containing 4% formaldehyde) for 15 min at 4 °C, washed in PBS, resuspended in permeabilizing solution (PBS containing 0.1% saponin and 0.1% sodium azide) in the presence of 10 mL of PI, and incubated at 4 °C for 15 min. The cells were then washed with PBS and immediately analyzed using flow cytometry.

Western blot analysis HeLa cells exposed to different concentrations of spider venom (10, 20, 40 mg/L and control) were incubated in six-well plates at a density of 2.5×10^5 cells/well for 48 h, followed by a further cultivation of 48 h with the culture medium replaced with 1 mL of serum-free RPMI-1640. The serum-free medium was totally collected. Equal amounts of proteins in each sample were resolved in 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) and the proteins were transferred onto nitrocellulose membranes. After being washed in 10 ml/L fat-free

milk, the membranes were incubated with the appropriate dilution of rabbit polyclonal caspase-3 antibody and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) antibody. The membranes were then incubated with a horseradish peroxidase-conjugated secondary antibody. Proteins were detected using an enhanced chemiluminescence (ECL) kit according to the manufacturer's protocol (Amersham, Amersham, Buckinghamshire, UK).

In vivo reduction in tumor size in nude mice using spider venom We induced cervical tumors by injecting HeLa cells (200 μ L) under the skin of nude mice with a concentration of 4×10^9 cells/L. Three weeks after tumor growth was established, treatment was initiated. Nude mice with tumors were randomly placed into three groups (10 mice/group) and treated with spider venom, 1.0, 2.0, 4.0 μ g/g body weight of mice three times per week for 3 weeks by tail vein injections. The control group of 10 mice received distilled water only as a placebo. The mice were killed and tumor size was evaluated by caliper measurements, and tumor volume was calculated as length \times width \times depth.

Statistical analyses Significant differences between groups were tested using Mann-Whitney *U* tests with a significance level of 95%. Differences between groups were considered statistically significant at $P < 0.05$. Analyses were carried out using the Prism software package (GraphPad, San Diego, CA, USA).

Results

Effects of spider venom on viability and apoptosis in HeLa cells Our study was carried out using HeLa cells grown in serum-free monolayer cultures. We observed using light microscopy that treatment with spider venom (10, 20, and 40 mg/L) initially produced clusters of packed cells (data not shown). After 24 h of treatment, the bulk of the cells appeared to be seriously damaged. To investigate the type of cell death induced by spider venom, the cells were stained with AO/EB, which allows the identification of viable, apoptotic and necrotic cells based on color and appearance. Staining with AO/EB of the samples treated with different concentrations of spider venom (Figure 1) showed different percentages of orange-stained cells. Viable cells were green with intact nuclei. Non-viable cells had bright orange chromatin. Apoptosis was demonstrated by the appearance of cell shrinkage with condensation and breaking up of the nuclei. Apoptotic cells were easily distinguished from necrotic cells because the latter appeared orange with a normal nuclear structure. This procedure was used to quantify the number of apoptotic cells after treatment with spider venom.

Figure 1. Identification of apoptotic cells using acridine orange-ethidium bromide staining and the effect induced by spider venom (10, 20, and 40 mg/L). Untreated cells (A) compared with cells treated with spider venom at 10 mg/L (B), at 20 mg/L (C) or at 40 mg/L (D) ($\times 200$)

A number of cells exhibited a flattened polygonal morphology, whereas other cells showed morphological features of apoptosis, consisting of a decrease in cell volume, membrane broken, and breaking up of the nuclei. Moreover, the majority of these non-viable cells, together with a number of vi-

able cells, showed broken nuclei and other signs of apoptosis.

Morphological observations After exposure to spider venom for 24 h, SEM confirmed that HeLa cells treated with spider venom had morphological features indicative of apoptosis (Figure 2A,2B). Compared to cells treated with

Figure 2. Morphological observations using scanning electron microscopy. (A) Control cells ($\times 8000$); (B) Spider-venom-treated cells (20 mg/L, 24 h) ($\times 8000$); Morphological observations using transmission electron microscopy; (C) Control cells ($\times 10\ 500$); (D) Spider-venom-treated cells (20 mg/L, 24 h) ($\times 10\ 500$).

control supernatants, approximately 25% of cells exposed to spider venom (20 mg/L) for 24 h appeared to be markedly reduced in size. These cells were devoid of the villous projections found on the surfaces of control cells. In addition, many of the spider-venom-treated cells exhibited perturbations of their plasma membranes as evidenced by membrane smoothing. Ultrastructural characterization of cells representative of the individual populations was achieved through cell sorting and subsequent evaluation using TEM. Cells treated with spider venom possessed well-defined plasma membranes and contained intact organelles with no evidence of nuclear condensation (Figure 2C). In contrast, the majority of cells in the venom-treated group exhibited morphological characteristics typical of cells in the early stages of apoptosis. These characteristics included a decrease in cell size, intact cell membranes, and flocculation of the nucleus (Figure 2D). None of these characteristics were present in untreated cells.

Effect of spider venom on [³H]TdR incorporation in HeLa cells Inhibition of DNA synthesis was examined in the presence of spider venom (Figure 3). Proliferating HeLa cells were exposed to different concentrations of spider venom for 24, 48, or 72 h. The cells were then treated with [³H]TdR for 12 h. Synthesis of DNA in these cells was inhibited, with IC₅₀ ranging from 20 to 30 mg/L after 24 h, 48 h, 72 h. The degree of growth inhibition of HeLa cells in the presence of spider venom was dose-dependent. Spider venom significantly decreased cell proliferation, but the degree differed with the variant concentrations (*P*<0.01). The spider-venom-induced inhibition of cell proliferation was also time

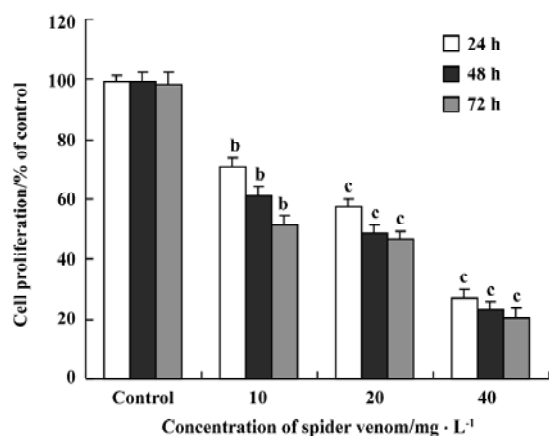

Figure 3. Effect of spider venom (10, 20 and 40 mg/L) on the proliferation of cells measured by [³H]TdR assay. Results are expressed as % of control cells (*n*=6. Mean±SD. ^b*P*<0.05, ^c*P*<0.01 vs control group) using an ANOVA with subsequent multiple comparison tests.

dependent. Spider venom significantly decreased cell proliferation, and again the decrease differed with time (*P*<0.01).

Cell cytotoxicity of spider venom on HeLa cells Cell cytotoxicity was directly measured by LDH release (Figure 4). After 24 h incubation, spider venom (0, 10, 20, and 40 mg/L) significantly increased cell cytotoxicity (*P*<0.05) compared with the control group (5.95%). Increased cell cytotoxicity occurred with increased concentrations of spider venom. The activity is to be time- and dose-dependent.

Figure 4. Effects of spider venom (10, 20, and 40 mg/L) on cell cytotoxicity in HeLa cells determined by lactate dehydrogenase (LDH) release. Values not sharing the same letter differed significantly (*n*=6. Mean±SD. ^c*P*<0.01 vs control group) using an ANOVA with subsequent multiple comparison tests.

Effect of spider venom on apoptosis, necrosis ratio, and cell cycle Cells were exposed to different concentrations of spider venom (10, 20, and 40 mg/L). Cells in the early phase of apoptosis were labeled using single annexin V fluorescence. The ratio of apoptosis and necrosis in the cells increased with increasing venom concentrations. The early stages of apoptosis and necrosis started 5 h after treatment of HeLa cells with 40 mg/L spider venom (Table 1).

Cell cycle distribution, cell proliferation and apoptotic

Effects of spider venom on the activity of caspase-3 To elucidate the pathway leading to apoptosis, we examined the activation of caspase-3, which was reported to initiate apoptosis after various stimuli. HeLa cells treated with spider venom (10, 20, and 40 mg/L) for 48 h were analyzed for enzymatic activity using a Western blot analysis. Caspase-3 activity changed at 48 h in HeLa cells (Figure 5). The activity

Figure 5. Effects of spider venom on the levels of caspase-3 protein in HeLa cells after treatment for 48 h. As an internal control, GAPDH protein was blotted concurrently. (A) Caspase-3 protein expression in control group (lane 1), and in the spider venom treatment groups (10 mg/L, lane 2; 20 mg/L, lane 3; 40 mg/L, lane 4). (B) Densitometric analysis of the levels of caspase-3 using an image analysis system. Data are expressed as the ratio to the internal standard. *n*=6. Mean±SD. ^c*P*<0.01 vs control group. ANOVA with subsequent multiple comparison tests.

was enhanced significantly (1.7-, 2.2-, and 4.3-fold, respectively, versus controls, *P*<0.01). Western blotting analysis, revealed that the exposure of HeLa cells to spider venom enhanced the activity of caspase-3, which became four-fold higher than that in the control cells (Figure 5).

***In vivo* reduction in tumor size in nude mice using spider venom** We have investigated the effect of spider venom in nude mice with tumors. Mice were killed 21 d after treatment and tumor size was determined. In the groups injected with various concentrations of spider venom by the tail vein, the size of the tumor inside the skin was significantly smaller (*P*<0.01) than in untreated mice (Table 3).

Control	0	55.5±0.4
Spider venom	1.0	39.7±0.6 ^c
	2.0	24.7±0.5 ^c
	4.0	12.2±0.2 ^c

Discussion

A number of possible biological and biochemical effects of spider venom were investigated in the present study.

Cells excluding vital dyes were considered to be viable. However, our current results suggest that many of these cells are actually undergoing apoptotic cell death despite having relatively intact cell membranes. Spider venom at doses of 40, 20, and 10 mg/L significantly decreased cell proliferation in HeLa cells, in a dose-dependent and time-dependent manner.

Aside from the inhibitory effect of spider venom on cell proliferation, spider venom at the same doses (10, 20, and 40 mg/L) significantly increased cytotoxicity determined by LDH release in the cells. The cytotoxic effect of spider venom reached a plateau at doses over 160 mg/L. The cytotoxic effect of spider venom could be attributed to necrosis^[24]. The total number of cells present will be directly proportional to the background-subtracted fluorescence values, which represent LDH activity. It is relatively easy to distinguish between complete cell lysis occurring at time zero versus 50% cell lysis at 24 h, 48 h, and 72 h and this result was observed in the "lysed" data (Figure 4).

Meanwhile, we directly measured apoptosis using flow cytometry. Apoptosis in HeLa cells was increased in the spider venom-treated groups. It is possible that apoptosis

contributes to the cytotoxic effect of spider venom. Changes in cells associated with the early phases of apoptosis include a loss of cell membrane phospholipid symmetry. The effect of spider venom on HeLa cells was analyzed using fluorescein-labelled annexin V-stained and PI-stained cells (Table 1). Thus, our findings revealed that spider venom resulted in direct necrosis and indirect apoptosis (Table 1) to kill HeLa cells.

To examine whether growth inhibition of HeLa cells by spider venom resulted from cell cycle arrest, cell cycles treated with spider venom were analyzed using flow cytometry. The inhibitory effect of spider venom on growth of the cells may result from G₀/G₁ cell cycle arrest.

Caspases are common and critical components of the cell death pathway. Among these caspases, caspase-3-like proteases mediate the initiation and/or execution stages of programmed cell death^[25,26]. The active enzyme takes part in the execution phase of apoptosis and it has been demonstrated that a high level of activity of effector caspase-3 in tumor cells plays a decisive role in their commitment to apoptosis^[27-30]. Caspase-3 is a key executioner of apoptosis, whose activation is mediated by the initiator caspases, such as caspase-9^[31]. Spider-venom-induced apoptosis was preceded by the activation of caspase-3, which was clearly observed after 48 h of treatment by direct estimation of its activity and by Western blotting analysis, which showed the conversion of procaspase-3 to the active form of the enzyme. This result is the same as norcantharidin-induced HeLa cell apoptosis resulting from an increase in caspase-3 activity^[32].

All these events preceded the appearance of the morphological signs of apoptosis, which were observed in a large percentage of cells only after 48 h of treatment (Figure 5). The results from the present study suggested that the cytotoxic effect of spider venom on the cells was related to the induction of apoptosis.

Importantly, the anti-tumor *in vivo* action of spider venom resulted in either complete or significant regression of the human cervical tumors established in nude mice. Our *in vivo* results demonstrate that spider venom confers a systemic effect of tumor regression in a xenograft in a dose-dependent manner.

In conclusion, we demonstrated that spider venom caused an inhibition of cell growth in HeLa cells as a result of cycle arrest and apoptosis. Moreover, a large part of our study essentially focused on the mitochondrial pathway and we determined that one action of spider venom was caspase-3 dependent. These new findings suggest that spider-venom-induced effects may have novel applications for the treatment of cancer.

Abstract

Aim: To determine the inhibitory effect of the synthetic STAT3 siRNA on the expression of STAT3 gene in human laryngeal cancer cell lines Hep2 and to investigate the effect of STAT3 siRNA on growth and apoptosis in Hep2 cells. **Methods:** A pair of DNA templates coding siRNA against STAT3-mRNA was synthesized to reconstruct plasmid of pSilencer1.0-U6 siRNA-STAT3. Hep2 cells were transfected with RPMI-1640 media (untreated), plasmid (empty), and STAT3 siRNA, respectively. Northern blot and Western blot analysis of STAT3 and pTyr-STAT3 expression in Hep2 cells and Western blot analysis of Bcl-2 expression in the Hep2 cell was performed 72 h after transfection. MTT, flow cytometry, and AO/EB assay were used for determination of cells proliferation and apoptosis in Hep2 cells. **Results:** pTyr-STAT3 was markedly expressed in untreated Hep2 cells and the vector-treated Hep2 cells, whereas pTyr-STAT3 expression was significantly reduced in STAT3 siRNA-transfected Hep2 cells, indicating that STAT3 siRNA inhibited the activity of STAT3. Transfection of Hep2 cells with STAT3 siRNA significantly inhibited STAT3 expression at both mRNA and protein level in Hep2 cells and the inhibition was characterized by time-dependent transfection. Treatment of Hep2 cells with STAT3 siRNA resulted in dose-dependent growth inhibition of Hep2, this significantly increased apoptotic cell rate, and decreased Bcl-2 expression level in Hep2 cells. STAT3 siRNA had an effect on induction of either early or late stage apoptosis. **Conclusion:** This study demonstrates that STAT3 siRNA effectively inhibits STAT3 gene expression in Hep2 cells leading to growth suppression and induction of apoptosis in Hep2 cells. The use of siRNA technique may provide a novel therapeutic approach to treat laryngeal cancer and other malignant tumors expressing constitutively activated STAT3.

Introduction

Laryngeal carcinoma especially at late-stage is associated with high morbidity and poor long-term survival due to the absence of effective treatment methods. Better understanding of molecular mechanisms underlying proliferation, differentiation, and survival of laryngeal carcinoma is critical for the development of optimal therapeutic modalities. Recent studies suggest that signal transducers and activator of transcription (STATs) have the potential as novel mo-

lecular targets for the development and survival of laryngeal carcinomas.

STATs are latent cytoplasmic transcription factors that function as intracellular effectors of cytokine and growth factor signaling pathways. Among the STAT family, STAT3 plays a key role in promoting proliferation, differentiation, anti-apoptosis, or cell cycle progression. Constitutive activation of STAT3 is implicated in a variety of tumor cell lines^[1–5], thereby suggesting that STAT3 is an important molecular target for tumor therapy.

In vitro studies have shown that inhibition of STAT3 activity in human tumor cells induces apoptosis and/or growth arrest. In human head and neck squamous carcinoma cells, blocking of STAT3 signaling by decoy oligonucleotide or antisense oligonucleotides abrogates transforming growth factor and suppresses oncogenic growth of these cells^[6,7]. STAT3 β is a naturally accruing dominant-negative STAT3 variant that is identical to STAT3 except for the absence of the transactivation domain^[8]. Bowman *et al*^[2] have reported that blockade of STAT3 signaling by STAT3 β in human myeloma cells down-regulates IL-6-induced expression of the antiapoptotic gene, Bcl-x_L, resulting in a dramatic sensitization of cells to Fas-mediated apoptosis *in vitro*. STAT3 β can promote apoptosis in breast cancer cells, inhibit Bcl-x_L expression, and induce apoptosis^[9]. Overall, these raise the possibility that targeting STAT3 may enhance antitumor responses *in vivo* in a variety of human cancers.

A relatively new technique using RNA interference (RNAi) provides a novel approach of experimental inhibition of gene expression. RNAi is triggered by the presence of double-stranded RNA (dsRNA) in the cell and results in rapid degradation of the targeted mRNA with homology to the double strand leading to potent and selective silencing of genes. This phenomenon was first observed from studies in *Caenorhabditis elegans* and *Drosophila melanogaster* and subsequently, in other organisms^[10]. Recent studies have shown that short interfering (21–25 bp) RNA molecules (siRNA), but not long dsRNA (greater than 30 bp), are key elements of RNAi. Only recently has the use of RNAi in mammalian studies been established by introducing siRNA^[14]. At present, siRNA has been adapted as a functional genomic tool and has potential as a therapeutic approach in cancer.

Intriguingly, blocking of STAT3 signaling pathways by siRNA has been shown to suppress growth and induce apoptosis in prostate cancer cell lines and astrocytoma cells^[15,16]. However, to date no studies have studied the effect of inhibition of STAT3 gene expression by siRNA on laryngeal cancer. Since STAT3 signaling is critical for the regulation of proliferation, differentiation, and apoptosis of tumor cells, we hypothesize that knockdown of STAT3 gene expression by siRNA should suppress tumor growths and induce apoptosis in laryngeal carcinoma that observed in models of prostate cancer and astrocytoma^[16,17].

The objectives of the present study were (1) to determine the inhibitory effect of the synthetic STAT3 siRNA on the expression of STAT3 gene in laryngeal carcinoma cells and (2) to investigate the effect of STAT3 siRNA on the growths and apoptosis in laryngeal carcinoma cells.

Materials and methods

Construction of plasmids that contain DNA templates for the synthesis of siRNAs were constructed under the control of the U6 promoter The pSilencer1.0-U6 (Ambion Inc Austin, TX, USA) was used for DNA vector-based siRNA synthesis under the control of U6 promoter *in vivo*. In brief, first, the double stranded DNA template encoding siRNA oligonucleotides (GeneBank: access numbers for the human STAT3: NM003150) that contained a sense strand of 19 nucleotide sequences followed by a short space (TTCAA-GAGA), the reverse complement of the sense strand, and five thymidines as a RNA polymerase III transcriptional stop signal were synthesized. The sequences were forward 5'-GCAGCAGCTGAACAACATGTTCAAGAGACATGTTGTTCAGCTGCTGCTTTTTT3' and reverse 5'-AATTAAAAAGCAGCAGCTGAACAACATGTCTCTTGAACATGTTGTTCAGCTGCTGCGGCC3' (locate on SH2 domain). The oligo nucleotides were annealed in a buffer (potassium acetate 100 mmol/L, 30 mmol/L HEPES-KOH pH 7.4, and magnesium acetate 2 mmol/L) and the mixture was incubated at 90 °C for 3 min and then at 37 °C for 1 h. The double stranded oligos were cloned into the *ApaI*-*EcoR* I sites of the pSilencer 1.0-U6 vector (Ambion Inc) where short hairpin RNAs (shRNA) were expressed under the control of the U6 promoter.

Cell culture and transfections The human laryngeal cancer cell lines Hep2 were obtained from ATCC. Hep2 cells were cultured in medium RPMI-1640 (Invitrogen, Inc Carlsbad, CA, USA) supplemented with 10% fetal bovine serum (FBS) and penicillin (100 kU/L) and streptomycin (100 mg/L) at 37 °C in a humidified incubator with 5% CO₂. For cell transfection, lipofectamine 2000 (Invitrogen) was used for transfecting the plasmids following the manufacturer instructions. In brief, pEGFP was cotransfected with pSilencer1.0-U6-siRNA-STAT3 or pSilencer empty vector at ratio of 1:20 to mark the positive transfected cells, respectively. The cells were cultured for 5–20 h and then transferred to fresh medium with 10% FBS and lysed for 24–72 h after transfection.

Northern blot Total RNA was extracted from cell samples with Trizol (Invitrogen, Carlsbad, CA, USA). Equal amounts of 20 μ g total RNA were electrophoresed on 1.2% agarose gel with formaldehyde 2.2 mol/L and transferred onto nylon membranes (Hybond-N, Amersham Pharmacia Biotech). Blots were incubated with ³²P-labeled cDNA against STAT3 and actin with Hyb and washed according to the manufacture directions. Visualization of blots was performed by overnight exposure to Kodak MS film. Quantification of blots developed on films was accomplished with a

Molecular Dynamics phosphorimager.

Western blot Total protein was extracted from the harvested sample cells with protein lysis buffer (5 mol/L edetic acid, 300 mmol/L NaCl, 0.1% Igepal, 0.5 mmol/L NaF, 0.5 mmol/L Na_3VO_4 , 0.5 mmol/L PMSF, and antiprotease mixture) using sonication. The lysates were centrifuged at $15\,000\times g$ for 30 min. Determination of protein concentrations of the supernatants was performed by the Bradford procedure (Bio-Rad Laboratory, Hercules, CA, USA). For STAT3 and pTry-stat3 analysis, the supernatant with 50 μg total protein was separated by electrophoresis on 10% SDS-Polyacrylamide gels and transferred onto PVDF membranes (Milipore, Bedford, MA) and blocked with 5% nonfat dry milk in PBS with 0.1% Tween-20. Blots were incubated with specific rabbit antibodies against STAT3 and pTry-stat3 and anti- β -actin antibody (Santa Cruz Biotech, Inc, Santa Cruz, CA, USA) and washed with TBST and subjected to corresponding HRP-conjugated secondary antibodies as indicated. For Bcl-2 analysis, 50 μg of total protein was electrophoresed on 12% SDS/PAGE gels and transferred onto PVDF membranes (Milipore, Bradford, MA, USA). The membranes were probed with mouse polyclonal antibodies against Bcl-2 antibody (Dako Biotech, Inc, Glostrup, Denmark) and washed with TBST and subjected to corresponding HRP-conjugated secondary antibodies as indicated. Blots were washed again with TBST and visualized by enhanced chemiluminescence detection system (Amersham Pharmacia Biotech, Uppsala, Sweden).

Proliferation and apoptosis assays *in vitro* Hep2 cells were incubated in 96-well plates. Cell proliferation was determined by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT, Sigma) assay whereby cell numbers were counted by hemocytometer 72h after transfection. The absorbance values at 570 nm (A_{570}) were determined on a multiwell plate reader. Cell growth inhibition rate was calculated according to the following formula:

$$\text{Growth inhibition rate (\%)} = [(A_{570c} - A_{570e}) / A_{570c}] \times 100\%$$

A_{570c} : A_{570} in control group; A_{570e} : A_{570} in experimental group.

For FACS analysis of apoptosis, Hep2 cells were transfected with siRNA-STAT3 or pSilencer empty vector. After 72 h, cells were collected and washed with cold PBS containing edetic acid 4 mmol/L. Cells were fixed in 70% cold ethanol, collected by centrifugation, and washed once again with PBS containing edetic acid 4 mmol/L. Cells were resuspended in PBS containing edetic acid 4 mmol/L, 20 mL/L of propidium iodide (Sigma), 0.2% Triton X-100, 40 mg/L RNase A, and incubated for at least 30 min at 4 °C. The cells were then analyzed by flow cytometry (FACScan, Becton Dickinson,

Franklin Lakes, NJ, USA), using Cell Quest software. For fluoromicroscopic determination of positive apoptosis cells, 95 μL floating cells were mixed with 0.1% AO/EB [acridine orange (Sigma)/ethidium bromide (Sigma)] and observed under microscope.

Statistical analysis Data were expressed as mean \pm SD. The square χ^2 analysis was performed to evaluate the significance of inter-group differences. Student's *t* test was used for single comparison between two groups. Two-way ANOVA using the Student-Newman-Keuls method was adopted for comparison of variables after treatment. $P < 0.05$ was considered significant. All statistical calculations were performed using SigmaStat statistical software package (SPSS 10.0, Chicago, IL, USA).

Results

STAT3 RNAi by siRNA specifically reduces STAT3 expression in Hep2 cells Since STAT3 levels are significantly higher in tumor cells (including laryngeal tumor) than that in normal cells, we attempted to determine whether the synthetic STAT3 siRNA could inhibit the expression of STAT3 gene in Hep2 cells. Treatment of Hep2 cells with siRNA-STAT3 resulted in a significant decrease of STAT3 expression at both mRNA (Figure 1) and protein (Figure 2A) level

Figure 1. Northern blot analysis of STAT3 mRNA expression in Hep2 cells in the untreated, empty (vector), and STAT3 siRNA groups 72 h after transfection.

compared to the untreated Hep2 cells and the vector-treated Hep2 cells, respectively. STAT3 expression was specifically targeted by STAT3 siRNA, since STAT3 siRNA unchanged the expression of β -actin (Figure 1, 2A). Of note is that pTyr-STAT3 was markedly expressed in untreated Hep2 cells and the vector-treated Hep2 cells (Figure 2B), indicating that the detected STAT3 was indeed in the form of tyrosine-phosphorylated (ie, activated) form. In the STAT3 siRNA Hep2 cells, Tyr-STAT3 expression was significantly reduced, indicating that STAT3 siRNA also inhibited the activity of STAT3. Furthermore, as shown by Figure 2C treatment of

Figure 2. Western blot analysis of STAT3 and pTyr-STAT3 protein expression in Hep2 cells. (A) STAT3 protein expression in Hep2 cells in the untreated, empty (vector), and STAT3 siRNA groups 72 h after transfection. (B) pTyr-STAT3 protein expression in Hep2 cells in the untreated, empty (vector), and STAT3 siRNA groups 72 h after transfection. (C) STAT3 protein expression in the STAT3 siRNA-treated Hep2 cells at different transfection time.

Hep2 cells with STAT3 siRNA caused time-dependent inhibitory effect on STAT3 expression in Hep2 cells.

STAT3 siRNA down-regulates Bcl-2 expression in Hep2 cells Recent data indicate that constitutive activation of STAT3 induces the expression of anti-apoptotic genes including Bcl-2^[17]. In order to determine whether Bcl-2 was involved in the STAT3-mediated apoptotic block in Hep2 cells, in this study Western blot analysis was performed. Figure 3 showed that Bcl-2 was remarkably expressed in the untreated Hep2 cells and the vector-treated Hep2 cells, whereas treatment of Hep2 cells with STAT3 siRNA signifi-

Figure 3. Western blot analysis of Bcl-2 protein expression in Hep2 cells in the untreated, empty (vector), and STAT3 siRNA groups 72 h after transfection.

cantly reduced the expression levels.

STAT3 siRNA inhibits growth and survival of Hep2 cells and induces apoptosis of Hep2 cells *in vitro* To determine whether synthetic STAT3 siRNA had an inhibitory effect on Hep2 cells growths, we accomplished determination of cell proliferation with MTT assay. Table 1 showed that treatment of Hep2 cells with STAT3 siRNA contributed to dose-dependent inhibition of Hep2 cells, whereas no inhibitory effect was observed in the untreated Hep2 cells and the vector-treated Hep2 cells.

Two different methods including flow cytometry analysis and AO/EB staining (nucleus condensation) were adopted for determination of apoptosis in Hep2 cells (Table 2 and Figure 4). Flow cytometry analysis showed that in the STAT3

siRNA treated cells the apoptosis rate was significantly higher than that in the untreated Hep2 cells and the vector-treated Hep2 cells, whereas the apoptosis rate in the vector treated Hep2 was slightly higher than that in the untreated Hep2 cells but no significance was achieved (Table 2), indicating that siRNA-STAT3 induced apoptosis in Hep2 cells. Moreover, AO/EB staining revealed that both early apoptotic and late apoptotic Hep2 cells were seen in the cells treated with STAT3 siRNA, suggesting that STAT3 siRNA had not only an effect on induction of early apoptosis but also late apoptosis in Hep2 cells (Figure 3).

Discussion

Constitutively activated STAT3 is critical to STAT3 signaling pathway-dependent mechanism of malignancies^[7,8,16]. A possible mechanism underlying transformation by activated STAT3 is the transcriptional upregulation of genes known to be involved in proliferation and apoptosis in laryngeal carcinomas and other malignant carcinomas. Under physiological conditions, STAT3 activation is transient and lasts from several minutes to several hours due to the transient nature of cytokine and growth factor signaling and the presence of proteins such as suppressor of cytokine signaling (SOCS) and PIAS (STAT blockade) that contribute to inhibition of STAT3 signaling. However, constitutive activation of protein tyrosine kinase (PTKs) occurs frequently during tumorigenesis due to activated mutations or aberrant growth factor or cytokine signaling, which results in constitutive activation of STAT3. Therefore, it is not surprising that constitutive activation of STAT3 is ubiquitous in human carcinomas^[3,17,18]. In most instances, STAT3 that is capable of regulating growth, differentiation, and survival of cells is characterized by growth promoting manner^[19-21]. At present, STAT3 has been recognized as an important oncogene^[2,21].

STAT3 is implicated in both embryogenesis and tumorigenesis. This may raise the question as to whether blocking STAT3 is beneficial for malignant carcinoma cells

but harmful to normal cells. Takeda *et al* revealed that homozygous deletion of STAT3 was embryonically lethal^[22]. Biochemical studies have shown that disruption of STAT3 signaling with dominant-negative approaches in murine fibroblasts does not inhibit normal cell growth^[23,24]. Also, blockade of STAT3 signaling by decoy oligonucleotides in head and neck cancer cells only decreases the amount of STAT3 in normal cell but has no significant effect on cell viability.

Grandis *et al*^[15] have reported that constitutive activation of STAT3 signaling abrogates apoptosis in squamous cell carcinogenesis *in vivo*. Treatment of tumor cells with inhibitors of STAT signaling results in decreased cell viability and induces apoptosis. Accumulated evidence has suggested that apoptotic regulatory proteins are implicated in STAT3 associated-apoptosis inhibition. It has been demonstrated that STAT3 regulates transcription from the Bcl-x promoter. Moreover, elevated expression levels of Bcl-x_L mRNA in cells transformed by constitutively active STAT3 are observed^[25].

Although the recently established approach of applying RNAi in mammalian studies by introducing siRNA can effectively inhibit gene expression^[14,26,27], siRNA at present has been adopted as a promising genomic tool^[17]. Such an approach overcomes many of the shortcomings previously experienced with approaches such as antibodies, antisense oligonucleotides, and pharmacological inhibitors. Intriguingly, RNAi targeting STAT3 by siRNA inhibits growth and induces apoptosis of prostate cancer and astrocytoma cells have been reported from different groups, however to date no one has known the effect of STAT3 siRNA on laryngeal cancer. Consequently, we have attempted to investigate the potential use of siRNA to block the expression of gene encoding STAT3 in laryngeal cancer.

To our knowledge we have successfully determined the inhibitory effect of the synthetic STAT3 siRNA on STAT3 expression in Hep2 cells at both mRNA and protein level (Figure 1, 2). We found that STAT3 was remarkably expressed in Hep2 cells, and treating Hep2 cells with STAT3 siRNA significantly reduced STAT3 expression levels characterized by a time-dependent inhibition of the gene expression. Increased STAT3 activation can occur through potential pathway of elevated constitutive levels of STAT3 protein and increased STAT3 tyrosine phosphorylation. In this study, the use of specific antibody of pTyr-STAT3 reveals that STAT3 siRNA inhibits not only STAT3 expression but also the activities of STAT3 in Hep2 cells (Figure 2), thereby confirming that the synthetic STAT3 siRNA can effectively inhibit STAT3 gene expressions in human laryngeal carcinoma

cells. Our results are consistent with others who have shown the potent inhibitory effect of STAT3 siRNA on STAT3 expression in the models of prostate cancer and astrocytoma cell lines^[16,17]. Moreover, other studies have shown that ubiquitous expression of STAT3 gene exhibits in a variety of human tumors and can be effectively inhibited by the introduction of STAT3 inhibitors, dominant negative STAT3, and/or blockade of tyrosine kinases besides STAT3 siRNA whereby treatment of tumors is achieved.

Recent data indicate that constitutive activation of STAT3 induces expression of anti-apoptotic genes including Bcl-2^[17]. In the present study, to determine whether STAT3-mediated cell apoptosis in Hep2 cells exists, Western blot analysis was used for the measurement of Bcl-2 protein expression. Additionally, quantification of apoptotic cells by flow cytometry was also performed in this study. We found that apoptosis in Hep2 cells was arrested as evidenced by low percentages of apoptotic cells ($0.42\% \pm 0.01\%$ and $2.87\% \pm 1.67\%$) and remarkable expression levels of Bcl-2 protein, whereas treatment of Hep2 cells with STAT3 siRNA significantly increased the number of apoptotic cells ($18.6\% \pm 4.3\%$, $P < 0.05$) and decreased Bcl-2 protein expression levels (Table 2 and Figure 3). This suggests that STAT3 gene expression is an important implication in the regulation of apoptosis in Hep2 cells. Furthermore, visualization of nucleus condensation using AO/EB dyes suggests that the synthetic STAT3 siRNA has an effect on both early and late apoptosis. Our study is consistent with two recent intriguing reports where STAT3 siRNA was also adopted for the study of astrocytomas and human prostate cancer^[16,17]. All are supportive for the proposed mechanism underlying STAT3 participating in oncogenesis is by inhibiting apoptosis through the induction of anti-apoptotic genes. Konnikova *et al*^[17] have demonstrated that STAT3 is required for the expression of the anti-apoptotic genes survivin and Bcl-x_L (a member of the Bcl-2 family of proteins) in astrocytoma cells. Likewise, Lee *et al*^[16] have also shown that inhibition of STAT3 gene expression by siRNA induces apoptosis of human prostate cancer. Moreover, emerging evidence suggests that constitutive activation of STAT3 appears to be ubiquitous in tumors, which renders tumors cells resistant to apoptotic death caused by unbalanced expression level between anti-apoptotic genes and apoptotic genes^[15,17,25]. Consistent with this, our recent work also has shown that human breast cancer cells implanted into nude mice exhibit remarkable expression of anti-apoptotic genes Bcl-2 but weak expression of apoptotic gene Bax accompanied by over-expression of STAT3 gene (Data not shown). The context is

altered by treatment of the breast cancer with STAT3 siRNA characterized by unchanged expression of Bcl-2 genes, increased expression of apoptotic Bax gene, and significant inhibition of expression of STAT3 gene, and suppression of tumor growth (Data not shown).

siRNA has been effectively used *in vivo* to suppress gene expression in rats and adult mice whereby it achieves effective treatment of various organ and/or tissue disorders, including hepatitis, liver ischemia-reperfusion injury, allogeneic transplanted hepatocytes rejection, and CNS disorders^[27-29]. This study also represents the first report that the synthetic STAT3 siRNA effectively suppresses Hep2 cells growths as evidenced by elevated inhibitory rate of Hep2 cell by STAT3 siRNA transfection (Table 1). In this study, an unexpected finding is that treatment of Hep2 cells with STAT3 siRNA is dose-dependent. Our results are consistent with other's reports that STAT3 has the potential as a promising therapeutic molecular target in tumors including laryngeal cancer, astrocytomas, and human prostate cancer, thereby extrapolating that STAT3 siRNA may represent a novel approach in tumor gene therapy.

Strategies for producing siRNA duplexes include direct chemical synthesis, transcription with T7 promoter *in vitro* and recombinant DNA construction by vector with U6 promoter. Our results demonstrate that pSilencer1.0-U6 STAT3 siRNA can result in a long-term target-gene inhibition in Hep2 cells leading to growth suppression and induction of apoptosis in Hep2 cells. The STAT3 signaling pathway has been shown to be critical for the survival of a number of human tumors. This therefore raises the possibility that STAT3 siRNA could become an effective therapeutic agent for STAT3-dependent tumors.

Conclusion

This study represents the first report that demonstrates that STAT3 siRNA effectively inhibits STAT3 gene expression in Hep2 cells leading to growth suppression and induction of apoptosis in Hep2 cells. The use of siRNA technique may provide a novel therapeutic approach to treatment of laryngeal cancer and other malignant tumors expressing constitutively activated STAT3.

Abstract

Aim: To investigate whether the pharmacodynamics and pharmacokinetics of rabeprazole are dependent on CYP2C19 genotype status in healthy Chinese Han subjects. **Methods:** The CYP2C19 genotype status of healthy Chinese Han volunteers was determined using the polymerase chain reaction-restriction fragment length polymorphism method. Twenty healthy subjects volunteered to participate in the study. There were seven homozygous extensive metabolizers (homEM), six heterozygous extensive metabolizers (hetEM), and seven poor metabolizers (PM). All subjects were *Helicobacter pylori*-negative, which was determined by serology and ¹³C-urea breath tests. Rabeprazole (20 mg) was taken orally once daily in the morning for 8 days, and intragastric pH values were monitored for 24 h by Digitrapper pH after day 1 (single dose) and day 8 (repeated dose). Meanwhile, blood samples were collected at various time-points for 24 h after administration. The serum concentrations of rabeprazole were measured using high-performance liquid chromatography. **Results:** The mean area under the curve (AUC) values for rabeprazole differed among the three different genotype groups, with a relative ratio of 1.0, 1.3, and 1.8 after a single dose and 1.0, 1.1, and 1.7 after repeated doses in the homEM, hetEM, and PM groups, respectively. Mean AUC values for rabeprazole after a single dose and after repeated doses were significantly different between the homEM and PM groups, but not between the homEM and hetEM or hetEM and PM groups. No significant differences in intragastric pH median, pH>4 total time, and pH>4 time percentage of 24 h, were observed among the three different genotype groups after a single dose or after repeated doses of rabeprazole. **Conclusion:** In healthy Chinese Han subjects, the pharmacokinetics of rabeprazole are dependent on a certain degree on CYP2C19 genotype status; however, the acid-inhibitory efficacy of rabeprazole is not influenced significantly by CYP2C19 genetic polymorphism.

Introduction

S-Mephenytoin-4'-hydroxylase (CYP2C19) is a genetically determined enzyme and its phenotypes can be classified as poor metabolizer (PM) and extensive metabolizer (EM) [1,2]. When CYP2C19 is the main metabolism enzyme of a drug, the pharmacokinetics of the drug are different between the PM and EM phenotypes, such as proton pump inhibitors (PPI). Recently, rabeprazole (RPZ) has been reported to

be metabolized mainly via a non-enzymatic pathway, with only minor CYP2C19 and CYP3A4 involvement^[3-6]. The pharmacokinetics of RPZ are assumed to be less influenced by the CYP2C19 phenotype. The incidence of PM for CYP2C19 in the Chinese population is very high (17.4%)^[7]. However, it is not clear whether the pharmacokinetics and pharmacodynamics of RPZ depend on the CYP2C19 genotype status in Chinese people. Thus, studies examining the effects of CYP2C19 genetic polymorphism on the metabolism of RPZ

in Chinese people are important. In the present study we observed the metabolic disposition characteristics and pharmacodynamics of RPZ after a single dose and after 8 days of repeated doses with reference to different CYP2C19 genotype groups to provide valuable data that should be considered when selecting PPI for patients with acid-related diseases with reference to the CYP2C19 genotype status.

Materials and methods

Subjects and CYP2C19 genotypes *Helicobacter pylori* (*H. pylori*) infection was screened using a serological test (Dot-immunogold kit, Lanbo Bio-Tech Institute, China) and a ¹³C-urea breath test. DNA was extracted from each individual's leucocytes using a commercially available kit (Promega, Madison, WI, USA). Genotyping procedures for identifying the CYP2C19 wild-type (CYP2C19*1) and the two mutated alleles, CYP2C19*2 and CYP2C19*3, were carried out using the polymerase chain reaction and restriction fragment length polymorphism method^[8].

A total of 20 *H. pylori*-negative healthy volunteers participated in this study. Seven subjects were classified as homozygous extensive metabolizers (homEM). Six were heterozygous for exon 5 mutation of CYP2C19 (*1/*2) or heterozygous for the exon 4 mutation (*1/*3) and were classified as heterozygous extensive metabolizers (hetEM). The remaining seven subjects were homozygous for the exon 5 mutation (*2/*2) and were classified as the PM group (Table 1).

Table 1. Demographic characteristics of subjects enrolled in the study with different CYP2C19 genotypes. Mean±SD.

CYP2C19 genotype	n	Sex	Age/a	Body weight/kg
homEM (*1/*1)	7	Male	23.5±0.6	62.1±1.3
hetEM (*1/*2 n=4) (*1/*3 n=2)	6	Male	22.5±0.8	60.5±2.6
PM (*2/*2)	7	Male	22.8±0.7	61.8±2.8

None of the subjects consumed alcohol or smoking. None of the subjects had taken any drugs for at least 4 weeks before or during the study. The Ethics Committee of Anhui Medical University approved the protocol in advance. Written informed consent was obtained from each subject before participation in the study.

Study protocol All healthy volunteers were orally treated with 20 mg RPZ (Pariet, Eisai Company, Tokyo, Japan) for an 8-day period. The medication was taken once daily at 8:00.

The 24-h intragastric pH monitoring and the measurement of serum levels of RPZ were carried out on day 1 and day 8. Two standard meals (12:00, 18:00), prepared at the hospital, were provided for each subject.

Intragastric pH measurement After overnight fasting, a glass electrode was inserted transnasally and placed approximately 5 cm below the cardia. The electrode was calibrated with standard buffers (pH 1.07 and 7.01) before recording the pH with a Digitrapper pH (Medtronic, Watford, UK). Intragastric pH recordings started after the oral dose of RPZ at 8:00 on d 1 and d 8.

Sample collection and concentration assays of rabeprazole Blood samples were collected before and 0.5, 1, 1.5, 2, 3, 5, 7, 10, 12, and 24 h after RPZ administration on day 1 and day 8. After collection, the blood samples were immediately centrifuged at 4000 r/min for 10 min and 100 µL of 1% diethylamine solution was added to the 1 mL sample of RPZ plasma. All samples were stored at -80°C until assayed. Plasma levels of RPZ were measured using high performance liquid chromatography^[9,10]. The lower detection limit for RPZ was 0.01 mg/L. A good linearity is obtained from 0.01–0.75 mg/L of RPZ with r=0.999. The standard curve of RPZ in serum is Y=124950X - 806.05 (n=5). The recoveries of three concentrations, 0.05, 0.1, 0.5 mg/L are 75.2%, 84.2%, and 91.0%, respectively. The RSD of intra-day variation of RPZ are 5.1%, 9.2%, and 6.8% and the RSD of inter-day variation are 8.2%, 3.5%, and 4.2% for the three concentrations, respectively.

Statistical analysis Intragastric pH characters were described by the median, mean, pH>4 total time and the pH>4 time proportion of 24 h from the raw pH values. The values for the areas under the serum concentration-time curves (AUC) from 0 to 24 h for RPZ were calculated using the 3P87 software. All P values are two-sided, and P<0.05 indicated statistical significance. Data were expressed as mean±SD. Statistically significant differences in the mean AUC values for RPZ and intragastric pH values between the three different CYP2C19 genotype groups were compared using a one-way analysis of variance (ANOVA) combined with the least significant method (LSD). Paired t-tests were used to determine whether there were differences in the AUC values and intragastric pH values for RPZ between single and repeated doses. Statistical calculations were carried out using SPSS 11.0 software (SPSS Inc, Chicago, USA).

Results

Role of the CYP2C19 genotype on the acid-inhibitory efficacy of rabeprazole Raw data on the mean intragastric

pH-time curves after single and repeated doses of RPZ in the three different genotype groups are shown in Figure 1. The characteristic values of the 24-h intragastric pH after single and repeated doses of RPZ in the three different genotype groups are summarized in Table 2. The median intragastric pH value of the PM group was the highest, followed by the hetEM group, and the homEM group had the lowest value.

No significant differences in intragastric pH values were observed between the three groups after a single dose or after repeated doses for 8 days of RPZ. In addition, no significant increments in intragastric pH values from single to repeated doses were observed in the three different genotype groups.

Role of the CYP2C19 genotype on the kinetic disposition of rabeprazole The pharmacokinetic parameters are shown in Table 3. The mean AUC values for RPZ after a single dose differed among the three different genotype groups, with a relative ratio of 1.0, 1.3, and 1.8 in the homEM, hetEM and PM groups, respectively. The mean AUC values for RPZ after repeated doses also differed among the three groups, with a relative ratio of 1.0, 1.1, and 1.7 in the homEM, hetEM and PM groups, respectively. The mean AUC values for RPZ after single and repeated doses were significantly different between the homEM and PM groups, but not between the homEM and hetEM or between the hetEM and

Figure 1. Intra-gastric pH 24-h profiles in the different CYP2C19 genotype groups after administration of a single dose (A) and repeated doses (B) of 20 mg rabeprazole.

PM groups. No significant increase in the mean AUC values for RPZ from single to repeated doses was observed in any

of the three different genotype groups. The C_{max} values were significantly different between the homEM and PM groups, and the hetEM and PM groups after single and repeated doses of RPZ. Whereas T_{max} and $T_{1/2}$ did not differ significantly between the three groups on day 1 and day 8.

Discussion

Proton pump inhibitors, such as omeprazole, lansoprazole, pantoprazole, and rabeprazole, have been used widely in the treatment of acid-related diseases. Recent research has paid more attention to the inhibitory effects of PPI in relation to the genetic polymorphism of CYP2C19, a major enzyme for the metabolism of PPI in the liver.^[11] These studies have shown that CYP2C19 genetic polymorphism has a significant influence on acid-inhibitory efficacy and the metabolism of omeprazole in healthy Chinese Han subjects. However, to date no studies examining the relationship between the CYP2C19 genotype and the metabolism of RPZ has been carried out in the Chinese Han population. *In vitro* human liver microsomal and *in vivo* human pharmacology studies have shown that RPZ is metabolized mainly via a non-enzymatic reduction to RPZ thioether, and that CYP2C19 and CYP3A4 are partially involved in the metabolism of RPZ^[3-6]. The existence of CYP3A4-related PM has not been reported in any Chinese population. Therefore, we did take into account CYP2C19-related genotyping factors in our study.

Rabeprazole has a rapid and powerful onset of pharmacological action^[12]. Our study showed that the AUC for RPZ after a single dose exceeded 80% of the AUC after repeated doses and there were no significant increments from single to repeated doses, which was consistent with Yasuda *et al*^[9]. In addition, we found that no significant increment in intragastric pH values was observed from single to repeated doses. These results suggest that the metabolism of RPZ after a single dose could attain maximum acid-inhibitory efficacy. And this appears to be the reason for pH values remaining elevated for more than 50% of the time, even with very modest exposures, and when the pharmacokinetic results on day 1 are consistent with the results on day 8.

Adachi and other researchers^[3-6] have found that the acid-inhibitory efficacy and metabolism of RPZ are not dependent on CYP2C19 genotype status. However, Horai *et al* and Inaba *et al*^[13,14] and Ieiri *et al*^[15] reported that CYP2C19 genotypic differences affected the metabolism and kinetics process of RPZ, and influenced gastric pH values and gastrin level in plasma. In the present study, we found that the AUC for RPZ differed markedly only between homEM and

PM, and the intragastric pH, the best and most direct pharmacological index when using PPI, was not significantly different among the different genotypes after a single or repeated doses of RPZ. As for the discrepancy between the kinetics and dynamics of RPZ, first we may hypothesize that the acid-inhibitory effect of RPZ is powerful and rapid, and that the serum levels of 20 mg RPZ are sufficient for acid-inhibitory efficacy in Chinese subjects, even in homEM subjects. Second, no direct and simple relationship between the serum concentration–time profile of the drug and the pharmacodynamic response has been reported because of the irreversible blockade of the therapeutic target by PPI. However, Hussein *et al*^[16] have shown a clear relationship using the maximum effect (E_{max}) model. According to the model, our study suggests a lower half-maximal effective AUC value (EAUC₅₀) for RPZ than 2 mg·L⁻¹·h. As shown in Table 3, the mean AUC values of RPZ corresponding to the maximum acid-inhibitory effect of RPZ in this study may be greater than this threshold. Therefore, there were no significant differences for intragastric pH among the three genotypes.

In conclusion, our study focused on investigating the pharmacodynamic and pharmacokinetic effect of RPZ with reference to different CYP2C19 genotypes. The acid-inhibitory effects of RPZ were independent on their pharmacokinetic characteristics as well as an individual's CYP2C19 genotype status. Therefore, RPZ may be a more effective PPI for treating acid-related disease in relation to CYP2C19 genotype status.

Abstract

Although the anatomical configuration of the amygdala has been studied a great deal, very little research has been conducted on understanding the precise mechanism by which this emotional regulatory center exerts its control on emotional and sexual behavior. By applying research methodology from the Neuroscience Research Institute, State University of New York, College at Old Westbury, we intended to demonstrate that much of the mediated effects of the amygdala, specifically the regulation of the male and female sexual response cycles, as well as related emotional considerations, exert their effects coupled to nitric oxide (NO) release. Furthermore, by using current anatomical and histological data, we demonstrated that amygdalar tissue rich in endocannabinoid and opiate, as well as catecholamine, receptors could exert its neurochemical effects within an NO-mediated paradigm. This paradigm, together with the existence of estrogen and androgen signaling within the amygdala, further lends credence to our theoretical framework. We begin with a brief anatomical and functional review of amygdalar function, and then proceed to demonstrate its relationship with NO.

Introduction to the structure and function of the amygdala

The region of the human brain commonly referred to as the amygdala comprises an area of approximately 3 cm³^[1,2]. At the dorsal base of the brain, the elevation of the parahippocampus at the uncus is in part a result of the amygdala, which resides dorsal to it. Although neuro-anatomists often make reference to this portion as a single unitary structure, the amygdala is actually three distinct collections of nuclei. The largest portion of the amygdaloid complex is the basolateral nuclear group, consisting of the lateral nucleus, the irregular basal nucleus, and the accessory basal nucleus. The other major portion consists of the centro-medial group, which comprises the central nucleus and the medial nucleus. The centromedial group communicates via fibers of the stria terminalis to the bed nucleus of the stria terminalis (BST)^[2] (Figure 1). Cell types in the BST are identical to those in the centromedial, causing the BST to be included in the classifi-

cation of amygdalar tissue. The BST lies in the basal forebrain, which also contains the basal nucleus of Meynert, the nucleus accumbens, and the ventral portions of the putamen and globus pallidus. Anatomically, the smallest portion of the amygdaloid complex is the cortical nucleus; with primary input originating from the olfactory bulb and olfactory cortex, undoubtedly this plays a role in emotion-associated olfaction^[2].

Nitric oxide correlates amygdalar function When we examine nitric oxide (NO) signaling, we notice two constitutive enzymatic components, the constitutive NO synthase (cNOS), including endothelial (eNOS) and neuronal (nNOS) isoforms. cNOS, as the name implies, is always expressed. When cNOS is stimulated, NO release occurs for a short period of time, but this level of NO can exert profound physiological actions for a long period of time^[3]. NO not only is an immune, vascular, and neural autoregulatory signaling molecule, but also performs vital physiological activities via

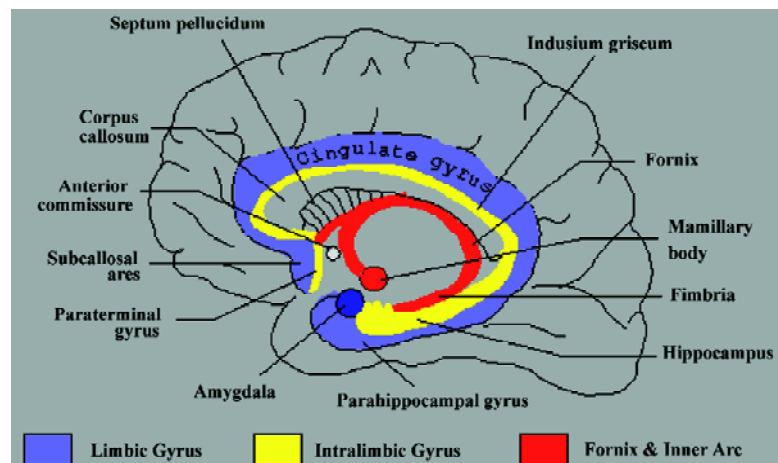

Figure 1. The limbic system.

its constitutive expression^[4,5].

Both the amygdala and the hippocampus contain numerous receptors for varying neurotransmitters. The central nucleus of the amygdala is most strongly modulated by dopamine, norepinephrine (NE), epinephrine, and serotonin^[6,7]. The basal nuclei receive moderately high inputs of dopamine, NE, and serotonin^[6,7], each of which has been demonstrated to exert their desired effect via NO^[4]. Taken together, we surmise that NE initially promotes a slight vasoconstriction of the artery during the amygdalar compensatory response, which is defined as the limbic system's inherent mechanism to maintain homeostasis and lower stress levels. This mechanism is indicated by a slight enhancement of sympathetic activity on stimulation (ie, emotional), and is immediately followed by the release of NO from the peripheral nitroxi-dergic nerve, which mediates a concentration-dependent vasodilation^[5]. In primates, the cerebral arterial diameter, under resting conditions, is maintained by tonic release of NO from the nerve (10%–20%), or from the nerve and endothelium (30%)^[8]. This observation is supported by other data from our laboratory because of the fact that basal NO is cNOS-derived and keeps particular types of cells in a state of inhibition^[5]. Endogenous superoxide dismutase in the cerebral artery appears to protect the relaxation induced by NO from perivascular nerves from the NO scavenger action of superoxide anions^[9]. This NO then produces the longer-lived phenomenon of smooth muscle relaxation. In another report, it was found that NE vascular hyperresponsiveness in hypertension was dependent on an impairment of NO activity that was realized through NE-induced oxygen free radical production^[10], providing an important contribution to the understanding of this regulatory process.

Amygdalar NO release and its relationship to sexual behavior

In addition to NO and the amygdala, new knowledge has emerged concerning the role of hypothalamic, limbic, and brainstem structures, neuropeptides, and brain monoamines in the control of partner preference, sexual desire, erection, copulation, ejaculation, orgasm, and sexual satiety – the details of which are discussed below. At least one important sex difference exists between the male and female amygdala of many species. Owing to the interplay of the differing sex hormones, males and females will experience pleasure from differing experiences (eg, it has been shown that males are more visually stimulated than females^[7,11]). In addition, modulating the concentration of testosterone may cause a male to partake in stereotypical “male behavior.” Likewise, modifying the concentration of estrogen may cause the female to partake in specified, stereotypical “female behavior”^[7,11]. The amygdala is intimately involved in sex and sexuality. It is important to note that the male amygdala is slightly bigger than that of the female. The medial part of the female amygdala plays an important role in pregnancy and appropriate coordination of the endocrine system. Stimulation of the amygdala will produce penile erection, sexual sensation, representations/memories of intercourse, and orgasm^[7,12,13]. Furthermore, precortical region epilepsy has been shown to elicit spontaneous sexual arousal and orgasm, thus clearly demonstrating the role of the amygdala in sexual pleasure^[12,13].

Stimulation of the corticomедial amygdala has been shown to induce ovulation in the female, and cutting the stria terminalis abolishes this effect. The introduction of tract lesions to the rat amygdala, including the medial nucleus, eliminates male libido, but not female libido^[2,7,11,14]. In humans, temporal lobe epilepsy has been associated with sexual

arousal in women to the point of orgasm; however, evidence of this in men is unsubstantiated^[12,13].

Nitric oxide release has been demonstrated as the critical link between corticomedial stimulation and its relationship with the densely packed estrogen/androgen regions within the amygdala^[15-19]. NO has been shown to be crucial for the occurrence of basal luteinizing hormone (LH) release in males^[15], and for the LH surge in ovariectomized females treated with estradiol plus progesterone^[16-18]. Furthermore, NO donors induce an LH surge in estradiol-treated ovariectomized females^[16-20], and thus, have a progesterone-like effect. Concomitant findings show that estradiol stimulates nNOS expression in the preoptic area and exerts a helping influence on NO-producing neurons^[17]. The released NO appears to be able to modulate the activity of gonadotrophic releasing hormone neurons (GnRH)^[17]. These observations implicate neuronal NO in the regulation of GnRH cell activity in the preoptic area^[20-23]. It is important to note that some studies suggest that at the median eminence (ME) level, the NO implicated in the modulation of GnRH release is endothelial in origin, rather than neuronal^[23]. This is consistent with the fact that, unlike in the preoptic area where GnRH perikarya are surrounded by nNOS-containing cells, nNOS fibers and GnRH fibers in the ME are distributed separately in the internal and external zones, respectively^[19]. Furthermore, in the ME, eNOS immunoreactivity is observed in endothelial cells of the pituitary portal blood vessels^[20], located in immediate proximity to the GnRH terminals^[21]. The endothelial origin of NO secreted from ME fragments is further substantiated by the results of prior reports that show that central administration of eNOS antisense is more efficacious than nNOS antisense administration in suppressing an estradiol-/progesterone-induced LH surge in ovariectomized females^[21]. These findings are directly related to amygdalar function by way of neuronal projections extending from the amygdala precortical region to the ME (interestingly, this relationship can be made without regard to whether ME signaling occurs via neuronal or endothelial NO). Thus, we can hypothesize a more robust signaling system involving both NO from amygdalar origins, as well as hypothalamic hormonal relationships.

Emotional stressors mediated via amygdalar NO release

Morphine and related compounds mediating NO release within the amygdala The endocannabinoids, anandamide, and 2-arachidonyl glycerol, are naturally occurring, constitutively expressed, NO-stimulating signaling molecules^[24]. Anandamide and morphine can also cause NO release from

human immune cells, neural tissues, and human vascular endothelial cells^[25]. Moreover, both anandamide and morphine can initiate invertebrate immune cell cNOS-derived NO^[26]. Additionally, estrogen can stimulate cNOS-derived NO in human immune and vascular cells^[27,28]. Anandamide, as part of the ubiquitous arachidonate and eicosanoid signaling cascade, serves to maintain and augment tonal NO in vascular tissues^[24].

Both the hippocampus and the amygdala (particularly the lateral nucleus) contain high concentrations of receptors for the endocannabinoids^[29,30]. In fact, reports have found endogenous morphine within the structure of the hippocampus^[29,30]. In addition, this morphine activates pleasure pathways via NO and has been shown to do so in the rat brain hippocampus and amygdala^[31-34]. Studies from our laboratory confirm the mediated release of NO via real-time amperometric measurement from the rat brain hippocampus^[34] and amygdala^[31]. This information can further be used to understand some of the pleasurable aspects of sexual activity that, indeed, are often found to have morphine-like properties and, perhaps, are mediated via these endocannabinoid and morphine laden amygdalar pathways^[31,35]. Further credence to these findings stems from lesional data. Humans with amygdala lesions show a decrease in emotional tension and related sexual dysfunction^[6,7]. It has been postulated that endocannabinoids and endogenous morphine may act on the lateral nucleus to prevent the linkage of sexual significance to sensory stimuli prior to conscious processing, thus interfering with the perception of sexually and emotionally charged stimuli^[36].

Estrogen mediates NO release within the amygdala Estrogen, through NO release, provides an additional pathway by which the system can downregulate immunocyte and vascular function in women^[37]. This may be because of both the immune and vascular trauma associated with cyclic reproductive activities, such as endometrial buildup, when a high degree of vascular and immune activities occur. Given the extent of proliferative growth capacity during peak estrogen levels in this cycle, NO may function to enhance down regulation of the immune system to allow for these changes. Therefore, enhanced cNOS activity would be a beneficial effect within the concept and time framework of amygdalar compensation (as defined earlier) and the subsequent sense of calm it induces. Thus, these signal molecules, especially endocannabinoid and opiate alkaloids, have the potential to make you “feel” good and relax^[38] by releasing NO, which may once again be part of the sexual resolution (post coitus) phase of the sexual cycle.

Emotionally charged events mediating NO release within the amygdala Within this context of varying stimuli evoking

NO release, emotional stresses such as fear and anxiety can induce cardiovascular alterations, such as cardiac dysrhythmias. These are some of the same events that occur when one is exposed to sexually charged stimulus, or engaged in a sexual act^[39–42]. These cardiovascular events are initiated at the level of the cingulate, amygdalar, and hypothalamic processes, as well as their projection into the higher level cerebral cortex, further altering the heart rate under stressful or sexually aroused conditions^[43]. Neurons in the insular cortex, the central nucleus of the amygdala, and the lateral hypothalamus, owing to their role in the integration of emotional and ambient sensory input, may be involved in the emotional link to the cardiovascular phenomenon^[44]. These include changes in cardiac autonomic tone with a shift from the cardioprotective effects of parasympathetic predominance to massive cardiac sympathetic activation^[45]. This autonomic component, carried out with parasympathetic and sympathetic preganglionic cells via subcortical nuclei from which descending central autonomic pathways arise, may therefore be a major pathway in how emotional state may affect cardiovascular function. The importance of an elicited emotional response (and therefore limbic activation) was further demonstrated in ischemic heart disease when patients with frequent and severe ventricular ectopic rhythms were subjected to psychological stress^[46]. The frequency and severity of ventricular ectopic beats increased dramatically during emotional activation of sympathetic mechanisms, but not during reflexively induced increased sympathetic tone. Perhaps we can even relate this mechanism to sexual orgasm, a process dominated by increased sympathetic tone.

The hard-wiring of emotional and sexual sensations coupled to cardiovascular neural processes probably involves many subcortical descending projections from the forebrain, midbrain, and, specifically, the amygdala^[47–50]. Cardiovascular changes were observed in experiments where the motor cortex surface was stimulated, eliciting tachycardia accompanied by and independent of changes in arterial blood pressure^[51]. The “sigmoid” cortex^[52] and frontal lobe^[53–55], and, in particular, the medial agranular region^[56], subcallosal gyrus^[57], septal area^[58], temporal lobe^[59], and cingulate gyrus^[60–62] appear to be involved. The insular cortex in cardiac regulation is important because of its high connectivity with the limbic system, suggesting that the insula is involved in cardiac rate and rhythm regulation under emotional stress^[53,54]. This form of regulation is mediated via a parasympathetic response, and is probably active in the resolution phase following orgasm^[2,6,12,13].

The amygdala, with respect to autonomic-emotional integration^[63,64], is composed of numerous subnuclei, which

play a major role in the elaboration of autonomic responses^[65]. There are profuse inputs to this region from the insular and orbitofrontal cortices, the parabrachial nucleus, and the nucleus tractus solitarius^[66]. Amygdalo-tegmental projections are viewed as a critical link in cerebral cortical control of autonomic function^[8,67]. This level of input allows for cerebral control of sexual behavior, such as showing sexual restraint and the ability to pass on sexual gratification. Indeed, a great deal of research center on sex-offenders’ inability for, or lack of, the above-mentioned amygdalo-tegmental projections^[68,69].

Mechanisms of amygdala-induced emotional compensation

As noted above, once individuals are exposed to sexually explicit or emotionally charged information, they experience peripheral vasodilation: warming of the skin, an increase in heart rate, and an ensuing sense of agitation^[5,70]. This experience is remarkably similar to the physiological state that exists throughout the sexual cycle, from initial arousal through to resolution. It is the function of the amygdala to aid in the relief of these altered states, through the amygdalar primary compensatory response as defined above^[2,6,7,53]. In examining a potential mechanism for this relief, besides the overriding central nervous system output via the autonomic nervous system, peripheral neuro-vascular processes would appear to be important. We surmise that NO is of fundamental importance in this response because of the increase in peripheral temperature (ie, vasodilation^[5]). For a complete review of possible related mechanisms as well as the related mechanisms outlined above, see the studies by Toda *et al*^[8], Lembo *et al*^[10], Okamura *et al*^[66], and Toda^[67].

We also surmise, based on current studies, that endothelial-derived NO, released through normal pulsations as a result of vascular dynamics responding to heart beat^[38], as well as acetylcholine-stimulated endothelial NO release, may contribute to the effect of NO in inducing smooth muscle relaxation^[5,70]. Furthermore, vascular pulsations may be of sufficient strength to also stimulate nNOS-derived NO release, limiting any basal NE actions^[5,70]. Interestingly, nitrosative stress, mediated by involvement of the reactive nitrogen oxide species, N_2O_3 , does inhibit dopamine hydroxylase, which, in turn, inhibits NE synthesis and contributes to the regulation of neurotransmission and vasodilation^[5,70]. This system may provide an autoregulatory mechanism involved in the neuronal control of peripheral vasomotor responses and may, once again, aid in the resolution phase of sexual intercourse (Figure 2).

Figure 2. Summary of amygdalar projections involved in the amygdalar-induced compensatory response.

Conclusion

Our conclusion is two-fold. We demonstrate that amygdalar regulation of the male and female sexual cycle is mediated by estrogen-/androgen-related signaling molecules, both of which exert their respective influences on ovulation and sexual behavior via coupled NO release. Furthermore, we propose that amygdalar-induced homeostatic control mechanisms acting in response to emotionally charged stimuli, including sexually stimulating sensations, appear to be mediated by a system of regulation involving NO as a neurotransmitter and as a locally acting hormone. Hence, these two principal roles of the amygdala exert their respective behaviors via NO.

In final summary, we have demonstrated numerous mechanisms and neurochemical pathways with regard to both emotion and sexual behavior (ovulation, arousal, *etc*), and we have shown a link between each of these complex pathways systems, as well as the use of NO as a major biochemical messenger. Moreover, throughout each of the aforementioned pathways, we have attempted to offer a possible relationship to sex, either as a mediator of direct sexual activity, or as a mediator of an individual aspect of the sexual cycle.

Acknowledgment

We thank John R HESSELINK, Professor of Radiology and Neurosciences at University of California San Diego Medical Center, San Diego, CA, for permission to use his figure of the limbic system (Figure 1).

Abstract

The *Caenorhabditis elegans* pharynx is a neuromuscular tube of which the function is to pump and crush bacteria, and inject them into the intestine. The 80-cell pharynx develops via the morphogenesis and differentiation of the cells that compose its semi-spherical primordium, and requires the activity of several evolutionarily conserved genes, such as *pha-4* (the homolog to the *Drosophila forkhead* and vertebrate FoxA), *ceh-22* (the homolog to the *Drosophila tinman* and vertebrate Nkx2.5), and *pha-2* (the homolog to the vertebrate Hex). There are 20 neurons in the pharynx, each with a reproducible unique trajectory. Developmental genetic analysis of axon guidance in the pharynx indicates that some axon trajectories are in part established without growth cones, whereas other parts necessitate growth cone function and guidance. Here we provide an overview of the developmental genetics of the *Caenorhabditis elegans* pharynx, with an emphasis on its nervous system.

Introduction

Caenorhabditis elegans (*C elegans*) is a 1-mm long free-living nematode that currently has tremendous popularity as a model organism, especially regarding questions of interest to developmental biologists. Given its ease of culture (it is typically grown on *Escherichia coli* lawns), a 3-d life cycle from egg to egg, a transparent body that allows visualization of any cell of interest, a fully described cell lineage, and the ease with which genetic screens can be carried out at low costs, it is no wonder that *C elegans* is such a versatile and popular laboratory model organism. The 97 Mb genome of *C elegans* is also completely sequenced, and computer algorithms predict nearly 20 000 functional genes. Furthermore, the *C elegans* research community has a traditional helpfulness and openness: thousands of mutants are freely available to academic laboratories from the *C elegans* Genetics Center (<http://biosci.umn.edu/CGC/CGChomepage.htm>), and public databases of anatomical and molecular information are available on the internet (<http://www.wormatlas.org/>; <http://www.wormbase.org/>).

Here, we review the developmental genetics of the *C elegans* pharynx, with an emphasis on the development of

its small 20-neuron network. However, here is one last introductory note: several lines of evidence suggest that the *C elegans* pharynx evolved from an organ that was also the common ancestor to the vertebrate heart. This evidence consists mostly of physiological and molecular similarities: (i) like the heart, the pharynx is a rhythmically contracting neuromuscular pump^[1]; (ii) the muscle cells of the pharynx have autonomous contractile activity reminiscent of cardiac myocytes^[2]; and (iii) *ceh-22*, the *C elegans* homolog to the homeobox gene NK2.5 that plays an important role in heart development in vertebrates, participates in pharyngeal development, and can partially be replaced functionally by the zebrafish NK2.5^[3]. The evolutionary relatedness of the *C elegans* pharynx and the vertebrate heart suggest that insights regarding heart development and function may be gained by studying the simpler and experimentally more convenient *C elegans* pharynx.

Pharynx form and function

The pharynx represents the foregut of the nematode digestive tract (Figure 1). Food (typically *E coli* in the laboratory) is pumped through the mouth by the action of the mus-

cular pharynx, ground by specialized cuticle lining the pharynx (the “grinder” in the posterior bulb), and transferred to the intestine via a pharyngeal-intestinal valve. The main anatomical features of the pharynx are, from anterior to posterior, the procorpus, the metacarpus, the isthmus, and the posterior bulb in which the grinder is located (Figure 1). The mature pharynx is composed of 62 cells (for a total of 80 nuclei, since several of the cells are binucleate as a result of cell fusion). These cells can be categorized into 5 types: neurons (20), muscles (20 cells; 37 nuclei), marginal cells (9), epithelial cells (9), and gland cells (4 cells; 5 nuclei). The muscle cells and marginal cells constitute a single-cell-thick tube, continuous at its anterior end with the tube of the hypodermis that encloses the worm. Muscle and marginal cells are joined by tight junctions, which divide the membrane into apical and basal surfaces. The apical surfaces face the lumen and secrete cuticle, continuous with the cuticle made by the hypodermis. The basal surfaces face a basal lamina that is continuous with the basal lamina that separates the hypodermis and intestine from the pseudo-coelom (fluid-filled body cavity) and mesoderm. Components of this basal lamina are likely produced by body-wall muscles^[4,5]. The 9 epithelial cells are arranged so as to form a narrow ring at the anterior end of the pharynx, where it connects with the buccal cavity. There is otherwise no epithelial sheet covering the bulk of the pharynx. Precise knowledge of pharyngeal anatomy is available at the ultrastructural level, thanks to detailed electron microscopy studies^[6].

Pharyngeal neurons lie deep within folds of the basal membrane of pharyngeal muscle cells (note that this is not a

“basal lamina” or “basement membrane”, but is that part of the muscle cell membranes that is on the “basal” side), between the muscle and basal lamina, just as the extrapharyngeal nervous system is between the basal membrane of the hypodermis and the basal lamina. No basal lamina separates pharyngeal motor neuron presynaptic terminals from the post-synaptic muscle membrane. In contrast, extrapharyngeal motor neurons are separated from the muscle cells on which they synapse by the basal lamina that separates the mesodermal muscle cells from the ectodermal neurons.

The role of the pharyngeal nervous system in regulating pumping is somewhat of a mystery. Normal feeding consists of two primary motions: pumping and isthmus peristalsis^[1]. A pump is a near-simultaneous contraction of the muscles of the corpus, anterior isthmus, and terminal bulb, followed by a near-simultaneous relaxation. The contractile fibers of the pharyngeal muscles are radially oriented, so contraction pulls the lumen open from its resting closed Y-shape to a triangular shape. The second motion, isthmus peristalsis, occurs after the main relaxation is complete. It is a peristaltic wave of contraction in the posterior isthmus that carries bacteria trapped in the anterior isthmus back to the grinder. Typically, only every fourth pump is followed by an isthmus peristalsis. The nervous system is not essential for pumping; pumping continues even when the entire pharyngeal nervous system is killed^[2]. However, many neurons are important; efficient pumping and trapping of bacteria by the pharynx requires the presence of the neurons I5, MC, M3, M4, and NSM^[2,7,8].

Development of the pharynx

In order to begin understanding how the pharyngeal neurons develop, it is necessary first to describe pharyngeal development itself (Figure 2). The *C elegans* pharynx offers a very simple model to understand morphogenesis and differentiation. The pharynx develops through the morphogenesis of a primordium composed of 80 undifferentiated cells (plus many apoptotic cells; there are 19 apoptotic cells that are sisters to final pharyngeal cells and that die within

Figure 2. General overview of pharyngeal anatomy and developmental genetics with the M2 neuron trajectory described in detail at bottom. Gene name explanation: *ceh*, *Caenorhabditis elegans* homeobox; *mnm*, M neuron morphology abnormal; *pha*, defective pharynx development; *sax*, sensory axon guidance; *slt*, slit (*Drosophila*) homolog; and *unc*, uncoordinated.

350–420 min of development^[9]). Morphogenesis is accompanied by differentiation but not by new cell divisions, so the mature pharynx contains 80 nuclei but only 62 cells as a result of cell fusion among some of the muscle and two gland cells; these fusions occur around the time of hatching and seem irrelevant to the developmental process^[9], although it would be interesting to understand how these fusions are regulated.

0–100 min: early cell divisions and establishment of main lineages The cells that make up the pharyngeal primordium originate from two early embryonic blastomeres: the ABa and the MS blastomeres. This is quite remarkable: members of two distinct lineages are recruited to form one organ. Not only that, but cells with these two very different ancestries may end up adopting nearly identical fates. For example, the muscle cell m3VL has the ancestry ABalpappppp, whereas the identical cell m3DL has the ancestry Msaapaaa (these two cells will fuse later). Note that even though each cell is normally specific to adopt a developmental fate, there is some degree of developmental plasticity. For example, Avery and Horvitz showed that the pharyngeal neuron M4 is essential for feeding in wild-type *C elegans*, but that in a *ced-3* mutant (in which the sister cell of M4 does not die of apoptosis), the now viable sister of M4 can sometimes take over the function of M4^[10].

The respective contributions of the ABa and MS lineages are more or less spatially consistent with their initial positions within the 8-cell embryo. For example, the anterior cell ABa contributes cells of the anterior pharynx, whereas the more posterior MS cell contributes mostly posterior pharyngeal cells. This observation holds true for later descendants and narrower scopes of spatial contributions. Figure 3 shows the adult pharyngeal contributions from the pharyngeal precursors of the 100-cell stage embryo, and emphasizes the preservation of spatial relationships during development. Thus, ABalpa contributes mostly to the anterior left subventral area, *etc.*

100–250 min: gastrulation At 100 min after first cleavage, when the egg comprises 28 cells, gastrulation begins. During gastrulation, several cells enter deep into the embryo through a ventral cleft. The first cells to enter are the gut precursor cells Ea and Ep. Next are the P4 and MS progeny at 120–200 min of development, and the AB-derived pharyngeal precursors enter more anteriorly at 210–250 min. The ventral cleft closes from posterior (230 min) to anterior (290 min). As gastrulation proceeds, the E cell descendants and the pharyngeal precursors form a central cylinder. Note that as gastrulation proceeds, so do cell divisions. Active pre-pharyngeal cell divisions continue until approximately

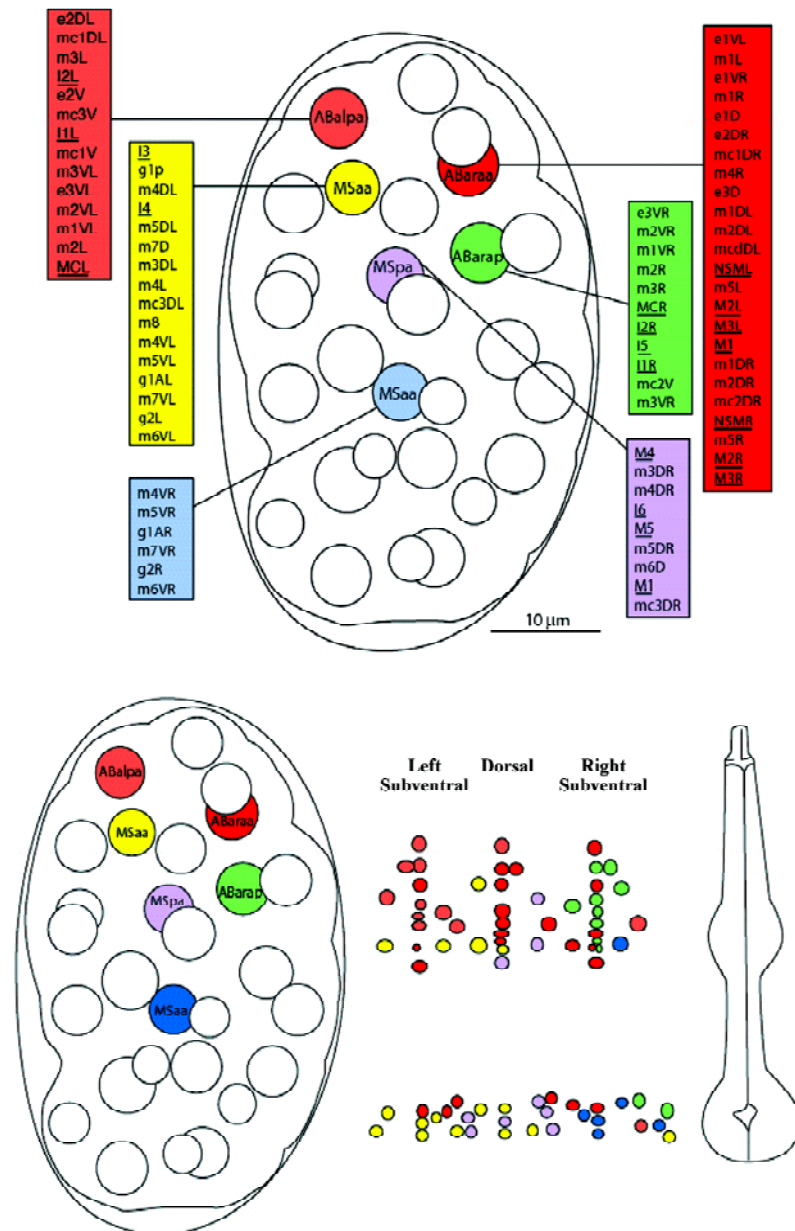

Figure 3. Color-coded cell fates of the pharyngeal precursor cells in the 28-cell embryo (A) and the location of their nuclei in the mature pharynx (B). Note preservation of spatial relationships in the mature pharynx, and absence of nuclei in the isthmus. Adapted from Sulston *et al*^[9] and Albertson and Thomson^[6].

350 min of development, and some late divisions occur until approximately 400 min.

250–400 min: compaction of pharyngeal primordium

Between 250 min and 400 min the pharyngeal primordium becomes clearly defined. The non-pharyngeal precursor cells are somehow excluded from the pharyngeal primordium. Perhaps they are squeezed out in a process by which the pharyngeal cells have more adhesive affinity to each other than to any other cell (in line with the theory of Malcolm

Steinberg; eg see Duguay *et al*^[11]). This aspect of primordium formation has not been investigated experimentally.

400–430 min: extension of pharyngeal primordium

The approximately 400-min-old primordium is insulated by a basement membrane (present at or before 400 min^[9]), such that the pharynx develops autonomously, perhaps with no extrapharyngeal cues, or with very few. Such autonomous development is also true of the 20-cell intestine that, together with the pharynx, makes up the entire *C. elegans* gut^[12]. At

approximately 400 min, the pharyngeal primordium is approximately spherical, and most of the cell nuclei appear located in spatial relationships that are consistent with their final positions, at least along the anterior-posterior axis, although the relative distances between these nuclei can be very different from those of the mature organ. For example, at approximately 430 min, the sister cells M2 and M3 have their nuclei next to each other, whereas in the final pharynx M2 has its nucleus in the posterior bulb and M3 in the metacarpus. It therefore seems that development of the pharynx is mostly a question of cell differentiation and morphogenesis, not of active cell migration. However, some cells do migrate within the developing pharynx. For example, Sulston *et al* observed that the 3 g1 gland cells migrate in a reproducible way. They wrote: “Their movements approximately follow the subsequent course of their secretory processes, and may be responsible for laying down the latter”^[9].

Beginning at approximately 400 min, the primordium elongates anteriorly then posteriorly. The primordium develops into a tube connected anteriorly to the buccal cavity and posteriorly to the midgut. The adherens junctions that connect many pharyngeal cells with each other form simultaneously with the process of elongation. Note that there is no evidence of any basement membrane within the elongated pharynx during or after elongation or at any other stage of development or adulthood^[5]. Portereiko and Mango have studied the morphogenesis of the pharyngeal primordium and divided the process into three stages: (i) lengthening of the nascent pharyngeal lumen by reorientation of the apicobasal polarity of anterior pharyngeal cells (“Reorientation”); (ii) formation of an epithelium by the buccal cavity cells, which mechanically couples the buccal cavity to the pharynx and anterior epidermis (“Epithelialization”); and (iii) a concomitant movement of the pharynx anteriorly and the epidermis of the mouth posteriorly to bring the pharynx, buccal cavity, and mouth into close apposition (“Contraction”)^[4].

430–800 min: completion of functional pharynx Between 430 min and 490 min, as elongation proceeds, the pharyngeal bulbs and isthmus become apparent. It is probably at this time that the pharyngeal cells interpret their final differentiation programs and adopt their final shapes. Between 600 min and 650 min, the pharyngeal cuticle is produced and the lumen becomes distinct. The pharyngeal glands are active by 720 min and the pharynx is pumping by 750 min. Hatching occurs at approximately 800 min following first cleavage.

Genetics of pharyngeal development

What follows is a brief overview of some of the genes that have been shown to play a role in pharyngeal development.

pha-4 *pha-4* encodes the *C. elegans* homolog of FoxA, a fork-head transcription factor^[13]. The *pha-4* gene is expressed in all pharyngeal cells, and also in some cells of the rectum^[13]. Expression of PHA-4 is detected in all pharyngeal precursor cells beginning from at least 200 min of development (and perhaps even earlier). By the comma stage (~430 min), all the pharyngeal cells are present and express PHA-4. PHA-4 is also expressed in the 6 cells of the pharyngeal intestinal valve, which is not considered a part of the pharynx *per se*. At 430 min, PHA-4 expression is also found in 6–8 rectal cells, including the 2 rectal valve cells and the 3 rectal epithelial cells. This expression pattern is therefore conserved with that of the *Drosophila forkhead* gene (high levels in the foregut/pharynx and hindgut/rectum). The *pha-4* mutants completely lack all pharyngeal cells, even though the AB and MS lineages are otherwise completely normal^[14]. It seems that *pha-4* acts as an organ identity factor. Indeed, Gaudet and Mango have proposed that the PHA-4 protein may directly activate most or all pharyngeal genes, with the expression timing being regulated by the presence of binding sites of varying affinity: poor binding sites will have delayed expression, as they will require higher levels of PHA-4 before becoming activated^[15]. The consensus binding site for PHA-4 has been defined as: TRTTKRY (R=A/G, K=T/G, Y=T/C). This site is present in the *myo-2* gene, a pharyngeal-specific muscle myosin that is a confirmed direct target of PHA-4^[13]. Ectopic expression of PHA-4 causes ectopic expression of *myo-2*, *ceh-22* (a homeodomain protein that is also a coactivator of the *myo-2* gene), *pha-2* (another homeodomain protein important for pharynx development, see below), and most likely other otherwise pharyngeal specific genes^[13,16].

pha-1 In *pha-1* mutants, the pharyngeal primordium appears to form normally, with a full complement of nuclei and surrounded by a basal membrane. In these mutants, elongation also appears normal up to at least 420 min of development, including the expression of an antigenic marker for the pharyngeal muscle cell precursors detected with the monoclonal antibody 3NB12^[17,18]. After elongating and contacting the buccal cavity, the developing organ detaches from the buccal cavity and retracts, causing a “Pun” (pharynx unattached) phenotype. The end result is a worm in which the incompletely formed pharynx is slightly elongated, surrounded by the visible basement membrane and unattached to the mouth. It is difficult to determine if all pharyngeal cell differentiation events take place in the *pha-1* mutant, but expression of

MYO-2::GFP is detected and a pharyngeal lumen forms^[17]. Thus *pha-1* affects pharynx development after pharynx cells are committed to a specific cell fate, but before terminal differentiation/morphogenesis of the different pharyngeal cell types occurs^[17,18].

Initial analysis of the PHA-1 amino acid sequence suggested that it was a basic leucine zipper (bZIP) transcription factor. Expression of a PHA-1::LacZ reporter also suggested restricted expression in pharyngeal cells as well as in body muscle cells^[18]. However, a more recent evaluation of the PHA-1 amino acid sequence indicates that *pha-1* actually does not encode a bZIP transcription factor^[17]. Consistent with this last analysis, a rescue-competent PHA-1::GFP fusion protein suggests that PHA-1 is a cytosolic protein^[17] that is widely expressed (essentially in all cells by the 100-cell stage). Because the biochemical function of PHA-1 is unknown at present, little can be said about its actual mechanism of action. However, genetic interaction experiments have shown that *pha-1*, *lin-35* (the *C. elegans* Retinoblastoma protein homolog), and *ubc-18* (a ubiquitin-conjugating enzyme) play partially redundant functions to control pharyngeal morphogenesis^[17]. Indeed, *lin-35/Rb*; *ubc-18* double mutants exhibit a synthetic pharyngeal phenotype; that is, failure to undergo pharyngeal primordium elongation, typically failing already at the reorientation step during which the anterior epithelial cells of the primordium should align their long axis with the dorsoventral axis of the embryo^[19]. The *ubc-18* and *pha-1* also both show strong synthetic pharyngeal phenotypes when combined with class B synthetic multivulval (SynMuv) genes. The SynMuv genes form two molecularly heterogeneous classes (class A and B) of genes that contribute redundantly to vulva development; class B SynMuv genes obviously also play a hitherto unknown role in pharyngeal development that is redundant with both *ubc-18* and *pha-1*^[17,19].

pha-2 The *pha-2* mutant worms exhibit a late defect in pharyngeal morphogenesis that results in the two pharyngeal bulbs being next to each other rather than being separated by a narrow, nucleus-free isthmus. We cloned the *pha-2* gene and found that it encodes a homeobox gene most homologous to the vertebrate Hex gene^[16]. Using a PHA-2::GFP translational fusion reporter in which a *pha-2* genomic fragment containing 2.7 kb of *pha-2* 5'UTR plus the entire gene fused to GFP at its C-terminal codon, we observed expression in several pharyngeal cells: the pm5 muscle cells that form the isthmus but have their cell bodies within the posterior bulb; the pm4 cells that make up the bulk of the metacarpus; and pharyngeal epithelial cells. As this translational fusion reporter was able to rescue the mutant pheno-

type, we are relatively confident that the expression profile of the reporter reflects normal PHA-2 expression. We hypothesize that PHA-2 confers an isthmus cell identity to the pm5 muscle pharyngeal cells that express it and that form the isthmus. The main characteristic of isthmus cells is that they have a long elongated shape extending into the isthmus, but that their cell bodies are embedded within the metacarpus or posterior bulb. This isthmus cell shape likely results from directional growth of the cells occurring after the comma stage (~430 min), because at this stage there is no nuclear-free zone along the length of the elongated primordium. As Sulston *et al* documented, it is during the 430–490 min interval, as the emerging pharynx continues its elongation, that the pharyngeal bulbs become apparent^[9].

What are the genes regulated by *pha-2*? Experimental evidence suggests that *pha-2* acts as a repressor of *ceh-22* in the pm5 cells. In wild-type animals, expression of a CEH-22::GFP reporter is downregulated in the isthmus by late embryogenesis. In contrast, in *pha-2* mutants the expression of the CEH-22::GFP reporter persists and even increases in the isthmus during late embryogenesis, and also post-embryonically. Because of the late effects of the *pha-2* mutation, we also surmise that at some downstream level, *pha-2* acts via genes that implement the differentiation program by driving the final cell shape changes, such as cytoskeletal genes. It is perhaps worth noting that located just next to the *pha-2* gene is the intermediate filament 2c gene, IF-C2 (M6.1), which is expressed in pharyngeal and intestinal desmosomes and thus likely plays a role in cell-cell connections^[20]. Given that intermediate filaments are important in several morphogenesis processes, including cell elongation^[21,22], there is a possibility that M6.1 contributes to pharyngeal morphogenesis. Consistent with this line of reasoning, the expression of IF-C2 begins in the late embryo, when final pharyngeal morphogenesis occurs.

ceh-22 Like vertebrate cardiac and smooth muscles, the pharyngeal muscles of *C. elegans* do not express any of the known members of the MyoD family of myogenic factors. In addition, like vertebrate cardiac muscle cells, the pharyngeal muscles exhibit an intrinsic rhythmic contraction activity that does not depend on any neuronal input. Two myosin heavy chain genes *myo-1* and *myo-2* are specifically expressed in pharyngeal muscles. In 1994, Okkema and Fire characterized the *myo-2* promoter and identified a transcription factor that binds this promoter and regulates its expression in pharyngeal muscles^[23]. This transcription factor was CEH-22, a homeobox protein most homologous to the vertebrate Nkx2.5 and the *Drosophila tinman*, which regulate heart development in their respective organisms. Furthermore, expression

of the zebrafish *nkx2.5* gene in *C. elegans* can activate *myo-2* and can rescue the *ceh-22* mutant, suggesting that *ceh-22* and *nkx2.5* share a conserved molecular function^[3]. Somewhat confusingly, the phenotype of the *ceh-22* mutant includes a slightly abnormal pharyngeal shape (slight thickening of the isthmus), but no defect in the expression of *myo-2*, suggesting that other regulatory pathways act in parallel with *ceh-22* to regulate *myo-2*^[24]. Okkema *et al* showed that PHA-1 itself also directly regulates the *myo-2* gene, and that a *pha-1*; *ceh-22* double mutant is more severe than either mutant alone; the early pharyngeal 3NB12 antigen is not even expressed^[24].

Development of the pharyngeal neurons

Pharyngeal nervous system overview The mature pharynx contains 20 neurons. Each establishes a unique and predictable morphology that is reproducible from worm to worm. The pharyngeal nervous system is organized into four general structures: two subventral nerve cords, one dorsal nerve cord, and one circular pharyngeal ring, which is located within the posterior half of the metacarpus and to which 12 neurons contribute processes^[6]. The synapses and gap junctions made by the pharyngeal neurons have also been described and thus a basic wiring diagram of the pharyngeal network exists^[6]. Speculations that the pharyngeal neural network plays an important role in regulating the pumping activity, as has been postulated for the intrinsic cardiac ganglia in the vertebrate heart^[25], are stunted by the above-mentioned observation that most of the pharyngeal neurons can be laser-ablated without visible effects on pharyngeal behavior.

How does the intricate network of axon trajectories and synapses become established within the small cramped space of the developing pharynx? In particular, it is important to re-emphasize that the pharyngeal neurons, in contrast to body neurons, are not projecting between a basal lamina and an epithelial cell. Rather, they project within muscle cell folds, directly in contact with the muscle cell surface. Does this rather unique substrate for the neurons involve guidance cues different from those guiding body neurons? Also of importance is the fact that the pharyngeal neuron cells are already present in undifferentiated form within the spherical pharyngeal primordium. This offers intriguing developmental possibilities. For example, the pharyngeal neurons can take advantage of instructive interactions between cells that are neighbors within the primordium but are widely separated in the mature pharynx.

Establishing axon trajectories without growth cones We

have shown that the M2 pharyngeal axons establish their trajectories via at least two independent mechanisms^[26]. The straight proximal M2 trajectory (between the cell body, through the isthmus, and reaching into the metacarpus; Figure 2) does not depend on genes that act as axon guidance cues or that are important for growth cone functions. Thus, this proximal straight trajectory is established in a growth-cone-independent manner. We have suggested that the M2 cell forms, within the primordium, a physical connection with some neighboring cell that is ultimately located within the metacarpus, and that these connections elongate to form the proximal M2 axon trajectory as the primordium undergoes morphogenesis. It is a long-standing observation that mechanical tension exerted on neuronal cells can induce formation of a projection that can elongate rapidly as tension is maintained, “as a fishing line from a reel”^[27,28]. Such mechanically induced axon formation and elongation can take place even when growth cone function is impaired^[29]. This would be a process similar to the scenario that Sulston *et al* described for the pharyngeal gland cell g1 (discussed earlier), and also similar to the immature sensilla neurons that, after contacting the tip of the head, move posteriorly while laying down their dendritic processes^[9]. The ability of a neuronal cell body to migrate and leave an extending axon behind has also been attributed to vertebrate facial motoneurons, although that particular case involves the movement of the cell nucleus (“nucleokinesis”) into a dendrite^[30]. In *Drosophila*, the larval optic nerve undergoes a period of elongation by intercalation of membrane as the neuron cell body and a distant guidepost cell move away from each other; later, a growth-cone-dependent process completes the establishment of the distal trajectory^[31]. Similarly, neurons of the larval imaginal leg disc also lengthen axons in keeping with the vast leg morphogenesis process^[32].

Distal ends are established using a growth cone Axon trajectories are usually established by specialized structures at their growing ends, the growth cones, that sense the molecular environment and interpret guidance cues so as to migrate along the correct paths^[33]. The distal end of the M2 axon, which exhibits a complex trajectory within the metacarpus (first turning outward laterally, then dorsally, before extending towards the midline to establish a gap junction with the contralateral M2 neuron), depends on basic growth cone function genes (*unc-73*, *unc-51*) as well as several well-known axon guidance cues and receptors for these cues (*sax-3*, *slt-1*, *unc-6*, *unc-5*, *unc-40*)^[26]. It is therefore our conclusion that the rough trajectories of pharyngeal neurons may be established during morphogenesis in the absence of growth cones, relying instead on cell-cell contacts

that are stretched to form axons during cell movements, but that fine-tuning of the ends of the trajectories depends on functional growth cones and multiple guidance cues. A screen for mutants with abnormal M2 trajectories allowed the isolation of several *mmn* (M neuron morphology abnormal) mutants, three of which specifically affected the formation of the distal M2 ends (Figure 2)^[26]. These mutations likely affect the function of genes important for the function/guidance of the M2 growth cones.

An instructive developmental role for neurons? Interestingly some of the pharyngeal neurons themselves may act as sources of guidance cues. At least 2 of the pharyngeal neurons likely play developmental roles. The interneuron I5 is a source of UNC-6^[34] that is likely to be important for the guidance of other axons, notably M2, which exhibits abnormal trajectories in a *unc-6* mutant background. The interneuron I4 expresses UNC-129^[35], also a secreted guidance molecule. Hence, it seems likely that many of the apparently unimportant pharyngeal neurons (most neurons of the pharynx can be ablated in the adult worm without impairing pharyngeal function) play an important role during development. It would be interesting to ablate the neuronal precursor in the embryo prior to pharyngeal morphogenesis end, and thus test directly the hypothesis that these neurons play an instructive developmental role. It would also be interesting to determine whether this is a function that neurons play in other developing organs and other organisms.

Welcome a new Advisory Board Member at Acta Pharmacologica Sinica!

Acta Pharmacologica Sinica is pleased to announce a new member of the advisory board, **Prof Demetrios A SPANDIDOS**, who brings wonderful insights from their research fields to the articles published in Acta Pharmacologica Sinica.

Demetrios A SPANDIDOS is Professor of Virology (since 1988) at the Medical School, University of Crete; Director of Clinical Virology Laboratory (since 1990) at the University Hospital in Heraklion, Crete, and he was Research Professor and Director of the Laboratory of Molecular Oncology and Biotechnology (1988–1998) at the Institute of Biological Research and Biotechnology at the National Hellenic Research Foundation in Athens, Greece. He is the founder and Editor of the International Journal of Oncology, Oncology Reports and International Journal of Molecular Medicine.

Dr Spandidos obtained his BSc in Chemistry from the University of Thessaloniki, Greece in 1971, a PhD in Biochemistry from McGill University in Montreal, Canada in 1976 and a DSc in Genetics from the University of Glasgow, UK in 1989. He is Fellow of the Royal Society of Health (1994) London, UK, Fellow of the Royal College of Pathology (1997) London, UK and corresponding Member of the Academia Nacional de Medicina de Buenos Aires, Argentina (1999). He has received the degrees of doctor honoris causa from the Universities of Bucharest (2002) and Cluj-Napoca (2004) Romania.

Dr Spandidos was the first scientist in the field of oncology to develop and apply the gene transfer technique, which has become a most potent tool to investigate oncogenes. Thus, his work assisted in development of the gene transfer technology that has been of paramount importance in revealing new oncogenes, as well as implementing the molecular understanding of oncogenes and how the normal proto-oncogenes become activated into their malignant transforming cognates. This field has expanded tremendously over the past twenty years and Dr Spandidos has continued to contribute actively, playing a major role in his scientific investigations on the ras oncogene. While at the Beatson Institute for Cancer Research in Glasgow he performed notable and important investigations on the nature of transformation of normal cells by introduction of single ras genes using retroviral LTRs and other strong promoters.

Invited review

Baculovirus as a highly efficient expression vector in insect and mammalian cellsYu-chen HU¹*Department of Chemical Engineering, National Tsing Hua University, Hsinchu, Taiwan, China***Key words**

Abstract

Baculovirus has been widely used for the production of recombinant proteins in insect cells. Since the finding that baculovirus can efficiently transduce mammalian cells, the applications of baculovirus have been greatly expanded. The prospects and drawbacks of baculovirus-mediated gene expression, either in insect or in mammalian cells, are reviewed. Recent progresses in expanding the applications to studies of gene regulation, viral vector preparation, *in vivo* and *ex vivo* gene therapy studies, generation of vaccine vectors, *etc* are discussed and the efforts directed towards overcoming the existing bottlenecks are particularly emphasized.

Introduction

Baculoviruses make up a family of viruses and are grouped into nuclear polyhedrosis viruses (NPV) and granulosis viruses. More than 500 different types of baculoviruses have been discovered and the host range is restricted to invertebrates, mostly to insects (eg, moths and butterflies); thus, several baculoviruses (eg, *Helicoverpa zea*, *Orgyia pseudotsugata*, and *Lymantria dispar*) have been registered for use as biological pesticides by the US Environmental Protection Agency^[1]. Among the numerous baculoviruses, *Autographa californica* multiple NPV (AcMNPV) is the most well studied and most extensively used. AcMNPV has a circular double-stranded DNA genome of approximately 130 kb, which is condensed with a protamine-like protein into the core and packed into the nucleocapsids. Nucleocapsids are synthesized in the nucleus of infected cells (typically 40 nm–50 nm in diameter and 200 nm–400 nm in length). Membrane-enveloped nucleocapsids are referred to as virus particles or virions. In nature, AcMNPV are occluded in a polyhedron (2 µm–15 µm in size) mainly consisting of polyhedrin protein. After ingestion by insects, the polyhedrin matrix is dissolved in the alkaline midgut, thus releasing the embedded virions, which subsequently infect the epithelial cells of the intestine. Early in the infection

cycle, the DNA genome is replicated and transcribed in the nucleus and the nucleocapsids are assembled. The budding of nucleocapsids through plasma membrane results in the release of budded virus, which is responsible for systemic transmission within an infected insect. Late in the infection cycle, progeny nucleocapsids become membrane-bound within the nucleus and are embedded into the polyhedra. After cell death and lysis, the polyhedra are released in the wild to spread the infection. Budded virus is highly infectious to cultured insect cells and is the primary form used in the laboratory as an expression vector.

Baculovirus infection of insect cells

The baculovirus has been widely used for the production of numerous recombinant proteins in insect cells^[2–4] because it has the following advantages: (i) proper post-translational modification, because insect cells are higher eukaryotes; (ii) a high capacity for multiple genes or a large insert, because of the huge and flexible viral genome (130 kb); (iii) biosafety, because baculovirus naturally does not infect humans; and (iv) a very high yield driven by the strong promoters polyhedrin or p10. Among the natural host cells, Sf-9 and Sf-21, derived from the ovarian tissue of *Spodoptera frugiperda*, and BTI-TN-5B1-4 (High-Five; Invitrogen,

Carlsbad, CA, USA), derived from *Trichoplusia ni*, which is suitable for the expression of secreted proteins^[5], are most popular. In addition to cultured cell lines, insect larvae are also excellent hosts for protein production. For example, *T ni* insect larvae can be readily infected by recombinant AcMNPV^[6,7], and silkworms can be readily infected by recombinant *Bombyx mori* NPV^[8]. Both systems have been employed for the production of numerous recombinant proteins^[6,9]. The products synthesized in insect larvae are almost identical to those produced in insect cells and mammalian cells and the yields are generally very high (eg 13 mg luciferase per larva^[10]). Therefore, baculovirus infection of live insects may represent an inexpensive and rapid approach for protein production^[11], but consistent infection and quality control are more difficult to achieve.

The large cloning capacity renders baculovirus an ideal tool for the synthesis of virus-like particles (VLP), which generally require simultaneous expression of multiple viral structural proteins for self-assembly. VLP are empty particles composed of viral structural proteins but devoid of viral nucleic acids; thus, they are non-infectious. VLP can generally induce broad and strong immune responses thanks to the preservation of many essential epitopes^[12,13]; therefore, VLP have gained increasing attention as potential vaccine candidates^[14,15] or diagnostic reagents^[16]. Extended applications of VLP as gene delivery vehicles have also been reported^[17,18]. To date, numerous VLP of different viruses, including HIV^[19], herpes simplex virus^[20], human papillomavirus^[21], polyomavirus^[22], parvovirus^[23], infectious bursal disease virus^[24], hepatitis C virus (HCV)^[16], and enterovirus 71^[25], have been expressed using the baculovirus/insect cell expression system. Very recently, the synthesis of severe acute respiratory syndrome coronavirus (SARS-CoV) VLP using the baculovirus/insect cell system has also been reported^[26,27]. The assembly of VLP using baculovirus enables the investigation of virus assembly process as well as the minimal requirements for viral capsid assembly. For example, Mortola and Roy demonstrated that coexpression of SARS-CoV envelope and membrane proteins is required and sufficient for the assembly of spikeless VLP^[27], yet additional coexpression of the spike (S) protein results in the incorporation of the S protein. The resultant VLP possesses distinctive spike projections, making it morphologically indistinguishable from the authentic virus. Through co-infection with different recombinant baculoviruses, one can manipulate the composition of the particles, obtaining higher specific immunogenicity^[28], or other biological functions by incorporating enzymes^[29] or affinity tags for downstream purification^[24]. In this regard, Conner *et al* successfully dem-

onstrated chimeric VLP formed by structural proteins of viruses isolated from different animals (bovine and simian)^[30]. By including viral proteins from different strains, referred to as phenotypic mixing, one can broaden the spectrum of the chimeric particles as a vaccine^[31].

There are drawbacks associated with the baculovirus/insect cell expression system. First, baculovirus infection ultimately results in cell death and lysis in a few days. Because the expression driven by a polyhedrin or p10 promoter usually reaches the maximum near the death of infected cells, protein processing is likely to be suboptimal at that time because of the compromise of post-translational machinery and secretory pathway. This may seriously affect the processing of proteins destined for plasma membrane or for secretion. Efforts have been directed towards alleviating this problem by the use of early baculovirus promoters (eg, IE1) in either transiently or stably transformed cells^[32]. The expression driven by early promoters is continuous and stable, and confers more efficient processing of the glycoprotein (eg tissue plasminogen activator), but the expression level is lower than those obtained with the lytic baculovirus system. Such a system is a feasible approach for expression in insect cells for products that are relatively poorly processed in lytic insect cells, and may be useful for functional studies of recombinant receptor proteins. To circumvent the protein degradation problem associated with cell lysis, a novel non-lytic baculovirus has recently been developed by random mutagenesis of viral genomes^[33] and subsequent selection. At 5 d post-infection, the non-lytic baculovirus shows only 7% cell lysis, in contrast to 60% cell lysis by lytic baculovirus. This system is thus a convenient alternative for the production of proteins vulnerable to degradation using lytic baculoviruses.

The second disadvantage is that glycosylation in insect cells differs in many aspects from in mammalian cells. For example, truncated oligosaccharides containing just 3 or even 2 mannose residues and sometimes fucose have been found on proteins expressed in insect cells. Besides, there appears to be no significant sialylation of *N*-glycans in insect cells^[34]. The glycoproteins lacking sialic acids have extremely short half-lives *in vivo*; therefore, the truncated *N*-glycans of glycoproteins produced in insect cells constitute a barrier to their use as therapeutics. One example to engineer the *N*-glycosylation pathway is the construction of transformed Sf-9 cells that constitutively express bovine β 1, 4-galactosyltransferase under *hr5-ie1* control^[35,36]. Baculovirus infection of this cell line results in the production of terminally galactosylated recombinant proteins. Other attempts and strategies to “mammalianize” or “humanize” the

N-glycosylation capacity of insect cells have been reviewed previously^[37–39]. Another limitation of the baculovirus/insect cell system is its inefficiency to properly process proteins that are initially synthesized as large inactive precursor proteins, such as peptide hormones, matrix metalloproteases, and fusogenic viral envelope glycoproteins. A family of mammalian proprotein convertases has been characterized to be involved in the cleavage, and it has been shown that coexpression of the prohormone convertase furin with transforming growth factor β 1 (TGF β 1) results in a 7.8-fold increase in the production of mature TGF β 1^[40].

Baculovirus transduction of mammalian cells

Baculovirus was originally regarded as infecting solely insects and invertebrates; but in 1983 Volkman and Goldsmith found that baculovirus can be internalized by non-target vertebrate cells (eg, human lung carcinoma cell line A427)^[41]. Carbonell *et al* further confirmed the entry of baculovirus into mammalian cells and very low level reporter gene expression under the control of polyhedrin and Rous sarcoma virus (RSV) promoters in mammalian cells^[42]. However, virus replication was not detected in either study. Their discovery was not widely noted until 10 years later when two pioneer groups reported that recombinant baculoviruses harboring a cytomegalovirus (CMV) promoter-luciferase gene cassette^[43] or an RSV long terminal repeat (LTR) promoter- β galactosidase (β -gal) gene cassette^[44] can efficiently transduce mammalian cells. Their data indicate a strong preference for baculovirus to enter hepatocytes of different origins, and suggest that the block to expression in less susceptible cells does not appear to result from the ability to be internalized by the target cells but rather by events subsequent to viral entry because high and low expressing cell lines internalize similar amounts of virus^[44]. One factor accounting for the low apparent transduction efficiency in other cell types is promoter strength. Shoji *et al* showed that cells that are not transduced by a baculovirus expressing β -gal under the control of a CMV promoter can be efficiently transduced by a baculovirus expressing the same reporter protein under the transcriptional control of a stronger CAG promoter^[45] (a composite promoter consisting of the CMV immediate early enhancer, chicken β -actin promoter and rabbit β -globin polyadenylation signal). Thus, it is of interest to examine different promoters of viral and cellular origins in the baculovirus context in mammalian cells. Following these findings, subsequent studies have rapidly expanded the list of permissive cells that include cell lines originating from human (eg, HeLa, Huh-7, HepG2, keratinocytes,

and bone marrow fibroblasts), rodent (eg, CHO, BHK), porcine (eg, CPK, PK-15), bovine (eg, BT)^[46], and even fish sources (eg, EPC, CHH-1)^[47]. Besides, baculovirus is capable of transducing non-dividing cells^[48]. Transduction of primary cells, such as human neural cells^[49], pancreatic islet cells^[50], and rat articular chondrocytes^[51], has also been observed. In addition, Wagle and Jesuthasan recently showed that baculovirus can successfully transduce the embryos of zebrafish^[52]. By injecting the baculovirus expressing ephrinB2a into specific tissues, ephrinB2a is normally expressed in the posterior region of developing somite and baculovirus-mediated misexpression causes abnormal somite boundary formation. Despite the rapidly growing list of susceptible cells, however, baculovirus transduction of cell lines of hematopoietic origin, such as U937, K562, Raw264.7^[53], LCL-cm, and Raji^[54], is inefficient.

The transduction efficiencies vary considerably depending on cell types and can be up to 95% for BHK cells or lower than 10% for NIH-3T3 cells^[54]. One possibility accounting for the high transduction efficiency in certain cell lines is the activation of mammalian promoters (eg, CMV promoter and heat shock promoter) by a DNA sequence upstream from the polyhedrin (*pu*) and a homologous region (*hr*) of AcMNPV^[55]. The *hr1* sequence enhances transcription from polyhedrin and *Drosophila* heat shock protein (*hsp70*) promoter in Sf cells^[56] and functions as an origin of replication (*ori*), but does not support *ori* activities in mammalian cells^[57]. *pu* and *hr* together function synergistically, resulting in as much as 18 000-fold promoter activation^[55]. The *hr1* can also function in mammalian cells as an enhancer when present *in trans*^[57]. The insertion of an additional copy of the *hr1* region in the AcMNPV genome thus represents an attractive approach to promoting overexpression of foreign proteins in mammalian cells as has been demonstrated in insect cells^[56]. The additional *hr1* can also help maintain the genetic stability of the bacmid-derived baculoviruses, because spontaneous deletion of the heterologous gene(s) in the foreign bacterial artificial chromosome sequences readily occurs^[58,59].

The transduction efficiency can be markedly enhanced by the addition of sodium butyrate, trichostatin A^[53], and valproic acid^[60]. These compounds are histone deacetylase inhibitors, inducing a hyperacetylation of the chromatin and enhancement of transcription, thus highlighting the importance of the chromatin state of the baculovirus genome in the transduced cells for transgene expression. However, cytotoxicity is often associated with the use of these drugs^[60]. Another approach to enhance the transduction efficiency is to alter the transduction protocol. For transduction, typically the virus is concentrated by ultracentrifugation and

resuspended in phosphate-buffered saline (PBS). The cells are then incubated with the virus for 1 h at 37 °C using growth medium (eg, DMEM) as the surrounding solution^[44,45,61]. Recently, we found that incubation of the unconcentrated virus (ie virus supernatant) at a lower temperature (eg, 25 °C) for 4 h–6 h using PBS as the surrounding solution results in gene transfer into HeLa and chondrocytes^[51,62] with efficiencies comparable or superior to those using the traditional protocols. This is in part because of prolonged virus uptake provided that sufficient amount of the virus is present. One key determinant accounting for the high transduction efficiency is PBS, which is superior to DMEM or TNM-FH (the medium for baculovirus production) as the surrounding solution in terms of enhancing the transduction efficiency and transgene expression^[51,62], although the exact mechanism awaits further elucidation. The same protocol also confers gene delivery into human mesenchymal stem cells (MSC) isolated from umbilical cord blood (uMSC) and bone marrow (bMSC) with efficiencies of up to approximately 72.8% and 41.1%, respectively^[63] (Figure 1). This protocol eliminates the need for virus ultracentrifugation; thus, it not only represents a simpler approach, but also considerably reduces possible virus inactivation during ultracentrifugation.

Baculovirus transduction is generally considered non-toxic to mammalian cells and does not hinder cell growth even at high multiplicity of infection^[43,64]. Our recent studies again confirm this notion because transduction with a wild-type baculovirus does not cause any observable adverse effect to chondrocytes or MSC^[51,63]. From the growth curves, however, we noted a slower cell proliferation on expression of enhanced green fluorescent protein (EGFP) under the transcriptional control of a CMV promoter. The slightly retarded cell growth is attributed to the EGFP overexpression because:

(i) EGFP overexpression could be toxic and might even induce apoptosis in some cells^[65,66]; and (ii) the transcriptional activation of CMV promoter could repress other viral or cellular gene expression^[67]. Fortunately, the cell growth rate may be restored after several passages, as EGFP expression attenuates^[63].

Mechanisms of baculovirus entry into mammalian cells Baculovirus enters insect cells via endocytosis followed by low pH-induced fusion of a viral envelope protein with the endosomal membrane, thus allowing viral entry into the cytoplasm and nucleus^[68]. Likewise, baculovirus is generally considered to follow the same route to enter mammalian cells, as gene expression is inhibited by lysosomotropic agents (eg, chloroquine), which block endosomal maturation^[43,44]. Initially it was suggested that the transduction is liver specific and the asialoglycoprotein could be involved in virus binding^[43,44]. However, van Loo *et al* showed that Pk1 cells, which do not express the asialoglycoprotein receptors, could be successfully transduced, thus asialoglycoprotein is not a key determinant^[48]. It was also shown that electrostatic interactions and the heparan sulfate moieties might be necessary for baculovirus binding to the mammalian cell surface^[69]. However, no follow-up report has confirmed their findings and the nature of the receptors remains unclear. In contrast, the viral envelope glycoprotein gp64 is shown to be essential for virus attachment and endosomal escape^[70]. Supporting this is the finding that a baculovirus over-expressing gp64 in addition to the endogenous copy of gp64 can incorporate approximately 1.5-fold the normal amount of gp64 on the virion surface and exhibit 10- to 100-fold more reporter gene expression in a variety of mammalian cells compared with similar viruses with a normal amount of gp64^[71]. In the same study, phospholipids on the cell surface are

Figure 1. Efficient transduction of human mesenchymal stem cells isolated from umbilical cord blood (A) and mesenchymal stem cells isolated from bone marrow (B) by a recombinant baculovirus expressing enhanced green fluorescent protein under the control of a cytomegalovirus promoter. The cells cultured on 6-well plates (5×10^5 cells/well) were transduced with 100 μ L unconcentrated virus (2×10^8 plaque forming units per milliliter) with 400 μ L phosphate-buffered saline as the surrounding solution for 4 h at 25 °C.

suggested to serve as an important docking point for gp64, thus facilitating viral entry into mammalian cells. By transient depletion of calcium using EGTA pretreatment, Bilello *et al* demonstrated that paracellular junction complexes are important for baculoviral entry into primary hepatocytes^[72].

It is generally assumed that the escape from the endosomes sets the block for transduction of some mammalian cells by baculovirus^[44,73]; however, a recent study showed that the transduction block lies not in the endosomal escape, but rather in the cytoplasmic trafficking or nuclear import of the virus capsids^[74]. In the cytoplasm, the nucleocapsids appear to induce formation of actin filaments, which probably facilitate the transport of viral nucleocapsids into the nucleus, as cytochalasin D strongly reduces the transduction efficiency but not the delivery of nucleocapsids to the cytoplasm^[48]. In contrast, we recently found that incubation of cells with PBS during transduction results in significantly higher virus entry and higher transduction efficiency compared with incubation with DMEM^[63], suggesting that virus internalization may be a bottleneck as well. Overall, the events responsible for virus uptake and detailed mechanisms of intracellular movement and nuclear entry of the virus are still largely unknown.

Baculovirus display The tropism and transduction efficiency of baculovirus has been manipulated by modifying the envelope protein. The modification can be performed by fusing a heterologous protein (or peptide) in-frame at the N-terminus of the gp64 gene under the control of a polyhedrin or p10 promoter. The fusion protein, after expression as an additional copy, is translocated to the plasma membrane and incorporated into the viral envelope on virus budding. Proof of this principle was first approached by fusing HIV-1 envelope proteins; the modified virus binds the CD4 receptor on T cells^[75]. A similar strategy has been applied to construct avidin-displaying baculovirus, which shows a 5-fold increase in transduction efficiency in rat malignant glioma cells and a 26-fold increase in rabbit aortic smooth muscle cells compared with the wild-type baculovirus^[76]. Baculovirus displaying heterologous envelope proteins, such as vesicular stomatitis virus G protein (VSVG), has also been constructed, which transduces human hepatoma and rat neuronal cells at efficiencies roughly 10- to 100-fold greater than baculovirus lacking VSVG^[73]. This pseudotyped virus also transduces cell lines that are transduced at very low levels or not at all by the unmodified baculovirus, thus broadening the tropism. The enhanced transduction efficiency and wider tropism are attributed to increasing transport of baculovirus DNA into nuclei rather than to increasing cell binding or virus uptake^[73]. In contrast, specific targeting of baculovirus to mam-

malian cells by displaying a single-chain antibody fragment specific for the carcinoembryonic antigen (CEA) or synthetic IgG binding domains is also demonstrated^[77,78]. In addition, the baculovirus display technology has been utilized to construct and screen a eukaryotic epitope library^[79]. In this context, the HIV-gp41 epitope "ELDKWA" specific for the neutralizing MAb 2F5 is inserted into the antigenic site of influenza virus hemagglutinin, flanked by additional random amino acids. This pool of hemagglutinin genes is cloned into baculovirus, and an individual clone displaying the epitope with markedly increased binding capacity out of a pool of 8000 variants is screened rapidly by fluorescence activated cell sorting.

Note, however, that the expression of gp64-fusion under the control of a late promoter may lead to a heterogeneous virus population that possesses various amounts of fusion protein and hence varied properties. This might be resolved by: (i) inserting the gp64 fusion gene into the genomic gp64 locus so that all gp64 copies contain the fusion partner; and (ii) expressing the gp64 fusion protein under an early promoter. More recently, baculovirus capsid display has also been developed in which the fusion can be made to the N- or C-terminus of the major capsid protein vp39 rather than to gp64 without compromising the viral titer or functionality^[74]. It has been demonstrated that the incorporation of green fluorescent protein (GFP) into the virus capsid does not interfere with the capsid assembly and allows for visualization of the virus biodistribution *in vivo*^[74]. This capsid-modified baculovirus holds great promise for the nuclear and subcellular targeting of the transgenes.

Viral vector generation and viral protein production

Thanks to the large DNA genome, recombinant baculovirus offers an attractive means for the production of other viral vectors for gene delivery/gene therapy purposes because the production of many viral vectors requires either plasmid transfection into producer cell lines or helper virus infection. For instance, all genes essential for replication and packaging of the adenoviral vector (38 kb) can be delivered and expressed by a single baculovirus, which is co-transfected with a plasmid vector harboring only the inverted terminal repeats (ITR) and packing signal of the wild-type virus as well as a reporter gene^[80]. The co-delivery results in the generation of a fully deleted adenovirus vector free of helper virus. This technique is also exploited for the production of adeno-associated virus (AAV), whose use is hampered by the lack of a simple and efficient vector production method. The mammalian producer cells are co-transduced with 3 viruses: 1 baculovirus harboring the reporter gene flanked by AAV ITR, 1 baculovirus expressing the AAV *rep* gene,

and a helper adenovirus expressing the AAV *cap* gene^[81]. The simultaneous delivery produces infectious recombinant AAV particles and constitutes an option for improving large-scale recombinant AAV vector production. Besides virus preparation, Ramos *et al* recently investigated the feasibility of using the baculovirus/mammalian cell system for protein production. They investigated two protocols for optimal cell culture and virus transduction and achieved volumetric yields for 3 secreted proteins (SAF-3-Fc, CD40-hexahis, and Asp 2-Fc) at 4 mg/L–25 mg/L^[82]. In our laboratory, the application of baculovirus is further expanded to the production of hepatitis delta virus (HDV) VLP. HDV can not replicate in cultured cell lines, and thus is difficult to propagate; therefore, studies of HDV particle assembly mainly rely on cDNA transfection, which suffers, however, from low efficiency and hinders subsequent structural and immunological studies of HDV VLP. We demonstrated that the co-transduction of hepatoma cell lines with 2 recombinant baculoviruses, one expressing hepatitis large delta antigen and another expressing hepatitis B surface antigen (HBsAg), leads to self-assembly and secretion of the HDV VLP^[83]. The yield (~150 ng HBsAg per mL in the secreted particle) is approximately 2-fold of that achieved by plasmid transfection. VLP synthesis has also been demonstrated in BHK cells and the process is transferred to a novel oscillating bioreactor for production on a larger scale^[84]. One bioreactor run (500 mL working volume) can yield over 400 µg HBsAg, which substantially increases the total particle yield and thus enables future structural and immunological studies of the VLP. In comparison with stable cell lines, the gene expression levels and the VLP composition can be easily manipulated simply by varying the virus concentration. In addition, the expressed proteins are obtained in a few days; therefore, this baculovirus/mammalian cell expression system may serve as a transient expression system for early evaluation of proteins of interest while stable cell lines are being generated and evaluated.

Studies of gene functions and viral infections Gene delivery into primary cells using transfection or electroporation either suffers from low efficiency or causes extensive membrane damage. Because baculovirus is generally non-toxic and non-replicative in mammalian cells, and the transduction efficiencies into various human primary cells are high, cell-based assays have been developed for gene function studies. Clay *et al* demonstrated that co-transduction of cells with 2 recombinant baculoviruses, one expressing an estrogen receptor and another expressing a reporter gene controlled by an estrogen receptor-responsive promoter, results in ligand-induced reporter gene activity, and this

approach is successfully applied to assay development in Saos-2 human osteosarcoma (HOS) cells^[85]. Similarly, a cell/cell fusion assay that mimics the HIV viral/cell fusion process was developed based on the baculovirus system^[86]. In the assay, HOS cells stably expressing CCR5, CD4, and LTR-luciferase serve as the recipient host cell. An HEK-293 cell line transduced with a baculovirus expressing the viral proteins gp120, gp41, tat, and rev represents the virus. Interaction of gp120 with CCR5/CD4 results in the fusion of 2 cells and transfer of tat to the cytoplasm of the HOS cell; tat, in turn, binds to the LTR region on the luciferase reporter and activates transcription, leading to an increase in cellular luciferase activity. This assay has been demonstrated to be a robust and reproducible high-throughput surrogate assay for evaluating the effects of compounds on gp120/CCR5/CD4-mediated viral fusion into host cells^[86]. This system could also facilitate the assessment of different promoters for their strength as well as temporal and spatial regulation across mammalian cells of different origins.

Similar to HDV, hepatitis B virus (HBV) and HCV are not capable of replication in cultured cells; thus, the evaluation of novel antiviral strategies have been hindered by the lack of a convenient and reliable *in vitro* culture system. To overcome this problem, recombinant baculoviruses are constructed to carry and deliver the genomes of HBV^[87] and HCV^[88] into hepatoma cells lines. With this approach, replication of HBV DNA and RNA, and expression of viral genes are detected^[87]. Viral replication is evidenced by the presence of high levels of intracellular replicative intermediates and protected HBV DNA in the medium. The successful HBV replication thus allows for the establishment of a highly flexible system for studying: (i) the effects of (-)-β-2',3'-dideoxy-3'-thiacytidine on HBV replication and accumulation of covalently closed circular DNA^[89]; and (ii) the cross-resistance profiles of HBV mutants against antihepadnaviral compounds^[90]. The HCV full-length and minigenome under the tetracycline-inducible promoter are also delivered into HepG2 cells and regulable transcription and viral polypeptide processing are demonstrated^[91], thus providing a novel tool for the analysis of HCV replication and host-cell interactions.

Generation of stable cell lines Normally, baculovirus-mediated gene expression lasts approximately 1–2 weeks as a result of cell division. The gradual extinction of transgene expression is also attributed to the degradation of baculoviral DNA, as degradation has been revealed in hepatoma cells^[83] and articular chondrocytes^[51]. However, it was found that transduction of CHO cells with a baculovirus expressing neomycin phosphotransferase results in the isolation of CHO

cells stably expressing GFP by selection using the antibiotic G418^[53]. The frequency of G418 resistant colony formation is approximately 1 in 50–100 of the transduced cells. The same group further confirmed that discrete portions of baculovirus DNA are randomly integrated as single-copy fragments ranging in size from 5 kb to 18 kb^[92]. Periodic assays on the stable clones show no loss of transgene expression over a 5 month period. Coupled with high transduction efficiency, the high frequency of emergence of stable transductants makes baculovirus a valuable tool to derive human cell lines that are either difficult to isolate in large numbers or are difficult to transfect by other methods.

In vivo gene therapy Thanks to highly efficient gene delivery, baculovirus has captured increasing interest as a vector for *in vitro* and *in vivo* gene delivery. However, reports of successful *in vivo* applications are limited. The complement system appears to be a potent barrier for *in vivo* gene therapy because the efficiency of gene transfer into hepatocytes of complement-deficient mice is greatly enhanced^[70]. Inactivation of baculovirus in human plasma and whole blood is prevented by treatment with cobra venom factor^[93]. An alternative approach is adopted by avoiding contact of baculovirus vectors with blood components. By using a silastic collar, transduction of adventitial cells in rabbit carotid arteries is achieved and the efficiencies are comparable to those obtained with adenoviral vectors^[94]. The gene expression is transient and the arterial structure and endothelium remain intact after baculovirus transduction, although signs of inflammation are detected. Unmodified baculovirus vectors have also been injected into the rodent brain where the complement proteins may not reach in the presence of an intact blood-brain barrier and/or the complement level in the brain is insufficient to affect the gene transfer^[95]. After *in vivo* injection into the brain, baculovirus specifically transduces the epithelium of the choroids plexus in ventricles and the transduction efficiency is as high as 76%±14%; thus, baculovirus seems to be especially useful for the targeting of choroids plexus cells^[95].

A more cutting-edge approach to alleviate the complement inactivation problem is the generation of complement-resistant baculovirus by displaying decay-accelerating factor, a regulator that blocks complement at the central step of both the classical and alternative pathways^[96]. Such a complement-resistant baculovirus vector expressing additional human coagulation factor IX (hFIX) allows for a substantial improvement of gene transfer into complement-sufficient neonatal rats *in vivo* after local injection into the liver parenchyma. Gene expression is transient probably as a result of the generation of antibodies directed against the

transgene product hFIX, which might lead to clearance of either expressed hFIX protein and/or positively transduced cells. Alternatively, baculovirus can be pseudotyped by displaying VSVG on the envelope. The VSVG-modified virus enhances gene transfer efficiencies into mouse skeletal muscle *in vivo* and the transgene expression lasts 178 d in DBA/2J mice and 35 d in BALB/c and C57BL/6 mice^[97]. The VSVG-modified baculovirus also exhibits greater resistance to inactivation by animal sera and can transduce the cerebral cortex and testis of mice by direct inoculation *in vivo*^[61].

Another potential barrier may be the presence of heparin or heparin-like factors, which block baculovirus-mediated gene delivery in cell culture^[93]. Intercellular junctions may be an additional hurdle because transient disruption of these junctions by EDTA treatment prior to transduction improves the gene delivery efficiency into long-term cultures of primary hepatocytes but does not lead to permanent alterations in hepatocyte ultrastructure, albumin mRNA, and protein expression profiles^[98]. Their studies also suggest the importance of the basolateral surface for virus entry at least for some cell types^[72]. In our laboratory, however, the transient disruption of cell junctions fails to effectively enhance the baculovirus-mediated gene transfer into chondrocytes and HepG2 cells that are cultured to over-confluence, implying that other factors in addition to the paracellular junction complexes might be involved in the transduction of these cells.

Another problem associated with baculovirus as a gene delivery vector is that purification by ultracentrifugation often leads to virus aggregation^[99]. In addition, the ultracentrifugation process is time-consuming, labor intensive, and difficult to scale up. To resolve these problems, we construct a recombinant baculovirus with a hexahistidine (His₆) tag displayed on the viral envelope, which enables virus purification by a simple immobilized metal affinity chromatography with high purity (~87%). This methodology obviates the need for successive ultracentrifugation steps^[100] and may be employed to purify other viral vectors for gene therapy studies.

Ex vivo gene therapy To date, most gene therapy studies using baculovirus vectors have focused on *in vivo* experiments, yet relatively little is known about the potential of baculovirus for *ex vivo* therapy. One relevant report was published by Sandig *et al*^[101] who established an *ex vivo* perfusion model for human liver segments. The recombinant baculovirus is perfused through the liver segments for 15 min and reasonable transduction rates are achieved in all perfused parts of the liver tissue. This study verifies for the first time that baculovirus-mediated gene transfer is pos-

sible in the liver tissue and encourages future studies including *in situ* perfusion of intact livers with baculovirus vectors in animal models.

Recently, we have also demonstrated the highly efficient baculovirus-mediated gene transfer into articular chondrocytes^[51] and human MSC^[63], both being candidate cell sources for cartilage tissue engineering. Importantly, normal differentiation states of chondrocytes and MSC are retained on baculovirus transduction. Our experiments regarding MSC suggest that the phenotypic changes along the adipogenic differentiation pathway positively influence the baculovirus transduction and may implicate two possible applications: (i) MSC may be transduced with baculovirus expressing specific factors (eg b-FGF or BMP-2) to promote the expansion or regulate the differentiation via autocrine and paracrine effects of the factors so that supplementation of these factors in the medium may be omitted; and (ii) differentiation of MSC towards a specific lineage pathway may be induced first and the committed progenitor cells can be transduced *ex vivo* by the recombinant baculovirus expressing appropriate growth factors (eg TGF β 1 or IGF-1), seeded onto polymeric scaffolds, and implanted into animal models for tissue regeneration. Although sustained transgene expression is restricted by the degradation of baculoviral DNA within the cells, the non-replication and degradation characteristics prove that baculovirus may be a safe gene delivery vehicle for tissue engineering in which long-term expression is not critical.

Immunological response and potential as a vaccine vector Host responses to baculovirus uptake, either *in vitro* or *in vivo*, were not evaluated until Gronowski *et al* reported that administration of baculovirus *in vitro* induces interferon (IFN) production from human and murine cell lines and induces *in vivo* protection of mice from encephalomyocarditis virus infection^[102]. A more recent study discovered that the presence of baculovirus disrupts the phenobarbital gene induction, a potent transcriptional activation event characteristic of highly differentiated hepatocytes, and represses expression of the albumin gene, but neither cAMP nor PKA activities are affected by the virus^[102]. Baculovirus transduction also induces expression of cytokines such as TNF- α , IL-1 α , and IL-1 β in primary hepatocytes^[103]. These findings raise concerns as to whether these properties will compromise the use of baculovirus vectors for *in vivo* gene therapy in humans, and more investigations will be needed to ensure the safety of baculovirus vectors. Despite these, the ability of baculovirus to induce immune responses has been exploited by Abe *et al*, who found that intranasal inoculation with a wild-type baculovirus elicits a strong innate immune

response that protects mice from a lethal challenge of influenza virus^[104]. The feasibility of using baculovirus as a vaccine carrier was also demonstrated by Aoki *et al*^[105], who found that a recombinant baculovirus expressing glycoprotein gB of pseudorabies virus induces antibodies against gB protein in mice, thus suggesting that this recombinant baculovirus could serve as a vaccine candidate for pseudorabies. Similarly, *in vivo* administration of a baculovirus expressing hFIX elicits antibodies against hFIX. The antibody titers are proportional to the amount of protein produced by the virus^[96]. More recently, Facciabene *et al* demonstrated that the intramuscular injection of a baculovirus expressing CEA induces measurable anti-CEA-specific CD4⁺ T-cell response^[106]. The immunogenic property of baculovirus is not restricted to CEA because the intramuscular injection of another baculovirus (Bac-E2) expressing E2 glycoprotein of HCV induces anti-E2 CD8⁺ T-cell response^[106]. Interestingly, when Bac-E2 is pseudotyped to display VSVG on the envelope, the minimal dose required to elicit a measurable T-cell response is 10-fold less, indicating that the VSVG-pseudotyped Bac-E2 appears to be a more potent immunogen than the unmodified virus. This finding agrees with the previous statement that baculovirus displaying VSVG confers a more efficient immunogen expression in transduced cells.

It is also likely that baculovirus can mediate an immune response against an antigen when it is displayed on the viral surface. In this regard, the immunodominant antigenic site of foot-and-mouth disease virus (FMDV) has been displayed on the baculovirus envelope^[107], which is able to bind a panel of FMDV-specific MAbs and indicates the preservation of antigenic epitopes on the virus envelope. A more recent study further showed that immunization with adjuvant-free baculovirus displaying rodent malaria *Plasmodium berghei* circumsporozoite protein (PbCSP) on the envelope induces high levels of antibodies and γ -interferon-secreting cells against PbCSP, and protects 60% of mice against sporozoite challenge^[108]. These studies substantiate the potential of baculovirus displaying immunogens as a vaccine candidate.

Conclusions and future prospects

The values of baculovirus for recombinant protein expression in insect cells have long been proven. The extremely high yield by baculovirus-infected insect cells or larvae makes it an attractive tool for pharmaceutical protein production. Despite its inability to process some proteins correctly, rapid advances in cell engineering may overcome these drawbacks and render baculovirus a proper system for

large-scale protein production. To the best of my knowledge, no insect cell-derived recombinant protein has gained official approval from the US Food and Drug Administration. Nonetheless, more and more proteins are produced in insect cells in the preclinical stage. Particularly promising is the field of viral vaccines, where the formation of virus-mimicking multimers can be essential for eliciting protective immune responses. An HCV vaccine might be the first human therapeutic expressed in insect cells^[109].

The broad range of susceptible mammalian cells, coupled with its non-toxic and non-replication nature, makes baculovirus a useful tool for studying the expression and function of gene products. As a gene therapy vector, baculovirus possesses the following extra advantages: (i) the AcMNPV genome is large, thus rendering the virus flexible to carry multiple genes or large inserts; (ii) recombinant baculoviruses are easy to construct and produce to high titers simply by infecting insect cells; and (iii) the purification of baculovirus can be readily performed by ultracentrifugation^[110] or, alternatively, by a newly developed affinity chromatographic technique^[100]. The last two features greatly simplify the large-scale preparation of high titer baculoviral vectors. In addition to therapeutic genes, baculovirus may serve as a promising vector for the delivery of cDNA of infectious RNA viruses towards antisense therapy approaches. The same concept may be applied to the delivery of siRNA to silence specific target genes. The combination of *ex vivo* gene transfer and tissue engineering holds great promise as well. One bottleneck to the application of baculovirus lies in the short duration of transgene expression. This may be overcome by selecting a proper promoter that is not silenced, and developing a proper superinfection protocol that can effectively deliver fresh genes into cells. The baculovirus may also be applied in conjunction with other viral vectors to escape either pre-existing or therapy-induced antiviral immunity. In summary, baculovirus can be used as an efficient vector for gene delivery into insect and mammalian cells for a wide variety of applications.

Abstract

Aim: To investigate the effect of gabapentin on neural [neuron-specific enolase (NSE)] and glial markers [glial fibrillary acidic protein (GFAP) and S100B] in different brain regions of diabetic rats. **Methods:** Diabetes was induced by a single intraperitoneal injection of streptozotocine (50 mg/kg body weight). Rats in one diabetic group received gabapentin (50 mg·kg⁻¹·d⁻¹) and rats in the other diabetic group received vehicle only for 6 weeks. The levels of GFAP, S100B, and NSE were determined by immunoblotting in the hippocampus, cortex, and cerebellum. Lipid peroxidation (LPO as malondialdehyde+ 4-hydroxyalkenals) and glutathione (GSH) levels were also determined in the same brain parts. **Results:** Total and degraded GFAP content and S100B protein expression in different areas of brain tissues significantly increased in diabetic rats compared to control rats. Similarly, NSE levels were also significantly elevated in hyperglycemic rats. In addition, there was a significant increase in LPO levels in the diabetic rat brain compared to control rat brains. Pretreatment with gabapentin prevented the upregulation of GFAP, S100B, and NSE in all brain regions of diabetic rats. The level of LPO was reduced, but not completely halted, by treatment with gabapentin. **Conclusion:** These results suggest that diabetes causes glial and neuronal injury, possibly as a result of elevated oxidative stress, and that gabapentin protects neurons and glial cells. Thus, we predict that gabapentin treatment will attenuate the hippocampal and cortical neurodegeneration observed during diabetes mellitus in rats.

Introduction

Diabetes mellitus is a common metabolic disorder that affects the peripheral as well as the central nervous system. Animal models of diabetes can make an important contribution to understanding the pathology of the effects of diabetes on the brain. Hyperglycemia provides more substrate for anaerobic glycolysis in the brain, resulting in lactic acidosis and enhanced damage to both glial and neuronal cells^[1]. Furthermore, enhanced formation of oxygen free radicals occurs in the tissues during hyperglycemia^[2]. These oxidant radicals also contribute to increased neuronal death by oxidizing proteins damaging DNA and inducing the lipoperoxidation of cellular membranes^[3].

One of the complications of diabetes is neuropathy. Gabapentin (GBP) is used to treat diabetic neuropathy. GBP is an anticonvulsant that reduces pain in peripheral neuropathy, including diabetic neuropathy^[4]. GBP is a hydrophilic analogue of the inhibitory neurotransmitter gamma aminobutyric acid (GABA). It readily penetrates the blood-brain barrier via an L-system amino acid transporter system^[5]. In addition, GBP has been shown to be neuroprotective in animals^[6]. However, to date, no study has examined the effects of GBP on neural and glial markers.

S100B and neuron-specific enolase protein (NSE), distributed mainly in the central nervous system, can provide qualitative information about the extent of brain injury and are sensitive markers of brain damage after stroke and cere-

bral hypoxia^[7,8]. NSE is a glycolytic enzyme that is a soluble cytoplasmic protein localized principally in neurons. Recent evidence has shown that NSE is a marker of neuronal damage following cerebral ischemia^[8,9]. S100B is an acidic Ca²⁺ binding protein, present mainly in astrocytes, that exerts paracrine trophic effects on several neuronal populations^[10]. Brain injury causes a selective leakage of S100B into the cerebrospinal fluid and blood so that serum S100B levels were found to be good indicators for the assessment of patients with cerebral ischemia^[11,12].

Glial fibrillary acidic protein (GFAP) is another astrocytic marker. GFAP is an intracellular intermediate filament protein of glial cells. It has been suggested that GFAP is essential for the formation of stable astrocytic processes in response to neuronal damage and this may be critical for morphogenesis of the central nervous system^[13]. Chemical or mechanical insults to the brain cause permanent changes, with astrocytes responding via a variety of reactions called reactive gliosis^[14]. A key indicator of glial reactivity is the increased synthesis of GFAP. Increases in GFAP are commonly used to examine the distributions of glial cells in response to neural injury^[14,15]. Recently, we have demonstrated that streptozotocine (STZ)-induced diabetes causes reactive gliosis^[15,16]. In the present study we aimed to examine the effects of GBP on neural and glial markers in STZ-induced diabetic rats.

Materials and methods

Sixty adult male Wistar rats (Animal Research Unit, Firat University, Elazig, Turkey) weighing 200–250 g were used in this study. The rats were housed in a temperature-controlled room (22–25 °C) with a 12/12 h light/dark cycle. Water and food were given *ad libitum*. Animals were assigned into a diabetic group ($n=30$) or an age-matched control group ($n=30$). Diabetes was induced by a single intraperitoneal (ip) injection of 50 mg/kg body weight STZ. STZ (Sigma Chemical Company, St Louis, MO, USA) was dissolved in sodium citrate buffer (pH 4.5). Blood glucose concentrations were determined 3 d after STZ injection. Rats with a blood glucose concentration above 250 mg/dL were declared diabetic. Diabetic rats were randomly assigned to two groups: the first group received GBP (Sigma) diluted in sterile physiological saline and administered ip (50 mg·kg⁻¹·d⁻¹) in a volume of 1 mL/kg. (STZ-GBP group, $n=15$). The second group received the vehicle alone (STZ group; $n=15$). Control rats were injected with the vehicle alone ($n=15$) or with the same dose of GBP (GBP group; $n=15$). Each animal's body weight and diabetic state were reassessed after 6 weeks just prior to

killing the animals. All animals were killed by decapitation after 5 weeks of treatment by GBP. The brain tissues were removed; the hippocampus, cortex, and cerebellum were dissected. Samples were used fresh or kept at -70 °C. All protocols described were reviewed and approved by the local Institutional Committee for the Ethical Use of Animals.

Western blotting Tissue samples were homogenized in Tris-HCl 10 mmol/L (pH 7.4), NaCl 0.1 mmol/L, phenylmethylsulphonyl fluoride 0.2 mmol/L, edetic acid 5 mmol/L, β -mercaptoethanol 2 mmol/L, and 1% Triton X-100 containing proteinase inhibitors, and centrifuged at 40 000×g at 4 °C for 60 min. Supernatants were collected, aliquoted, and stored at -70 °C until required.

Sodium dodecyl sulfate (SDS)-polyacrylamide gradient gel electrophoresis was carried out as previously described^[17]. Samples and standard protein markers were submitted to the SDS-polyacrylamide gradient gel and the separated proteins were transferred to nitrocellulose filters (Schleicher & Schuell Incorporated, Keene, NH, USA). Non-specific binding was blocked by incubation with 1% bovine serum albumin. The blots were then incubated with primary antibodies (Santa Cruz Biotechnology Incorporated, Santa Cruz, CA, USA) as follows: GFAP 1:2 000; S100 1:1000; NSE 1:1000. After a 1-h incubation the blots were washed extensively in TBS-Tween (Tris-HCl 25 mmol/L, NaCl 0.2 mmol/L, 0.1% Tween-20). The blots were then incubated for 1 h with a secondary antibody, a goat anti-rabbit Ig peroxidase conjugated (Sigma, Dorset, UK). Specific binding was detected using diaminobenzidine and H₂O₂ as the substrates. The relative amounts of immunoreactive GFAP, S100B, and NSE were quantified in arbitrary units by scanning blots using a computerized software program (LabWorks 4.0; UVP Incorporated, Cambridge, UK).

Levels of tissue protein, glutathione, and LPO Protein determinations were carried out according to the Lowry procedure using a protein assay kit (Sigma Chemical Company, Deisenhofen, Germany). Tissue lipid peroxidation (malondialdehyde+4-hydroxyalkenals) was determined using a LPO-586 kit (Oxis International Incorporated, Corvallis, OR, USA); the method is based on the reaction of *N*-methyl-2-phenylindole with malondialdehyde and 4-hydroxyalkenals at 45 °C. Glutathione (GSH) levels were determined using the method of Ellman^[18]. Tissue homogenates were centrifuged with 5% trichloroacetic acid to centrifuge out the proteins. Two milliliters of phosphate buffer, 0.5 mL of 5,5' dithiobis (2-nitrobenzoic acid) and 0.4 mL of distilled water was added to 0.1 mL of this homogenate. The mixture was vortexed and the absorbance was read at 412 nm.

Statistical analysis Results were expressed as mean±SD and significant differences between groups were evaluated

using ANVOA followed by a *post-hoc* Bonferroni test. A level of significance of $P<0.05$ was considered to be statistically significant.

Results

Estimation of glial and neuronal markers A common marker for reactive gliosis is an increase in GFAP. GFAP showed many immunopositive protein bands with relative molecular weights of 49 kDa (main band) and several small molecular weight bands at roughly 42–47 kDa (degraded product of GFAP), respectively (Figure 1). Although Western blot measurement of brain 49 kDa GFAP contents after 6 weeks of STZ-induced diabetes showed no significant difference, the amount of degraded GFAP product increased significantly compared with the non-diabetic controls. The beneficial effects of the repeated administration of GBP were

Figure 1. Western blot analysis of GFAP protein from hippocampal, cortical, and cerebellar homogenates of control, STZ, and GBP groups. H, hippocampus; Cor, cortex; Cer, cerebellum.

manifested by downregulation of the degradation products of GFAP (Figure 1, Table 1).

The immunoblots of the brain homogenates showed a single S100B-immunoreactive polypeptide band with a molecular weight of approximately 11 kDa. The levels of S100B protein in the hippocampus, cortex, and cerebellum were significantly higher in STZ-treated rats than that in the control group. Similarly, GBP prevented the increase of S100B protein in all studied brain areas (Figure 2, Table 1).

Figure 2. Western blot detection of S100B protein from the hippocampus, cortex, and cerebellum of control, STZ, and GBP groups. H, hippocampus; Cor, cortex; Cer, cerebellum.

In the brain regions of STZ-treated rats, the NSE contents showed a significant increase compared with the controls. Similarly to GFAP and S100B, NSE levels were reduced by treatment with GBP (Figure 3, Table 1).

Estimation of LPO and GSH Likewise, STZ-induced diabetes led to a marked elevation in the levels of malondialdehyde+4-hydroxyalkenals in the cortex, hippocampus, and

au, arbitrary units; GBP, gabapentin; LPO, lipid peroxidation as malondialdehyde plus 4-hydroxyalkenals; STZ, streptozotocine.

Figure 3. Western blot of NSE protein from the hippocampus, cortex, and cerebellum of control, STZ, and GBP groups. H, hippocampus; Cor, cortex; Cer, cerebellum.

cerebellum compared with the control group. A significant positive correlation was found between the levels of malondialdehyde +4-hydroxyalkenals and the GFAP contents in the cortex and hippocampus ($r=0.625$, $P<0.01$; $r=0.604$, $P<0.01$, respectively). Treatment with GBP significantly reduced the levels of malondialdehyde+4-hydroxyalkenals in the brain homogenates of diabetic rats compared to the controls (Table 1).

In the present study we measured the amount of GSH in the homogenates of cortex, hippocampus and cerebellum. In each of these brain parts, the levels of GSH were lower in the STZ-diabetic rats than in the control animals. Treatment with GBP led to a slight but non-significant reduction in the levels of GSH compared with the levels in the STZ group (Table 1).

Discussion

In the experiment reported here, we investigated the effects of GBP on glial and neuronal markers in different brain regions of diabetic rats. We found that diabetes induced overexpression in both glial and neuronal markers and GBP prevented the elevation of these markers. Interestingly, treatment with GBP did not change the levels of both neuronal and glial markers in non-diabetic rats. Furthermore, GBP treatment moderately inhibited, but did not completely reverse, the elevation in LPO induced by STZ diabetes. GFAP and S100B can be trophic or toxic depending on their concentrations. Over production of both glial markers causes glial and neuronal death, whereas in low concentrations they can act as neurotrophic factors, which may be important during both development and nerve regeneration^[19,20].

Herein we report a new role for GBP that is associated with neuroprotection. These data provide the first indication that GBP regulates the expression of neural and glial markers. Although the mechanism of action of GBP was not specifically investigated in this study, the present findings provide some clues.

It has been reported that GBP is neuroprotective in chronic neural diseases^[21]. Current findings appear to support this idea. The mechanism by which GBP reduced LPO

levels and inhibited the expression of neuronal and glial markers is not known. This process may occur through a free radical mediated pathway. Tissue damage is observed during untreated diabetes with very high glucose levels and this is attributed to oxidative injury resulting from the production of free radicals^[22]. One of the consequences of such damage is the depletion of the cellular antioxidant, GSH. A decreased defense system against free radicals and elevated glutamatergic activity in diabetes may cause glial sensitivity^[23]. Diabetes-related sensitivity to oxidative stress of astrocytes makes neurons more susceptible to injury. Neuronal and glial injury leads to the over production of NSE, GFAP, and S100B. In agreement with the present findings we recently hypothesized that glial reactivity was closely related to the oxidative environment^[15].

The current results show that treatment with GBP significantly prevents glial reactivity by reducing the over production of GFAP and S100B. Similarly GBP inhibited the elevation of NSE, a neuronal marker. The exact mechanism by which GBP inhibits reactive gliosis is not entirely clear; however, one possible explanation is that GBP may reduce oxidative stress via an unknown mechanism. Oxidative stress is known to exacerbate glial reactivity^[15,16]. Decreased LPO levels as a result of GBP treatment in the present study supports this explanation.

Hyperglycemia causes a reduction in extracellular GABA, which exacerbates neuronal injury by reducing generalized neuroinhibition^[23,24]. Reduced GABAergic action in the cerebral cortex in diabetes has been shown to be increased by GBP treatment^[25]. Several investigations have confirmed that GBP has the ability to increase the GABA content of the brain, influence GABA receptor activity, and exhibit anticonvulsant activity^[26,27]. An increase in GABAergic activity by GBP would promote inhibitory neurotransmission in the central nervous system. This is a potent mechanism by which GBP acts as a neuroprotector.

The other possible explanation for the effect of GBP is a drug-induced decrease in glutamatergic neurotransmission^[28]. Glutamate neurotoxicity has been implicated in the neurodegeneration associated with several neurodegenerative diseases. Diabetes may increase the release of glutamate and activate NMDA receptors^[29]. Glutamate causes a transmembrane ion imbalance, in particular a calcium influx, which in turn generates reactive oxygen species. These free radicals actively attack macromolecules within neuron and glial cells, resulting in structural and functional changes in proteins. Glial cells respond to the oxidative insult by producing GFAP and S100B^[30,31]. The present findings are in agreement with recent reports that clearly show that reactive

gliosis occurs in diabetes, possibly as a result of oxidative stress. This is consistent with our previous studies in diabetic rats in which the protective effects of antioxidants against reactive gliosis were attributed to their free radical scavenging properties^[15,16]. As we previously described, antioxidant vitamin E^[32] and melatonin^[15] treatment improved reactive gliosis induced by hyperglycemia via a dramatic reduction in oxidative stress. Compared with antioxidants, the effect of GBP on oxidative stress is considerably more modest. The present results suggest that GBP prevents reactive gliosis and oxidative stress in an indirect way, possibly by reducing glutamate neurotoxicity, which causes free radical production in brain tissue. Previous studies have shown that repeated administration of GBP inhibits excitatory glutamatergic neurotransmission via direct blockage of excitatory receptors or alteration of glutamate metabolism or release^[32]. In the present study we have shown that the production of glial and neuronal markers is increased in the brain by hyperglycemia and that this increase is attenuated by treatment with GBP. Thus, we predict that GBP treatment will attenuate the hippocampal and cortical neurodegeneration observed during diabetes mellitus in rats.

Abstract

Aim: To determine the role of dietary low histamine on the seizure development of pentylenetetrazol (PTZ)-induced kindling in rats. **Methods:** After 14 d of feeding on a low histamine diet (LH, containing 0.145 $\mu\text{mol/g}$ of histamine), the rats were chemically kindled by repeated intraperitoneal injection of a subconvulsant dose of PTZ (35 mg/kg) once every 48 h, and seizure activity of kindling was recorded for 30 min. Histamine in brain samples was analyzed using a high performance liquid chromatography system with a fluorescence spectrofluorometer. **Results:** The LH diet induced an increase in seizure response (seizure susceptibility) to the first trial of PTZ, and resulted in facilitation of subsequent PTZ kindling process (seizure development). The histamine levels in the cortex, hippocampus, and hypothalamus of LH-treated rats decreased significantly and these changes correlated well with seizure behavior ($r=0.875, 0.651, \text{ and } 0.796$, respectively). In addition, chronic kindled seizures resulted in a significant increase of the histamine content in the cortex and hypothalamus in the LH-fed groups. **Conclusion:** These findings indicate that the histamine in daily food could influence the brain histaminergic function, and play an important role in regulating seizure susceptibility.

Introduction

Since Churchill first described certain antihistaminics enhance epileptic extent^[1], a number of studies have indicated that brain histamine is involved in mechanisms regulating seizure susceptibility, and the anticonvulsant action of histamine has been well documented^[2–5]. Histamine increases the threshold for amygdaloid kindling and pentylenetetrazol (PTZ)-induced seizures^[6,7]. A marked increase in α_1 -receptor binding has been observed around the epileptic foci of complex partial seizures and may be involved in inhibiting the spread of seizure activity^[8]. In addition, we have recently reported severe seizure development of PTZ-induced kindling in H_1 receptor knockout mice (H_1R KO) and histidine decarboxylase-deficient ($HDC^{-/-}$) mice^[9].

It has recently been reported that long-term treatment with high histamine level diets could increase brain histamine levels in $HDC^{-/-}$ mice, which lack the ability to synthesize hista-

mine^[11,12]. These results suggest that histamine can be absorbed from the digestive tract and distributed to the brain^[12]; furthermore, histamine levels in various diets might influence the histaminergic system and so affect certain neuronal functions, such as epilepsy. Yet, so far there is only limited information about the effects of dietary histamine on these neurotransmitters.

Kindling has been accepted as an experimental animal model for analyzing epilepsy and epileptogenesis, and estimating the effectiveness of antiepileptic drugs. It is generally known that PTZ-induced kindling creates proconvulsant and convulsant effects in rodents, and is considered as an adequate model of human absence epilepsy and myoclonic, generalized tonic-clonic seizure^[13]. We therefore designed the present study to further elucidate the possible relationship between the appearance of seizures and histamine in daily diet.

Materials and methods

Animals Male Sprague-Dawley rats (4–5 weeks old) were purchased from Japan SLC (Shizuoka, Japan), and were maintained in individual cages under constant temperature (22–24 °C) and humidity (40%–70%) with a 12-h light/dark cycle (lights on from 6:00 AM–18:00 PM). The rats were fed with basal histamine diets (BH, containing 79.6 nmol/g of histamine, Nihon Nosan Kogyo KK, Yokohama, Japan) or low histamine diets (LH, containing 1.45 nmol/g of histamine, Ver 3 from Nihon Nosan Kogyo KK, Yokohama, Japan), and water was given *ad libitum*. Behavioral studies were carried out each day between 10.00 AM and 17.00 PM. All experiments were carried out in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals.

Chemical kindling After 2 weeks of LH feeding, the rodents were intraperitoneally injected with PTZ (35 mg/kg) every 48 h until the animals were fully kindled^[4,5,14]. After PTZ injections, the seizure intensity was scored for 30 min using the following scale: Stage 0, no response; Stage 1, ear and facial twitching; Stage 2, myoclonic body jerks; Stage 3, clonic forelimb convulsions; Stage 4, generalized clonic convulsions, turn over on to side position; Stage 5, generalized clonic-tonic convulsions or died within 30 min. In addition, the latency to the onset of myoclonic jerks were measured and analyzed statistically. In the absence of seizures within 30 min, the latency was taken as 1800 s. When the rat had a seizure score of 4 or 5 at three consecutive injections, it was defined as fully kindled.

Measurements of brain histamine The rodents were killed by decapitation. The brain was quickly removed, and placed on an ice-cold stainless steel plate, and dissected according to the methods of Glowinski and Iversen^[15]. These tissues were stored at -80 °C until assayed. The brain tissue was weighed and homogenized in 3% perchloric acid. The homogenate was centrifuged at 15 000×g for 20 min at 4 °C to obtain a clear supernatant. After filtration (0.22 μm), histamine was analyzed fluorometrically with *o*-phthalaldehyde after separation on an HPLC system (CCP & 8010 series, Tosoh, Tokyo, Japan, particle size 5 μm). The fluorescence intensity was measured at 450 nm with excitation at 360 nm in a spectrofluorometer (model C-R3A, Shimadzu, Kyoto, Japan)^[9,10].

Statistical analysis All data were expressed as mean±SEM. One-way analysis of variance with Dunnett's test was used for calculating a significant difference. Statistical significance was set at $P<0.05$.

Results

Effects of LH diet on seizure development induced by PTZ-kindling After 2 weeks on a LH diet, compared with BH, histamine levels significantly decreased in the cortex (23.2%), hippocampus (16.5%), and hypothalamus (43.7%) ($P<0.05$) (Figure 1). Rats fed with the LH diet for 2 weeks showed greatly enhanced development of PTZ-induced kindled seizures (Figure 2). They were fully kindled through less chemical stimuli compared with those fed with the BH diet. Rats fed with the LH diet and control rats fed with the BH diet became fully kindled at d 8 and d 14, respectively. In addition, rats fed with the LH exhibited more severe seizure stages than rats fed with the BH diet ($P<0.05$ for the first 8 d of PTZ injection). The latency to the onset of seizures was also significantly shorter in the LH group ($P<0.05$ for the first 3 d of PTZ injection).

Figure 1. Changes of histamine levels in the brain of rats after 2 weeks on the LH diet. BH: basal histamine diets; LH: laohistamine diets. $n=10-12$. Mean±SEM. ^b $P<0.05$ vs BH-fed group.

Correlation between the decrease in brain histamine levels and the increase in seizure stage after the first PTZ injection To investigate the relationship between the increase in seizure scores and the decrease in the histamine levels in the brain induced by the LH diet, the regression line of Y (decrease in histamine levels of the cortex, hippocampus, and hypothalamus) on X (increase in seizure scores) and the correlation coefficient (r) were calculated (Figure 3). The correlation coefficients of the cortex, hippocampus, and hypothalamus were 0.875, 0.651, and 0.796, respectively.

Effects of chronic kindled seizures on levels of histamine in the brain of rats Twenty-four hours after fully kindled, the rats were killed by decapitation. The histamine in the brain tissues was measured. Compared with control rats fed

Figure 2. Effects of LH diet on seizure development induced by PTZ-kindling. *n*=15–16 rats. Mean±SEM. ^b*P*<0.05 vs BH-fed group.

Figure 3. Correlation between the decrease in brain histamine levels and the increase in the scores of seizure stage after the first PTZ injection. *n*=9. Mean±SEM.

Figure 4. Effect of chronic PTZ administration on brain histamine levels in rats fed with the LH diet. *n*=10–11. Mean±SEM. ^b*P*<0.05 vs the control group.

the LH diet without PTZ treatment, chronic PTZ kindled elicited significant increases in histamine levels both in the cortex (137.6%) and hypothalamus (195.7%), but not in the hippocampus (Figure 4).

Discussion

The interactions between histamine levels in food and normal physiological functions have recently excited interest^[11,12]. This study provides the first evidence that dietary histamine affects the onset and development of seizures induced by chronic PTZ kindling in rats. Relative to BH diets, LH diets significantly augmented the onset of seizures induced by chronic PTZ-kindling, and further resulted in facilitation of subsequent PTZ kindling process. Meanwhile, significant decreases in histamine levels in the cortex,

hippocampus, and hypothalamus were observed following the 2-week LH diets. Interestingly, a strong correlation was found between decreased histamine levels in the cortex and hypothalamus and increased seizure scores following PTZ treatment. It is therefore likely that the reduced histamine plays an important role in the seizure susceptibility. We previously reported that α -fluoromethylhistidine, an inhibitor of HDC, accelerates seizure development induced by PTZ-kindling in rats^[4].

The chronic kindled seizures markedly increased histamine levels in the cortex and hypothalamus in rats fed with the LH diet. It has been reported that increased histamine levels in the cortex and hypothalamus are induced by PTZ kindling seizures in H1R KO mice^[9], and by maximal electroshock in mice^[16]. However, the histamine levels significantly decrease in the amygdala of electrical stimulation site after the development of amygdaloid kindling^[6,17,18] and in the cortex and hypothalamus following acute PTZ kindled seizure^[16]. These differences might be due to variations in the experimental methods, the species used, drug dosages, or routes of administration. PTZ kindling is the animal model for human primary generalized (or absence) epilepsy. Our data at least suggest that the chronic development of this epileptic seizure is different from the acute one^[16], and other epilepsy styles, such as temporal lobe epilepsy, generalized seizure, and so on^[16,17]. At present, we have no explanation for why chronic kindling could increase histamine levels in rats fed with LH diets. Further experiments are needed to elucidate its mechanism. An increase in histamine levels in the cortex and hypothalamus might reflect a compensating and protective physiological mechanism after long-term low levels of histamine induced by LH diets. These results further support the concept of histamine as an endogenous anticonvulsant.

An interesting finding in the present study is that there was no significant changes of histamine levels in the hippocampus in the fully PTZ-kindled rats. This suggests that once it is fully kindled by PTZ, the type of seizure is less sensitive to histamine levels in the hippocampus, although it is well known that the hippocampus plays an important role in electrically kindled seizures^[17,19,20]. Furthermore, we have also reported that PTZ-kindling is independent of the hippocampal *N*-methyl-*D*-aspartate receptor subunit 2B, which was strongly associated with amygdaloid kindled seizures in rats^[9]. These results suggest that the different types of kindled seizures may be associated with region-dependent foci and circuits, and therefore results from different mechanisms. For example, Mirski *et al* found that separate neuronal circuits mediate PTZ and maximal electroshock sei-

zures^[21].

Therefore, the present study indicates that histamine in daily food can influence histaminergic function in the brain, and may play an important role in regulating human primary generalized (or absence) epilepsy. These findings further suggest that more attention should be paid to daily dietary containing low and high histamine, and their possible influence on seizure susceptibility of human primary generalized (or absence) epilepsy.

Abstract

Aim: To explore the modulatory effect of bradykinin (BK) on 5-HT₃ receptor-mediated current in trigeminal ganglion (TG) neurons in rats. **Methods:** The whole-cell patch-clamp technique was used to record 5-HT-activated currents (I_{5-HT}) in neurons freshly dissociated from rat TG. Drugs were applied by rapid solution exchange. **Results:** The majority of the neurons examined responded to 5-HT applied externally with an inward current (76.3%, 74/97) that could be blocked by the 5-HT₃ receptor antagonist, ICS-205,930 (1×10^{-6} mol/L). In 66 of the 74 cells sensitive to 5-HT (89.2%), pretreatment for 30 s with BK (1×10^{-6} – 1×10^{-10} mol/L) could potentiate I_{5-HT} with the maximal modulatory effect occurring at 10^{-7} mol/L BK ($71.6\% \pm 4.9\%$). BK shifted the 5-HT concentration-response curve upwards with an increase of $68.9\% \pm 7.2\%$ in the maximal current response, but with no significant change in the EC₅₀ value (19.1 ± 3.2 μ mol/L vs 20.9 ± 3.5 μ mol/L; *t*-test, $P > 0.05$; $n = 8$). BK potentiated I_{5-HT} in a holding potential-independent manner and did not alter the reverse potential of I_{5-HT} . This BK-induced potentiation of I_{5-HT} was almost completely blocked by Hoe 140 (5×10^{-7} mol/L), a selective B₂ BK receptor antagonist, and was removed after intracellular dialysis of GF-109203X (2 μ mol/L), a selective protein kinase C (PKC) inhibitor, with the re-patch clamp. **Conclusion:** Pre-application of BK exerts an enhancing effect on I_{5-HT} via a PKC-dependent pathway in rat TG neurons, which may explain the peripheral mechanism of pain and hyperalgesia caused by, for example, tissue damage and inflammation.

Introduction

Serotonin (5-HT), a major component of the inflammatory chemical milieu, is released from platelets, mast cells, or basophils that infiltrate an area of tissue damage^[1]. Once released, 5-HT is free to interact with a number of molecularly distinct receptor subtypes, including the 5-HT₃ receptor expressed in primary afferent nociceptors^[2,3], and is capable of evoking pain and hyperalgesia^[4]. To date, receptors for 5-HT can be classified into seven types and can be further distinguished into at least 13 subtypes. Unlike all other known 5-HT receptor subtypes, which are G-protein coupled, the 5-HT₃ receptor is a member of the excitatory ligand-gated ion channel (LGIC) superfamily^[5,6]. Research-

ers believe that 5-HT₃ receptors located on sensory nerve terminals are mainly responsible for 5-HT-induced pain and hyperalgesia, although other subtypes of 5-HT receptors are also involved^[4,7–10]. Recently we have demonstrated the potentiation of 5-HT₃ receptor function by substance P and α -methyl-5-HT, an agonist of 5-HT₂ receptor, through a protein kinase C (PKC)-dependent pathway in primary sensory neurons^[11,12].

Bradykinin (BK) is an inflammatory mediator that plays a pivotal role in pain and hyperalgesia by exciting nociceptors and sensitizing them through activation of PKC^[13]. BK responses are mediated by BK receptors. There are two main types of BK receptors, B₁ and B₂. B₂ BK receptors are constitutively and abundantly expressed in primary sensory neu-

rons^[14]. The B₂ BK receptor has been implicated in BK-induced nociceptor activities and nociceptive behaviors^[15–17], and animals deficient in B₂ BK receptors show hypoalgesia and reduced inflammatory responses^[18,19]. The cDNA of the B₂ BK receptor has already been cloned^[20] and evidence for the contribution of the PKC pathway to the B₂ BK receptor-mediated algescic action of BK has accumulated^[17,21]. Thus, it is highly possible that 5-HT₃ receptor function is also enhanced by BK through a PKC-dependent pathway. The present study aimed to explore whether the modulation of BK in 5-HT₃ receptor-mediated current could occur in trigeminal ganglion (TG) neurons.

Materials and methods

Isolation of TG neurons Sprague-Dawley rats, 2–3 weeks old, were anesthetized with ether and decapitated. The TG were removed and transferred immediately into Dulbecco's modified Eagle's medium (DMEM, Sigma, St Louis, MO, USA) at pH 7.4. After removal of the surrounding connective tissues the TG were minced with fine spring scissors and the ganglion fragments were placed in a flask containing 5 mL DMEM in which trypsin (type II-S, Sigma) 0.5 g/L, collagenase (type I-A, Sigma) 1.0 g/L, and DNase (type IV, Sigma) 0.1 g/L had been dissolved, and incubated at 35 °C in a shaking water bath for 30–35 min. Soybean trypsin inhibitor (type II-S, Sigma) 1.25 g/L was added to stop trypsin digestion. Dissociated neurons were placed into a 35 mm Petri dish and kept for at least another 30 min before electrophysiological recording. The neurons selected for the patch-clamp experiment measured 20–45 μm in diameter.

Electrophysiological recordings Whole-cell patch-clamp recordings were carried out at room temperature (22–24 °C) using a whole-cell patch-clamp amplifier (CEZ-2400, Nihon Kohden, Tokyo, Japan). Pipettes were filled with internal solution containing (in mmol/L): KCl 140, CaCl₂ 1, MgCl₂ 2.5, HEPES 10, egtazic acid 11, and ATP 5; the pH was adjusted to 7.2 with KOH and the osmolarity was adjusted to 310 mOsm/L with sucrose. Cells were bathed in an external solution containing (in mmol/L): NaCl 150, KCl 5, CaCl₂ 2.5, MgCl₂ 2, HEPES 10, and *D*-glucose 10; the osmolarity was adjusted to 340 mOsm/L with sucrose and the pH was adjusted to 7.4 with NaOH. The resistance of the recording pipette was in the range of 2–5 MΩ. A small patch of membrane underneath the tip of the pipette was aspirated to form a gigaseal and then more negative pressure was applied to rupture it, thus establishing a whole-cell configuration. The adjustment of capacitance compensation and series resistance compensation was done before recording the membrane currents. The holding potential was set at -60 mV, unless otherwise

indicated. Membrane currents were filtered at 10 kHz (-3 dB), and the data were stored and analyzed in a computer with data acquisition software and hardware systems (Huazhong University of Science and Technology, Wuhan, China) and recorded using a pen recorder (Nihon Kohden).

Drug application Drugs used in the experiments included: serotonin hydrochloride (5-HT, Sigma), bradykinin (BK, Sigma), 2-methyl-5-hydroxytryptamine maleate (Research Biochemicals Incorporated, Natick, MA, USA), ICS-205,930 (Research Biochemicals Incorporated), Hoe 140 (Sigma), and GF 109203X (Research Biochemicals Incorporated). All drugs except GF 109203X were dissolved in the external solution just prior to use and held in a linear array of fused silica tubes (od/id=500/200 μm) connected to a series of independent reservoirs. The distance from the tube mouth to the cell examined was approximately 100 μm. The application of each drug was driven by gravity and controlled by the corresponding valve, and rapid solution exchange could be achieved by shifting the tubes horizontally with a micromanipulator. Cells were constantly bathed in normal external solution flowing from one tube connected to a larger reservoir between drug applications. In a number of the experiments GF 109203X needed to be applied intracellularly and was dissolved in the internal solution.

Data analysis Data were statistically analyzed using Student's *t*-test or analysis of variance (ANOVA). Statistical analysis of the concentration-response data was carried out using the non-linear, curve-fitting program ALLFIT. Current values were expressed as mean±SEM.

Results

Current mediated by the 5-HT₃ receptor in rat TG neurons In our experiments neurons freshly isolated from rat TG were round or elliptic in shape under light microscopy. The majority of the cells examined responded to 5-HT applied externally with a concentration (1×10⁻³–1×10⁻⁶ mol/L)-dependent inward current (76.3%, 74/97). This 5-HT-activated current (*I*_{5-HT}, 1×10⁻⁴ mol/L) could be mimicked by 2-methyl-5-HT (1×10⁻⁴ mol/L), a specific 5-HT₃ receptor agonist, and could be blocked by ICS-205,930 (1×10⁻⁶ mol/L), a selective antagonist of 5-HT₃ receptor, indicating that this current was mediated by the 5-HT₃ receptor (Figure 1A).

When 5-HT was applied regularly for 3-s durations with 3-min intervals, the *I*_{5-HT} was repeated stably within at least 90 min, and the change in amplitude was within 8% (data not shown). Thus, we used this pattern of 5-HT applications in the following experiments.

Potentiation of *I*_{5-HT} by pre-application of BK BK applied for 30 s prior to the application of 5-HT (1×10⁻⁴ mol/L)

Figure 1. Potentiation of I_{5-HT} by BK. (A) The current traces show that 5-HT (1×10^{-4} mol/L) activated an inward current in TG neurons, which could be mimicked by the application of 2-methyl-5-HT (1×10^{-4} mol/L), and blocked by ICS-205,930 (1×10^{-6} mol/L) ($n=7$). All current traces were recorded from the same neuron. (B) BK potentiated I_{5-HT} in a concentration-dependent manner. The duration of BK pre-application lasted for 30 s. Each point represents the mean \pm SEM of 7–9 neurons. The current traces in the inset show that BK (1×10^{-7} mol/L) potentiated I_{5-HT} . (C) The enhancing effect of BK (1×10^{-7} mol/L) on I_{5-HT} (1×10^{-4} mol/L) increased with increments in BK pre-application duration from 0 to 120 s ($n=6-9$).

potentiated I_{5-HT} reversibly in the majority of the neurons examined (66/74, 89.2%). In 18 of the 74 (24.3%) cells sensitive to 5-HT there was also a response to BK with a very small inward or outward current (<150 pA), which showed slow desensitization (data not shown). The BK potentiation

of I_{5-HT} was observed irrespective of whether BK evoked an inward or outward current, or no response. The I_{5-HT} was potentiated by the pre-application of BK (1×10^{-6} – 1×10^{-10} mol/L) in a concentration-dependent manner. Figure 1B shows that with an increase in BK concentration from 1×10^{-10} to 1×10^{-6} mol/L, the amplitude of I_{5-HT} (1×10^{-4} mol/L) increased stepwise until it reached its maximum at a concentration of 1×10^{-7} mol/L BK (71.6 \pm 4.9%). Thereafter this potentiating effect did not increase further, but rather decayed with further increases in BK concentration until 10^{-6} mol/L (Figure 1B).

Effect of the duration of BK pre-application on I_{5-HT} To explore the relationship between the effect of BK on I_{5-HT} and the duration of the pre-application of BK, different BK pre-application durations ranging from 15 to 120 s were tested. Figure 1C illustrates that the amplitude of I_{5-HT} (1×10^{-4} mol/L) increased with increasing BK (1×10^{-7} mol/L) pre-application durations. With the duration of BK pre-application at 120 s, the amplitude of I_{5-HT} increased (1.97 \pm 0.13)-fold compared with that of the control. However, there was no enhancing effect observed when 5-HT and BK were co-applied for 3 s ($n=7$; data not shown).

Effect of the B₂ BK receptor antagonist Hoe 140 on BK potentiation of I_{5-HT} To verify whether the BK potentiation of I_{5-HT} was mediated by the receptor for BK, we examined the effect of the pre-application of both BK and Hoe 140, a selective B₂ BK receptor antagonist, on I_{5-HT} . The pre-application of both BK and Hoe 140 abolished BK-induced potentiation of I_{5-HT} significantly (Figure 2A,B, paired *t*-test, $P < 0.01$, $n=7$).

Concentration-response relationship for 5-HT with and without BK pre-application Figure 3A demonstrates the concentration-response curves for 5-HT with or without the pre-application of BK (1×10^{-7} mol/L). The threshold concentrations of 5-HT in the two concentration-response curves for 5-HT with or without BK pre-application were similar at approximately 3×10^{-6} mol/L; and the EC₅₀ values were also very similar (19.1 \pm 3.2 μ mol/L and 20.9 \pm 3.5 μ mol/L; *t*-test; $P > 0.05$; $n=8$); whereas the maximal response induced by 5-HT with BK pre-application increased by 68.9% \pm 7.2% of that without BK pre-application. The present results reveal that the concentration-response curve for 5-HT pre-treated with BK shifts upwards compared with the curve for 5-HT alone.

Current-voltage (*I-V*) relationship for I_{5-HT} with or without BK pre-application I_{5-HT} (1×10^{-4} mol/L) with or without the pre-application of BK (1×10^{-7} mol/L) was recorded at different holding potentials. All current values from the same cell were normalized to the current response induced by

Figure 2. Blockade of BK-induced potentiation of I_{5-HT} by the B_2 BK receptor antagonist Hoe 140. The current traces in (A) and the bar graph in (B) show that the potentiation of I_{5-HT} by BK pre-applied alone was abolished by the co-application of BK and Hoe 140, a selective B_2 BK receptor antagonist (paired t -test, $^*P < 0.01$ vs BK+5-HT).

5-HT alone at a holding potential of -60 mV when I - V curves were drawn (Figure 3B). The reverse potential values for the two curves were essentially the same at 0 mV. The amplitude of I_{5-HT} with BK pre-application was greater than that without BK pre-application at all holding potentials from -80 to +40 mV, and the BK-induced alteration of I_{5-HT} did not correlate with the change in holding potential (ANOVA; $P > 0.05$, $n = 8$), which suggests that the potentiation of I_{5-HT} by BK occurs in a voltage-independent manner and the reverse potential of I_{5-HT} is unchanged by BK.

Intracellular signal transduction mechanism underlying BK potentiation of I_{5-HT} To explore whether this enhancing effect is mediated through BK-receptor-induced intracellular signal transduction, for example, activating PKC, GF-109203X, a selective PKC inhibitor^[22], was included in the recording pipette for intracellular dialysis using the re-patch technique. In the control experiment with the pipette filled with normal internal solution, the BK-induced potentiation of I_{5-HT} was $72.2\% \pm 5.2\%$. In contrast, when using a pipette filled with GF-109203X (2 μ mol/L) containing internal solution the BK-induced potentiation of I_{5-HT} was $13.5\% \pm 4.3\%$. It is evident that GF-109203X applied intracellularly removes the enhancing effect of BK on I_{5-HT} (Figure 4).

Discussion

The 5-HT-activated current we recorded from TG neu-

Figure 3. Concentration-response and current-voltage relationships for 5-HT with or without the pre-application of BK. (A) The concentration-response curves for 5-HT with or without BK (1×10^{-7} mol/L) pre-application, each point represents the mean \pm SEM of 7–11 neurons. All 5-HT-induced currents were normalized to the response induced by 10^{-4} mol/L 5-HT applied alone (marked with asterisk). The holding potential was set at -60 mV. The data for 5-HT alone is a good fit to the logistic equation $I = I_{max} / [1 + (EC_{50}/C)^n]$, where C is the concentration of 5-HT, I is the normalized I_{5-HT} value, and EC_{50} is the concentration of 5-HT for half maximal current response. The Hill coefficients (n) for the cases with and without BK pre-application were 0.98 and 0.96, respectively. It is evident that the curve for 5-HT with BK pre-application shifts upwards compared with the curve for 5-HT applied alone. (B) The I - V curves for 5-HT (1×10^{-4} mol/L)-activated current with or without BK (1×10^{-7} mol/L) pre-application. BK did not alter the reverse potential of I_{5-HT} (0 mV in both cases). All current values from the same cell were normalized to the current response induced by 5-HT (1×10^{-4} mol/L) alone at the holding potential of -60 mV (marked with asterisk). BK pre-application potentiated I_{5-HT} at all holding potentials from -80 to +40 mV. Each point represents the mean \pm SEM of 7–9 neurons. This experiment was carried out using recording pipettes filled with CsCl containing internal solution.

Figure 4. Reversal of the BK potentiation of I_{5-HT} by intracellular dialysis of GF-109203X. The diagram in the upper row in (A) schematically shows the experiment of intracellular dialysis of GF-109203X, a selective PKC inhibitor, on an individual cell. The current traces in the lower row in (A) demonstrate that intracellular dialysis of GF-109203X (2 $\mu\text{mol/L}$) markedly reversed the potentiating effect of BK on I_{5-HT} . The bar graph in (B) shows the percentage increases in the I_{5-HT} induced by BK pre-application with recording pipettes filled with the normal internal solution or with GF-109203X containing internal solution. $n=7$. Mean \pm SEM. (paired t -test, $^{\circ}P<0.01$ vs normal).

rons was mediated by the 5-HT₃ receptor, the sole ligand-gated ion channel (LGIC) in the family of 5-HT receptors, because it was blocked by ICS-205,930, a selective antagonist of the 5-HT₃ receptor (Figure 1A). There was evidence to indicate that 5-HT₃ receptors were present in rat TG neurons^[23]. Similarly, B₂ BK receptors were also expressed in TG neurons^[14]. In the present study we recorded both B₂ BK receptors and 5-HT₃ receptors in TG neurons, and in the majority of these neurons (89.2%, 66/74) the pre-application of BK (1×10^{-7} mol/L) potentiated I_{5-HT} (1×10^{-3} – 1×10^{-6} mol/L). This potentiation was mediated by B₂ BK receptors because the selective B₂ BK receptor antagonist Hoe 140 blocked this potentiating effect, obviously and reversibly (Figure 2). However, a previous study has reported that the inflammatory mediators BK, 5-HT, and prostaglandin E₂ do not cooperate to elevate intracellular calcium concentration when applied simultaneously for 10 s in cultured dorsal root ganglion neurons^[24]. The distinction possibly results from different observation indices and specimens, or may be caused

by the different treatment of BK. In the present experiment, there was also no enhancing effect observed when 5-HT and BK were co-applied for 3 s, whereas I_{5-HT} was potentiated by the pre-application of BK for more than 15 s (Figure 1C).

It is evident from Figure 1B that the enhancement of amplitude of I_{5-HT} increased gradually with incremental increases in the concentration of BK from 10^{-10} to 10^{-7} mol/L. However, when the concentration of BK increased to 10^{-6} mol/L the modulatory effect of BK on I_{5-HT} did not increase further. The decrease in potentiation of I_{5-HT} by BK (10^{-6} mol/L) might be a non-specific action of the agonist that emerges at high concentrations because very high concentrations of drug or ligand may block the channel and/or shelter the binding site of the receptor^[25].

From the comparison between the concentration-response curves for 5-HT with and without the pre-application of BK (Figure 3A) it is clear that: (i) pre-application of BK shifted the curve upwards; (ii) the maximal response induced by 5-HT with BK pre-application increased by 68.9%, whereas the threshold concentrations of 5-HT in both cases were similar; and (iii) the EC₅₀ values of the two curves were very close (19.1 ± 3.2 $\mu\text{mol/L}$ vs 20.9 ± 3.5 $\mu\text{mol/L}$). This implies that the intrinsic efficacy of the 5-HT₃ receptor increases after pretreatment with BK; however, its affinity does not change.

From the I - V curves for I_{5-HT} with and without BK pretreatment, it can be seen that the reverse potentials were the same (0 mV), indicating that there was no change in the ionic components mediating this current. This enhancement was not caused by the release of the channel blocker, as is the case in the voltage-dependent Mg²⁺ block of NMDA-gated ion channel, because the BK-induced alteration of I_{5-HT} was not correlated with the change in holding potential (Figure 3B). This implies that the potentiation of I_{5-HT} by BK occurs in a voltage-independent manner.

The potentiation of I_{5-HT} by BK may involve intracellular signal transduction because there was no enhancing effect observed when 5-HT and BK were co-applied; nevertheless, BK applied prior to 5-HT application induced the enhancement of I_{5-HT} and this effect was positively related to the duration of BK pretreatment, implying that this enhancement is a time-consuming process. Furthermore, this potentiation was blocked by Hoe 140, a selective B₂ BK receptor antagonist. B₂ BK receptors belong to the superfamily of G-protein-coupled receptors (GPCR)^[20]. When activated by BK, the B₂ BK receptor is coupled to PLC β_1 via G_{q/11} protein; which in turn catalyzes PIP₂ into secondary messengers, IP₃ and DAG. The latter activates PKC. Reports have shown

that 5-HT₃ receptor function is enhanced by the activation of PKC^[26,27]. In the present experiment, the enhancing effect of BK on *I*_{5-HT} was evidently blocked by intracellular dialysis of GF-109203X, a selective PKC inhibitor^[22], indicating that potentiation occurs via a PKC-dependent pathway. How does PKC affect the function of 5-HT₃ receptors? Recently, a novel mechanism for 5-HT₃ receptor modulation by the activation of PKC was demonstrated^[28]; that is, the PKC-induced potentiation of 5-HT₃ receptor mediated current in *Xenopus* oocytes and mouse NIE-115 neuroblastoma cells resulted from the enhancement of F-actin-dependent trafficking of 5-HT₃ receptors instead of direct phosphorylation of the 5-HT_{3A} receptor protein.

What is the physiological significance of this BK modulation on *I*_{5-HT} or 5-HT₃ receptor function? In this work we used the cell body of TG neurons as a simple and accessible model to examine the characteristics of the membrane of peripheral terminals. The nerve endings of the peripheral axon of primary sensory neurons, including TG neurons, are sensitive to many inflammatory chemical mediators, of which BK and 5-HT are two potent stimulating mediators. In the case of inflammation and/or tissue damage these two substances are released. On the one hand, they exert a stimulating effect on the nerve endings and initiate nociceptive information through their corresponding receptors located on the membranes of separate nerve endings. On the other hand, in the present study we found that in the case of coexistence of B₂ BK receptors and 5-HT₃ receptors in TG neurons the inward current mediated by the 5-HT₃ receptor could be strengthened by pretreatment with BK, indicating that B₂ BK receptors and 5-HT₃ receptors may “cross-talk” in producing algescic information at nociceptors. Behavioral experiments have also demonstrated that 5-HT causes marked potentiation of BK-induced pain responses through 5-HT₃ receptors^[29]. The present study may provide a hint for explaining the peripheral mechanism of pain and hyperalgesia caused by, for example, tissue damage and inflammation.

Abstract

Aim: To determine whether ONO-1078 (pranlukast), a potent cysteinyl leukotriene receptor 1 (CysLT₁) antagonist, has an effect on *N*-methyl-*D*-aspartate (NMDA)-induced brain injury and vascular cell adhesion molecule-1 (VCAM-1) expression in rats. **Methods:** Brain injury was induced by direct microinjection of NMDA (0.3 μmol in 1 μL of sterile 0.1 mol/L PBS, pH 7.4) into the cerebral cortex. The lesion volume (area), brain edema and neuron density were assessed by an image analyzer and the expression of VCAM-1 in the cortex was detected by Western blot 24 h after NMDA injection. ONO-1078 (0.03, 0.1, or 0.3 mg/kg) and edaravone (MCI-186, 10 mg/kg), a neuroprotective agent, were ip injected 30 min before and after NMDA injection. **Results:** NMDA microinjection produced well-defined focal lesions (Figure 1) dose- and time-dependently. ONO-1078 (0.1, 0.3 mg/kg) and edaravone (10 mg/kg) decreased the total lesion volume, lesion area and brain edema induced by NMDA. Furthermore, ONO-1078 (0.1, 0.3 mg/kg) significantly inhibited the enhanced expression of VCAM-1 in the injured cortices, but edaravone did not have this effect. **Conclusion:** CysLT₁ receptor antagonist ONO-1078 attenuates NMDA-induced brain damage in rats, and this might relate to the attenuation of NMDA receptor-dependent neurotoxicity and the inhibition of the upregulation of VCAM-1 expression.

Introduction

It is well known that *N*-methyl-*D*-aspartate (NMDA) receptors play a critical role in the initiation of cerebral ischemia [1]. The excitotoxicity mediated by NMDA receptors contributes to the damage that occurs in the early stages (min to h), and inflammation and programmed cell death in the late stages (h to weeks) of cerebral ischemia [1,2]. Among many factors involved in inflammation, adhesion molecules, including vascular cell adhesion molecule 1 (VCAM-1), can modulate ischemic injury in the brain [3,4]. However, cysteinyl leukotrienes (CysLTs, including LTC₄, LTD₄, and LTE₄), 5-lipoxygenase (5-LOX) metabolites of arachidonic acid, are potent inflammatory mediators [5] that are also involved in pathogenic processes of cerebral ischemia. CysLT levels were elevated after global and focal cerebral ischemia and 5-lipoxygenase inhibitor attenuated

CysLT production and ischemic brain injury [6–8]. Furthermore, we have previously found that ONO-1078 {pranlukast, 4-oxo-8-[*p*-(4-phenylbutyloxy)benzoyl-amono]-2-(tetrazol-5-yl)-4H-1-benzopyran hemihydrate}, a CysLT₁ receptor antagonist, protects rats and mice against focal cerebral ischemic injury [9,10].

Recently, we reported that global cerebral ischemia induces brain injury and time-dependently increases the expressions of NMDA receptor subunit proteins and VCAM-1 in different regions of the brain in rats [11]. We also found that ONO-1078 attenuates ischemic injury and inhibits the increased expressions of NMDA receptor subunit NR2A and VCAM-1 [12]. However, whether ONO-1078 protects rats from chemically induced injury, and if NMDA receptor activation directly links to the increased VCAM-1 expression, remains unknown. Thus, in the present study, we induced cortical injury by NMDA microinjection to evaluate the

protective effect of ONO-1078. Also, we observed VCAM-1 expression after NMDA receptor activation and the influence of ONO-1078. Edaravone (MCI-186, 3-methyl-1-phenyl-2-pyrazolin-5-one), a novel neuroprotective agent for ischemic stroke^[13,14], was used as a control drug.

Materials and methods

Drugs and reagents NMDA was purchased from Sigma (St Louis, MO, USA); ONO-1078 was provided by Dr Masami Tsuboshima (Ono Pharmaceutical Co, Osaka, Japan). This compound was dissolved in 100% ethanol (10 g/L), and freshly diluted with saline before use. Edaravone injection was obtained from Hangzhou Conba Pharmaceutical Co; polyclonal goat antibody against VCAM-1 from Santa Cruz, CA, USA; rabbit anti-goat IgG-HRP was obtained from Zhong-Shan Biotech Co, Beijing; enhanced chemiluminescence (ECL) reagent was obtained from Renaissance, New England Nuclear-Dupont. Other reagents were commercial products with analytic purity.

NMDA microinjection in neocortex Male Sprague-Dawley rats weighting 250–300 g were from the Experimental Animal Center of Zhejiang Academy of Medical Sciences (Grade II, Certificate No 2001001). Rats were housed in groups of 4 per cage at a constant temperature (25 °C) and allowed free access to laboratory chow and water. In chloral hydrate-anesthetized (350 mg/kg, ip) rats, the dura overlying the parietal cortex was exposed, and a microinjector was inserted into the parietal cortex at a site 3.0 mm caudal to bregma, 5.0 mm from the midline, and 1.5 mm below the dural surface. NMDA (0.1, 0.2, and 0.3 μ mol in 1 μ L of sterile 0.1 mol/L PBS, pH 7.4) or 0.1 mol/L PBS alone (control) was injected according to the method described by Iadecola *et al*^[15]. The microinjector was left in place for 10 min, to minimize the back-flux of NMDA, and then removed.

After these procedures, the incisions were closed and rats were returned to their cages. ONO-1078 (0.03, 0.1, and 0.3 mg/kg), edaravone (10 mg/kg) or the same volumes of saline were ip injected 30 min before and after NMDA injection.

Evaluation of tissue injury Twenty-four hours after NMDA microinjection, the rats were anesthetized with chloral hydrate again and decapitated. Brains were removed immediately and sectioned coronally into 6 slices (2 mm-thick). Brain slices were stained in 0.5% 2,3,5-triphenyl tetrzolium chloride at 37 °C for 30 min, followed by fixation with 10% formalin, overnight. All the brain slices were photographed using a CCD camera (MV-CP-230, Panasonic, Japan) on an anatomy microscope (XTL 2600, Shanghai, China). The volume and area of NMDA-injured cortex were measured by an image analyzer (AnalyPower1.0, Zhejiang University,

Hangzhou, China).

Histopathological assessment Under chloral hydrate anesthesia, the rats were infused with 100 mL of heparinized saline followed by 300 mL of 10% formalin, before being decapitated. Brains were removed and fixed in 10% formalin for 7 d; paraffin sections (5 μ m) were then cut and stained with hematoxylin and eosin. The densities of survival neurons in the cortex were counted using the image analyzer (AnalyPower1.0, Zhejiang University, Hangzhou, China).

Western blot analysis Western blot analysis was performed as described by Kang *et al*^[16]. The injured and contralateral cortices were dissected and homogenized in buffer A (10 mmol/L Tris-HCl, pH 7.4, containing 320 mmol/L sucrose). The homogenate was centrifugated at 700 \times g for 10 min at 4 °C, and the supernatant was further centrifuged at 37 000 \times g for 40 min at 4 °C. The resultant pellet was resuspended in buffer B (10 mmol/L Tris-HCl, pH 7.4), and protein concentration was determined by the Lowry method.

The protein samples of 7.5 μ g were separated by 7.5% SDS-PAGE and transferred to a nitrocellulose membrane in transfer buffer (Tris 25 mmol/L, glycine 192 mmol/L, 20% methanol, 0.05% SDS, pH 8.3). The nonspecific binding was blocked in 5% fat-free drymilk in TBST (Tris-HCl 20 mmol/L, NaCl 140 mmol/L, 0.1% Tween-20, pH 7.4) for 30 min at room temperature. The membrane was incubated with polyclonal goat antibody against VCAM-1 (1:500) overnight at 4 °C. After washing with TBTS, the membrane was then incubated with HRP-conjugated rabbit anti-goat IgG (1:2000) for 2 h at room temperature followed by repeated washing with TBST. At the end, the membrane was incubated in enhanced chemiluminescence (ECL) solution for 1 min and then exposed to X-ray film. The protein bands on an X-ray film were scanned by a GS-800 Laser Densitometer (Bio-Rad, USA) and analyzed by Met Imaging Series 5.0 (Bio-Rad, USA). As a standard, a protein sample from normal rat brains was used and the relative expression of VCAM-1 was calculated as the ratio of tested/standard sample densities.

Statistical analysis Data were reported as mean \pm SD. Statistical evaluation was carried out by the independent-sample *t*-test or one-way ANOVA (SPSS 11.0 for Windows, SPSS Inc, USA), according to the experimental design. *P*<0.05 was considered statistically significant.

Results

NMDA-induced injury *in vivo* NMDA microinjection produced well-defined focal lesions (Figure 1) dose- and time-dependently in TTC-stained brain slices. The lesion volumes induced by NMDA 0.3 μ mol (32.4 \pm 10.7, *n*=5) were

Figure 1. TTC-stained brain slices after direct microinjection of NMDA into the cerebral cortex in rats. A: brain slices 24 h after NMDA microinjection with various dose; B: brain slices 1–24 h after NMDA microinjection (0.3 μmol). Arrowheads show the injection sites.

significantly larger than those by 0.1 and 0.2 μmol (11.1 ± 5.5 and 15.6 ± 7.6 , $n=5$, $P<0.01$, respectively) 24 h after NMDA injection. The lesion volumes at 24 h after NMDA (0.3 μmol) microinjection (35.4 ± 7.0 , $n=4$) were larger than those at 1, 3, or 6 h after injection (21.8 ± 8.0 , 25.1 ± 8.8 , or 30.7 ± 9.2 , respectively, $n=4$, $P<0.05$).

Histopathological changes in the lesion regions 24 h after NMDA (0.3 μmol) injection were characterized by neu-

ronal damage with eosinophilic cytoplasm and serious pyknotic nucleus, and survival neuron decreased markedly in the injured cortices; however, no cell damage was observed in the contralateral cortices or in PBS-injected control cortices (Figure 2).

Effects of ONO-1078 and edaravone on NMDA-induced injury ONO-1078 at 0.1 and 0.3 mg/kg significantly reduced the lesion volume ($P<0.05$ or $P<0.01$, Table 1) and the lesion

Figure 2. Histopathologic changes 24 h after direct microinjection of PBS (control) or NMDA into the cerebral cortex in rats. areas in individual 2 mm-thick consecutive slices ($P < 0.05$ or $P < 0.01$, Table 2), and the enlargement of injected cortices (indicated as I/C ratio) at 0.1 mg/kg ($P < 0.05$, Table 1). The survival neuron densities in NMDA-injured regions showed a tendency to increase in the rats treated with ONO-1078, but no significant difference was found among these groups ($P > 0.05$, Table 1). Edaravone (10 mg/kg) exhibited a similar effect to ONO-1078 (Tables 1, 2).

Effects of ONO-1078 and edaravone on VCAM-1 expression in NMDA-injected cortex To assess the relation between the protection of ONO-1078 and the expression of inflammatory adhesion molecule VCAM-1, we detected the local expression of VCAM-1 in contralateral and injured cortices 24 h after NMDA injection. VCAM-1 level did not remarkable change among the groups in the contralateral cortices without damage. In the injured cortices, however, VCAM-1 expression was up-regulated. ONO-1078 (0.1 and 0.3 mg/kg) significantly inhibited the increased VCAM-1 expression ($P < 0.05$ or $P < 0.01$), however, edaravone did not show a significant effect ($P > 0.05$, Figure 3).

Discussion

The findings in the present study show that NMDA microinjection produces serious neocortical damage and a CysLT₁ receptor antagonist ONO-1078 possessed protective effect on NMDA-induced brain injury. This effect of ONO-1078 on chemically-induced brain injury is consistent with its protective effect on brain ischemic injuries discussed in our previous studies^[12]. Furthermore, the results of the present study indicates that NMDA microinjection up-regulates the local expression of VCAM-1, and ONO-1078 inhibits the enhanced VCAM-1 expression in the injured cortices.

The excessive release of excitory amino acids and activation of NMDA receptor are important events in cerebral ischemia and other brain injuries. NMDA receptor activation has been reported to be related to CysLT production in focal cerebral ischemia because NMDA receptor antagonist MK 801 reduces both CysLT production and ischemic injury^[17]. Also, LTC₄ synthesis inhibitor azelastine protects cultured hippocampal slices from hypoxic or NMDA-induced injury *in vitro*^[18]. Therefore, the protective effect of ONO-1078 in this study might be via antagonizing the actions of resultant CysLTs after NMDA receptor activation.

However, the increased VCAM-1 expression by NMDA injection suggests a possibility that excitotoxicity might initiate inflammation in the brain. It has been reported that NMDA receptor activation can up-regulate the expression of inflammatory cytokines, such as TNF- α and MCP-1^[19,20], and induce neuronal signal transduction-associated adhesion molecules, such as PSA-NCAM and NCAM-180^[21,22]. Our results further confirmed that NMDA increases the expression of inflammatory adhesion molecule VCAM-1. Evidence has shown the involvement of VCAM-1 in cerebral ischemic injury and inflammation. Serum level of soluble VCAM-1 increased in patients with ischemic stroke, at its peak 5 d after ischemia^[4]. VCAM-1 expression also increased in astrocytes and endothelial cells from the infarcted brain areas in patients who died of acute ischaemic stroke^[23], and in cultured human cerebrovascular endothelial cells after being subjected to ischemia-like insults or inflammatory cytokinins (IL-1 and TNF- α)^[24]. VCAM-1 promotes intracerebral inflammation by affecting leukocyte rolling, adhesion^[25] or earlier steps of interaction between inflammatory cells (such as T lymphocytes) and microvascular endothelial cells^[26]. Furthermore, we found that ONO-1078 inhibits NMDA-increased VCAM-1 expression. In other reported studies, CysLTs only slightly augmented VCAM-1 expression in human umbilical vein endothelial cells^[27]; CysLT₁ receptor antagonist ONO-1078^[16, 28] and montelukast^[29] sup-

pressed VCAM-1 expression in the lung after allergen challenge. Based on these findings, we hypothesized that NMDA receptor activation induces CysLT production, CysLTs activate their receptors followed by VCAM-1 expression. This might partially explain our previous results that ONO-1078 reduces VCAM-1 expression in rat global ischemia^[12].

As a control drug used in this study, edaravone protected NMDA-induced injury but did not reduce VCAM-1 expression compared with ONO-1078. Edaravone is a scavenger reacting with hydroxyl radical (OH)^[30] and might act on the signal pathways other than those of ONO-1078. In cultured human dermal microvascular endothelial cells, antioxidants show different actions on TNF- α -induced expressions of VCAM-1, ICAM-1 and E-selectin: pyrrolidine dithiocarbamate had inhibiting effects, but N-acetylcysteine did not^[31]. In our previous study of rat global ischemia, edaravone also did not significantly inhibit VCAM-1 expression^[12]. Its neuroprotective effect might be mediated by other actions, such as inhibition of mitochondrial permeability transition pore, upregulation of Bcl-2^[32], normalization of irradiation-reduced endothelial nitric oxide synthase expression^[33], and protection against hypoxia/ischemia-induced endoplasmic reticulum dysfunction^[34].

In the present study, we found that ONO-1078 reduced NMDA-induced lesion size, but did not increase survival neurons in the lesion, suggesting incomplete protection. We have not yet explained the details of NMDA receptor activation in CysLTs production, VCAM-1 expression and brain injury, however, the results of the present study indicate that CysLT₁ receptor antagonist ONO-1078 inhibits NMDA-induced brain injury and pro-inflammatory VCAM-1 expression, supplying further evidence for its neuroprotective effect on ischemic brain injury.

Abstract

Aim: To examine whether the prostaglandins (PGs) pathway is involved in triggering delayed neuroprotection by ischemic preconditioning (IPC) and evaluate the effects of IPC on cyclooxygenase-2 (COX-2) expression following focal cerebral ischemia and reperfusion in rats. **Methods:** IPC was induced by 10 min of saline infusion into the left internal carotid artery with the right common carotid artery clamped at the same time. Middle cerebral artery occlusion (MCAO) and reperfusion model was produced using intraluminal filament method. **Results:** IPC 48 h prior to MCAO significantly reduced infarct area as compared with MCAO alone. A nonselective inhibitor of COX indomethacin (3 mg/kg ip) applied 1 h prior to or 1 h after IPC failed to affect its protective effects. IPC had no direct effect on the cortex COX-2 mRNA and protein expression 72 h later, but decreased the expression of COX-2 mRNA and protein following ischemia and reperfusion insult. **Conclusion:** PGs pathways was not involved in triggering delayed neuroprotection by IPC, and IPC induced down-regulation of COX-2 following focal cerebral ischemia and reperfusion in rats *in vivo*.

Introduction

A short period of ischemia is known to increase tolerance of the brain to a subsequent prolonged ischemia by reducing brain infarction and apoptosis, this phenomenon is termed as ischemic preconditioning (IPC) or ischemic tolerance^[1]. The neuroprotection of cerebral ischemic preconditioning is divided into acute and delayed effects^[2]. Delayed neuroprotection occurs 24 h after IPC, then becomes manifest thereafter and lasts up to 7 d.

Recently, it has been reported that indomethacin, a non-selective inhibitor of cyclooxygenase (COX), applied 1 h prior to lipopolysaccharide (LPS) treatment abolished the LPS-induced delayed neuroprotection against focal cerebral ischemia and reperfusion injury^[3]. The results suggested that PGs pathway or inflammatory pathway might be involved in triggering delayed neuroprotection by LPS^[3]. It has also been reported that PGs increased to a high level in the brain tissues within hours following a short period of ischemia^[4]. However it is still unknown whether a rise of PGs in the brain

is involved in the delayed neuroprotection induced by IPC.

COX, also known as prostaglandin H2 synthase, is the rate-limiting enzyme in the metabolism of arachidonic acid into prostanoids (PGs and thromboxanes). COX-2, which is normally expressed in the neurons of the brain, is inducible in response to mitogen, endotoxin, and cytokines. Previous studies have demonstrated that focal cerebral ischemia induced strongly expressed COX-2 in neurons in penumbra and contributed significantly to enlargement of infarction^[5]. Since IPC limits infarction induced by ischemia and reperfusion injury, it may prevent the up-regulation of COX-2 following focal cerebral ischemia and reperfusion insult. Recently it was shown that IPC stimulus reprogrammed the response of gene transcription to subsequent ischemia and reperfusion insult in mice. It was found that COX-2 showed lower expression of mRNA by IPC using a microarray analysis^[6].

In the present study, the PGs pathway was examined to evaluate whether it is involved in triggering cerebral IPC, and effects of IPC on COX-2 expression were evaluated fol-

lowing focal cerebral ischemia and reperfusion.

Material and methods

Materials Indomethacin (Sigma-Aldrich, St Louis, MO, USA) was dissolved in Me₂SO. The compound 2,3,7-triphenyltetrazolium chloride (TTC, Sigma-Aldrich, St Louis, USA) was dissolved in saline. TRI-REAGENT-LS extraction kit was purchased from Molecular Research Center, Inc (Cincinnati, USA). RNasin, dNTP, oligo (dT) 18 primer, and *Taq* DNA polymerase were obtained from Sangon Biotechnology Co (Shanghai, China). M-MuLV reverse transcriptase was from Fermentas Inc (Vilnius, Lithuania). The DNA Master SYBR Green I was from Roche Co (Mannheim, Germany). BCA protein assay kit and ECL chemiluminescence system were purchased from Pierce Co (Rockford, USA). Goat Polyclonal antibody specific for COX-2 was from Santa Cruz Biotechnology, Inc (Santa Cruz, USA, working concentration 1:500). Rat mono-antibody specific for beta-actin was from Sigma-Aldrich (St Louis, USA, working concentration 1:5000). Supersignal West Pico Trial Kit was from Pierce Co (Rockford, USA).

Animals and experiment design Male Sprague-Dawley rats weighing 220–250 g (the Shanghai Experimental Animal Center of Chinese Academy of Sciences) were used in this study. The rats were randomly divided into six groups ($n=8$ each). In the sham group (sham), the left common carotid artery was exposed, and the external carotid artery and its branches were isolated and coagulated without middle cerebral artery occlusion (MCAO). The rats of the ischemia and reperfusion group (I/R) were subjected to MCAO (90 min) and reperfusion (24 h). For the IPC group (IPC), IPC was applied 48 h before MCAO and reperfusion. For indomethacin group 1 (Indo1+IPC+I/R), the rats were treated with indomethacin (3 mg/kg ip) 1 h prior to IPC, and MCAO and reperfusion was applied 48 h later. For indomethacin group 2 (Indo2+IPC+I/R), the rats were treated with indomethacin (3 mg/kg ip) 1 h after IPC, and MCAO and reperfusion were applied 48 h later. The last group was used to exclude the effects of indomethacin itself on injuries of MCAO and reperfusion. The rats were treated with indomethacin (3 mg/kg ip) 48 h before MCAO and reperfusion (Indo+I/R).

COX-2 mRNA and protein expression Another series of experiments were performed. The rats were divided into four groups ($n=6$ each). In the sham operation group, the left common carotid artery was exposed, and the external carotid artery and its branches were isolated and coagulated without MCAO. The rats of the ischemia and reperfusion group were subjected to MCAO (90 min) and reperfusion (24 h). In

the third group, IPC was applied 48 h before MCAO and reperfusion. In the last group, only IPC was applied.

Model of IPC IPC was induced as described previously with minor modification^[7]. Briefly, the left common carotid artery was exposed, and the external carotid artery and its branches were isolated and coagulated. A branch of the left internal carotid artery (the left pterygopal artery) was isolated and coagulated. The right common carotid artery was exposed. Then a cannula was inserted into the external carotid artery stump and advanced into the internal carotid artery to infuse saline into the brain. The saline infusion rate was 12 mL/h, which was controlled by a Harvard apparatus compact infusion pump (USA). A surgery artery nip was used to clamp the right common carotid artery. To achieve marked neuroprotection, we chose 48 h after IPC as the time interval to apply ischemia and reperfusion insult.

Evaluation of infarct area Coronal sections of the brain (2 mm thick) were cut and immersed in a 1% solution of TTC. The stained slices were then fixed by immersion in phosphate-buffered 10% formaldehyde. The infarct area and hemispheric area of each section were photographed by a digital camera and quantitated using the public domain image processing and analysis program developed at the National Institute of Health, USA. The infarct area was expressed as percentage to the contralateral hemisphere.

Real-time reverse transcription PCR The expression of RNAs was determined by quantitative real-time RT-PCR using a Continuous Fluorescence Detector (MJ Research Incorporated, DNA Engine Opticon 2) with the DNA Master SYBR Green I. Animals were killed 24 h after reperfusion and their brains removed. A 4-mm-thick coronal brain slice was cut at the levels of the optic chiasm, and the infarcted cortex was dissected using the corpus callosum as a ventral landmark^[8]. Total RNA was prepared from the samples with TRI-REAGENT-LS extraction kit according to manufacture's instructions. Complementary DNA was created from RNA using TrueScript MMLV reverse transcriptase and oligo d (T)₁₈ primers. A 0.2 µg amount of RNA was included in each reaction in a total volume of 20 µL. The reaction was performed at 42 °C for 2 h. Thereafter the mix was diluted five-fold, and 2 µL was added to the PCR reaction mixture to yield a total volume of 20 µL. The COX-2 primers were forward, 5'-CCATGTC AAAAC CGT GGT GAATG-3'; reverse: 5'-ATG GGA GTT GGG CAG TCA TCA G-3', which result in a PCR product of 374 bp. The amplification reaction consisted of 35 cycles of denaturation (94 °C, 30 s), annealing (64 °C, 30 s), and elongation (72 °C, 45 s). The beta-actin primers were forward, 5'AAG ATG ACC CAG ATC ATG TT3'; reverse: 5'TTAATG TCA CGC ACG ATT T3', which resulted in a PCR

product of 286 bp. The amplification reaction consisted of 35 cycles of denaturation (94 °C, 30 s), annealing (56 °C, 30 s), and elongation (72 °C, 45 s). Cycle numbers (crossing points, when amplification starts its exponential phase) were used for statistical analysis. The lower the cycle number indicates the higher the amount of initial template. The PCR products were verified by agarose gel electrophoresis.

Western blot analysis A 4-mm-thick coronal brain slice was cut at the levels of the optic chiasm, and the infarcted cortex was dissected using the corpus callosum as a ventral landmark^[8]. The isolated cortex was homogenized in ice-cold lysis buffer. The protein content was determined by BCA protein assay. Equal amounts of protein per lane (50 μg) were loaded onto an 8 % polyacrylamide gel and separated by electrophoresis at 120 V. Proteins were then transferred to PVDF membrane at 25 mA for 90 min, and the membrane was blocked with 5% nonfat dry milk in 1X TBS, 0.1% Tween-20 at 25 °C with gentle shaking, overnight. The PVDF membrane was then incubated with a goat polyclonal antibody specific for COX-2 (1:500) 1 h at 25 °C followed by horseradish peroxidase-conjugated secondary antibody (rabbit anti-goat) for 1 h at 25 °C. Antibody labeling was detected by Supersignal West Pico Trial Kit. After being stripped, the same PVDF membrane was incubated with mono-antibody specific for beta-actin (1:5000) as an internal control. Western blot results were quantified by density.

Data analysis All data were expressed as mean±SD. Differences between different groups were assessed by a one-way analysis of variance and Student-Newman-Keuls test. A value of $P < 0.05$ was considered statistically significant.

Results

Protective effects of IPC At 24 h after operation, sham-operated rats did not show any cerebral tissue damage in TTC staining (not shown). IPC reduced the infarct area by 63% as compared with the MCAO alone group. Indomethacin (3 mg/kg ip), a nonselective inhibitor of COX, applied 1 h prior to or 1 h after IPC failed to affect these protective effects. Indomethacin itself had no effect on infarction by ischemia and reperfusion injury (Figure 1).

Effects of IPC on COX-2 mRNA expression In agreement with previous study, low levels of COX-2 PCR products were observed in the brain of sham-operated rats (to achieve the crossing points, the cycle number 25.8 ± 2.4 was needed). After transient 90 min MCAO and 24 h reperfusion, COX-2 mRNA expression was significantly up regulated (the cycle number decreased to 19.9 ± 1.9 , $P < 0.01$). IPC significantly prevented the up-regulation of COX-2 mRNA expression following ischemia and reperfusion injury (the cycle

number decreased to 23.7 ± 2.4 , $P < 0.01$), while IPC itself had no effect on the expression of COX-2 mRNA 72 h later (Figure 2).

Effects of IPC on COX-2 protein expression COX-2 protein was expressed at a low level in the brain of sham-operated rats (132 ± 35). IPC itself had no effects on expression of COX-2 protein 72 h later (135 ± 32). Ischemia and reperfusion markedly increased COX-2 protein expression (362 ± 28 , $P < 0.01$). IPC prevented the up regulation of COX-2 protein following ischemia and reperfusion injury (225 ± 21 , $P < 0.01$) (Figure 3).

Discussion

IPC is a fundamental adaptive response of organisms against deleterious stress such as ischemia and other severe stimuli. In fact, this phenomenon exists in most organs such as brain, heart, skeletal muscle, lung, liver, stomach, intestine, and kidney. IPC shares some common mechanisms in different organs. The elements that constitute this molecular cascade of delayed IPC can be conceptually subdivided into three major components: (i) “triggers” or sensors, (ii) “effectors” or mediators, and (iii) “transducers”, signaling pathways that connect these two groups of molecules^[1,9]. Endogenous active substances and bio-synthesized proteins have been suggested as triggers and end effectors of brain IPC, respectively. Adenosine, glutamate, oxygen free radical, and nitric oxide (NO) are these candidate substances that trigger brain IPC^[1].

PGs are endogenous active substances that are suggested to be involved in IPC in the heart. It has been reported that pretreatment with indomethacin attenuated PGs release and abolished acute cardioprotection by IPC in

different animal models *in vivo* or *in vitro*^[10,11]. Exogenous PGs perfusion in isolated hearts mimicked cardioprotection induced by cardiac IPC^[12]. The mechanisms of cardioprotection mediated by PGs are mainly related to the direct effects of PGs on the heart, including antagonism of adenylyl cyclase, activation of ATP-sensitive potassium channels, inhibition of calcium influx, and attenuation of neutrophil infiltration^[13]. However, there was no study on the role of PGs in neuroprotection induced by IPC. A period of ischemia as short as 5 min can induce an early increase in PGs levels after 2 h of reperfusion in the brain^[4]. However, cerebral IPC dose not seem to be triggered by increased PGs, since indomethacin failed to affect the protective effects of IPC. The negative role for PGs pathway may be attributed to the specific model of focal cerebral ischemia used for preconditioning. Saline infusion compromised oxygen and glucose supply, however, inflammatory response could be smaller, due to maintained idle perfusion at least partial being able to prevent from disturbed microcirculation and reduce leukocyte-endothelial cell adhesive interaction and so on. This in turn potentially diminished the inflammatory signal (including PGs pathway) as a trigger for preconditioning mechanisms. The result suggested the delayed neuroprotection by our model of IPC has different triggering mechanisms from that of delayed ischemic tolerance induced by LPS.

Three types of COX isoforms have been documented: COX-1, COX-2, and COX-3. COX-1 is constitutively expressed under physiological conditions. COX-3 is identical in sequence to COX-1 except for the in-frame retention of intron 1. Like its counterpart COX-1, COX-3 does not generally appear to be induced by acute inflammatory stimulation^[14]. Several studies have demonstrated that COX-2 played an important role in the development of ischemic injury. In rodents as well as in humans, cerebral ischemia up-regulated COX-2 in neurons, blood vessels, and inflammatory cells in the injured brain^[4,15,16]. Although COX-2 mRNA was not induced in the ischemic core, it was induced in the penumbral area in permanent or transient MCAO in rats. The up regulation of COX-2 began 6 h after ischemia, reached a maximum at 12–24 h and subsided at 48 h^[4,8,17]. NS398, a selective COX-2 inhibitor, decreased infarction volume when administered 6 h after induction of ischemia^[18]. In COX-2-deficient mice, there was a significant reduction in the MCAO-induced brain injury^[19,20]. Our results that COX-2 mRNA and protein in the MCA cortex increased at 24 h after reperfusion in the rats of MCAO and reperfusion group were consistent with these previous studies. The mechanisms of the cytotoxicity of COX-2 induction may be related to the excessive release of arachidonic acid, and its products

such as PGs, thromboxane and free oxygen radicals. These factors may act as the major inflammatory substances involved in the pathogenesis of ischemia and reperfusion^[8]. COX-2 reaction products may also contribute to NMDA-induced neuronal injury and the pathogenesis of nitric oxide after ischemia^[21,22].

Evidence has shown that COX-2 was an obligatory effector in delayed IPC in the heart^[13]. Increased expression of COX-2 protein was observed 24 h after IPC with an increased enzymatic activity^[23]. NS-398 and celecoxib, two selective inhibitors of COX-2, abolished the cardioprotection conferred by IPC^[24]. It was also demonstrated that the expression of COX-2 subsided 48 h after a short period of ischemia in the brain^[4,8,17]. Since the delayed neuroprotection produced by IPC lasts as long as 7 d and is much longer than that of delayed cardioprotection (72 h), the up-regulated COX-2 does not seem to be the effector of delayed neuroprotection by IPC in the brain. In the present study, we examined the expression of COX-2 after IPC or IPC followed by ischemia and reperfusion injury. Our results demonstrated that IPC had no direct effect on the cortex COX-2 mRNA and protein expression 72 h later. Thus, it is not likely that an up-regulation of COX-2 contributes to the delayed neuroprotection by IPC in the brain. In the present study, we demonstrated that IPC significantly prevented the up-regulation of COX-2 mRNA and protein expression with a reduced infarction of the brain following ischemia and reperfusion injury. These results are similar to the previous finding that hyperbaric oxygen confers neuroprotection by depressing COX-2 expression and activity following ischemia and reperfusion injury^[8]. So we speculate that while the up-regulation of COX-2 contributes to the delayed cardioprotection by IPC in the heart, it is probably that COX-2 takes an inverse role in delayed neuroprotection by IPC in the brain. Our results are consistent with the recent observation that COX-2 expression was down-regulated by ischemic preconditioning in the gerbil brain^[25].

Recently, it has been shown that preconditioning stimulus reprogrammed the response of gene transcription to subsequent ischemia and reperfusion injury in mice. This feature mimics specific adaptive neuroprotective strategies seen in hibernation^[6]. Depressed protein synthesis may be mediated in part via translational mechanisms that affect both initiation and elongation^[6,26]. Since IPC confers robust neuroprotection, one presumption is that ischemic preconditioning may induce pro-survival factors that would negatively regulate COX-2. To date, three major mechanisms have been suggested to contribute to the neuroprotection by IPC, including anti-excitotoxic mechanisms, anti-apoptosis

mechanisms, and anti-inflammatory mechanisms^[1]. COX-2 has been verified to take an important role in pro-inflammatory action. We speculate that down-regulation of COX-2 may cooperate with other protective mechanisms and ultimately result in neuroprotection. However, more studies are needed to verify this hypothesis.

Abstract

Aim: To compare the acute effects of ascorbic acid on vasodilation of veins and arteries *in vivo*. **Methods:** Twenty-six healthy non-smokers and 23 healthy moderate smokers were recruited in this study. The dorsal hand vein compliance technique and flow-mediated dilation were used. Dose-response curves to bradykinin and sodium nitroprusside were constructed to test the endothelium-dependent and -independent relaxation before and after acute infusion of ascorbic acid. **Results:** Smokers had an impaired venodilation with bradykinin compared with non-smokers ($68.3\% \pm 13.2\%$ vs $93.7\% \pm 20.1\%$, respectively; $P < 0.05$). Ascorbic acid administration in the dorsal hand vein significantly increased the venodilation with bradykinin in smokers ($68.3\% \pm 13.2\%$ vs $89.5\% \pm 6.3\%$ before and after infusion, respectively; $P < 0.05$) but not in non-smokers ($93.7\% \pm 20.1\%$ vs $86.4\% \pm 12.4\%$ before and after infusion, respectively). Similarly, the arterial response in smokers had an impaired endothelium-dependent dilation compared with that in non-smokers ($8.8\% \pm 2.7\%$ vs $15.2\% \pm 2.3\%$, respectively; $P < 0.05$) and ascorbic acid restored this response in smokers ($8.8\% \pm 2.7\%$ vs $18.7\% \pm 6.5\%$ before and after infusion, respectively; $P < 0.05$), but no difference was seen in non-smokers ($15.2\% \pm 2.3\%$ vs $14.0\% \pm 4.4\%$ before and after infusion, respectively). The endothelium-independent dilation did not differ in both the groups studied. No important hemodynamic change was detected using the Portapres device. **Conclusion:** Smokers had impaired endothelium-dependent vasodilation responsiveness in both arterial and venous systems. Ascorbic acid restores this responsiveness in smokers.

Introduction

Chronic cigarette smoking is a major risk factor for cardiovascular disease and is associated with dose-dependent arterial endothelial dysfunction and hemodynamic changes^[1–3]. The cause of endothelial dysfunction in smokers is not known. Carbon monoxide and nicotine have been implicated^[4–6], but the mechanism that seems to have the greatest effect is oxidant injury^[7,8].

Although probably multifactorial, it has been hypothesized that the adverse effects of smoking may result from an accumulation of oxidative damage caused by the reactive oxygen species (ROS) on endothelial cells^[9]. Low plasma concentrations of nitric oxide (NO)^[10], which is a possible

sign of endothelial dysfunction, along with low plasma concentrations of ascorbic acid (AA) have been reported in long-term habitual smokers^[11]. AA has a broad spectrum of antioxidant activities because of its ability to react with numerous aqueous free radicals and ROS and it effectively protects lipids in human plasma against peroxidative damage^[12]. It has been demonstrated that the administration of AA in arterial beds markedly improves endothelium-mediated vasodilation in chronic smokers^[13], but its *in vivo* effect in veins has not been studied yet.

In contrast to the continuous production of NO in the arterial endothelium, a very low basal production of NO has been demonstrated in the venous endothelium^[14,15]. In contrast, in the cultured endothelial cells of rats, higher en-

dothelial isoform of the nitric oxide synthase (NOS) protein levels, nitric oxide synthase (NOS) activity, and intracellular *L*-arginine have been found in veins compared with that in arteries^[16]. There is considerable evidence of heterogeneity between the arterial and the venous endothelium^[17]. The goal of the present study was to compare the acute response of AA in both vascular beds in smokers.

Materials and methods

Study population The volunteers for this study were as follows: the control group comprised 26 healthy subjects without familial history of coronary artery disease or arterial hypertension (blood pressure < 140/90 mmHg), who were also non-hypercholesterolemic, non-diabetic and non-smokers without a history of being regular passive smokers. The smoker group comprised 23 regular smokers (normally 20 cigarettes daily) without familial history of coronary artery disease or arterial hypertension, who were also non-hypercholesterolemic and non-diabetic.

None of the subjects was taking regular medications and all were clinically well. Subjects with cardiac or cerebral ischemic vascular disease, impaired renal function, or other major pathologies were excluded from the study. In accordance with current legislation, all patients were aware of the investigational nature of the study and gave their written informed consent before participating. The Institutional Committee for Ethics in Research approved this study.

Experimental procedure All studies were initiated at 8:00 AM after overnight fasting, with the subjects lying in the supine position in a quiet air-conditioned room (22–24 °C). The subjects were admitted in the outpatient clinic of the Campinas State University Hospital (HC-UNICAMP) on 2 different occasions for 4 h studies. During the first study, measurements were performed after infusion of saline solution at a rate of 75 mL/h, iv. The second study was performed with infusion of saline solution (75 mL/h, iv) plus AA at a rate of 25 mg/min, iv.

Dorsal hand vein technique The dorsal hand vein technique, previously modified by Aellig^[18], as used in our laboratory has been described in detail^[5]. Briefly, a 23 G butterfly needle was inserted into a suitable vein on the back of the hand, with the arm positioned at an upward angle of 30 ° to allow the complete emptying of the veins. A tripod, holding a linear variable differential transformer (LVDT; Schaevitz Engineering, Pennsauken, New Jersey, USA) was mounted on the back of the hand with its central aperture, containing a movable metal core, at a distance of 10 mm downstream from the tip of the needle. The signal output of the LVDT, which is linearly proportional to the vertical movement of the core, gave a measurement of the diameter of the vein. Readings were taken under a congestive pressure of

40 mmHg by inflating a blood pressure cuff placed on the upper portion of the arm under study. Results were presented as normalized dose-response curves in which the diameter of the vein during saline infusion is defined as 100% dilation. The vein was pre-constricted to 20% of the baseline size by infusing increasing doses of phenylephrine (12–3166 ng/min). This dose rate of phenylephrine was defined as the ED₈₀ dose and this degree of constriction was defined as 0% dilation for the purposes of subsequent calculations. The vasodilation effects expressed in this study were calculated as a percentage in the range between 0% and 100% dilation. Drugs were infused using a Harvard infusion pump (Harvard Apparatus, South Natick, MA, USA) at a flow rate of 0.3 mL/min. Blood pressure and heart rate were monitored in the opposite arm with a Dynamap Blood Pressure Monitor (Critikon, Tampa, FL, USA). After pre-constriction of the vein by phenylephrine, dose-response curves of bradykinin (1–278 ng/min) and sodium nitroprusside (0.0187 ng/min–3166 ng/min) were constructed with 5 ng/min infusion rates in both smoker and non-smoker volunteers. AA (25 mg/min) was co-infused during the second study of each volunteer. Infusions at each rate lasted for 5 min with the sphygmomanometer cuff inflated to 45 mmHg for the last 2 min of the infusion.

Flow-mediated dilation Brachial artery flow-mediated dilation was measured with a 7.0 MHz linear array transducer and an ATL HDI system (Advanced Technology Laboratories, Seattle, WA, USA) according to the manufacturer's instructions^[19]. The brachial artery was scanned longitudinally 5–10 cm above the elbow and a holder probe was used to hold the transducer in the same position throughout the procedure. The focus zone was set to the depth of the near wall of the artery. Depth and gain settings were set to optimize images of the lumen-arterial wall interface. The images were magnified by a resolution box function and measurements were taken from the anterior to posterior "m" line at the R-wave peak of the electrocardiogram. The brachial artery diameter was measured by identifying a clear section of the vessel in B-mode.

After the baseline-resting scan, a pneumatic cuff, placed at the wrist, was inflated to 300 mmHg for 5 min. The second scan was performed 45–120 s after cuff deflation. Fifteen minutes were allowed for vessel recovery, after which a second baseline scan was performed. Glyceryl trinitrate (0.4 mg; Nitrostat, Parke-Davis, Morris Plain, New Jersey, USA) was then administered and the 4th scan of the brachial artery was undertaken. When the brachial artery diameter and blood flow had returned to baseline, flow-mediated dilation was determined after AA infusion (25 mg/min, iv; 10 min). Blood flow and brachial artery diameter data for glyceryl trinitrate and vitamin C represent measurements during the last minute

of each infusion^[20]. Two independent observers unaware of the subjects' clinical details, and the type and stage of the study measured the vessel diameter. Repeated measurements in individuals using this technique are consistent and reproducible.

Statistical analysis Descriptive data were expressed as mean±SD. The dose-response curves were fitted to a sigmoid model^[21], and the maximum effect (E_{max}) and the dose that causes 50% of the E_{max} (ED_{50}), were determined. Parametric tests (Student's paired and unpaired *t*-tests) were used to compare the E_{max} and $lgED_{50}$ values. The sample size was calculated for a power of 0.80. $P<0.05$ was considered to be statistically significant.

Results

Clinical characteristics No statistical difference between smokers and non-smokers in terms of clinical characteristics was detected (Table 1). Chronic smokers had a history of 23.1±6.1 cigarettes a day. No side-effect was observed during the studies.

Table 1. Clinical characteristics of the participants in the study. Mean±SD. BMI, body mass index; F, female; M, male; MBP, mean blood pressure.

	Control	Smokers
Sex (M/F)	12/14	13/10
Age (years)	36.1±6.4	39.0±8.4
BMI (kg/m ²)	23.8±5.0	22.5±2.5
Daily cigarettes	–	23.1±6.1
MBP (mmHg)	83.1±4.7	86.9±6.6
Glycemia (mg/dL)	97.3±6.4	88.1±7.2
Total cholesterol (mg/dL)	171.0±38.3	181.2±32.3
Triglyceride (mg/dL)	112.3±47.2	103.2±41.4
Creatinine (mg/dL)	0.7±0.3	0.9±0.1

Dorsal hand vein Smokers had an impaired endothelium-dependent venodilation with bradykinin compared with non-smokers (68.3%±13.2% and 93.7%±20.1%, respectively; $P<0.05$) (Table 2; Figure 1). AA administration significantly increased the venodilation to bradykinin in smokers (68.3%±13.2% and 89.5%±6.3% before and after AA infusion, respectively; $P<0.05$), restoring it to levels similar to those observed in non-smokers (93.7%±20.1% and 86.4%±12.4% before and after AA infusion, respectively; $P>0.05$) (Table 2). The endothelium-independent venodilation response did not show significant differences (Table 3; Figure 1).

Flow-mediated dilation The arterial response measured by flow-mediated dilation showed an impaired endothelium-dependent vasodilation in smokers compared with non-smok-

in the heart rate.

Discussion

The present study demonstrates that impaired endothelium-dependent vasodilation in chronic smokers could be markedly improved in both arterial and venous endothelium beds by acute administration of the anti-oxidant AA. In contrast to the continuous production of NO by the arterial

endo-thelium, the basal production of NO from the venous endothelium is very low^[22]. However, its production from the venous endothelium can be increased in response to bradykinin or other molecules^[23]. Recently, Wagner *et al* found higher eNOS protein levels, NOS activity, and intracellular *L*-arginine levels exhibited in cultured venular endothelial cells from rat mesenteric circulation compared with cultured endothelial cells from their paired arterioles^[16]. Bohlen reported that, although the mean NO concentration was not significantly different between vessel types because of the high variability in absolute values, the venous wall NO concentration was higher than the arterial wall NO concentration in approximately 80% in terms of small mesenteric artery vein pairs studied *in vivo*^[24]. Other studies have suggested that the venous endothelium does not have a larger capacity for NO synthesis than the arterial endothelium and in some cases may generate less NO. For example, shear stress and acetylcholine stimulate less NO release from the jugular vein than from the nearby carotid artery^[25] and shear stress elicits a smaller NO-dependent dilation in coronary venules than in their respective arterioles^[26].

Many studies have demonstrated the superior long-term patency of arterial grafts compared with the saphenous vein, based on endothelial function^[27]. A higher basal release of NO and endothelium-derived hyperpolarizing factor in arterial grafts^[15], intact endothelial function and absence of intimal thickening in arterial grafts when compared with saphenous grafts^[28], and the maintenance of the physiological NO and prostacyclin metabolisms, both soon after surgery and in long-term follow up, in arterial rather than venous grafts^[29] suggest a higher bioavailability of NO in arterial beds. All these findings highlight the growing consensus that there is a marked regional and segmental heterogeneity in vascular endothelial function, with NO release and/or its vascular effects varying between and within specific vascular beds^[17].

Previously, we demonstrated an impaired vasodilation in smokers using the dorsal hand vein technique^[30] and flow-mediated dilation^[31]. Now, our data show that acute AA administration reverses this abnormal response caused by cigarette smoking in both vascular beds. Clinical observations have shown oxygen-derived free radicals as mediators of smoking-induced endothelial dysfunction. Ascorbate improves or reverses endothelial dysfunction suggesting that there is a link between this and NO production or its metabolism. Depleted levels of AA, have been demonstrated in chronic smokers^[11,32]. Ascorbate has been shown to reverse NO-dependent endothelial dysfunction present in the coronary arteries of patients with atherosclerosis^[33], hyperhomocysteinemia^[34], hypercholesterolemia^[35], hypertension^[36], and diabetes^[37]. There are many mechanisms for the improvement of endothelial function by ascorbate^[38]: (i)

prevention of endothelial dysfunction induced by oxidized cholesterol low-density lipoproteins; (ii) ascorbate-induced release of NO from *S*-nitrosothiols in plasma; (iii) reduction of nitrite to NO; (iv) scavenging of superoxide by ascorbate; (v) thiol-dependent redox regulation of eNOS interaction with ascorbate; (vi) regulation of eNOS through tetra-hydrobiopterin; (vii) ascorbate as a cofactor for eNOS; and (viii) effects on stimulation of guanylyl cyclase by NO. Many studies have shown these improvements in the arterial beds of regular smokers using flow-mediated dilation, impedance plethysmography, and intra-arterial infusions, but not in venous vascular beds.

Our findings demonstrate that endothelial dysfunction in smokers can be reversed by AA in venous and arterial vascular beds. Arteries and veins have different biological activities in terms of the endothelium, probably by marked regional and segmental heterogeneity in vascular endothelial function, but we have demonstrated similar findings in this specific vascular bed. The precise mechanism for this needs further investigation. Because veins are not susceptible to atherosclerosis, we have demonstrated that the dorsal hand vein technique can be used as a tool to assess vascular responsiveness in smokers.

These results show that there is a similar impaired responsiveness in arterial and venous endothelial-dependent vascular reactivity in smokers, and that after acute infusion of AA there is an improved responsiveness in both vascular beds.

Abstract

Aim: To identify and classify all potential hemolysin candidates of *Leptospira interrogans* serogroup Icterohaemorrhagiae serovar Lai. **Methods:** All of the potential hemolysin encoding genes were characterized *in silico*. These genes were cloned and expressed in *Escherichia coli*. The hemolytic activities of the expressed proteins were assayed observing the hemolysis on sheep blood agar plates. Sphingomyelinase activities of the hemolysin candidates were measured by thin-layer chromatography (TLC) and HPLC for sphingomyelin-hydrolysis. Expression and secretion of the hemolysins in *L interrogans* were studied by reverse transcription polymerase chain reaction, Western blot, and enzyme-linked immunosorbent assays. **Results and Conclusion:** The hemolytic activities of hemolysin candidates (LA0327, LA0378, LA1027, LA1029, LA1650, LA3050, LA3937, LA4004) from *L interrogans* strain Lai were confirmed. They were further divided into two groups, sphingomyelinase hemolysins and non-sphingomyelinase hemolysins, based on their ability to hydrolyze sphingomyelin. Most of these hemolysins were actually expressed in living *L interrogans* and some of them were secreted into the environment. This study establishes an essential and complete basis for further studying the contribution of hemolysins to the pathogenesis of *L interrogans*.

Introduction

Leptospirosis is a worldwide zoonosis caused by pathogenic species of *Leptospira*, particularly, *Leptospira interrogans* serovar Lai^[1]. Pathogenic *Leptospira* infection causes leptospirosis (Weil's syndrome), which manifests with jaundice and renal failure^[2–4] along with prominent respiratory symptoms. In some cases, severe pulmonary hemorrhages may happen, which may lead to sudden death. Although potential virulence factors, such as hemolysin, lipopolysaccharide (LPS), and heat shock proteins, are suggested for leptospiral infection, the pathogenetic mechanism of leptospirosis is yet to be clarified.

Among these suggested virulence factors, bacterial hemolysin has been demonstrated in several pathogenic bacteria^[5,6] and a limited number of them have been identified in *L interrogans*^[7]. Annotation of the complete genomic sequence of *L interrogans* serogroup Icterohaemorrhagiae serovar Lai^[8] indicated that there were ten putative hemolysin genes located on the large chromosome (CI, GB: AE010300), of which, one (LA3540) had been previously identified^[7]. Our current work characterized all the other genes, except LA0177 because of its extremely short nucleotide sequence. The classification of the hemolytic activities and their expression and secretion in *L interrogans* were investigated.

Materials and methods

Bacterial strains and plasmids The virulent *L interrogans* serogroup Icterohaemorrhagiae serovar Lai type strain 56601 used in this study was maintained by the Institute for Infectious Disease Control and Prevention, Beijing, China. The avirulent strain of *L interrogans* serogroup Icterohaemorrhagiae serovar Lai (strain IPAV) was given as a gift by Dr PICARDEAU, M (Institute Pasteur, Paris, France). Strains were grown in liquid Ellinghausen-McCullough-Johnson-Harris (EMJH) medium^[1] at 28 °C under aerobic conditions and collected at a density of approximately 1×10^8 bacteria per mL. *Escherichia coli* DH5 α and BL21 (DH3) were used for the cloning and expression of hemolysin candidates, respectively. The pUCm-T and pET28b plasmids were served as the vectors for cloning and expression, respectively.

Characterization of hemolysin candidates First, coding sequences (CDSs) potentially encoding hemolysin candidates were identified during the genomic annotation^[8]. Second, amino acid sequences of those hemolysin candidates were analyzed with the SWISS-PROT/TrEMBL non-redundant databases^[9] to obtain homologous proteins, which were further compared with BioEdit (Tom Hall, North Carolina State University, Carolina, USA). Third, the domain structures of the hemolysin candidates were predicted by Pfam^[10], PROSITE^[11] or ProDom^[12]. The secondary structures of the proteins were predicted by Jpred^[13]. Finally, multiple sequence alignments were made for sphingomyelinase-like hemolysin homologous proteins using clustW, and Mega² (Sudhir Kumar, Arizona State University, Arizona, USA) was used to establish their phylogenetic tree.

Cloning, expression, and purification of the recombinant hemolysin candidates in *E coli* Genomic DNA was isolated from *L interrogans* strain 56601 cultivated in EMJH medium. The hemolysin candidate genes were obtained by polymerase chain reaction (PCR), ligated with pUCm-T vector and transformed into DH5 α cells. The confirmed recombinant plasmids were digested with corresponding enzymes, ligated with pET28b vector and then transformed into BL21 (DH3) cells. *E coli* cells were grown in Luria-Bertani medium supplemented with kanamycin at 50 mg/L at 37 °C. Protein expression was induced at A_{600} of 0.6 by addition of isopropyl-beta-D-thiogalactopyranoside (IPTG) at 0.6 mmol/L for 3 h. The harvested cells were suspended in Tris-HCl buffer (20 mmol/L Tris-HCl, pH 7.9) and lysed by sonication. The insoluble inclusion bodies were dissolved in the buffer (Tris-HCl 20 mmol/L, pH 7.9, NaCl 0.5 mol/L, 10% glycerol, guanidium HCl 6 mol/L) and then centrifuged at 20 000 \times g for

20 min. The soluble supernatant was applied to Ni-NTA His-Bind resin and the His-tag fusion protein was eluted by an imidazole gradient from 10 mmol/L to 1000 mmol/L in the elution buffer (20 mmol/L Tris-HCl pH 7.9, 0.5 mol/L NaCl, 10% glycerin). The purified proteins were analyzed by sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE) with coomassie brilliant stain.

Hemolytic activity assay on sheep blood agar plates Sheep blood plates, 10% (v/v) supplemented with 25 mmol/L MgCl₂ and 100 mg/L kanamycin, were used to measure hemolytic activities. Lysate of *E coli* cells expressing hemolysin candidate proteins (100g/L) was dropped onto the plates, and the plates were incubated at 37 °C for 16 h, and then placed at 4 °C for 30 min. Sphingomyelinase C (0.1 U, Sigma, St Louis, MO, USA) and lysate of *E coli* cells harboring pET28b (100 g/L) were used as positive and negative controls, respectively.

Sphingomyelinase assay by thin-layer chromatography and HPLC The biphasic system consisted of an ether: methanol (9:1 v/v) organic phase containing sphingomyelin (2 g/L) and a water phase (25 mmol/L MgCl₂) containing the lysate of *E coli* cells expressing hemolysin candidate proteins (100 g/L). This biphasic solution was shaken at 37 °C for 4 h. After that, the organic phase (15 μ L) was applied on a silica gel-60 coated glass plate. The chromatogram was developed with a mobile phase (chloroform:methanol:water: 25% ammonia 58.0:35.0:3.5:3.5 v/v). Lipids were visualized by spraying on a plate with 30% H₂SO₄ at 110 °C for 10 min. For HPLC, sphingomyelinase activity was determined in a biphasic system as described above, except for the organic phase containing sphingomyelin (1 g/L). The organic phase (7.5 μ L) was applied to HPLC (YWG C₁₈ 5 μ m, 200 mm \times 4.6 mm, China) and the elutes were monitored by absorption at 207 nm. The mobile phase was a mixture of acetonitrile: methanol:water (154:45:81 v/v). The flow rate was 1 mL/min. Sphingomyelinase C (0.1 U) and lysate of *E coli* cells harboring pET28b (100 g/L) were used as positive and negative controls, respectively.

Validation of hemolysin encoding gene expressions in *Leptospira interrogans* strain Lai by reverse transcription RCR and Western blot According to the manufacturer's instructions, total RNA was extracted with TRIzol reagent (Invitrogen, Carlsbad, California, USA) from *L interrogans* strain Lai cultivated in EMJH medium. Total RNA (1 μ g) from each sample was reverse-transcribed into cDNA according to the instructions provided with the cDNA Synthesis Kit (Invitrogen, Carlsbad, California, USA). Equal amounts of the product of the reverse transcription reaction were subjected to PCR amplification. The primers and related infor-

mation are shown in Table 1. After amplification, 5 µL of each PCR reaction product was electrophoresed on a 1.5% (w/v) agarose gel containing ethidium bromide (0.5 mg/L). For Western blot analysis, *L. interrogans* strains cultivated in EMJH medium were harvested by centrifugation at 14 600×g for 10 min, electrophoresed on 10% SDS-PAGE gels and electrotransferred to nitrocellulose membrane under a constant voltage of 5 mA/cm² for 1 h. The blot was first masked by the blotting buffer (10% skim milk in 10 mmol/L Tris-HCl buffer with NaCl 150 mmol/L and 0.1% Tween-20) for 2 h and then incubated with rabbit anti-hemolysin antibody (1:5000) for 2 h. After being washed with TBST 3 times, the blot was incubated for 1 h with alkaline phosphatase (AP)-conjugated goat anti-rabbit IgG antibody (1:7500) and the color was developed by addition of bromo-chloro-indoryl phosphate/nitroblue tetrazolium (BCIP/NBT) for AP reaction.

Detection of hemolysin secretion in *L. interrogans*
Briefly, the culture supernatant (100 ng/well) of *L. interrogans* in Korthof^{f1} was coated onto 96-well ELISA plates by incubation at 37 °C for 2 h. After the removal of blocking solution and washing 3–5 times with phosphate-buffered saline buffer (PBS) containing 0.1% Tween (PBS-Tween), anti-hemolysin antibodies were incubated in the plate at 37 °C for 2 h. The plate was washed 3–5 times with PBS-Tween and then incubated with AP-conjugated goat anti-rabbit IgG antibody (1:1500) at 37 °C for 1 h. The plate was washed 3–5 times with PBS-Tween and incubated with the BCIP/NBT for 20 min in the dark. Absorbance at 492 nm was recorded using an automated ELISA microplate reader.

Results

The *in silico* structural analysis indicated that there were at least two kinds of hemolysin candidates from *L. interrogans* Genomic annotation of *L. interrogans* strain Lai

indicated that there were 10 genes putatively encoding proteins highly similar to hemolysins reported in the NCBI/Genbank and SwissProt/TrEMBL databases (Table 2).

Domain structure analysis of the candidate proteins indicated that 5 of them had barring of the characteristic domains of the phosphatase family. Specifically, the Pfam-based domain analysis indicated that all of LA1027, LA1029, LA4004, and LA3050 barred a conserved domain PF03372 of the phosphatase family. The ProDom-based analysis showed that all of the proteins, except LA3050, were highly similar to *L. interrogans* serovar hardjo sphingomyelinase-like hemolysin (SP17627/SwissProt), barring phosphatase domains of PD011673, PD447657, and PD041204 in similar regions of the proteins. Although LA3050 was reasonably similar to SP17627 (67%) and also had the PD041204 domain, it lacks the other two domains mainly because of its short primary peptide sequence. Although LA3540 had PD011673, PD041204, and the phosphatase conserved domain PF03372, LA3540 had previously been identified as a pore-forming hemolysin^[5].

Amino acid sequence analysis of these sphingomyelinase-like hemolysin candidates indicated that the conserved Mg²⁺-complexing glutamic acid and asparagine involved in substrate binding were identified in LA1029, Glu²⁰⁰, and Asn³⁴³, corresponding to the Glu¹³¹ and Asn²⁷⁴ of SP17627, respectively. For LA4004, only Asn²⁶⁷ was identified as corresponding to the conserved Asn²⁷⁴ of SP17627. Protein secondary structures were predicted by Jpred², and their similarities are shown in Figure 1.

The remaining 5 candidate proteins have little sequence similarity to those of sphingomyelinase-hemolysin proteins. Based on the *in silico* analysis, they do not have any phosphatase family domains or share any common domains. Therefore, these hemolysin candidates, if they are active, may function based on the mechanism of pore formation and

Figure 1. Primary and secondary structure comparisons of SP17627 and *Leptospira interrogans* sphingomyelinase-like hemolysins. Multiple amino acid sequence alignment was performed using BioEdit. Identical amino acids are shaded in red. Similar amino acids are shaded in yellow. The Mg²⁺-complexing glutamic acid and asparagine involved in substrate binding are indicated by arrows; these were Glu¹³¹ and Asn²⁷⁴ in SP17627. Correspondingly, the conserved sites were found at Glu²⁰⁰ and Asn³⁴³ in LA1029, and Asn²⁶⁷ in LA4004. Protein secondary structures were predicted by Jpred², and only the results of SP17627 (up) and LA1029 (down) are shown (the grey belts are alpha-helices and the black belts are beta-sheets).

Table 2. Hemolysin candidate genes of *Leptospira interrogans*.

other mechanisms.

Phylogenetic analysis was performed on the sphingomyelinase-hemolysin proteins. An neighbor-joining unrooted phylogenetic tree was established including sequences of SP17627, LA1027, LA1029, LA4004, LA3050, and other similar proteins, with a cut-off amino acid identity of 53% and similarity of 67%. Hemolysins from *Staphylococcus aureus*, *Bacillus cereus*, *Listeria ivanovii*, and *Pseudomonas* sp strain TK4 made up one branch of the tree, and the sphingomyelinase-like proteins of *L interrogans* made up another branch (Figure 2).

Figure 2. Comparison of sphingomyelinase-hemolysin protein sequences by neighbor-joining method shown in unrooted tree. STAAU, *Staphylococcus aureus*; BACCE, *Bacillus cereus*; LISIV, *Listeria ivanovii*; PSESP, *Pseudomonas* sp strain TK4; LEPIN, *Leptospira interrogans*.

The hemolytic activities of the recombinant hemolysin candidates from *L interrogans* were determined Among the 10 hemolysin candidates from *L interrogans*, LA3540

had previously been identified^[7], whereas LA0177 is extremely short in its sequence and has no detectable phosphatase domain. Therefore, only the remaining 8 hemolysin candidate genes were cloned into *E coli* and the recombinant proteins were purified to homogeneity determined by

Figure 3. Purification of recombinant hemolysins. Protein markers: 97 400 Da, 66 200 Da, 43 000 Da, 31 000 Da, 20 100 Da, 14 400 Da.

SDS-PAGE followed by coomassie brilliant stain (Figure 3).

Crude cell lysates of *E coli* expressing cloned hemolysin candidates were spotted onto sheep blood agar plates and, after incubation at 37 °C for 16 h, clear hemolytic zones were observed for all the candidates via a cold-warm hemolytic procedure (Figure 4). The hemolytic zone of LA1029 appeared at first and the area of hemolysis was the biggest. Clear hemolytic zones of LA1027 and LA4004 appeared a little later. Hemolysis caused by LA3050 appeared last and the area of the hemolytic zone was the smallest. For those predicted to be in the non-sphingomyelinase-hemolysin family, hemolytic abilities were also different: LA3937 was the highest and LA0327, LA0378, and LA1650 were second

Figure 4. Hemolysis of recombinant hemolysin candidates on sheep blood planes.

highest, third highest, and lowest, respectively.

The sphingomyelinase activities of hemolysin candidates were detected The sphingomyelinase activities of recombinant hemolysin candidates were detected by TLC assay. Results showed that only LA1027, LA1029, LA4004, and LA3050 could hydrolyze sphingomyelin. These results were confirmed by HPLC assay. The peak area of sphingomyelin was diminished after hemolysin treatment and the percentages of hydrolyzed sphingomyelin are displayed in Table 3. The percentages of hydrolyzed sphingomyelin of sphingomyelinase (SphC), LA1029, LA1027, LA4004, and LA3050 were 73.99%, 68.87%, 61.10%, 56.52%, and 48.04%, respectively. LA3937, LA0327, LA0378, and LA1650 could not hydrolyze sphingomyelin under the same condition.

Hemolysin gene expression and hemolysin secretion in *L interrogans* RT-PCR analysis indicated that all the 8 candidates, LA0327, LA0378, LA1027, LA1029, LA1650, LA3050, LA3937, and LA4004, were transcribed in *L interrogans* strain Lai and strain IPAV cultivated in EMJH or Korthof culture medium (Figure 5). The transcription levels of some hemolysin encoding genes, LA0378, LA0327, and LA3050, were higher in *L interrogans* cultivated in Korthof medium than those in the EMJH medium. Western blot can detect hemolysin proteins in strain Lai cell crude extracts for all the candidates except LA1027 (Table 4). In addition, we failed to detect this protein by Western blot in the strain IPAV cultured in EMJH medium. In addition, we failed to detect LA3050 under the same condition, whereas the other 6 hemolysin candidates were all detected. LA1029, LA4004, LA3050, LA1650, and LA3937 were secreted into the environment, as determined by ELISA, and the secretion levels were higher in strain Lai than those in strain IPAV (Figure 6). LA0327 was secreted into the environment both in strain Lai and in strain IPAV. LA1027 was not secreted either in strain Lai or in strain IPAV.

Discussion

In 1956, Alexander *et al*^[14], for the first time, discovered that *L interrogans* had a hemolysin-like substance that could hemolyze red blood cells of ruminants, such as sheep, cows,

LA3937	+	+

and goats. Its hemolytic activity was completely lost after being heated at 56 °C for 5 min, indicating its heat-labile character. Later, hemolysins were detected in many pathogenic *L interrogans*^[15].

L interrogans gene encoding hemolysin was first cloned from the pathogenic serovar hardjo. This protein obviously possessed both hemolytic and sphingomyelinase C activi-

ties^[16]. The only hemolysin gene cloned from serovar lai before our efforts was CDS LA3540^[7]. Although this gene encoded a hemolytically active protein with a phosphatase-like domain, the purified protein did not have any detectable sphingomyelinase activity. Therefore, it was proposed that it was a transmembrane pore formation protein. The concept of transmembrane pore formation by bacterial protein toxins was first brought forward by Fussle *et al*^[17] to explain the mechanism of action of staphylococcal alpha-toxin and it is apparent today that the majority of medically relevant pathogens produce pore-forming proteins^[18]. Many of these toxins have been designated as hemolysins because of their lytic action on red blood cells.

Our studies have proven experimentally that, besides the previously characterized LA3540 and the very short hemolysin candidate gene, LA0177, the recombinant proteins encoded by the candidate genes from *L interrogans* strain Lai (LA0327, LA0378, LA1027, LA1029, LA1650, LA3050, LA3937, LA4004) were hemolysin. According to the *in silico* structure analysis, LA1027, LA1029, LA4004, and LA3050 are highly similar to SP17627, the hemolytic sphingomyelinase C from serovar hardjo, with respect to domain organizations, amino acid sequences, and the predicted secondary structures. These predictions were further confirmed by sphingomyelinase assays. Other candidates, LA0327, LA0378, LA1650, and LA3937, were confirmed to be non-sphingomyelinase hemolysins. They are likely either to be pore-forming proteins or to have other mechanisms of hemolytic activity.

Spirochetes are evolutionarily primitive and *L interrogans* is a facultative free-living pathogen possessing a large number of different kinds of hemolysins. Therefore, questions about the possibilities of convergence, divergence, or other models of evolution should be addressed in the future. In this study, the phylogenetic analysis of sphingomyelinase from *L interrogans*, both serovar lai and serovar hardjo, with those from other bacteria indicated that the sphingomyelinase hemolysins of *L interrogans* are closely related but distantly different from those of the others. Thus, this group of hemolysins is more likely to be evolved from a common ancestor with a divergence mechanism. For the other group of hemolysins, because of their high level of diversity, the possibility of horizontal gene transfer cannot be excluded.

Almost all of these hemolysins were expressed *in vivo* under normal culture conditions. Among them, LA1029, LA4004, LA1650, and LA3937 were secreted into the environment and the secretion level was significantly higher ($P < 0.01$) in the virulent strain Lai than in the avirulent strain IPAV (Figure 6). LA0327 was secreted into the environment both in strain Lai and IPAV without significant difference.

Figure 6. Secretion of hemolysin candidates in *Leptospira interrogans* by enzyme-linked immunosorbent assay. C, control (blank Korthof medium); NV, avirulent strain IPAV; V, virulent strain Lai. ^b $P < 0.05$; ^c $P < 0.01$ vs control. ^e $P < 0.05$, ^f $P < 0.01$ vs NV.

LA1027 was not expressed or secreted in either strain Lai or IPAV, which was testified by ELISA and Western blot assay (Figure 6, Table 4). The significant difference in hemolysin expression and secretion between the virulent strain Lai and the avirulent strain IPAV may suggest that hemolysins might play an important role in the pathogenesis of *Leptospira*.

Abstract

Aim: To investigate the expression and regulation of PD-1 ligand 1 (PD-L1) in peripheral blood mononuclear cells (PBMC). **Methods:** The cDNA encoding human PD-L1 precursor was cloned from the total RNA extracted from the resting and phorbol dibutyrate plus ionomycin- or phytohemagglutinin-activated PBMC, by reverse transcription polymerase chain reaction (RT-PCR), and independent clones were sequenced and analyzed. The expression and subcellular localization were examined in transiently transfected cells. The *PD-L1* gene expression in different PBMC was also analyzed by RT-PCR. **Results:** A novel human *PD-L1* splice variant was identified from the activated PBMC. It was generated by splicing out exon 2 encoding an immunoglobulin variable domain (Igv)-like domain but retaining all other exons without a frame-shift. Consequently, the putative translated protein contained all other domains including the transmembrane region except for the Igv-like domain. Furthermore, the conventional isoform was expressed on the plasma surface whereas the novel isoform showed a pattern of intracellular membrane distribution in transiently transfected K562 cells. In addition, the expression pattern of the PD-L1 splice variant was variable in different individuals and in different cellular status. **Conclusion:** PD-L1 expression may be regulated at the posttranscriptional level through alternative splicing, and modulation of the PD-L1 isoform expression may influence the outcome of specific immune responses in the peripheral tissues.

Introduction

The signals provided by B7 family members are critical for both stimulating and inhibiting T-cell activation^[1]. In conjunction with signaling through the T-cell receptor, CD28 ligation by B7 molecules stimulates antigen-specific proliferation of T cells and enhances production of cytokines, differentiation, and the effector function of T cells^[2]. In contrast, B7 interaction with cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4, or CD152) delivers a negative signal that inhibits T-cell proliferation, IL-2 production, and cell cycle progression^[3]. In addition to CTLA-4, several studies have indicated that PD-1, a member of the immunoglobulin (Ig) superfamily and a CD28 homolog, functions as an important negative regulator of the immune system^[2]. The

ligands of PD-1, PD-L1 (B7-H1), and PD-L2 (B7-DC) have recently been identified^[4–6], which deliver an inhibitory signal by binding to the common receptor PD-1^[4], although some studies suggest a stimulatory signal is delivered by the PD ligand (PD-L) through a putative receptor other than PD-1^[2,5]. PD-L1 and PD-L2 are homologous to B7 molecules and belong to the Ig superfamily^[2]. Despite their homology with B7 molecules, PD-L1 and PD-L2 do not bind to CD28 or CTLA-4^[5,6], suggesting that they possess different roles from B7 molecules.

Because of their important roles in the immune response, the expression of the B7 family is strictly regulated. Moreover, their expression is further modulated by alternative splicing of the transcripts^[2]. Some of these alternatively spliced isoforms play an important part in the modulation of

immune responses. Study on CTLA-4 isoforms, for instance, indicates an association of lower mRNA levels of the soluble alternative splice form with susceptibility to autoimmune disease^[7]. Similarly, differential splice variants have also been identified for B7-1 and B7-2 genes and its receptor CD28^[8-10]. It has been demonstrated that a soluble B7-2 is a costimulatory molecule for human T cells^[9]. Recently, we have identified two alternatively spliced variants of human PD-L2^[11], although their functional implications remain to be discovered.

The present study reports the identification of a novel splicing variant of human *PD-L1* mRNA, which encodes an isoform lacking immunoglobulin variable domain (Igv)-like domain in the extracellular region. The expression and subcellular localization of this isoform was compared with the conventional product. Differential expression patterns of PD-L1 variants of different statuses suggest alternative splicing of PD-L1 may modulate the immune response in peripheral tissues.

Materials and methods

Cell preparation and activation To prepare peripheral blood mononuclear cells (PBMC), heparinized human peripheral blood was collected from two adult volunteers by venipuncture. Blood samples were diluted 1:2 with phosphate-buffered saline (PBS) and a mononuclear cell fraction was obtained by centrifugation over a Ficoll-Hypaque density gradient (Lymphoprep; NYCOMED, Elverum, Norway). PBMC were collected from the interface and washed twice with PBS and resuspended in RPMI-1640 medium supplemented with 10% (v/v) fetal bovine serum, 10 mmol/L glutamine, 2-mercaptoethanol 50 μ mol/L, benzylpenicillin 100 kU/L, and streptomycin 100 mg/L (Invitrogen, Carlsbad, CA, USA) at a final concentration of 2×10^9 cells/L. The cells were incubated in a humidified atmosphere with 5% CO₂ for 48 h at 37 °C in the presence of 1×10^{-7} mol/L phorbol 12,13-dibutyrate (PDB; Calbiochem, San Diego, CA, USA) and 0.5 μ g/mL ionomycin (Sigma, St Louis, MO, USA) or 10 mg/L phytohemagglutinin (PHA; Sigma).

Reverse transcription polymerase chain reaction amplification (RT-PCR) of PD-L1 cDNA Heparinized human peripheral blood was collected from two donors by venipuncture. Total RNA was extracted from freshly isolated and activated PBMC using TRIzol reagent (Invitrogen). cDNA were synthesized from the isolated RNA using the ThermoScript RT-PCR system according to the recommended procedure (Invitrogen). RNA integrity was verified by both electrophoresis in 1% (w/v) agarose gels and PCR amplifica-

tion of the cDNA of a house-keeping gene, glyceraldehyde-3-phosphate dehydrogenase (GAPDH). PCR amplification of the resultant cDNA was performed in a total volume of 50 μ L containing high fidelity DeepVent *Taq* polymerase (New England Biolabs, Beverly, MA, USA). For amplification of PD-L1, PCR was performed with an initial denaturation for 2 min at 94 °C, followed by 35 cycles of 94 °C for 30 s, 50 °C for 30 s, and 72 °C for 1 min, and a final extension for 10 min at 72 °C. The primers (5'-CCG CGAATT CAT GAG GAT ATT TGC TGT CTT TA-3' and 5'-ATC AGG TAC CTT ACG TCT CCT CCA AAT GTG TAT C-3') were designed to amplify the entire coding sequence of human PD-L1 cDNA^[4]. For amplification of the GAPDH cDNA, PCR was performed as above, except that the annealing temperature was 60 °C and the primers (5'-AAG GCT GAG AAC GGG AAG CTT GTC ATC AAT-3' and 5'-TTC CCG TCT AGC TCAGGGATGACCTTGCCC-3') were designed to amplify the target sequence. All primers were synthesized at BioAsia (Shanghai, China).

Cloning and sequencing of PD-L1 cDNA The PCR products were separated by electrophoresis in 1% (w/v) agarose gels containing ethidium bromide and recovered from the gel using a QIAquick Gel Extraction kit (QIAGEN, Hilden, Germany). The fragments of 873 bp and 532 bp were digested separately with *EcoRI* and *KpnI*, and cloned into a pEGFP-N1 vector (ClonTech, Palo Alto, CA, USA). Randomly selected transformed DH5 α clones were screened with *EcoRI* and *KpnI* cutting for the presence of a correctly sized insert. Nucleotide sequences of independent clones from the samples of 2 donors were determined using dye-labeled deoxy-terminator, a 377 automated DNA sequencer (Applied Biosystem, Foster City, CA, USA).

Expression of PD-L1-EGFP fusion proteins in K562 cells PD-L1 type I or type II cDNA containing the sequence encoding signal peptide was separately subcloned into the mammalian expression vector pEGFP-N1 to construct the vectors for the fusion proteins of PD-L1 isoforms with enhanced green fluorescent protein (EGFP). These vectors were named pEGFP/PD-L1I (for the type I isoform) and pEGFP/PD-L1II (for the type II isoform). A Kozak sequence was included at the translational initiation region and the stop codon was deleted. EGFP was thus fused at the C-terminus of the PD-L1 isoform. For transient transfection, K562 cells were grown in RPMI-1640 supplemented with 10% (v/v) fetal bovine serum at 37 °C in a CO₂ incubator. Cells were transfected using a Cell Line Nucleofector kit V and Nucleofector Device (Amaxa, Cologne, Germany) according to the recommended protocol with 2 μ g of the expression vector pEGFP/PD-L1I, pEGFP/PD-L1II, or empty vector pEGFP-N1, respectively, and left for 24 h in a CO₂ incubator.

These cells were subsequently stained with phycoerythrin (PE)-labeled mouse-antihuman PD-L1 monoclonal antibody (PE-*PD-L1*, e-Bioscience, San Diego, CA) and fixed with 4% (w/v) paraformaldehyde. The fluorescence of EGFP and PE was then analyzed by flow cytometry (FACSCalibur; Becton Dickinson, San Jose, CA, USA) and confocal microscopy (Spinning Disk Confocal Microscope; Perkin Elmer, Wellesley, MA, USA).

Western blot Cells (1×10^6) were dissolved in loading buffer and separated using sodium dodecyl sulfate-polyacrylamide gel electrophoresis (10% w/v) according to Laemmli's discontinuous system^[12]. After electrophoresis, the gels were blotted onto nitrocellulose paper (Bio-Rad, Hercules, CA, USA) for Western blot analysis to visualize the specific protein bands. The Western blots were incubated with the goat antihuman PD-L1 antibody (R&D, Minneapolis, MN, USA). Horseradish peroxidase-conjugated rabbit-antigoat antibody (Jackson ImmuneResearch, West Grove, PA, USA) was used as the secondary reagent, and the color reaction was developed using 4-chloro-1-naphthol as a substrate. The molecular mass was evaluated with a software package (PhotoCapt Ver11.01; Vilber Lourmat, Marne La Vallée, France).

Bioinformatics Homology analyses of the cloned sequences were performed using a BLAST^[13] search on the NCBI website and a PROSIS software package (Hitachi Software, Yokohama, Japan). The human genomic DNA sequence (submitted to the GenBank database under accession number AL162253) from clone RP11-574F11 on chromosome 9, which contains the *PD-L1* gene, was used to analyze exon-intron junction sequences. The transmembrane regions were predicted using TMpred, a web-based program^[14]. SignalP^[15] was used to identify the potential signal peptide.

Results

Cloning and sequence analysis of a *PD-L1* splice variant RT-PCR was performed to amplify the full coding sequence of *PD-L1* mRNA with specific primers. PCR product resolution on agarose gel revealed that the product of activated PBMC had one main band of 873 bp and a minor band of 532 bp (Figure 1A, lane 3), whereas that of freshly isolated PBMC only had the shorter one (Figure 1A, lane 2). The fragments of 873 bp and 532 bp were inserted separately into the pEGFP-N1 vector. Nine independent transformed DH5a clones were identified to have the expected inserts. DNA sequencing of these clones showed that 5 clones contained the 873 bp DNA fragment, which was the complete

coding sequence for conventional PD-L1 (designated PD-L1I, submitted to the GenBank database under accession number AY254342), and which was identical to the previously reported cDNA of human PD-L1 (submitted to the GenBank database under accession number AF233516^[4]). The other 4 clones contained the 532 bp fragment and were identical to PD-L1 cDNA except for a deletion of a 341 bp fragment as revealed by BLAST analysis. Sequence homology searches performed with the BLASTn algorithm^[13] revealed that this sequence might be an alternatively spliced variant of *PD-L1* mRNA.

To examine how this variant was generated, the exon-intron junction sequences (Figure 1B) were analyzed based on the DNA sequence containing the *PD-L1* gene (submitted to the GenBank database under accession number AL162253). The result showed that this variant was an alternatively spliced variant, which was produced by splicing out exon 2 to the canonical acceptor site at the 5' end of exon3 while retaining all other exons (Figure 1A). This splice variant was designated PD-L1II (submitted to the GenBank database under accession number AY291313).

Analysis of amino acid sequence deduced from PD-L1 splice variant To analyze the putative translated protein of the PD-L1II, the deduced amino acid sequence was aligned with the conventional product PD-L1I using the PROSIS program. PD-L1I and PD-L1II variants contain open reading frames of 290 and 176 amino acid residues, respectively (Figure 2). Both of them contain the transmembrane domain as predicted with the TMPred program^[14], and the signal peptide identified with the SignalP program^[15], whereas the alternatively spliced isoform PD-L1II lacks an IgV-like domain but retains all other domains.

Expression and subcellular localization of the PD-L1II isoform fused with EGFP PD-L1 is a transmembrane protein, which would be expressed on the plasma surface, but direct visualization of its subcellular localization has not been reported. To determine whether the conventional product, PD-L1I, was located at the cell surface, and to investigate the distribution of PD-L1II, we examined the subcellular localization of their proteins in K562 cells transfected with pEGFP/PD-L1I or pEGFP/PD-L1II by flow cytometry and confocal microscopy. The expression of PD-L1I-EGFP and PD-L1II-EGFP fusion proteins was verified by Western blot (Figure 3). The estimated molecular masses of these two products were 74.3 kDa and 52.3 kDa, respectively, which were larger than the theoretical molecular masses of PD-L1I-EGFP (60 kDa) and PD-L1II-EGFP (47 kDa), probably because of posttranslational glycosylation. Thus, the glycosylation extent of PD-L1II was likely to be lower than that of PD-L1I. Moreover, flow cytometry analysis revealed that only the cells transfected with pEGFP/PD-L1I expressed PD-L1 on the

Figure 3. Western blot analysis of PD-L1-enhanced green fluorescent protein (EGFP) fusion proteins expressed in transiently transfected K562 cells. M, molecular weight marker; lane 1, control cells; lane 2, pEGFP-N1; lane 3, pEGFP/PD-L1I; lane 4, pEGFP/PD-L1II.

cell surface, whereas no PD-L1 could be detected on the surface of the cells transfected with pEGFP/PD-L1II using antihuman PD-L1 antibody (Figure 4). To further investigate the subcellular distribution of the fusion proteins, confocal microscopy showed that PD-L1I-EGFP was largely located on the plasma membrane in the pEGFP/PD-L1I transfected cells, which could be stained by the specific monoclonal antibody for human PD-L1, indicating that it could be transported to the cell surface. Interestingly, PD-L1II-EGFP showed a pattern of intracellular membrane distribution as revealed by EGFP fluorescence, and those cells transfected with pEGFP/PD-L1II could not be stained by the specific antibody (Figure 5).

Differential expression of PD-L1 variants To compare the expression pattern of these PD-L1 mRNA variants in the resting and activated PBMC, total RNA of freshly isolated (resting) and activated PBMC of two unrelated donors were

examined by RT-PCR (Figure 6). There was only the *PD-L1II* mRNA variant in the resting PBMC from donor 1, whereas both *PD-L1I* and *PD-L1II* variants existed in the PDB plus ionomycin-activated cells of the same donor, although the level of the *PD-L1II* variant was much lower. However, only the PD-L1I variant was detected in PHA-activated cells. In contrast, only the *PD-L1I* mRNA variant was amplified in the activated PBMC from donor 2 and there was a very low level of the PD-L1II mRNA variant in the resting cells from donor 2.

Discussion

Alternative splicing of costimulatory molecules is a com-
