Abstract

Aim: To study the effects of propyl gallate on the interaction of tumor necrosis factor- α (TNF- α) with its soluble receptor, sTNFR-I. **Methods:** Interactions between TNF- α and sTNFR-I were analyzed using an IAsys biosensor. sTNFR-I was immobilized on the carboxymethyl dextran (CMD) surface of the IAsys biosensor cuvettes, and TNF- α preincubated with different concentrations of propyl gallate was added to the cuvettes. The resonant angle shift caused by the binding between TNF- α and sTNFR-I was then recorded. **Results:** sTNFR-I was immobilized on the CMD surface at a density of 2.76 ng/mm². TNF- α then bound the immobilized sTNFR-I specifically, and propyl gallate was able to enhance the binding between TNF- α and sTNFR-I in a dose-dependent manner. **Conclusion:** The binding between TNF- α and sTNFR-I is one of the targets that propyl gallate can act on *in vivo*. The IAsys biosensor offers a new clue as to the study on the mechanisms of action of propyl gallate.

Introduction

Propyl gallate (PG) is a well-known synthetic antioxidant on the US Food and Drug Administration list (Figure 1). It is a derivative of gallic acid, which is one of the active ingredients of *Paeoniae Radix*, a commonly used traditional Chinese medicine (TCM). Besides its antioxidant activity, PG has many pharmacological effects such as free radical elimination^[1,2], inhibiting platelet aggregation^[3,4], anti-inflammatory effects^[5] and anti-tumor activities^[6]. It is used widely to nourish blood, activate circulation, alleviate pain, regulate menstruation and treat liver disease and cancer. However, until now the research on PG has been focused on its curative effects at the holistic level. There are no detailed studies on the mechanism and dynamics of action at the molecular level, which limits the further clinical use of PG.

Tumor necrosis factor- α (TNF- α) is produced mainly by activated macrophages and monocytes. Mature TNF- α molecules are released as 17 kDa monomers, under physiological conditions, and the monomers associate non-covalently to form a homotrimer that is biologically active^[7,8]. TNF- α is one of the most pleiotropic cytokines; besides its antitumor

activity *in vitro* and *in vivo*, it plays an important role in many physiological and pathophysiological responses, such as inflammatory reactions, thrombosis, cardiac failure, infection, immune regulation, antiviral responses and endotoxic shock, as well as in the pathogenesis of certain autoimmune diseases^[9–13].

The biological activities of TNF- α are mediated by binding to 2 distinct membrane TNF receptors (TNFR), TNFR-I (p55, ~55 kDa) and TNFR-II (p75, ~75 kDa). Although both TNFR-I and TNFR-II bind TNF- α with high affinity, it has been generally believed that most of the cellular TNF responses are dominated by TNFR-I. Membrane TNFR (mTNFR) can be cleaved proteolytically to release soluble forms of the receptors (sTNFR). Though sTNFR lacks an intracellular domain, it binds free TNF- α with high affinity, competing with mTNFR^[14,15].

Though their physiological roles are not fully understood, sTNFR might regulate the function of TNF *in vivo* through 2 different mechanisms: (i) by eliminating mTNFR and thereby reducing cellular reactivity to TNF, sTNFR may protect the cell from TNF pathological injury; and (ii) whereas sTNFR inhibits the activity of TNF by binding and neutralizing the cytokines at high concentrations, it may also enhance TNF

Figure 1. Chemical structure of propyl gallate, M_r 213.

activity at low concentrations by stabilizing TNF trimer molecules and prolonging their availability for binding mTNFR, thereby acting as an immunoregulator^[16,17].

Because sTNFR is present constitutively in serum derived from receptor shedding after cellular activation by stimuli such as TNF- α production^[18], sTNFR serum level is considered a reliable indicator of TNF- α system activation^[19]. Moreover, TNF- α and sTNFR are considered to be key disease molecules and therapeutic targets^[9,20]. Because the pharmacological functions of PG and the biological activity of TNF- α are probably correlative, the TNF- α -mTNFR-sTNFR system may be a potential target of PG *in vivo*. In order to find out if this is the case, in the present paper, an affinity biosensor, the cuvette-based IAsys biosensor, was used to study the effects of PG on the interaction of TNF- α with sTNFR-I.

Materials and methods

Chemicals *N*-hydroxysuccinimide (NHS), 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC), ethanolamine and PG were purchased from Sigma-Aldrich (St Louis, MO, USA). TNF- α and sTNFR-I were purchased from PeproTech EC (London, UK). Carboxymethyl dextran (CMD) dual-well cuvettes were purchased from Labsystems Affinity Sensors (Cambridge, UK). Phosphate-buffered saline Tween-20 (PBST, pH 7.4) was composed of 10 mmol/L $\text{Na}_2\text{HPO}_4/\text{NaH}_2\text{PO}_4$, 138 mmol/L NaCl, 2.7 mmol/L KCl and 0.05% Tween-20. All solutions were made by using deionized water. All reagents were of analytical grade and were used without further purification.

Apparatus All analyses were carried out using an IAsys Plus optical biosensor (Labsystems Affinity Sensors, Cambridge, UK), which is based on resonant mirror technology. This instrument employs a dual-well stirred cuvette (pre-derivatized with CMD) and monitors the interaction between a pair of biomolecules inside the reaction cuvette^[21–23]. One of the biomolecules, the ligand, is immobilized to the sensing surface of the cuvette. Its binding partner,

the ligate, is then injected into the cuvette. Changes in refractive index and thickness on the sensing surface occur upon binding (association) of ligate to the immobilized ligand. The IAsys biosensor detects these changes continuously, producing a plot of responses that are measured in arc seconds^[24–27]. Following each interaction, the surface of the cuvette is regenerated to remove bound ligate, and another ligate can then be introduced to the sensing surface. The IAsys biosensor has been applied to many kinds of studies on molecular recognition, affinity, kinetics, solute concentrations and multi-molecular interactions. It is especially useful for capturing measurements quickly and in real time, and can eliminate the need for radiolabels or other chemical tags. Compared to traditional methods, numerous additional steps are saved.

sTNFR-I immobilization To examine the binding of TNF- α to sTNFR-I, the receptor protein was immobilized onto the cuvette surface through its residual amine groups via amide with CMD. The IAsys instrument parameters were set at 100% for stirring, and 0.3 s for the sampling interval. The running buffer was PBST. Data acquisition then began and baseline data was gathered for several minutes. The surface of the cuvette was activated with 40 μL of a 1:1 (v/v) EDC/NHS mixture (0.4 mol/L EDC and 0.1 mol/L NHS) for 7 min. The function of EDC/NHS is to activate and promote the formation of covalent linkages by forming the *N*-hydroxysuccinimide ester. The carboxyl on the CMD bound NHS under the action of EDC and created active ester intermediates that bound the primary amines of sTNFR-I to make the amide bonds. Thus, sTNFR-I can be covalently immobilized on the CMD. The cuvette was subsequently washed with PBST and 10 mmol/L acetate (pH 5.5). After gathering baseline data in the acetate buffer, 10 μL diluted sTNFR-I was added to the cuvette to begin the electrostatic uptake of protein and covalent coupling. After a sufficient reaction time, 15 min or so, unreacted NHS esters were blocked by 40 μL 1 mol/L ethanolamine (pH 8.5) and the baseline was stabilized by washing with PBST.

At the same time, another cuvette channel was used as the blank control, without anchoring of sTNFR-I. The acetate buffer was injected instead of the sTNFR-I solution.

Binding detection The sTNFR-I modified and unmodified cuvettes were both rinsed 3 times with 40 μL PBST, and 10 μL TNF- α (0.01 mg/mL) was then added into each of the cuvettes to equilibrate for 15 min, before they were washed with PBST. The resonant angle response was recorded. The chip surface was then regenerated by adding 10 mmol/L HCl, until the response signal returned to baseline to proceed with another binding cycle. To evaluate the affinity binding

of TNF- α and sTNFR-I, a wide range of TNF- α concentrations (from 0.625 $\mu\text{g/mL}$ to 20 $\mu\text{g/mL}$) were used.

Effects of PG on binding of TNF- α and sTNFR-I After 3 times of washes with 40 μL PBST, 10 μL TNF- α (0.01 mg/mL), preincubated with different concentrations of PG, was added into the sTNFR-I-modified cuvette. Binding between TNF- α and sTNFR-I was detected as described above.

Results

sTNFR-I immobilization on the surface of cuvettes As described in the "sTNFR-I immobilization" section, the sTNFR-I molecules were immobilized onto the surface of the IAsys cuvette by the ester exchange reaction of NHS to COOH groups on CMD. Figure 2 shows the response sensorgram of the IAsys biosensor to EDC/NHS activation as well as to the consequent sTNFR-I immobilization (solid line). Phase (1) is the initial baseline obtained when the surface of the cuvette was exposed to the PBST; phase (2) is the addition of EDC/NHS mixture to the sensor chip; phase (3) is the buffer washing to remove unreacted EDC/NHS mixture; phase (4) is the washing with acetate buffer; phase (5) is the addition of sTNFR-I; phase (6) is the dissociation course by washing with PBST; phase (7) is the blocking of non-coupled activated CMD sites with ethanolamine; phase (8) is the baseline stabilization. Arrow (9) is the resonant angle shift caused by the immobilization of sTNFR-I onto the cuvette surface. The broken line indicates the reference channel signal in order to follow non-specific binding on the biosen-

Figure 2. Sensorgram of EDC/NHS activation and soluble tumor necrosis factor receptor-I (sTNFR-I) immobilization. (1) Initial baseline obtained when the surface of the cuvette was exposed to the phosphate-buffered saline Tween-20 (PBST); (2) addition of the EDC/NHS mixture to the sensor chip (7 min reaction time); (3) PBST washing to remove unreacted EDC/NHS mixture; (4) acetate buffer re-equilibration; (5) addition of sTNFR-I; (6) PBST washing to allow dissociation; (7) blocking of non-coupled activated carboxymethyl dextran sites with ethanolamine; and (8) baseline stabilization. Arrow (9) is the resonant angle shift caused by the sTNFR-I immobilization.

sor surface.

The amount of immobilized sTNFR-I was calculated by subtracting the baseline level after phase (4) from that after phase (8), described in Figure 2 as arrow (9), which is approximately 450.61 arc seconds. The sensitivity of the CMD cuvette is 163 arc seconds/ng per mm^2 . Thus the density of immobilized sTNFR-I is 2.76 ng/mm^2 . Dual-well IAsys cuvettes have a sensor area of 4 mm^2 , so the total amount of sTNFR-I immobilized was 11.04 ng.

Detection of interaction between sTNFR-I and TNF- α Figure 3 shows the comparison of TNF- α binding to the sTNFR-I modified cuvette surface (solid line) and the unmodified surface (broken line). The results showed that there was no specific binding on the unmodified cuvette surface except for non-specific absorption, which was easily washed away. This indicates that TNF- α bound sTNFR-I on the cuvette surface specifically.

Figure 3. Sensorgram of the interaction between soluble tumor necrosis factor receptor-I (sTNFR-I) and tumor necrosis factor- α (TNF- α) on the cuvette surface. (1) phosphate-buffered saline Tween-20 (PBST) re-equilibration and baseline stabilization; (2) TNF- α addition with increase in irreversible response; (3) PBST washing to remove non-specific absorption.

The dissociation equilibrium constant (K_D) of binding of TNF- α and sTNFR-I were determined by using the FASTfit program, which is specifically designed for biomolecular interaction analysis using the IAsys biosensor. The K_D value was 5.05×10^{-7} mol/L, while the K_D of TNF- α /mTNFR-I binding has been reported as about 1×10^{-9} mol/L^[28]. It can be inferred that though sTNFR-I can bind TNF- α with high affinity, its binding ability is lower than mTNFR-I. The results indicate that sTNFR-I binding affinity for TNF- α is decreased, which is probably attributable to the denaturation that occurred when sTNFR-I was produced.

Effects of PG on the interaction between TNF- α with sTNFR-I Figure 4 shows the experimental results obtained at a PG concentration of 500 nmol/L. With the presence of PG, the initial velocity of TNF- α /sTNFR-I binding increased

Figure 4. Comparison between the binding reactions of tumor necrosis factor- α (TNF- α) (b) and TNF- α -propyl gallate mixture (a) on the soluble tumor necrosis factor receptor-I-modified surface.

and the time taken to approach equilibrium decreased, which indicated that PG was able to enhance the binding of TNF- α to sTNFR-I.

The concentration-dependent effects of PG on the binding of sTNFR-I and TNF- α were studied. The PG concentrations varied from 5 nmol/L to 500 nmol/L, and the results are summarized in Figure 5. The increase in amplitude of the initial velocity of TNF- α /sTNFR-I binding, as well as the decrease in amplitude of the time taken to approach equilibrium, both increased as PG concentration increased, which indicated that PG enhanced TNF- α /sTNFR-I binding in a dose-dependent manner.

Figure 5. Binding reactions on a CMD surface of immobilized sTNFR-I and TNF- α with 500 nmol/L PG (a), 50 nmol/L PG (b), 5 nmol/L PG (c) and without sTNFR-I (d).

Discussion

Recent researches showed that the pathogenesis of the traditional Chinese medicine syndromes is the result of perturbation of cytokine networks, and the mechanism of TCM

is to regulate and correct the perturbation of cytokine networks. It has been observed for many years that Chinese prescriptions can regulate the gene expression level of cytokines or their receptors. But for the initial step of the cytokine action, the binding to the corresponding receptor, there is few reports mainly due to the lack of appropriate methods. In the present study, an affinity biosensor, the IAsys biosensor, was used to explore the interaction of the cytokine and its receptor. The involvement of TNF- α in the pathogenesis of various diseases makes it an obvious and attractive therapeutic target. The effects of PG on the interaction between TNF- α and sTNFR-I were examined by using the IAsys biosensor in an *in vitro* assay. The experimental results showed that PG enhanced TNF- α /sTNFR-I binding in a dose-dependent manner. Though the mechanisms of PG are not clear and the roles of TNF- α and sTNFR-I are debated, it can be concluded that the binding between TNF- α and sTNFR-I is another target that PG can act on *in vivo*. Researches showed that serum level of sTNFR-I are often increased in a variety of conditions which are characterized by an antecedent increase in TNF- α , such as sepsis, inflammatory responses, autoimmune diseases, human immuno-deficiency virus infection, transplant rejection and malignant tumor^[29-32], which indicated that sTNFR-I production seems to neutralize and reduce the toxicity associated with the elevated serum TNF- α level. PG can enhance the cellular protection of sTNFR-I through increasing neutralization to TNF- α , which is in agreement with the experimental and clinical results reported^[33]. Thus it may sound theoretically that PG is helpful for therapy or assistant therapy in TNF- α corresponding diseases, which may leads to the new therapeutic application of PG. These are the first results obtained using affinity biosensors for studying the interactions of these molecules. This finding offers a new clue to the study of the mechanism of action of PG. The IAsys biosensor could be used widely as a reliable tool for similar studies. With respect to most of the other available methodologies to study biomolecular interactions, there are many advantages of this new method, such as real time measurement, high sensitivity, high selectivity and high veracity, as well as being easy to handle and eliminating the need for labeled compounds. It has tremendous application prospects in studies on the mechanisms of TCM *in vitro*. It will be more compellent when data on bioactivity, such as from cell experiments, were acquired to support the results from those from biosensor technology. Further studies in this area are in progress.
