Abstract

Aim: The possibility that angiotensin-converting enzyme inhibitors can protect hypertensive kidneys independently of any blood pressure (BP) decrease remains a matter of controversy. The present study investigates this theory in Lyon genetically-hypertensive (LH) rats. **Methods:** Male rats were used in the present study and were untreated (controls) or orally received 0.4, 0.1, 0.04, and 0.01 mg·kg⁻¹·d⁻¹ doses of perindopril from 3 to 17 weeks of age. At 16 and 23 weeks of age (ie during treatment and 6 weeks after its cessation), systolic BP (SBP) was measured by plethysmography, and urine was collected to measure the urinary protein (Uprot) and *N*-acetyl-seryl-aspartyl-lysyl-proline-to-creatinine (Cr) concentrations. The kidneys were dissected for a semiquantitative histological analysis. **Results:** SBP was significantly lowered (−18%±2% and −11%±1% from controls at 16 and 23 weeks, respectively) with a 0.4 mg·kg⁻¹·d⁻¹ dose of perindopril. Lower doses did not affect SBP. Uprot/Cr decreased, and Ac-SDKP/Cr increased with all the doses of perindopril used. Uprot/Cr remained lower at 23 weeks in the rats treated with 0.1 mg·kg⁻¹·d⁻¹ and smaller doses. The ratio of Uprot/Cr was closely ($r=0.6$) related to the histological lesions score. **Conclusion:** In LH rats, low doses of perindopril induce renoprotection which is independent of SBP decrease and persists after withdrawal of treatment.

Introduction

Since an increase in blood pressure (BP) is a direct determinant of progression of renal failure^[1], one of the goals of hypertension treatment is to prevent a decline in renal function, especially of proteinuria, which is the most important risk factor for the prediction of renal outcome^[2]. Originally, the renoprotective effects of antihypertensive agents were attributed solely to their BP-lowering potential. However, blockers of the renin-angiotensin system (RAS), such as angiotensin-converting enzyme (ACE) inhibitors, seem able to provide renoprotection even without modifying BP^[3–11]. However this concept of BP-independent renoprotection by RAS blockers was recently challenged on the basis that episodic measurements of BP did not allow an accurate assessment of the pressure load to the kidneys. In effect, authors using a telemetric measurement

of BP in a remnant kidney model of hypertensive rats have observed that renoprotection was closely ($r\geq 0.80$) related to continuously monitored BP^[12,13]. In addition, clinical studies which indicated that RAS blockers were more protective for the kidneys than other antihypertensive agents were also associated with a better control of BP^[14,15].

Using the Lyon model of genetically-hypertensive (LH) rats, which associates spontaneous hypertension and increased proteinuria^[16], we observed that hypertension fully disappeared after an early RAS blockade^[17], and that after cessation of the treatment, while BP levels were rapidly restored to pretreatment levels, proteinuria levels remained decreased^[18].

Therefore, the aim of the present work was to determine whether in LH rats low non-antihypertensive doses of perindopril could afford significant renoprotection not only during treatment, but also after its cessation.

Material and methods

Forty-eight 3-week-old male LH rats were used in 2 successive experiments. The rats were maintained under a constant temperature (21±1 °C), humidity (60%±10%), and light (8:00–20:00 hours), and had free access to a standard rat chow (UAR A03; Epinay-sur-Orge, France) and tap water. The rats served as controls (no treatment) or received different doses of perindopril, which was included in the drinking water for rats aged 3–14 weeks, that is, from the time of weaning up until the stabilization of hypertension. Systolic blood pressure (SBP) was measured using tail-cuff plethysmography (Narco Biosystems, Houston, TX, USA) in unrestricted and preheated (38 °C for 10 min) rats at 16 and 23 weeks of age. The rats were then placed into metabolic cages, and their urine was collected at 24 h, and stored at –20 °C after centrifugation. The day after, the 23 week-old rats were killed, the kidneys were dissected, halved, and fixed in alcohol, formalin, and acetic acid for the semiquantitative evaluation of glomerular and interstitial lesions. The histological score was the sum of the number of glomeruli exhibiting focal and segmental sclerosis among the 50 examined, as well as signs of interstitial fibrosis and inflammation. These 2 latter parameters were graded from 0 to 3: (0=normal, 0.5=minimal, 1=slight, 2=moderate, and 3=severe). The urinary creatinine (Cr) concentration was measured using Jaffe’s reaction, and the urinary protein (Uprot) was determined using the pyrogallol red method and *N*-acetyl-seryl-aspartyl-lysyl-proline (Ac-SDKP) with a previously-described enzyme immunoassay^[19,20].

Protocols In the first experiment, 4 groups of 8 LH rats were randomly assigned to receive tap water (controls), 0.04

(P0.04), 0.1 (P0.01), or 0.4 mg·kg⁻¹·d⁻¹ (P0.4) of perindopril, an ACE inhibitor.

In the second experiment, 4 LH rats served as controls, and 2 groups of 6 animals received 0.01 (P0.01) or 0.04 mg·kg⁻¹·d⁻¹ (P0.04) perindopril. The doses were chosen according to a previous study^[17] and unpublished preliminary trials. These protocols followed our institutional guidelines for animal care and experiments.

Statistical analysis Data are mean±SEM. Comparisons between groups used one-way ANOVA followed by Fisher’s exact test. *P*<0.05 was considered as significant.

Results

As indicated in Table 1, perindopril did not change the body weight of the rats. In order to facilitate the comparison between the 2 sets of experiments, the SBP values were expressed as the percentage of those measured in the 16 week-old controls (169±5 and 157±7 mmHg for experiments 1 and 2, respectively). However, for the correlation studies, only absolute values were used. At the end of the treatment period, only the highest dose of perindopril used (0.4 mg·kg⁻¹·d⁻¹) induced a significant decrease in SBP, which persisted 6 weeks after the cessation of treatment. The lower doses of perindopril were devoid of effects on SBP.

Proteinuria was expressed as the ratio Uprot/Cr so as to be independent of any mistake during the urines collection period. As well as for SBP, data are percentages of the values obtained in 16 week-old controls. Baseline proteinuria was as usual in LH rats, high and increasing from 16 to 23 weeks of age (182±24 to 260±27 and 191±13 to 370±32 mg per 24 h in experiments 1 and 2, respectively).

Body weight (BW), indirect systolic blood pressure (SBP), urinary excretion of proteins (Uprot.V), ratio urinary protein/creatinine concentrations (Uprot/Cr) and histological score in LH rats never treated (C) or treated with various (0.01, 0.04, 0.1, and 0.4 mg·kg⁻¹·d⁻¹) doses of perindopril from weaning to 17 weeks of age.

At the end of the treatment, perindopril dose-dependently decreased Uprot/Cr. A maximum was reached with the $0.1 \text{ mg}\cdot\text{kg}^{-1}\cdot\text{d}^{-1}$ dose. The ratio Ac-SDKP/Cr, an index of ACE inhibition, was significantly and dose dependently increased with all the doses of perindopril used.

Six weeks after the cessation of the treatment Uprot/Cr remained significantly below the values observed in the control LH rats, but not in those that received the highest dose of perindopril ($0.4 \text{ mg}\cdot\text{kg}^{-1}\cdot\text{d}^{-1}$).

Considering the histological data, the score summarizing the lesions of focal and segmental glomerular sclerosis, interstitial fibrosis, and inflammation was significantly reduced in all of the treated animals. Again, the $0.1 \text{ mg}\cdot\text{kg}^{-1}\cdot\text{d}^{-1}$ dose seemed the most efficient.

Interestingly, in the first experiment Uprot/Cr was related to SBP at the end of the treatment ($r=0.422$, $n=27$, $P<0.02$) and 6 weeks after its cessation ($r=0.431$, $n=32$, $P<0.01$, Figure 1). Such a relationship could not be disclosed in the second experiment, probably due to the narrow range of SBP values. As shown in Figure 2, in both experiments Uprot/Cr was closely related to the histological score. Similarly, Ac-SDKP/Cr of 16 weeks-old rats was inversely related with Uprot/Cr ($r=-0.40$) and with the histological score measured 6 weeks later ($r=-0.45$). When the data of the 2 successive experiments were pooled, the

Figure 1. Relationships between SBP and the Uprot/Cr ratio measured in rats aged 16 and 23 weeks.

relationships between the histological score and the Uprot/Cr ratio reached highly significant ($P<0.001$) values of $r=0.73$ ($n=45$) and 0.67 ($n=48$) at 16 and 23 weeks of age, respectively.

Discussion

The present work demonstrates that in LH rats, an early and chronic treatment with very low, non-antihypertensive doses of perindopril, an ACE inhibitor induces a significant decrease in the proteinuria which is closely related to the state of renal lesions, and this renoprotection persists at least 6 weeks after the cessation of treatment.

SBP was measured using the tail-cuff method, which obviously does not allow to exclude that, even very low doses of perindopril, may have blunted short lasting peaks in SBP which could have been deleterious for the kidneys as suggested by Kurtz^[21]. However this seems unlikely to be of importance since renal blood flow is well protected against increases in SBP as observed in sinoaortic denervated rats^[22], and the dose of perindopril used in the second series of experiments is 40 times lower than the lowest dose exhibiting modest antihypertensive activity.

For practical reasons the study included 2 sets of experiments. This induced an additional variability, which is why we expressed the data as percentages of the values observed as means in the control 16 week-old rats of each set of experiments. However, it may represent an advantage since it gives more power to the findings when they are consistent among the 2 experiments.

As expected, hypertension was fully established at 16 weeks of age and did not vary in the control rats up to 23 weeks of age. On the contrary, despite this stable SBP, proteinuria increased with age, and this increase was more marked in the rats used in the second set of experiments than in those of the first. This more severe spontaneous evolution of proteinuria was in good accordance with more marked renal lesions in these animals although they did not display higher SBP levels.

In the treated LH rats, when the dose of perindopril was high enough to lower SBP ($0.4 \text{ mg}\cdot\text{kg}^{-1}\cdot\text{d}^{-1}$), there was a significant relationship between SBP and proteinuria either at the end of the treatment or 6 weeks after its cessation. However, the strength of this correlation is low, which suggests that SBP is not the only factor determining proteinuria. This partial pressure independency of proteinuria is fully confirmed when much lower doses of perindopril significantly decreased proteinuria without affecting SBP. It may also find its roots in genetics since urinary albumin excretion is controlled by chromosomal loci, which

for a vast majority, differ from those linked to SBP^[23]. In addition, since angiotensin II plays a unique role in the pathophysiology of proteinuria^[24-31], it can be hypothesized that even very low doses of perindopril are able to lower the intrarenal formation of angiotensin II, and consequently slow the development of renal lesions. This hypothesis is strengthened by the fact that all the doses of perindopril used elevated the excretion of Ac-SDKP, which demonstrates a blockade of renal ACE^[32].

The other prominent observation made in the present work is that the renoprotective effect of very low non-anthypertensive doses of perindopril weakens, but remains highly significant 6 weeks after the end of the treatment, as shown by the values of proteinuria and the score of histological lesions.

In conclusion, this work demonstrates for the first time that, at least in LH rats, early and chronic treatment with an ACE inhibitor exerts renoprotective effects, which can be fully independent of BP decrease and persist after withdrawal of the treatment.
