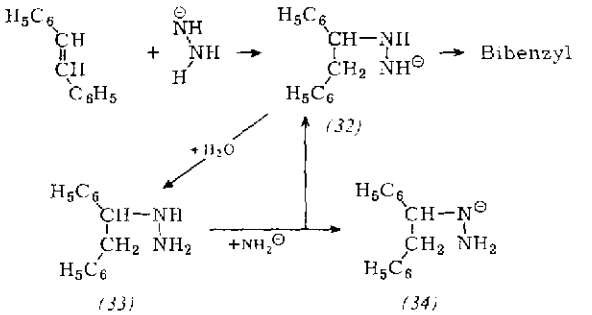
[38] Cf. *Th. Kauffmann, H. Henkler*, and *J. Schulz*, Angew. Chem. *74*, 502 (1962); Angew. Chem. internat. Edit. *1*, 514 (1962).

This interpretation is supported by the observation that sodium methylhydrazide, with which addition assisted by a hydrogen atom in the β-position to the nucleophilic center is also possible, reacts like sodium hydrazide with *p*-fluorotoluene by an addition-elimination mechanism at *ca.* 30 °C, whereas sodium *N,N*-dimethylhydrazide, whose anion does not possess a hydrogen atom on the β-nitrogen, reacts by the aryne mechanism [36] and requires a temperature of about 80 °C (in benzene).

The hydrazinonaphthalenes that are obtained along with naphthalene by the reaction of monohalogenonaphthalenes with sodium hydrazide/hydrazine [cf. Section 3c)] are also formed by substitution through an addition-elimination mechanism, since the hydrazino group is introduced exclusively into the position previously occupied by the halogen atom [7, 39].

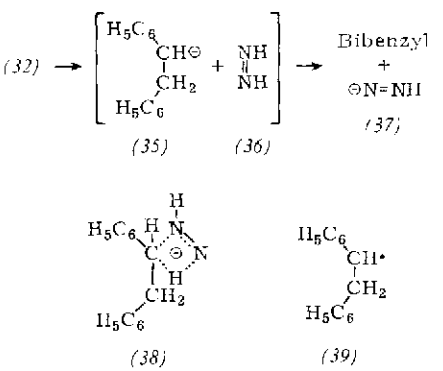
## 3. Reduction Reactions

### a) Reduction of Unsaturated and Aromatic Compounds



Reductions are often observed in the reactions of sodium hydrazide with unsaturated or polycyclic aromatic hydrocarbons, with nitrogen heterocycles, and with azoxy and nitro compounds [27, 40]. These reductions proceed very smoothly when free hydrazine is present in the reaction mixture. Some examples are shown in Table 5. Intense colors are always formed during the reductions. When compounds of simple structure are reduced, the yields are usually high; with higher aromatic hydrocarbons, mixtures of several reduction products are often formed; some of these are very unstable to oxygen.

Table 5. Reduction of unsaturated and polycyclic aromatic compounds with sodium hydrazide/hydrazine.



| Compound | Temp. [°C] | Color produced during reaction | Product | Yield [%] |
|---|---|---|---|---|
| Cyclooctatetraene | 34 | black | 1,3,5-cyclooctatriene | 85 |
| *trans*-Stilbene | 0 | brown-black | bibenzyl | 92 |
| Phenanthrene | 50 | green | 9,10-dihydrophenanthrene | 92 |
| Chrysene | 0 | blue | hexahydrochrysene (m.p. 132 °C) [a] | 45 |
| Quinaldine | 0 | red | 1,4-dihydroquinaldine | 84 |
| 2,2'-Azopropane | 40 | yellow | *N,N'*-diisopropylhydrazine | 95 |
| Azoxybenzene | 0 | red | hydrazobenzene | 98 |
| Nitrobenzene | 0 | red | azobenzene | 82 |
| 4-Nitrobiphenyl | 0 | red-black | 4,4'-azoxybiphenyl | 95 |

[a] Structure unknown.

The reduction of *trans*-stilbene to bibenzyl (1,2-diphenylethane) has been studied closely, and probably proceeds through the hydrazide adduct *(32)*, which on hydrolysis yields the product *(33)*, which could be isolated. As expected, sodamide converts *(33)* into bibenzyl (36 %); simultaneous formation of up to 40–50 % toluene and benzaldehyde hydrazone is plausibly explained by fragmentation [cf. Section 4a)] via the ion *(34)*.

Studies that are in progress on the mode of conversion of the intermediate *(32)* into bibenzyl, and the observation that diisopropyldiimide is formed in the reduction of acridine with sodium *N,N'*-diisopropylhydrazide, suggest that the second stage of the reduction takes the course shown below. Whether diimide *(36)* occurs free or as part of a transition complex such as *(38)* remains uncertain. It is very unlikely that *(32)* decomposes via the radical *(39)* [cf. Section 6)], since the stable dimer, 1,2,3,4-tetraphenylbutane [41], of *(39)* could not be detected in the crude product.

In the decomposition of *(32)*, free diimide is formed at the most in very low concentration because, if compounds with isolated C=C double bonds are added [42] to the mixture, they remain unattacked. This does not exclude the possibility that diimide can be split off from *(32)*, since *(36)* should be more strongly "acidic" than hydrazine by analogy with the increase in acidic character in the series ethane<ethylene<acetylene, and then loses a proton immediately to the carbanion *(35)* or to excess hydrazide present in the mixture, giving the diimide anion *(37)*. The latter, in contrast to diimide *(36)*, does not appear to reduce isolated C=C double bonds [43].

[39] *H. Zengel*, Diploma Thesis, Technische Hochschule Darmstadt 1962.

[40] *Th. Kauffmann, Ch. Kosel*, and *W. Schoeneck*, Chem. Ber. *96*, 999 (1963).

[41] *E. Fromm* and *O. Achert*, Ber. dtsch. chem. Ges. *36*, 539 (1903).

[42] Reduction of such compounds by diimide: cf. for example, *S. Hünig, H.-R. Müller*, and *W. Thier*, Tetrahedron Letters *1961*, 353; *E. E. van Tamelen, R. S. Dewey*, and *R. J. Timmons*, J. Amer. chem. Soc. *83*, 3725 (1961).

[43] The intermediate formation of diimide in the decomposition of benzenesulfonylhydrazine in aqueous alkali is discernible not only from the reduction of added compounds with isolated C=C double bonds [42], but also from the evolution of hydrogen and nitrogen [*F. Raschig*, Angew. Chem. *23*, 972 (1910)]. Benzenesulfonylhydrazine also evolves hydrogen and nitrogen on treatment with sodamide in anhydrous tetrahydrofuran at 60 °C; in this reaction reduction of added compounds containing isolated C=C double bonds could not be detected [11]. Decomposition of the diimide anion: cf. *S. Hünig, H.-R. Müller*, and *W. Thier*, Angew. Chem. *75*, 298 (1963); Angew. Chem. internat. Edit. *2*, 214 (1963).

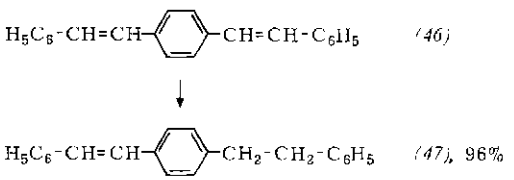
A plausible explanation of the much greater instability of the hydrazide adduct of stilbene *(32)* compared with that of styrene *(5)* is that the (δ-)- or (−)-charge which is produced on the carbon atom shown in bold type in *(32)* during the elimination of the diimide anion *(37)* or of diimide *(36)* is partly transferred to the attached phenyl residue. In general, it may be said that the hydrazido anion $-NH-NH^{\ominus}$ is always easily eliminated when, as in the structures *(40)*–*(42)*, it is attached to a group that can readily accept a negative charge because of its electronegativity or its ability to mesomerize.

*(40)*

*(41)*, e.g. Cyclooctatetraene-hydrazide adduct

*(42)*, e.g. Diisopropyldiimine-hydrazide adduct

Reductions of diaryl ketones and of some nitrogenous compounds appear to proceed through dianions. One example of these reductions, which require excess hydrazide and usually an elevated temperature (*ca.* 50 °C for benzophenone and azobenzene, in comparison with 0 °C for acridine), is that of quinaldine to 1,4-dihydroquinaldine. In this reaction the excess hydrazine is probably necessary in order to convert the adduct *(43)* in which the negative charge does not extend to the β-nitrogen of the hydrazino group [cf. however *(32)*] because of mesomeric distribution in the nitrogenous ring system, into the dianion *(44)*. The fact that *(44)* does not decompose below 50 °C, although it contains the otherwise labile system *(40)*, may be due to refusal of the negatively charged residue to accept an additional (δ-)- or (−)-charge during the elimination of the diimide anion *(37)* or of diimide *(36)*. Because the normal course of reaction is blocked in this way, and because of the tendency of organic dianions to decompose into radicals (discussed in Section 6), the hydrazido group would be expected to be eliminated from *(44)* homolytically with radical formation [cf. *(74)* in Section 6], at least as a side reaction.

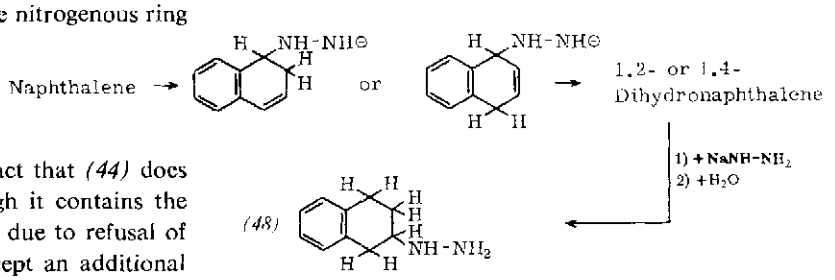


*(43)* *(44)* *(45)*

The dianion *(45)* appears to be stable, although it also contains a system *(40)* that is usually unstable, since acetophenone slowly adds on sodium hydrazide at 60 °C [7] but is not reduced by sodium hydrazide/hydrazine as are aliphatic ketones.

The products obtained in reductions with sodium hydrazide/hydrazine are often the same as those obtained by reduction with Na/liquid $NH_3$ [44] and similar systems. It is therefore interesting that ethers with one or two aromatic residues, which are generally split smoothly by Na/liquid $NH_3$ [44], are very resistant to sodium hydrazide/hydrazine [cf. Section 4e)].

Another interesting use of sodium hydrazide as a reducing agent is in the partial reduction of 1,4-distyrylbenzene *(46)* to *(47)* [40].



*(46)*

*(47)*, 96%

### b) Reductive Hydrazination

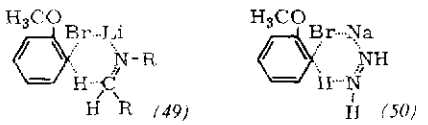
This variant of normal sodium hydrazide reduction occurs when the primary reduction product can form a stable adduct with the excess of sodium hydrazide. We have encountered it in the (slow [45]) reaction between naphthalene and sodium hydrazide/hydrazine in benzene at 50 °C [46]. Up to 72 % of the product consists of 2-hydrazino-1,2,3,4-tetrahydronaphthalene *(48)*. As has already been mentioned, the same compound is obtained in the reaction of 1,2- or 1,4-dihydronaphthalene with sodium hydrazide; *(48)* is therefore probably formed from naphthalene by the following route:

A hydrazinotetrahydro compound (hydrochloride; m.p. 115–118 °C) of unknown structure is formed analogously, but much more rapidly, in 70 % yield by the action of sodium hydrazide/hydrazine on fluoranthene in benzene at 50 °C [46]. Azulenes similarly form hydrazinotetrahydro compounds of unknown constitutions [7], together with other products.

### c) Reductive Dehalogenation

The reaction of sodium hydrazide/hydrazine with the compounds shown in Table 6 and similar [47] aryl halides, unlike that with halogenobenzenes [cf. Section 2b)], results in considerable or exclusive replacement of the halogen by hydrogen [47]. This dehalogenation

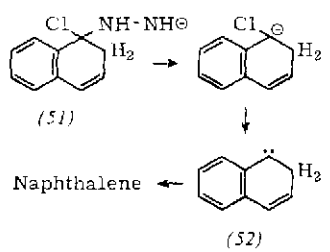
[44] Review: *G. W. Watt*, Chem. Reviews *46*, 289 (1950).



[45] Only 20 % of the naphthalene are used up after 2 h.

[46] *W. Schoeneck*, Ph. D. Thesis, Technische Hochschule, Darmstadt 1962.

[47] *Th. Kauffmann, H. Henkler*, and *H. Zengel*, Angew. Chem. *74*, 248 (1962); Angew. Chem. internat. Edit. *1*, 214 (1962).



reaction usually occurs even below 20 °C and is accompanied by vigorous evolution of $NH_3$ and $N_2$; in the examples studied, the $NH_3/N_2$ ratio was 1.4-2.0. Excess sodium hydrazide must be added, since it reacts with sodium halides to form 1:1 addition complexes in which the hydrazide is largely deactivated. Deactivation increases in the order NaF < NaCl < NaBr.

The work of *Benkeser* and *DeBoer* [48] has shown that reductive dehalogenation of *o*-bromoanisole with lithium amides probably proceeds through *(49)*, and the transition state *(50)* can therefore be assumed for the

*(49)* *(50)*

analogous reaction with sodium hydrazide. Another possible course of reaction to be considered for halogenonaphthalenes is that formulated below for 1-chloronaphthalene, via the adduct *(51)* and the carbene *(52)*.

*(51)* *(52)*

Replacement of the halogeno by the hydrazino group via the aryne mechanism (*e.g.* with bromoanisole [39] and 3-chloropyridine [32]) or by the addition-elimination mechanism (*e.g.* with 1- and 2-halogenonaphthalenes [7, 39]) usually competes with the reductive dehalogenation.

Table 6. Reductive dehalogenations with sodium hydrazide/hydrazine.

| Halide | Temp. [°C] | Product | Yield [%] |
|---|---|---|---|
| Bromomesitylene | 25 | mesitylene | 82 |
| *o*-, *m*-, *p*-Bromoanisole | 20 | anisole | 58, 30, or 38 |
| 1- or 2-Chloronaphthalene | 0 | naphthalene | 65 or 75 |
| 9-Bromoanthracene | 0 | anthracene | 90 |
| 2,3-Dibromocoumarone | 0 | coumarone | 85 |
| 4-Bromoisoquinoline | 0 | isoquinoline | 57 |
| 1-Chloroferrocene | 0 | ferrocene | 97 |

## 4. Cleavage Reactions

### a) With Alkenes

Sodium hydrazide splits arylethylenes (Table 7) in boiling ether at the olefinic double bond [49–51] according to the equation

$$R(Ar)C{=}CR^1R^2 \xrightarrow[2)\ H_2O]{1)\ NaNH{\cdot}NH_2(35°C)} \begin{matrix} R(Ar)CH_2 \\ + \\ H_2N{-}N{=}CR^1R^2 \end{matrix}$$

The behavior of arylethylenes towards sodium hydrazide is thus analogous to that of carbonyl compounds or azomethines [O or RN instead of R(Ar)C]. Free hydrazine in the reaction mixture usually facilitates the fission, but suppresses it in the case of stilbene by competitive reduction to bibenzyl.

Table 7. Cleavage of C=C double bonds by sodium hydrazide in ether at 35 °C.

| Alkene | Reaction time [h] | Fission [%] |
|---|---|---|
| Styrene | 2 | 81 |
| β-Methylstyrene | 6 | 85 |
| β-Phenylstyrene | 6 | 97 |
| α-Methylstyrene | 6 | 85 |
| α-Ethylstyrene | 6 | 83 |
| α,α-Dimethylstyrene | 8 | 74 |
| α-Methyl-β-phenylstyrene | 6 | 72 |
| *trans*-Stilbene | 1 | 32 |
| 1-Methyl-2-vinylbenzene | 6 | 75 |
| 1,3-Dimethyl-2-vinylbenzene | 6 | 62 |
| 1,3,5-Trimethyl-2-vinylbenzene | 5 | 53 |
| 1-Vinylnaphthalene | 6 | 65 |
| 2-Vinylpyridine [a] | 2 | 63 |
| α,*o*-Dimethyl-β-phenylstyrene | 5 | practically no cleavage |
| 4-Methoxy-1-propenylbenzene | 6 | practically no cleavage |
| 4-Hydroxy-1-propenylbenzene | 6 | practically no cleavage |
| 4-Isopropenylbenzoic acid | 6 | practically no cleavage |

[a] Temperature: 20 °C, product: 2-methylpyridine. Up to 53 % 2-hydrazino-6-methylpyridine is formed at 60 °C.

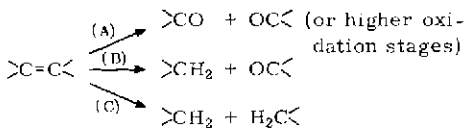
Isolated C–C double bonds are not split by sodium hydrazide. Double bonds allylic to an aromatic ring represent a special case; they are first displaced into conjugation with the ring, then ruptured.

The new fission reactions could be of value in the elucidation of structures and for syntheses for the following reasons:

1. All known methods for the cleavage of C=C double bonds employ strong oxidizing agents ($O_3$, $RuO_4$, $OsO_4/Pb(OAc)_4$, $KMnO_4/NaIO_4$), follow reaction course (A), and sometimes cause oxidation at other sites in the molecule. In contrast, sodium hydrazide is a reducing agent and fission takes course (B) [formally hydrolysis of a C–C double bond] if followed by hydrolysis with acid.

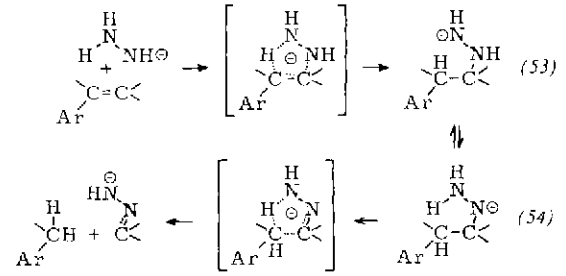
2. Since fission of the system Aryl–C=C–R (R = alkyl or aryl) with sodium hydrazide leads to a hydrazone, it can be combined with the Huang-Minlon modification [52] of the Wolff-Kishner reduction in a one-step reaction, as an experiment with stilbene has confirmed, resulting in reductive cleavage according to route (C).

3. Since sodium hydrazide does not attack isolated double bonds, it can be used for selective cleavage of C=C double bonds that are conjugated with an aromatic group.



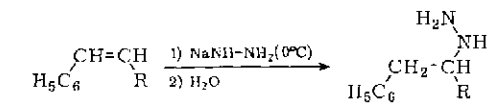
[48] *R. A. Benkeser* and *C. E. DeBoer*, J. org. Chemistry *21*, 281 (1956).

[49] *Th. Kauffmann, H. Henkler, Ch. Kosel, E. Rauch, J. Schulz*, and *R. Weber*, Angew. Chem. *74*, 650 (1962); Angew. Chem. internat. Edit. *1*, 456 (1962).

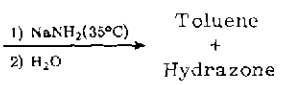


[50] *K. Lötzsch*, Diploma Thesis, Technische Hochschule Darmstadt, 1963.

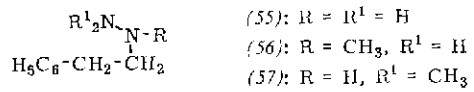
[51] No hydrazone could be isolated when $R^1 = R^2 = H$.



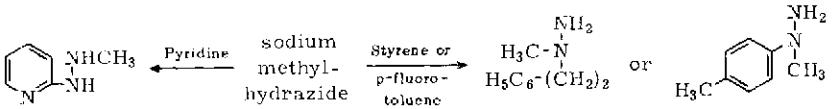
[52] *Huang-Minlon*, J. Amer. chem. Soc. *68*, 2487 (1946). According to *D. J. Cram, M. R. V. Sahyun*, and *G. R. Knox*, J. Amer. chem. Soc. *84*, 1734 (1962), Wolff-Kishner reductions proceed in dimethylsulfoxide at temperatures as low as 20 °C.



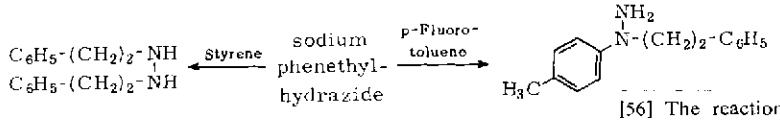
In our opinion, the most likely mechanism for the fission of C=C double bonds by sodium hydrazide (hydrazidolysis) is that shown below, according to which the rupture of both π- and the σ-bond takes place through a 5-membered cyclic transition state, just as with ozonolysis [53].



Two facts lend major support of this mechanism: the fissions can be carried out in two stages [4, 54],



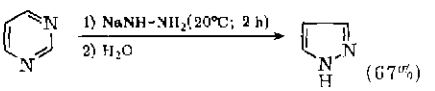
(R = Alkyl, $C_6H_5$)



and *(56)*, *(57)*, and phenethylamine, unlike *(55)*, do not split off toluene when treated with sodamide in boiling ether [11, 54].

The supposition that equilibrium is established between *N'*-alkylhydrazide ions *(53)* and *N*-alkylhydrazide ions *(54)* is supported by the addition and substitution reactions of sodium methylhydrazide and sodium phenethylhydrazide formulated below, from which it is evident that these compounds can react both as $NaN(Alkyl)\text{-}NH_2$ and as $NaNH\text{-}NH(Alkyl)$ [2, 18, 36, 54].

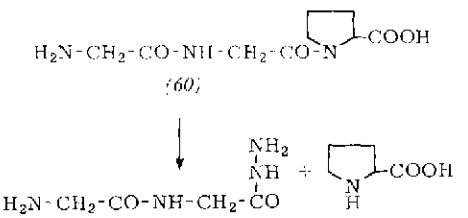
*(58)* [55]



[53] Cf. *R. Huisgen*, Angew. Chem. *75*, 631–633 (1963); Angew. Chem. internat. Edit. *2*, 592–594 (1963).

[54] *D. Wolf*, Ph. D. Thesis, Technische Hochschule Darmstadt, anticipated for 1964.

[55] Structure *(58)* follows from its hydrogenation to give 89% *N*-methyl-*N*-phenethylamine [54]. Since no hydrazone could be obtained with *p*-nitrobenzaldehyde, and sodium phenethylhydrazide gives *(59)* on reaction with styrene, *(58)* was originally assumed to be *N*-methyl-*N'*-phenethylhydrazine [2].



### b) Azomethines

Several recorded data show that sodium hydrazide can also split C=N double bonds: treatment of *N*-benzylideneaniline with sodium hydrazide/hydrazine at *ca.* 0 °C for 2 h splits it into aniline + benzaldehyde hydrazone (85%); similarly, the aromatic azines benzaldazine (dibenzylidenehydrazine) and 4,4'-dimethoxybenzaldazine (bis-4-methoxybenzylidenehydrazine) are split into the hydrazones almost quantitatively [56], although the azine of the aliphatic aldehyde myristaldehyde does not react [11]. Under similar conditions, both C=N double bonds of quinoxaline are ruptured to give *o*-phenylenediamine (85%) [30]. Rupture of one of the C=N double bonds of pyrimidine is probably the first stage in the following interesting ring contraction [30, 57]:

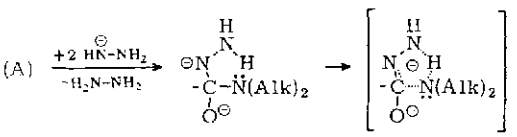
### c) N,N-Dialkylamides

Experiments with *N*-caproylpiperidine, *N*-benzoylpiperidine [59], *N*-benzyl-2-pyrrolidone, diglycyl-L-proline *(60)*, and glycyl-L-4-hydroxyproline show that amides containing the group $-CO-N(Alk)_2$ [A] are split

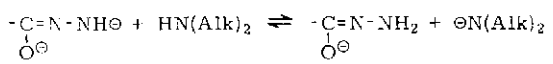
practically quantitatively within an hour by treatment at 0 °C with sodium hydrazide in ether containing

[56] The reactions were carried out in tetrahydrofuran with azines, and in ether with the other compounds mentioned in Section 4b). If ether is used instead of tetrahydrofuran, the dibenzylidenehydrazine is hydrogenated to *N*-benzylbenzylidenehydrazine (54%) by sodium hydrazide/hydrazine [11].

[57] We wish to reserve the application of this reaction to pyrimidine derivatives for ourselves.



[58] *Th. Kauffmann* and *J. Sobel*, Angew. Chem. *75*, 1177 (1963); Angew. Chem. internat. Edit. *2*, 743 (1963).

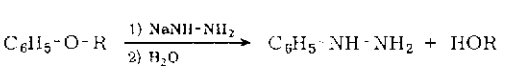


[59] *N,N'*-Dibenzoylhydrazine is formed as well as benzoylhydrazine.

hydrazine, followed by hydrolysis with water, in the manner illustrated by the example *(60)* [60].

Amides (*e.g.* 2-pyrrolidone, diglycylglycine, caproamide, asparagine) which contain a -CO-NH-Alk [B] or -CO-$NH_2$ [C] group and which can form mesomeric anions, are stable under these conditions. The consequent expectation that amides containing a (B) or (C) group as well as an (A) group would be split selectively at (A) has been realized for the combination (A) + (B) in the reaction shown above, in which only traces of glycine hydrazide are formed. Prospects for experiments on the selective fission of proteins [60a] at the amino acids proline and 4-hydroxyproline seem favorable, since anhydrous hydrazine [61] is a solvent equally suitable for sodium hydrazide and for proteins, and since natural amino acids, except those containing sulfur are stable to sodium hydrazide at 0 °C.

The following mechanism can be assumed for the cleavage of *N,N*-dialkylamides with sodium hydrazide by analogy with the fission of non-enolizable ketones with sodamide [62], and with the hydrazidolysis of C=C double bonds mentioned above:



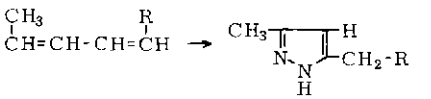
d) Esters [46, 63]

It is not surprising that esters are rapidly split into acyl hydrazides and alcohols by sodium hydrazide at 0 °C, presumably by a route analogous to the above scheme, since esters are usually readily split even by hydrazine hydrate [64]. Sodium hydrazide might be of value for selective cleavage of ester groups (*e.g.* for removal of protecting groups) in molecules that also contain the -CO-$NH_2$ or -CO-NH-Alk amide group.

e) Ethers [46]

Aliphatic ethers are stable to sodium hydrazide at 60 °C. Ethers with one or two aromatic residues are also fairly resistant: when heated at 50 °C for five hours with sodium hydrazide in benzene containing free hydrazine, anisole and diphenyl ether are split to the extent of only 9 % and 21 %, respectively. The course of fission is essentially as follows:

(R = $CH_3$ or $C_6H_5$)



The formation of *N,N*- and *N,N'*-diphenylhydrazines as by-products indicates that benzyne is formed in these reactions, just as in the cleavage of diphenyl ether with phenylsodium [65], by elimination of NaOR from a primary metalation product [cf. Section 2b)].

## 5. Dehydrogenative Hydrazination of Dienes

Although, as already mentioned, 1,3-butadiene adds on sodium hydrazide in ether to form *N,N*-dicrotylhydrazine, isoprene, 2,3-dimethyl-1,3-butadiene, 1,3-pentadiene, and 2,4-hexadiene in ether or benzene only react with sodium hydrazide if free hydrazine is present in the reaction mixture. These reactions usually proceed at room temperature (50–60 °C for hexadiene) with vigorous evolution of $NH_3$ and yield, not substituted hydrazines, but α,β-unsaturated azines, pyrazoles, and pyrazolines, *i.e.* products containing less hydrogen [10]. This dehydrogenation is brought about by the free hydrazine, which is hydrogenated to ammonia. Methyl groups on the central carbon atoms of the butadiene system promote azine formation; on the outer carbon atoms they cause pyrazole formation [66].

63 or 70% yield when R = *H* [67] or $CH_3$

54 or 53% yield when R = H or $CH_3$

These reactions are of particular interest, as there are no other known methods for direct conversion of dienes into azines and pyrazoles.

In the simplest dehydrogenative hydrazination, the conversion of butadiene into 5-methyl-2-pyrazoline *(61)* (in 25 % yield) by the action of sodium hydrazide/hydrazine, 32 % adduct (*N,N*-dicrotylhydrazine) and polymeric nitrogenous compounds are also formed. Here the following mechanism seems likely: Addition of hydrazide ion onto the butadiene gives the *N*-crotylhydrazide ion *(8)*. This is probably [cf. Section 4a)] in

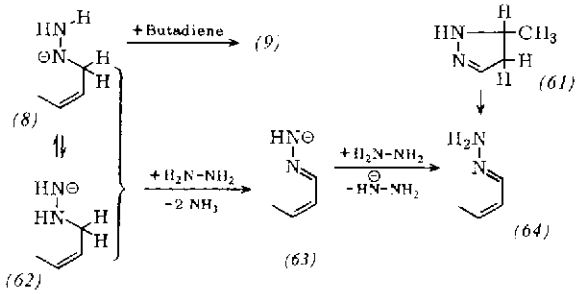
[60] Attempts to effect similar cleavage with sodamide at 0 °C or 35 °C were unsuccessful [58]. According to *B. Witkop* (Advances in Protein Chemistry. Academic Press, New York 1961, Vol. 16, p. 235), "certain *N*-acylhydroxyproline amides", but not ordinary peptides of hydroxyproline, can be split with sodamide + metallic sodium in liquid ammonia.

[60a] Note added in proof: By treating insuline, which contains no 4-hydroxyproline and only one proline residue, with sodium hydrazide at 0 °C in anhydrous hydrazine, we were able to split off selectively the peptide Pro-Lys-Ala-COOH from the carboxyl end of the B-chain [63].

[61] Peptide bonds are split extremely slowly by anhydrous hydrazine at 0 °C.

[62] "Bauer-Haller fission", cf. Org. Reactions *9*, 1 (1957). Degradation of ketones with sodium hydrazide has not yet been observed.

[63] *J. Sobel*, Ph. D. Thesis, Technische Hochschule Darmstadt, anticipated for 1964.

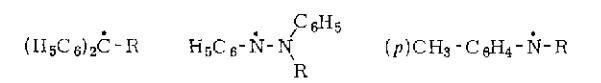


[64] Cf. Org. Reactions *3*, 367 (1947).

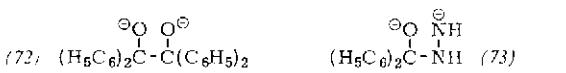
[65] *A. Lüttringhaus* and *K. Schubert*, Naturwissenschaften *42*, 17 (1955).

[66] The reaction between dienes with substituents other than methyl groups and sodium hydrazide/hydrazine has not yet been studied.

[67] Up to 15 % 5,5'-dimethyl-2-pyrazoline is also formed.



equilibrium with the *N'*-crotylhydrazide ion *(62)*, and can react with further butadiene to form the *N,N*-dicrotylhydrazide ion *(9)*. Either *(8)* or *(62)* is dehydrogenated by hydrazine to the crotylidenehydrazide ion

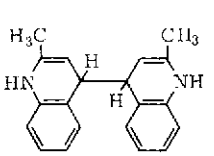


*(63)*, which undergoes ring closure either as such or, after addition of a proton, in the form *(64)*. It is known that crotylidenehydrazine is not stable and rearranges spontaneously to 5-methyl-2-pyrazoline *(61)* [68].

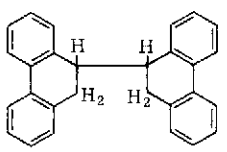
## 6. Occurrence of Free Radicals

Comparison of the dimers (*e.g.* hexaphenylethane) of the radicals *(65)*, *(66)* [69], and *(67)* [70] with the doubly negatively charged dimers, *e.g.* *(72)*, of the anionic radicals *(68)* [71], and *(69)–(71)* [72] shows that, like phenyl groups, anionic groups can labilize neighboring bonds. Dianions, such as could be formed from the hydrazide adducts of aromatic or polyunsaturated compounds, *e.g.* *(44)* or *(73)*, and possibly even the hydrazide adducts themselves, would therefore be expected to dissociate into radicals.

*(65)*, R = $-C_6H_5$ *(66)*, R = $-C_6H_5$ *(67)*, R = $-C_6H_4-CH_3(p)$
*(68)*, R = $-O^{\ominus}$ *(69)*, R = $-O^{\ominus}$ *(70)*, R = $-O^{\ominus}$
*(71)*, R = $-N=NO$



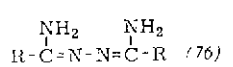
*(72)* *(73)*



The reaction between benzophenone and excess sodium hydrazide gives rise to a deep blue coloration [73] and was therefore studied from this point of view. According to electron spin resonance measurements [74], the small concentration of radicals present in a suspension of sodium hydrazide in ether containing free hydrazine increases by one-hundred fold on addition of the ketone (at 20 °C). The blue reaction mixture has almost the same ESR spectrum [75] as "sodium benzophenone" (blue; anion *(68)*] and on hydrolysis gives, apart from much benzophenone and other products, a small amount (2 % after reaction for 10 min at 20 °C) of tetraphenylethylene glycol, the characteristic product of hydrolysis [71] of "sodium benzophenone" [76].

It can therefore be assumed that the radical ion *(68)* is formed by the addition of excess sodium hydrazide onto benzophenone. It probably results from homolytic fission of the deprotonated adduct *(73)* of benzophenone and hydrazide. No formation of tetraphenylethylene glycol could be detected in the reduction of benzophenone to benzhydrol (98 %) with excess sodium hydrazide at 55 °C [7].

The by-products *(74)* and *(75)* obtained in 9 and 6 % yields, respectively, in the reductions of quinaldine and phenanthrene indicate that free radicals are also formed in these reductions, which, characteristically, only proceed in the presence of excess hydrazide [cf. Section 3a)]. It is possible that the intense colors observed in reactions with sodium hydrazide are largely due to free-radical by-products or intermediates.



*(74)*

*(75)*

## 7. Future Developments

The most important reactions of sodium hydrazide with organic compounds [77] have probably been discovered in the investigations described above. It cannot be said, however, that the field has been studied exhaustively. It is not yet certain, for instance, how sodium hydrazide reacts with sulfur or phosphorus compounds, or whether liquid ammonia is a suitable solvent for reactions involving sodium hydrazide. It seems particularly attractive to replace the sodium cation with other cations and perhaps discover metal hydrazides that are less explosive, are soluble in organic solvents, or react differently. Preliminary experiments in this direction have shown that dialkylaluminum hydrazides are readily soluble in benzene, are safe to handle, and react differently from sodium hydrazide [cf. Section 1c)] with nitriles, giving $\alpha,\alpha'$-diamino amines *(76)* [78].

# Recent Advances in the Synthesis of 19-Norsteroids

BY THOMAS B. WINDHOLZ AND MARTHA WINDHOLZ

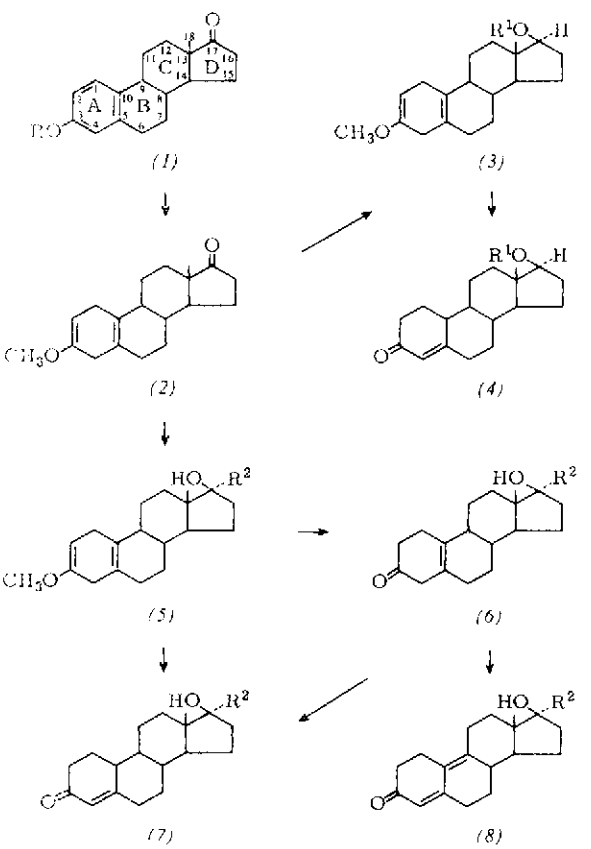
MERCK SHARP & DOHME RESEARCH LABORATORIES, RAHWAY, N. J. (U.S.A.)

*This review describes approaches for improved preparations of 19-norsteroids. They are based on novel total syntheses of estrone and on intramolecular functionalization and elimination of the C-19 methyl group in androstane derivatives.*

Introduction

A. Total syntheses
1. Synthesis scheme AD → ABCD
2. Synthesis scheme CD → ACD → ABCD
3. Synthesis scheme AB → ABD → ABCD
4. Miscellaneous syntheses

B. Aromatization of ring A



C. Intramolecular functionalization of C-19

D. Practicable syntheses of 19-norsteroids

## Introduction

Nonaromatic 19-norsteroids have gained importance in the last decade as anabolic agents [1] and as progestogens [2] for ovulation control. Some representative anabolic agents with favorable anabolic/androgenic ratios are 19-nortestosterone *(4)*, $R^1$ = H, a number of its esters *(4)*, $R^1$ = acyl, and its 17α-alkyl derivatives such as *(7)*, $R^2 = C_2H_5$. Progestational activity combined with marked gonadotropin inhibition is exhibited by, for example, norethisterone *(7)*, $R^2$ = C≡CH, norethynodrel *(6)*, $R^2$ = C≡CH, and the recently described 19-nor-$\Delta^{4,9(10)}$-androstadien-3-ones *(8)*, $R^2$ = C≡CH [3] and $R^2$ = C≡CCl [4], when administered *per os*.

Until 1961, the preparation of these compounds [5] was based almost entirely on Birch reduction [6] of the only 19-norsteroid generally available, *viz.* estrone *(1)*, R = H, or its methyl ether *(1)*, R = $CH_3$. The dihydroaromatic derivative obtained was then oxidized to reform the

ketonic group at C-17 giving *(2)*, the key intermediate for subsequent synthesis of the various endproducts.

Stereoselective reduction of *(2)*, *e.g.* with $NaBH_4$, afforded the 17β-ol *(3)*, thus providing a short route to 19-nortestosterone *(4)*, R = H, and by esterification to its esters *(4)*, R = acyl. Reaction of *(2)* with the appropriate Grignard or organolithium reagents resulted in a series of 17α-alkyl, vinyl, ethynyl, or chloroethynyl derivatives *(5)* with a protected A-ring. Controlled hydrolysis of these yielded 19-nor-3-keto-$\Delta^{5(10)}$-steroid derivatives *(6)* which could be rearranged to the conjugated 3-keto-$\Delta^4$-steroids *(7)* or dehydrogenated further to give 19-nor-$\Delta^{4,9(10)}$-androstadien-3-ones *(8)*.

The recent increase in medical interest in 19-norsteroids has generated intensive chemical research in this field. Since the problems related to the partial synthesis *(1)* → *(6)*, *(7)*, *(8)* have been solved satisfactorily [5, 6], it became clear that further improvements could only be achieved by either broadening the raw material basis or finding entirely new methods for the preparations of 19-norsteroids. Consequently, efforts were made to develop simpler total syntheses of estrone from readily available starting materials, and, more recently, to effect functionalization and elimination of the C-19 angular methyl group of appropriate androstane derivatives.

## A. Total Syntheses

The classical total synthesis [6d] of estrone by *Cole*, *Johnson*, *Robins*, and *Walker* [7] and the versatile steroid synthesis of *Velluz* and *coworkers* [8] represent probably the ultimate in stereoselectivity attainable at present in this field [9]. However, the number of steps involved limit the applicability of these procedures [10] to large scale production.

A number of seemingly unrelated organic chemical developments, such as availability of 2-methylcyclopentane-1,3-dione [11], a practical method for the preparation of 1,2,3,4-tetrahydro-6-methoxy-1-vinyl-1-naphthol *(25)* [11a], *etc.*, have led over the past few years to several new, relatively short total syntheses in the estrone field, that are also potentially applicable for industrial use.

[6d] The structural formulae in this section show only one enantiomer, and even though (±) is mostly omitted, this text deals only with racemates.

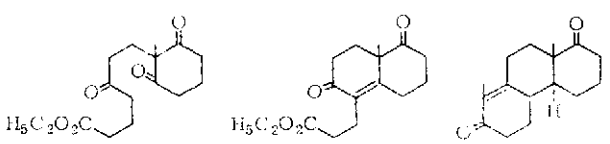
Common characteristics of these new syntheses are a) the use of a preformed five- or six-membered D-ring already containing the potential C-18 methyl group [11b], and b) stereoselective introduction of three (out of four) asymmetric carbon atoms in the last two steps of the synthesis. In the following sections, these new syntheses are systematized according to the sequences used for building up the steroid skeleton.

### 1. Synthesis Scheme AD → ABCD

The availability of 2-methylcyclopentane-1,3-dione [11] added emphasis to an ingenious total synthesis of estrone by *Hughes* and *Smith* [13], which consisted in incorporating preformed rings A and D into a molecule *(12)* suitable for subsequent cyclization. Both *(12a)*

*(12a)*, n = 2
*(12b)*, n = 3



*(13)*, R = Br
*(14)*, R = -C≡CH
*(15)*, R = $-C\equiv C-CH_2-N(C_2H_5)_2$
*(16)*, R = $-CO-(CH_2)_2-N(C_2H_5)_2$
*(17)*, R = $-CO-CH=CH_2$

and *(12b)* were prepared starting from 3-(*m*-methoxyphenyl)propyl bromide *(13)* which was treated with sodium acetylide to give *(14)*.

Mannich condensation of *(14)* with formaldehyd and diethylamine led to *(15)* which after hydration with $H_2SO_4$–$HgSO_4$ gave a mixture of 2-dimethylamino-

[11b] A preformed six-membered D-ring was already used by *Miescher* et al. [12] in their total synthesis of D-homoandrostane-3,17a-dione. These authors condensed 2-methylcyclohexane-1,3-dione and ethyl 7-chloro-5-oxoheptanoate with trimethylamine to give the triketo ester *(9)*,

*(9)* *(10)* *(11)*

which was cyclized to the diketo ester *(10)*. Further transformations through a series of lengthy and mostly non-stereoselective reactions gave D-homoandrostane-3,17a-dione via the tricyclic intermediate *(11)*.

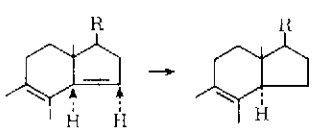
ethyl *m*-methoxyphenylpropyl ketone *(16)* and its elimination product *m*-methoxyphenylpropyl vinyl ketone *(17)*. Michael condensation of a mixture of *(16)*, *(17)*, and 2-methylcyclohexane-1,3-dione gave *(12b)* [14]. Analogous condensation with 2-methylcyclopentane-1,3-dione later yielded *(12a)*. In the preferred version of the *Hughes* and *Smith* synthesis, *(12a)* was cyclodehydrated directly to 3-*O*-methyl-8,14-bisdehydroestrone *(18)*, with *p*-toluenesulfonic acid in boiling benzene. This tetracyclic ketone has become an important intermediate in other total syntheses.

*(18)* *(19)* *(1b)*

Stereoselective hydrogenation of the 14,15-double bond in the presence of palladium on calcium carbonate afforded a high yield of the diastereoisomer *(19)*, having the required C/D-*trans* junction [15]. Correct stereochemistry at C-8 and C-9 was obtained in the next step leading to *(1b)* by reduction of *(19)* with potassium in liquid ammonia, the A-ring being left intact [15a]. Some reduction occurred at C-17, but subsequent reoxidation regenerates the C-17 ketone, to give (±)-3-*O*-methylestrone *(1b)*.



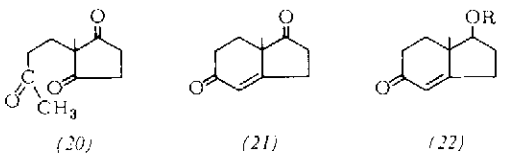
More recently, *Smith*, *Hughes* et al. [15b] reported that *(17)* can also be condensed with higher homologues *(19a)* of 2-methylcyclopentane-1,3-dione the corresponding C-18 homologue of *(12)* and *(18)* being obtained. These were used for the preparation of a number of steroid-like compounds of potential biological interest.

*(19a)*, R = ethyl, n-propyl, isopropyl, etc.

[14e] *C. B. C. Boyce* and *J. S. Whitehurst*, J. chem. Soc. (London) *1959*, 2022.

[15] In the total synthesis of equilenin, *Johnson* et al. [16] achieved preferential hydrogenation by attack from the rear side of the molecule, utilizing the shielding effect of the C-18 methyl group. It was later found by other investigators [17] that a second, β-oriented substituent (R) at C-17 was needed for exclusive formation of the 14α-isomers:

The stereoselective hydrogenation of *(18)* which has a carbonyl group at C-17, is of definite practical importance.



[15a] This method was first used by *Johnson* et al. [18a] in the reduction of a styrene type double bond: *trans*-addition of the hydrogen occurred, leaving the aromatic ring intact. Later, *Johnson* and coworkers [18b] found that addition of lithium to this reaction mixture reduces the aromatic ring as well to give the corresponding dihydroaromatic derivative.

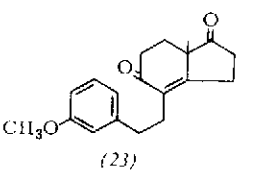
## 2. Synthesis Scheme CD → ACD → ABCD



In 1959, *Boyce* and *Whitehurst* [14e] reported the preparation of *(20)* as well as its cyclization to *(21)* in good yields.

Utilization of *(21)* as a CD building block for an estrone synthesis was recently reported by *Crispin* and *Whitehurst* [19], who prepared the tetrahydropyranyl ether *(22)* which was alkylated with *m*-methoxyphenethyl *p*-toluenesulfonate, and yielded *(23)* after hydrolysis

*(20)* *(21)* *(22)*

and reoxidation at C-17 (steroid numbering). Compound *(23)* was then cyclized to 3-*O*-methyl-8,14-bisdehydroestrone *(18)* which had previously been converted into estrone by *Hughes* and *Smith* [13]. Direct alkylation of the ketone *(21)* with 2-*m*-methoxyphenethyl bromide to yield *(23)* is described by *Smith*, *Hughes*, and *McLoughlin* [20].

*(23)*

As no yields were reported in the preliminary communications, the practical value of this route is difficult to compare with the first synthesis of *Smith* and *Hughes* [13], in which high yields are reported for the individual steps.

## 3. Synthesis Scheme AB → ABD → ABCD

In 1957, *Nazarov* and coworkers [11a] successfully reacted the readily available compound 6-methoxy-α-tetralone *(24)* [21] with the vinylmagnesium bromide reagent described by *Normant* [22] and obtained the vinyl carbinol *(25)* in excellent yield.

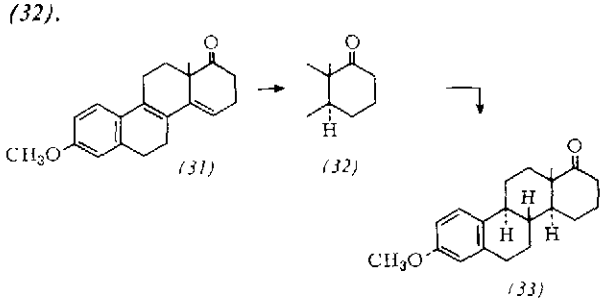
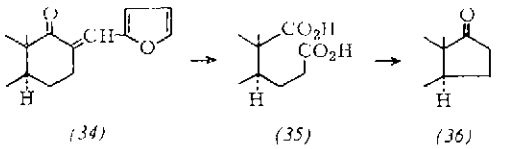
[22] *H. Normant* in *R. A. Raphael*: Advances in Organic Chemistry. Interscience, New York 1960, Vol. II, p. 1.

(24) (25) (27) (26)



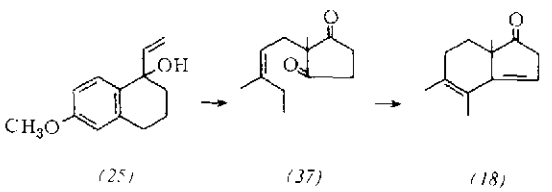
On the basis of their previous model experiments [23, 24], summarized here by the formulae *(28)* → *(29)* → *(30)*, utilization of *(25)* appeared promising for the

(28) (29), R = Br (30), R = $H_3C$



preparation via *(26)* of compounds of the type *(27)*. First attempts to obtain the substituted vinyl bromide *(26)* from *(25)* proved unsuccessful [25]. Later, however, *Ananchenko* and *Torgov* [26] succeeded in preparing *(27)* directly from *(25)* in 50 % yield by condensing *(25)* with 2-methylcyclohexane-1,3-dione in the presence of basic catalysts. The mechanism of this interesting reaction is still not understood.

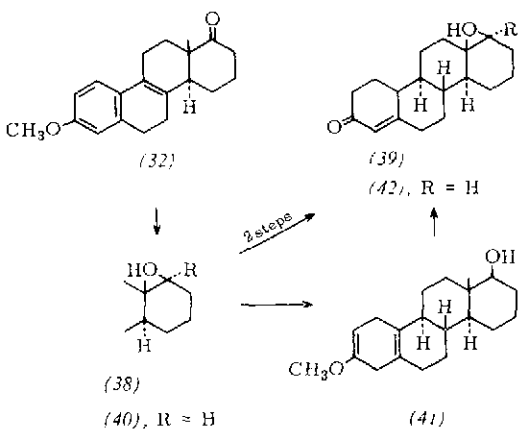
Subsequently, the Russian workers [27] cyclodehydrated *(27)* to *(31)*, which on selective hydrogenation [15] gave *(32)*.



(31) (32) (33)

In the first version of this total synthesis, four additional steps were required to go from *(32)* to 3-*O*-methyl-D homoestrone *(33)*. In a later publication [28], the reduction of *(32)* to *(33)* in 42 % yield using potassium in liquid ammonia is described [cf. *(19)* → *(1b)*]. Conversion of the D-homoestrone methyl ether to (±)-3-*O*-methylestrone *(1b)* was accomplished in three steps [reaction sequence *(34)* → *(35)* → *(36)*] using *W. S. Johnson*'s method of ring D contraction [29].

(34) (35) (36)



The shortest total synthesis of (±)-estrone methyl ether from readily available starting materials was reported independently in 1963 by five research groups [9b, 15b, 30, 31]. This synthesis follows the AB + D → ABCD scheme [reaction sequence *(25)* → *(37)* → *(18)*].

(25) (37) (18)

Conversion of *(18)* into estrone methyl ether *(1b)* is carried out by the procedure of *Hughes* and *Smith* [13]. Thanks to the high yields in the first steps [30b], this total synthesis seems to compare favorably with that of *Hughes* and *Smith* [13].

The Russian workers [32] subsequently directed their attention to 19-nor-D-homotestosterone *(42)* and its derivatives *(39)*, which reportedly also possess anabolic activity. The more important reactions, starting out from 3-*O*-methyl-9,10-dehydro-D-homoestrone *(32)*, are summarized in the formulae *(38)* through *(42)*; for processes leading to the stereoisomers, see [15a].

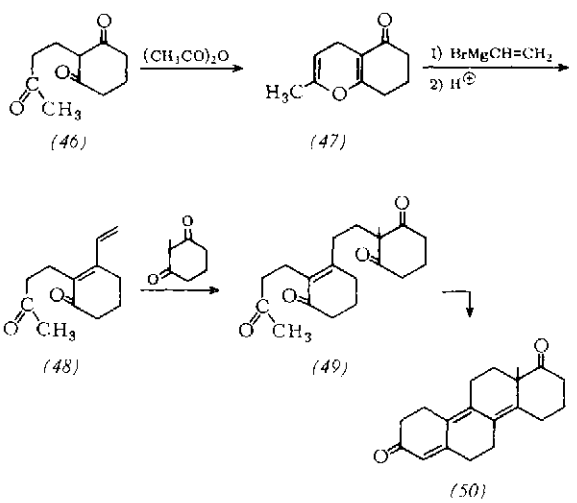
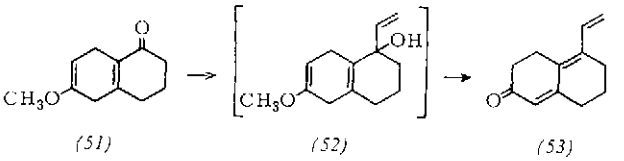
## 4. Miscellaneous Syntheses



Introduction of a $\Delta^{9(10)}$-double bond *(8)* into steroids of the norethisterone type *(7)* increases their progestational activity [3, 4]. The preparation of a compound with extended conjugation *(54)* was achieved by total synthesis.

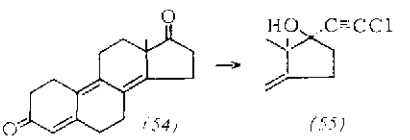
This work had its origin in 1953 when *Eschenmoser, Schreiber*, and *Julia* [33] carried out the reaction sequence *(43)* → *(45)* which is based on a vinylogous Michael addition.



*(43)* *(45)* *(44)*

*Panouse* and *Sannié* [34] performed the same reactions with 2-methylcyclopentane-1,3-dione and obtained a tricyclic compound corresponding to the BCD-rings of a steroid molecule [35]. The importance of this work became evident in 1961, when *Zavialov* et al. [36] prepared *(48)*, an analogue of *(43)* containing a side chain that was eventually used for building up ring A. The preparation of *(48)*, its condensation with 2-methylcyclohexane-1,3-dione, and cyclization of the obtained *(49)* to the final product *(50)* are shown.

*(46)* *(47)* *(48)* *(49)* *(50)*

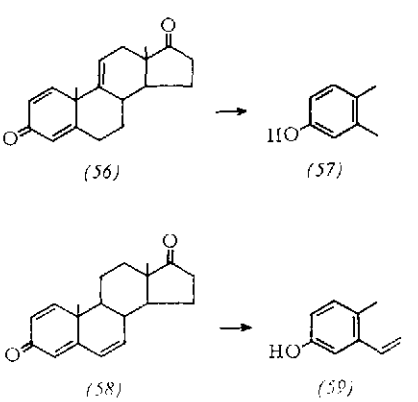


A simpler procedure was found by *Gajdamovich* and *Torgov* [37], who prepared 2,3,4,6,7,8-hexahydro-1-vinylnaphthalen-6-one *(53)* from 1,2,3,4,5,8-hexahydro-1-oxo-6-methoxynaphthalene *(51)* [38] and vinylmagnesium bromide [23] via the carbinol *(52)*.

*(51)* *(52)* *(53)*

Condensation of *(53)* with methylcyclohexane-1,3-dione then gave a tetracyclic carbinol corresponding to *(44)*, which was subsequently dehydrated to *(50)*, which proved to be identical with the compound prepared by *Zavialov* [36].

Lately *Windholz* et al. [39] prepared (±)-19-nor-$\Delta^{4,8(14),9(10)}$-androstatriene-3,17-dione *(54)* in approx. 17% yield in a one-step reaction from *(53)* and 2-methylcyclopentane-1,3-dione. Ensuing selective chloroethynylation at C-17 gave *(55)*.



*(54)* *(55)*

The progestational activity of this racemic compound was found to be intermediate between that of *(7)* and *(8)*.

### B. Aromatization of Ring A

In addition to the total syntheses discussed above, another new development, which once again focused attention on the original method of *Inhoffen* for the aromatization of the A-ring [40], will be reported here.

*Tsuda* et al. [41] described an unusually mild method of achieving A-ring aromatization by refluxing an ap-

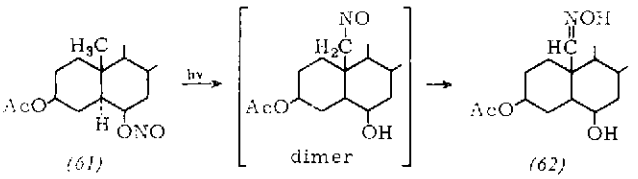
propriate cross-conjugated steroid with zinc in moist pyridine. An impressive 75 % yield of 9-dehydroestrone *(57)* is obtained from *(56)*. However, the much more accessible 3-keto-$\Delta^{1,4,6}$-triene *(58)* gave only 10–15 % of the useful intermediate 6-dehydroestrone *(59)*, thus considerably limiting the applicability of this method.

### C. Intramolecular Functionalization of C-19

Besides the partial syntheses carried out in the late 1950's and described in the introduction, there were two other possibilities for the preparation of 19-norsteroids: a) chemical transformation of naturally occurring steroids with an oxygen function at C-19, *e.g.* strophanthidin, and b) enzymatic oxidation of the C-19 methyl group. Because of the limited supply of potential starting materials in the first case, and because of the nonselective nature of the enzymatic attack in the second case, neither of these methods appeared promising for industrial purposes.

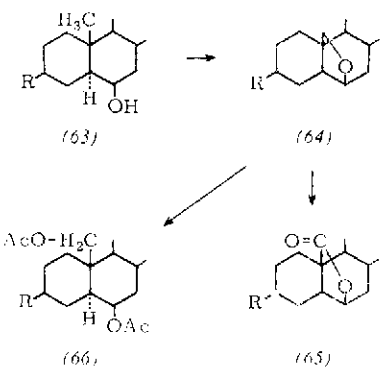
The successful chemical functionalization of the C-18 methyl group [42a - g] achieved during extensive search for a partial synthesis of aldosterone paved the way to spectacular advances in the field of 19-norsteroids. Here, however, besides functionalization, the problem consisted also in developing efficient methods for elimination of the C-19 group without simultaneous aromatization of ring A.



Intramolecular attack on a non-activated $CH_3$ group is initiated by abstraction of one of its hydrogen atoms and is brought about by oxygen radicals generated by homolysis of an –OR bond [R being NO, halogen, or $Pb(OAc)_3$] attached to a γ-carbon atom relative to the methyl group to be functionalized [42 h]. As shown in *(60)*, steroids containing a β-hydroxyl group on carbon atoms 2, 4, 6, 8, or 11 meet the above requirements.

*(60)*

Structure *(60)* also suggests that attack from C-8 and C-11 could lead to simultaneous functionalization of the equidistant C-18 and C-19 positions, hence utilization of substitutents at C-8 and C-11 would be impractical. The 6β-hydroxy steroids are readily accessible and became the natural choice for efficient functionalization of the C-19 methyl group, since 2- and 4-hydroxy compounds are relatively difficult to obtain, and 8-hydroxy compounds practically unknown.



*Barton* and coworkers carried out the pioneer work on hydrogen abstraction from non-activated carbon atoms by photolytic attack in the steroid field [42c, e] and described the following C-6 → C-19 attack as early as 1960 [43a, b].

*(61)* *(62)*

Photolysis of the 6β-nitrite *(61)* to give the 19-oxime *(62)* via a dimeric nitroso derivative was the first known chemical functionalization at C-19, but was not pursued further at that time.

While investigating the reactions of various steroidal secondary alcohols with lead tetraacetate, *Bowers* et al. [44] found that by refluxing *(63)* in benzene for 18 hours, a good yield of the transannular cyclic ether *(64)* could be obtained. This was then either oxidized to the

*(63)* *(64)* *(66)* *(65)*

lactone *(65)* or cleaved with $BF_3$ in acetic anhydride to give *(66)*, a functionalized C-19 derivative.

Excellent yields are reported by *Meystre* et al. [45a] for the 6,19-oxides *(64)* obtained when 6β-alcohols are treated with lead tetraacetate and excess iodine in the presence of light. This reaction has been called the "hypoiodite reaction" and is discussed in detail by *Heusler* and *Kalvoda* [42d].

It has been shown very recently that the reaction *(63)* → *(64)* with lead tetraacetate can also be performed photolytically at 16–18 °C [45b].

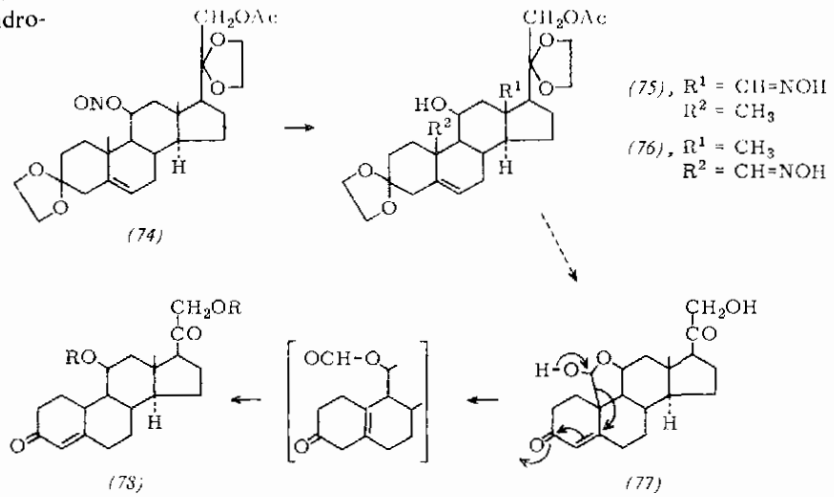
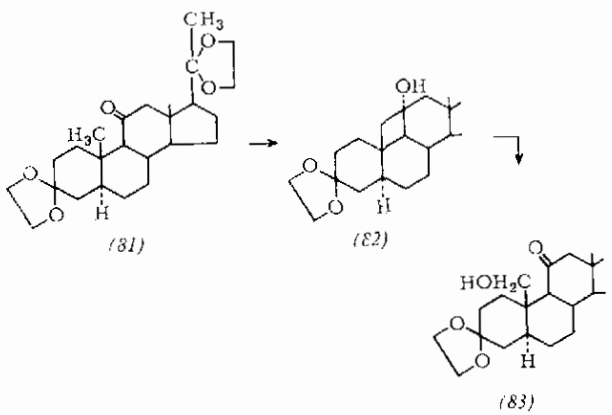
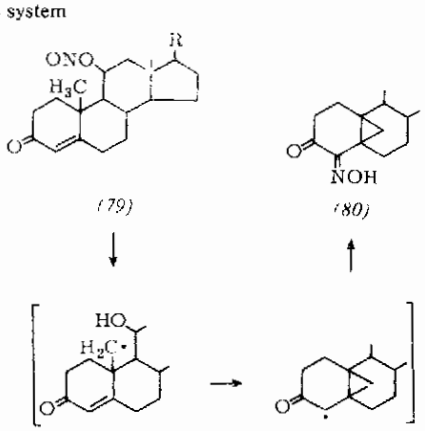
The lead tetraacetate reaction was recently applied to 3,5-cyclosteroids *(67)* [46a–c]. The 6,19-oxido-3,5-cyclosteroids *(68)* obtained in 25 % yield were solvolysed directly or via the functionalized 3,5-cyclosteroids *(69)* to the desired derivatives of type *(70)*, in both the androstane and cholestane series.



Working independently, *Akhtar* and *Barton* [47], and *Mills* and *Petrow* [48] found that hypochlorites of 6β-hydroxy steroids *(71)* can form 6,19-oxides *(72)* via the intermediate 19-chloro derivatives *(73)* which were not characterized. This reaction apparently has not found practical application so far.



Simultaneous functionalization at C-18 and C-19 using an 11β-substituent was achieved by *Barton* and *Beaton* [49]. Photolysis of the 11β-nitrite *(74)* afforded a mixture of the 18- and 19-oximes *(75)* and *(76)*. Deoximation of *(76)* under the usual conditions with nitrous acid led to the expected hemiacetal *(77)*, a 19-isomer of aldosterone. Alkaline treatment of *(77)* resulted in a retroaldol elimination to yield 19-norcorticosterone *(78)* via the intermediate 11-formate. This represents the first elimination of a chemically functionalized C-19 angular methyl group [49c]. Subsequent photolysis of the 11-nitrite of *(78)* eventually led to the preparation of 19-noraldosterone.



*Jeger* and coworkers, who performed the early work on functionalization of the steroidal C-18 methyl group [42a], used one of their methods [50] for an indirect

functionalization of C-19. In this approach [51], photochemical isomerization of a C-11 carbonyl group *(81)* serves to establish a new C–C bond between C-11 and C-19, with formation of a tertiary cyclobutanol *(82)*.

[49c] A photolysis of an 11-nitrite *(79)* resulting in an attack of C-19 was first described by *Barton* [42c]; however the unprotected 3-keto-Δ -ene system

was responsible for formation of the undesired product *(80)*.

Selective fragmentation of the new C–C bond is accomplished with lead tetraacetate, and a 19-hydroxy steroid *(83)* is obtained in good yield.

The intramolecular attack on the C-19 methyl group of 2β- and 4β-hydroxy steroids by various methods is discussed in detail by *Heusler* and *Kalvoda* [42d].

### D. Practicable Syntheses of 19-Norsteroids

Although the functionalizations described above were a prerequisite for the preparation of 19-norsteroids, methods for efficient elimination of the oxygenated angular methyl group still had to be found.

The best preparative solutions to this problem came almost simultaneously and independently from several laboratories in 1961–1963; this explains some unavoidable overlap in the methods used. As early as 1960, *Hagiwara*, *Noguchi*, and *Nishikawa* [52] described the elimination of 19-formyl and 19-carboxyl groups in excellent yields. However, their starting materials, the 19-hydroxy compounds were obtained by microbial oxidation.

The new 19-norsteroid syntheses summarized in the formula scheme apply the best methods of intramolecular functionalization to the readily available 6β-hydroxy steroids *(85)*, followed by smooth elimination of C-19 in such a way as to provide a variety of desired products. Most of these methods are equally well applicable in the androstane, pregnane, and cholestane series; consequently the formulae are generalized, having only an R group at C-17.

Thanks to the high yields of *(58)* obtained by addition of hypochlorous or hypobromous acid to the abundantly available 3β-acetoxy-$\Delta^5$-steroids *(84)*, these 5α-halogeno-6β-hydroxy compounds became the basic starting materials for all practical syntheses.

19-Hydroxy derivatives *(88)* can be obtained from *(85)* by two methods. In the first, developed by the CIBA group [53], *(85)* is treated with lead tetraacetate in the presence of iodine ("hypoiodite reaction") to form the cyclic ether *(86)* [54]. The 3-keto-$\Delta^4$-ene group *(87)* is then introduced and subsequent reductive ring cleavage with zinc/acetic acid leads to *(88)*. The other method was developed by the Syntex group [55] and starts with treatment of *(85)* with lead tetraacetate alone to yield

[52] *H. Hagiwara, S. Noguchi*, and *M. Nishikawa*, Chem. Pharm. Bull. (Tokyo) *8*, 84 (1960).

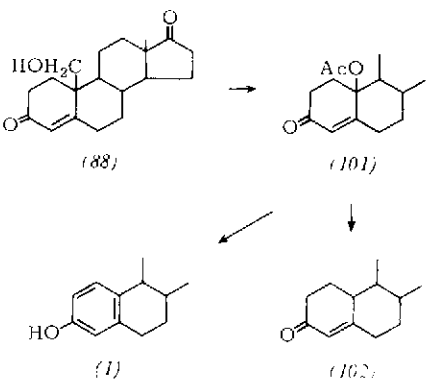
[53d] *J. Kalvoda, K. Heusler, H. Ueberwasser, G. Anner*, and *A. Wettstein*, Helv. chim. Acta *46*, 1361 (1963).

[54] Cf. *J. F. Bagli, P. F. Morand*, and *R. Gaudry*, J. org. Chemistry *28*, 1207 (1963).

[55a] *A. Bowers, R. Vilotti, J. A. Edwards, E. Denot* and *D. Halpern*, J. Amer. chem. Soc. *84*, 3204 (1962).

[55b] *B. Berkoz, E. Denot*, and *A. Bowers*, Steroids *1*, 251 (1963).



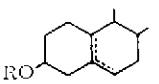
the cyclic ether *(86)*; the epoxide ring is opened under mild conditions with zinc and isopropanol, and the A-ring is then oxidized [*(86)* → *(88)*] in two steps. Oxidation of *(88)* to the 19-carboxy derivative *(89)* and elimination of the angular substituent by treatment with acid gave the required end products *(90)* and *(91)* in good overall yields. The best example of the Syntex procedure so far is the conversion of pregnenolone acetate *(84)*, R = $COCH_3$, into 19-norprogesterone *(91)*, R = $COCH_3$, in 37% yield [55a]. Another industrial application reported by the CIBA group [53b] entailed large scale preparation of *(90)* in the androstane series and its conversion into *(92)*. The latter compound is comparable in its reactions to *(2)*, since it has an easily removable protecting group on the A-ring, and a number of important 19-norsteroids may be obtained from it.

The lactones *(93)* prepared by oxidation of the cyclic ethers *(86)* [53a] can also be transformed into 19-norsteroids by two alternative routes, *viz.* ring opening followed by elimination *(93)* → *(94)* → *(91)* [55], or formation of the 3-keto-$\Delta^4$-ene group in ring A, followed by lactone opening and elimination *(93)* → *(95)* → *(91)* [56].

Compound *(85)* is also used as starting material in practical syntheses based on the Barton reaction [57], in which nitrites *(96)* are smoothly photolysed to the oximes *(97)*. These oximes are converted into the hemiacetals *(98)* according to *Akhtar* and *Barton* [56] and the latter are oxidized in good yields to the lactones *(93)*. The reaction sequence *(93)* → *(95)* → *(91)* then leads to the 19-norsteroids.

*Gardi* and *Pedrali* [58] dehydrated the oximes *(97)* to the angular nitriles *(99)*, which after saponification and oxidation in two steps gave the 19-carboxy compounds *(94)*. The conversion of *(94)* into *(91)* was accomplished by a new and mild method of decarboxylation using Girard T reagent [59a].

Application of the fragmentation of monohydric alcohols with lead tetraacetate to the now easily accessible 19-hydroxy compound *(88)* resulted in yet another elimination reaction [59b]. Good yields are reported for



*(88)* *(101)* *(1)* *(102)*

the steps *(88)* → *(101)* → *(102)*. Thermal elimination applied to *(101)* resulted in concomitant aromatization to estrone *(1)* [60].

Received, October 28th, 1963 [A 357/149 IE]
German version: Angew. Chem. *76*, 249 (1964)

[59a] A recent improvement of this procedure involves reductive elimination of the 19-cyano group to give an intermediate mixture formulated as *(100)* from which *(91)* is obtained in good yields [58c].

# Organosodium and Organopotassium Compounds

## Part II: Preparation and Synthetic Applications [1]

BY DR. M. SCHLOSSER

UNION CARBIDE EUROPEAN RESEARCH ASSOCIATES, BRUSSELS (BELGIUM)
AND ORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT HEIDELBERG (GERMANY) [*]

*A selection of well established procedures for the preparation of the most common organosodium and organopotassium compounds is given. The wide synthetic applicability of organoalkali-metal compounds is shown by means of examples. Unlike Part I, Part II deals not only with "true" organoalkali compounds, but also with salt-like compounds such as sodium acetylides and sodiocarboxylic esters, since these possess considerable preparative value.*

A. Preparative Methods
1. From metal derivatives
a) Transmetalation
b) Metalation with alkali amides
c) Other methods
2. Reactions with metals
a) Metal-metal exchange
b) Direct metalation
c) Halogen-metal exchange
d) Cleavage of ethers
e) Cleavage of carbon-carbon bonds
f) Addition of metals to multiple bonds
B. Experimental procedures
1. Alkali metals
2. Organoalkali-metal compounds
3. Syntheses using organoalkali-metal compounds

## A. Preparative Methods

A distinction is to be drawn between methods which lead to the creation of new organometallic bonds by the action of elemental alkali metals, and those which merely effect transfer of the organometallic bond from one organic residue to another. We shall first consider the latter type, in which a readily accessible organometallic compound, or occasionally an alkali metal amide or alkoxide, is used for the preparation of an organometallic reagent.

### 1. From Metal Derivatives

#### a) *Transmetalation*

By analogy with an acid-base reaction, the weaker organometallic base may be obtained from the corresponding hydrocarbon and a more strongly basic organometallic compound. The first transmetalation of this type was observed by *Schorigin* [2] [*(1)* → *(2)*]. Tables 1 and 2 list examples of such transmetalations.

$$\underset{(1)}{\text{i-H}_9\text{C}_4\text{—Na}} + \text{H}_5\text{C}_6 \rightarrow \underset{(2)}{\text{H}_5\text{C}_6\text{—Na}} + \text{i-H}_{10}\text{C}_4$$

b) *Metalation with Alkali Amides*

True organometallic compounds are not required for the anionization of ketones, nitriles, esters, sulfoxides, and other compounds containing activated hydrogens. The exchange of hydrogen for metal may be accomplished with even relatively weak proton acceptors such as sodium dispersions, potassium hydroxide, sodium hydride, sodium ethoxide, or potassium t-butoxide. Sodamide or potassamide in liquid ammonia are even more effective. However, these amides are too weakly basic to metalate purely aliphatic or monophenylated hydrocarbons [31]. On the other hand, alkali-metal benzyls, *e.g. (9)*, are rapidly ammonolyzed with decolorization by liquid ammonia.

$$\underset{(9)}{H_5C_6{-}CH_2{-}Na} + NH_3 \rightarrow H_5C_6{-}CH_3 + NaNH_2$$

The reactive hydrogens in acetylene [31a] or fluorene [32] are readily metalated by alkali-metal amides. As a rule, alkali-metal benzyls such as *(15)* and *(16)* are obtained smoothly with these amides if at least one additional activating group is present besides one aryl

$$\underset{(13)}{H_5C_6{-}CH_2{-}COOH} + 2\,NaNH_2 \rightarrow \underset{(14)}{H_5C_6{-}CHNa{-}COONa} + 2\,NH_3$$

$$(H_5C_6)_2CH_2 + NaNH_2 \rightarrow \underset{(15)}{(H_5C_6)_2CH{-}Na} + NH_3$$

$$(H_5C_6)_3CH + KNH_2 \rightarrow \underset{(16)}{(H_5C_6)_3C{-}K} + NH_3$$

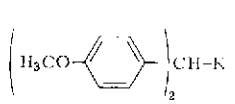
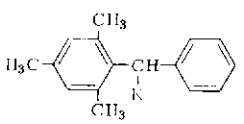
residue. This is illustrated by the preparation of sodium α-sodio-α-phenylacetate *(14)* [33], diphenylmethylsodium *(15)* [31], and triphenylmethylpotassium *(16)* [34].



These transformations are equilibrium reactions. In the case of di-*p*-anisylmethane *(17)* [35], the equilibrium lies more to the left.

$$(H_3CO-C_6H_4)_2CH_2 + NaNH_2 \rightleftharpoons (H_3CCO-C_6H_4)_2CH^-Na^+ + NH_3$$

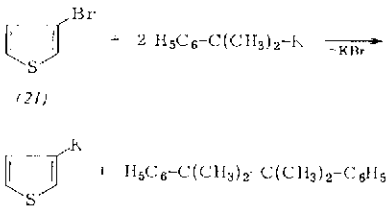


*(17)*

With diphenyl- and triphenylmethane, it is only in the ammonia solution that the equilibrium seems to be shifted completely towards the organometallic compound. Even on careful (vacuum) removal of the ammonia from a solution of triphenylmethylsodium, the residue is simply a mixture of triphenylmethane and sodamide. Addition of an organic solvent before the removal of the ammonia does not prevent the aminolysis [36a, 36b]. In contrast to diphenyl- and triphenylmethylsodium, the corresponding potassium derivatives may be isolated from their ammonia solutions with no difficulty, immaterial of whether the ammonia is evaporated off directly or whether an organic phase is first admixed [36a, 36b]. The fact that here the reversion to the hydrocarbon is suppressed does not necessarily imply that the organopotassium compound is more stable; the phenomenon could also be due to extremely slow attainment of the aminolysis-equilibrium in the case of the organopotassium derivative [37].

Di-*p*-anisylmethylpotassium *(18)* and mesitylphenylmethylpotassium *(19)* are stronger bases. If the attempt is made to isolate them from ammonia solution, they are protonated to regenerate the hydrocarbon just like the organosodium compounds [36a, 36b].

*(18)*



*(19)*

### c) *Other Methods*

New organosodium and organopotassium reagents may also be prepared by the reactions of organosodium and -potassium compounds with olefins *(20)* (addition), with halides *(21)* (halogen-metal interconversion), and with organometallic compounds, particularly those of mercury *(22)* (metal-metal interconversion). None of these reactions is of major preparative significance.

$$(H_5C_6)_2C{=}CH_2 + n\text{-}H_{11}C_5\text{-}Na \longrightarrow (H_5C_6)_2C(n\text{-}C_6H_{13})\text{-}Na \quad [38]$$

*(20)*

*(21)*

$$+ H_5C_6\text{-}C(CH_3)_2\text{-}C(CH_3)_2\text{-}C_6H_5 \quad [39]$$

$$(H_5C_6)_2Hg + 2\ n\text{-}H_9C_4\text{-}Na \longrightarrow 2\ H_5C_6\text{-}Na + (n\text{-}H_9C_4)_2Hg \quad [40]$$

*(22)*

## 2. Reactions with Metals [*]

### a) *Metal-Metal Exchange*

The first organoalkali-metal compounds were prepared from organomercury compounds [*(23)* and Table 3] and sodium [2, 41, 42], and were even isolated [43].

$$(H_5C_6)_2Hg + 2\ Na \rightarrow 2\ H_5C_6\text{-}Na + Na/Hg$$

*(23)*

Lithium and potassium derivatives may be obtained analogously. Since these are equilibrium reactions, the

alkali metal is always introduced in great excess. Often no attempt is made to separate the resulting organoalkali-metal compound from the unused alkali metal and the amalgam, although the separation procedure is a simple one [43a].

Although many organomercury compounds are easily prepared, this method soon fell out of favor, since it is not suitable for the preparation of large quantities of organoalkali compounds. The insidious toxicity of liquid mercury derivatives is a further serious disadvantage. Nowadays the mercury/alkali metal exchange is used only for the preparation of limited amounts of salt-free organosodium or organopotassium compounds when drastic conditions must be avoided.

The displacement method can be applied to other organometallic compounds, provided that the metal to be displaced is more electronegative than sodium. Alkylpotassium compounds are thus obtained elegantly from lithium alkyls and potassium metal in hydrocarbons [48]; transmetalation in benzene leads directly to phenylpotassium *(11)* in 86 % yield [11]:

$$R{-}Li \xrightarrow{K} R{-}K \xrightarrow{Benzene} H_5C_6{-}K \qquad (11)$$

b) *Direct Metalation*

The direct replacement of hydrogen by the elemental metal provides the simplest means of access to organoalkali compounds.

$$R{-}H + M \rightarrow R{-}M + {}^1/_2\,H_2$$

The controlling factors in direct metalation are the acidity of the hydrocarbon, the electropositivity and particle size of the metal used, and the nature of the solvent. The conversion of triphenylmethane into triphenylmethylpotassium by means of molten potassium, which reacts with the hydrocarbon above 200 °C, is accompanied by side reactions [49]. Metalation may be accomplished quite easily, however, with the blue solution of potassium in liquid ammonia [50], or with the corresponding solution of sodium [51]; the latter, however, reacts more sluggishly. Sodium dispersions (see Section B.1) and sodium aromatic complexes [52] are far superior to solid sodium in the anionization of carboxylic esters and aliphatic nitriles. Potassium reacts more vigorously with thiophene [22] than sodium does, and metallic cesium displaces even the hydrogen atoms of paraffins [53]. Table 4 gives a list of some organosodium and organopotassium compounds obtained by hydrogen-metal exchange. The displaced hydrogen is not always liberated as gas. With acetylene [54], fluorene [55], and triphenylmethane [56], the reaction mixtures contain hydrogenation products as well as the appropriate organometallic base. The metalation of toluene to give benzylpotassium *(24)* in the presence of sodium oxide is especially noteworthy in this respect [57].

$$2\,H_5C_6{-}CH_3 + 2\,K + Na_2O \xrightarrow{3^h,\ 110\,^\circ C} 2\,H_5C_6{-}CH_2{-}K + NaH + NaOH$$

*(24)*, 87 %

Table 4. Organosodium and organopotassium compounds obtained by hydrogen-metal exchange.

| Organic residue | Reference | |

and organolithium compounds, *i.e.* by the action of the metal on organic halides.

Many years ago, *Schorigin* [2] postulated the occurrence of the alkylsodium compounds *(1)*, which were supposed to be formed by halogen-metal exchange, as intermediates in the Wurtz synthesis and in certain addition reactions:

$$i\text{-}H_9C_4\text{—}Br + Na \rightarrow i\text{-}H_9C_4\text{—}Na \rightarrow \text{Products.}$$

*(1)*

Nevertheless, it was a long time before this procedure became a standard method, surpassing in importance all other preparations of organosodium and organopotassium compounds. The high reactivity of the organometallic compounds at first frustrated any attempts at their isolation; instead, they were consumed by subsequent reactions with the solvent or with unreacted halide.

It was only after the studies of *Morton* [72–75] that it became possible to suppress secondary processes such as transmetalation, elimination, and Wurtz condensation. The use of finely divided sodium, high-speed stirring, and effective temperature control permit the preparation of numerous organosodium compounds in quantitative yield. Thus, a continuous unit [71] is capable of handling more than 1 kg of sodium powder per hour to give phenylsodium in 75 % yield [71].

The greater reactivity of sodium and potassium derivatives, relative to the Grignard and lithium compounds used previously, extends the scope of organometallic reagents in preparative reactions. Furthermore, organometallic compounds may now be prepared economically from sodium and alkyl or aryl chlorides, using cheap solvents, and are thus suitable for industrial applications. Grignard compounds are mostly obtained from expensive bromides or iodides, whereas all of the organoalkali-metal derivatives in Table 5, with but a single exception [84], are derived from chlorides.

*E. Müller* [85] described some interesting exchange reactions of the disodium adduct of tetraphenylethylene, which behaves like dissolved sodium. Thus, *o*-bromofluorobenzene is converted by it into *o*-fluorophenylsodium at −70 °C in tetrahydrofuran; treatment of this with benzophenone leads to a 65 % yield of *o*-fluorophenyldiphenylmethanol. Under the same conditions, *o*-bromophenylsodium, which is obtained similarly from *o*-dibromobenzene, is unstable, dehydrobenzene derived from its decomposition can be trapped with furan in 15–36 % yield.

[b], [c]: See corresponding footnotes in Table 1.

d) *Cleavage of Ethers*

The cleavage of ethers by alkali metals [86–88] is formally analogous to the halogen-metal exchange, but differs from it in one significant respect: purely aliphatic ethers are stable toward metals below 200 °C. Only aryl and benzyl ethers are cleaved; with mixed aryl ethers *(25)*, the oxygen remains attached to the aromatic residue, while the alkyl residue becomes part of the organometallic compound. Benzyl aryl ethers *(26)* are decomposed to the more weakly basic benzylalkali-metal compound and alkali phenoxide.

$$H_5C_6-O-CH_3 + 2\,K \rightarrow H_5C_6-K + KOCH_3$$
(25)

$$(H_5C_6)_3C-O-C_6H_5 + 2\,K \rightarrow (H_5C_6)_3C-K + KOC_6H_5$$
(26)

A convenient source of metal is a liquid Na/K alloy [87], an excess being used. Cleavage is generally quantitative (see Table 6, K derivatives). Only a few very labile ethers react at low temperatures with pulverized or solid sodium (see Table 6, Na derivatives). Ether cleavage provides a means of degrading complex ethers and thioethers [88,94]. Acetals are cleaved with particular ease. The resulting α-metalated ethers sometimes undergo Wittig rearrangement [91].

e) *Cleavage of Carbon-Carbon Bonds*

Polyarylethanes *(27)* are reported by *Schlenk* [95] to be cleaved by alkali metals at their weakened central C–C bond, giving two molecules of organometallic compound.

$$(H_5C_6)_3C-C(C_6H_5)_3 \xrightarrow{Na/Hg} 2\,(H_5C_6)_3C-Na$$
(27)

With sodium powder, hexaphenylethane *(27)* is largely irreversibly isomerized to *p*-diphenylmethylphenyltriphenylmethane.

The tendency of the ethane derivatives to dissociate may be roughly estimated from the nature of the metal required for cleavage. Hexaphenylethane reacts even with 1 % sodium amalgam, 9,9′-dimethylbixanthyl requires 40 % sodium amalgam [96], while 1,1,2,2-tetraphenylethane [87] is cleaved only with liquid Na/K alloy to yield diphenylmethylpotassium. Table 7 gives a survey of the organosodium and organopotassium compounds obtained from symmetrical ethanes by such cleavage reactions. The cleavage of unsymmetrical hydrocarbons such as pentaphenylethane [95] and 1,1,1,2-tetraphenylethane [87] is also possible. In this case, mixtures of two organometallic compounds are obtained.

Table 7. Organosodium and organopotassium compounds obtained by cleavage of symmetrical ethanes.

The preparation of triphenylmethylsodium [43] from triphenylmethyl chloride and Na/Hg certainly involves hexaphenylethane as an intermediate. The latter is then cleaved by excess metal to give triphenylmethylsodium. Benzyl chloride does not react with sodium to give benzylsodium, since condensation occurs instantaneously to give 1,2-diphenylethane, which cannot be cleaved [96, 99].

Polyarylated disilanes, digermanes, distannanes, and diplumbanes react with alkali metals in a manner similar to the polyarylethanes. They are cleaved in ether (or, preferably, in liquid ammonia) to give "quasi-organometallic" compounds. For example, hexaphenyldisilane is converted into triphenylsodium [101] and diphenylsilylpotassium [101, 102]. Other preparations of this type include $(CH_3)_3GeNa$ [103–106], $(CH_3)_3SnNa$ [107], $(C_6H_5)_3SnNa$ [108], and $(C_6H_5)_3PbNa$ [109]. The triaryl derivatives are chemically very similar to the triarylmethylalkali-metal compounds.

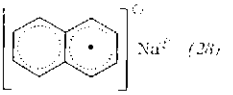
f) *Addition of Metals to Multiple Bonds*

*Beckman* [110a] was the first to observe that a solution of benzophenone in dry ether acquires a deep blue-violet color when it is shaken with sodium powder or when boiled with sodium wire. A brief induction period precedes the reaction, in which the sodium ketyl *(29)* is formed. The reaction has been studied extensively by *Schlenk* [110b]. Later, numerous other intensely colored metal adducts became known including those of ketones, nitriles, Schiff bases, hydrazones, azo compounds, ketazines

nitrogen heterocycles, and derivatives of styrene, stilbene and tolane (diphenylacetylene), as well as of allenes and polycyclic aromatics [111, 112].

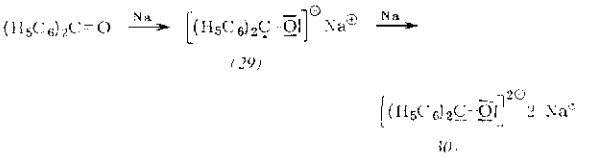
Most of these unsaturated systems also add on organometallic reagents readily. However, a few aromatic hydrocarbons, such as naphthalene, appear to add on only the elemental metals.



The ability of such compounds to undergo addition reactions increases with the number of their double bonds. Thus, sodium adds much more rapidly onto anthracene than onto naphthalene, while it does not add onto benzene at all at 80 °C. Strong electropositivity of the metal likewise facilitates the reaction. Benzene probably forms an adduct with potassium under drastic conditions [113], but no adduct is obtained with sodium; ethylene will not react with potassium, but it does react with cesium to yield ethylenedicesium [114].

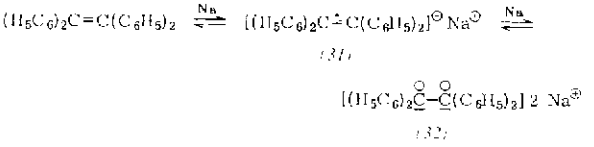
Lithium appears superior to the heavier alkali metals in additions to triple bonds; for example, it is taken up by tolane much faster than other metals [115]; (it is also the only metal which reacts with molecular nitrogen at room temperature to form a nitride [116]).

Depending on the composition of the products obtained, one can distinguish between



a) 1:1 adducts (radical anions)
b) 2:1 adducts, and
c) 2:2 adducts (dimeric adducts).

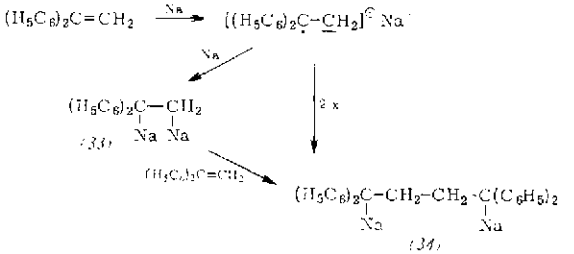
A typical 1:1 complex is naphthalenesodium [51, 117a], which exists as the undissociated ion pair *(28)* [112, 117b].



*(28)*

The 1:1 adducts can take up additional atoms of metal, particularly at high temperature. Thus, the blue-violet sodium ketyl *(29)* affords red-violet benzophenone-disodium *(30)* [118a, 118b].

*(29)* *(30)*



In the case of tetraphenylethylene in ether, the 2:1 adduct *(32)* is so favored that none of the 1:1 adduct *(31)* can be detected, no matter how much olefin is present. It is only when the equilibrium between *(31)* and *(32)* is shifted by changing the solvent (*e.g.* by replacing ether with 1,2-dimethoxyethane) that the radical anion *(31)* can be detected by its ESR signal [119].

*(31)* *(32)*

Many hydrocarbons can bind metal atoms to go beyond the 2:1 adduct, giving highly metalated products such as anthracenedecasodium [120].

With 1,1-diphenylethylenes, adduct formation proceeds by a fundamentally different process. Here, in a formal sense, two radical anions combine to form a dimer that is substituted with metal at the 1- and 4-positions. In this process, however, the 2:2 adduct *(34)* does not appear to be generated by coupling of two radicals, as *Schlenk* assumed [118a, 121], but rather by addition of the organometallic 2:1 complex *(33)* onto a second molecule of olefin, as proposed by *Ziegler* [122].

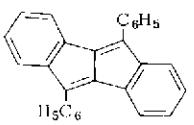
[122] *K. Ziegler* and *O. Schäfer*, Liebigs Ann. Chem. *479*, 150 (1930).



The normally high readiness of a methylene-sodium bond to undergo addition reactions should be even further increased in the adduct *(33)* by the neighboring diphenylmethyl anion. The increase in reactivity due to directly neighboring organometallic bonds[123] may also be responsible for adduct formation in the case of tolane. Compounds *(35)* derived from the monomer presumably appear as intermediates, which promptly take up a second molecule of tolane. In ether, lithium adds smoothly onto tolane, giving tetraphenylbutadiene-1,4-dilithium. The analogous greenish-blue adduct *(36)* is formed with Na/K alloy in dioxan. Its hydrolysis yields, besides tolane (35 %), 1 % diphenyldibenzopentalene *(37)*, 2 % *cis,trans*-1,2,3,4-tetraphenylbutadiene, and 5 % 1-benzyl-2,3-diphenylindane [124].

$$M-(H_5C_6)C=C(C_6H_5)-M$$

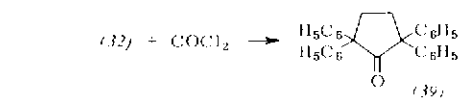
*(35)*

$$K-(H_5C_6)C=C(C_6H_5)-(H_5C_6)C=C(C_6H_5)-K$$

*(36)*

*(37)*

The chemical behavior of most of the 1:1 and 2:1 adducts based on the monomeric hydrocarbons is similar to that of a solution of the appropriate alkali metal in an organic solvent. Thus, when stilbene disodium *(38)* is treated with methyl iodide, benzyl chloride, aryl halides, oxygen, sulfur, or arsenic(III) chloride, the original hydrocarbon is always regenerated [121, 125a - 125c].



$$\underset{(38)}{H_5C_6-CHNa\ \ CHNa-C_6H_5} \xrightarrow[-2\ NaI]{2\ CH_3I} H_5C_6-CH=CH-C_6H_5 + H_3C-CH_3$$

In other cases, stilbene disodium *(38)* reacts like an organometallic compound. For example, it reacts with proton donors to give diphenylethane, with dimethyl sulfate to give racemic and *meso*-2,3-diphenylbutane, and with carbon dioxide to give *meso*-2,3-diphenylsuccinic acid (together with some racemate) [125a-125c].

Unlike the 1:1 and 2:1 adducts, the dimeric (2:2) adducts find many preparative applications, since they only rarely revert to the parent hydrocarbon; for example, 1,1,4,4-tetraphenylbutylene-1,4-disodium *(34)* may be cleaved with mercury [121, 126], and the analogous dipotassium compound is cleaved with iodine, methylene iodide, or tetramethylethylene dibromide [127], reverting to 1,1-diphenylethylene.

$$\underset{(34)}{Na-(H_5C_6)_2C-CH_2-CH_2-C(C_6H_5)_2-Na} \xrightarrow{Hg} 2\,(H_5C_6)_2C=CH_2 + Na/Hg$$

The other reactions of the 2:2 adducts, including those with alkyl and acyl halides, esters, aldehydes, or nitrosyl chloride, give the corresponding 1,4-disubstituted derivatives, *e.g. (39)* [121].

*(39)*

Under mild conditions, 2:2 adducts of butadiene [128], styrene [129], and α-methylstyrene [129] may also be obtained. To inhibit polymerization, polar ethers such as dimethyl ether, tetrahydrofuran, or dimethoxyethane are used as solvents. In these media, adduct formation occurs with sufficient rapidity even at −30 °C. A small amount of *o*-terphenyl serves as a carrier for the dispersed sodium. The metal is transferred to the olefin via the aromatic sodium complex initially formed.

The dimeric adduct of butadiene *(40)* and sodium is now being produced on an industrial scale. The mixture of unsaturated $C_{10}$ dicarboxylic acids which results from carboxylation of *(40)* is sold commercially in the hydrogenated form [128, 130].

$$H_2C=CH-CH=CH_2 \rightarrow Na-CH_2-CH=CH-CH_2-Na$$

$$\downarrow$$

2-Ethylsuberic acid 51 %
Sebacic acid 38 %
2,5-Diethyladipic acid 11 %

The alkali metal adducts are important in many reactions, in which they act as intermediates that cannot be isolated. The chief examples are the Birch-Hückel-Ziegler [131] and Bouveault-Blanc [132, 133] reductions using the elemental metals in the presence of proton donors. Related to these is a convenient method for the preparation of diphenylmethyl-type organosodium and organopotassium compounds, in which the metal is added onto derivatives of 1,1-diphenylethylene in liquid ammonia. All the alkali-metal atoms attached to an

[123] This principle was formulated by *K. Ziegler* et al. [Liebigs Ann. Chem. *511*, 64 (1934)] to explain the fact that 2,3 dimethylbutadiene dimerizes – but does not polymerize – in the presence of lithium metal. 1,4-Dilithium-2,3-dimethyl-2-butene, $Li-CH_2-C(CH_3)=C(CH_3)-CH_2-Li$, an adduct with two vinylogously vicinal organolithium bonds, does indeed add more rapidly onto 2,3-dimethylbutadiene than the subsequent products $Li\ CH_2-C(CH_3)-C(CH_3)\ CH_2\ R$, in which the organometallic bond is isolated.

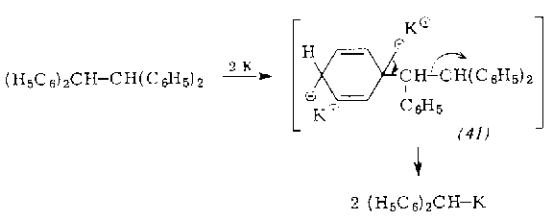
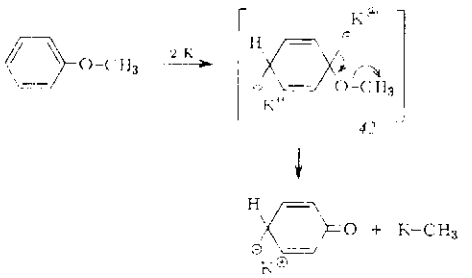
alkyl or benzyl group of the intermediate 2:1 adduct are immediately replaced by hydrogen, while organometallic bonds with two neighboring aryl groups are resistant to the aminolysis. Examples are given in Table 8.

Table 8. End-products of the reaction of olefins with sodium in liquid ammonia.



| Olefin | Na derivative | Ref. |
|---|---|---|
| $(H_5C_6)_2C{=}CH_2$ | $(H_5C_6)_2C(CH_3){-}Na$ | [134, 135] |
| $(H_5C_6)_2C{=}CH{-}CH_3$ | $(H_5C_6)_2C(C_2H_5){-}Na$ | [135] |
| $(H_5C_6)_2C{=}CH{-}C_6H_5$ | $(H_5C_6)_2C(CH_2{-}C_6H_5){-}Na$ | [135] |
| $(H_5C_6)_2C{=}CH{-}CH(C_6H_5)_2$ | $(H_5C_6)_2CNa{-}CH_2{-}CH(C_6H_5)_2$ | [135] |
| $(H_5C_6)_2C{=}C{=}C(C_6H_5)_2$ | $Na{-}(H_5C_6)_2C{-}CH_2{-}C(C_6H_5)_2{-}Na$ | [135] |

Addition of the intermediate 1,1-diphenylethylenedisodium onto unreacted 1,1-diphenylethylene resulting in a 10–30% yield of 1,4-disodium-1,1,4,4-tetraphenylbutane competes with its ammonolysis [135].



Liquid ammonia promotes the addition of metal to an extraordinary degree. Thus, 1,1-diphenyl-1-propene reacts smoothly with sodium in ammonia, although it forms no sodium adduct in ether [121, 125c]. Moreover, tetraphenylethylenedisodium, which is otherwise stable, seems to be cleaved at the central C–C bond by excess sodium in liquid ammonia [135, 136].

$$(H_5C_6)_2C{=}C(C_6H_5)_2 \xrightarrow{2\,Na} (H_5C_6)_2C(Na){-}C(Na)(C_6H_5)_2 \xrightarrow{2\,Na} 2\,(H_5C_6)_2CNa_2\ (?)$$

It may be presumed that alkali metal/hydrocarbon adducts play a decisive role in the cleavage of carbon-carbon bonds and in the cleavage of ethers. Of course, the reaction of hexaphenylethane with sodium to form triphenylmethylsodium may also be formulated as a dissociation equilibrium producing triphenylmethyl radicals, which are then trapped by the metal (cf. *Paneth*'s demonstration of methyl radicals [137]). However, no corresponding radical mechanism can be postulated for the cleavage of tetraphenylethane or of 1,2-di-*p*-biphenylylethane, since here there is no evidence for a dissociation equilibrium at room temperature. None the less, it may well be that in the first of the above cases a potassium adduct *(41)* occurs as an intermediate from which the two halves of the molecule are separated to form the final product.

In a similar manner, the cleavage of ethers by alkali metals [137a] may be considered as the result of adduct formation *(42)*.

On the other hand, the exchange processes, in which a chlorine, bromine, or iodine atom bound to an organic residue is replaced by a metal, may be completely explained by a nucleophilic attack on the halogen, which is capable of enlargement to an electron decet; this is the reason that aliphatic halides can also react in this way. However, alkali metal adducts must again be assumed as intermediates in the exchange of halogen by metal in fluorinated aromatics [138], in the Emde degradation of ammonium salts [139], and in the analogous cleavage of phosphonium salts [140].

## B. Experimental Procedures

### 1. Alkali Metals

It is advantageous to use sodium in solution in ammonia, as an ether-soluble aromatic/sodium adduct, or as a dispersion [141, 142]. Thirty and fifty per cent sodium stock dispersions are available as mobile suspensions, generally stabilized against sedimentation by small amounts of additives [149]. The preparation of sodium dispersions is described in Procedures 2β and 2δ. The average size of the sodium particles in Procedure 2δ is 2–3 μ. Metallic potassium is generally used as a fine powder or in the form of the readily prepared liquid alloy with sodium [90, 102, 143].

### 2. Organoalkali-Metal Compounds

#### α) Methylsodium [43]

A Schlenk tube is charged under nitrogen with 60 ml of dry ligroin (b.p. *ca.* 80 °C), fine chips of sodium, and 3.0 g (13 moles) of dimethylmercury. The sodium should be present in four-fold excess [9], although still covered by the liquid. The Schlenk tube is sealed and kept for several days in a drying oven at 65 °C. The tube is then placed in an ice-salt mixture, after which it is shaken vigorously to loosen the yellowish incrustations of methylsodium from the unreacted sodium and sodium amalgam. The methylsodium is thus obtained as powder and flakes. The light particles of methylsodium can be decanted off with the ligroin and are washed with petroleum ether [144]. The corresponding preparations of ethylsodium, higher sodium alkyls, and phenylsodium proceeds much more rapidly; the reaction is completed within a few hours at room temperature.

[144] It is often possible to omit this rather bothersome separation step, since the presence of sodium and sodium amalgam has no deleterious effect on many of the reactions of sodium alkyls.

β) n-Amylsodium [3,5,73,145]:

A 1-liter three-necked flask with two creases (Morton flask [146a]) is charged under nitrogen with 23 g (1 gram-atom) of sodium, which is then covered with about 300 ml of olefin-free n-octane. This mixture is heated to 110 °C and stirred for at least one minute with a propeller-type agitator (10000 rpm). After cooling, the "sodium sand" (average particle size 25 μ) is allowed to settle, the octane is siphoned off under nitrogen, and the sodium washed several times with dry n-pentane. Such a sodium dispersion in about 200 ml of pentane or octane is mixed with 53.2 g (0.5 mole) of n-amyl chloride, which is added dropwise at −10 °C over a period of one hour while stirring is continued at approx. 5000 rpm [146b]. The mixture usually becomes blue. Finally it is stirred for further 30 min at −10 °C. The yield of n-amylsodium is 80 %. As a safety precaution, it is inadvisable to use more than one gram-atom of sodium at a time.

γ) Phenylsodium/Phenyl-lithium Solution [147]:

Diphenylmercury (0.9 g = 2.5 mmoles) in 15 ml of absolute ether is mixed in a Schlenk tube with 1 g (43.5 mmoles) of sodium wire and 5 ml of a 1 N phenyl-lithium solution prepared from diphenylmercury and lithium chips in ether; glass fragments are added, and the tube is sealed and shaken for 3 h. The solution is decanted from the greyish white precipitate and the lump of amalgam into a storage burette, where it is diluted with 40 ml of absolute ether. The solution decomposes slowly by reacting with the ether.

Variations of this method include the action of Li/Na alloy on diphenylmercury and the combination of phenyl-lithium with phenylsodium. Ether suspensions with higher phenylsodium/phenyl-lithium mole ratios (*e.g.* 5:1) have also been described [147].

δ) Phenylsodium [13,42]:

A Premier Mill laboratory dispersion unit [148,142] (high-speed stirrer with a dispersing head) is filled with nitrogen, and 150 g of dry toluene and 27 g (1.17 gram-atom) of sodium are introduced [149]. The sodium melts when the temperature is raised to 105 °C. The stirrer is then gradually brought to maximum speed (15000–18000 rpm) and maintained there for 5–15 min; the grey mixture is then cooled to room temperature [150]. A mixture of 56.3 g (0.5 mole) of chlorobenzene and 50 g of toluene is then prepared in a dropping funnel and 10–15 ml of it is rapidly added to the sodium mixture with gentle stirring. As a rule, reaction begins suddenly within a few minutes, with a noticeable increase in temperature and the appearance of black particles of phenylsodium. Otherwise the reaction may be initiated with 2 ml of amyl alcohol. The remainder of the chlorobenzene is then added dropwise over 20–30 min, but precaution must be taken to maintain the reaction temperature at 30–35 °C. The yield of phenylsodium is 99–100 %.

ε) Benzylsodium [13]:

A suspension of phenylsodium in toluene is heated for 2 hours under reflux in a nitrogen atmosphere. Benzylsodium is thus obtained in 99–100 % yield. A modification of this procedure is applied for the preparation of benzylsodium in the n-butylbenzene synthesis (cf. Procedure 3 γ).

ζ) Triphenylmethylsodium [78]:

A 1 % sodium amalgam is prepared under nitrogen in a 1 liter Schlenk tube by introducing 5.53 g (0.25 gram-atom) of sodium as small pieces speared on the end of a pointed glass rod into 575 g of pure mercury; (this operation must be performed in a hood). After cooling, 750 ml of absolute ether are added, followed by 31.5 g (0.113 mole) of triphenylmethyl chloride [m.p. 112–113 °C; recrystallized from a 10:1 ligroin (b.p. 100 °C)/acetyl chloride mixture]. The Schlenk tube is sealed off and shaken vigorously, whereupon the solution becomes deep orange. The exothermic reaction is moderated by cooling the tube with wet cloths, or by occasional immersion in ice water. The reaction is largely complete after fifteen minutes' shaking; to obtain total conversion, the tube is shaken for three hours on a horizontal mechanical shaker. After the sodium chloride produced has settled out, the tube is opened under nitrogen, and the organometallic solution is transferred to a storage burette through polyethylene tubing, into which a plug of glass wool has been loosely inserted. The yield is practically quantitative, as shown by titration of a sample with 0.1 N acid. If the mercury is not objectionable, the triphenylmethylsodium can be prepared more simply in a three-necked flask, and then used directly for further reaction [79].

η) Sodium Acetylide [59b,151]:

A one-liter flask is fitted with a glass or Hershberg stirrer (with mercury seal) and a dry-ice condenser (or a freezing mixture at −35 °C). Anhydrous liquid ammonia (300 ml) is added. Acetylene gas is passed through a cold trap at −70 °C and two wash bottles containing conc. sulfuric acid and is bubbled through the liquid. Simultaneously 5.5 g (0.24 gram-atom) of sodium are added slowly in small pieces so that the blue color disappears before the next piece is added. As soon as all of the sodium has been introduced and the solution has lost color, the flow of acetylene is discontinued. This method can be used with only minor variations to produce large quantities of sodium acetylide (13 moles in 6 l of ammonia) [59a,59b]. Large amounts can also be obtained with sodamide in liquid ammonia [152]. The excess acetylene in solution, inevitable in these preparations, generally causes no difficulty in further use.

ϑ) Sodium Phenylacetylide [61]:

A mixture of 3.06 g (30 mmoles) of phenylacetylene, 0.46 g (20 mmoles) of finely divided sodium, and 30 ml of absolute ether is stirred at room temperature. After about 8 h all of the metal is consumed; this is shown by absence of hydrogen evolution when a few drops of the suspension are hydrolysed. The corresponding reaction with potassium, which yields potassium phenylacetylide, usually requires 48 h.

κ) *p*-Tolylpotassium [48]:

A solution of *p*-tolyl-lithium (95 mmoles) in ether is evaporated *in vacuo* (at the end for 30 min at 60 °C) to remove the solvent completely. Dry benzene (45 ml) and an alloy of 7.8 g (0.2 gram-atom) of potassium with 2 g (0.087 gram-atom) of sodium are now added, and the mixture is stirred for 10 h at 20 °C. An aliquot of the dark brown mixture is withdrawn and filtered. A small alkali content of the filtrate indicates that the reaction has been almost quantitative. The preparations of ethyl-, n-propyl-, n-butyl, s-butyl, and t-butylpotassium and other potassium alkyls are analogous [11,48].

[148] Premier Mill Co., Geneva, N.Y. (U.S.A.).

[149] It often happens that the dispersion cannot be used at once in further reactions, or must be prepared in benzene or an alkane rather than in toluene. In these cases, it is advisable to intdroduce 1 % oleic acid (based on the weight of sodium) or another additive before making the dispersion.

λ) α-Phenylisopropylpotassium [6, 153]:

A mixture of α-methylstyrene and methanol in a molar ratio of 1:2) is treated with 0.05 % of its weight of 70 % perchloric acid solution and allowed to stand for 48 h at 50 °C. Aqueous sodium hydroxide is then added, the methanol completely extracted from the oil layer with water, and the oil layer dried with $CaCl_2$. Fractional distillation *in vacuo* yields 26 % unreacted α-methylstyrene (b.p. 64–65 °C/23 mm, $n_D^{20} = 1.5372$) and 62 % methyl α-phenylisopropyl ether (b.p. 83–84 °C/23 mm, $n_D^{20} = 1.4956$) [6]. Methyl α-phenylisopropyl ether (5.0 g, 33 moles), 6 g of potassiumsodium alloy (5:1), and 400 ml of absolute ether are filled into a large Schlenk tube under nitrogen. The tube is sealed off and shaken vigorously. The intense red color of the organopotassium compound develops within two minutes. The reaction is complete after two days' shaking. The tube is opened under nitrogen and the solution transferred to a storage burette through a polyethylene tube containing a plug of glass wool [153]. Phenylisopropylpotassium may also be obtained as a suspension in hydrocarbons or, free of by-products, in solid form [6].

μ) Diphenylmethylpotassium [154]:

A two-liter 3-necked flask, fitted with a dry-ice condenser and a Hershberg stirrer (with a mercury seal), is filled with 800 ml of liquid ammonia, and 21.5 g (0.55 gram-atom) of potassium are added in small pieces with thorough mixing. The deep blue solution is decolorized within two hours, this indicating the formation of potassium amide [155]. A solution of 84.0 g (0.5 mole) of diphenylmethane in 800 ml anhydrous ether is added, and, after the dry-ice condenser has been replaced by a water-cooled condenser, the ammonia is evaporated off on a water bath. Sufficient ether is added to bring the total volume up to 800 ml, and the mixture is refluxed for further two hours. Carboxylation of the orange-red solution gives a 90 % yield of diphenylacetic acid. Alkylation, acylation, and other reactions may also be carried out in the ammonia-ether medium before the ammonia is evaporated off [154]; with diphenylmethyl*sodium*, it is essential that these reactions be performed before evaporation [35].

## 3. Syntheses Using Organoalkali-Metal Compounds

α) Vinylacetic Acid [156]:

A Morton flask is charged under nitrogen with 5.8 g (0.25 gram-atom) of "sodium sand" (see Procedure 2β). The octane is replaced by hexane, and 14.7 g (0.15 mole) of diallyl ether dissolved in an equal volume of hexane are added dropwise over a period of one hour, the mixture being stirred at 5000 rpm and an average temperature of 35 °C being maintained. After further 30 min, the purely white, moderately viscous reaction mixture is transferred from the flask by pressure (via an outlet tube) onto solid carbon dioxide. After addition of 200 ml of water and extraction with ether, 8.3 g of vinylacetic acid (b.p. 61–62 °C/3 mm, $n_D^{23} = 1.4220$) are isolated (77 % yield based on sodium).

β) Phenylmalonic Acid [13]:

A suspension of benzylsodium in toluene, prepared by Procedure 2ε [13] using 112.6 g (1 mole) of chlorobenzene, is carboxylated by introducing carbon dioxide gas with stirring at 30–60 °C. In this operation about half of the theoretical quantity of gas is added during the first ten minutes, stirring is continued for 30 min, and more carbon dioxide is introduced during 80 min to complete the carboxylation slowly. The excess sodium is now destroyed with steam in a hydrolysis apparatus, the aqueous phase removed and decolorized with animal charcoal, and then neutralized with hydrochloric acid at 0 °C [157]. Large quantities of phenylmalonic acid are precipitated. Additional product is obtained by extraction of the mother liquor with ether [157]. The total yield of acid, m.p. 145–148 °C, is 67 % (based on chlorobenzene). The phenylacetic acid (28 %) present as a by-product is previously removed by benzene extraction.

γ) n-Butylbenzene [158]:

A 1-liter three-necked flask is charged under nitrogen with 300 ml of toluene and 27.5 g (1.2 gram-atom) of sodium wire. Over a period of two hours, 68 g (0.6 mole) of chlorobenzene are added dropwise at 30–35 °C with vigorous stirring (blade-type stirrer, mercury seal). The reaction begins quickly. The mixture is then refluxed for 35 min, the heating bath is removed, and 49 g (0.4 mole) of n-propyl bromide are added dropwise to the benzylsodium suspension at 103–105 °C over a period of 20 min. After cooling, any benzylsodium remaining is destroyed with a stream of carbon dioxide, and the excess sodium with water. The toluene layer is separated off, dried, and fractionally distilled twice; 40 g of pure n-butylbenzene (b.p. 181–181.5 °C, $n_D^{20} = 1.4898$) is obtained (74 % yield based on n-propyl bromide). In contrast, the condensation of phenylsodium and n-butyl bromide gives only a 44 % yield of n-butylbenzene.

δ) 1-Chloro-5-nonyne [59b]:

A solution of sodium acetylide in ammonia is prepared from 5.5 g (0.24 gram-atom) of sodium, and 41 g (0.24 mole) of n-propyl iodide are added to it slowly, stirring being continued for four hours. A solution of 0.25 gram-atom of sodamide (prepared from 5.8 g of sodium) in 150 ml of liquid ammonia [59b] is then added in portions to the thoroughly cooled mixture, which is stirred for another hour. Next 41 g (0.24 mole) of 1-chloro-4-bromobutane are slowly added dropwise, and the cooled reaction mixture is stirred for further 12 h. Then 15 g (0.28 mole) of ammonium chloride are added, the ammonia is evaporated off, and the residue is extracted with water and ether. Distillation of the dried organic phase gives 5.3 g (13 %) of unreacted 1-chloro-4-bromobutane and 24.2 g (64 %) of 1-chloro-5-nonyne (b.p. 83–84 °C/13 mm, $n_D^{18} = 1.4620$).

ε) 1,8-Cyclotetradecadiyne [159]:

α,ω-Nonadiyne (0.1 mole) is added with stirring to a solution of 0.2 mole of sodamide [59b] in 1 liter of liquid ammonia. After one hour, 0.1 mole of α,ω-dibromopentane is added, again with agitation. Stirring under a condenser cooled with dry ice is continued for four days, and the ammonia is then removed by evaporation. Water is added, the mixture is extracted with ether, the ether extracts are dried, the ether is evaporated off, and the residue is distilled at 100–110 °C and $10^{-3}$ mm Hg. The diyne thus obtained is crystallized from alcohol and melts at 97–98 °C. The yield (56 %) may be increased to more than 70 % by working in more dilute solution.

ζ) *p*-Nitrophenyl Phenethyl Ketone [160]:

A solution of 1.2 g (4 mmoles) of di-t-butyl benzylmalonate in 25 ml of dry benzene is stirred gently in a three-necked flask under slight reflux and treated with 0.15 g (6 mmoles) of

sodium hydride. As soon as the evolution of gas has ceased (after about 2.5 h), 0.75 g (4 mmoles) of *p*-nitrobenzoyl chloride is added without interrupting the stirring or reflux. One hour later the mixture is cooled, and the excess sodium hydride is decomposed with 0.35 g (2 mmoles) of anhydrous *p*-toluenesulfonic acid. The salts precipitated are filtered off, the benzene is distilled off, and the residual oil is refluxed for one hour with a mixture of 0.1 g of *p*-toluenesulfonic acid in 25 ml of glacial acetic acid containing about 2 % (by volume) of acetic anhydride. The evolution of gas ceases after about 45 min. The mixture is poured onto ice, neutralized with dilute alkali, and the white precipitate is filtered off (0.83 g; 81 % yield). After recrystallization from ethanol, colorless leaflets are obtained which melt at 74.5–75 °C.

### $\eta$) Diphenylenephenylphosphine [161]:

A Schlenk tube is charged under nitrogen with 21.6 g (83 moles) of triphenylphosphine and a suspension of phenylsodium (prepared from 8.5 g of chlorobenzene and 3.5 g of sodium) in 40 ml of benzene, then sealed and shaken for 10 h at 20 °C and for 30 h at 70 °C. After decomposition of unreacted starting material with methanol and addition of water, the benzene layer is dried, the solvent is evaporated, and the residue distilled. Thirteen grams of distillate are collected at 0.05 mm Hg and 155–160 °C. This is mulled with aqueous HCl (2 parts conc. HCl, 1 part $H_2O$) to extract 10.2 g of triphenylphosphine. After recrystallization from methanol, the residue melts at 93–94 °C. The yield varies from 8 to 15 %. For reasons of safety, larger-scale preparations should be carried out in a three-necked flask with thorough mixing (Vibrator).

### $\vartheta$) Tetraphenylgermane [162]:

A mixture of 10 g (47 mmoles) of germanium tetrachloride, 100 ml of toluene, 9 g (39 mg-atom) of sodium and 30 g (190 mmoles) of bromobenzene is carefully heated. As soon as the reaction has begun, cooling must be applied. When the reaction has subdued, the mixture is refluxed for another hour. The hot solution is hydrolysed with hydrochloric acid. Additional 100 ml of warm toluene are added, and the toluene layer is separated off, filtered, and concentrated to a small volume. The dark colored solution yields a precipitate of 9.6 g of purely white crystals (53 % yield).

## The o-Nitrophenylsulfenylimine Radical [1]

By Doz. Dr. Ulrich Schmidt, Dipl.-Chem. K. H. Kabitzke, and Dipl.-Chem. K. Markau

Chemisches Laboratorium der Universität and
Institut für Elektrowerkstoffe der Fraunhofer-Gesellschaft
Freiburg/Brsg. (Germany)

Di-(*o*-nitrophenylsulfenyl)hydrazine *(1)* dissociates in toluene at about 50 °C into *o*-nitrophenylsulfenylimine radicals *(2)*. The ESR spectrum shows three lines of equal intensity which indicates a spin density at the nitrogen. As the equidistant line-spacing is only about half as great (11 Gauss) as in the spectrum of diphenylpicrylhydrazyl (DPPH), one must assume a high spin density at an atom without nuclear spin, in this case at the sulfur [formula *(2a)*]. Also, the high g-factor (2.0076) which lies in the region of the values found for sulfur radical ions ($CH_3OC_6H_4-\overset{\oplus}{S}-C_6H_4OCH_3$: g = 2.0079 [2]) and away from the g-values of *N*-radicals (DPPH: g = 2.0036) indicates an important participation of resonance structures with radical sulfur.

On cooling, the signal dies away and appears on reheating, indicating a reversible dissociation. Above 80 °C in toluene, nitrogen is evolved from *(1)*. The sulfenylimine radical *(2)* probably decomposes into a sulfur radical, which recombines to give the disulfide *(3)*, and into imene which reduces the sulfenylimine radical *(2)* to sulfenylamine *(4)*. Compounds *(3)* and *(4)* were identified. Dry decomposition of *(1)* gave rise to *(3)*, $N_2$, and $NH_3$. Decomposition of *(1)* in acrylonitrile resulted in polymerisation.

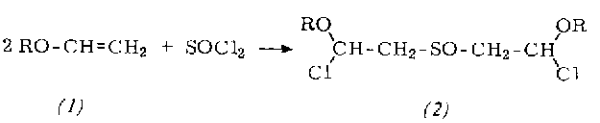
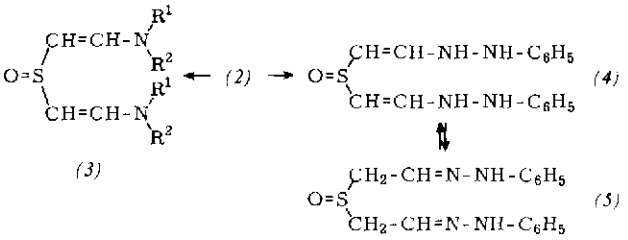
## Formation of Bis-(β-chloro-β-alkoxyethyl) Sulfoxides by Addition of Thionyl Chloride onto Alkyl Vinyl Ethers



By Dr. F. Effenberger and cand. chem. J. Daub

Institut für Organische Chemie und Organisch-Chemische Technologie der Technischen Hochschule Stuttgart (Germany)

*Dedicated to Professor H. Bredereck on the occasion of his 60th birthday*



2-Chloro-2-ethoxyethanesulfinyl chloride has been described [1] as the unstable product of the addition of thionyl chloride onto ethyl vinyl ether.

The reaction of thionyl chloride and alkyl vinyl ethers *(1)* in a molar ratio of 1:3 has now yielded bis-(β-chloro-β-alkoxyethyl) sulfoxides *(2)*.

When absolute ether was used as solvent, the sulfoxides *(2)* crystallized directly as colorless compounds that are readily

recrystallizable from $CCl_4$ [R = $C_2H_5$, 97 % yield, m.p. 20 °C (decomp.); R = s-$C_4H_9$, 80 % yield, m.p. 30–32 °C (decomp.); R = n-$C_4H_9$, 90 % yield, m.p. 41–43 °C (decomp.)]. The action of secondary amines on *(2)* yields compounds of type *(3)* [$R^1$ $R^2$ = $(CH_2)_5$, m.p. 78–80 °C, $R^1$ $R^2$ = $(CH_2)_2$–O–$(CH_2)_2$, m.p. 79–81 °C], while phenylhydrazine produces *(4)*, m.p. 118–120 °C, which could also be formulated as *(5)*.

*(3)*

Tertiary amines eliminate hydrogen chloride from *(2)*, R = $C_2H_5$, yielding a product of formula $C_8H_{14}O_3S$, the structure of which has not yet been established.

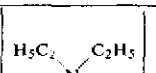
## Dependence of the Electron Excitation of Open-Chain Cyanine Dyes on the Valence Angle of Their Nitrogen Atoms

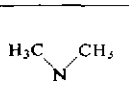
By Prof. Dr. G. Scheibe, Dipl.-Chem. D. Grosse, and Dipl.-Ing. J. Heiss

Institut für physikalische Chemie
der Technischen Hochschule München (Germany)

In contrast to the statements of the simple theories on the light absorption in cyanine dyes, the electron-excitation energy depends not only upon the chain length but also on the angle imposed on the residual valences of nitrogen by its incorporation into rings of varying size. The energy differences amount to about 1 kcal/mole and decrease with increasing

$$[R=\overset{\oplus}{N}=(CH-CH)_n=CH-N=R]\ ClO_4^{\ominus} \qquad (1)$$





$$[R-N-CH=CH-C(CH_3)=CH-CH=\overset{\oplus}{N}=R]\ ClO_4^{\ominus} \qquad (2)$$

chain length. The cause is probably hybridization of the nitrogen atom, depending on the angle involved; this alters the s-portion of the N–C bond and, therefore, the coupling capacity of the nitrogen. The light absorption of the cyanine dyes therefore yields the series 4-<5-<6-ring for the coupling capacity of the nitrogen as a function of the ring size; this corresponds to the order observed by *Lippert* and *Prigge* [4] for the electron-donor capacity of the nitrogen atom in free cyclic imines.

Further work is in progress, also on cyanine dyes with longer chains.

## Synthesis of Ribodinucleotides with Terminal 3′-Phosphate Groups

By Dr. D. Söll [*] and Prof. Dr. H. G. Khorana

Institute for Enzyme Research, University of Wisconsin, Madison, Wis. (U.S.A.)

*Dedicated to Professor H. Bredereck on the occasion of his 60th birthday*

Ribodinucleotides with 3′-phosphate end groups can be polymerized chemically to give ribopolynucleotides, which are of importance for the experimental analysis of the amino acid code.

Using CpUp *(1)* as an example, we wish to describe in the following the simplest and most satisfactory approach yet discovered to dinucleotides with 3′-phosphate end groups. *N*-Acetyl-2,5-di-*O*-acetylcytidine 3′-phosphate *(2)* (0.1 mmole) [1] was treated with 0.1 mmole of uridine 2′(3′)-phosphate *(3)* in pyridine in the presence of 1.5 mmoles of dicyclohexylcarbodiimide. Subsequent treatment with Dowex-50 ($H^{\oplus}$-form) was used to decompose the *N*-phosphorylureas formed [2]. The resultant *N*,2′,5′-triacetylcytidyl-3′→5′-uridine 3′(2′)-phosphate was treated with dicyclohexylcarbodiimide in the presence of triethylamine to form the dinucleotide with the terminal 2′,3′-cyclophosphate *(4)*. Treatment of *(4)* with pancreatic ribonuclease at pH 7.0 leads to *N*,2′,5′-triacetylcytidyl-3′→5′-uridine 3′-phosphate. Subsequent removal of the ribonuclease on a column of Dowex-50X2 (pyridinium form) and final deacetylation with 7 N ammonia leads to CpUp *(1)*, which was isolated pure in 53 % yield by chromatography on DEAE-cellulose. Using the same method, ApUp and IpUp were prepared in 47 % and 44 % yields, respectively. Enzymatic degradation showed that the synthetic dinucleotides contained exclusively the C(3′)-C(5′) internucleotidic linkage.

Other workers have recently described [3] syntheses of ribodinucleotides using the tetrahydropyranyl group [4] to protect the 2′-hydroxyl group. However, removal of this acid-labile protecting group frequently leads to simultaneous isomerization of the internucleotidic linkage [3, 5].

## Enolization of γ-Lactones

By Prof. Dr. W. Theilacker, Dr. K.-H. Bremer, and Dr. L. Seidl

Institut für organische Chemie
der Technischen Hochschule Hannover (Germany)

The reaction of 2,6-dimethylphenolate with chloramine gives a doubly unsaturated ε-caprolactam which is converted with mineral acid to α-methyl-γ-acetonyl-γ-butyrolactone *(1a)* [1]. An incorrect structure was initially assigned to this compound as it was shown by the Zerewitinoff technique to contain about one active hydrogen atom. After the structure *(1a)* was confirmed, we investigated the behavior towards Zerewitinoff reagent ($CH_3MgI$) of *(1a)*, α-methyl-γ-n-propyl-γ-butyrolactone *(1b)* [derived from *(1a)* by Clemmensen reduction], and γ-butyrolactone *(1c)*. Compounds *(1a)*, *(1b)*, and *(1c)* proved to contain, respectively, 0.5, 0.4 and 0.4–0.5 active hydrogen atoms. The infrared and NMR spectra do not show OH groups, and when *(1c)* is warmed with tritiated water, its hydrogen atoms do not exchange. It is probable that $CH_3MgI$ induces the enolization *(1)* → *(2)*; this enolization and the reaction of the Grignard reagent with the C=O group probably proceed at comparable rates, thus enabling methane to be produced by reaction of the Zerewitinoff reagent with *(2)*.

*(a)*: R = $CH_3$, R' = $CH_2COCH_3$
*(b)*: R = $CH_3$, R' = $CH_2CH_2CH_3$
*(c)*: R = R' = H

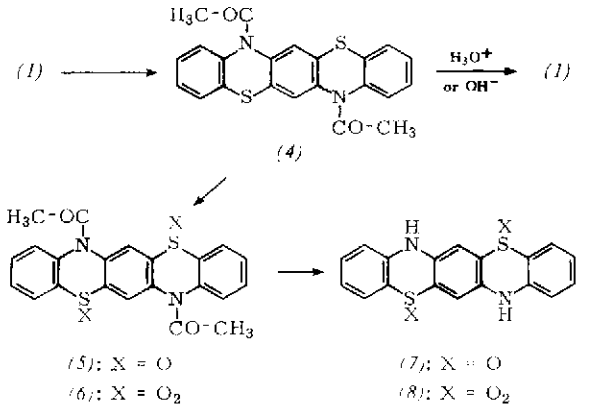
## 7,14-Dihydrotriphendithiazine Bis-S-oxides

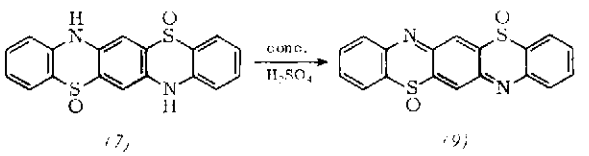
By Dr. O. Christmann

Farbenforschungslaboratorium der Badischen
Anilin- & Soda-Fabrik AG., Ludwigshafen am Rhein
(Germany)



*Dedicated to Professor H. Bredereck on the occasion of his 60th birthday*

Triphendithiazine *(1)* [1], 7,14-dihydro-6,13-dioxotriphendithiazine *(2)* [2, 3], and derivatives of these two parent compounds are known [1, 2], but compounds derived from 7,14-dihydrotriphendithiazine *(3)* have not yet been described. Attempts to prepare such derivatives remained without success [4].



Compounds of type *(3)* are distinguished from the deeply colored quinonoid systems *(1)* and *(2)* principally by their central benzenoid ring. Although *(2)* and its derivatives can be reduced to hydroquinones, the latter are immediately reoxidized by atmospheric oxygen to the quinones [3].

By reductive acetylation of triphendithiazine *(1)* with zinc in glacial acetic acid/acetic anhydride, we succeeded in preparing 7,14-diacetyltriphendithiazine *(4)*. Deacetylation in acidic or basic media immediately reconverts *(4)* into the starting material *(1)*. Stable representatives of the benzenoid type *(3)* are accessible when *(4)* is oxidized by 30% $H_2O_2$ in glacial acetic acid to 7,14-diacetyltriphendithiazine bis-*S*-oxide *(5)* or *S*-dioxide *(6)*. Deacylation of the *S*-oxides *(5)* or *(6)* with NaOH/*N*-methylpyrrolidone affords orange alkali salts and hence, lemon-yellow 7,14-dihydrotriphendithiazine bis-*S*-oxide *(7)* or *S*-dioxide *(8)*, respectively. Compounds *(7)* and *(8)* are highly stable and extremely insoluble in organic solvents, and have properties reminescent of quinacridone.

(5): X = O
(6): X = O$_2$
(7): X = O
(8): X = O$_2$

Compounds (7) and (8) are distinguishable by their behavior in sulfuric acid: whereas (8) may be reprecipitated unchanged from concentrated sulfuric acid, (7) is successively changed into a dark-blue sulfate and a violet compound. All

(7) (9)

the observations made so far suggest that the benzenoid system (7) is converted into the energetically more favorable quinonoid form (9).

## Hydrogen Fluoride Glasses

By Dr. J. Schröder

Philips Zentrallaboratorium GmbH,
Laboratorium Aachen (Germany)

Stable glass phases have been found in many systems of metal fluorides and hydrogen fluoride within extensive ranges of concentration. We have succeeded in preparing transparent stable glasses from hydrogen fluoride and the following metal fluorides, which may be added alone or in admixture in any desired proportions (cf. Table 1): Fluorides of the metals of the second and third main and auxiliary groups of the periodic table, of the lanthanides and some actinides, as well as $ZrF_4$, $HfF_4$, $PbF_2$, and $BiF_3$. All other solid metal fluorides can be added to these glasses in limited amounts. Large proportions of phosphates can also be incorporated into the glasses. Pyroceramic materials may be obtained by addition of certain transition metal fluorides or by heat treatment.

Compared with other compounds containing HF, the binding forces of the HF in the glasses are remarkably strong, probably owing to the formation of very strong hydrogen bonds. The glass phases are stable over large ranges of composition; mixtures of only one metal fluoride and less than 20 mole-% HF give stable glasses with scarcely any tendency towards devitrification or cristallization.

Table 1. Composition of various hydrogen fluoride glasses

| Glass No. | Metal fluoride | [mole-%] | HF [mole-%] | Glass No. | Metal fluoride | [mole-%] | HF [mole-%] |
|---|---|---|---|---|---|---|---|
| 1 | $MgF_2$ | 76 | 24 | 15 | $MgF_2$ | 11 | 44 |
| 2 | $CaF_2$ | 81 | 19 | | $BaF_2$ | 6 | |
| 3 | $SrF_2$ | 74 | 26 | | $LaF_3$ | 11 | |
| 4 | $BaF_2$ | 67 | 33 | | $GaF_3$ | 22 | |
| 5 | $PbF_2$ | 42 | 58 | | $ThF_4$ | 6 | |
| 6 | $YF_3$ | 64 | 36 | 16 | $LaF_3$ | 31 | 38 |
| 7 | $LaF_3$ | 84 | 16 | | $GaF_3$ | 31 | |
| 8 | $LaF_3$ | 67 | 33 | 17 | $GaF_3$ | 20 | 60 |
| 9 | $AlF_3$ | 63 | 37 | | $ThF_4$ | 20 | |
| 10 | $GaF_3$ | 57 | 43 | 18 | $MgF_2$ | 35 | 30 |
| 11 | $BiF_3$ | 70 | 30 | | $PbF_2$ | 35 | |
| 12 | $ZrF_4$ | 53 | 47 | 19 | $MgF_2$ | 18 | 28 |
| 13 | $ThF_4$ | 45 | 55 | | $SrF_2$ | 4 | |
| 14 | $ThF_4$ | 12 | 88 | | $BaF_2$ | 28 | |
| | | | | | $PbF_2$ | 4 | |
| | | | | | $LaF_3$ | 4 | |
| | | | | | $BiF_3$ | 14 | |

Most of the hydrogen fluoride glasses are non-toxic. Nearly all are moisture-resistant under normal conditions, and many have been exposed to boiling water for some hours without showing the slightest chemical attack or loss in weight.

The refractive index of some hydrogen fluoride glasses and the relative dispersion are extremely low, *e.g.* $n_d < 1.27$. The glasses are transparent from 2000 Å to 5 $\mu$ except for a small absorption band at 2.8 $\mu$. Their thermal expansion coefficients are rather high and can be controlled by changing the composition. We have succeeded in preparing strong leak-proof seals between hydrogen fluoride glasses and magnesium, aluminum, and several alloys of these metals.

## Reactions of Halides of Group IV Elements with Trifluoroacetic Acid [1]

By Dr. P. Sartori and Dipl.-Chem. M. Weidenbruch

Institut für Anorganische Chemie und Elektrochemie
der Technischen Hochschule Aachen (Germany)

Some trifluoroacetates, mainly of metals which form basic oxides, have been prepared by *F. Swarts* [2] and later by *G. H. Cady* [3]. We obtained some new compounds by the reaction of the tetrachlorides of Group IV elements with anhydrous trifluoroacetic acid (Table 1).

Table 1. Preparation of trifluoroacetates.

| Metal chloride | Conditions | Product | Yield [%] |
|---|---|---|---|
| $SiCl_4$ | 70 °C, 250 h benzene | $Si(OCOCF_3)_4$ water-clear liquid, b.p. 25 °C/$10^{-3}$ mm | 25 |
| $TiCl_4$ | 70 °C, 250 h homogeneous phase | $3\,TiO(OCOCF_3)_2 \cdot 2\,CF_3COOH$ white crystals | 100 |
| $ZrCl_4$ | 40 °C, 4 h heterogeneous phase | $Zr(OCOCF_3)_4$ white crystals | 100 |
| $ThCl_4$ | 70 °C, 24 h heterogeneous phase | $Th(OCOCF_3)_4$ white crystals | 100 |

Germanium and tin tetrachloride do not react with trifluoroacetic acid, probably because of insufficient polarization of the metal-chlorine bond.

$SiCl_4$ does not react quantitatively. It gives partially acylated by-products which could not be separated by distillation. $Ti(OCOCF_3)_4$ could not be obtained. Obviously the formation of $TiO(OCOCF_3)_2$ is preferred which crystallizes from the solution as $3TiO(OCOCF_3)_2 \cdot 2CF_3COOH$ *(1)*. In addition, $(CF_3CO)_2O$ is formed, which reacts further with the hydrochloric acid formed simultaneously to give trifluoroacetyl chloride:

$$TiCl_4 + 4\,CF_3COOH \rightarrow TiO(OCOCF_3)_2 + (CF_3CO)_2O + 4\,HCl$$
$$(CF_3CO)_2O + HCl \rightarrow CF_3COCl + CF_3COOH$$

On heating in high vacuum at 60 °C, *(1)* looses trifluoroacetic acid and yields $TiO(OCOCF_3)_2$ *(2)*, which sublimes at 180 °C in high vacuum. It follows from the infrared spectrum that the compound has a markedly salt-like character, as have $Zr(OCOCF_3)_4$ and $Th(OCOCF_3)_4$. In $Si(OCOCF_3)_4$ on the other hand, the bonds are mainly covalent.

The reaction of $TiOCl_2$ with trifluoroacetic acid, also yields *(1)* and from it *(2)*. The latter forms an etherate $TiO(OCOCF_3)_2 \cdot C_2H_5OC_2H_5$ *(3)*. When *(1)* is reacted with ether, trifluoroacetic acid is replaced with the formation of *(3)* and the ether adduct of trifluoroacetic acid $3\,CF_3COOH \cdot 2\,C_2H_5OC_2H_5$, which can also be obtained directly from trifluoroacetic acid and ether [4].

The products of the exothermic thermal decomposition in high vacuum are shown in Table 2.

Table 2. Thermal decomposition of trifluoroacetates.

| Compound | Decomposition temperature [°C] | Decomposition products |
|---|---|---|
| $TiO(OCOCF_3)_2$ | 240 | $(CF_3CO)_2O$ |
| $TiO(OCOCF_3)_2$ | 272 | $CO_2$, $COF_2$, $(CF_3CO)_2O$, $CF_3COF$, CO |
| $Zr(OCOCF_3)_4$ | 280 | $CO_2$, $COF_2$, $(CF_3CO)_2O$, $CF_3COF$, CO |
| $Th(OCOCF_3)_4$ | 272 | $CO_2$, $COF_2$, $(CF_3CO)_2O$, $CF_3COF$, CO |

## Triethylstannylboranes

By Priv.-Doz. Dr. H. Nöth and
cand.-chem. K.-H. Hermannsdörfer

Institut für Anorganische Chemie
der Universität München (Germany)

Dimethylamino groups on the boron atom stabilize the B–Si bond in silylboranes [1]; analogous stabilization occurs in organostannylboranes [2], described here for the first time. When triethylstannyl-lithium is reacted with equivalent amounts of dimethylaminochloroboranes in ether, LiCl is eliminated and yellow to brown liquids are formed from which colorless stannylboranes can be isolated by high-vaccum distillation. The following are examples of compounds so prepared:

$[(CH_3)_2N]_2B{-}Sn(C_2H_5)_3$, *(1)*, b.p. 32–35 °C/*ca.* $10^{-3}$ mm;
$[(CH_3)_2N]ClB{-}Sn(C_2H_5)_3$, *(2)*, b.p. 26–28 °C/*ca.* $10^{-3}$ mm;
$(CH_3)_2NB[Sn(C_2H_5)_3]_2$, *(3)*, b.p. 91–93 °C/*ca.* $10^{-3}$ mm.

The rapid hydrolysis according to

$$(1) + 3\,H_2O \rightarrow 2\,(CH_3)_2NH + B(OH)_3 + HSn(C_2H_5)_3$$

and the reaction with halogens (X = Br, I)

$$(1) + X_2 \rightarrow [(CH_3)_2N]_2BX + XSn(C_2H_5)_3$$

as well as other data (molecular weight, elemental analysis, infrared spectrum, dipole moment) prove the presence of covalent B–Sn bonds. HCl attacks the B–N bond before the B–Sn bond.

The stannylboranes are less stable than the analogous silylboranes. Compound *(1)* decomposes at about 100 °C into $B_2[N(CH_3)_2]_4$ and $Sn_2(C_2H_5)_6$; from *(3)* one obtains $B_4[N(CH_3)_2]_6$, $Sn_2(C_2H_5)_6$ and further products. Compound *(2)* decomposes slowly even at room temperature.

So far, no definite B–Sn compound has been obtained from the reaction between $(C_2H_5)_3SnLi$ and $(C_6H_5)_2BCl$ or $(C_4H_9)_2BCl$. The prediction that organogermanyl- and organoplumbyl-dimethylaminoboranes would be stable appears to be correct; their synthesis is under investigation.

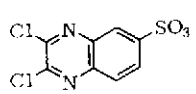
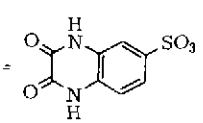
## Dimethylformamide-onium Salts

By Dr. H. Machatzke and Dr. E. Siegel

Wissenschaftliches Hauptlaboratorium
der Farbenfabriken Bayer AG., Leverkusen (Germany)



*Dedicated to Professor H. Bredereck on the occasion of his 60th birthday*



In concentrated sulfuric acid, dimethylformamide is protonated at the oxygen atom *(1a)* [1].

*(1a)*, X = $HSO_4$

Salts of dimethylformamide were previously unknown as isolable chemical entities. We found that 2,3-dichloroquinoxaline-6-sulfonic acid and 2,3-dihydroxyquinoxaline-6-sulfonic acid both form stable, readily crystallizable onium salts [*(1b)* and *(1c)*, respectively] with dimethylformamide.

*(1b)*, X = 

*(1c)*, X = 

To prepare these compounds, 2,3-dichloroquinoxaline-6-sulfonyl chloride [2] or 2,3-dihydroxyquinoxaline-6-sulfonyl chloride [3] is dissolved in absolute dimethylformamide; on addition of one mole of water, a considerable amount of heat is evolved and colorless crystals of *(1b)*, m.p. 130–131 °C, 85 % yield, or *(1c)*, m.p. 232–234 °C (decomp.), 95 % yield, rapidly separate. Compound *(1c)* crystallizes with one molecule of water of crystallization, *(1b)* is free from chloride ions. The formation, properties and reactions of these compounds indicate that they are salt-like, and exclude isomeric *O*-acyl derivatives of dimethylformamide such as Vilsmeyer adducts [4]. The compounds *(1b)* and *(1c)* dissolve very readily in water with liberation of one mole of acid; they are insoluble in ether. Compound *(1b)* can be recrys-

tallized from absolute ethanol, chloroform, dimethylformamide and acetone and can be precipitated from solution in thionyl chloride with ether.

Compounds *(1b)* and *(1c)* react instantaneously with NaI in absolute dimethylformamide to give the sparingly soluble sodium salts of the parent quinoxalinesulfonic acids. On addition of aniline to a solution of *(1b)* in acetone, anilinium 2,3-dichloroquinoxalinesulfonate precipitates immediately. Mercaptobenzthiazole reacts with *(1b)* in acetone to form 2-chloro-3-(2'-mercaptobenzthiazolyl)quinoxalinesulfonic acid.

The infrared spectra of *(1b)* and *(1c)* show a strong absorption at 1680 $cm^{-1}$, *i.e.* in the region of the C=N vibration [5].

## Synthesis of Halogenoalkyldichloro-s-triazines and Bis(halogenoalkyl)chloro-s-triazines

By Dr. H. Herlinger

Wissenschaftliches Hauptlaboratorium
der Farbenfabriken Bayer AG., Leverkusen (Germany)

*Dedicated to Professor H. Bredereck on the occasion of his 60th birthday*

Mixed trimerization of trichloroacetonitrile with aliphatic or aromatic nitriles (molar ratio 2:1) affords triazine derivatives in high yields [1]; however it was not hitherto possible to convert trichloroacetonitrile with cyanogen chloride in molar ratios of 1:2 or 2:1 into the triazines *(2)* and *(3)* in good yields [2]. Since the trimerization of cyanogen chloride and of trichloroacetonitrile alone yields cyanuryl chloride *(1)* and tris(trichloromethyl)-*s*-triazine *(4)*, respectively, it was to be expected that their mixed trimerization would yield a mixture of the triazines *(1)–(4)*.

*(1)*: $R^1 = R^2 = R^3 = Cl$
*(2)*: $R^1 = R^2 = Cl$; $R^3 = CCl_3$
*(3)*: $R^1 = Cl$; $R^2 = R^3 = CCl_3$
*(4)*: $R^1 = R^2 = R^3 = CCl_3$

When, however, hydrogen chloride is passed into a mixture of trichloroacetonitrile and cyanogen chloride in a molar ratio of 2:1 at −25 °C, 2,4-bis(trichloromethyl)-6-chloro-*s*-triazine *(3)* is formed in 90 % yield, together with small amounts of *(4)*; the mixture can be separated by distillation [*(3)* b.p. 164–168 °C/12 mm, m.p. 55–56 °C, *(4)* b.p. 176–178 °C/12 mm, m.p. 96 °C]. At a molar ratio of 1:2, large amounts of *(1)* are formed, together with 2-trichloromethyl-4,6-dichloro-*s*-triazine *(2)*. The reaction products can be separated by distillation or by crystallization from petroleum ether [*(1)* b.p. 198 °C, m.p. 146 °C, *(2)* b.p. 142–146 °C/12 mm, m.p. 115–116 °C]. At a molar ratio of 1:1.6, *(2)* and *(3)* are formed in 51 and 33 % yield respectively. The infrared spectra lend themselves to quantitative determination of the triazines *(1)–(4)* in the reaction mixture. The solubility in petroleum ether increases from *(1)* to *(4)*. As in the case of cyanuryl chloride *(1)*, the chlorine atoms of *(2)* and *(3)* can be replaced selectively by nucleophilic agents, *e.g.* aliphatic and aromatic amines, alcohols, phenols, and thiols. Other α,α-dihalogeno nitriles, such as α,α,β-trichloropropionitrile [3] also undergo mixed trimerization with cyanogen chloride.

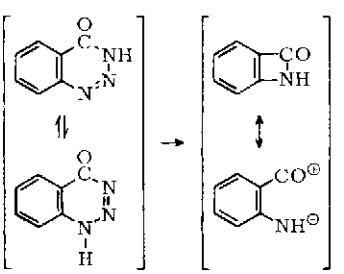
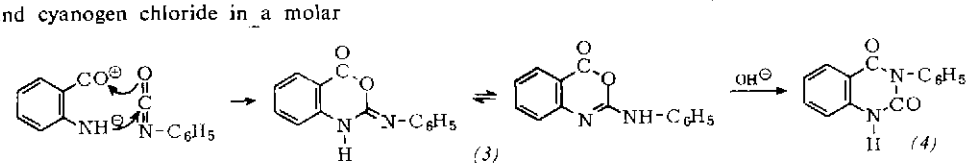
## The Reaction of Benzotriazinones with Isocyanates



By Dr. H. Herlinger

Wissenschaftliches Hauptlaboratorium
der Farbenfabriken Bayer AG., Leverkusen (Germany)



*Dedicated to Professor H. Bredereck on the occasion of his 60th birthday*

Thermal decomposition of benzotriazinone *(1)* yields first the unstable lactam of anthranilic acid *(2)*; this compound is a strong acylating agent. When benzotriazinone and phenylisocyanate are heated together, they react immediately at 140–160 °C, undergoing cycloaddition to form the tautomeric heterocycle 2-phenyliminobenzo-3,1-oxyzine-4-one *(3)*, m.p. 191 °C, in 80 % yield.

The structure of the tautomers was proved by their rearrangement in aqueous-alcoholic NaOH to 3-phenylquinazoline-2,4-dione *(4)*. The melting point and infrared spectrum of *(3)* agreed with the figures shown by a product prepared from *N*-phenyl-*N'*-(2-carboxyphenyl)thiourea with mercuric oxide [1]. When benzotriazinone was treated with *m*-chlorophenyl isocyanate under the same conditions as with phenyl isocyanate, it gave 2-(*m*-chlorophenylimino)-benzo-3,1-oxazine-4-one, m.p. 214 °C, in 80 % yield. In the reaction with methyl isocyanate, the primary product rearranged immediately to 3-methylquinazoline-2,4-dione.

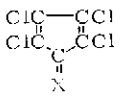
## Tetrachlorodiazocyclopentadiene from Hexachlorocyclopentadiene



By Dr. H. Disselnkötter

Wissenschaftliches Hauptlaboratorium der Farbenfabriken Bayer AG., Leverkusen (Germany)

*Dedicated to Professor H. Meerwein on the occasion of his 85th birthday*

Hexachlorocyclopentadiene reacts with hydrazine hydrate or with substituted hydrazines in lower alcohols to form the intensely red hydrazones *(1a)–(1c)* of tetrachlorocyclopentadienone [1]. To prepare *(1a)*, 300 g (6 moles) of hydrazine hydrate were added dropwise to a boiling solution of 545 g (2 moles) of hexachlorocyclopentadiene in 1500 ml of methanol within 30 minutes. After boiling for further 30 min the mixture was cooled to 40 °C and poured into 15 l of water. The crystals formed were filtered off with suction, pressed and washed with petroleum ether. On drying *in vacuo*, 340 g of crude product were obtained. Recrystallization from benzene gave 210 g of *(1a)* (yield 45 %). Compounds *(1b)* and *(1c)* were obtained by dropwise addition of a three-fold molar excess of the appropriate hydrazine to a cold solution of hexachlorocyclopentadiene in ethanol, stirring for a few hours and processing as described for *(1a)*.

Previously, only aryl-substituted hydrazones such as *(1c)* had been prepared (by coupling of diazonium salts with tetrachlorocyclopentadiene) [2].

*(1)*

| | X | M.p. [°C] | Yield [%] |
|---|---|---|---|
| *(a)* | $N-NH_2$ | 176 (from benzene) | 45 |
| *(b)* | $N-N(CH_3)_2$ | 89 (from petroleum ether) | 70 |
| *(c)* | $N-NHC_6H_5$ | 136 (from cyclohexane) | 69 |

Compound *(1a)* is insoluble in hydrochloric acid and does not form azines either with an excess of hexachlorocyclopentadiene or with carbonyl compounds. An aqueous hypochlorite solution oxidizes *(1a)* in ethyl acetate/methanol (2:1 by vol.) smoothly to tetrachlorodiazocyclopentadiene *(1d)*, X = $N_2$, m.p. 103 °C (decomp.), bright yellow needles. The yield after crystallization from methanol is 60 %. Compound *(1d)* is thus more readily obtained than tetrabromodiazocyclopentadiene [3]. Like diazocyclopentadiene, *(1d)* reacts with compounds of trivalent phosphorus [4]. In cyclohexane at 20 °C, it forms the addition compounds *(1e)*, X = $N-N=P(C_6H_5)_3$, m.p. 132 °C (decomp.), and *(1f)*, X = $N-N=P[N(CH_3)_2]_3$, m.p. 113 °C, in yields of 76 and 98 %, respectively.

A solution of *(1d)* in acetic acid is fairly stable up to about 80 °C; above 100 °C, nitrogen is split off rapidly. With chloral at 100–120 °C a crystalline product (b.p. 80–85 °C/0.1 mm, m.p. 62 °C, yield after distillation and crystallization from methanol: 48 %) is formed with additional liberation of carbon monoxide. According to its NMR spectrum it appears to be 5-trichloromethyl-1,2,3,5-tetrachlorocyclopenta-1,3-diene or the 1,2,4,5-tetrachloro compound.

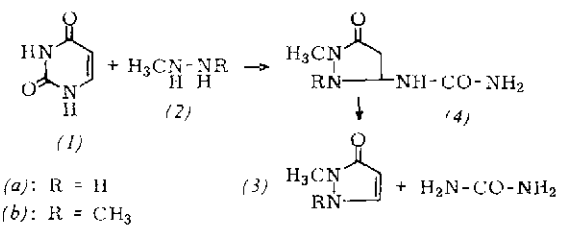
## The Reactions of Hydrazine and Alkyl-Substituted Hydrazines with Pyrimidines



By Doz. Dr. F. Lingens and Dipl.-Chem. Helga Schneider-Bernlöhr

Biochemische Abteilung im Chemischen Institut der Universität Tübingen (Germany)

The reaction of a pyrimidine with hydrazine yields a pyrazolone and urea [1]. In an analogous manner, uracil *(1)* and a 5- to 8-fold excess of monomethylhydrazine *(2a)* react (80 °C, 15 h) to form 1-methylpyrazol-5-one *(3a)*, m.p. 104–108 °C, 30 % yield, and urea. Under the same conditions *(1)* and 1,2-dimethylhydrazine *(2b)* are converted in 30 % yield into 1,2-dimethylpyrazol-5-one *(3b)*, m.p. of picrate 162 °C, and urea. Compounds *(3a)* and *(3b)* were isolated by distillation in a high vacuum.

Compounds *(3a)* and *(3b)* can also be prepared by dropwise addition of ethyl propiolate to a stirred and cooled solution of *(2a)* or *(2b)*. After stirring at 20 °C for 6 hours, the mixture is neutralized and extracted with ethyl acetate. The yields of *(3a)* or *(3b)* are 65 %.

When uracil *(1)* is reacted under mild conditions (6 h, 80 °C) with 10 % solutions of *(2a)* or *(2b)*, the following intermediary products, which are stable at pH 7 to 10, can be isolated: 1-methyl-3-ureidopyrazolid-5-one *(4a)*, m.p. 140 °C, 30 % yield, and 1,2-dimethyl-3-ureidopyrazolid-5-one *(4b)*, m.p. 165 °C, 60 % yield. Isomeric open-chain structures, *e.g.* $H_2N\ CO\ NH-CH=CH\ CO\ N(CH_3)-NHR$, could be excluded on the basis of NMR and ultraviolet spectra.

*(1)* + *(2)* → *(4)*

*(a)*: R = H
*(b)*: R = $CH_3$

*(3)* + $H_2N-CO-NH_2$

The pyrazolones *(3a)* and *(3b)* were obtained in 30 % yield from *(4a)* and *(4b)* by decomposing with 2 N HCl, neutralizing, and extracting with ethyl acetate.

Thymine reacted considerably more slowly with the hydrazines; on reaction with *(2a)*, only 1,4-dimethylpyrazol-5-one (m.p. 130–132 °C) and urea were isolated. Cytosine reacted with *(2a)* to give a pyrazolone hydrazone (m.p. of picrate 153 °C). No reaction occurred with *(2b)*. Ribonucleic acid is attacked by *(2b)* preferentially at the uracil residues. Hydrazine and alkyl-substituted hydrazines cause mutations in *Escherichia coli* [2] and *Salmonella typhimurium* [3].

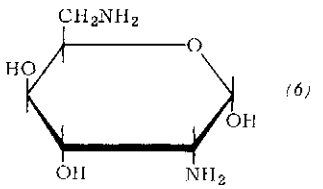
## A New Synthesis of Oxazolidones and the Preparation of 2,6-Diamino-2,6-dideoxy-D-gulose

By Dr. P. H. Gross, Dr. K. Brendel, and Prof. Dr. H. K. Zimmerman

Department of Chemistry, University of the Pacific, Stockton, Cal. (U.S.A.)



When benzyl-*N*-Cbo-3-*O*-acetyl-4,6-di-*O*-mesyl-α-D-glucosamine [1] (m.p. 137 °C; $[\alpha]_D^{20} = +99°$, c = 1 in pyridine) is treated with potassium acetate in acetic acid/acetic anhydride, benzyl-*N*-Cbo-3,6-di-*O*-acetyl-4-*O*-mesyl-α-D-glucosamine

(m.p. 85 °C, $[\alpha]_D^{20} = +102°$; c = 1 in pyridine) is obtained in 84 % yield. On hydrolysis with KOH in water/dioxan, the latter compound affords benzyl-*N*-Cbo-3,4-anhydro-α-D-galactosamine *(1)* (m.p. 158 °C; $[\alpha]_D^{20} = +71°$, c = 1 in pyridine) in 86 % yield. Mesylation of *(1)* yields the 6-mesyl derivative *(2)* (m.p. 124 °C; $[\alpha]_D^{20} = -64°$, c = 1 in pyridine) in 92 % yield. Compound *(2)* is obtained more simply in 98 % yield from benzyl-*N*-Cbo-3-*O*-acetyl-4,6-di-*O*-mesyl-α-D-glucosamine and sodium isopropoxide in dioxan/isopropanol at 0 °C. Its preparation by both these routes excludes the possibility of the formation of 4,6- and 3,6-anhydro sugars.

*(1)*: R = OH
*(2)*: R = $OSO_2CH_3$

*(3)*: R = OH, R' = H
*(4)*: R = $OSO_2CH_3$, R' = $COCH_3$
*(5)*: R = $N_3$, R' = $COCH_3$

*(6)*

The preparation of these new *N*-Cbo-amino-sugar epoxides has revealed stereospecifically interesting routes to the gulosamine series by way of oxazolidones. When heated in 50 % acetic acid, *(1)* yields benzyl-α-D-gulopyranosido-[2,3-*d*]oxazolid-2'-one *(3)* (m.p. 114 °C; $[\alpha]_D^{20} = +65°$, c = 1 in pyridine) in 90 % yield. On successive alkaline hydrolysis, acetylation, and acidic hydrolysis, *(3)* yields D-gulosamine hydrochloride [2]. When boiled with acetic acid and subsequently acetylated, *(2)* is converted quantitatively into benzyl-4-*O*-acetyl-6-*O*-mesyl-α-D-gulopyranosido[2,3-*d*]oxazolid-2'-one *(4)* (m.p. 177 °C; $[\alpha]_D^{20} = +72°$, c = 1 in pyridine). On treatment with sodium azide in dimethylsulfoxide, *(4)* yields the 6-azido compound *(5)*, which can be converted by catalytic hydrogenation and hydrolysis into 2,6-diamino-2,6-dideoxy-D-gulose dihydrochloride *(6)*, which mutarotates: $[\alpha]_D^{20} = +35°$ after 10 min and $-10°$ after 36 h, c = 2.7 in water. The infrared spectrum of *(6)* coincides almost completely with that of gulosamine hydrochloride [2] and contains band displacements only between 730 and 960 $cm^{-1}$, as compared with the corresponding glucose derivative.

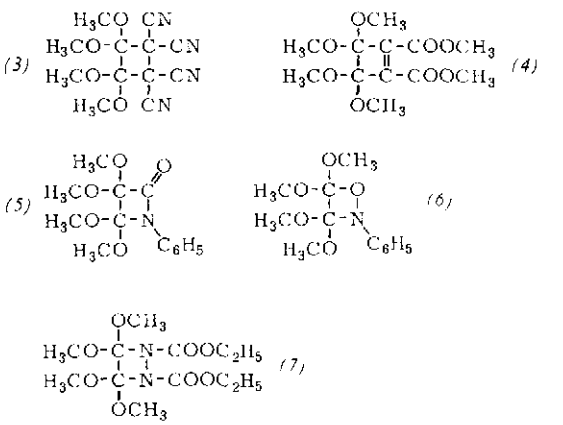
## Carbocyclic and Heterocyclic Four-Membered Rings from Tetramethoxyethylene by Cycloaddition

By Dr. R. W. Hoffmann and cand. chem. H. Häuser

Organisch-Chemisches Institut
der Universität Heidelberg (Germany)

Tetramethoxyethylene *(2)* is readily obtained by subjecting 7,7-dimethoxybicyclo[2,2,1]heptadiene derivatives *(1)* to thermal decomposition [1].



*(1)*

*(2)*

R = $C_6H_5$, Br

Being a double ketene acetal, *(2)* exhibits high reactivity. For example, it adds on ethanol or water spontaneously. It is readily alkylated even with $CCl_4$. Cycloadditions take place at 40–80 °C. Thus, the cyclobutane derivative *(3)*, m.p. 179 °C, is formed from tetracyanoethylene in 63 % yield [2]; with methyl acetylenedicarboxylate one obtains the addition product *(4)*, b.p. 150 °C/0.01 mm, in 97 % yield (characterized as the dicarhoxylic acid, m.p. 134 °C).

*(3)* *(4)*

*(5)* *(6)*

*(7)*

Addition of tetramethoxyethylene *(2)* onto double bonds between elements of the first main group leads smoothly to heterocyclic four-membered rings. Thus, phenyl isocyanate gave *(5)*, b.p. 132 °C/0.01 mm, in 76 % yield; reaction of *(2)* with nitrosobenzene or azodicarboxylic ester resulted in quantitative formation of the addition products *(6)*, m.p. 83 °C, and *(7)*, m.p. 111 °C. Addition onto nascent sulfene was not successful [3].

## Tricyanomethanido Metal Complexes Containing Carbon Monoxide and Nitric Oxide

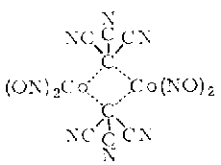
By Priv.-Doz. Dr. W. Beck, Dipl.-Chem. R. E. Nitzschmann, and Dipl.-Chem. G. Neumair

Anorganisch-Chemisches Laboratorium der Technischen Hochschule München (Germany)

Potassium tricyanomethanide, $K[C(CN)_3]$, has become readily accessible by a new method of preparation [1]. Two-fold reaction of pentacarbonylmanganese halides [2], $Mn(CO)_5X$ (X = Cl, Br, I), with potassium or silver cyanomethanide in tetrahydrofuran gave tricyanomethanidopentacarbonylmanganese, $Mn(CO)_5C(CN)_3$, in the form of yellow needles, stable in air for prolonged periods, sparingly soluble in tetrahydrofuran and insoluble in petroleum ether. To prepare this substance, $Mn(CO)_5I$ is shaken in tetrahydrofuran with a slight excess of silver tricyanomethanide for 10 hours at 20 °C under exclusion of light and air.

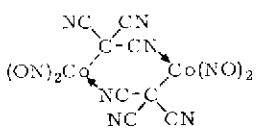
On heating with phosphines or phosphite in tetrahydrofuran, $Mn(CO)_5C(CN)_3$ reacts with substitution of one mole of CO:

$$Mn(CO)_5C(CN)_3 + L \rightarrow Mn(CO)_4LC(CN)_3 + CO \quad (1)$$



$L = P(C_6H_5)_3$, $P(C_6H_{11})_3$, $P(OC_6H_5)_3$

The infrared spectra of the yellow compounds *(1)* show two CO stretching vibrations in the region of 1850–2000 $cm^{-1}$ in addition to the CN absorption at 2200 $cm^{-1}$. The occurrence of only two CO frequencies indicates a *trans*-configuration of the $C(CN)_3$ and phosphine ligands.



Whereas tetracarbonyliron halides do not form tricyanomethanido complexes with potassium or silver tricyanomethanide, $C_5H_5Fe(CO)_2C(CN)_3$ (decomposition point 110 °C) is obtained in the form of light brown crystals when $C_5H_5Fe(CO)_2I$ [3] is reacted with $Ag[C(CN)_3]$ in methanol. Analogous reactions of nitrosylmetal halides, such as $[Co(NO)_2Cl]_2$ [4] and $[Ni(NO)I]_n$ [5], with $K[C(CN)_3]$ in methanol lead to the formation of the tricyanomethanido compounds $[Co(NO)_2C(CN)_3]_n$ and $[Ni(NO)C(CN)_3]_n$.

Light brown, crystalline $[Co(NO)_2C(CN)_3]_n$ reacts with phosphines to give $Co(NO)_2PR_3C(CN)_3$ ($R = C_6H_5$, $C_6H_{11}$); when the blue compound $[Ni(NO)C(CN)_3]_n$ is reacted with phosphines, the compounds $[Ni(NO)PR_3C(CN)_3]_2$ and $Ni(NO)(PR_3)_2C(CN)_3$ can be isolated. These nitrosyltricyanomethanides of cobalt and nickel which contain phosphine have a structure analogous to that of the corresponding nitrosyl halide complexes [6].

In $[Co(NO)_2C(CN)_3]_n$ and $[Ni(NO)PR_3C(CN)_3]_2$ the presence of tricyanomethanide bridges must be assumed by analogy with the nitrosyl halide complexes [6]. For the cobalt complex with n = 2, for instance, the structures *(2)* and *(3)* may be envisaged.

*(2)*

*(3)*

In addition to the intense CN absorption at about 2200 $cm^{-1}$, these compounds exhibit a further CN band which is displaced towards shorter wavelengths by about 50 $cm^{-1}$. This CN absorption indicates the occurrence of $C-C\equiv N$ bridges [structure *(3)*].

## Bis-Dithione Complexes of Transition Metals

By Priv.-Doz. Dr. G. N. Schrauzer, Dr. V. Mayweg, Dipl.-Chem. H. W. Finck, cand.-chem. U. Müller-Westerhoff, and cand.-chem. W. Heinrich

Institut für Anorganische Chemie
der Universität München (Germany)

The reactive α,β-dithiodiketones, which normally do not exist as free monomers, form stable complexes of type *(1)* with transition metals. Bis-dithiobenzilnickel, the first representative of this new class of compounds, is obtained *e.g.* by the reaction of diphenylacetylene with nickel sulfides [1,2] or by the action of $H_2S$/HCl on benzoin in the presence of nickel chloride [3]. Analogous complexes are formed by the reaction of disubstituted alkynes with metal carbonyls in the presence of sulfur. These methods give, however, only low yields and are not sufficiently general. We wish to report the following method: Acyloins are reacted in inert solvents (*e.g.* xylene) by heating with $P_2S_5$ to give phosphorothioic esters of the dithioacyloins. Frequently these react directly with metal salt solutions to yield the complexes *(1)*. In this way we have prepared bis-dithione complexes of V, Cr, Mo, W, Re, Fe, Co, Ni, Ru, Os, Pt (Table 1).

Bis-dithiobenzil complexes of transition metals with an even number of electrons are diamagnetic. The corresponding compounds of vanadium and rhenium are paramagnetic and exhibit E.P.R. signals with fine structure. The dithiobenzil complexes listed in Table 1 are stable to air even at elevated temperatures. On heating they decompose into the metal sulfide, sulfur, 2-phenylthionaphthene and in some cases also into tetraphenylthiophene. Most complexes are resistant to concentrated non-oxidizing acids. They have very similar infrared and ultraviolet spectra and must be planar by analogy with bis-ditbiobenzilnickel. The highest occupied molecular orbital is spread over the whole molecule and the corresponding lowest antibinding molecular orbital lies only 1.7–1.8 eV above it. All complexes thus show an allowed electronic transition in the near infrared ($\lambda_{max}$ = 700–800 mμ, ε *ca.* 20000). On account of the low excitation energy the complexes are readily reduced taking up one or two electrons. The salts of the mono- and dianions were isolated and are dia- or paramagnetic depending on the number of electrons. Attempts to obtain the uncharged manganese compound of dithiobenzil have so far been unsuccessful. The compound is polar and decomposes in acidic media.

*(1)*

Table 1. Complexes of the type *(1)*.

| M | R | R' | M.p. [°C] | Color | |

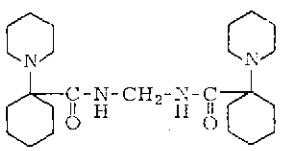
## The Synthesis of 1,1-Diisonitrilomethane

By Doz. Dr. R. Neidlein



Institut für Pharmazeutische Chemie und Lebensmittelchemie der Universität Marburg/Lahn (Germany)

Compounds with more than one isonitrile group at one carbon atom were previously unknown. Bis(formylamino)-methane *(1)* [1] was used as starting material for the preparation of 1,1-diisonitrilomethane *(2)*. When 0.05 mole of *(1)* was treated with 0.1 mole of phosgene at *ca.* −60 °C in the presence of 35 ml of triethylamine, two molecules of water were eliminated [2] to give 1,1-diisonitrilomethane, which was extracted with methylene dichloride. The product is stable for 10–20 min at *ca.* 30 °C in solution; on evaporation of the solvent, it rapidly polymerizes with considerable evolution of heat to give a black mass. If the cold methylene

*(1)* $O{=}C(H)-N(H)-CH_2-N(H)-C(H){=}O \longrightarrow C{\equiv}N-CH_2-N{\equiv}C$ *(2)*

*(3)*

*(4)*

dichloride extract is immediately treated with equimolar amounts of *N*-cyclohexenylpiperidine and hydrazoic acid in benzene [3], the bis-tetrazole derivative *(3)* (m.p. 243–244 °C) is formed and may be isolated by removal of the solvent. A further derivative, *N,N'*-bis-(1-piperidinocyclohexylcarbonyl)methylenediamine *(4)* (m.p. 106–107 °C), was obtained by *Ugi*'s method [3].

## A New Synthesis of Pyrrole-2-carboxylic Acid Derivatives

By Prof. Dr. G. Kresze and Dipl.-Chem. J. Firl

Organisch-chemisches Institut
der Technischen Hochschule München (Germany)

Diene syntheses involving butadienecarboxylic esters *(1)* and nitrosobenzenes in $CH_2Cl_2$ afford 1,2-oxazine derivatives *(2)* as residues after removal of the solvent by vacuum distillation. The reaction of *(1)* with 1-chloro-1-nitrosocyclohexane in ethanol produces the hydrochlorides *(3)* (cf. Table 1). Compounds of types *(2)* and *(3)* which contain an acidic hydrogen on C-6 can be converted by dehydration into the pyrrole-2-carboxylic acid derivatives *(4)* and *(5)*; the dehydration is effected by bases, but most effectively simply by chromatography with an anhydrous non-polar solvent (benzene, carbon tetrachloride) on an approximately tenfold quantity of neutral aluminum oxide (from Messrs. Woelm, activity I).

*(1)* *(2)* *(3)* *(4)* *(5)*

R = $CH_3$

The products are formed directly in high purity. The crude products of the diene syntheses may be employed for the dehydration without further purification. Table 1 gives a list of the pyrrolecarboxylic acid derivatives synthetized so far by this route; the range of application and mechanism of the reaction will be discussed in greater detail elsewhere.

Table 1. Substituents and properties of compounds *(2)*–*(5)*.

| Compound | $R^1$ | $R^2$ | Ar | M.p. [°C] | Yield [%] | Compound | M.p. [°C] | Yield [%] [a] |

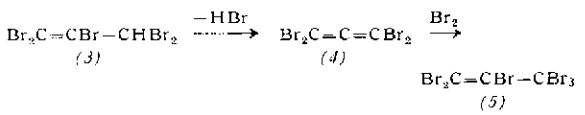
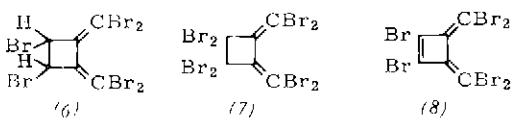
## Tribromoallene and Perbromoallene

By Prof. Dr. A. Roedig, Dipl.-Chem. N. Detzer, and Dr. H. J. Friedrich



Chemisches Institut der Universität Würzburg (Germany)

Tetrabromocyclopent-1-ene-3,4-dione *(1)* is split by liquid $NH_3$ in propane at −75 °C into oxamide and tribromoallene *(2)*, the latter being isolated in 75 % yield after removal of the solvent at −70 °C *in vacuo*.



*(1)* *(2)*

Tribromoallene *(2)* is rapidly brominated in $CCl_4$ at room temperature to give pentabromopropene *(3)*, which can be smoothly dehydrobrominated by the method reported for the dehydrochlorination of 3-*H*-pentachloro-1-propene [1], to give perbromoallene *(4)* (80 % yield). The addition of bromine onto *(4)* gives perbromopropene *(5)*.

The infrared spectra of *(2)* and *(4)* as liquid films, show characteristic allene vibration bands at 5.14 and 5.12 μ, respectively. Perbromoallene *(4)* shows less, and tribromoallene *(2)* very much less tendency to dimerize than does perchloroallene [1]. In $CCl_4$ at 40 °C, the allene vibration band of *(4)* disappears in 45 min while the allene band of *(2)* disappears in 90 hours. The dimer of *(2)*, which is formed in 50 % yield, can also be prepared by treatment of *(1)* with NaOH [2]. Contrary to reports in the literature [3] it is a hexabromo-1,2-dimethylenecyclobutane of structure *(6)* (m.p. 137 °C). The dimerization of *(4)* gives perbromo-1,2-dimethylenecyclobutane *(7)* (m.p. 131 °C) which can be smoothly debrominated with Al turnings in ether to give perbromo-1,2-dimethylenecyclobutene *(8)* (m.p. 165 °C).

The ultraviolet spectra of *(6)*, *(7)*, and *(8)* in n-heptane are very similar to those of the corresponding chloro compounds [1,4]. The structure *(7)* was confirmed by Raman spectroscopy [5].

The structure *(6)* with protons on the ring was deduced from the NMR spectrum, which excludes cyclic and open-chain structures with olefinic protons. The $^1H$ signal of *(6)* at $\tau$ = 5.46 ppm (in $CCl_4$ with tetramethylsilane as standard) corresponds to that of cyclobutyl bromide ($\tau$ = 5.53 ppm) and is significantly different from that of 1,2-dibromoethylene ($\tau$ = 3.00 ppm). The $\tau$-value calculated for the $^1H$ resonance in *(6)* by the method of *Primas*, *Arndt*, and *Ernst* [6], is 5.49 ppm while that calculated for olefinic protons is 2.95 ppm.

## Pentafluoro-orthotelluric Acid, $HOTeF_5$

By Doz. Dr. A. Engelbrecht and F. Sladky

Institut für Anorganische und Analytische Chemie
der Universität Innsbruck (Austria)

On heating $BaTeO_4$ with $HSO_3F$ (molar ratio 1:10) for 3 hours to 160 °C, a mixture of volatile tellurium compounds is obtained instead of the unknown $TeO_2F_2$, the formation of which would be expected by analogy with $SeO_2F_2$ [1]. The main constituent isolated from the crude fraction distilling between 58 and 65 °C was a compound of the composition $HTeOF_5$ (yield 25 %), which turned out to be a fluoro acid of hexavalent tellurium (molecular weight determined from the vapour density at 20 °C: 243.5; calculated: 239.6; m.p. 40 ± 1 °C; b.p. 60 ± 1 °C; density of the liquid at 40 °C: 2.626 g/cm³; vapour pressure at 0 °C: 40.2 mm).

The colorless compound solidifies to a glassy-crystalline mass; above 40 °C it is a mobile, strongly refractive liquid. It does not attack glass, mercury, and polyethylene at room temperature. As cock grease we used "halocarbon oil" [2].

The aqueous solution immediately displays a strong acid reaction. Qualitative measurements of the conductivity of such solutions showed that $HOTeF_5$ rapidly hydrolyses to telluric and hydrofluoric acid. It has not been possible to precipitate a sparingly soluble compound of the anion $OTeF_5^-$ from aqueous solutions.

HCl, HF, or $CO_2$ are liberated, when $HOTeF_5$ is condensed on solid KCl, KF, or $K_2CO_3$. In the reaction with KCl the weight increase corresponded to the formation of $KOTeF_5$ with a yield of about 95 %.

The infrared spectrum of $HOTeF_5$ displays a very sharp OH-band at 3670 $cm^{-1}$.

Formally the compound corresponds to the hydroxofluoro anions of elements of groups 4 and 5 of the periodic system [3]. Since, however, the group number of tellurium is 6, $HOTeF_5$ is not a hydroxofluoro anion but a strong, volatile acid. Its stability is undoubtedly due to the attainment of an octahedral configuration by the hexavalent tellurium, with the 5 fluoride ions and the OH ion as ligands.

## Aliphatic Nitrile Oxides [1]

By Prof. Dr. G. Zinner and H. Günther

Institut für Pharmazie und Lebensmittelchemie
der Universitäten Marburg und Münster (Germany)

By elimination of HCl from hydroxamic chlorides *(1)* in inert solvents at about −15 °C, several aliphatic nitrile oxides *(2)* were prepared and isolated. Their infrared spectra displayed a clearly defined absorption band at 4.40 μ; as is to be expected, they dimerize to furoxans *(3)* at room temperature. They undergo addition reactions, *e.g.* with mercaptans [to give *(4)*], with amines [to *(5)*], and with hydrazines [to *(6)*], as well as cycloadditions, *e.g.* with diphenylketene [to *(7)*] and with butadiene [to *(8)* and *(9)*].

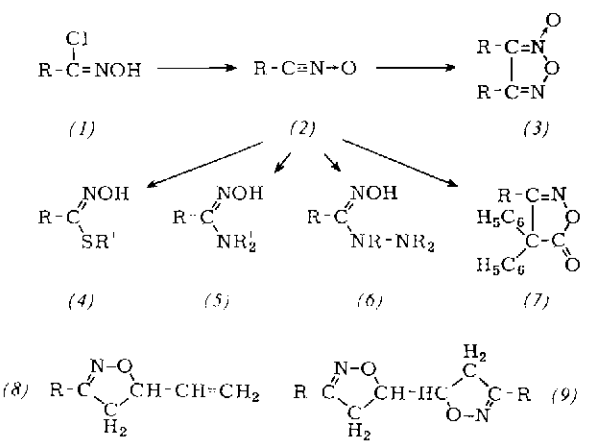

Table 1. Substituents and melting points of compounds *(1)*–*(9)*.

| R | Melting points [°C] | | | | |
|---|---|---|---|---|---|
| | *(1)* | *(2)* | *(3)* | *(4)* | *(5)* |
| $CH_3$ | –3 [2] | –5 | –13 [3] | 55 [a] | 92 [b] |
| $(CH_3)_3C$ | 33 | 18 | 67 | 74 [c] | 139 [b] |
| $(C_2H_5)_2CH$ | 17 | –33 | –2 | 77 [c] | 57 [b] |

| R | *(6)* | *(7)* | *(8)* | *(9)* |
|---|---|---|---|---|
| $CH_3$ | 64 | | | |
| $(CH_3)_3C$ | | 138 | –3 | 177 |

[a] R' = n-$C_4H_9$; [b] $R_2 = (CH_2)_5$; [c] R = $C_6H_5$–$CH_2$.

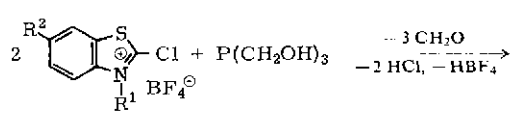
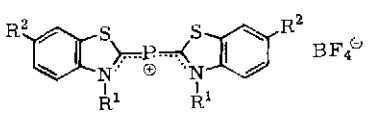
## Phosphacyanines, a New Class of Compounds Containing Trivalent Phosphorus



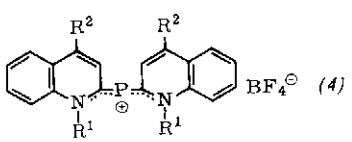
By Prof. Dr. K. Dimroth and Dr. P. Hoffmann

Chemisches Institut
der Universität Marburg/Lahn (Germany)



*Dedicated to Professor H. Meerwein on the occasion of his 85th birthday*

A solution 0.02 mole of *N*-ethyl-2-chlorobenzothiazolium fluoroborate *(1)*, $R^1 = C_2H_5$, $R^2 = H$, and 0.01 mole of tris-(hydroxymethyl)phosphine *(2)* in 10 ml of *N,N*-dimethylformamide (DMF) was treated at 0 °C under nitrogen with 0.03 mole of diisopropylethylamine dissolved in 10 ml of DMF and yielded orange-red crystals of *(3b)*, with elimination of formaldehyde.



We obtained analogous compounds from variously substituted 2-chlorobenzothiazolium salts and 2-chloroquinolinium salts; it appears therefore that phosphacyanines *(3)*

*(1)* *(2)*

*(3)*

*(4)*

or *(4)* (*i.e.* analogues of the azacyanines) have been formed (yields: 40–50 %). Some of their properties are listed in Table 1.

Table 1. Properties of compounds *(3a)*–*(3d)*, *(4a)*, and *(4b)*.

| Compound | $R^1$ | $R^2$ | M.p. [°C] | $\lambda_{max}$ [mμ] | ε · 10⁻⁴ |
|---|---|---|---|---|---|
| *(3a)* | $CH_3$ | H | 225–230 | 472 | 4.37 |
| *(3b)* | $C_2H_5$ | H | 214–220 | 472 | 4.37 |
| *(3c)* | $CH_3$ | $OCH_3$ | 208–220 | 485 | 4.34 |
| *(3d)* | $C_2H_5$ | $OCH_3$ | 215–223 | 485 | 4.34 |
| *(4a)* | $C_2H_5$ | H | 126 (decomp.) | 592 | 4.27 |
| *(4b)* | $C_2H_5$ | $CH_3$ | 178–185 | 587 | 4.11 |

Oxidation of *(3a)*–*(3d)*, *(4a)*, and *(4b)* by alkaline hydrogen peroxide affords 2-benzothiazolones or 2-quinolones, together with phosphoric acid, in quantitative yields.

The NMR-spectra are compatible with the cyanine structure; the chemical shift of the phosphorus resonance (–26.05 ppm), however, is unexpectedly large and without parallel [*]. The excellent agreement of the electron spectra with those of the analogous aza- and methinecyanines supports the constitution proposed.

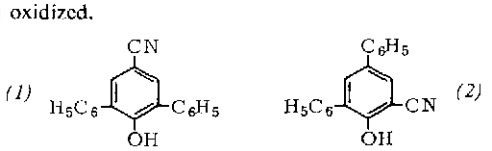
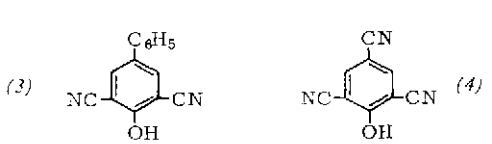
## Arylcyanophenols and 2,4,6-Tricyanophenol

By Prof. Dr. K. Dimroth and Dr. K. J. Kraft



Chemisches Institut
der Universität Marburg/Lahn (Germany)



*Dedicated to Professor H. Meerwein on the occasion of his 85th birthday*

The observation that 4-cyano-2,6-diphenylphenol *(1)* can be dehydrogenated to a stable, green phenoxyl radical [1] prompted us to prepare further arylcyanophenols. 2-Cyano-4,6-diphenylphenol *(2)* was obtained from 2,4-diphenylanisole by bromination, conversion into the corresponding organolithium compound, carboxylation, preparation of the amide, dehydration, and demethylation with pyridine/HCl [2]. Compound *(2)* can be dehydrogenated to a red, stable phenoxyl radical.

2,6-Dicyano-4-phenylphenol *(3)* was prepared from 4-hydroxydiphenyl by condensation with formaldehyde to give 2,6-bishydroxymethyl-4-phenylphenol, methylation, oxidation to the dicarboxylic acid, conversion into the diamide, dehydration, and demethylation. Phenol *(3)* is oxidized with lead tetraacetate in glacial acetic acid to give a blue radical which has not yet been closely investigated.

Finally, we have prepared 2,4,6-tricyanophenol *(4)* by conversion of methoxytrimesic acid into the triamide, dehydration, and demethylation. Like picric acid, *(4)* is a strong acid ($pK_c = 1.0$ at 20 °C and ionic strength $\mu = 0.02$); it has not yet been oxidized.

The half-wave potentials were measured polarographically in acetonitrile/water (9:1) containing 0.01 M $N(CH_3)_4OH$ and $N(CH_3)_4Cl$ with a rotating graphite electrode and a silver/

silver chloride reference electrode [3]. The potentials increase considerably with increasing cyanation (Table 1).

Table 1. Half-wave potentials.

| Compound | M.p. [°C] | $E^1/_2$ [mV] | Color of radical |
|---|---|---|---|
| 2,4,6-Triphenylphenol [4] | 149–150 | + 211 | red |
| 4-Cyano-2,6-diphenylphenol | 165–166.5 | + 549 | green |
| 2-Cyano-4,6-diphenylphenol | 138–139 | + 593 | red |
| 2,6-Dicyano-4-phenylphenol | 215 (decomp.) | > + 800 | blue |
| 2,4,6-Tricyanophenol | 185 (decomp.) | — | — |

These results show that for stabilization phenoxyl radicals need not necessarily have bulky substituents at the 2-, 4-, and 6-positions. All the radicals were characterized by ESR measurements [5].

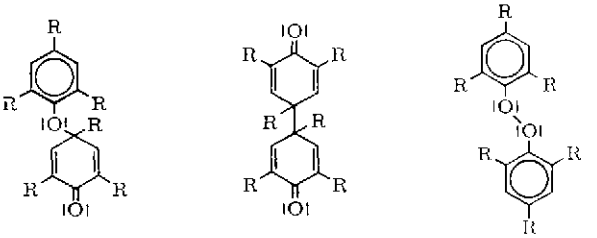
## The Constitution of the Dimer of 2,4,6-Triphenylphenoxyl

By Prof. Dr. K. Dimroth and Dipl.-Chem. A. Berndt

Chemisches Institut
der Universität Marburg/Lahn (Germany)



*Dedicated to Professor H. Meerwein on the occasion of his 85th birthday*

2,4,6-Triphenylphenol is readily dehydrogenated to a red free radical, which is perfectly stable towards oxygen [1] and which crystallizes as a colorless dimer. In solution, the dimer dissociates partly into 2,4,6-triphenylphenoxyl radicals (dissociation constant in benzene: $4\times10^{-5}$ at 20 °C, heat of dissociation: *ca.* 10 kcal/mole). Equilibrium between the colorless dimer and red monomer is reached so quickly that solutions of the former may be readily and without retardation redox-titrated, *e.g.* by using a solution of hydroquinone.

Introduction of large substituents (bromine or one or two phenyl groups) into the central nucleus of triphenylphenol displaces the position of equilibrium considerably in favor of the dimer and reduces the speed with which this equilibrium is attained. These observations cast some doubt on the validity of formula *(1)* for the dimer. Although the infrared spectrum of the dimer has a doublet at 1665 and 1642 $cm^{-1}$, which may be ascribed to the C=O vibrations of a quinol [2], the result would also agree with the presence of a diquinol *(2)*. A band at 958 $cm^{-1}$, *i.e.* in the region of –O–O– absorption, suggests a diphenyl peroxide structure *(3)* [3].

Formulation of the dimer as an ion pair [4] is incorrect, since neither the anion nor the cation [5] absorb in the region of the doublet.

By reaction of 2,4,6-triphenylbenzenediazonium fluoroborate with $CH_3{}^{18}OH$ [*] and cleavage of the resulting methyl ether with pyridinium chloride, we obtained [$^{18}$O]-2,4,6-triphenylphenol. Oxidation of this gave the dimer containing *ca.* 55 atom-% of $^{18}$O. The displacement of the infrared absorption bands (Table 1) demonstrates conclusively that the

*(1)* *(2)* *(3)*

doublet at 1665 and 1642 $cm^{-1}$ originates from a C=O vibration. The peroxide structure *(3)* is thus eliminated, all the more so as the band at 958 $cm^{-1}$ is not significantly displaced. The occurrence of a shift in the ether region excludes structure *(2)*.

Table 1. Characteristic absorption bands of dimeric [$^{16}$O]- and [$^{18}$O]-2,4,6-triphenylphenoxyl *(1)* (approximately 55 atom-% $^{18}$O) in $CCl_4$.

| $\tilde{\nu}$[$^{16}$O]-*(1)* [$cm^{-1}$] | $\tilde{\nu}$[$^{16}$O]-*(1)* + $\tilde{\nu}$[$^{18}$O]-*(1)* [$cm^{-1}$] | | $\Delta\tilde{\nu}$ [$cm^{-1}$] |
|---|---|---|---|
| 1665 | 1665 | 1620 | 45 |
| 1642 | 1642 | 1597 | 45 |
| 1201 | 1185 | | 16 |
| 958 | 956 | | 2 |

The quinol structure *(1)* is thus demonstrated. The *o*-quinol structure is not disproved by the above experiments, but seems less likely. Scission of the C–O bond of *(1)* in solution to form the radical, *i.e.* dissociation of the dimer *(1)*, requires only a very small energy of activation.

The present results are confirmed by an X-ray analysis of dimeric 3-bromo-2,4,6-triphenylphenoxyl; this work shows in addition that the product in question is a *p*-quinol derivative [6].

## Complexes of Organotin Compounds with Aluminum Halides

By Priv.-Doz. Dr. W. P. Neumann,
Dipl.-Chem. R. Schick [1], and Dr. R. Köster

Chemisches Institut der Universität Gießen and
Max-Planck-Institut für Kohlenforschung,
Mülheim/Ruhr (Germany)

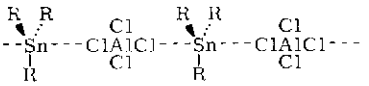
In carrying out alkylations on tin, *Köster* [2] obtained in 1955 the crystalline complexes *(3)* and *(7)*. Up to then, only compounds of organotin halides with Lewis bases were known [3]. In preparing starting materials such as tin tetraalkyls, we came again across these complexes [4, 5].

Solutions of these compounds (0.1 mole/l) in benzene and nitrobenzene at 35 °C displayed relatively high conductivities: in the case of *(3)* we obtained $33\times10^{-4}$ and $86\times10^{-1}$ mho/cm²; for *(7)* we found $0.3\times10^{-4}$ and $2.9\times10^{-1}$ mho/cm². This suggests the formulae $[R_3Sn]^+[AlCl_4]^-$ for *(3)* and $[R_2SnCl]^+[AlCl_4]^-$ for *(7)*, at least as equilibrium states [6].

On heating equimolar amounts of organotin halide and aluminum halide to 90–100 °C (clear melt) for a short period, followed by cooling and recrystallization from benzene, we obtained the colorless compounds listed in Table 1, mostly in the form of well-shaped crystal needles. As these substances are extremely sensitive to moisture, careful exclusion of air (argon) is essential.

Table 1. Melting points and cryoscopic data of compounds *(1)–(9)*.

| Compound | M.p. [°C] | Mean particle weight [a] per formula weight at a concentration [mole/l] of | | | | | |
|---|---|---|---|---|---|---|---|
| | | 0.01 | 0.02 | 0.04 | 0.06 | 0.08 | 0.10 |
| *(1)*, $(CH_3)_3SnCl\cdot AlCl_3$ | 91 | 1.04 | 1.40 | — | — | — | — |
| *(2)*, $(CH_3)_3SnBr\cdot AlBr_3$ | 111 | — | — | — | — | — | — |
| *(3)*, $(C_2H_5)_3SnCl\cdot AlCl_3$ | 23 | 1.09 | 1.52 | 2.48 | 3.50 | 4.51 | 5.52 |
| *(4)*, $(C_2H_5)_3SnBr\cdot AlBr_3$ | 49 | 0.95 | 1.03 | 1.31 | — | — | — |
| *(5)*, $(i\text{-}C_4H_9)_3SnCl\cdot AlCl_3$ | 90 | 0.92 | 0.98 | 1.15 | 1.37 | 1.63 | — |
| *(6)*, $(CH_3)_2SnBr_2\cdot AlBr_3$ | 73 | 0.91 | 0.93 | 0.97 | — | — | — |
| *(7)*, $(C_2H_5)_2SnCl_2\cdot AlCl_3$ | 84 | 0.92 | 0.94 | 1.00 | 1.06 | — | — |
| *(8)*, $(C_2H_5)_2SnBr_2\cdot AlBr_3$ | 72 | 0.94 | 0.96 | 0.98 | — | — | — |
| *(9)*, $(n\text{-}C_4H_9)_2SnCl_2\cdot AlCl_3$ | 55 | — | 0.96 | 1.01 | 1.05 | — | — |



[a] Determined cryoscopically in benzene.

When *(3)* and *(7)* are subjected to mild alcoholysis no gas is evolved; the compounds do therefore not contain alkyl groups bound to aluminum. Prolonged heating of *(3)* on the other hand leads to the formation of a small amount of $(C_2H_5)AlCl_2$.

Trialkyltin halide is a stronger complexing agent than dialkyltin halide. Thus, heating of *(7)* with an equimolar amount of $(C_2H_5)_3SnCl$ causes displacement of $(C_2H_5)_2SnCl_2$ which can be distilled off at a vacuum of 11 mm Hg, leaving *(3)* behind. A complex of $(C_2H_5)SnCl_3$ with $AlCl_3$ could not be isolated. At 90 °C, $C_2H_5Cl$ is rapidly given off by the mixture, leaving $SnCl_2$ behind. In contradiction with other reports [6], we did not observe the formation of stable complexes between tin tetraalkyls and $AlCl_3$.

The mean particle weight of the dialkyltin dihalide complexes *(6)–(9)* in benzene undergoes little change with the concentration; they dissociate to a slight extent (Table 1). The symmetrical Sn–C vibration in the infrared spectrum of dimethyltin dibromide at 514 $cm^{-1}$ splits into two absorptions of approximately half the intensity, occurring at 508 and 521 $cm^{-1}$, when the complex *(6)* is formed (suspension in nujol).

The mean particle weight of the trialkyltin halide complexes *(1)* and *(3)–(5)* in benzene, on the other hand, is very sensitive to changes in concentration (Table 1); association takes place. In the infrared spectrum of *(2)* the symmetrical Sn–C vibration at 512 $cm^{-1}$ weakens (as compared with the asymmetric vibration at 543 $cm^{-1}$) when the concentration in benzene is increased and disappears in the solid state (suspension in nujol). Thus, in the polymer, the $(CH_3)_3Sn$ group is completely or at least nearly planar: there is penta-coordination around the tin atom:

On the basis of the results of particle-weight determinations this probably applies also to the trialkyltin halide complexes *(1)* and *(3)–(5)*. Analogous structures have been proved or assumed for trialkyltin acylates [7], amides [8] and fluoro salts [9].

## The Metabolism of cis-β,γ-Enoyl-Coenzyme A Compounds

By Doz. Dr. W. Stoffel, Dipl.-Chem. R. Ditzer, and Dipl.-Chem. H. Caesar

Physiologisch-Chemisches Institut der Universität Köln (Germany)

Coenzyme A derivatives of cis-β,γ- or cis-α,β-unsaturated fatty acids are formed in the course of the β-oxidation of mono- and polyunsaturated fatty acids with cis-olefinic double bonds. We have investigated the further metabolism of the cis-β,γ-enoyl-CoA compounds, using *cis*-3-dodecenoyl-CoA *(1)* as an example. This compound is formed in the β-oxidation of oleic acid.

Contrary to earlier reports [1–3] crotonase does not hydrate *(1)*. Instead, a cis-β,γ-enoyl hydrase isolated from liver mitochondria catalyses this reaction. The product is D-(−)-β-hydroxylauroyl-CoA *(2)*. It is racemized by a racemase isolated from mitochondria to L-(+)-β-hydroxylauroyl-CoA *(3)* which is dehydrogenated by β-hydroxyacyl dehydrogenase (HOADH) [specific for the L-(+)-form] to β-ketolauroyl-CoA *(4)* and so removed from the equilibrium.

The following observations confirm this course of reaction:

1. Reduced pyridine nucleotide (DPNH) is formed only in presence of cis-β,γ-enoyl hydrase, racemase and HOADH. D-(−)-β-Hydroxylauroyl-CoA *(2)* is dehydrogenated to *(4)* only in presence of racemase and HOADH.

2. After incubation of 35 μmoles of [5-$^{14}$C]-cis-3-dodecenoyl-CoA *(1)* with cis-β,γ-enoyl hydrase and racemase, 3.0 mg of methyl rac.β-hydroxylaurate (m.p. 27 °C) were isolated by saponification, esterification and gas-chromatographic separation. The optical rotation of methyl D-(−)- or L-(+)-β-hydroxylaurate ($[\alpha]_D^{20} = \pm 19.5°$; c = 1 in $CHCl_3$)did not change in the blank under the conditions of isolation.

Through these reactions the unsaturated fatty acids are connected with the metabolic cycle of the saturated fatty acids [4], so that our knowledge of the β-oxidation of all the fatty acids occurring in the animal kingdom is thereby complete.

## New Syntheses of Pyrylium Salts

By Dr. Richard Schmidt

Institut für Organische Chemie
und Organisch-Chemische Technologie
der Technischen Hochschule Stuttgart (Germany)

*Dedicated to Professor H. Bredereck on the occasion of his 60th birthday*

By reacting phenylacetylene with aromatic acid chlorides in the presence of Lewis acids, pyrylium salts *(1)* could be obtained in good yields:

*(1)*

The reactions went best with excess acid chloride acting as both reactant and diluent at 5 to +15 °C. The pyrylium salts prepared are shown in Table 1.

Table 1. Properties of the pyrylium salts *(1)*.

| | Ar | Hexachlorostannate | | Perchlorate | | |
|---|---|---|---|---|---|---|
| | | m.p. [°C] (decomp.) | yield [%] | m.p. [°C] | λmax [mμ] | log εmax |
| *(1a)* | Phenyl | 290–298 | 73 | 287–290 (288–290 [1]) | 360 408 [2] | |
| *(1b)* | *o*-Chlorophenyl | 294–298 | 72 | 209 | 314 | 3.90 |
| *(1c)* | *p*-Chlorophenyl | 290–294 | 81 | 200–202 | 320 | 3.98 |
| *(1d)* | *p*-Tolyl | 273–277 | 55 | 230–232 (224 [3]) | 325 415 | 4.09 2.89 |

$SnCl_4$ has been the most suitable Lewis acid. The hexachlorostannates could be converted to perchlorates with perchloric acid in dimethylformamide/water. The pyrylium salts are yellow and fluoresce strongly in solution. The ultraviolet spectra were taken in methanol. By comparison of *(1a)* with authentic 2,4,6-triphenylpyrylium perchlorate [1] and by conversion of *(1a)* to 2,4,6-triphenylpyridine [4] the course of the reaction was clarified.

# CONFERENCE REPORTS

## Colloquium in Honor of G. Scheibe

On the occasion of Prof. *G. Scheibe*'s 70th birthday a colloquium was held in Munich (Germany) on November 29th and 30th, 1963. The following is a selection from the papers read.

### Influence of Heavy Atoms on the Polarization of Triplet/Singlet Phosphorescence of Organic Compounds

*F. Dörr*, *H. Gropper*, and *N. Mika*, München (Germany)

The triplet/singlet phosphorescence of organic molecules in isotropic solid solution, when excited with linearly polarized light, is itself partially polarized. On theoretical grounds, a degree of polarization $\rho = 0.5$ is to be expected in the plane perpendicular to the electric vector of the exciting light source, if the absorbing and the emitting transition moments in the molecule are parallel. If they are perpendicular to each other, $\rho = 0.33$ [1]. The π–π absorption transitions of planar molecules are all polarized in the plane of the molecule. For numerous aromatic hydrocarbons, the triplet/singlet phosphorescence consists essentially of only one intense component, which is polarized perpendicularly to the plane of the molecule [2]. However, halogeno substituents, *e.g.* in naphthalene, intensify other components of the phosphorescence that are polarized in the plane of the molecule. The resulting intensification of emission is known as the heavy atom effect [3]. The superimposition of differently polarized components is also manifest in the degree of polarization, which becomes increasingly positive with increasing atomic number of the substituting element [4]. A similar influence has now been observed in the series fluorene, dibenzofuran, carbazole, and dibenzothiophene, in which $\rho$ rises from −0.32 to +0.04.

The theory of triplet/singlet transitions [5] provides selection rules for the mixing of singlet and triplet states via

the different components of the spin orbit operator {LS}. On the assumption that for the compounds under examination, only the lowest triplet state $T_0$ of the symmetry $^3L_a$ or $^3L_b$ is noticeably influenced by spin orbit coupling, the following combinations result as the most probable ones. (Coordinates: x = longitudinal axis, z = transverse axis, y = normal to plane of molecule).

1. If $T_0 \equiv {}^3L_a$ (z-symmetry), the following states mix:

(a) via $\{LS\}_x$, an $S(\sigma,\pi^*)$-state; polarization along y;

(b) via $\{LS\}_y$, an $S_x$-state (probably $^1L_b$); polarization along x.

2. If $T_0 \equiv {}^3L_b$ (x-symmetry), the following states mix:

(a) via $\{LS\}_y$, an $S_z$-state (probably $^1L_a$); polarization along z;

(b) via $\{LS\}_z$, an $S(\sigma,\pi^*)$-state; polarization along y.

## The Boltzmann Occupation of the Energy Terms of Atoms and Molecules

*H. Krempl*, München (Germany)

It is known from Boltzmann statistics that

(a) for absorption, the cross-sectional area of a band represented by the extinction coefficient $E_A$ obeys the law

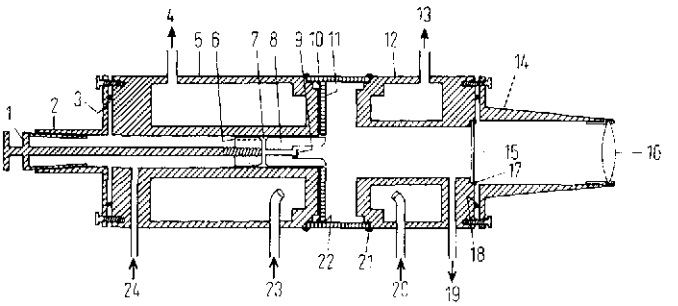
$$E_A = \log I_0/I = \varepsilon_A \cdot c \cdot \exp(-U_a/kT) \cdot d \qquad \text{and}$$

(b) for emission, the intensity $E_E$ of any line obeys the law

$$E_E = \varepsilon_E \cdot c \cdot \exp(-U_a/kT) \cdot d \ ,$$

where c is the concentration of the materials concerned, d is the thickness of the layer, and $U_a$ is the appropriate height of the term above the ground state. $\varepsilon_A$ and $\varepsilon_E$ are atomic and molecular constants, respectively (transition probability functions).

Both these laws were examined over a wide range of temperature (a) for the first band of benzene, $\lambda$ = 2700 Å, over the range of −176 to +100 °C; (b) for the atoms and ions of C, Mg, Al, Zn, Pb over the range of 8000 to 40000 °C, by means of spectrochemical thermoanalysis in an electrically heated plasma.



At moderate concentrations, *i.e.* as long as Beer's law holds (a) or in optically thin plasmas (b), the law predicted statistically by Boltzmann proved to be valid.

For initial terms close to the ionization limit, a lower degree of occupation was observed in the case of emission than is to be expected theoretically; this may be ascribed to the action of the surrounding plasma fields on the undisturbed term system.

## The Hollow Cathode as a Light Source for Emission Spectrography in the Vacuum Ultraviolet Region

*G. Milazzo*, Rome (Italy)

The hollow cathode (Fig. 1) is based on the principle of cathode sputtering and is superior as a light source to arc and spark discharges mainly for two reasons. Through cooling and by its mode of construction, the Doppler and Stark effects are largely avoided, so that background-free spectra with very sharply defined lines are obtained. By combining the hollow cathode with a vacuum spectrograph, spectra of nonmetals (*e.g.* Br, I) and metalloids (*e.g.* Si, Ge, As) can be measured in the vacuum ultraviolet region simply and with great accuracy. (An atlas of the spectra of several elements in the vacuum ultraviolet region is under preparation, in collaboration with the Vatican Astronomical Observatory.) Where possible, the cathode itself is made from the material under examination. Alternatively (Cl, Br), it suffices to introduce the sample into a carrier material (Al, Mg). In this very simple way it is possible to employ spectroanalytical methods for non-metals also, which have their analytically most sensitive lines in the vacuum ultraviolet region. In this way, iodine can be detected with certainty down to $10^{-8}$ g. Traces of oxygen can be detected indirectly by means of the CO spectrum.

## Photochemistry and Spectroscopy of Acridines

*V. Zanker, F. Mader*, and *W. Körber*, München (Germany)

Earlier investigations [6] of the photochemical behavior of acridine proved that the same end products, *viz.* the sparingly soluble dimer 9,9′-diacridanyl and, presumably, the more soluble 9,10-dihydro derivative acridan, occur in H-containing solvents, both in the presence and absence of $O_2$. Our investigations showed in addition that on photolysis in ethanol saturated with nitrogen, acridine (conc. $> 5\times10^{-4}$ M) forms a colorless product, (purified by recrystallization from dimethyl sulfoxide) m.p. 262 °C under nitrogen. This substance exhibits a split acridan band in the ultraviolet – an indication of substitution at C-9 – and a weak band at 360 mμ, which is characteristic for diacridanyls. Its infrared spectrum is identical with that of synthetic 9,9′-diacridanyl prepared from acridine with Na/Hg. The results of its elemental analysis also correspond to the formula of diacridanyl. The mass spectrum yields fragments of mass number 180. This shows that the 9,9′-bond is the weakest one and that the compound dissociates into acridinium ions. By analogy to *N,N′*-dimethyl-9,9′-diacridanyl, the molecular weight of which (388) can be determined as a result of its superior solubility, and the mass spectrum of which yields ostensibly similar fragments with mass number 194, it must be assumed that the photochemical reduction product obtained from acridine is 9,9′-diacridanyl (mol. wt. 360).

At acridine concentrations of $< 5\times10^{-4}$ M in H-containing solvents, a "soluble acridan" is formed as photochemical product and could be isolated from dioxan and cyclohexane. The ultraviolet spectra again point to acridans substituted at C-9 (split acridan band), and the elemental analyses and molecular weights tally with 9-dioxanylacridan and 9-cyclohexylacridan, respectively. The conclusion is that acridans substituted at C-9 are formed from acridine also in other H-containing solvents. On the basis of these results, we explain the reaction in terms of radicals, the primary reaction consisting of hydrogen transfer from the solvent with the formation of a 9-acridanyl radical. It was possible to prove spectroscopically the presence in solutions containing oxygen, of an $O_2$-adduct, probably diacridanyl peroxide, and its stable decomposition product, acridone. The spectra of some acridans and diacridanyls were analysed by fluorescence and fluorescence polarization. The characteristic acridan band devoid of fine structure at 300 mμ is a superimposition of the

$^1L_b$-band upon the $^1L_a$-band. The splitting of the acridine band in the 9-substituted derivatives is to be explained by a bathochromic shift of the $^1L_b$-band.

The preband, occurring at about 360 mμ with the diacridanyls is markedly influenced by temperature and disappears almost completely at −183 °C. This implies the existence of two different conformations of diacridanyl, the conformer richer in energy absorbing at the longer wave length (at 360 mμ). In the frozen state, the diacridanyls undergo an interesting photolysis involving splitting of the 9,9'-bond and electron detachment, acridinium cations being formed. On melting the solution, diacridanyl is reformed.

## Studies of the Tetrahydrate of Hydrogen Bromide $H_9O_4^{\oplus}Br^{\ominus}$

*H. Zimmermann, J. Rudolph*, and *G. Henning*, München (Germany)

At low temperatures, hydrogen bromide forms a crystalline tetrahydrate, m.p. −56 °C [7]. Its infrared spectrum was examined at −170 °C. In contrast to that of the corresponding acid solutions at room temperature, it exhibits a fine structure [8]. In particular, the long-wave infrared spectrum shows groups of sharply defined bands, for which it was possible to set up a term series for the vibrational states. This term system indicates that the substance is present in the form $H_9O_4^+Br^-$. The $H_9O_4^+$ complex consists of a pyramid-shaped $H_3O^+$ ion that is linked to three further water molecules by exceptionally strong hydrogen bonds. This complex has therefore a structure similar to that of the $H_9O_4^+$ ion, which is present in aqueous solutions of acids, according to *Wicke, Eigen*, and *Ackermann* [9].

From the infrared spectra of the tetrahydrate of hydrogen bromide, it appears probable that the proton in the hydrogen bonds under discussion moves in an asymmetrical potential field with two minima. At low temperatures, it is fixed in the lower potential trough. Proton mobility therefore is very low, and the conductivity at −180 °C amounts to $K < 10^{-9}$ mho · cm$^{-1}$. The conductivity varies with temperature and shows a sharp point of inflection at −90 °C. A discontinuous change in the properties of the substance at −90 °C can be similarly proved in the wide-band nuclear resonance spectrum, but not in the infrared spectrum. [VB 780/136 IE]

## Chemical Reactions with (n, γ), β⁻, and Fission Recoil Atoms

*F. Baumgärtner*, München (Germany)

Recoil atoms resulting from nuclear reactions are capable of forming new molecules. Nuclear reactions thus represent a means for synthetizing molecules independently of preparative chemical methods. Thus, by β-disintegration of the parent substances, it was possible to prepare the hitherto unknown compounds dicyclopentadienylrhodium *(1)*, dienzene technetium(I) *(2)*, and cyclopentadienyltricarbonyltechnetium *(3)*. These substances were purified by sublimation. *(2)* is a stable Tc cation, which has also been synthetized macroscopic amounts.

$$^{105}Ru(C_5H_5)_2 \xrightarrow{\beta^-} {}^{105}Rh(C_5H_5)_2 \qquad (1)$$

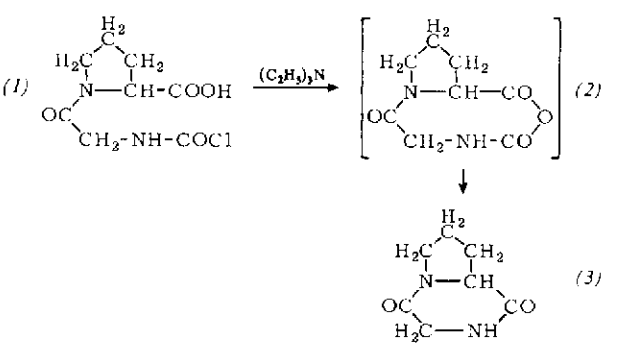
$$^{99}Mo(C_6H_6)_2 \xrightarrow{\beta^-} {}^{99m}Tc(C_6H_6)_2^+ \qquad (2)$$

$$(C_5H_5)_2{}^{99}Mo_2(CO)_6 \xrightarrow{\beta^-} (C_5H_5){}^{99}Tc(CO)_3 \qquad (3)$$

To extend the range of syntheses with recoil atoms, *i.e.* in order to be independent of specific parent substances, we used two-phase mixtures of uranium oxide and the target material. In the uranium phase, energy-rich recoil atoms were produced by nuclear fission and some of these, *e.g.* $^{105}Ru$, $^{131}I$, $^{99}Mo$, react with the target compound. The following radioactive molecules have been prepared via uranium fission:

$$U(n,f) + Fe(C_5H_5)_2 \rightarrow Ru(C_5H_5)_2$$
$$U(n,f) + Fe(C_5H_5)_2 \rightarrow C_5H_5FeC_5H_4I$$
$$U(n,f) + Cr(CO)_6 \rightarrow Mo(CO)_6$$
$$U(n,f) + Cr(C_6H_6)_2 \rightarrow Mo(C_6H_6)_2$$
$$U(n,f) + Cr(C_6H_6)_2 \rightarrow Tc(C_6H_6)_2^+$$
$$U(n,f) + C_6H_5{-}X \rightarrow C_6H_5{-}I \quad (X = Cl, Br, \text{or } I)$$

According to the last equation, organically bound halogen may be substituted very selectively by fission iodine. Between 500 and 4 °K the yields of these recoil syntheses are independent of the temperature.



[Chemische Gesellschaft Heidelberg (Germany), January 14th, 1964] [VB 790/131 IE]

German version: Angew. Chem. *76*, 307 (1964)

## Chemical Synthesis of Polypeptides and the Hydrodynamic Properties of Their Solutions

*G. Spach*, Strasbourg (France)

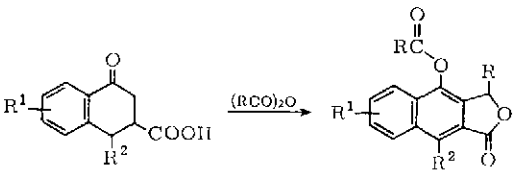
Condensation of the tripeptide L-alanylglycylglycine with dicyclohexylcarbodiimide or ethyl metaphosphate yields only products with a degree of polymerization < 6. In order to obtain high molecular-weight copolypeptides with the amino acids in a regular order, a new synthesis depending on internal anhydride formation was considered. In a preliminary investigation, the carbamyl chloride *(1)* was synthetized by the action of phosgene on glycyl-L-proline. The substituted diketopiperazine *(3)* containing an intramolecular peptide link was formed from *(1)* with the stoichiometric quantity of triethylamine. The intermediate anhydride *(2)* was not isolated and is probably of low stability [1].

Examination of dilute solutions of the homopolypeptides polybenzyl-L-glutamate and polycarbobenzoxy-L-lysine in dimethylformamide showed that the molecules exist in the form of a helix of type $3.0_{10}$, with three monomers per turn, while in the solid state they assume an α-helix configuration with 3.6 monomers per turn [2].

Polybenzyl-DL-glutamate exists in both the A and B forms depending on the polymerization solvent. The A form appears

[1] *A. Brack*, Thèse 3e cycle Université de Strasbourg, 1963.

[2] *G. Spach, L. Freund, M. Daune*, and *H. Benoit*, J. molecular Biol. *7*, 468 (1963).



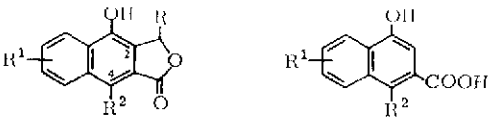
to be a flexible chain of rod-like units of about 100 Å length each; it is probably a block-copolymer in which sequences of D and L residues alternate. The rigid molecules of the B form can be considered in a first-stage model as a mixture of polybenzyl-L- and -D-glutamate.

[GDCh-Ortsverband Marburg/Lahn (Germany)
January 24th, 1964] [VB 797/137 IE]
German version: Angew. Chem. 76, 381 (1964)

## A New Synthesis of Hydroxyphthalides

*A. Sieglitz*, München (Germany)

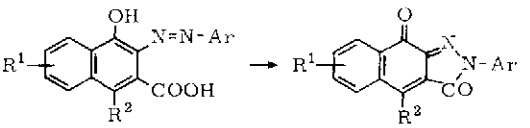
1-Oxotetralin-3-carboxylic acids *(1)* react with carboxylic anhydrides to yield acyloxyphthalides *(2)*.



*(1)* *(2)*

The reaction was carried out with numerous derivatives of *(1)*, including 3-oxo-1,2,3,10*b*-tetrahydrofluoranthene-1-carboxylic acid [1] and 1-oxo-4,5-methylene-1,2,3,4-tetrahydrophenanthrene-3-carboxylic acid [2], and gives positive results with numerous anhydrides of aliphatic, aromatic, alkylaromatic, and heterocyclic carboxylic acids.

[1] *A. Sieglitz, H. Tröster*, and *P. Böhme*, Chem. Ber. *95*, 3013 (1962).



[2] *A. Sieglitz* and *W. Schidlo*, Chem. Ber. *96*, 1098 (1963).

The acyloxyphthalides *(2)* are hydrolysed under mild conditions to the free hydroxyphthalides *(3)*. More vigorous attack opens the lactone ring, producing 1-hydroxynaphthalene-3-carboxylic acids *(4)* and aldehydes R CHO [3].

*(3)* *(4)*

Hydroxyphthalides with a free 4-position *(3)*, $R^2$=H, couple with diazonium compounds in this position. Those with a substituted 4-position ($R^2$=$CH_3$,$C_6H_5$) and hydroxyphthalides derived from 3-oxo-1,2,3,10*b*-tetrahydrofluoranthene-1-carboxylic acid undergo coupling in the 2-position,

*(5)* *(6)*

with simultaneous elimination of the aldehyde RCHO. The azo dyes *(5)* thus obtained (also accessible from *(4)* when the 4-position is substituted) are readily dehydrated to form *o*-quinonoid indazolone dyes *(6)*.

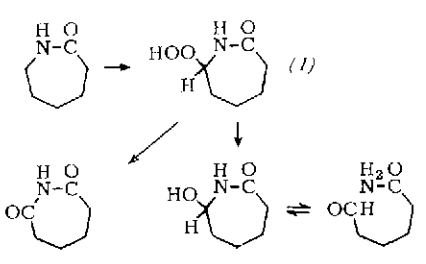
# SELECTED ABSTRACTS

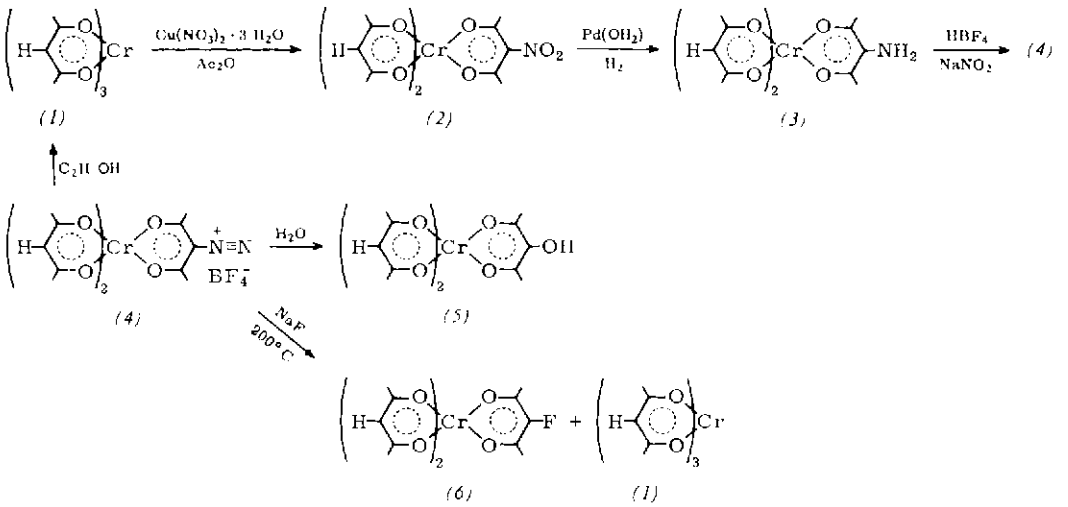
**The role of formylpyruvic acid** in forming the dyestuff of the Warren reaction has been clarified by *R. Kuhn* and *R. Lutz*. The Warren reaction is used for colorimetric determination of free sialic acids. Formylpyruvic acid was thought to occur as an intermediate in this reaction, but neither it nor the dyestuff were known in the free state.



*(1)*

*Kuhn* and *Lutz* synthetized ethyl ethoxymethylenepyruvate *(2)*, b.p. 135–138 °C/11 mm, in 23 % yield from ethyl pyruvate and triethyl orthoformate. Claisen saponification of *(2)* gave red-brown flakes of the sodium salt of formylpyruvic acid; when an aqueous solution of this salt was heated with 2-thiobarbituric acid, it became deep red. Tiny blue crystals separated out of the red solution (45 % yield). This blue dyestuff *(1)* has the same absorption spectrum as the dyestuff of the Warren reaction ($\lambda_{max}$ = 550 mμ, $\varepsilon_{max}$ = $1.34\times10^5$ in cyclohexanone). / Biochem. Z. *338*, 554 (1964) / –De. [Rd 838/219 IE]

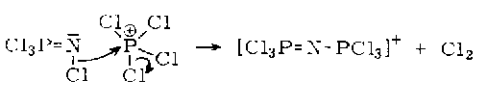
**Separation of the geometric isomers of cobalt complexes** has been achieved by *H. Seiler, C. Biebricher*, and *H. Erlenmeyer* using thin-layer chromatography. For complexes of the type [Co $en_2Cl_2$]X (X = Cl, $NO_3$, or CNS; en = ethylene diamine), a suitable mobile phase is a chloride-free, methanolic acetate buffer. The *trans*-complex always migrates further than the *cis*-complex, independently of their solubilities; apparently the polarity and water content of the mobile phase are very important. *cis*-Isomers are generally more labile than the *trans*-isomers, and partial isomerization always occurs. However, even the geometrically isomeric nitro complexes which are very poorly separable by fractional crystallizatio owing to the close similarity of their physical and chemic properties, can be satisfactorily separated by thin-lay chromatography. The mobile phase suitable for this separation is an ammonium acetate buffer in a mixture of methanol and ethanol. / Helv. chim. Acta *46*, 2636 (1963) / –Ko. [Rd 848/233 IE]



**Caprolactam hydroperoxide,** the first representative of a new type of peroxide, was prepared by *A. Rieche* and *W. Schön*. A caprolactam melt takes up oxygen at 75 °C to give the hydroperoxide *(1)* in very low yield. Pure, crystalline *(1)* melts at 139 °C with vigorous frothing. Co(II) and Fe(II) salts catalyse the conversion of *(1)* into adipimide *(2)* which is also obtained on oxidation of caprolactam at 100 °C. On

*(1)* *(2)* *(3)*

hydrogenation, *(1)* forms ω-formylpentanoamide *(3)*. Caprolactam hydroperoxide disturbs the polymerization of caprolactam in the same manner as air. / Z. Chem. *3*, 451 (1963) / –Kr. [Rd 842/220 IE]



**The reaction of phosphorus pentachloride with hydroxylammonium chloride** in tetrachloroethane was studied by *M. Becke-Goehring, W. Gehrmann,* and *W. Goetze*. Mixtures of the three substances were heated to 100 °C for a desired reaction time, rapidly cooled to 50 °C and examined 2 hours later. $PCl_5$ and $(NH_3OH)Cl$ (in a molar ratio of 1:1-2) gave $P_2NOCl_5$ *(1)* in good yield after a reaction time of 1 hour.

When the reaction time was only 15 min (with a molar ratio $PCl_5$:$(NH_3OH)Cl$ of 1:1–1.5) colorless crystals of the tetrachloroethane adduct of *(2)* were formed in addition to *(1)*. At a molar ratio $PCl_5$:$(NH_3OH)Cl$ greater than 1.5:1, *(3)* was also formed in addition to a small amount of *(1)* and *(2)*. With 100 % excess $PCl_5$, only *(1)* and *(3)* were found. Obviously, *(1)* and *(3)* are secondary products of *(2)*.

$$H_2NOH + PCl_5 \rightarrow Cl_3P{=}NOH + 2\,HCl$$

$$Cl_3P{=}N{-}OH + PCl_5 \rightarrow Cl_3P{=}N{-}Cl + HCl + OPCl_3$$

$$[Cl_3P{=}N{-}PCl_3]Cl \qquad [Cl_3P{=}N{-}PCl_3][PCl_6]$$
$$(2) \qquad (3)$$

$$[Cl_3P{=}N{-}PCl_3]^+ + (H_3NOH)Cl \rightarrow Cl_3P{=}N{-}P(O)Cl_2 + Cl_2 + (NH_4)^+$$
$$(1)$$

The corresponding reaction of $C_6H_5PCl_2$, $PCl_5$, and $(NH_3OH)Cl$ led to $[C_6H_5P(Cl_2){=}N{-}P(Cl_2)C_6H_5]Cl$ and $[C_6H_5P(Cl_2){=}N{-}P(Cl_2)C_6H_5]PCl_6$. / Z. anorg. allg. Chem. *326*, 127 (1963) / –Kr. [Rd 843/221 IE]

**A stable chelate diazonium salt** has been prepared by *J. P. Collman* and *M. Yamada* and has been employed to confirm the aromatic character of 1,3-diketone/metal complexes. Chromium(III) acetylacetonate *(1)* was nitrated by less than a molar quantity of cupric nitrate in acetic anhydride. The resulting mixture of mononitrochromium(III) acetylacetonate *(2)* and the corresponding dinitro and trinitro derivatives was separable by chromatography, *(2)*, m.p. 178–180 °C, being obtained in 64.5 % yield. Hydrogenation of *(2)* with $H_2/Pd(OH)_2$ gave aminochromium(III) acetylacetonate *(3)*, m.p. 221.5–223 °C, in 69 % yield. Compound *(3)* has the properties of an aromatic amine; mineral acids effect a color change and yield salts, while acetic anhydride causes acetylation. Treatment of an aqueous solution of the fluoroborate of *(3)* with sodium nitrite in the cold affords the diazonium salt *(4)* as a purple-red precipitate; because of its sensitivity towards water, this must be isolated without delay (yield: 55 %). At room temperature in a dry atmosphere *(4)* is stable and decomposes at 165–167 °C. With water, the hydroxy chelate *(5)* is formed, which was isolated as the dodecahydrate. Alcohol reduces *(4)* to chromium(III) acetylacetonate *(1)*. Distillation of a mixture of *(4)* and NaF at 200 °C *in vacuo* yields fluorochromium(III) acetylacetonate *(6)* in 6 % yield, in addition to unsubstituted *(1)*. / J. org. Chemistry *28*, 3017 (1963) / –Ko. [Rd 852/222 IE]

**The reaction between phosphorus pentoxide and hydrogen peroxide** is described by *P. W. Schenk* and *K. Dommain*. Commercial $P_2O_5$ consists mainly of the "M" form, which crystallizes in a molecular lattice ($P_4O_{10}$ with the urotropine structure). Absolute $H_2O_2$ was obtained from commercial 35 % $H_2O_2$ by evaporation and fractional condensation. In large quantities $P_2O_5$ and $H_2O_2$ react explosively with evolution of oxygen.

On mixing the two components in liquid $NH_3$, no reaction occurs even after 8 days, but the components react on evaporation of the $NH_3$. When small quantities of $P_2O_5$ are dusted into well-cooled $H_2O_2$, the nature of the reaction products depends on the amount of water available. With over 90 % $H_2O_2$, only peroxomonophosphate plus di- and triphosphate were found; with dilute $H_2O_2$, tetrametaphosphate also resulted. Tetrametaphosphate is decomposed by $H_2O_2$ in the presence of acids. / Z. anorg. allg. Chem. *326*, 139 (1963) / –Kr. [Rd 841/237 IE]

**The crystal structure of potassium methoxide** has been investigated by *E. Weiss*. The X-ray powder pattern of $KOCH_3$ indicates it to be tetragonal with a = 3.95 Å, c = 8.77 Å, Z = 2, space group $P4/nmm\text{-}D^4_{7h}$, $\rho_{calc.}$ = 1.70 ± 0.006 g/cm$^{-3}$, $\rho_{exp.}$ = 1.2–1.5. Each oxygen atom is surrounded by five $K^+$ ions and a methyl group in the form of a distorted octahedron. The compound has a double-layer structure in which the $KOCH_3$ units are perpendicular to the plane, and the methyl groups alternate on the sides of the plane. The arrangement of O and K here is very similar to that in KOC≡COK. / Helv. chim. Acta *46*, 2051 (1963) / –Mn. [Rd 854/239 IE]

**The preparation and rate of decomposition of thiosulfuric acid** have been reported by *Max Schmidt* and *M. Wieber*. Free thiosulfuric acid is obtained in 93 % yield by double decomposition of ice-cold aqueous $Na_2S_2O_3$ and HCl solutions in a reaction capillary. The acid is stable in acetone at –70 °C. Up to 5 % $H_2S_2O_3$ solutions are obtainable. To measure the

rate of decomposition, the length and diameter of the reaction capillary were varied to alter the duration of retention therein. To stop its decomposition, the reaction solution was injected into NaOH solution. The mixture was then acidified with glacial acetic acid and samples with and without formalin (which combines with $SO_3^{2-}$ resulting from the decomposition) were titrated with iodine. The difference between the titres indicates the amount of thiosulfuric acid. Decomposition intervals of 1–50 sec can be measured. In 2–3 M solution at room temperature *ca.* 10 % is decomposed after 10 sec and *ca.* 25 % after 40 sec. Naturally no conclusions can be drawn from the decomposition curve concerning the decomposition mechanism. / Z. anorg. allgem. Chem. *326*, 174 (1963) / –Jg. [Rd 833/238 IE]

**Free thio acids of phosphorus and arsenic** have been prepared by *Max Schmidt* and *M. Wieber* by double decomposition of the corresponding salts with HCl. Ice-cold solutions of the salts were injected together with 2N HCl into a reaction capillary, and 0.1 sec later the jet was lead into acetone at –70 °C. Thus, starting from $Na_3PS_4$, 96 % yields of $H_3PS_4$ were obtained. $H_3PS_4$ decomposes irreversibly into $H_2S$ and $P_2S_5$, well below room temperature. Since $H_3PS_4$ is the least stable of the thiophosphoric acids, the acids $H_3PO_xS_y$ can be prepared similarly. On attempting to obtain $H_3AsS_4$ analogously, the latter decomposed in the reaction capillary within 0.1 sec; however, $H_3AsO_2S_2$ and $H_3AsO_3S$ (94 % yield) were isolated in this way. / Z. anorg. allgem. Chem. *326*, 182 (1963) / –Jg. [Rd 834/240 IE]

# BOOK REVIEWS

**Medizinische Biochemie** (Medical Biochemistry). By *S. M. Rapoport*. A text-book for students and doctors. VEB Verlag Volk und Gesundheit, Berlin 1962. 1st Edit,. XVI, 992 pp., 189 ill., 146 tab., linen DM 53.– (about $ 13.25).

*S. M. Rapoport*, director of the Physiologisch-chemisches Institut of the Humboldt University in Berlin, presents a text-book of medical biochemistry which surpasses the better known student text-books in scope and volume. It can justifiably claim to be the first Chemical Biology written in German and specifically designed to suit the requirements of medical students.

The traditional division into descriptive and dynamic sections has been abandoned and, instead, descriptions of compounds, physical chemistry, and methodological information are interlinked in a skilful and stimulating manner. The book starts with a discussion of the original primitive biological environment of water and electrolytes and progresses via a discourse on proteins and nucleic acids to masterful chapters dealing with the thermodynamics and kinetics of biological reactions, catalysis, and enzyme activity, culminating relatively quickly (on p. 162) in the description of a first synthesis of the unit of life, with a discussion of the structure and function of the cell. An essay on *Oparin*'s hypothesis concerning the origin of life and biological evolution follows.

The second large section, entitled "Intermediary Metabolism", begins – the reviewer finds especially successfully – with a chapter on the methods employed in classical and modern biochemistry. It is a matter of experience that students find difficulty in grasping the complicated interplay of the reactions of intermediary metabolism. Schemes and diagrams only enable the reaction sequences and cycles which they illustrate to be committed more easily to memory, whereas an indication of the method which led to any particular discovery provides an intimate approach to the material. Another welcome feature is that examination questions are included at the end of each section, and important reviews and journals are named at the end of the book.

A considerable amount of space – 400 pages in all – is occupied by the sections on functional biochemistry, general metabolism, and nutrition. These include interesting chapters on tumor metabolism, the biochemical effects of ionizing radiation, and immunochemistry; however, not surprisingly, these are not all of the same brilliance as the first sections of the volume. Instead of these chapters, it would have been better to include a description of photosynthesis, but unfortunately this subject, together with those of plant and bacterial metabolism, has been purposely omitted.

If one disregards this unfulfilled preference, and also the fact that the author, a fervid Marxist, has deemed it necessary to include a series of quotations from *Friedrich Engels* in his scientific text, this volume can be recommended as the most modern and the best "large" German-language text-book of biochemistry available at present.

*Herbert Fischer* [NB 134/71 IE]

**Bodenphysik und Bodenkolloidik** (Soil Physics and Soil Colloid Science). By *J. di Gleria, A. Klimes-Szmik*, and *M. Dvaracsek*. VEB Gustav Fischer Verlag, Jena 1962. 1st edit., 795 pp., 265 illustrs., 255 tables, cloth, DM 124.60 (about $31.–).

The book is divided into nine parts: introductions to physical chemistry and colloid science; the mineral and organic constituents of soils; the physical chemistry and colloid science of soils; soil structure; water and air in the soil; soil heat; and soil cultivation and improvement.

The authors have industriously collected together many important and many more unimportant research results. This applies both to the text and to the 543 literature references. Unfortunately, the authors appear to be unaware of many of the basically important advances made in the last twenty years in the knowledge of the physico-chemical and colloidal behavior of soil constituents, in the light of which they could have compiled their material much more critically and intelligibly. The volume is also unsuitable as a textbook owing to its size. Nevertheless it can be of use in many ways to the research worker in the field of soil science. Perhaps it was from this point of view that the publishers set the price so high. The presentation is thoroughly pleasing with regard to both the print and the illustrations.

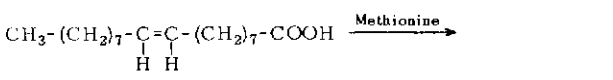
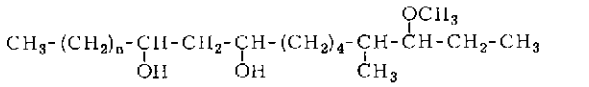
# Biosynthesis, Structure, and Biological Action of the Lipids of the Tubercle Bacillus [*]

BY PROF. DR. E. LEDERER



INSTITUT DE CHIMIE DES SUBSTANCES NATURELLES, GIF-SUR-YVETTE, AND LABORATOIRE DE CHIMIE BIOLOGIQUE, FACULTÉ DES SCIENCES, PARIS (FRANCE)

*The extensive studies of R. J. Anderson between 1926 and 1946 and the subsequent work of Stenhagen, Polgar, and Cason, and of the author's laboratory have demonstrated the astonishing abilities of the tubercle bacillus in synthetizing lipids. Numerous branched-chain fatty acids, glycolipids, peptidolipids, and peptidoglycolipids have been isolated, and their structures more or less elucidated. Such work is of interest not only to natural-product chemists, and biochemists, but especially to biologists and pathologists who are concerned with the harmful effects caused by the tubercle bacillus. The present article discusses chiefly three points: 1. The biogenesis of the branched-chain fatty acids. – 2. The structures of several glyco-, peptido-, and peptidoglycolipids. – 3. Adjuvant activity and immunization by the lipids of the tubercle bacillus.*



## I. Biogenesis of Branched-Chain Fatty Acids

### a) Substances with Methyl Side-Chains

The most important compounds with one methyl side-chain which are produced by the tubercle bacillus are tuberculostearic acid *(1)* and phthiocerol *(2)*. *Bloch* and coworkers [2] have shown that tuberculostearic acid *(1)* is formed from oleic acid by *C*-methylation in the presence of methionine.

*(1)*

*(2)*, n = 20 or 22

These studies, which were carried out on *Mycobacterium phlei*, were confirmed at Gif by *Gastambide-Odier* using the human strain $H_{37}R_a$ [3]. *Tanaka* and *Umezawa* [4] also investigated the biosynthesis of a methyl branched-chain fatty acid from the antibiotic variotin, and similarly established *C*-methylation of an unsaturated precursor. The mechanism of this *C*-methylation in the presence of methionine has yet to be explained.

It was known from the work of *Hofmann* [5] that, in *Lactobacilli*, lactobacillic acid *(3)* is formed from vaccenic acid in the presence of methionine. This suggested the possibility that an isomeric cyclopropanecarboxylic acid *(4)* might be a precursor in the biosynthesis of tuberculostearic acid. This acid *(4)* was synthetized at Gif by *Noble* and *Sarda* [6] from oleic acid and $^{14}CH_2I_2$. However, no conversion of *(4)* into tuberculostearic acid could be established [6] on incubation of the labelled cyclopropanecarboxylic acid with *M. phlei*.

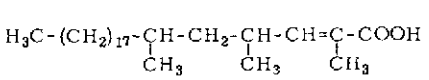
*(3)*

*(4)*

The biosynthetic route to phthiocerol *(2)* has recently been established by *Gastambide-Odier* [7]; it was found that the methyl group of methionine is incorporated only into the methoxy group of phthiocerol. The branched moiety of the carbon chain originates from propionic acid. Thus the Scheme 1 proposed earlier [1f] is probably correct. Phthiodiolone, which also appears in Scheme 1, is frequently associated with phtbiocerol.

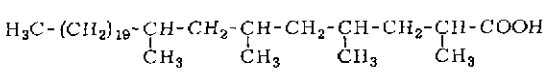
Scheme 1. Biosynthesis of phthiocerol.

n = 20 or 22



*C = carbon atom derived from sodium [3-$^{14}$C]propionate

°C = carbon atom derived from sodium [1-$^{14}$C]propionate



•C = carbon atom derived from [*Me*-$^{14}$C]methionine.

These results indicate again how dangerous it is to draw inferences about biogenetic reactions on grounds of structural analogy. Nature is much more imaginative than the "paper chemist".

The tubercle bacillus also uses propionic acid to huild up compounds with several methyl side-chains. There are two series of acids in this category: the α,β-unsaturated, dextrorotatory phthienoic acids *(5)* and the saturated, laevorotatory mycocerosic acids *(6)*.

*(5)*

*(6)*

[7] *M. Gastambide-Odier, J. M. Delaumény,* and *E. Lederer,* Chem. and Ind. *1963,* 1285.

The former appear only in virulent strains, and their biosynthesis has therefore not been studied very closely. The mycocerosic acids *(6)* are more easily available.

Preliminary experiments, performed a few years ago with *Grisebach,* using [*Me*-$^{3}$H,*carboxy*-$^{14}$C]propionic acid showed clearly that propionic acid is incorporated [8a]. In more recent experiments stress was laid on extreme purity of the $C_{32}$-mycocerosic acid; repeated gas chromatography of its methyl ester yielded this compound in homogeneous form, its purity being checked by mass spectrometry. The radioactive $C_{32}$-mycocerosic acid which was obtained by incubation of $H_{37}R_a$-bacilli with [1-$^{14}$C]propionic acid was then decarboxylated; 22 % of the radioactivity appeared as $CO_2$. Incorporation of 4 molecules of propionic acid would have given a value of 25 % [8b]. A radioactive $C_{26}$-mycocerosic acid was also obtained in this experiment.

It is perhaps superfluous to add that the incorporation of propionic acid into the branched-chain macrolides of streptomycetes has already been demonstrated by *Grisebach* and *Achenbach* [9], by *Kaneda* et al. [10] for erythromycin, by *Birch* et al. [11] for methymycin, by *Ollis* et al. [12] for ε-pyrromycinone, and by *Grisebach* and *Achenbach* [13] and by *Gilner* and *Srinivasan* [14] for magnamycin.

### b) Substances with Long Side-Chains

Prominent members of this group are the mycolic acids, *i.e.* "acids which have a long aliphatic side-chain in the α-position and a hydroxyl group in the β-position" [15].

To date, three types of mycolic acids have been isolated from acid-resistant bacteria:

1. From diphtheria bacilli (*Corynebacterium diphtheriae*) corynomycolic acid *(7)* [16] and corynomycolenic acid *(8)* [17] with 32 carbon atoms.

2. From *Nocardia* species, the nocardic acids *(9)* [18] with approximately 50 carbon atoms.

3. From mycobacteria, the mycolic acids *(10)* and *(11)* with 84–88 carbon atoms [1a–f, 15].

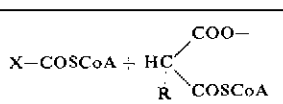
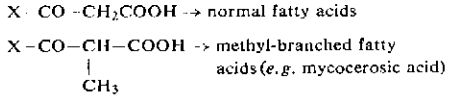
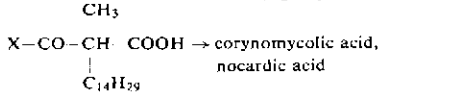
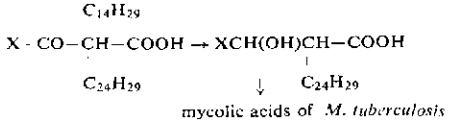
(11)









*Biosynthesis of the Mycolic Acids*

It was shown in experiments in collaboration with *Gastambide-Odier*, that incubation of live diphtheria bacilli with [1-$^{14}$C]palmitic acidy ields radioactive corynomycolic acid which, as expected, is labelled exclusively in carbon atoms 1 and 3. This demonstrates the direct condensation of two molecules of palmitic acid to the $C_{32}$-corynomycolic acid *(7)* [19]. It has not yet been shown whether this reaction scheme is also valid for the nocardic acids *(9)* and the mycolic acids *(10)* and *(11)* of mycobacteria. However, it can be assumed that the nocardic acids are built up from three molecules of long-chain fatty acids, and the mycolic acids from four molecules (*e.g.* $2\times C_{26} + 2\times C_{18} - C_{88}$). We have already published detailed reviews on this problem [1b -f].

Formulae *(10)* and *(11)* for the mycolic acids from *M. tuberculosis*, derived from the degradative studies of *Asselineau* [1c, 20] and from biogenetic considerations are only to be regarded as ideal cases; many structural variations are certainly possible.

Table 1 gives a generalized summary of the different possible fatty-acid syntheses, which probably all depend ultimately on the condensation of an acyl coenzyme A with a malonyl coenzyme A. Apparently the only variation is in the nature of this malonyl-CoA derivative.

Table 1. The biosynthesis of fatty acids in bacteria.

## II. Structures of Glycolipids, Peptidolipids, and Peptidoglycolipids

### a) Glycolipids

*Cord-Factor*

In 1960 we reported [1d] in detail upon the elucidation of the structure, the synthesis, and the biological activity of the cord factor [21a]. Formula *(12)* shows the structure of this trehalose 6,6′-dimycolate. Since then this formula has been confirmed chiefly by Japanese investigators; they also showed that in different strains the $C_{88}$-mycolic acid may be replaced by "shorter" mycolic acids (*e.g.* $C_{68}H_{136}O_4$) [21b].

(12)

The cord factors of *M. phlei* and *M. smegmatis* contain mycolic acids with two carboxyl groups (approx. $C_{67}H_{134}O_6$) [21c], while active cord-factor preparations containing dibasic mycolic acids of approximate formula $C_{84}H_{164}O_6$ have been isolated from *M. avium* [22].

Japanese authors [23] have recently isolated a diarabinose mycolate and a D-arabinose 5-*O*-mycolate from the "strongly bound" lipids of tubercle bacilli.

[21a] Elucidation of the structure of the cord factor: *H. Noll, H. Bloch, J. Asselineau*, and *E. Lederer*, Biochim. biophysica Acta *20*, 299 (1956). – Syntheses: *T. Gendre* and *E. Lederer*, Bull. Soc. Chim. France *1956*, 1478; *J. Polonsky, G. Ferréol, R. Toubiana*, and *E. Lederer*, ibid. *1956*, 1471; *G. Brochéré-Ferréol* and *J. Polonsky*, ibid. *1958*, 714. – Review articles: *H. Noll*, Adv. Tuberc. Res. *7*, 149 (1956); *E. Lederer*, Festschrift Arthur Stoll, Birkhäuser, Basel 1957, p. 384.

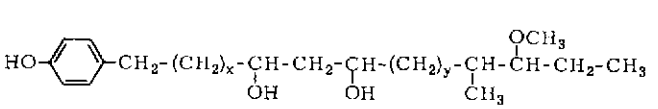
[23] *J. Azuma* and *Y. Yamamura*, J. Biochemistry (Tokyo) *52*, 142, 200 (1962); *53*, 275 (1963).

*Mycosides A and B*

The mycosides are "type-specific glycolipids from mycobacteria" [24]. The following three types are known at present [25]:

Mycoside A: characteristic of the so-called atypical photochromogenic strains (*M. kansasii*).

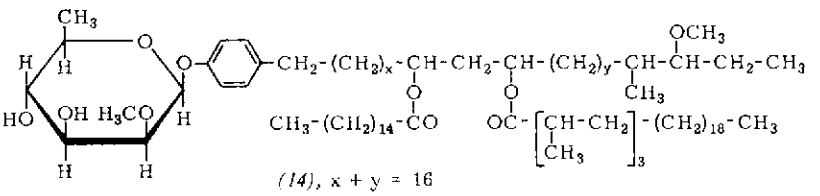
Mycoside B: characteristic of bovine strains.



Mycoside C: characteristic of avian and related strains. The first two groups are glycolipids; the 'C' mycosides are peptidoglycolipids and will be considered further below.

Mycoside A: the exact structure of this compound is not yet known; it is certainly very closely related to mycoside B, whose structure has recently been determined by *Demarteau-Ginsburg* [27].

Mycoside B: *Smith* et al. [26] showed this substance (m.p. 25 °C, $[\alpha]_D = -22°$) to be a glycolipid containing one molecule of 2-*O*-methylrhamnose and two molecules of mycocerosic acid in combination with an "aromatic analogue of phthiocerol".



The mycoside B which we analyzed contained one molecule of normal fatty acid (mainly palmitic acid) and one molecule of mycocerosic acid (mainly the $C_{29}$-mycocerosic acid). The sugar was identified as 2-*O*-methyl-D-rhamnose [27]. Elementary analysis and mass spectrometry of the "aromatic analogue of phthiocerol", which we call "phenol-glycol B", gave the formula $C_{32}H_{58}O_4$. Ultraviolet, infrared, and nuclear magnetic resonance measurements showed the presence of a *p*-phenol; mass spectrometry of the methyl ether of the phenol showed further that this substance contained the fragment $CH_3O{-}C_6H_4{-}CH_2$. The presence of a methoxy group as well as a probably secondary β-glycol grouping indicates a close similarity to phthiocerol; this was demonstrated by the mass spectrum. Peaks at mass numbers 73 and 101 tally with the mass spectrum of phthiocerol for the groups $-CH(OCH_3){-}CH_2{-}CH_3$ (m/e = 73) and $-CH(CH_3){-}CH(OCH_3){-}CH_2{-}CH_3$ (m/e = 101).

Both ends of the aliphatic chain of "phenol-glycol B" are thus defined, and it can be assigned the formula *(13)*.

x + y = 16 *(13)*

In mycoside B, the sugar is bound by a β-glycosidic linkage to the phenolic hydroxyl group of "phenol-glycol B". The two fatty acids are present as esters of the aliphatic hydroxyl groups. Mycoside B thus has the formula *(14)* [27].

*(14)*, x + y = 16

*Phospholipids*

The work of *Anderson* [1a] showed *inter alia* that the phospholipids of mycobacteria have low nitrogen contents, and contain inositol and D-mannose. A "mann-inositose" formed from two molecules of D-mannose and one molecule of *myo*-inositol was characterized [1a]. Recent work at Gif by *Vilkas*, in part with *Ballou*, has shown that the main types of nitrogen-free phospholipids occurring in human strains, in BCG [*] and in *M. phlei* are as follows [28]:

1. A sugar-free phosphoinositide in which, as in all other such compounds of plant or animal origin, the phosphoric acid is bound to the L-1-hydroxyl group of the *myo*-inositol.

2. A mono-α-D-mannopyranoside of a phosphoinositide; according to synthetic work of *Angyal* and *Shelton* [29] the mannose is bound to the D-1-hydroxyl of the *myo*-inositol.

3. A di-α-D-mannopyranoside of a phosphoinositide; according to *Vilkas*, an α-(1→6)-D-mannobiose is present [30].

4. A pentamannoside of a phosphoinositide [31, 32].

The presence of the trimannoside postulated by us earlier [1f] could not be confirmed recently.

The amino acids, chiefly L-ornithine, which were often found in phospholipids in earlier work [33], probably originate from contaminations by peptidolipids [34]. *Houtsmuller* and *Van Deenen* [35] have, however, recently isolated a phosphatidylglycerol from *M. cereus* which contains ornithine bound in an ester linkage (see also [36]).

**b) Peptidolipids**

The peptidolipids and peptidoglycolipids described below are remarkable for several reasons:

1. They represent a new form of fat-soluble peptide derivative.

[*] BCG = *Bacillus Calmette-Guérin.*

[36] *M. A. Lanéelle, G. Lanéelle*, and *J. Asselineau*, Biochim. biophysica Acta *70*, 99 (1963).

2. Almost without exception they contain one or more D-amino acids.

3. They occasionally contain types of amino acids which occur very seldom in nature.

4. Some of them have interesting biological properties.

The study of these well-defined compounds is also of interest in view of more recent theories [37] that a lipid-soluble stage is involved in protein synthesis.

Fortuitin ($C_{53}H_{95}N_7O_{11} \pm 2CH_2$, m. p. 199–202 °C, $[\alpha]_D = -72°$) was isolated from *M. fortuitum*; it contains a mixture of homologous fatty acids (chiefly palmitic acid) which are bound by amide links to a heptapeptide, $Val_3$, $Thr_2$, $Ala_1$, $Pro_1$ [38].

Fortuitin is the only compound in this group known at present, that contains only L-amino acids.

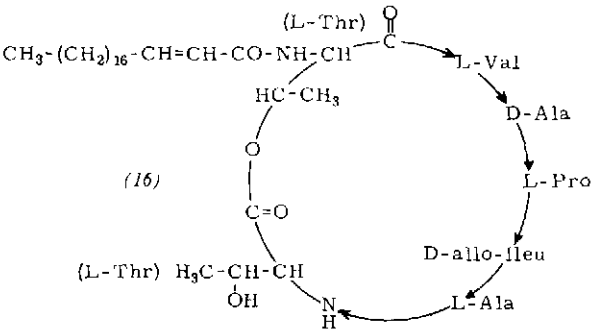
The presence of a methoxy group, the neutral reaction of fortuitin, and its positive hydroxamate reaction indicate that the peptide chain is esterified by methanol; the NMR spectrum of fortuitin does in fact show a signal at 3.64 ppm which could indicate a methoxycarbonyl group.

$$CH_3(CH_2)_nCO\text{-}Val\text{-}Val\text{-}Val\text{-}\overbrace{Thr\text{-}Thr}^{Ac}\text{-}Ala\text{-}Pro\text{-}OCH_3$$

*(15)*, n = 16, 18, 20

Partial hydrolysis by chemical and enzymatic means has finally led to the formula *(15)* for fortuitin [39], in which a molecule of acetic acid esterifies the hydroxyl group of one of the threonine molecules.

Peptidolipin NA: In 1958 we described, with *Guinand* and *Michel* [40], a mixture of peptidolipids which was isolated from *Nocardia asteroides*; recently *Guinand* and *Michel* [41] succeeded in separating a pure compound from this mixture by counter-current distribution. The name peptidolipin NA was proposed; the substance (m. p. 232–233 °C; $[\alpha]_D = +42°$; $C_{47}H_{83}N_7O_{12}$) contains a fatty acid which is bound by an amide link to a heptapeptide L-$Thr_2$, L-$Ala_1$, D-$Ala_1$, L-$Val_1$, D-*allo*-$Ileu_1$, L-$Pro_1$.



D-*allo*-Isoleucine, found in peptidolipin NA by *Ikawa* and *Snell* [42], has up till now only been isolated from actinomycin $C_3$ by *Brockmann* et al. [43].

The fatty acid obtained by vigorous acidic hydrolysis of peptidolipin NA has been demonstrated to be homogeneous by gas chromatography, and identified as *trans*-2-eicosenoic acid [44].

Partial acidic hydrolysis yields an *N*-acyl-L-threonine, free L-threonine, and a hexapeptide L-Thr-L-Val-D-Ala-L-Pro-D-*allo*-Ileu-L-Ala.

Since peptidolipin NA has no free carboxyl group, gives a positive hydroxylamine reaction, and on reduction with $LiAlH_4$ gives threoninol [45], we assume that it has a cyclic structure in which the carboxyl group of one threonine molecule is esterified with the hydroxyl group of the second.

Careful hydrolysis with acid opens the ring at the ester linkage, and a substance is obtained which still contains the fatty acid, as well as all seven amino acids. A *C*-terminal threonine is then found in this compound.

Formula *(16)* explains satisfactorily all the reactions of peptidolipin NA [44] [*]. It is reminiscent of the structures of several antibiotics, *e.g.* etamycin [46] and telomycin [47], actinomycin [48], staphylomycin [49] and ostreogrycin [50]; all of these have a lactone ring containing 5–7 amino acids, in which an *N*-acylated molecule of threonine closes the ring.

Peptidolipids from *M. paratuberculosis*. *Lanéelle* and *Asselineau* [51] isolated a mixture of peptidolipids from *M. paratuberculosis (M. johnei)*; the main fraction appears to be the n-eicosamide of a tetrapeptide containing one molecule each of D- and L-phenylalanine and two molecules of L-alanine; the *C*-carboxyl group of the peptide chain is again esterified with methanol.

### c) Peptidoglycolipids

*The Mycosides C*

Two representatives of this group have been examined in detail, *viz.* mycoside $C_2$ (m.p. 200 °C; $[\alpha]_D = -34°$; $C_{89}H_{153}N_5O_{21} \pm 3\ CH_2$) from *M. avium* [52], and

[44] *M. Guinand*, *G. Michel*, and *E. Lederer*, unpublished work.

[45] Not alaninol as was stated erroneously in a previous communication [41].

[*] Recent experiments seem to indicate that *trans*-2-eicosenoic acid is formed during hydrolysis of peptidolipin NA with strong acid by a β-elimination from 3-hydroxyeicosanoic acid; the hydroxyl group of this acid is most probably esterified with the carboxyl group of the *C*-terminal threonine. Both threonine molecules would then have their hydroxyl groups free, and formula *(16)* for peptidolipin NA would have to be modified.

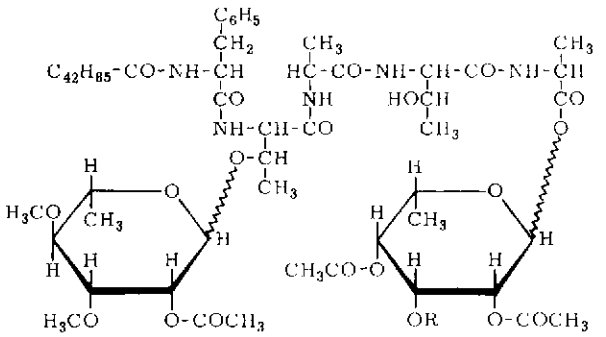
[51] *G. Lanéelle* and *J. Asselineau*, Biochim. biophysica Acta *59*, 731 (1962).

[52] *M. Chapat*, *G. Michel*, and *E. Lederer*, Biochim. biophysica Acta *78*, 329 (1963).

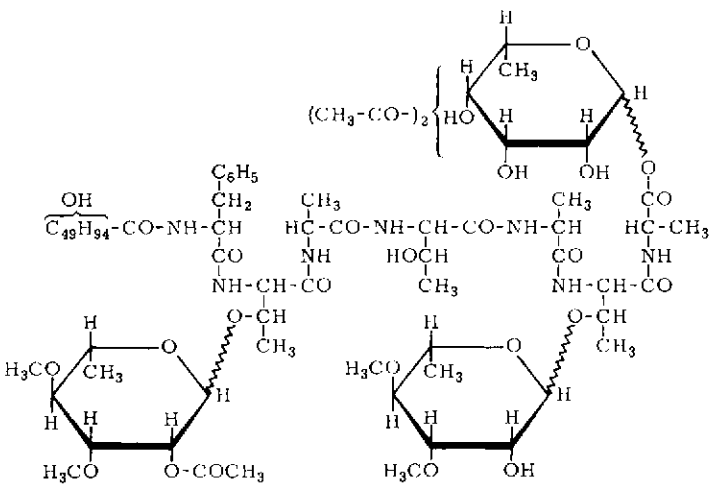
mycoside $C_m$ (m.p. 198–200 °C; $[\alpha]_D$ = −31 °; $C_{108}H_{185}N_7O_{28}$ ± 3 $CH_2$) from *M. marianum* [53].

Both compounds have the following properties:



1. The lipid portion is bound by an amide link to the amino group of a molecule of D-phenylalanine; the latter is the *N*-terminal amino acid of an oligopeptide.

2. The peptide moiety has the structure D-Phe-(D-*allo*-Thr-D-Ala)$_n$, where n = 2 for mycoside $C_2$ and n = 3 for mycoside $C_m$. It is noteworthy that only D-amino acids are present; moreover, this is the first time that D-*allo*-threonine has been found in nature [54].



3. The *C*-terminal carboxyl group of a molecule of D-alanine is bound by an ester link to the reducing hydroxyl of a deoxysugar. This linkage is readily hydrolysed by hydroxylamine with liberation of the sugar. Sodium borohydride reduces the linkage to form the corresponding deoxyhexitol; this establishes that the carboxyl group of the amino acid is bound to the reducing hydroxyl group of the deoxysugar.

4. One or two molecules of deoxysugar are bound to the hydroxyl group of one or two molecules of D-*allo*-threonine.

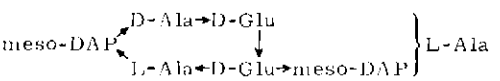
5. Two to three molecules of acetic acid esterify the remaining free hydroxyl groups of the sugar in these mycosides.

*(17)*, Mycoside $C_2$, R = H, $CH_3$

*(18)*, Mycoside $C_m$

With *Chaput* and *Michel* [53], the formulae *(17)* and *(18)* were proposed for the two mycosides [*]; mycoside $C_2$ is actually a mixture of two peptidoglycolipids, one of which has 6-deoxy-L-talose at the end of the peptide chain, and the other 3-*O*-methyl-6-deoxy-L-talose. Further details of the structure determination are to be found in the complete reports [52,53].

It is remarkable that three different methods are used here by nature to make a sugar fat-soluble: reduction of the hydroxymethyl group in position 6 to a methyl group, *O*-methylation, and *O*-acetylation.



### *Wax D*

All mycobacterial strains contain 2–8 % of a glycolipid fraction which can be extracted with chloroform and which is insoluble in boiling acetone [1b–f]. The main components of these so-called wax D fractions of bovine, avian, and saprophytic strains are glycolipids which contain no amino acids and in which the mycolic acids are esterified by a polysaccharide containing arabinose, galactose, and mannose. The wax D fractions of human strains of *M. tuberculosis* also contain a peptide portion and amino sugars bound to the polysaccharide. The peptide component is especially interesting as it appears to be necessary for the immunological adjuvant activity [**] of the wax D fractions.

This peptide portion contains the typical "cell-wall amino acids" of mycobacteria, namely *meso*-α,α'-diaminopimelic acid (*meso*-DAP), D-glutamic acid, and D- and L-alanine [55]. In most cases the proportions are almost exactly *meso*-$DAP_2$, D-$Glu_2$, D-$Ala_1$, L-$Ala_2$ [56]. These seven amino acid molecules form a heptapeptide for which two tentative structures, *(19)* or *(20)*, have been considered [57].

meso-DAP-D-Ala-D-Glu-D-Glu-L-Ala-meso-DAP-L-Ala

*(19)*

*(20)*

The linkage binding the heptapeptide to the polysaccharide is resistant to reduction with sodium borohydride and to 0.01 N NaOH; this behavior appears to rule out an ester bond. In fact, the heptapeptide is clearly joined by the carboxyl group of one *meso*-DAP to the amino group of galactosamine by an amide link; the amino sugar is bound to arabinose by a glycosidic linkage.

[*] The formula of the lipid fragment is derived only from the elemental analysis of the intact mycoside by subtraction of the amino acids and sugars. The material is actually a complex mixture.

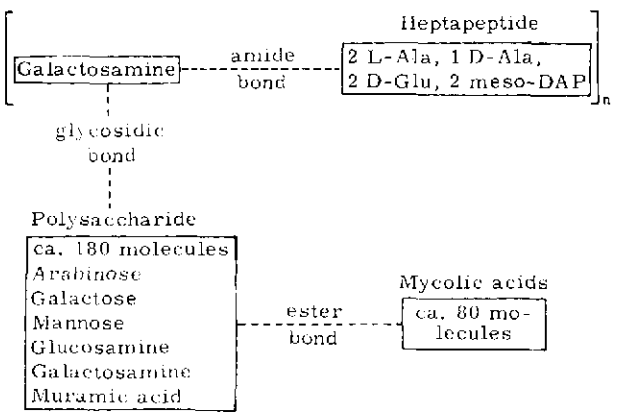
[**] An adjuvant is a substance which, when applied together with an antigen, stimulates the formation of antibodies (see below).

[53] *M. Chaput, G. Michel,* and *E. Lederer,* Biochim. biophysica Acta *63,* 310 (1962).

[54] *M. Ikawa, E. E. Snell,* and *E. Lederer,* Nature (London) *188,* 558 (1960).

[55] *C.S.Cummins* and *H.Harris,* J.gen.Microbiol. *18,* 173 (1958).

[56] *J. Asselineau, H. Buc, P. Jollès,* and *E. Lederer,* Bull. Soc. Chim. biol. *40,* 1953 (1958).



[57] *P. Jollès, H. Nguyen-Trung-Luong-Cros,* and *E. Lederer,* Biochim. biophysica Acta *43,* 559 (1960).

Resolution of wax D from human strains into several distinctly different fractions was recently achieved by ultracentrifugation in ether [58]:

1. a "light" fraction (6–10 % of the wax D), which remained soluble in ether, is free from amino acids and shows no adjuvant activity, and

2. several "heavy" fractions which sedimented after 15–150 minutes. All the "heavy" fractions contained the amino acids already mentioned, in the rough proportion *meso*-$DAP_2$, $Glu_2$, $Ala_3$. In one fraction one Glu is replaced by Gly.

The presence of muramic acid (3-*O*-lactyl-D-glucosamine) was first established in these fractions which had been purified by ultracentrifugation; this again indicates the biochemical analogy between wax D and the cell wall [59].

*(21)*, n = 1, 2, 3

All our results concerning the wax D of human strains seem to indicate that one, two, or three molecules of heptapeptide are bound to the polysaccharide through galactosamine. Formula *(21)* shows a hypothetical structure.

From the results of the ultracentrifugation of the water-soluble fraction of the wax D, the molecular weight of the peptide-containing mucopolysaccharide is about 35000. As the wax D contains about 25 % mucopolysaccharide, the minimum molecular weight of the intact wax D is approximately 140000. Ultracentrifugation of ether solutions of wax D from bovine, avian, and saprophytic strains has yielded similar fractions, but with the difference that the "heavy" fraction is normally obtained only in small amount, the major part remaining in the ether. These soluble fractions contain no amino acids and are inactive as adjuvants [59, 60].

Several "heavy" fractions from *M. avium* and *M. phlei* contain a peptide portion which is very similar to that of the wax D from human strains; these fractions also have adjuvant activity.

The wax D of the so-called "atypical photochromogenic" strains (*M. kansasii*) occupy a special position; they behave exactly like the wax D of human strains on ultracentrifugation in ether: they are almost entirely sedimented, and contain the typical heptapeptide and amino sugars; they are active as adjuvants [59, 60].

## III. Biological Activity

Table 2 gives a summary of the biological activities of the lipid fractions from the tubercle bacillus.

Only older data are available concerning the development of the tubercle; these were reviewed in 1960 [1d].

Table 2. Relationships between the biological activity and the chemical constitution of the lipids from tubercle bacilli.

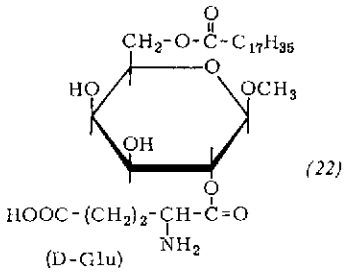
| Biological action | Chemical constitution of the lipid |
|---|---|
| Formations of tubercles | Branched-chain fatty acids (phthienoic acids, mycocerosic acids, mycolic acids and their esters) |
| Loss of weight, haemorrhage, death | Cord factor (trehalose 6,6'-dimycolate) |
| Adjuvant action, granuloma, delayed hypersensitivity | Wax D (peptidoglycolipids) |
| Immunization | Phosphoglycolipids (?) |

During recent years we have been chiefly interested in adjuvant activity and immunization.

### a) Adjuvant Activity

It is known, mainly from the work of *Freund* [61], that killed tubercle bacilli suspended in paraffin oil exhibit an adjuvant effect; injection of an animal with the bacterial suspension together with an antigen, leads to a marked rise in antibody formation. *White, Bernstock, Johns,* and *Lederer* [62] demonstrated that the wax D fractions are responsible for this activity and that only the wax D of human strains, *i.e.* only those in which the three amino acids Ala, Glu, and *meso*-α,α'-diaminopimelic acid occur, are active.

Since then wax D fractions have been purified further and it has been found, as already mentioned, that wax D of non-human strains also contains a small amount of peptidoglycolipid, which is chemically very similar to the main fraction of the wax D of human strains [59].



The biological experiments of *White* at London Hospital have shown that only the fractions containing the heptapeptide $DAP_2$, D-$Glu_2$, $Ala_3$ exhibit adjuvant activity. This activity appears to be proportional to the amount of the heptapeptide present in the wax D [62a]. The following substances are inactive: the water-soluble portion of the wax D, mycolic acids, the waxes A, B, and C, fortuitin, peptidolipin NA, mycosides $C_2$ and $C_m$, a synthetic galactolipid *(22)*, methyl 6-*O*-stearyl-2-

[61] *J. Freund,* Adv. Tuberc. Res. *7*, 130 (1956).

[62] *R. G. White, L. Bernstock, R. G. S. Johns,* and *E. Lederer,* Immunology *1*, 54 (1958).

[62a] *R. G. White,* unpublished work.

D-glutamyl-β-D-galactopyranoside [63], and the distearylamide of dimethyl *meso*-α,α'-diaminopimelate.

(22)

According to *White*, the adjuvant activity always parallels the formation of a granuloma at the point of injection, and the delayed hypersensitivity typical of tuberculosis [*].

It should be noted further that the adjuvant activity of the wax D lasts much longer than that brought about by the endotoxins of Gram-negative bacteria [65].

We are currently working with *Bricas* [66] on the use of enzymes in the stereospecific preparation of peptides of *meso*-α,α'-diaminopimelic acid; such peptides will have to be linked to mycolic esters of sugars, in order to obtain synthetic adjuvants.

### b) Immunization

Most authors seem to agree that neither tuberculin, nor other proteins or polysaccharides of the tubercle bacillus are able to immunize animals against experimental tuberculosis.

On the other hand, there are some reports that more or less purified lipid fractions have this property. Thus, over 30 years ago, *Boquet* and *Nègre* [67], at the Pasteur Institute in Paris, prepared a methanol extract of *M. tuberculosis* which they called "antigène méthylique" and with which they were able to immunize animals against tuberculosis. These results were confirmed and extended in 1956 by *Weiss* and *Dubos* [68]. Since then we also have been interested in this fraction, whose immunogenic activity was tested on mice by *H. Bloch*. For some time the activity appeared to be concentrated in an ether-insoluble phosphatide fraction, and we thought we had obtained a pure fraction analysing as phosphatidylinositotrimannoside [11]; this, however, has not been confirmed, so that the immunizing substance (or substances) in "antigène méthylique" have still to be identified.

There are also reports on the immunizing activity of so-called PmKo [69], a lipid fraction which is chemically very closely related to the wax D we have described. According to *Crowle* [70] three out of four such PmKo preparations were active; the same author also found wax B to be active, a behavior which hitherto had not been observed.

*Larson, Ribi* et al. [71] found that cell walls of *M. tuberculosis* (BCG) have no immunizing activity when the bacilli are broken up in water, but only when this is done in paraffin oil. The explanation for this finding is not yet clear.

On the other hand, it is probable *a priori*, that a strong immunity, comparable to that brought about by BCG, can only be produced by the application of two or more antigens. Indications of such duality are seen in the work of *Williams* and *Dubos* [72].

The problem is, moreover, complicated by the simultaneous appearance of "non-specific resistance", which can also be brought about by the endotoxins of Gram-negative bacteria.

*The present work was supported by the Fondation Waksmann pour le Développement des Recherches Microbiologiques en France, and by Grant AI-02838 of the National Institute of Allergy and Infectious Diseases (U.S. Public Health Service). The supply of isotopes was made possible by a grant of the Commissariat à l'Energie Atomique (Saclay).*

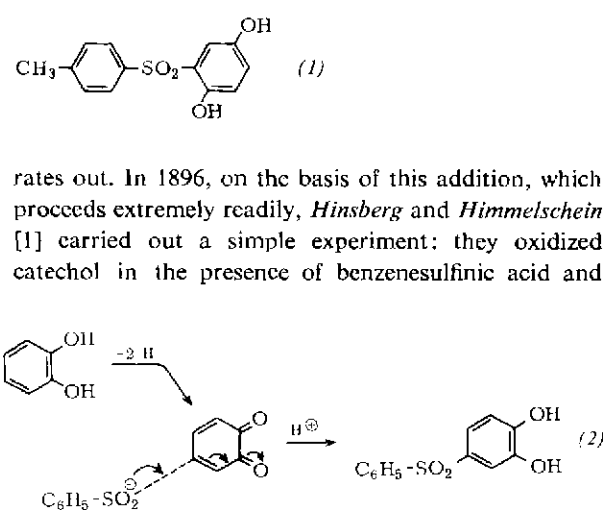
# New Methods of Preparative Organic Chemistry IV [*]

## Syntheses with Nascent Quinones

BY PROF. DR. H. W. WANZLICK



FROM WORK CARRIED OUT IN COLLABORATION WITH DIPL.-ING. M. LEHMANN-HORCHLER, DR. S. MOHRMANN, DIPL.-ING. R. GRITZKY, DIPL.-ING. H. HEIDEPRIEM, AND DIPL.-CHEM. B. PANKOW

ORGANISCH-CHEMISCHES INSTITUT DER TECHNISCHEN UNIVERSITÄT BERLIN (GERMANY)

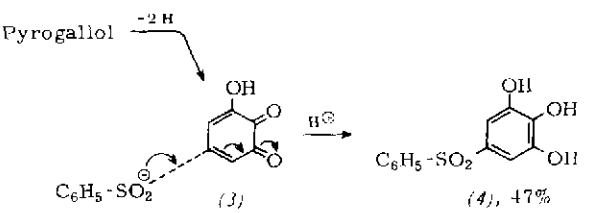
*If catechol or other hydroquinones are dehydrogenated in the presence of a nucleophilic reagent, the latter reacts, usually by Michael addition, with the quinone formed in situ. The wide range of possible variations offered by this synthetic method is comprehensively described in the present paper. Procedures are given for carrying out typical reactions.*

### 1. Introduction

*Demonstration Experiment*: A solution of 3 g of sodium *p*-toluenesulfinate in 50 ml of water and 10 ml of acetic acid is poured into a solution of 1 g of *p*-benzoquinone in 10 ml of acetic acid and 50 ml of water. The mixture is decolorized within a few seconds and purely white 2,5-dihydroxyphenyl *p*-tolyl sulfone *(1)* immediately separates out. In 1896, on the basis of this addition, which proceeds extremely readily, *Hinsberg* and *Himmelschein* [1] carried out a simple experiment: they oxidized catechol in the presence of benzenesulfinic acid and

obtained the sulfone *(2)*. Their clear conception of this experiment, which is given here in its modern formulation, is shown by their own words [1]:

"Benzenesulfinic acid combines with quinones and iminoquinones, and reacts rapidly at normal temperatures to yield hydroxy or amino derivatives of sulfones [2]. If benzenesulfinic acid is present at the moment of formation of a quinone (or iminoquinone) of low stability, the former is converted into the corresponding sulfone, and is thus prevented from reacting further..... the formation of a hydroxy or amino sulfone indicates that the quinone was present in the oxidation mixture, even if only for a short time."



This analytical conception contains a synthetical principle, an account of which is given below. The syntheses in question have the following point in common: dehydrogenation of catechol or another quinone former in the presence of a nucleophilic reagent yields a product which is (normally) formed by Michael addition of the nucleophile onto the quinone produced *in situ*.

### 2. Simple Examples

#### a) Additions of Sulfinic Acids, Sulfite, and Thiourea

In the course of work on the mechanism of the formation of purpurogallin, *Horner* et al. studied the dehydrogenation of pyrogallol in the presence of benzenesulfinic acid to form the sulfone *(4)* [3,4].

The sulfinic acid adds onto the 3-hydroxy-*o*-benzoquinone *(3)* formed *in situ*; *(3)* has never been isolated.

Dehydrogenation of alizarin *(5)* in the presence of *p*-toluenesulfinic acid leads via the *o*-quinone *(6)* to the sulfone *(7)* [5]. Sulfite can also add onto *(6)* to form the sulfonic acid *(8)*.

[*] The papers of the previous three series are collected in three volumes published in English by Academic Press, New York, London.

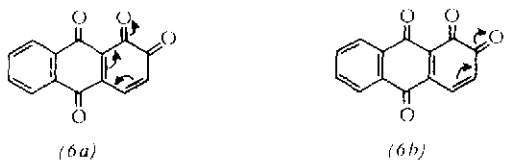
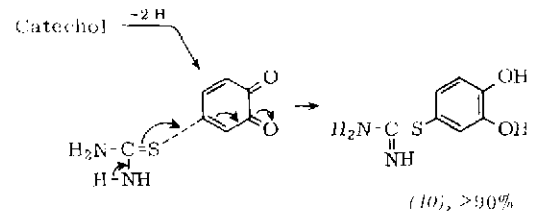
[2] *O. Hinsberg*, Ber. dtsch. chem. Ges. *27*, 3259 (1894); *28*, 1315 (1895).



[3] *L. Horner* and *W. Dürckheimer*, Z. Naturforsch. *14b*, 743, 744 (1959).

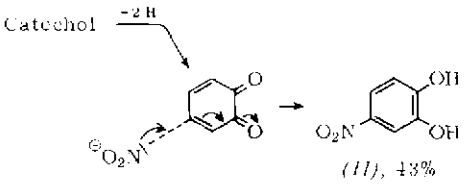
[4] *L. Horner* and *S. Göwecke*, Chem. Ber. *94*, 1267 (1961); *L. Horner, K. H. Weber*, and *W. Dürckheimer*, ibid. *94*, 2881 (1961).



[5] *H. Heidepriem*, Ph. D. Thesis, Technische Universität Berlin, 1964.

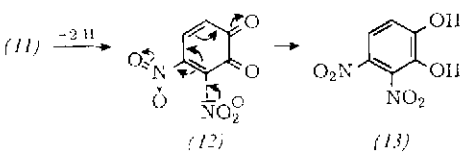
The addition in the 3-position is remarkable. It means that polarization of the diquinone *(6)*, which is so far only known in solution [6], in the direction indicated in *(6a)* predominates over the expected polarization *(6b)*.

The addition of thiourea onto nascent *o*-benzoquinone proceeds satisfactorily [7] to yield *S*-(3,4-dihydroxyphenyl)isothiourea *(10)*.



*Procedure:*

A solution of 65 g of potassium hexacyanoferrate(III) and 100 g of crystalline sodium acetate in 230 ml of water is rapidly added dropwise to a mechanically stirred solution of 13 g of catechol and 7.6 g of thiourea in 100 ml of water. The reaction product begins to separate out even during the dropwise addition. Further 100 g of crystalline sodium acetate are added, and the mixture is stirred for another hour, filtered by suction, and washed with a little water. The crude product is purified by dissolving it in dilute hydrochloric acid and stirring the clarified solution into a concentrated sodium acetate solution. The acetate of *S*-(3,4-dihydroxyphenyl)isothiourea *(10)* is obtained in over 90 % yield. M.p. ca. 180 °C (decomp.).



### b) Nitrite Addition

In 1878, *Benedikt* [8] discovered an unusual route to 4-nitrocatechol *(11)* by treatment of pyrocatechol with nitrous acid. A more recent, improved procedure [9] gives yields of up to 37 %. Increase in the quantity of nitrite used leads to 3,4-dinitrocatechol *(13)* as the principal product [9]. Nothing was previously known of the mechanism of the reaction.

On the basis of the idea that the reaction might proceed via *o*-benzoquinone as an intermediate, the nitrous acid playing the double role of dehydrogenating agent and nucleophilic reagent, we developed a new, simple procedure in which catechol is dehydrogenated with $K_3Fe(CN)_6$ in the presence of sodium nitrite [10].

Preliminary experiments showed that repeated dehydrogenation of *(11)* in the presence of nitrite leads to *(13)* [5]. The electron-attracting effects of the carbonyl and nitro groups indicated in *(12)* must be jointly responsible for the entry of the second nitro group [11] at position 3.

*Procedure:*

A solution of 20 g of potassium hexacyanoferrate(III) and 17 g of crystalline sodium acetate in 100 ml of water is added to a solution of 3.3 g of catechol, 2.1 g of sodium nitrite, and 2.2 g of crystalline sodium acetate in 50 ml of water. The resulting dark red mixture is filtered after 5 minutes and extracted with 200 ml of ether in several portions. The extract is dried with sodium sulfate, the ether is distilled off, and the brownish residue is pressed out on porous tile to yield about 2 g (43 %) of practically pure 4-nitrocatechol *(11)*. This may be completely purified by recrystallization from water or by sublimation *in vacuo*. M.p. 174 °C.

Dehydrogenation of alizarin *(5)* in the presence of nitrite yields alizarin orange *(9)* [5].

### c) Amine Addition

Since the groups introduced into the phenols in Sections 2a) and 2b) increase their oxidation potentials [12], it is easy to find conditions under which the reaction can be stopped after completion of the first dehydrogenation-addition process. On the other hand, if substituents which decrease the oxidation potential [12] are introduced, then secondary reactions become inavoidable. The formation of 4,5-dianilino-*o*-benzo-

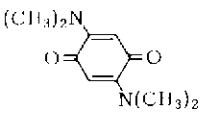
[11] Compare this with the formation of 2,3-dicyanohydroquinone (*J. Thiele* and *J. Meisenheimer*, Ber. dtsch. chem. Ges. *33*, 675 (1900)]. The participation of the carbonyl group at C-9 in promoting the polarization in *(6a)* should also be taken into consideration in the additions of alizarinquinone *(6)*.

[12] *L. F. Fieser* and *M. Fieser:* Organic Chemistry. 2nd Edit., Heath, Boston 1950, p. 755.

quinone *(15)* during the dehydrogenation of catechol in the presence of aniline has long been known [13]. The widely adaptable synthesis which involves the series of steps D–A–D A–D [14] is the subject of recent patents [15]. *Horner* and *Lang* [16] added secondary amines onto *o*-quinones produced *in situ* and obtained *inter alia* the aminoquinones *(14)*, *(16)*, and *(17)*.

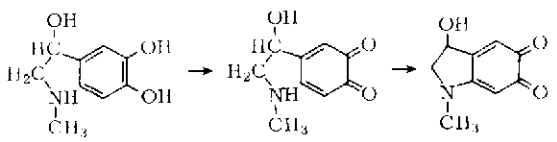
*(14)*, 84%



*(15)*, R = $C_6H_5$-NH-
*(16)*, R = $(CH_3)_2N$-, 53%
*(17)*, R = $(CH_2)_2N$-, 72%

*N*-Methylaniline adds on only once. The steps in the formation of *(14)* are therefore D–A–D [14].

*Procedure:*



Catechol (0.55 g) is dissolved in 100 ml of acetone, and 7 g of silver oxide and 10 g of calcined sodium sulfate are added. The solution is cooled to 0 °C, treated with 2 ml of dimethylamine from a well-cooled pipet, and shaken. Processing after 10 minutes gives *(16)*, m.p. 149 °C (decomp.), in 53 % yield.

Cu(II)-catalysed autoxidation of hydroquinone in the presence of dimethylamine leads quantitatively to *(18)* [17].

*(18)*, 100%

Intramolecular amine additions are also possible and have been known for some time. The formation of adrenochrome *(21)* has been studied particularly thoroughly and might also be mentioned and formulated at this point [18].

*(19)* *(20)* *(21)*, 60%

Dehydrogenation of epinephrine *(19)* initially gives rise to *(20)*, which can be detected for a short time [19]. Subsequent A–D steps [14] lead to the formation of adrenochrome *(21)*.

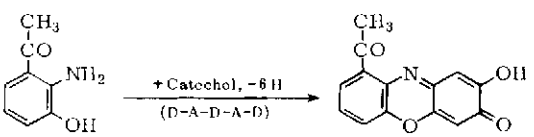
### d) Additions of Water and Alcohols

Only one example can be given here for the addition of water and alcohols onto nascent quinones. *Horner* and *Göwecke* dehydrogenated catechol in methanolic mineral acid solution and obtained products, *e.g. (22)* from 3-methoxycatechol, which are formed by way of hemiketals [20].



*(22)*, 71%

If isolated *o*-quinones are used as such in this reaction, methoxylation only occurs in particular cases and in considerably poorer yields.

## 3. Bifunctional Addends

The initial product of the reaction of an amine with *o*-benzoquinone is the monoaminoquinone of type *(14)*. If the amine contains another nucleophilic group in a favorable position, intramolecular secondary reactions take place.

In work on insect pigments, *Butenandt* et al. [21, 22] were able to show that dehydrogenation of catechol in the presence of the *o*-aminophenol *(23)* yields 5-acetyl-3-hydroxy-2-phenoxazone *(24)* [23].

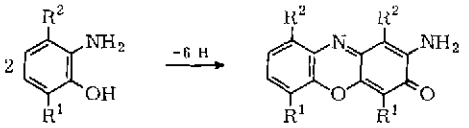
*(23)* *(24)*, 43%

*Procedure:*

A suspension of 200 mg of 2-amino-3-hydroxyacetophenone hydrochloride, 200 mg of catechol, and 2.1 g of powdered potassium hexacyanoferrate(III) is prepared in 5 ml of acetic acid dried over copper sulfate, and the mixture is shaken in an atmosphere of carbon dioxide at room temperature. Separation of the product starts right at the beginning of the reaction and is brought to completion by controlled addition of water. Compound *(24)* is obtained in 43 % yield, m.p. > 400 °C.

A fundamentally similar combination takes place when *o*-aminophenols are dehydrogenated alone; the products are 3-amino-2-phenoxazones. Important syntheses of natural products may be quoted in this connection: in particular those of *Brockmann* et al. in the series of

[19] *A. Kodja* and *S. Bouchilloux*, C. R. Séances Soc. Biol. Filiales *153*, 1407 (1959); Chem. Zbl. *1960*, 15436.



[20] For details of the mechanism, see *L. Horner* and *S. Göwecke*, Chem. Ber. *94*, 1291 (1961).

[21] *A. Butenandt*, Angew. Chem. *69*, 16 (1957).

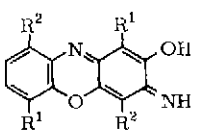
[22] *A. Butenandt*, Verhandl. Ges. dtsch. Naturforscher, Ärzte *1959*, 152.

[23] *A. Butenandt*, *E. Biekert*, and *G. Neubert*, Liebigs Ann. Chem. *602*, 72 (1957).

actinomycins [24,25] and those of *Butenandt* et al. in the field of ommochromes [21,22]. The dehydrogenation of 2-amino-3-hydroxyacetophenone *(23)* proceeds smoothly to yield 3-amino-4,5-diacetyl-2-phenoxazone *(25)* [26]. 3-Hydroxykynurenine *(26)* yields *(27)*, which can be converted into the ommochrome xanthommatin [26,27].

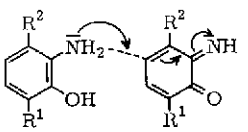
*(23)*, $R^1$ = H, $R^2$ = CO-$CH_3$ — *(25)*, 80%

*(26)*, $R^1$ = H, $R^2$ = CO-$CH_2$-CH($NH_2$)COOH — *(27)*, 90%



*(28)*, $R^1$ = $CH_3$, $R^2$ = $COOCH_3$ — *(29)*, 67%

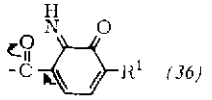
*(30)*, $R^1$ = $CH_3$, $R^2$ = CO-NH-$CH_2$-$COOCH_3$ — *(31)*, >90%



*(32)*, $R^1$ = H, $R^2$ = COOH — *(33)*, 50%

Dehydrogenation of *(28)* yields *(29)*, *i.e.* the chromophore of the actinomycins [28], and actinocylbis(glycine methyl ester) *(31)* is obtained from *(30)* [28]. These results finally led to the total synthesis of actinomycin $C_3$ by a similar method [24].

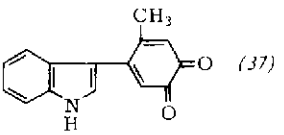
There is no doubt that these syntheses largely correspond to the course of the biosynthesis [28,28a], as is also true of the biogenesis of cinnabaric acid *(33)* and similar natural products [29]. The dehydrogenation of *(32)*, which results in the formation of *(33)*, was carried out even before the discovery of the natural product [30]. One prerequisite for the smooth occurrence of these phenoxazone syntheses is the "correct" combination of the aminophenol with the iminoquinone formed from it *in situ*; compounds of type *(34)* do not occur at all, or are only present as by-products.



*(34)*

*(35)*

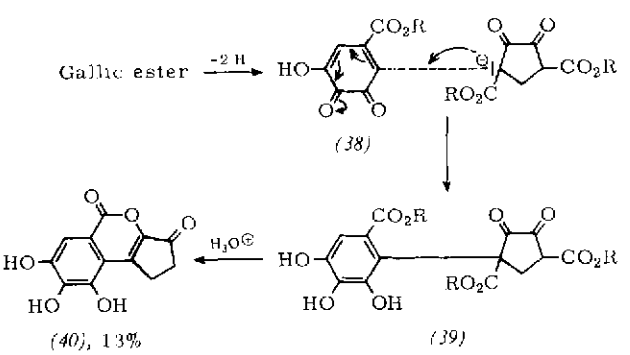
The strongly nucleophilic character of the amino group and the extreme proneness of the group C=C-C=N- to undergo addition reactions (greater than that of the system C=C-C=O [31]) must be assumed to determine the direction of the primary addition to give preferentially *(35)*. Since, in the syntheses considered in the present paper, the residue $R^2$ contains a carbonyl group attached directly to the ring, it is possible that the



*(36)*

primary addition formulated in *(35)* is further promoted by polarization in the sense shown in *(36)* (cf. *(12)* and [11]).

## 4. C-C Bonding



In the course of their investigations on the formation of melanins, *Bu'Lock* and *Harley-Mason* [32] dehydrogenated 4-methylcatechol in the presence of indole and obtained *(37)*.

*(37)*

To our knowledge, this is the first case of intentional formation of a C–C bond via a nascent quinone.

We found the conditions (D–A [14]) particularly simple in the synthesis of brevifolin *(40)* [34], a tannin constituent discovered and identified by *Schmidt* and *Bernauer* [33]. Gallic ester is dehydrogenated in the presence of cyclopentane-1,2-dione-3,5-dicarboxylic ester; Michael addition of this CH-acidic compound onto the *o*-quinone *(38)* which occurs as an intermediate (but which has not yet been isolated) yields *(39)*, which is converted into *(40)* simply by treatment with acid.

*(40)*, 13% — *(39)* — *(38)*

If the coreactant contains an active methylene group, the primary adduct is readily dehydrogenated further. Pyrocatechol and isopropylidene malonate (Meldrum's acid) *(41)* yield *(42a,b)*; it is the quinone-methide form *(42b)* that occurs in red crystals [10]. The mesomeric anion corresponding to the tautomers *(42a,b)* is intensely

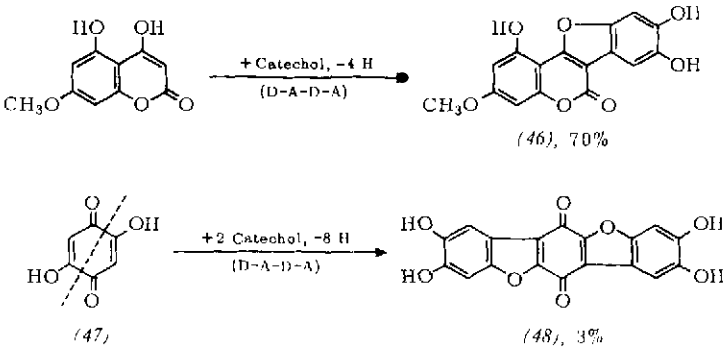
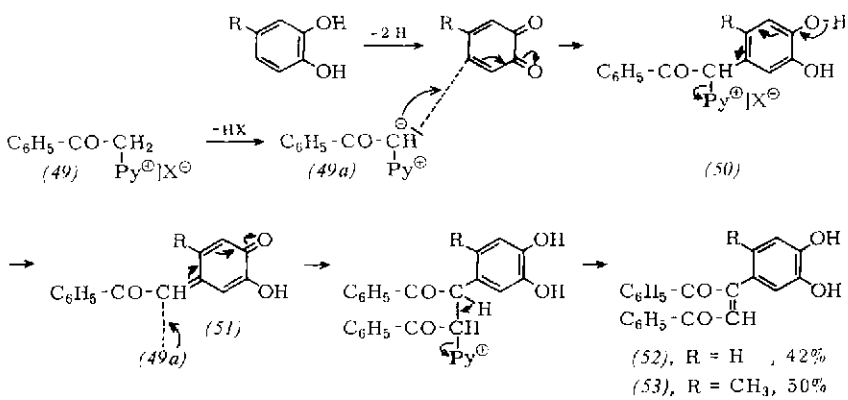
blue, and aqueous solutions of the alkaline salts are stable for some time.



If *(41)* is replaced by dimedone *(43)*, the corresponding product *(44)* cannot be isolated (but can be observed for a short time in solution, see below). A subsequent spontaneous intramolecular addition leads to the formation of the cumarone derivative *(45)* [35,36].

*Procedure:*

A solution of 3 g of potassium hexacyanoferrate(III) in 30 ml of water is added in two portions to a solution of 1 g of catechol, 2 g of dimedone, and 12 g of sodium bicarbonate in 150 ml of water. The resulting blue color is visible for a few seconds. The cumarone derivative *(45)*, m.p. ca. 280 °C (decomp.), precipitates out immediately.



This new synthesis of 5,6-dihydroxycumarone derivatives of type *(45)* is very adaptable. Thus, wedelolactone *(46)* [35], which was isolated and whose structure was elucidated by *Govindachari* et al. [37], and thelephoric acid *(48)* [5], the constitution of which was first recognized and which was synthetized by a classical method by *Gripenberg* [38], can be prepared without appreciable difficulty.

The 2,5-dihydroxy-*p*-benzoquinone *(47)* used in the synthesis of thelephoric acid functions as a double 1,3-dicarbonyl system in the sense indicated.

The strong tendency of pyridinium salts of type *(49)* to undergo addition and condensation reactions is known from the comprehensive investigations of *Kröhnke* et al. [39]. Additions onto quinones introduced as such gave remarkable results [40]. It was therefore natural to attempt similar syntheses with nascent quinones.

If catechol is dehydrogenated in the presence of *(49)*, the product is the dibenzoylethylene derivative *(52)*. The reason for this surprising result is as follows: addition of *(49)* or *(49a)* onto *o*-quinone formed *in situ* initially yields *(50)*. This readily splits off pyridine and so, as a potential quinone methide *(51)*, can add on another molecule of *(49a)* as shown. Further elimination of pyridine finally leads to *(52)*.

*Procedure:*

A solution of 3.29 g of potassium hexacyanoferrate(III) in 100 ml of water is added to a solution of 0.62 g of 4-methylcatechol, 2,78 g of phenacylpyridinium bromide, and 10 g of

[35] *H.-W. Wanzlick, R. Gritzky*, and *H. Heidepriem*, Chem. Ber. *96*, 305 (1963).

[36] *B. Eistert* and *F. Geiss* [Tetrahedron *7*, 1 (1959)], have shown that Meldrum's acid *(41)* and dimedone *(43)* exhibit differences in their tendencies towards enolization: only *(43)* enolizes. The difference between the reactions mentioned above is therefore understandable.

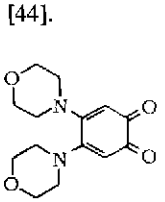
[41] *B. Pankow*, Ph. D. Thesis, Technische Universität Berlin, 1964.

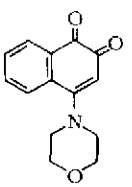
crystalline sodium acetate in 200 ml of water and 100 ml of acetone. After 12 hours, the reaction mixture is extracted with ether and worked up in the usual manner. Yield: about 50 % of *(53)*, m.p. 175 °C.

By altering the experimental conditions, it is possible to isolate the salt *(50)*, R = $CH_3$, initially formed. Further reaction of this with *(49)* in acetate-buffered solution leads smoothly to *(53)*, confirming the reaction sequence formulated above. Compounds *(52)* and *(53)* react readily with hydrazine to form pyridazines *(54)*. The fact that *(50)* can be isolated opens up a route to further syntheses, which will be reported elsewhere [41].



*(54)*, R = H or $CH_3$

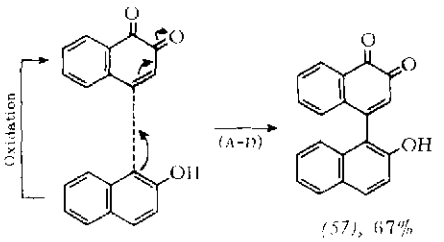
Other reactions proceeding with the formation of a C–C linkage will be discussed in the next Section. The dimerization of *o*-quinones [42] and the formation of purpurogallin [3,4] (cf. also [43]) can only be referred to.



Hydroquinones can be used as starting materials in syntheses with nascent quinones. However, in special cases it is also possible to produce the hydroquinones *in situ*, *e.g.* by hydroxylation of phenols.

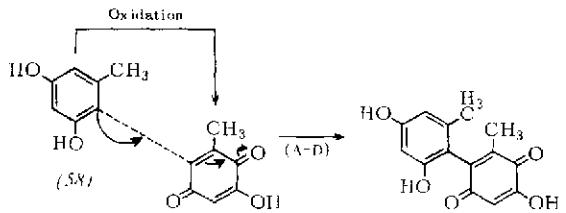
## 5. Special Cases

Model investigations on the oxidation of tyrosinase led *Brackman* and *Havinga* to remarkable and preparatively valuable results [44]. The Cu(II)-catalysed autoxidation of phenols in the presence of secondary amines proceeds smoothly to yield aminoquinones. Phenol itself condenses with morpholine to give *(55)*, and the corresponding reaction with β-naphthol yields *(56)*. Many other examples are quoted in the original publications [44].



*(55)*, 64%

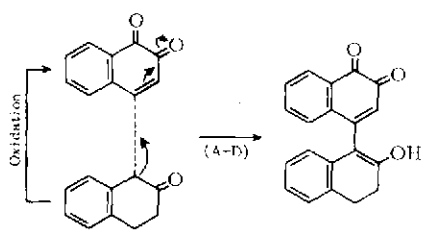
*(56)*, 84%



The course of these reactions is clear: *o*-hydroxylation of the phenols, dehydrogenation of the resulting catechol derivatives to *o*-quinones, and single or double addition of amines onto the latter (cf. Section 2c).

The oxidation of β-naphthol with $H_2O_2$ catalysed by molybdate, leads to the formation of *(57)* [45]. This product results from the addition of the naphthol onto the β-naphthoquinone initially formed.

*(57)*, 67%



In the autoxidation of resorcinols, which was studied in detail by *Musso* et al. in the course of work on orcein and litmus dyestuffs [46], biphenyl derivatives are formed, partly by Michael addition of the resorcinols onto quinones which are formed as intermediates. An example of this is the formation via *(59)* of *(60)* in the oxidation of orcinol *(58)* [47,48]. The process largely corresponds to the oxidation of β-naphthol to *(57)*.

*(58)* *(59)* *(60)*

These processes are closely related to the reactions which lead to the characteristic "blue color of β-tetralone" [49]. It was shown [50], that autoxidation of β-tetralone *(61)* in alkaline solution yields the dyestuff *(62)* as red crystals; the mesomeric anion is deep indigo blue; cf. *(42)* and *(44)*.

The reaction mechanism was proved by the addition of labeled and normal β-naphthoquinones, and the constitution of the dyestuff *(62)* was determined by dehydrogenation to *(57)*.

*(61)* *(62)*

## 6. Biochemical Examples

Nowadays, many biosyntheses are known to pass through quinoid intermediates. The present knowledge of the formation of melanin and humic acid was recently reviewed by

[42] Cf. *L. Horner* and *W. Dürckheimer*, Chem. Ber. *95*, 1219 (1962), where references to earlier literature are given.

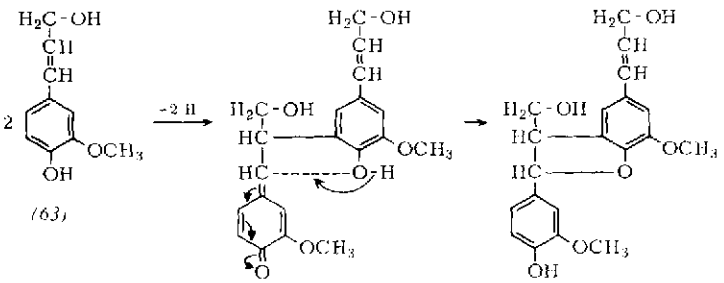
[46] *H. Musso* et al., Angew. Chem. *73*, 665 (1961).

[47] *U. v. Gizycki*, Ph. D. Thesis, Universität Marburg 1963.

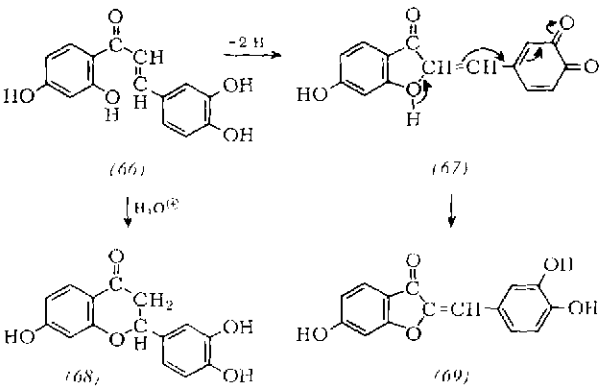


[48] *H. Musso*, Angew. Chem. *75*, 965 (1963); Angew. Chem. internat. Edit. *2*, 723 (1963).

[49] *F. Straus* and *A. Rohrbacher*, Ber. dtsch. chem. Ges. *54*, 46 (1921).

[50] *H.-W. Wanzlick*, *M. Lehmann-Horchler*, and *S. Mohrmann*, Chem. Ber. *90*, 2521 (1957).

*Thomson* [51]. The function of nascent quinones in the pupation of insects (sclerotization), which is compared with tanning by quinones (cf. [53]), is also dealt with in this article. Other examples, with references, may be found in reviews by *Musso* [48] and *van Tamelen* [54]. The biological significance of the phenoxazone syntheses discussed in Section 3 and the model experiments on the formation of melanins (Section 4) have already been referred to [32].

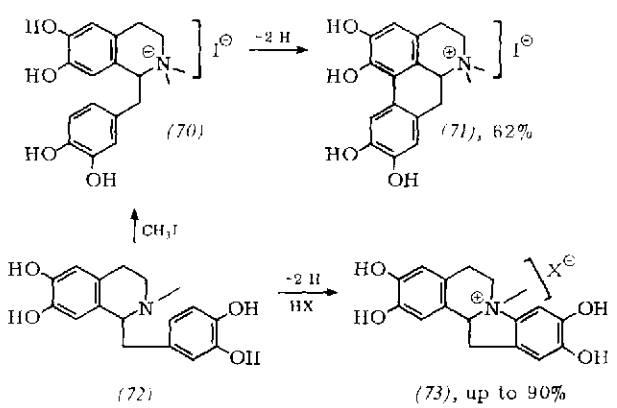


The investigations of *Freudenberg* et al. on the biosynthesis of lignin have brought to light the importance of quinone methide structures which occur there as intermediates [55]. One example of this is the condensation of two coniferyl alcohol units *(63)* with the elimination of hydrogen to form *inter alia* dehydrodiconiferyl alcohol *(65)*, a reaction which can also be carried out *in vitro* [56]. One-electron oxidation of the phenol group in *(63)* and dimerization of the mesomeric free radical produced yields the quinone methide *(64)* which is then converted into *(65)* by intramolecular addition.

*(63)* *(64)* *(65)*

The formation of lignin also involves intermolecular additions onto quinone methides, in which water, acids, phenols, alcohols, and carbohydrates participate competitively as nucleophilic reagents [55].

In the formation of aurones from chalcones, which is exemplified here by the conversion of butein *(66)* into sulfuretin *(69)* [57], intervention of *o*-quinonoid intermediates is indicated by two findings: 1. all the naturally occurring aurones known to date [58] (including bractein [59], which has only recently been isolated) contain a catechyl group; 2. The formation of aurones, which proceeds extremely easily even *in vitro*, is blocked by even partial methylation in the catechol residue, as was shown by *Geissman* et al. [57]



*(66)* *(67)* *(68)* *(69)*

The strong tendency of quinonoid systems to undergo additions is shown by the fact that the reaction *(66)* -> *(69)* proceeds readily *in vitro* and requires no catalyst, whilst the conversion of butein *(66)* into the flavanone butin *(68)* requires the usual treatment with hot mineral acid [60]. The polarization of the double bond initially present in the chalcone is not only reversed in the reaction leading to *(67)* but is also considerably intensified.

## 7. Concluding Remarks

The reactions discussed here offer rewarding exercises to the theoretical chemist. Even the addition mechanism, which is generally accepted nowadays, and which has been used in the present article, does not appear to have yet been rigorously proved. It is also reasonable to ask whether all the reactions discussed here pass through the quinone stage after all, since it is known that a semiquinone (which is often detectable [61]) may be formed initially in the dehydrogenation of a hydroquinone. The work of *Franck* et al. on biogenetic-type syntheses of alkaloids [62] may be mentioned at this point. The dehydrogenation of

laudanosoline methiodide *(70)*, for example, which leads smoothly to aporphine *(71)* [63] may be justifiably assumed [64] to be a free-radical reaction.

On the other hand, the dehydrogenation of laudanosoline *(72)*, in which the nitrogen is not quaternized, proceeds smoothly with the formation of the dibenzotetrahydropyrrocoline derivative *(73)*, whose trimethyl ether occurs in nature as cryptaustoline [65]; it is certainly justified to include this reaction among the quinone additions [66, 67].

*We are sincerely grateful to all those who have helped us in word and in deed, with encouragement and criticism, and to the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and to Schering A.G.*

# New Reactive Dyes

BY DR. K. G. KLEB

LABORATORIUM DER ZWISCHENPRODUKTEN-ABTEILUNG
DER FARBENFABRIKEN BAYER AG. LEVERKUSEN (GERMANY)

AND DR. E. SIEGEL AND DR. K. SASSE

WISSENSCHAFTLICHES HAUPTLABORATORIUM
DER FARBENFABRIKEN BAYER AG. LEVERKUSEN (GERMANY)

*Dedicated to Professor H. Bredereck on the occasion of his 60th birthday*

*Two new groups of reactive dyestuffs have been developed. One group (Levafix® dyes) comprises compounds which contain $-SO_2NH-CH_2-CH_2-OSO_3H$ or $-CH_2-N(alkyl)-CH_2-CH_2-OSO_3H$ as reactive groups. The dyes of this group react with cellulose fibers to form cellulose ethers, e.g. $R-SO_2NH-CH_2-CH_2-O$-cellulose. The substances in the second group (Levafix-E® dyes) consist of the amides formed from 2,3-dichloroquinoxaline-6-carboxylic acid and dyestuffs containing primary or secondary amino groups.*

## Introduction

The development of new reactive dyes requires solutions to problems which fall essentially into two categories:

1. The discovery of reactive systems which are suitable for incorporation into dyestuffs and which react efficiently with the substrate to be dyed under the conditions of textile dyeworks.

2. The combination of the reactive systems with dyestuffs, either already known or new, to give reactive dyes of high fastness.

The first problem is the more difficult one, since the reactive group both prescribes the type of dyestuff and largely determines the properties and scope of application of the dyes obtained with it.

Our work has led to two groups of dyestuffs:

(a) the Levafix dyes containing the reactive group

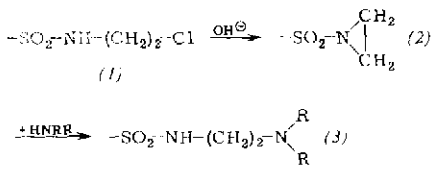
$-SO_2-NH-CH_2-CH_2-OSO_3H$ or $-CH_2-\underset{R}{N}-CH_2-CH_2-OSO_3H$,

and

(b) the Levafix-E dyes containing 2,3-dichloroquinoxaline-6-carboxylic acid bound as its amide as the reactive group.

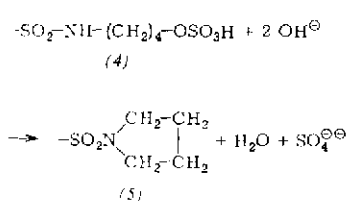
### 1. Reactive Dyes with Sulfatoalkyl Groups Activated by Neighboring Groups [*]

In 1940, *H. Schweitzer* and *O. Bayer* described dyes containing *N*-(β- or γ-chloroalkyl)sulfonamido groups which imparted colors to wool [1] more wash-fast than comparable deyings. The action of alkalies on *N*-(β-chloroalkyl)sulfonamides *(1)* readily produces *N,N*-ethylenesulfonamides *(2)* [2], which react with primary or secondary amines – probably also with the amino groups in wool – to effect alkylation to form *(3)* [3].



[*] Based on work by *K. G. Kleb*.

[1] *H. Schweitzer* and *O. Bayer*, German Patent 743766 (April 19th, 1940); cf. *O. Bayer*, Angew. Chem. *73*, 343 (1961).

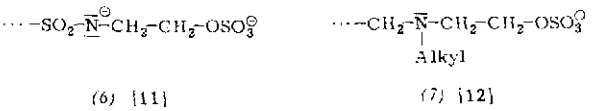


[2] *J. Nelles* and *E. Tietze*, German Patent 698597 (Feb. 8th, 1939).

[3] *J. Nelles*, *E. Tietze*, and *O. Bayer*, German Patent 695331 (April 29th, 1939).

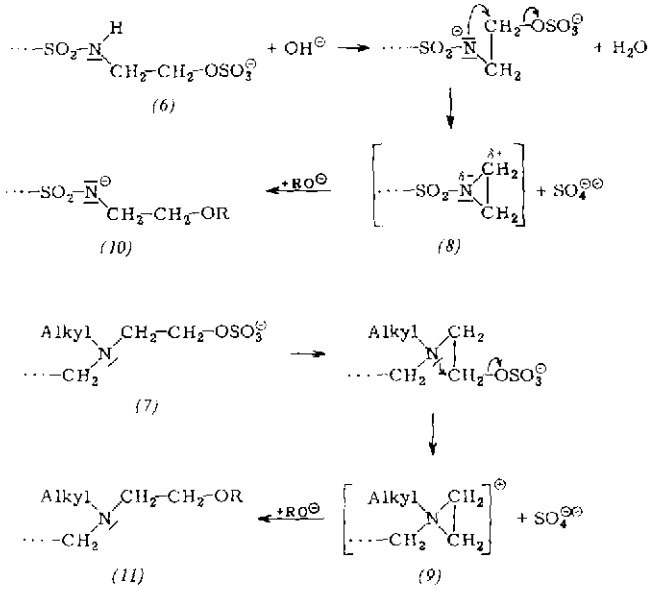
*N*-Alkylsulfonamides with sulfato groups *(4)* in the δ- or ε-position were used in order to make the dyes originally water-soluble and then to attach them to the

textile substrate in an insoluble form produced by the action of alkalies and heat during the dyeing; the reaction leads to sulfonylpyrrolidines *(5)* or sulfonylpiperidines, respectively, by intramolecular alkylation [4].



Recently several research groups studied the applicability of sulfatoalkyl groups to dyes which could react with cellulose by alkylation. As a result it was found that the reactivity of the sulfatoalkyl groups was enhanced by the introduction of the hetero-atoms O, S, or N in the γ- or even better in the β-position to the sulfato group. By themselves, alkyl hydrogen sulfates can be used as alkylating agents only under drastic conditions.

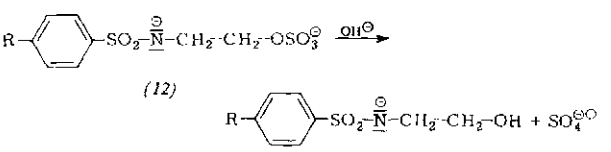
The effectiveness of the hetero-atoms and of their derivatives varies widely. Aryloxy groups [5] have only a weak action, but with hydroxyl [6], alkylthio [7], and dialkylamino groups [7,8], and with sulfonamide anions [9] as "activators", it is possible to raise the reactivity of the sulfatoalkyl group to the level required for practical application as a reactive group in textile dyeing. Carboxamide groups in the β-position are not suitable as "activators", since they react to form oxazoline derivatives by intramolecular alkylation [10].



### a) Reaction Mechanism

Sulfonamide anions *(6)* or aliphatically bonded tertiary amino groups *(7)* serve to activate the sulfatoalkyl groups in the Levafix dyes.

*(6)* [11] *(7)* [12]



Their action can be explained by a neighboring-group effect [13]. Both groups contain a strongly nucleophilic nitrogen atom. The nitrogen atom participates in the reaction by means of an initial nucleophilic attack on the α-carbon atom, with displacement of the sulfato group, to form the reactive, cyclic intermediates *(8)* or *(9)*. In the second step, these react with external nucleophilic partners to give the stable products *(10)* and *(11)*, respectively.

The reaction sequence indicated may be considered as certain for compounds of type *(7)* by analogy with numerous other mechanisms [14].

A proof for the mode of reaction of *(6)* by direct detection of the *N,N*-ethylenesulfonamide *(8)* has not yet been achieved. Confirmation was therefore sought in other ways:

α) The reaction *(12)* → *(13)* is slowed down by electron-attracting substituents R and accelerated by electron-donating substituents. Thus, the reaction rate (Fig. 1)

*(12)* *(13)*

varies in the same direction and to about the same extent as the pK-value (Table 1) for the dissociation of the sulfonamido group [15].

Since the kinetic measurements were undertaken in 0.1 N NaOH, in which the sulfonamido group is fully

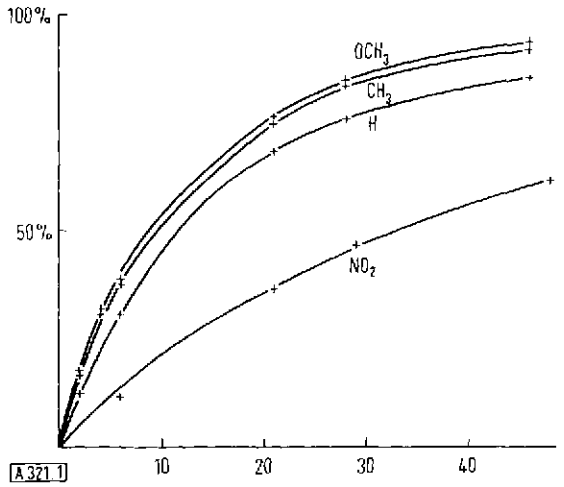
[15] Investigations by *E. Grigat.*



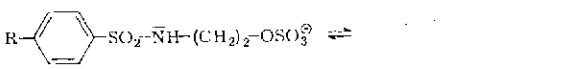


Fig. 1. Rate of the hydrolysis *(12)* → *(13)* in 0.1 N NaOH at 50 °C in relation to the substituent R.
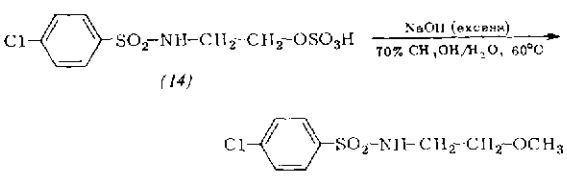
Ordinate: conversion [%]
Abscissa: time [hours]

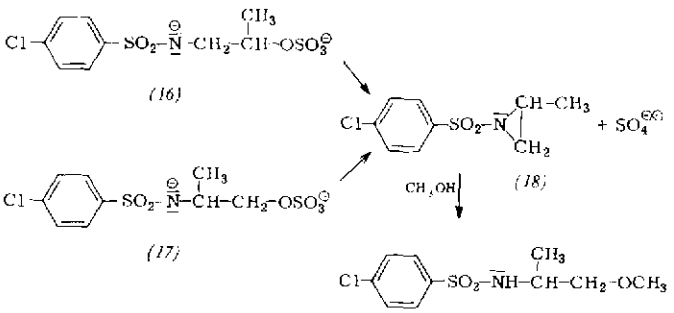


dissociated, the results can only be satisfactorily explained by the hypothesis of a neighboring-group effect. If the basicity and nucleophilicity of the sulfonamide nitrogen atom are assumed to be comparable, then the reactivity of the group *(12)* must be higher, the more basic the nitrogen atom of the sulfonamide group is or, in other words, the greater its pK value is. Thus, although electron-release by the substituent R inhibits dissociation of the sulfonamido group, it assists the hydrolysis – complete dissociation being assumed – by raising the electron density at the nitrogen atom.

Table 1. pK-Values for the dissociation

| R | pK |
|---|---|
| $NO_2$ | 9.85 |
| H | 10 55 |
| $CH_3$ | 11.0 |
| $OCH_3$ | 11.05 |

β) At 60 °C in the presence of excess sodium hydroxide, *N*-(β'-sulfatoethyl)-4-chlorobenzenesulfonamide *(14)* reacts in 70 % aqueous methanol by a first order process (half-life: 373 min) to give *N*-(β-methoxyethyl)-4-chlorobenzenesulfonamide *(15)*.



*(14)*

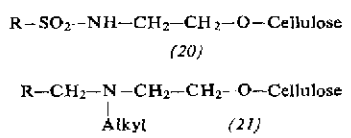
*(15)*, m. p. 61–62°C

If this reaction proceeds according to a normal $S_N2$ mechanism, then under equivalent conditions, the formation of two isomeric *N*-methoxypropylamides would be expected from the two isomeric *N*-sulfatopropyl-4-chlorobenzenesulfonamides *(16)* and *(17)*, with constitutions corresponding to those of the starting materials. In fact, however, *(16)* and *(17)* react to give a single *N*-methoxypropylamide, which from its nuclear magnetic resonance and infrared spectra possesses the constitution of *N*-(methoxyprop-2-yl)-*p*-chlorobenzenesulfonamide *(19)* [16].

In agreement with the data of *Winstein* and *Grunwald* [17] concerning the influence of a β-methyl group upon reactions activated by neighboring groups, *(17)* reacts about 20 times faster (half-life: 18.5 min) than *(14)*. On the other hand, the reaction of *(16)* (half-life: 138 min) proceeds more slowly than expected [17a], probably because of steric effects caused by the sulfonamide anion.

*(16)*

*(17)*

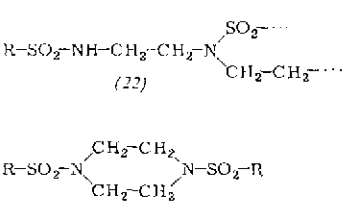


*(18)*

*(19)*, m. p. 68–69°C

These findings lead to the conclusion that a common intermediate *(18)* is formed in the first, rate-determining step of the reaction of both the isomeric *N*-(β-sulfatopropyl)sulfonamides *(16)* and *(17)*. After attack by an external nucleophilic reagent upon the carbon atom of the $CH_2$ group which is the more positive of the two ring-carbon atoms owing to the influence of the methyl group, the faster subsequent reaction leads to the end-product *(19)*.

### b) Reactions during the Dyeing Process

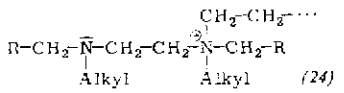


Sulfatoalkyl groups activated by neighboring groups can react with several nucleophiles during the dyeing process. The preferred reaction occurs with the hydroxyl groups of cellulose (or their anions); as a result, the β-substituted ethyl ethers of cellulose *(20)* and *(21)* are formed.

*(20)*

*(21)*

The accompanying alkylation reactions of the reactive groups with each other can lead to the formation of the products *(22)* and *(23)* from compounds of type *(6)*.



*(22)*

*(23)*

[16] Measurement and discussion of the spectra by *H. Walz*.
[17] *S. Winstein* and *E. Grunwald*, J. Amer. chem. Soc. *70*, 830 (1948).
[17a] *S. Winstein* and *E. Grunwald*, J. Amer. chem. Soc. *70*, 832–833 (1948).

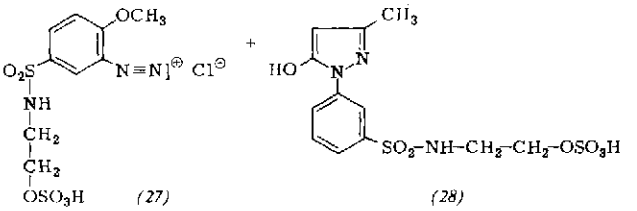
Quaternary ammonium compounds *(24)* may be formed from compounds of type *(7)*.

*(24)*

These reactions are desired, when they cause dyestuff molecules to become indirectly bound firmly to the fiber, *i.e.* by interspersion of other dyestuff molecules as bridges.

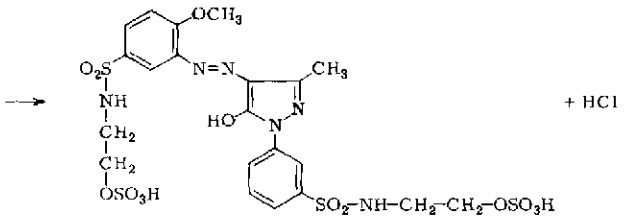
The alcohols *(25)* and *(26)* may appear as a result of hydrolysis owing to the presence of water and hydroxide ions during the dyeing process.

*(25)* *(26)*



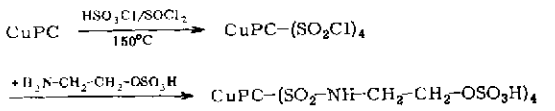
### c) Constitution of the Dyes

The Levafix dyes are combinations of a chromophoric molecule with two or more reactive groups of formulae *(6)* and *(7)*. Representatives of the azo, anthraquinone, vat, or phthalocyanine series, for example, serve as the fundamental dyeing substances. Reactive groups of type *(6)* are bound to the dye-substance either directly through the sulfonamido group or by a bridge, *e.g.* a benzene ring. Reactive groups of type *(7)* are preferably combined with large dyestuff molecules, such as those found among the vat dyes, which have hydrophilic groups (*e.g.* sulfonamido groups) attached to improve their solubility.



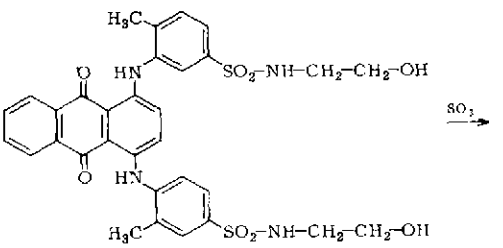
The substantivity of most dyes is reduced by replacing nuclearly bound sulfonic acid groups with reactive groups of type *(6)* or with sulfonamide links. This is especially true when all the sulfonic acid groups of this type have been replaced. This effect is applied to make dyes with very low substantivity. Starting from chromogens with low affinity for the fiber, only reactive groups are used as solubility-conferring constituents of the dyes, with the exclusion of additional ionizing groups, such as nuclearly bound sulfo or carboxyl groups. In the Levafix dyes, the reactive sulfatoalkyl groups must therefore fulfil the additional function of conferring solubility in water. In general, the solubility required for application is attained with two reactive groups per dyestuff molecule; more than two groups are necessary for large dyestuff molecules or for those which associate readily.

### d) Synthesis of the Dyes

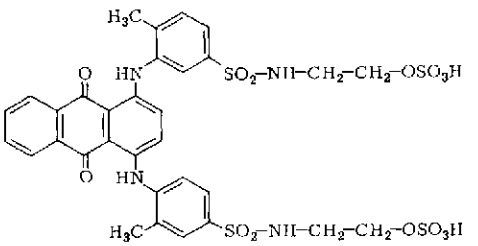


The reactive group *(6)* is prepared from 2-aminoethanol (ethanolamine) by reaction of the amino group with a sulfonyl chloride and by esterification of the hydroxyl group with sulfuric acid, in whichever sequence is desired. The sulfonyl chlorides of dyestuff intermediates or of ready-made dye-substances can be used as starting material. In the first case, intermediates with reactive groups are obtained, *e.g. (27)* and *(28)*, which can then be transformed into dyes, *e.g.* by coupling.

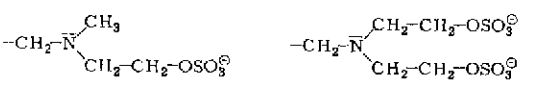
*(27)* *(28)*



In the second case, the finished dye is prepared directly by reaction with 2-aminoethyl hydrogen sulfate.



CuPC = copper phthalocyanine



In the case of a dyestuff which must be prepared under conditions which decompose the reactive group, it is advisable to prepare the dyestuff with $-SO_2-NH-CH_2-CH_2-OH$ groups *(29)* first and then to convert this into the reactive group by sulfatation, *e.g.* with concentrated sulfuric acid or pyridine/$SO_3$.

*(29)*

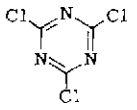
Dyestuffs with the reactive group *(7)* are prepared according to similar methods, starting from amino alcohols with functional groups which allow combination with the chromogens. Here the number of variations is greater, since the bridging group to the dyestuff can be altered at will, and since the alkyl group attached to the activating nitrogen atom can differ. The systems *(7a)* and *(7b)* have probved to be useful.

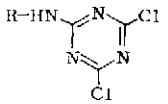
*(7a)* *(7b)*

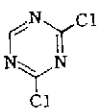
### e) Application

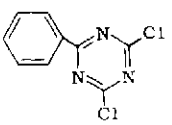
As a result of their low substantivity [*], the Levafix dyes are suitable only for dyeing processes in which substantivity is unnecessary or even undesirable. They are therefore used in calico printing and in pad dyeing of native or regenerated cellulose, where they are applied from concentrated solutions or printing pastes containing alkali (*e.g.* soda, potash, or caustic soda) and an auxiliary (*e.g.* urea). The yields of fixed dyestuff are very high (90 % or more) when the dyeing is carried out at 100–120 °C in steam boilers or at 130–150 °C by dry-heat treatment, provided several reactive groups and no additional groups conferring solubility in water are present in the dyestuff molecule. Heavy contamination does not occur in the baths used to elute the alkali, auxiliaries, and unreacted dye from the fiber in the washing process which follows that of dyeing. Since it possesses no or only low substantivity, unreacted dye does not run onto unprinted portions of the fabric or onto portions colored by other dyes.

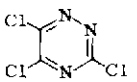
The Levafix dyes can be combined not only with one another, but also with dyes of other classes, *e.g.* Naphthol-AS combinations, vat dyes, sulfuric esters of leuco vat dyes, pigment dyes, and aniline black. Emphasis is laid upon the good wash-fastness of the colors on printed or dyed fabrics, which is due to the stable dye-fiber bonds.

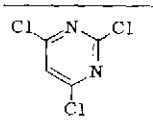


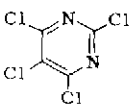


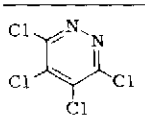












## 2. Reactive Dyes with 2,3-Dichloroquinoxaline as Reactive Group [**]

Levafix dyes with an aliphatic reactive group are little suited for application from dilute dye liquors, or for the cold pad-batch process which is continually gaining in importance [18]. In order to be useful for dyeing, a reactive dye must not display too great substantivity but must have a reactivity towards cellulose which is as high as possible; in addition, the reactive group should be able to align itself sterically on the surface of the cellulose in such a way as to favor nucleophilic substitution by a hydroxyl group of the cellulose.

These requirements are fulfilled by quasi-aromatic heterocyclic nitrogen compounds with mobile chlorine atoms of the kind existing in cyanuryl chloride or tetrachloropyrimidine. As a result of the formation of hydrogen bonds between the hydroxyl groups of the cellulose and the heterocyclic nitrogen atoms, which have a high electron density, the chlorine atoms become aligned on the cellulose surface in a sterically favorable way. Moreover they possess very good reactivity at the optimum dyeing temperatures.

In the search for new reactive dyes, the greatest outcome was therefore promised by examination of heterocyclic nitrogen compounds with mobile chlorine atoms. Hitherto, it is almost exclusively chlorotriazines and chlorodiazines that have been described; these are the reactive groups that are closest to cyanuryl chloride (Table 2). The most mobile chlorine atom of these compounds is caused to react with the amino group of a dyestuff molecule; the remaining halogen atoms are available for reaction with the fiber [18–20].

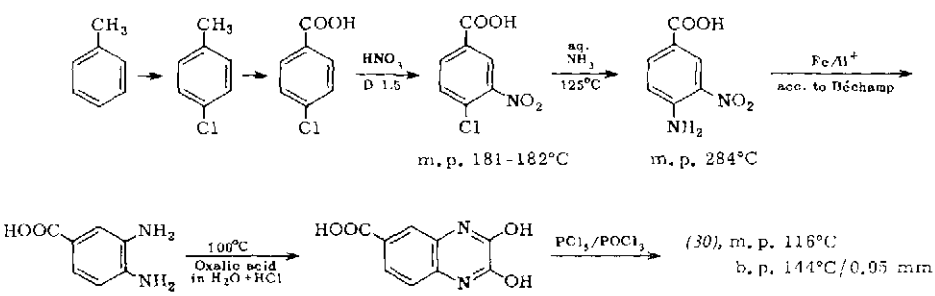
### a) Synthesis of New Reactive Groups

We studied heterocyclic nitrogen compounds possessing fused-rings and mobile chlorine atoms. Hitherto these substances had scarcely been examined. Since it was to be expected that polynuclear fused systems would lead to sparingly soluble dyestuffs of low molecular color strength, we first studied 2,3-dichloroquinoxaline, which had previously been investigated by *Sasse* and *Wegler*[30]. This substance is not suitable on its own as a reactive group, since difficulties are encountered in its selective attachment to a molecule of an amino dyestuff with preservation of one of the mobile chlorine atoms, and since the remaining chlorine atom is too strongly deactivated after introduction of the substituted amino group into the molecule.

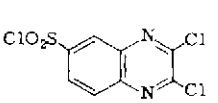
On the other hand, we obtained valuable reactive dyestuffs *(31)* when we linked 2,3-dichloroquinoxaline to amino dyestuffs by way of a chlorocarbonyl or chlorosulfonyl group bound to the benzene ring. Since the reactivity of the chlorine atom in the chlorocarbonyl or chlorosulfonyl group is greater than that of the chlorine atoms in the heterocyclic nucleus, selective acylation of primary or secondary amino groups is achieved with preservation of the chlorine atoms in positions 2 and 3.



*(30)*

*(31)*

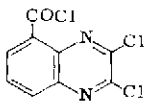
6-Chlorocarbonyl-2,3-dichloroquinoxaline *(30)* is readily accessible technically in the way indicated in Scheme 1.



Scheme 1. Synthesis of 6-chlorocarbonyl-2,3-dichloroquinoxaline.

Compound *(30)* can be distilled *in vacuo* [31]. It is colorless and has the typical odor of carbonyl chlorides. The substance is only slowly hydrolysed by water, but reacts smoothly at 40–70 °C with aminoazo or aminoanthraquinone dyes as well as with phthalocyanine dyes or dyestuff precursors containing amino groups in aqueous solution, by acylation of the amino groups with the chlorocarbonyl group.

We then looked for further useful reactive components in other fused bicyclic systems such as 1,4-dichlorophthalazine, 2,4-dichloroquinazoline, 2-chlorobenzoxazole, 2-chlorobenzothiazole, and 2-chlorobenzimidazole as well as in the 2,3-dichloroquinoxaline series.



### α) Quinoxaline Derivatives

Among the chloroquinoxaline derivatives *(32)* to *(37)*, 6-chlorocarbonyl-2(3)-monochloroquinoxaline *(34)* affords the best reactive dyestuffs; 6-chlorosulfonyl-2,3-dichloroquinoxaline *(32)* is not quite so well suited for the construction of reactive dyes as the carbonyl chlorides *(30)* and *(34)*, since the substantivity of azo dyes with a sulfonamido group in the molecule is lower than that of azo dyes with a carboxamido group.

*(35)*

m. p. 122–123 °C

*(36)*

*(37)*

The connection of 2,3-dichloroquinoxaline to the dyestuff through a carboxamido or sulfonamido group has an activating influence on the chlorine atoms in the quinoxaline nucleus. Model experiments showed that this influence of substituents in the 6-position is very marked and that the activating effect increases with increasing electron-attracting character of the substituent (*i.e.* increasingly positive value of its Hammett σ-constant). The influence of substituents in the aniline nucleus of *2,3-dichloroquinoxaline-6-carboxanilide (38)* is less strong, but clearly present, and is opposed to the course of the Hammett constants in an unusual way. The anilide *(38)* can be considered as a model for dyestuffs based on 2,3-dichloroquinoxaline-6-carboxylic acid. It is known from studies of the dichlorotriazine dyes that dyestuffs with the same reactive group often differ in reactivity by a factor of 10 or more (Table 3) [32,33].

### γ) Phthalazine and Quinazoline Derivatives

Introduction of a chlorocarbonyl group into the 6-position of 1,4-dichlorophthalazine also transforms this substance, which otherwise reacts slower ($k_{OH^-}$ = 0.012 min$^{-1}$) than 2,3-dichloroquinoxaline ($k_{OH^-}$ = 0.052 min$^{-1}$), into a useful reactive component *(39)* [34]. On the other hand, a chlorocarbonyl or carboxamido group in the 7-position *(40)* activates the chlorine atoms of 2,4-dichloroquinazoline, which is already very reactive as such ($k_{OH^-} > 1$ min$^{-1}$), so strongly that selective acylation of a dyestuff containing an amino group by the chlorocarbonyl group is hardly possible, and the reactive dyes formed are rapidly hydrolysed.

### γ) Benzoxazole and Benzothiazole Derivatives

We also obtained very useful reactive dyes from the 2-chlorobenzoxazole and 2-chlorobenzothiazole derivatives *(41)* to *(44)* [34]. The 2-chlorobenzoxazole dyes are very reactive, but the colorings obtained from them are not so resistant to boiling as those obtained from the 2,3-dichloroquinoxaline dyes.

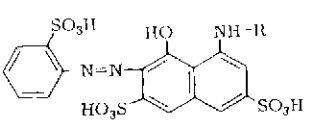
### b) Synthesis of the 2,3-Dichloroquinoxaline Dyes

Many of the azo, anthraquinone, and phthalocyanine dyestuffs, and their intermediates frequently used in reactive dyes and having a primary or secondary amino group in the molecule can be acylated with 6-chlorocarbonyl-2,3-dichloroquinoxaline. For example, the red reactive dye *(45)* is obtained by stirring a suspension of

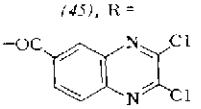
*(45)*

finely powdered 6-chlorocarbonyl-2,3-dichloroquinoxaline into an aqueous solution of an equimolar quantity of the disodium salt of 1-amino-8-hydroxynaphthalene-3,6-disulfonic acid at 40 °C and pH 4–6, and finally coupling the acylation product with diazotized 1-aminobenzene-2-sulfonic acid at pH 7–8.



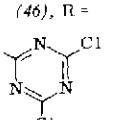
Since the relatively large 2,3-dichloroquinoxaline nucleus markedly diminishes the solubility of the dyestuffs in water, sometimes more groups which confer solubility in water must be present than are required in the corresponding dichlorotriazine dyes.

Monoazo dyestuffs, such as are obtained by coupling diazotized anilinesulfonic acids with 1-phenylpyrazolones, are the basis of brilliant greenish-yellow shades; clear orange and red shades are produced by the dyes, *e.g. (45)*, obtained by coupling diazotized anilinesulfonic acids with hydroxynaphthalenesulfonic acids, especially aminohydroxynaphthalenesulfonic acids. Derivatives of 1-amino-4-phenylaminoanthraquinone-2-sulfonic acid which contain amino groups are the basis of brilliant blues. Dyes with a turquoise tint contain copper or nickel phthalocyaninesulfonic acids as chromogens. Copper, chromium, and cobalt complexes of mono- and bisazo dyestuffs afford violet, navy-blue, brown, grey, and black shades. The 2,3-dichloroquinoxaline dyes are known in the trade by the name Lefafix-E® dyes [34].

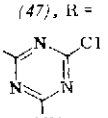


### c) Coloring Properties of the 2,3-Dichloroquinoxaline Dyes

An ideal reactive dye should react with cellulose as quickly and as fully as possible and moreover be stable to hydrolysis in alkaline aqueous media. These requirements are not readily compatible with one another, yet the 2,3-dichloroquinoxaline dyes fulfil them surprisingly well.



The dyeing properties of the new reactive dyes may be illustrated by the example of the dye *(45)*. We have



*(45)*, R =

*(46)*, R =

*(47)*, R =

chosen for comparison the dichlorotriazine dye *(46)* and the monochlorotriazine dye *(47)*.

The optimum temperature for dyeing from dilute liquors is a measure of the reactivity of the reactive groups: for *(46)*, this is 25 °C; for *(45)*, 40 °C; and for *(47)*, 80 °C. The 2,3-dichloroquinoxaline dyes therefore come next to the very reactive dichlorotriazine dyes. This is also shown by their behavior in the cold pad-batch process [35]:

Figure 2 presents the proportion of dye which reacts at room temperature with the cellulose fabric as a function of time. Mercerized poplin was steeped in a solution containing $10^{-2}$ mole/l of pure dye in each case, together with the acid-binding agent and additives specified; the excess moisture was squeezed out between rubber rollers, and the cloth was rolled up and left standing at room temperature for different periods of time for the dye to react with the cellulose. Finally, the unfixed portion of the dye was washed out and estimated colorimetrically.

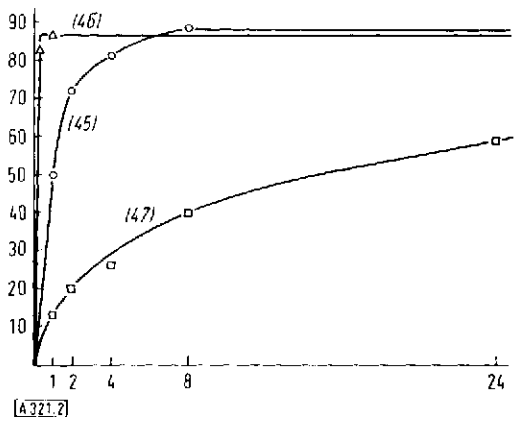


Fig. 2. Dye fixed to mercerized poplin as a function of time. The figures beside the curves indicate the identity of the dyes.

In the case of *(45)* and *(46)*, 20 g/l of soda and 100 g/l of urea were added; in the case of *(47)*, 30 ml/l of 32% caustic soda and 10 g/l of sodium sulfate were used instead.

Ordinate: amount of dye fixed [% of the total quantity]
Abscissa: time [hours]

The reaction rate is greatest for the dichlorotriazine dye *(46)*: it reached its maximum degree of fixation of 87% after only 15–20 minutes, while the 2,3-dichloroquinoxaline dye *(45)* reached its maximum (88%) only after 6–8 hours. On the other hand, the monochlorotriazine dye *(47)* had not reacted fully even after 24 hours, and its degree of fixation at that time lies considerably below the values for *(45)* and *(46)*.

Although the 2,3-dichloroquinoxaline dye *(45)* reacts with cellulose rapidly and in very high yield, its rate of hydrolysis in the alkaline dye solution ("padding liquor") is considerably smaller than that of the monochlorotriazine dye and very much smaller than that of the dichlorotriazine dye (Fig. 3) [35]. This stability to hydrolysis in the alkaline padding liquor is important for the cold pad-batch process, since the intensity of the color must not drop markedly during the padding.

The dye solutions used in the cold pad-batch process were allowed to stand at room temperature for 0, 2, or 6 hours after the addition of alkali and then padded onto the mercerized poplin, which was then laid aside for 24 hours. Moreover, an intermediate value was measured for the dye *(46)* 10 minutes after the addition of alkali. The degrees of fixation obtained in the case of immediate padding correspond to the maximum yields in Figure 2. The greater the slope of the curve in Figure 3, the more rapidly the dye is hydrolysed.

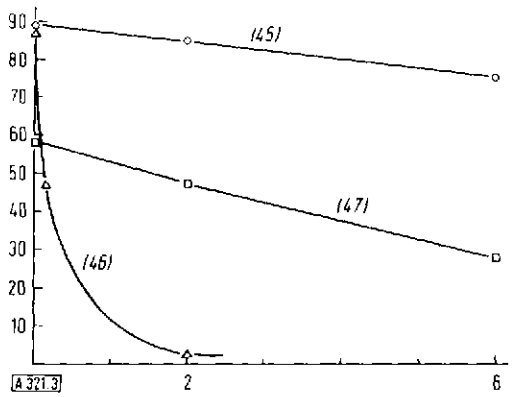

Fig. 3. Stability to hydrolysis of the dyes *(45)* to *(47)* in alkaline aqueous solution. For details see text.
Ordinate: amount of dye fixed [% of the total quantity]
Abscissa: time after addition of alkali [hours]

High reactivity towards cellulose with the greatest possible stability to hydrolysis is desired not only in dyeing, but also in calico printing; there has lately been a great demand for reactive dyes with good stability towards the alkaline printing paste and the ability to fix out in very short steaming times of 30–60 seconds. Although the very reactive dichlorotriazine dyes fulfil the second requirement, they are not sufficiently stable in the alkaline printing paste [32]. At the present time, the dichloroquinoxaline dyes are the only ones which have the ability to react completely within a steaming time of 30 seconds and to keep for over three weeks in the alkaline printing paste. Although the 2,3-dichloroquinoxaline dyes do not quite reach the standard of wet-fastness shown by the "Indanthrene"® fast reactive dyes based on sulfatoethyl groups activated by neighboring groups (see above), they are comparable in their degree of fastness to the dichlorotriazine dyes.

### d) Studies of the Dyeing Mechanism

The measurements of *Hildebrand* [36] provided information about the reactivities of the 2,3-dichloroquinoxaline dye *(45)* and the dichlorotriazine dye *(46)* towards water and towards sorbitol (as a model for cellulose [33]). He determined the rate constants for the pseudo-monomolecular reaction by working up the reaction mixtures after different times; the analysis procedure involved paper chromatographic separation, elution, and colorimetric estimation of the products.

As Table 4 shows, the ratio $k_{sorbitol}/k_{H_2O}$ is less favorable for the dichloroquinoxaline dye *(45)* than for the dichlorotriazine dye *(46)*. The fact that *(45)* nevertheless attained just as high a degree of fixation as *(46)* (Fig. 2) is connected with the rate of diffusion during the heterogeneous reaction with cellulose: the dichloro-

[35] Measurements by *W. Beckmann* and *K. Greiner*.

[36] *W. Beckmann, D. Hildebrand*, and *H. Pesenecker*, Melliand Textilber. *43*, 1304 (1962).

Table 4. Rate constants for the pseudo-monomolecular reactions of the dyes *(45)* and *(46)* with water and with sorbitol (50 g of sorbitol/l) at pH 10 and 25 °C.

| Dye | $k_{sorbitol}$ [$min^{-1} \cdot mole^{-1}$] | $k_{H_2O}$ [$min^{-1}$] | $\frac{k_{sorbitol}}{k_{H_2O}}$ |
|---|---|---|---|
| *(45)* | 0.42 | $1.8 \times 10^{-4}$ | 2340 |
| *(46)* | 12.40 | $33 \times 10^{-4}$ | 3760 |

triazine dye is partly hydrolysed within the time necessary for its diffusion into the fiber [half-life period of diffusion: 12 min; of hydrolysis: 30 min for *(46)*, 550 min for *(45)*]. Moreover, the 2,3-dichloroquinoxaline dye has greater substantivity than the dichlorotriazine dye, which is attributed to the greater expansiveness and substantivity of the dichloroquinoxaline system [37].

The elemental analysis of cotton fabric dyed by different methods with 2,3-dichloroquinoxaline red *(45)* showed that only one of the two chlorine atoms reacts with the cellulose during the cold pad-batch process at 25 °C and in the case of exhaustion dyeing at 40 °C. Under more energetic conditions of fixing, *e.g.* with steam at 103 °C or on baking at 140 °C ("thermofixing"), the second chlorine atom also enters into reaction with the cellulose or water, so that thereafter only about 15 % of the chlorine content corresponding to the second chlorine atom is still detectable.

[37] Measurements by *W. Beckmann.*

*The studies described and the preparative work leading to the Levafix dyes were carried out in the ZW-Laboratorium der Farbenfabriken Bayer under the direction of Dr. D. Delfs. Those notably concerned with the development of the Levafix-E dyes were Drs. R. Pütter, J. Singer, W. Wolf, H. Jäger, and K. Gerlach of the Wissenschaftliches Hauptlaboratorium der Farbenfabriken Bayer as well as Drs. K. Greiner, H. Gutjar, and M. Söll of the Anwendungstechnische Abteilung der Farbenfabriken Bayer. We thank Professor Otto Bayer for his intensive support of this work.*

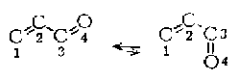
# Acrolein Polymers



BY PROF. DR. R. C. SCHULZ [1]

ORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT MAINZ (GERMANY)

*The unsaturated aldehyde acrolein is a suitable source for different types of high polymers. If it is regarded as a 1,3-diene analogous to butadiene, then all the known modes of its polymerization can be systematically described and further possibilities predicted. A survey is given on this basis of the results obtained during the past decade. It is shown that acrolein is one of the few monomers which contain two polymerizable groups of differing reactivities. This fact allows the formation from acrolein of new homopolymers, copolymers, and graft copolymers, a scope which is not encountered with many other monomers.*

## 1. The Structure of the Monomer

As an α,β-unsaturated aldehyde, acrolein *(1)* contains a conjugated double-bond system, and can thus be considered as a 1,3-diene. This comparison is expressed by the numbering in the formulae shown below. The analogy between acrolein and butadiene and that between methacrolein and isoprene is obvious.

*(1a)* *(1b)*

It therefore follows that various polymers may be built up from acrolein. In contrast to butadiene, the two double bonds in acrolein possess unequal reactivities, so that additional variations are possible.

According to recent measurements [2, 2a], the bond lengths and angles in acrolein are as follows:

| | | | |
|---|---|---|---|
| C=C | 1.36 ± 0.02 Å | ∢ $C_1C_2C_3$ | 120 ± 3 ° |
| C–C | 1.46 ± 0.03 Å | ∢ $C_2C_3O$ | 120 ± 3 ° |
| C=O | 1.21 ± 0.02 Å | | |

The (C-2)–(C-3) bond is said to exhibit 37 [3] or 55 % [4] double bond character. Owing to the resultant restriction of free rotation, geometrical isomerism is a possibility. *Wagner* et al. [5] found that at room temperature about 95 % of the *s-trans* isomer *(1a)* is present at equilibrium. This form is more stable than the isomeric structure *(1b)* by 2.5 kcal/mole [2a].

## 2. Polymerization of the Vinyl Group (1,2-Polymerization)

Our initial investigations were aimed at the construction of macromolecules with aldehyde side-groups *(2)* [6].

*(2)*

At that time polymers of this type were unknown. In view of literature reports describing the difficulties encountered in work with acrolein, we first investigated polymethacrolein [7], which in contrast to polyacrolein is soluble in numerous organic solvents. The following descriptions deal however only with acrolein and its polymers.

### a) Free-Radical Homopolymerization

High and reproducible yields can be obtained by polymerizations of acrolein initiated with water-soluble redox systems [8]. The polymers formed are produced almost exclusively by polymerization of the vinyl group [9].

Only certain combinations of oxidizing and reducing agents can be used with acrolein [10]. Systems composed of potassium peroxydisulfate and ferrous ammonium sulfate, sodium thiosulfate, or silver nitrate were found to be particularly effective. Redox systems recommended for the polymerization of acrylonitrile, such as $K_2S_2O_8/Na_2S_2O_4$ or $K_2S_2O_8/Na_2S_2O_5$ cannot be utilized with acrolein [11].

The best procedure is to add the acrolein to an aqueous solution of the oxidizing agent and then to add the reducing agent drop by drop to the resulting mixture. Acidic conditions must be maintained in the medium during the entire polymerization since competitive condensation reactions take place even at pH $\approx$ 8, leading to polyacroleins of a different type.

The polymerizations initiated by redox systems proceed by a free-radical chain mechanism [12]. The mechanisms of the redox reactions themselves can vary appreciably and are influenced by the presence of the monomers in a very complex manner [13].

Monomeric acrolein dissolves in water to the extent of 20 % [2a]. Since the polymer is insoluble, the polymerization always involves precipitation. Nevertheless, kinetic studies showed the same dependence of the overall rate of reaction on the concentration of the redox system as in other vinyl polymerizations performed under similar conditions [10].

Polymerizations in suspension and emulsion were also studied [14, 14a]. For this purpose, the adduct of polyacrolein and sodium hydrogen sulfite or sulfur dioxide proved a particularly effective emulsifying agent (see Section 5). Kinetics of the emulsion polymerization showed an anomalous relationship between the overall rate and the concentration of the emulsifying agent, but this was traced back to the water-solubility of the monomer [15].

Polymerization can also be carried out in organic media using azoisobutyronitrile as catalyst, but this technique offers no advantage since here, too, the polymer precipitates out and has properties quite similar to those of the product obtained by emulsion polymerization. No polymer is initially precipitated on polymerization in dimethylformamide, but at conversions beyond 15 %, the charge sets to a gel. The overall rate of reaction indicates that even in the initial stage of polymerization the reaction proceeds, at least partly, in a gel or microgel structure [16, 17].

During the storage of unstabilized acrolein or during distillation, polymerization sets in without any addition of catalyst [18] and can be recognized by the formation of turbidity in the liquid and separation of an insoluble powder. Neither this spontaneous nor the radical-catalysed bulk polymerization is recommended as a method for the preparation of polyacrolein, since the yields and properties of the polymer are difficult to reproduce. At elevated temperatures, the free-radical catalysed polymerization may proceed explosively. The heat of polymerization of acrolein is 19.1 kcal/mole [19].

### b) Free-Radical Copolymerization

Studies of the copolymerization of two monomers provide information about their relative reactivities, and in addition lead to polymers exhibiting novel properties. Both criteria determined the choice of vinyl and acrylic compounds used for copolymerization with acrolein.

A pair of monomers is characterized by the copolymerization parameters $r_1$ and $r_2$. These are obtained from the composition of the copolymers resulting from various monomer mixtures [20], according to the equation:

$$\frac{m_1}{m_2} = \frac{[M_1]}{[M_2]} \cdot \frac{r_1[M_1] + [M_2]}{[M_1] + r_2[M_2]} \qquad (a)$$

where [M] are the molar fractions of the monomers in the monomer mixture, and m the molar fractions of the monomer units in the resulting copolymer.

| Vinyl acetate | $H_2O$ | 2.3 ± 0.1 | 0.1 ± 0.05 | 0.2 | 0.69 |
| Methyl acrylate | $H_2O$ | 0 | 7.7 ± 0.2 | — | — |
| 2-Vinylpyridine | DMF | 4 | 0 | — | — |

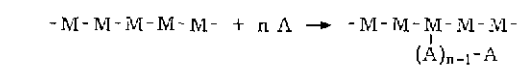
[a] DMF = Dimethylformamide.

The copolymerizations carried out [21,22] and the parameters found are shown in Table 1. Although all the copolymers precipitated out in aqueous systems, homogeneous reaction took place in dimethylformamide and in dioxan up to conversions of about 20 %.

After precipitation and drying, most copolymers containing more than 20 mole-% of acrolein units are insoluble in organic solvents; only those based on acrolein/methacrylonitrile or acrolein/methacrolein are readily soluble, even at acrolein contents of 70 mole-%.

Rather surprisingly, the parameters for a particular pair of monomers (*e.g.* acrolein/acrylonitrile or acrolein/acrylamide) are influenced by the nature of the reaction medium [22]. The same effect has recently been described for other pairs of monomers (acrylonitrile/ethyl acrylate; itaconic anhydride/styrene) [23,24]. To explain this behavior, it is necessary to assume that concentration changes occur during the reaction when the copolymer is precipitated, so that the monomer ratios in the liquid and solid phases differ appreciably from each other and from the originally selected composition. Factors which govern the validity of Equation (a) are thereby invalidated.

In contrast, the Q and e values [*] for acrolein, calculated from the parameters of different homogeneous copolymerizations, are in good agreement, even when different solvents are used (lines 1 and 2 in Table 1). These values should therefore be the most reliable ones.



By application of statistical techniques, the most probable arrangements and the number of successive identical monomer units (lengths of sequences) can be calculated from the copolymerization parameters. Since spectroscopic measurements [25,26] provide an alternative source of information concerning the number of isolated acrolein monomer units, study of the copolymers made an important contribution to the elucidation of the structure of the homopolymer.

Copolymerizations of acrolein with styrene, acrylonitrile, methyl methacrylate, vinyl acetate, methyl acrylate, and allyl alcohol were carried out [17,27], with practical applications in mind. It was hoped that the acrylonitrile/acrolein copolymers would yield a material with improved fiber characteristics.

It may be of practical interest that the copolymers show the chemical properties, typical of polyacroleins, even at relatively low acrolein contents (see Section 5). For example, acrylonitrile/acrolein copolymers dissolve in aqueous sulfur dioxide solutions [28] to give solutions from which films can be cast or fibers spun by wet spinning [28a].

### c) Graft Copolymerization

Graft copolymerization is particularly easy to initiate with γ-irradiation. If a thin film of poly(methyl methacrylate) is dipped into a methanolic solution of acrolein, the monomer diffuses into the polymer. On subsequent irradiation, branches of acrolein units are grafted onto the polymethacrylate chains [29].

M = methyl methacrylate; A = acrolein.

The acrolein that has diffused into the polymer polymerizes much more rapidly than acrolein does on irradiation in bulk.

Separation of the polymeric components by extraction is impossible which indicates that graft copolymerization has indeed occurred. Moreover, the products are entirely insoluble in all solvents. The polyacrolein chains grafted on contain aldehyde groups which can undergo the same chemical reactions as those in homopolymers (see Section 5). The aldehyde groups can be detected, for example, by the coloration they give with fuchsin-sulfurous acid (Schiff reagent).

The conditions prevailing during the diffusion of monomer can be selected in such a way that only a thin surface layer is grafted on. In this way, plates are formed whose interiors consist of unchanged soluble poly(methyl methacrylate), while their surface layers are insoluble and exhibit the properties of a polymeric aldehyde. The thickness of this layer can be rendered visible by dyeing.

An alternative method for the preparation of surface graft copolymers is described in Section 5.

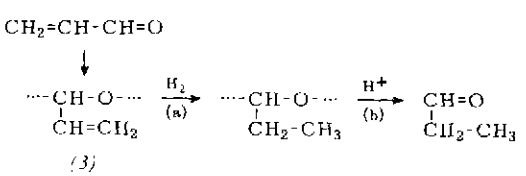
## 3. Polymerization of the Carbonyl Group (3,4-Polymerization)

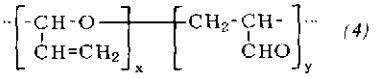
The C=O double bond of acrolein can also undergo polymerization, but ionic catalysts are the only effective agents for initiating this process.



It has long been known [30] that, under the influence of bases, acrolein is converted into oily or solid products which differ in solubility and fusibility from the spontaneously formed "disacryl" polymer [18] and the free-radical polymers. The formation of oligomers was interpreted as a Michael reaction [31]. The structure of the higher molecular-weight products was not clarified; polycondensation reactions were postulated [31a].

Suitable catalysts for this type of polymerization include sodium hydroxide [31, 31a], potassium carbonate [31a], sulfur dioxide [32], thiourea [33], oxides of copper, silver, mercury, and lead [34], as well as alkali-metal and alkaline-earth nitrites [35], sulfuric acid/diethyl ether [8, 9], boron trifluoride/diethyl ether [8, 9], boron trifluoride [35a], and metallic sodium [35b].

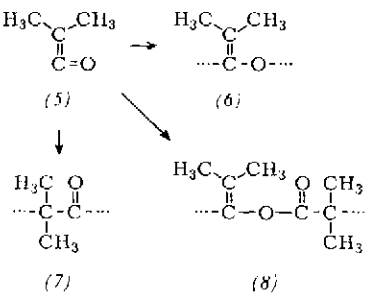
On the basis of earlier observations [8], we used specially purified acrolein and selected typical anionic polymerization catalysts, *e.g.* sodium naphthalene, triphenylmethylsodium, n-butyl-lithium, sodamide, or metallic sodium [36]. Provided that oxygen and moisture are carefully excluded, reproducible polymerization reactions can be obtained between +30 and −60 °C. The solvent influences the rate of polymerization and the properties of the resulting polymer.



Infrared spectra show that the polyacroleins thus obtained must differ entirely from the redox polymers. They contain only few aldehyde groups, as indicated by their nitrogen content after reaction with phenylhydrazine. On the other hand, they take up as much as 0.7 molecule of hydrogen per acrolein unit on catalytic hydrogenation [Reaction (a)].

The hydrogenated polymers produce propionaldehyde on hydrolysis with acid (Reaction (b)]. Accordingly, the polyacroleins produced with the aid of strongly anionic catalysts have been formed mainly by polymerization in the 3,4-positions, and consist mainly of chains of the unit *(3)*.

*(3)*

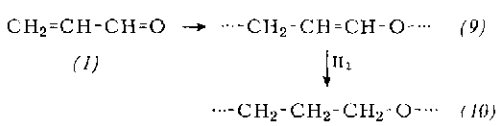


However, unit *(2)* also occurs in these polymers. The content of double bonds and carbonyl groups depends on the catalyst and the reaction conditions, and the x:y ratio in structure *(4)* can vary within wide limits.

*(4)*

Polymers possessing this structure represent a peculiar type of copolymer, since the monomeric units are isomeric.

A similar case is the ionic polymerization of dimethylketene *(5)* described by *Natta* et al. [37]. This monomer is also an unsaturated carbonyl compound, in which either the C=C double bond *(7)* or the C=O double bond *(6)* can polymerize, as well as both *(8)* at the same time. In contrast to acrolein, the double bonds in *(5)* are cumulative.



*(5)* *(6)* *(7)* *(8)*

The vinyl side-groups of polymers *(3)* or *(4)* are still capable of free-radical polymerization. Under conditions similar to those involved in the cross-linking of unsaturated polyesters, these polyacroleins can be copolymerized with, for example, styrene or methyl methacrylate, to form clear, hard, and insoluble, shaped articles. Combination of these two polymerizations involves a new principle in the preparation of copolymers [38].

## 4. 1,4-Polymerization

If acrolein is considered as a 1,3-diene, then polymerization in the 1- and 4-positions should be possible. Linear 1,4-additions would lead to polymers containing the structural unit *(9)*.

*(1)* *(9)* *(10)*

Although such structural units have formed the subject of some discussions [9, 39], they have not yet been detected in any polyacroleins. It has merely been

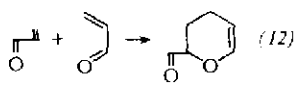
[37] *G. Natta* et al., Makromolekulare Chem. *44/46*, 546 (1961); *51*, 148 (1962).

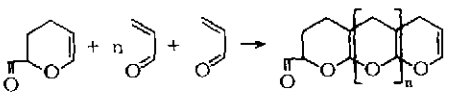
[38] *R. C. Schulz* and *W. Passmann*, Makromolekulare Chem. *72*, 198 (1964).



[39] *R. C. Schulz*, Angew. Chem. *73*, 777 (1961).

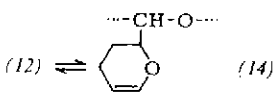
shown that they do not occur in the anionic polymers described above. On hydrogenation, polyethers *(10)* identical with polyoxabutane [36] would be formed.

A cyclizing 1,4-addition leading to polymers of structure *(13)* is also feasible. According to *Alder* and *Rüden* [40], acrolein can add onto dienophiles in the same way as butadiene. In the simplest case, the reaction leads to 2-formyl-$\Delta^5$-dihydropyran *(12)*, in analogy to the formation of vinylcyclohexene *(11)* [41].



*(11)*

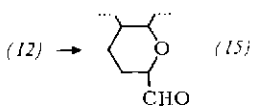
*(12)*



*Scherlin* et al. [42] postulated that further 1,4-additions follow the dimerization of acrolein, with possible formation of polymers *(13)*.

*(13)*

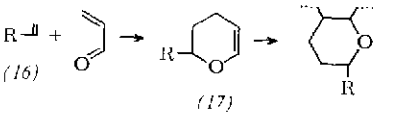
Such a sequence of reactions has not yet been established but it is possible that compounds of this type occur in the non-volatile residues obtained during the preparation of *(12)*. The same structural unit as occurs in *(13)* is formed when adjacent aldehyde groups of polyacroleins *(2)* formed by free-radical catalysts react with ring closure to give *(18)*. The difference between *(13)* and *(18)* lies in the end-groups.



The product of dimerization of acrolein is again an unsaturated aldehyde *(12)*. It is known that this initially fluid compound becomes viscous on storage and ultimately sets to a cloudy, sticky resin. The infrared spectra of purified samples indicate that this process, which is generally designated as a "spontaneous polymerization", entails formation of a polymeric acetal *(14)* [43,44a,b].

*(12)* *(14)*

Almost complete depolymerization can be achieved by heating this material above 185 °C.

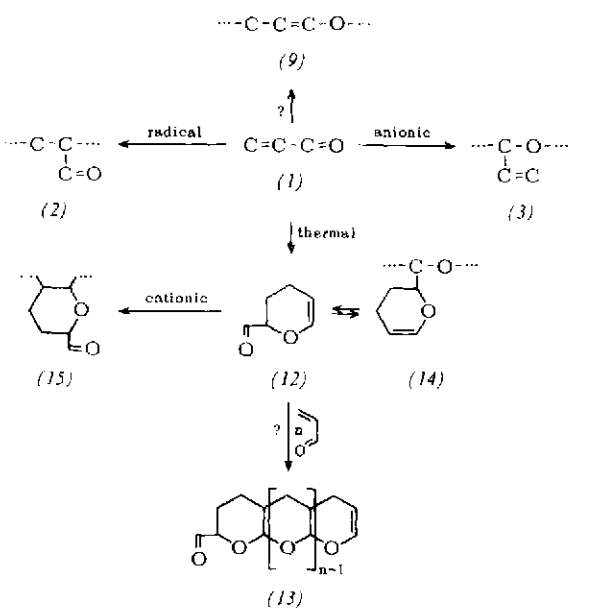


As a vinyl ether, formyldihydropyran *(12)* can be polymerized under the conditions used for cationic polymerization [44a]. The products soften without decomposing at 240–269 °C. Infrared spectra and chemical reactions indicate the structure *(15)*.

*(12)* *(15)*

On the basis of the molecular formulae of their monomeric units, *(14)* and *(15)* can be designated as polymers of acrolein, although they differ substantially from the polymers described above.

Preliminary formation of the dimer provides a further method for the preparation of acrolein copolymers [43]. Acrolein adds onto numerous vinyl and acrylic compounds *(16)* to form diene adducts, *viz.* 2-substituted dihydropyrans *(17)* [45].



*(16)* *(17)*

The addition onto *N*-vinyl compounds proceeds particularly readily [46], *e.g.* *(16)*, R = NH–CO–OR′ or NH–CONHR′. Similarly to *(12)*, compounds of type *(17)* can be considered as cyclic vinyl ethers and are capable of polymerization. The resulting polymers represent a novel type of 1:1 copolymers of acrolein and the unsaturated compound *(16)*.

Dihydropyran [*(17)*, R=H] can also undergo polymerization [47a,b]. Since the monomer decomposes on heating to form acrolein and ethylene [48], polydihydropyran may be regarded as a 1:1 copolymer of these two substances.

The reactions leading to polymers from acrolein discussed in Sections 2–4 are listed in Scheme 1. This

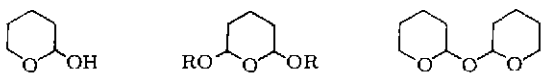
makes it clear that acrolein occupies a special place among monomers, since the choice of polymerization conditions determines the propagation mechanism and hence the chemical structure of the units making up the chain. With most other vinyl and acrylic compounds, the catalysts influence merely the molecular weight, the degree of branching, the end-groups, or the tacticity. The physical and chemical properties of polyacroleins thus depend far more strongly on the conditions of their preparation than do those of other polymers. The various types of copolymers further increase the number of possible variations. This multiplicity of structural units naturally makes characterization and elucidation of the structure of the polymer more difficult, and may explain the frequently contradictory reports concerning the properties of polyacroleins. The differences in properties reported are not simply a consequence of varying molecular weights but are mostly produced by differences in chemical composition.

The uses of acrolein in polycondensation reactions are beyond the scope of this work (see *e.g.* [31a, 49, 50]).

## 5. Chemical Reactions of Polyacroleins



Polyacroleins obtained with the aid of redox systems in aqueous media are chemically very uniform in nature. They are characterized by great chemical reactivity, since every monomer unit contains an aldehyde group, although most of these are present not in the free form but as an aldehyde hydrate ether [51]. Without going into details about the elucidation of the structure, physical and chemical investigations [9, 52–54] have shown reliably that formula *(18)* (n = 0, 1, or 2) represents the most frequently occurring structural unit.

*(18)*, n = 0, 1, 2

Sequences of 2–4 monomer units form fused tetrahydropyran rings along the main carbon chain with a degree of polymerization of 100 to 20000. These are separated by 10–20 mole-% of isolated units with free aldehyde groups. Side reactions during polymerization give rise to branched structures, C–C double bonds, and keto groups, but these almost certainly do not amount to more than 8–10 mole-%. Cross-links, if any, can be formed only through hydrate ether groups which can easily be split.

The reactions of redox polymers of acrolein have been described in several papers [9, 51, 55–57]. Some reactions of low molecular-weight model compounds, *e.g. (19)* to *(21)*, were also studied [54]. These comparisons gave an indication of the optimum experimental conditions, possible side reactions, intermediates, and limitations to the reaction with polyacrolein. They also supplied reference substances for the assignment of infrared bands.

*(19)* *(20)* *(21)*

It was thus shown that the structural unit in *(18)* (like those of corresponding model compounds) often gave the reactions of an aldehyde group, but not invariably. This behavior explains the differences in the maximum yields obtainable in reactions with polyacroleins.

Table 2 gives a list of the most important reactions of polyacroleins together with the maximum degrees of conversion. Details can be found in the original publications cited in the Table.

All the reactions can be explained by assuming structure *(18)* for the polymer, and can be grouped into four types:

a) Reactions in which all the pyran rings are opened, and each monomer unit produces the corresponding aldehyde derivative. In these reactions, polyacrolein behaves like a polymeric monaldehyde, *i.e.* each monomer unit reacts independently of its neighbors. Practically complete conversion is achieved. Consequently, the principal use of these reactions is for quantitative determination of the aldehyde groups. Examples: formation of oximes, phenylhydrazones, oxidation, reduction.

b) Reactions in which two aldehyde groups participate. The pyran rings favor such reactions, polyacrolein behaving like a polymeric dicarbonyl compound; this mode of reaction is even more highly developed in poly(methyl vinyl ketone) [58]. For statistical reasons, conversion is limited to a maximum of 86 mole-% [58a]. Example: the Cannizzaro disproportionation reaction.

c) Reactions which occur only in the hemiacetal-like hydroxyl groups, without opening of the pyran rings. Since an average of 2 hydroxyl groups are available for every 2–4 monomer units, the conversions (per aldehyde group) lie between 50 and 25 mole-%. Examples: reactions with alcohols, thiols, secondary amines, cyanoacetic esters, and other compounds possessing a reactive methylene group.

[58a] *P. J. Flory,* J. Amer. chem. Soc. *61*, 1518 (1939); *64*, 177 (1942).

d) Reactions which proceed only in the presence of free aldehyde groups. These are practically completely suppressed by the presence of the pyran rings. This behavior explains the absence of reactions with peroxides and of radical chain-transfer reactions. Similarly, autoxidation has so far never been observed [59]. Because of its resistance to molecular oxygen, dry polyacrolein is absolutely stable, is easy to handle, and can be stored indefinitely, even in the presence of air.

Since the redox polymers are insoluble in all organic solvents [60], each reaction commences in a heterogeneous system. If possible, the experimental conditions should be so selected that the polymeric products pass into solution as the reaction proceeds. The limitations imposed on the conditions by the low solubility of the polymer and the high viscosities of the solutions obtained are often the cause of failure to achieve the maximum conversions mentioned above.

Table 2. Chemical reactions with redox polymers of acrolein.

| Reaction | Reagent or catalyst | Monomer unit determined | Degree of conversion [a] | Ref. |
|---|---|---|---|---|
| Reduction | $KBH_4$ | $-CH_2-CH-$ <br> $CH_2OH$ [b] | >90 | [53, 61] |

A special place among polyacrolein reactions is occupied by the addition reactions of sulfurous acid or sodium hydrogen sulfite, yielding water-soluble derivatives of high reactivity. Most of the above reactions can also be carried out with these polyacrolein/sulfurous acid adducts.

The adduct *(22)* is in equilibrium with sulfurous acid and a hydrated form *(23)* of the polyaldehyde [59]. It cannot be isolated, so the degree of conversion cannot be determined. It is however certain that the addition of only a few molecules of sulfurous acid per macromolecule is sufficient to make polyacrolein soluble in water,

although insoluble polyacrolein is reformed on evaporation or freeze-drying of the solution. The polyacrolein/sulfurous acid adducts are strong polyelectrolytes, with the properties of wetting agents, and can be used as high molecular-weight emulsifying agents [15]. The ability of sulfur dioxide-solubilized polyacrolein to react with the reactive groups of other polymers is particularly noteworthy [56,57]. In this way "composite polymers" *(24)* are formed which are cross-linked through primary valences.

A = $CH(OH)_2$; B = OH; SH; NH; $NH_2$
C = acetal-, mercaptal-, azomethine groups.

The unreacted aldehyde groups can be identified by color tests, and are available for other reactions. Under certain conditions these composite polymers are formed only at the surface of films, fibers, thin sections, *etc.* In this way, novel surface graft copolymers are obtained by a method different from that described in Section 2c.

Most copolymers of acrolein can, like the homopolymers, undergo the reactions of Table 2. The properties of the polymeric derivatives can be varied over a wide range, according to the nature of the comonomer and the aldehyde group content.

Apart from the reactions cited above with the aldehyde or hemiacetal-like hydroxyl groups, reactions are also possible with the α-hydrogens (with respect to the CO group) of the main chain; one example of such a reaction is the aldol condensation with formaldehyde.

*The author wishes to take this opportunity to express his sincere gratitude to Professor W. Kern for introducing him to the study of this field and for many years of encouragement and advice. Thanks are also due to H. Cherdron, P. Elzer, H. Fauth, C. Gutweiler, R. Holländer, E. Kaiser, K. Kamio, J. Kovács, I. Löflund, M. Marx, E. Masuhara, K. Meyersen, M. Miething, E. Müller, R. Neeb, H. Ohse, W. Passmann, S. Potnis, R. Schaaf, K. Shohara, and S. Suzuki, who participated in the present work. All our thanks are also due to Degussa, Frankfurt/Main, who advanced generous financial support for this work.*

# A New Method for the Determination of Fluorine

BY PROF. DR. F. SEEL, DIPL.-CHEM. ELLI STEIGNER, AND INGE BURGER

INSTITUT FÜR ANORGANISCHE CHEMIE DER UNIVERSITÄT DES SAARLANDES
SAARBRÜCKEN (GERMANY)

*A new, particularly simple and reliable method of quantitative fluorine analysis is described; it is based on the conversion of insoluble silver oxide into soluble silver fluoride by fluorosilicic acid released from the sample by Willard-Winter-Tananaev steam distillation, the silver fluoride then being determined volumetrically according to Volhard.*

In contrast to the ease of analysis for the majority of the elements, quantitative determination of fluorine demands meticulous attention to details in executing individual operations. Several methods [1] give excellent results if extreme care is exercised, and if the analyst has acquired the necessary routine. However, at present there is no procedure which is entirely satisfactory with respect to simplicity and reliability of the analytical technique. A first step in this direction has undoubtedly been taken with the introduction of steam distillation of fluorine as fluorosilicic acid, a generally applicable technique developed independently by *Willard* and *Winter* [2], and by *Tananaev* [3]. However, the methods recommended for the subsequent analytical determination of fluorine – usually precipitation of lead chloride fluoride or bromide fluoride, or thorium fluoride – are not normally simple to conduct.

We have now succeeded in simplifying the second step in such a way that even an unskilled operator can conduct fluorine determinations with rapidity and high accuracy. In our procedure fluorosilicic acid is liberated from the fluorine-containing material and used to dissolve silver oxide.

$$SiF_6^{2-} + 2\,H^+ + 3\,Ag_2O + (n-1)\,H_2O \rightarrow 6\,F^- + 6\,Ag^+ + SiO_2 \cdot n\,H_2O$$

The amount of silver equivalent to the fluorine in the solution may then be determined according to *Volhard*. The determination of fluorine is thus simply reduced to a volumetric determination of silver. The solubility of silver oxide ($Ag_2O + H_2O \rightarrow 2\,AgOH$) can only be neglected if 1 mole of silver nitrate per val $F^-$ is added to the distilled solution of fluorosilicic acid prior to the addition of the silver oxide. Standard silver nitrate and thiocyanate solutions are therefore required.

For the volatilization of fluorosilicic acid [4], the silicic acid/phosphoric acid procedure [5] was preferred, since phosphoric acid does not form a soluble silver salt, in contrast to sulfuric or perchloric acid, which have also been recommended for the Willard-Winter-Tananaev distillation. The solution of the sample was heated to 240 °C in an electrical heating mantle. The steam was superheated to 220–240 °C in a quartz coil by internal electric heating before entering the sample vessel. Recirculation of the water – considered essential by *Pietzka* and *Ehrlich* [6] – thus proved unnecessary. The amount of distillate normally required for 1 val $F^-$ is 100–150 ml. Details of the apparatus are shown in Figure 1.

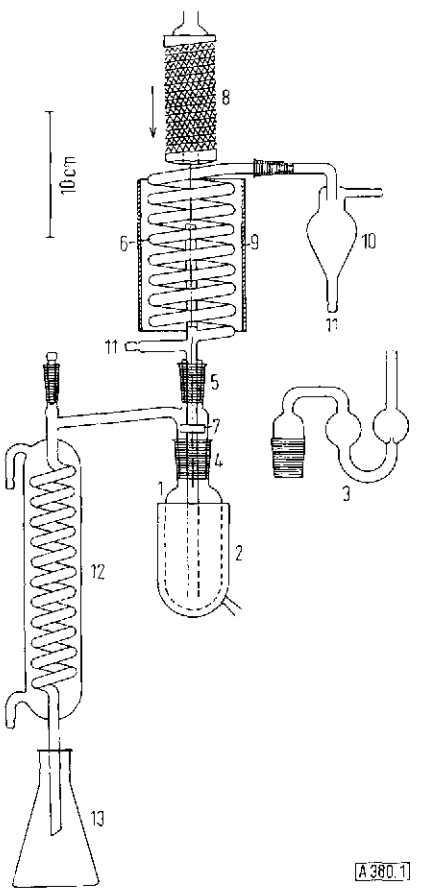

Fig. 1. Apparatus for distilling fluorosilicic acid by means of superheated steam. 1: sample vessel, 2: electrical heating mantle, 3: ball-tube adapter, 4: ground joint with Teflon sleeve, 5: ground joint with Teflon stopper, 6: quartz coil, 7: Teflon disc, 8: heating coil (removed from quartz coil), 9: heat insulation (asbestos cylinder, shown in section), 10: drip catch, 11: steam outlet, 12: condenser, 13: receiver.

[3] *I. Tananaev,* Zhur. Prikl. Khim. *5*, 834 (1932).

[4] Proof that it is actually $H_2SiF_6$ that distills over was provided by determining the atomic ratio *Si*:F in the distillate.

[5] *E. Rinck,* Bull. Soc. Chim. France (5) *15*, 305 (1948).

[6] *G. Pietzka* and *P. Ehrlich,* Angew. Chem. *65*, 131 (1953).

Volatile acids which form soluble silver salts must be rendered involatile or destroyed prior to the distillation. Sulfuric acid distils over at the high temperature employed but can be bound by adding barium phosphate prior to distillation. If large amounts of chlorine, bromine, or iodine are present, the addition of silver phosphate to the sample solution is advantageous. Nitrate is the most difficult ion to remove. We finally succeeded in preventing the formation of nitric acid by fusing any samples containing nitrate or nitrite with ammonium sulfate.

Naturally, the procedure is limited to the scope of the Willard-Winter-Tananaev distillation, and the interferences associated with this method must be taken into account. Metal ions ($Ca^{2+}$, $Pb^{2+}$, $Th^{4+}$, $Al^{3+}$, $Sb^{5+}$) which form insoluble salts or complexes with fluoride ion hardly affect the rate of distillation under the conditions given above. Boric acid steam-distils over with the fluorosilicic acid, but does not interfere. Substances containing difficultly or non-hydrolysable fluorine (*e.g.* sulfanuric fluoride, organic fluorine compounds) must be decomposed in a suitable manner.

## Examples

### a) *Analysis of Lead Chloride Fluoride*

For the determination of fluorine in PbFCl, samples of 0.2–0.5 g, *ca.* 1 g of silicon dioxide powder, and 0.75 g of silver phosphate are placed in a 100 ml pyrex flask (1 in Fig. 1), and 20 ml of 85 % phosphoric acid are added. The flask is preheated for a few minutes using the electrical heating mantle, which is provided with a control for maintaining an inner temperature of 240 °C [7]. Steam is then introduced, and finally the quartz spiral is heated by means of the heating coil of a large hair-dryer in order to superheat the steam to 220–240 °C. The volume of liquid in the sample flask remains essentially constant under these conditions. If steam is passed through the sample at a rate corresponding to ca. 250 g of water per hour, the distillate is no longer acidic after distillation of 100–150 ml. To the solution of fluorosilicic acid in the receiver are then added 10.0 ml of 0.1 N silver nitrate and 0.5 g of silver oxide. The solution is boiled briefly and cooled again and filtered through a sintered glass funnel, and the filtrate is then titrated according to *Volhard*. Table 1 gives a list of the results of analyses on 5 samples of PbClF.

Table 1. Analysis of five samples of PbClF.

| PbFCl [mg] | 0.1 N KSCN [ml] | F found [mg] | F calc. [mg] | Deviation [%] |
|---|---|---|---|---|
| 491.0 | 18.50 | 35.20 | 35.60 | −1.1 |
| 268.3 | 10.30 | 19.60 | 19.50 | +0.5 |

[7] If no degradations need to be carried out in the sample flask, the heating mantle can be replaced by a vacuum mantle. Also an aluminum block can be used for heating instead of the electrical heating mantle.

### b) *Analysis of a Mixture of Sodium Fluoride and Potassium Nitrate*

The sample is mixed with 0.7 g of ammonium sulfate per val $NO_3^-$ and heated with 2–3 ml of 1 N NaOH in the distillation flask, after the ball tube (3 in Fig. 1) has been attached. Heating is continued until the mixture melts. Any silicon tetrafluoride resulting from attack of ammonium fluoride on the glass is absorbed by the alkali. After cooling, the contents of the ball tube are rinsed into the flask, and silicon dioxide powder, phosphoric acid, and 1.2 g of precipitated barium phosphate are added. Before introducing the superheated steam, the volume of the solution must be reduced to the original volume of the 85 % phosphoric acid added by heating with the heating mantle. The reliability of the procedure is shown by the five examples set out in Table 2.

Table 2. Analysis of five samples of NaF + $KNO_3$ (≈1:1).

| NaF [mg] | 0.1 N KSCN [ml] | F found [mg] | F calc. [mg] | Deviation [%] |
|---|---|---|---|---|
| 46.5 | 11.00 | 20.90 | 21.00 | −0.5 |
| 64.0 | 15.28 | 29.00 | 28.95 | +0.15 |
| 54.0 | 12.95 | 24.6 | 24.4 | +0.9 |
| 63.9 | 15.15 | 28.8 | 28.9 | −0.4 |
| 42.1 | 10.1 | 19.2 | 19.1 | |

Figure 2 shows a graph of the relative error of the fluorine determination on 100 samples, most of which contained 1–6 mg-at. of fluorine plus varying amounts

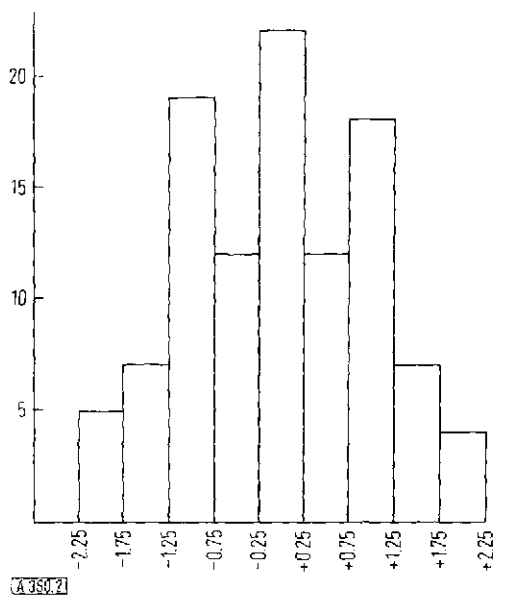

Fig. 2. Relative errors in 100 determinations of fluorine by the silver fluoride method.
Ordinate: Number of analyses.
Abscissa: Relative error [%].

of $Cl^-$, $Br^-$, $I^-$, $NO_3^-$, $SO_4^{2-}$, $Ca^{2+}$, $Pb^{2+}$, $Th^{4+}$, or $B(OH)_3$. The symmetrical distribution of deviations indicates that the procedure does not involve any systematic error. The mean error is found to be ±1.0 %. This also includes the general errors associated with volumetric determinations, *i.e.* inaccuracies of weighing, reading, *etc.*

# Equilibrium and Nonequilibrium in the Glycolysis System [*]

BY PROF. DR. TH. BÜCHER AND CAND. MED. W. RÜSSMANN

INSTITUT FÜR PHYSIOLOGISCHE CHEMIE
DER UNIVERSITÄT MARBURG/LAHN (GERMANY)

*Dedicated in gratitude and admiration to Otto Warburg on the occasion of his 80th birthday*

*The relationship between the metabolic throughput within the network of energy-furnishing metabolism and the deviation of its composite reacting units from equilibrium is discussed. Measurements have been made of the steady-state relaxation times, and, following a suggestion by Alberty, their application is described. The results confirm and extend the concepts of intracellular redox relationships which the authors' research group outlined five years ago in this journal. The maximum difference between the redox potentials of the lactate/pyruvate and of the DPN/DPNH systems was calculated to be 2 mV. Deviations of the α-glycerophosphate/dihydroxyacetone phosphate system measured in vivo are correlated with the rate of flow in the glycerophosphate cycle.*

## 1. Ordering of Nonequilibria

(The principle of opposing changes of potential differences)

The phenomenon of continuous nonequilibrium in living matter is an old problem in the philosophy of nature. A quantitative exploration was started by *Liebig*'s "law of minimum" and by *Blackman*'s concept of the "limiting factor". Especially *Blackman*'s statement "...the rate of a process is limited by the pace of the slowest factor" [1] as well as consecutively coined terms like "rate-limiting reaction" [2,3] "master reaction" [4,5], "pace-maker" [6], "bottle-neck", etc. not only describe but also require a formal and quantitative arrangement of nonequilibria within the living material.

The main point in this connection may well be illustrated by comparing wild and controlled streaming of a river. Figure 1a represents an uncontrolled waterway, in which the total gradient is distributed approximately equally among the various section along the flow line. The same flow may be tamed by constructing flood gates; the river is thus divided into reservoir – or backwater – and waterfall sections (Fig. 1b). The greater cross-sectional area of the water in the dammed up zone offers less resistance to flow and thus compensates for the minute gradients existing in the river before the dam.

*Michaelis* used a similar model (locks regulating a waterway) in describing redox pathways [7]. From the organizational point of view, the ordering of nonequilibria produced by regulation of the waterway has three effects: it facilitates control of the levels and of the rate of flow

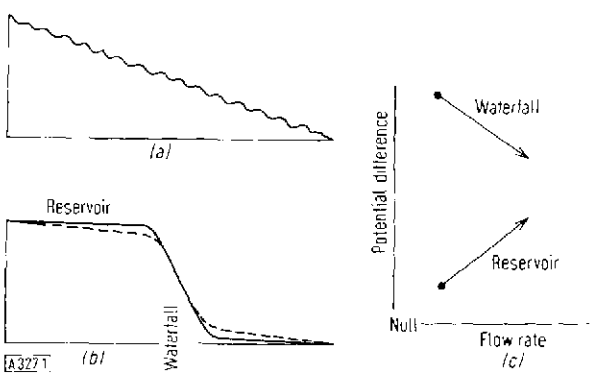

Fig. 1. Schematic representation of (a) an unregulated waterway, (b) a regulated stream, and (c) the changes in the potential gradient at increasing rates of flow (throughput).

and it concentrates the capacity of the system to do useful work. To regulate the rate of flow of water or, more generally spoken, to regulate the *throughput* of matter within the system, the "flood gate" need only be raised or lowered.

As the throughput increases, the gradients undergo a characteristic change, as shown by the dashed lines in Figure 1b. The rate-controlling factor, *i.e.* the potential drop at the "flood gate", decreases, while at the same time the potential difference between the two ends of the reservoir increases. This is indicated graphically in Figure 1c. This *principle of opposing changes in potential differences* is always encountered when a waterway (or a metabolic chain) is subdivided by "flood gates" (or limiting steps). It can help us in locating such limiting steps and their controlling factors.

## 2. An Example

(Metabolic patterns of skeletal muscle)

Tissues in which the metabolic rate can change considerably and at short notice as a function of the activity of the system provide a fairly simple object on which to test the above principle. Voluntary skeletal muscle is an example. In it, the rate of energy-releasing metabolism can increase by several orders of magnitude, especially in the Embden-Meyerhof glycolytic reaction chain (Fig. 2). Recently, *Hohorst* et al. [8,9] studied the changes in the metabolite pattern of the Embden-Meyerhof pathway of rat abdominal wall muscle when the latter went into tetanic contraction. Figure 3 shows some of these measurements. If we want to interpret them via the model of the regulated river, we must first calculate *ratios of the "levels"* (see [40a]) *of the metabolites* [10, 11] and compare these ratios with the known (apparent) equilibrium constants. By convention, the levels of the reaction products are placed in the numerators of the ratios. Equilibrium constants are also presented in the Figure. These can be found without difficulty for most pairs of metabolites, since they belong to two-component reactions [12] (see [*] on p. 431). However, a special assumption

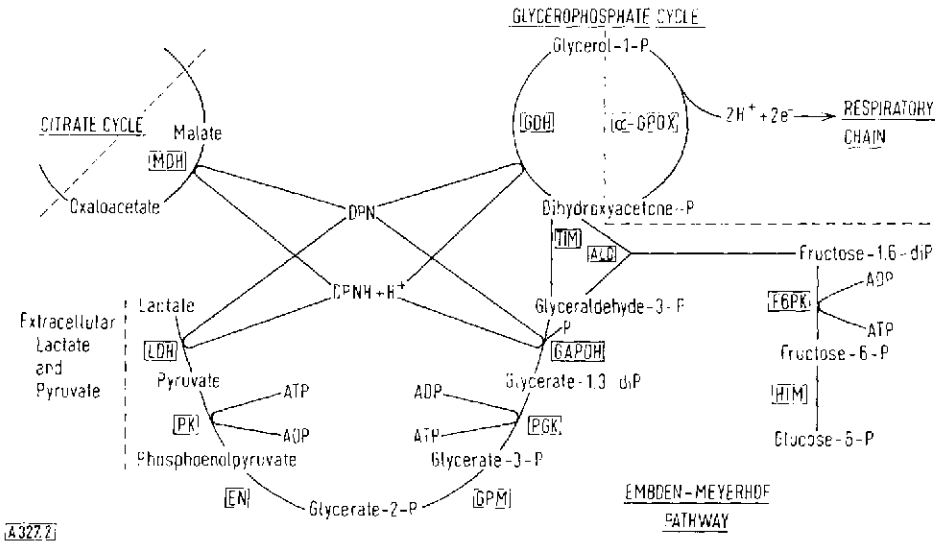

Fig. 2. Schematic diagram of the interrelationships in carbohydrate metabolism [*]

[*] The following abbreviations are used in this paper:

| | |
|---|---|
| ALD | = aldolase |
| ADP | = adenosine diphosphate |
| ATP | = adenosine triphosphate |
| DAP | = dihydroxyacetone phosphate |
| DPN | = diphosphopyridine nucleotide |
| DPNH | = reduced DPN |
| EN | = enolase |
| FDP | = fructose-1,6-diphosphate |
| F6P | = fructose-6-phosphate |
| F6PK | = phosphohexokinase (6-phosphofructokinase) |
| GAP | = glyceraldehyde-3-phosphate |
| GAPDH | = phosphoglyceraldehyde dehydrogenase |
| GDH | = glycerol-1-phosphate dehydrogenase |
| α-GP | = glycerol-1-phosphate (α-glycerophosphate) |
| G6P | = glucose-6-phosphate |
| GPM | = phosphoglyceric mutase |
| α-GPOX | = glycerol-1-phosphate oxidase |
| HIM | = phosphohexose isomerase |
| Lac | = lactate |
| LDH | = lactic dehydrogenase |
| MDH | = malic dehydrogenase |
| P | = inorganic phosphate |
| PEP | = phosphoenolpyruvate |
| PGK | = phosphoglycerokinase (ATP phosphoglyceric transphosphorylase) |
| PGA | = phosphoglyceric acid (glycerate phosphate) |
| PK | = pyruvate phosphokinase |
| Pyr | = pyruvate |
| TIM | = triosephosphate isomerase |

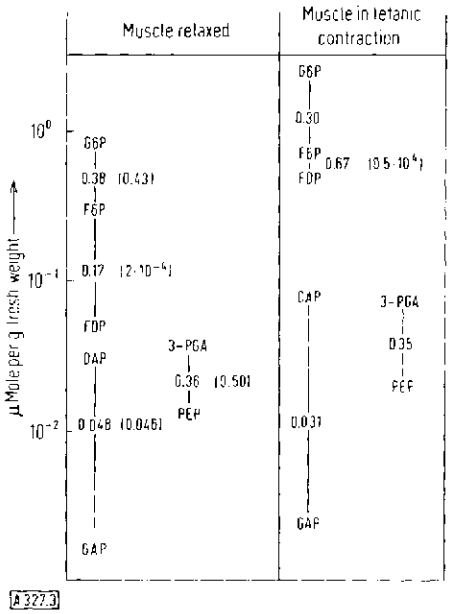

Fig. 3. Metabolite levels in rat abdominal muscle [8,9].
For the analytical method, see [11]. Ratios calculated from metabolite levels are included between metabolite pairs, while (apparent) equilibrium constants [16] are in parentheses. In the case of phosphohexokinase ratios [see Equation (a), p. 428], the [ATP]/[ADP] ratio was calculated from the levels of creatine phosphate (CP) and Creatine (C):
$[ATP]/[ADP] = 10 \times \{CP\}/\{C\}$.
$[FDP]/[F6P] = Kapp \times [ATP]/[ADP] = 10 \times 10^{3} \times \{CP\}/\{C\}$.

[12] *Th. Bücher,* Pure appl. Chem. *6*, 209 (1963).

must be made for the pair F6P/FDP (see legend to Fig. 3), since it is part of a four-partner reaction.

Comparison of the ratios of the steady-state metabolite levels with the equilibrium constants reveals two facts:

1. The ratios can be classified into two categories: the first contains ratios which are of the same order of magnitude as the equilibrium constants; here the difference of potentials is small. In the second case (F6P/FDP), there is considerable difference between the two; there exists a considerable drop of potential.

2. As a consequence of the transition from the quiescent to the active state of the muscle, ratios of the first category show a decrease, while those of the second category show an increase (F6P/FDP by a factor of 4).

Employing the concepts developed in Section 1, it is obvious that the following reaction which is catalysed by the enzyme phosphofructokinase (see also Figure 2):

Fructose-6-phosphate + ATP
$\Downarrow\Uparrow$ F 6 PK (a)
Fructose-1,6-diphosphate + ADP

is a limiting step. We can attribute the other metabolite pairs to the sections with a low gradient of the chemical potential.

In a somewhat similar fashion, *Holzer* and *Holldorf* [13] defined "rate-controlling reactions" and "equilibrium reactions" (hexose monophosphate isomerase, aldolase, triose phosphate isomerase, alcohol dehydrogenase) for the fermentation process in yeast. *Hess* [14] divides the complete sequence of metabolites of glycolysis in Ehrlich ascites tumors into three groups of "quasi-equilibrium intermediates", separated or controlled by "quasi-irreversible" reactions: phosphohexokinase, phosphoglyceric kinase, and pyruvic phosphokinase. His values and those of *Mann* et al. [15], who also performed pioneer work on the dynamics of the *metabolite pattern*, are shown in Table 1.

Table 1. Ratios of metabolite levels in various cells. Apparent equilibrium constants $K_{app}$ [16] are given in parentheses in the first column.

| | Yeast [15] | Ascites tumor [14] | Skeletal muscle [7] Rest | Work |
|---|---|---|---|---|
| G6P/F6P (0.43) | 0.33 | 0.23 | 0.38 | 0.30 |
| 3-PGA/2-PGA (0.17) | 0.45 | 0.43 | 0.12 | 0.30 |
| 2-PGA/PEP (3.0) | | 1.6 | 3.0 | |

## 3. Limiting Steps

(Energetics and Definitions)

It has already been mentioned that organization of a system into "low-gradient" sections with an intervening potential drop "concentrates" its ability to do useful work: metabolic "power-plants" can only be located within a range involving a drastic drop of potential. At the same time, it should be kept in mind that the production of a maximum amount of useful work destroys the nonequilibrium and thus removes the possibility of control. The variability and controllability of a system require that at least one unidirectional step (nonequilibrium) is involved [17].

However, an ideally functioning power plant can also act as an *indirect* controlling factor in the system, for the resistance it offers depends upon the output it produces. Since it is coupled to the process which utilizes the free energy of the system, the controlling nonequilibrium is shifted towards the energy-consuming process. Such relationships are of fundamental importance in the control of energy-supplying metabolism via the cyclic participation of phosphate. In this sense, the "cross-over" theorem of *Chance* [18] may be regarded as a special case of the principle outlined above of opposing directions of changes in the potential gradients that is applicable to the region of *indirect* controlling factors.

The phosphofructokinase reaction, the limiting step in the section of the Embden-Meyerhof pathway treated in Figure 3, is not a power plant, *i.e.* it does not produce energy for the cycle. It is thus a *direct* controlling step. As such, it transforms a considerable quantity of free energy into heat. This is analogous to the problem of maintaining pressure in a leaky vessel. Maintenance of a steady nonequilibrium in such a chain of reactions is accompanied by a continuous transformation of free energy into heat [19, 20]. The *work* per unit of time per unit of volume required, which is represented by L in Equation (1), is proportional to the *metabolic throughput* $V_{st}$ (molarity per unit of time) and to the potential difference (*deviation from equilibrium* [*]).

$$L = V_{st} RT \ln \frac{\Gamma}{K_{app}} \qquad (1)$$

where $K_{app}$ = the thermodynamic equilibrium constant, see Equation (2), and $\Gamma$ = "mass-action ratio" of nonequilibrium, see Equation (4).

The continuous loss of free energy is small in those parts of the reaction chain where the potential differences and hence the deviations from equilibrium are small, but is large in the phosphofructokinase reaction. This is the energy price which the system must pay for its ability to vary its throughput.

Equation (1) follows from the thermodynamic definition of *equilibrium* and *nonequilibrium*. It is known that at equilibrium, the work which the system is capable of

[*] $\ln \Gamma/K_{app}$ is approximated by $\Gamma/K_{app}-1$ in the neighborhood of $\Gamma/K_{app}=1$. Terms like $\Gamma/K_{app}-1$ may serve also as expressions for the *deviation* of the "mass-action ratio" from equilibrium in the treatment of the "small-deviation" sections of the metabolic pathway.

[20] *L. v. Bertalanffy:* Biophysik des Fließgleichgewichts. Sammlung Vieweg, Braunschweig 1953.

doing is zero, while the entropy reaches a maximum ($dS = 0$). In this sense, equilibrium is a static condition. The observed concentrations or, to be exact, the activities of the reaction partners obey the law of mass action.

$$K_{app} = \frac{[P][Q]\cdots}{[A][B]\cdots} \qquad (2)$$

Nonequilibria can be "stationary", "nonstationary", or "steady" [*]. The stationary-state nonequilibrium is also called "flow-equilibrium" [20a].

## 4. Pacemakers

*Krebs* and *Kornberg* [6] wrote the following about the pacemaker reaction: "There is a general principle which may guide the search for pacemakers. As pacemakers are reactions of variable rate, the level of substrate concentration of the pacemaker must vary inversely with the rate: it must increase when the reaction rate decreases." In view of this definition, can the phosphohexokinase reaction be classified as a pacemaker reaction? It can be seen in Figure 3 that the metabolite levels of both F6P and FDP increase with the flow rate. Thus, the change produced is opposite to that required by *Krebs* and *Kornberg* for a "pacemaker". Actually, this phenomenon is caused by other limiting reactions taking place upstream from the metabolic sequence in question, *viz.* by the phosphorylase reaction and the glucokinase reaction. In particular, activation of phosphorylase causes the instantaneous discharge of glucose phosphates from the glycogen reservoir [21–23]. This can also be seen in Figure 3.

The above facts also explain why the phosphofructokinase reaction has been omitted from consideration in so many articles on regulation of glycolysis.

Although we cannot enter here into a detailed discussion of some recent findings concerning the functions and mechanism of this reaction [10,24–27], it is worthwhile calling attention to the advantages of analyzing processes in terms of relative rather than absolute changes in metabolite levels.

## 5. Metabolite Patterns at Rest and during Activity

(The principle of functional readiness)

In principle, a single controlling step is sufficient for control of any metabolic chain [4,5]. However, as has just been discussed, glycolysis in muscle involves *several* limiting reactions. Since we are dealing with a biological system, it is permissible to inquire about the purpose of this greater complexity.

Our problem may be considered in terms of the need for reversibility of the metabolic flow. Since the free energy is stored in standardized quantities as "high-energy" phosphate compounds and since chemical potential is consumed in this form, energetically practicable sections must be present, just as series of locks are usually needed between the higher and lower levels of a canal.

Another aspect of the problem which has received even less attention [12,27] is "functional readiness". In the metabolic organization, the entry of new substrate molecules into the glycolytic pathway is controlled by the pathway's output. The existence of this coupling means that, after disappearance of intermediate metabolites, the flow through the pathway can be restored to a steady state only after a long induction period. In fermentation research, this well-known phenomenon is called "Angärung". However, in rapidly responding tissues, such as skeletal muscle, the power output and consequently the metabolic throughput may change within a fraction of a second. Here not only well-filled energy reservoirs are required, but also a preparation of the metabolite pattern at rest counteracting any depletion of intermediate levels.

In the two sections of Figure 3, the throughput differs by at least a factor of 100. In view of this, any changes observed in the pattern of the metabolite levels, and especially any changes in their relative proportions, must be considered as relatively small. This phenomenon becomes meaningful when considered in terms of physiological requirements for functional readiness. *Functional readiness* produced by *homeostasis of cellular metabolite ratios* necessitates the interaction of several controlling reactions. Approximately one-third of the metabolite levels is controlled by these reactions. As is shown impressively in Figure 3, the other two-thirds of the levels approach (and are controlled by) equilibrium. It is with this second fraction of metabolite levels that we shall deal in the following sections.

[*] The term "stationary state" applies to a compound in a reaction sequence where there is a continuous and constant supply of substrate from an infinite reservoir, while "steady state" applies to a compound during a prolonged period of transition. In a muscle at rest the metabolites are in a "stationary state". After stimulation for reversible contraction the metabolites can be considered to be in the "steady state" [20a].

## 6. Metabolic Throughput and Deviation from Equilibrium

Let us imagine that one of the reacting units in a metabolic pathway (*i.e.* the reactants and the catalytic agent) were momentarily separated from the rest of the active pathway. Just before the separation our reaction, as a link in a metabolic chain, is *deviated from equilibrium* to a certain extent, which is a function of the throughput within the pathway. The isolated reaction would then immediately tend to attain a state of equilibrium. The initial rate (molarity per unit of time) of this relaxation process would be equal to the throughput mentioned.

As an example, let us assume that the enolase reaction system

$$\text{2-Phosphoglycerate} \underset{}{\overset{\text{Enolase}}{\rightleftharpoons}} \text{Phosphoenolpyruvate} + H_2O \qquad \text{(b)}$$

has been isolated from the metabolic sequence of the working muscle, shown in Figures 2 and 3 (*i.e.* we isolate the metabolite, the enzyme, and the activating $Mg^{2+}$).

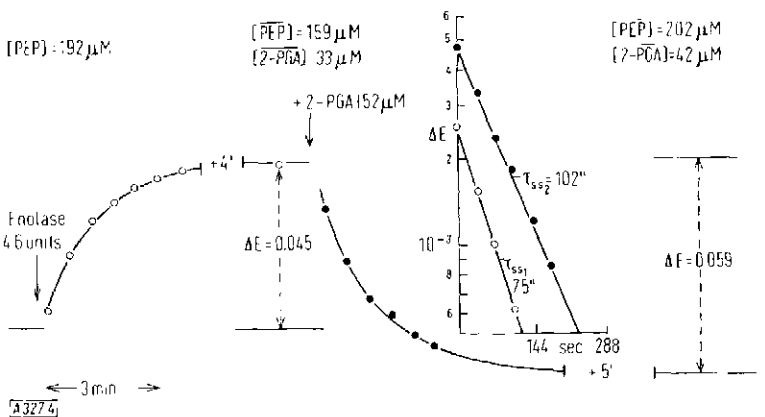

Fig. 4. Attainment of the equilibrium
2-Phosphoglycerate ⇌ Phosphoenolpyruvate
in the enolase reaction. The reaction starts (on the left) following addition of 4.6 units [34a] of enolase from rabbit muscle [34]. Extinction registered at 240 mµ (light path: 1 cm) on a Beckmann DKI instrument. 100 mM imidazole buffer, 0.8 mM $MgSO_4$, pH 6.8, 37 °C. In addition a *semi-logarithmic* plot of the measurements (o and •) is shown, applying corrections for the dilution on addition of substrate. ΔE = Change in extinction.

As *Warburg* and *Christian* have shown [28], the reaction proceeds to equilibrium by a first-order process. Therefore, the reaction rate is always proportional to the deviation $\Delta[A]_t$ of the substrate concentration from the equilibrium value:

$$\frac{d(\Delta[A])}{dt} = k\Delta[A]_t \qquad (3)$$

$$\text{or } \Delta[A]_t = \Delta[A]_o\, e^{-kt}$$

where [A], [P] = arbitrary concentrations of substrate and product and $[\bar{A}]$, $[\bar{P}]$ = concentrations at apparent equilibrium

$\Delta[A] = [A]-[\bar{A}]$ = deviation of the substrate concentration from equilibrium [28a] as in: $\Gamma = ([P] - \Delta[A])/([\bar{A}] + \Delta[A])$ (4)

[28] *O. Warburg* and *W. Christian*, Biochem. Z. *310*, 384 (1941).

With $K_{app} = [\bar{P}]/[\bar{A}]$ we obtain:

$$\Delta[A] = \frac{[A]}{1 + \frac{1}{K_{app}}}\left(1 - \frac{\Gamma}{K_{app}}\right)$$

*or*

$$\Delta[A] = -\frac{[\bar{A}]}{1 + \frac{1}{\Gamma}}\left(\frac{K_{app}}{\Gamma} - 1\right)$$

*or* (4)

$$\Delta[A] = \frac{[P]}{1 + K_{app}}\left(\frac{K_{app}}{\Gamma} - 1\right)$$

*or*

$$\Delta[A] = \frac{[\bar{P}]}{1 + \Gamma}\left(1 - \frac{\Gamma}{K_{app}}\right)$$

In the first part of the enolase experiment (left part of Fig. 4, open circles) this type of kinetics appears straight on from the start (addition of enzyme). If equilibrium is again disturbed by addition of a small amount of metabolite to the system, then the process of relaxation is repeated (full circles in Fig. 4).

The relaxation time [30a] $\tau_{ss}$, the reciprocal of the constant k of the monomolecular reaction

$$\tau_{ss} = \frac{1}{k} \qquad (5)$$

is the time during which the deviation decreases to the e-th part of the initial value. This is also evident from the semi-logarithmic plot in Fig. 4.

Employing the concept developed at the beginning of this Section we replace $\Delta[A]_t$ in Equation (3) by $\Delta[A]_{st}$,

[28a] In a previous article [29], we designated the ratio of concentrations in the mass action equilibrium with Q and in the nonequilibrium with Q. We shall now use $K_{app}$ for the former and the symbol Γ, which has been previously introduced by *W. Kuhn* [19], for the latter. This is done to avoid confusion with the efficient system of notation, developed by *Cleland* for enzyme kinetics [30]. In that system, [Q] is the concentration of a second product, see Equation (14).

[29] *H. Schimassek, B. Kadenbach, W. Rüßmann*, and *Th. Bücher* in *G. Weber:* Advances in Enzyme Regulation. Pergamon Press, London 1963, Vol. 1, p. 103.

[30] *W. W. Cleland*, Biochim. biophysica Acta *67*, 104 (1963).

[30a] The relaxation time $\tau_{ss}$ is understood to be the relaxation time of the enzymic steady state, defined from the point of view of enzyme kinetics. In this case, the notation of *Hammes* and *Alberty* [31] has been used.

the deviation of any reaction in the stationary or even in the steady state of a metabolic sequence, and $-\frac{d(\Delta[A])}{dt}$ by its metabolic throughput $V_{st}$. This yields

$$V_{st} = k\,\Delta[A]_{st} = -\frac{\Delta[A]_{st}}{\tau_{ss}} \quad \text{[molarity per unit of time]} \qquad (6)$$

from which it can be seen that there is a simple relationship between the deviation and the metabolic throughput. This relationship is due to the pioneering work of *Alberty* and his research group [32], who pointed out that Equation (6) is analogous to Ohm's law:

*current = potential/resistance*

In conformity with the relaxation concept itself, Equation (6) is valid only for small deviations from equilibrium. However, it still may be used in practice because fortunately a large number of enzymatically catalysed reactions approach first-order kinetics, even at quite large deviations from equilibrium. Processes which obey this relationship include not only the enolase reaction, which we have used as an example, but also such reactions as the complicated test system of phosphoglyceric kinase [33] (see also Fig. 9).

## 7. $\tau_{ss}$ of the Two-Partner Reaction [*]

(Enolase system)

In conformance with the method of *Hammes* and *Alberty* [31], we can derive the relaxation of an enzymatic reaction from the general equation for the rate of reaction. This general equation is obtained from the Michealis-Haldane theory by assuming steady-state concentrations of the intermediate enzyme-substrate or enzyme-product complexes. We shall use the nomenclature developed by *Cleland* [30], see Equations (1)- (3).

$$-\frac{d[A]}{dt} = \frac{\frac{V_1}{K_a}[A] - \frac{V_2}{K_p}[P]}{1 + \frac{[A]}{K_a} + \frac{[P]}{K_p}} \qquad (7)$$

$K_a$, $K_b$ = Michaelis constants

$V_1$, $V_2$ = maximum velocities of forward and back reactions.

From Equation (4) $[A] = [A] + \Delta[A]$ and $[P] = [P] - \Delta[A]$. When $\Delta[A] \ll [A]$, $[P]$, it follows that

$$-\frac{d\Delta[A]}{dt} = \Delta[A]\,\frac{\frac{V_1}{K_a} + \frac{V_2}{K_p}}{1 + \frac{[A]}{K_a} + \frac{[P]}{K_p}} \qquad (8)$$

Since it also applies that

$$-\frac{d\Delta[A]}{dt} = \frac{\Delta[A]}{\tau_{ss}} \qquad (3)$$

it is also valid that

$$\tau_{ss} = \frac{1 + \frac{[A]}{K_a} + \frac{[P]}{K_p}}{\frac{V_1}{K_a} + \frac{V_2}{K_p}} \qquad (9)$$

By using the "Haldane-Alberty relationship" [32]

$$\frac{V_1 \cdot K_p}{V_2 \cdot K_a} = K_{app} = \frac{[P]}{[A]} \qquad (7a)$$

we obtain

$$\tau_{ss} \cdot V_1 = [P]\,\frac{1 + \frac{V_1}{V_2}}{K_{app} + 1} + \frac{K_{app} K_a}{K_{app} + 1} \qquad (10)$$

Figure 5 summarizes the relaxation measurements made with the enzyme enolase (crystallized from rabbit muscle [34]). Values measured in the experiment discussed above (Fig. 4) are marked with a "plus"

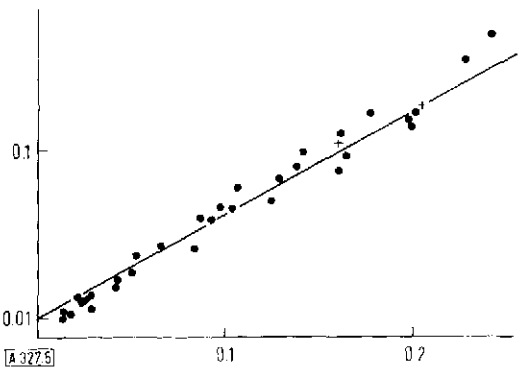

Fig. 5. Enolase reaction: Relaxation time×units of enzyme per unit volume (ordinate) versus equilibrium concentration of phosphoenolpyruvate (abscissa). The "plus" signs mark the values obtained in the experiments represented in Figure 4. Constants for the regression line, see text [Equation (11)].

Ordinate: $\tau_{ss} \cdot V_1$ [mmole/l].

Abscissa: [PEP] [mmole/l].

sign. It can be seen that the relaxation time is a function of the enzymatic acitivty used (established from the rate of the forward reaction $V_1$ [enzyme units [34a] per ml]) and of the metabolite concentrations at equilibrium. By analogy to Equation (10), the regression line is given by Equation (11):

$$\tau_{ss} \cdot V_1 = 0.0056\,[\overline{PEP}] + 0.01 \quad [\mu\text{mole/l}] \qquad (11)$$

where $V_1$ = enzyme units per ml [34a].

To apply these relationships according to the concept outlined in Section 6 and according to the measurements on muscle described in Section 2, we can convert Equations (4) to

$$\Delta[A]_{st} = \frac{[P]}{1 + K_{app}}\left(\frac{K_{app}}{\Gamma} - 1\right) \text{ etc.} \qquad (4a)$$

In this equation, $\Gamma$ is the "mass-action ratio" in steady-state nonequilibrium [see Equations (1) and (4)]. The factor $\Delta[A]_{st}$

[*] Reaction involving a single substrate and a single product, see [12].

[34] *R. Czok* and *Th. Bücher*, Adv. Protein Chem. *15*, 315 (1960).

[34a] One enzyme unit corresponds to the conversion of one µmole of substrate per hour in a standard test [35] at the temperature of the relaxation experiment.

has already been defined in connection with Equation (6). We can substitute the relationship given in Equation (4a) for $\Delta[A]_{st}$ in Equation (6), and obtain:

$$V_{st} = \frac{1}{\tau_{ss}} \frac{[\bar{P}]\,(K_{app} - \Gamma)}{K_{app}\,\Gamma + K_{app}} \qquad (6a)$$

To obtain the relaxation time of the tissue enzyme, the value measured *in vitro* is divided by the ratio [enzyme units in tissue]/[enzyme units in the relaxation experiment] (see also [34a]). To obtain these data, the

$$(\tau_{ss})_{tissue} = \frac{(\tau_{ss} \cdot V_1)_{exp.}}{(V_1)_{tissue}} \qquad (12)$$

enolase localized in the muscle is exhaustively extracted and tested under the same conditions (30000 units/g fresh weight at 37 °C) as described for obtaining $V_1$ in the relaxation experiment (4–10 units/ml). Thus, we dare to assume that the enzyme molecule behaves in the same way in a dilute, homogeneous solution as it does in its cellular environment where it is present at a concentration which is many hundred times higher. With this assumption we obtain

$$V_{st} = \frac{(V_1)_{tissue}}{(\tau_{ss} V_1)_{exp.}} \cdot \frac{[\bar{P}](K_{app} - \Gamma)}{K_{app}\,\Gamma + K_{app}} \qquad (13)$$

It is with this assumption that the relationships between the rate of flow in glycolysis in rat abdominal wall muscle at work (see Fig. 3) and the deviation of the enolase reaction from equilibrium are presented in Figure 6 for different equilibrium concentrations of phosphoenolpyruvate. Actually the glycolytic throughput ($V_{st}$) determined *indirectly* from the diagram (Fig. 6) using the deviations ($\Gamma/K_{app}$) measured in the organ (about 0.8, see Table 1) is of the same order of magnitude as the *directly* measured glycolytic throughput (formation of lactate *in situ*): about 5 mmoles per gram of fresh tissue per hour.

## 8. Four-Partner Reaction [*] Near Equilibrium

(Lactate/pyruvate and the extramitochondrial DPNH/DPN system)

The treatment of symmetrical four-component reactions

$$A + B \rightleftharpoons P + Q$$

is considerably more difficult than that of two-component reactions. However, such processes are important, because the action of coupling nucleotides in intermediary metabolism usually takes place via four-component reactions. Therefore, four-component reactions provide information on the state of the coupling nucleotide systems. This information sometimes cannot be obtained in any other way [10, 11, 36]. From the definition of equilibrium, the potential difference between two opposing compounds (*e.g.* lactate and pyruvate, see Equation (c) below) is numerically equal (but of opposite sign) to that of the other pair (*e.g.* DPNH and DPN). Thus the redox potential of the DPNH/DPN system can be calculated from the concentration ratios of the appropriate pair of metabolites if the deviation from equilibrium may be neglected.

Five years ago, we used our own observations and those made by the groups of *Lynen* and *Holzer* [36] to derive some conclusions, applicable to cell physiology, about the redox state of the *extramitochondrial* pyridine nucleotides in the liver [10]. Our evidence that equilibrium is a sufficient approximation for the treatment of the lactic dehydrogenase system was based on the good

$$\text{Pyruvate} + \text{DPNH} + \text{H}^{\oplus} \underset{\text{Lactic dehydrogenase}}{\rightleftharpoons} \text{Lactate} + \text{DPN} \qquad (c)$$

agreement between redox potentials of three DPN-specific extramitochondrial substrate pairs in resting liver [11]. In the meantime, *Hohorst* et al. have shown that this agreement between the redox potentials continues even if the absolute values change, either by cutting off the blood supply (ischemia) [37] or by the influence of the diet or the endocrine situation [38].

*Schimassek* has been able to obtain new evidence by continuing his perfusion experiments on rat liver, using a synthetic medium (see note [a] in Table 3) in a closed-circuit, extracorporeal circulation [39,40]. The possibility of loss of the nascent lactate into metabolizing regions outside the liver is excluded under these conditions. Since there are no opportunities worth men-

tioning for utilizing lactate in the region of the liver parenchyma without the participation of lactic dehydrogenase, the lactate/pyruvate system is thus on a blind alley.

When in the perfusion changes occur of oxygen supply (Fig. 7), or when lactate is added [40], the observed adaptability of the system is indicative of its dynamic characteristics. In this case, the isolated organ produces roughly the same concentrations and redox ratios as those found in blood plasma, even though the volume of the perfusion system is considerably larger (100 ml as compared to 10–15 ml of blood).

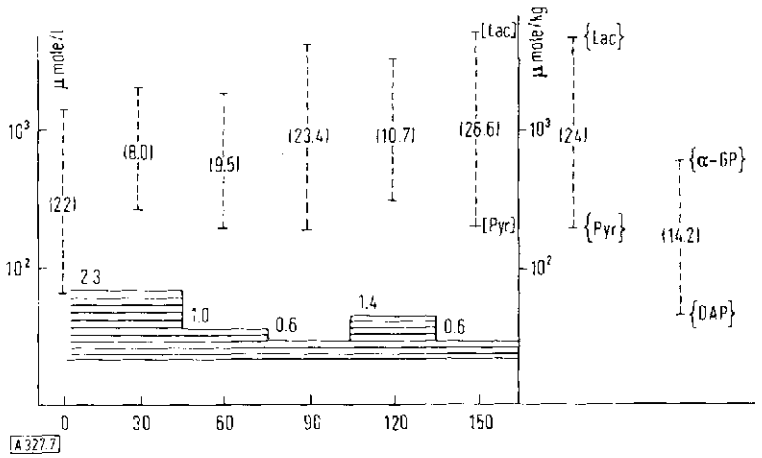

Fig. 7. Perfusion of isolated rat liver with synthetic "blood" (see note [a] in Table 3) in a closed circuit [39,40]. Ordinate: Concentrations of lactate (above) and pyruvate (below) in the medium at various rates of perfusion. Concentration ratios in parentheses. At rates of flow < 1, the oxygen consumption of the tissue (200 µatom/g/h) is not completely accounted for. The high quotient at the start of the experiment is a result of the ischemia of the organ during its transfer to the artificial circuit.

The metabolite levels (see [40a]) in the perfused liver at the end of the experiment are shown on the right: $(\{\alpha\text{-GP}\}/\{\text{DAP}\}) \times (\{\text{Pyruvate}\}/\{\text{Lactate}\}) = 0.59$ (cf. Table 4).

The figures above the profile diagram at the bottom of the section on the left indicate the rates of flow in ml/min per g of liver.

Ordinate: Concentration [µmole/l] or level [µmole/kg fresh weight]. Abscissa: Time [min].

Furthermore, it follows from these experiments that there is agreement between the levels [40a] of metabolites found in the cells by tissue analysis and the concentrations measured in the perfusion fluid

Table 2. Perfusion of isolated liver in closed system. Metabolite levels in the tissue (corrected for the content of medium and interstitial fluid) and in the medium after three hours' perfusion under standard conditions [40].

| | Cellular [*] level [11] [mmole/kg] | Concentration[*] in medium [mmole/liter] |
|---|---|---|
| Lactate | 3.5 | 3.5 |
| Pyruvate | 0.37 | 0.33 |
| Lactate/Pyruvate | 9.5 | 10.5 |

[*] See also [40a].

[40a] The term "level" is used to express analytical data in the form of moles (millimoles, micromoles) per gramm of fresh weight of whole tissue ("Gewebsgehalt" [11,37]) or of the intracellular tissue fraction ("Zellulargehalt", corrected for the extracellular space). The term "concentration" has the meaning of moles per liter of cellular or extracellular water (thermodynamic concentration). { } indicate levels, [ ] indicate concentrations.

(Table 2). *Lynen*'s postulate [41] "that the calculation of absolute concentrations from analytical data is meaningless if the cell structure is destroyed to obtain them" does not hold in this case. On the contrary, the conditions described in *Schimassek*'s system permit completely objective and meaningul correlation of the absolute levels of metabolites with *cellular concentrations* which can be evaluated thermodynamically.

Thus, the redox potential calculated from cellular levels is thermodynamically valid, and *Schimassek*'s experiments deserve special consideration because of the fundamental significance of the redox potential in the extramitochondrial DPNH/DPN system. In the section which follows we shall present further (kinetic) evidence to show that the lactate/pyruvate system is a useful indicator of this potential.

In studies, of which we were unaware when writing previous papers, *Huckabee* [42] demonstrated the following in man and in animal experiments: it is the lactate/pyruvate ratio and not the change in the lactate level of plasma which is relevant for detection of an oxygen deficiency in cells. He was able to produce large fluctuations in the lactate level without affecting the lactate/pyruvate ratio by injecting either the metabolites or bicarbonate and by hyperventilation. This offers a close analogy to the perfusion experiments described above.

Table 3. Effect of various perfusion conditions on the lactate/pyruvate ratio in the liver and in perfusion medium [40].

| Perfusion conditions | Organ $\frac{\{\text{Lactate}\}}{\{\text{Pyruvate}\}}$ | Medium $\frac{[\text{Lactate}]}{[\text{Pyruvate}]}$ |
|---|---|---|
| Homologous blood | 9.6 | 8.0 |
| Synthetic medium [a] | | |
| Control | 10 | 10 |
| Reduced perfusion rate | 25 | 26 |
| Addition of prednisolone (perfusion rate normal) | 17.7 | 18.2 |

[a] Tyrode solution, serum albumin, cattle erythrocytes [39].

This aspect is expanded in Table 3. The Table demonstrates the effects of regulatory mechanisms on the redox potential in the extramitochondrial, DPN-specific area

[41] *F. Lynen* in: Proceedings of the International Symposium on Enzyme Chemistry, Tokyo and Kyoto 1957. Pergamon Press, London 1958, in particular p. 28.

in an extracorporeal system, as has already been partially done by *Hohorst* et al. [38] in animal experiments.

The agreement between the redox potentials in tissue and plasma leads us to conclude that the interstitial fluid and blood plasma are to a certain extent, "*common-level reservoires*" of the *extramitochondrial* lactic dehydrogenase system of the cells of an organ and, in the final analysis, of any organ [10] (Fig. 8). *Klingenberg* [43] recently

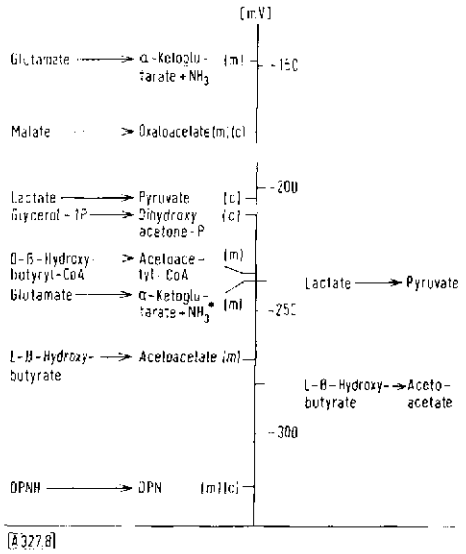

Fig. 8. On the coordination of cellular redox potentials by the blood plasma. Left: Mid-potentials [43a] of cellular redox systems at pH 7 and 37 °C. Right: Potentials ("1st" potentials [10]) of the redox systems in blood plasma. The systems of the extramitochondrial region (marked with (c), c-region [10, 52]) of cells (left) are coupled via the lactate/pyruvate system (right). The homeostasis of this potential forms the basis for the redox variation in DPN-dependent systems in the extramitochondrial region. Analogous discussions of the mitochondrial (m)-systems for the β-hydroxybutyrate/acetoacetate pair in plasma can be found in [43] and [44–46].
*$[NH_3]$ in mmole/l.

extended this hypothesis to the coupling of *mitochondrial* compartments with the β-hydroxybutyrate/acetoacetate system (see also [45, 46]).

## 9. The Deviation $K_{app}/\Gamma$-1 of the Four-Partner Reaction

(Indicator error at the indirect determination of the DPN/DPNH-potential)

As the experiment represented in Fig. 9 shows, measurement of the relaxation times in a four-component reaction does not involve much greater difficulties in the optical assay than the measurement of two-component reactions. The difficulties mentioned above with regard to the evaluation of results arise from the much more complicated enzyme mechanisms and the larger number of reactants.

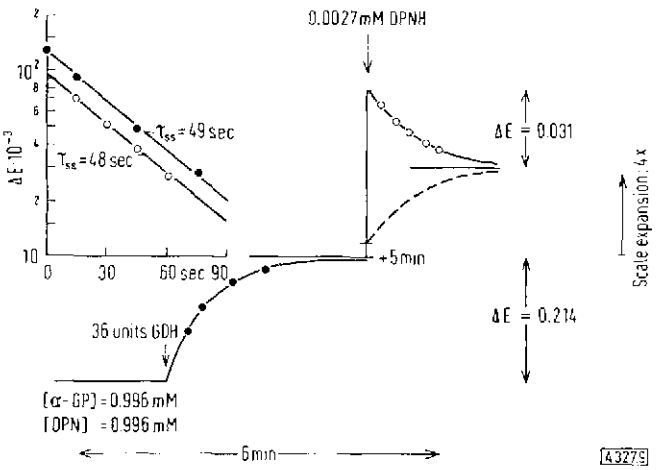

Fig. 9. Attainment of the equilibrium and relaxation (after addition of DPNH) of the glycerophosphate dehydrogenase reaction

$$\text{Dihydroxyacetone phosphate} + \text{DPNH} + \text{H}^+ \;\underset{\text{GDH}}{\rightleftarrows}\; \text{L-Glycerol-1-phosphate} + \text{DPN} \qquad \text{(d)}$$

measured by an optical assay. The reaction starts (on the left) on addition of 36 units/ml of GDH from rabbit muscle [34]. Measurements were made at 334 mμ (light path: 4 cm) on an Eppendorf Photometer. Scale expanded 4× before addition of a small amount of DPNH. $KH_2PO_4$/$K_2HPO_4$ buffer, ionic strength $\mu$ = 200 mM, pH 6.88, 37 °C. The dashed curve indicates the decrease in the concentration of dihydroxyacetone phosphate; this was calculated on the assumption that $\Delta DAP = \Delta DPNH$.

The special case in which one of the metabolite concentrations remains constant and the concentrations of two other reactants are adjusted in such a way that they are large in comparison to the deviation $\Delta[A]_t$ (see Equa-

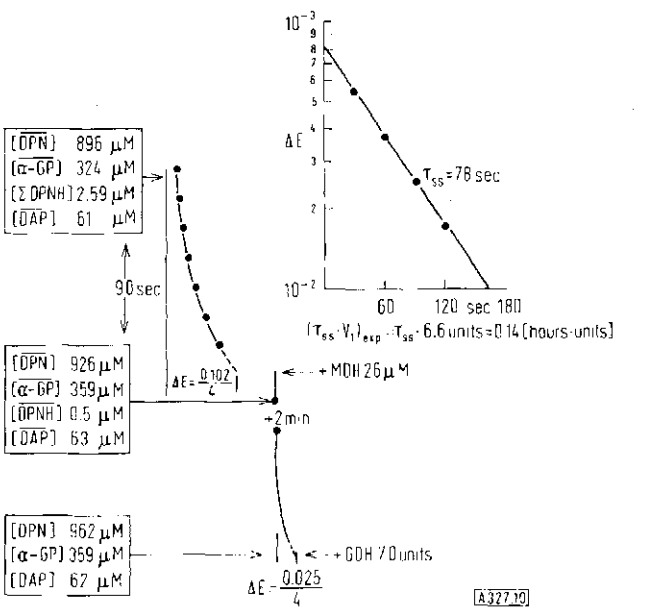

Fig. 10. Relaxation of the glycerophosphate dehydrogenase reaction after addition of enough malic dehydrogenase (as DPNH binding protein) to buffer the DPNH. The reaction starts (at the bottom) on addition of 7 units of enzyme per ml in accordance with Figure 9. Measurements at 334 mμ (light path: 2 cm) with an Eppendorf Photometer [46b]; Scale expansion 4×; K phosphate buffer, ionic strength $\mu$ = 60 mM; 0.7 mM EDTA; pH 7.2; 25 °C. Addition of 26 μmoles/l of malic dehydrogenase ($36 \times 10^3$ g/mole) results in an unspecific increase in the extinction. [ΣDPNH] = free DPNH + DPNH linked to MDH.

[45] *P. Borst* in *Th. Bücher:* Redoxfunktionen cytoplasmatischer Strukturen, Symposium, Vienna 1962. Wiener Medizinische Akademie für Ärztliche Fortbildung. Vienna 1962, in particular p. 189.

[46] *P. Borst* in *P. Karlson:* Funktionelle und Morphologische Organisation der Zelle. Springer, Berlin–Göttingen–Heidelberg 1963.

tion (3) on p. 430) is feasible from the experimental standpoint. It is also justified from the standpoint of cell physiology, provided steady-state metabolism exists in the tissues. Such an arrangement, in which the numerical values were chosen in conformity with cellular ratios, is presented in Figure 10.

The departure from equilibrium is produced by addition of a DPNH-binding protein (dialysed malic dehydrogenase [46a] in a buffering concentration). The MDH protein binds 1 mole of DPNH per $36\times10^3$g. The dissociation constant was determined by fluorimetric titration with DPNH in the presence of DPN, α-GP, and DAP.

$$K_{DPNH\text{-}MDH} = \frac{[MDH]\,[DPNH]}{[\overline{MDH-DPNH}]} = 3\ [\mu mole/l]$$

Titration also showed that the rate at which the MDH-DPNH complex is formed does not produce any appreciable error in the results. The reaction was followed at 334 mμ, roughly at an isosbestic point [47]. Relaxation times measured at 25 °C and based on one enzyme unit per ml were roughly identical for lactic and glycerophosphate dehydrogenases from rabbit muscle [34, 46b]. In a large number of experiments, they ranged from 0.12 to 0.25 h/unit/ml. There was interference due to the superposition of a small but constant background decrease in extinction of unknown cause on the observed variation in extinction. With the large scale expansion required, accurate determination of the absolute values was thus difficult.

If, in analogy to Equation (4), we set up an equation for the symmetrical four-component reaction:

$$\Gamma = \frac{[P]\,[Q]}{[A]\,[B]} = \frac{([P]-\Delta[B])([Q]-\Delta[B])}{([\overline{A}]+\Delta[B])([\overline{B}]+\Delta[B])} \qquad (14)$$

then, assuming that [A] = const. (A = DPNH)

$$\Gamma = K_{app}\,\frac{1-\dfrac{\Delta[B]}{[\overline{P}]}\cdot\dfrac{\Delta[B]}{[\overline{Q}]}+\dfrac{(\Delta[B])^2}{[\overline{P}]\,[\overline{Q}]}}{1+\dfrac{\Delta[B]}{[\overline{B}]}} \qquad (15)$$

If we also assume

$$\frac{\Delta[B]}{[\overline{P}]} \ll 1 \text{ and } \frac{\Delta[B]}{[\overline{Q}]} \ll 1$$

(where B = pyruvate or dihydroxyacetone phosphate), then Equation (15) can be simplified to

$$\frac{\Delta[B]}{[\overline{B}]} = \frac{K_{app}}{\Gamma} - 1 \qquad (16)$$

By using Equations (6), (12), and (16), we obtain

$$\left(\frac{V_{st}}{V_1}\right)_{tissue} = \frac{[\overline{B}]_{st}}{(\tau_{ss}\cdot V_1)_{exp}}\left(\frac{K_{app}}{\Gamma} - 1\right) \qquad (17)$$

which is analogous to Equation (13).

Equation (17), obtained by making these simplifying assumptions, is evaluated in Figure 11 as a function of the relaxation times mentioned above of the DPN-specific dehydrogenases. The relationship between the rate of flow $V_{st}$ and the maximum enzymatic activity $V_1$ of the tissue is plotted on the ordinate. Thus, the curve can be used for evaluating the relationships existing in various tissues. However, it should be kept in mind that $(\tau_{ss}\cdot V_1)_{exp}$ was measured only with glycerophosphate and lactic dehydrogenases from skeletal muscle of rabbit.

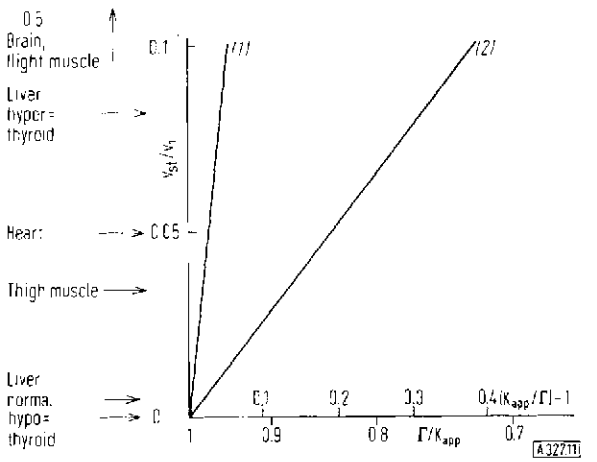

Fig. 11. Relationships between the rate of flow and the deviation of the mass-action ratio $K_{app}/\Gamma$-1 in the lactic dehydrogenase reaction (1) and in the glycerophosphate dehydrogenase reaction (2) [Equation (17)].

Curve (1): $[\overline{B}] = 0.3$ mmole/l.

Curve (2): $[\overline{B}] = 0.04$ mmole/l.

$(\tau_{ss}\cdot V_1)exp = 0.15$ mmole/l.

Ordinate: $Vst/V_1$.

Abscissa: upper scale: $(K_{app}/\Gamma)-1$.
lower scale: $\Gamma/K_{app}$.

The arrows on the ordinate indicate the proportions of the enzymatic activity of α-GPOX and GDH (cf. Table 5, Column 5) in rat tissues and in the flight muscle of the locust.

The straight line with the greater slope (Curve 1), corresponding to a pyruvate concentration of 0.3 mmole/l, is the one pertinent to the discussion of the lactic dehydrogenase system, which follows below, whereas the discussion of the glycerophosphate system is given in the last paragraph.

The activity of the lactic dehydrogenase extracted from 1 g of rat liver (fresh weight) and tested *in vitro*, was 30–40 mmole/h at 37 °C. This is the maximum value which can be assigned to $(V_1)_{tissue}$. The minimum value was calculated to be 1.7 mmole/g fresh weight/h, using the value for lactate formation in the organ at the onset of ischemia (Table 4, Column 7). The actual value of $(V_1)_{tissue}$ is probably closer to the upper limit.

As far as the metabolic throughput $V_{st}$ (lactate → pyruvate) is concerned, it can be stated that it must be considerably less than the maximum respiration value in the organ. The maximum respiratory value in rat liver is $0.6\times10^{-3}$ atoms of oxygen per g fresh weight per hour. This value also agrees with the conversion of energy-rich phosphate ($2\times10^{-3}$ atoms/g fresh weight/h) estimated from the ischemia experiments.

The ratio of the maximum value of the metabolic throughput to the minimum $(V_1)_{tissue}$, *i.e.* the upper

[46a] We wish to thank Dr. *H. U. Bergmeyer* of C. F. Boehringer u. Soehne GmbH., Biochemical Division, Tutzing (Germany), for the malic dehydrogenase.

[46b] *G. Beisenherz, H. J. Boltze, Th. Bücher, R. Czok, K. H. Garbade, E. Meyer-Arendt*, and *G. Pfleiderer*, Z. Naturforsch. *8b*, 555 (1953).

[47] *A. Pfleiderer* and *E. Hohnholz*, Biochem. Z. *331*, 245 (1959).

limiting value, is

$$\left(\frac{V_{st}}{V_1}\right)_{max} = \frac{0.6}{1.7} = 0.35. \quad (18)$$

From Fig. 11, Curve 1, this corresponds to a maximum mass-action ratio deviation of 15 % (see also [*] on p. 428).

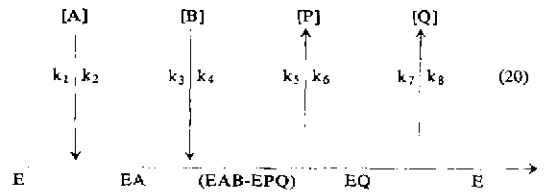
$$\left(\frac{\Gamma}{K_{app}}\right)_{pyr.-lac.} = 0.85. \quad (19)$$

Since $\tau_{ss}$ is independent of the direction of the deviation, the calculated value of 15 % is valid for both the forward and the reverse reaction. The deviation from the mass-action ratio is proportional to the potential difference

$$\Delta E = -\frac{RT}{2F} \ln \frac{\Gamma}{K_{app}} = 2 \text{ mV}.$$

Our calculation gives a maximum value for the deviation of the redox potential of the DPNH/DPN system from that of the lactate/pyruvate system at the site where the lactic dehydrogenase is operative. Even under extreme conditions, the actual physiological deviation is considerably smaller since the actual rates of flow are very likely to be smaller and, above all, since the actual $(V_1)_{tissue}$ must be assumed to be considerably larger than the value used in the calculation.

These calculations close the ring of evidence around the status of the lactate/pyruvate system in the liver with regard to its use as an indicator for the redox potential of the extramitochondrial DPN/DPNH system. They also show that the indicator error can be neglected.



## 10. Glycerophosphate Dehydrogenase

($\tau_{ss}$, calculated and experimental)

Enzymatic catalysis of the reaction $A + B \rightleftharpoons P + Q$ can proceed via several conceivable mechanisms. These were discussed by *Bloomfield* et al. [48] and *Cleland* [30]. As far as the mechanism of the reaction catalysed by glycerophosphate dehydrogenase (von Euler-Baranowski enzyme, see also Fig. 2, top right) is concerned, it can

Dihydroxyacetone phosphate + DPNH + H$^+$
⇅ GDH (d)
L-Glycerol-1-phosphate + DPN

be deduced from fluorimetric titrations that DPNH and DPN react directly with the protein of the enzyme. Our mechanism, which was selected only for approximate calculations, is characterized by the formation of "central complexes". To simplify the calculations and for the sake of greater lucidity, we used an ordered sequence for the formation of transitory complexes, according to the following scheme which was introduced by *Cleland* ("ordered BiBi") [*]:

(20)

By using the method of *King* and *Altmann* (cited in [30]), the following equation for the steady-state reaction rate can be derived from this scheme:

$$-\frac{d[A]}{dt} = \frac{(k_1k_3k_5k_7[A][B] - k_2k_4k_6k_8[P][Q])\,E_t}{k_2(k_4 + k_5)k_7 + k_1(k_4 + k_5)k_7[A] + k_2(k_4 + k_5)k_8[Q] + k_3k_5k_7[B] + k_2k_4k_6[P] + k_1k_3(k_5 + k_7)[A][B] + (k_2 + k_4)k_6k_8[P][Q] + k_1k_4k_6[A][P] + k_1k_3k_6[A][B][P] + k_3k_5k_8[B][Q] + k_3k_6k_8[B][P][Q]} \quad (21)$$

In the nomenclature of *Cleland*, it may be represented in the following manner (see [30], especially p. 127):

$$\frac{d[A]}{dt} = \frac{V_1V_2\left([A][B] - \frac{[P][Q]}{K_{app}}\right)}{K_{ia}K_bV_2 + K_bV_2[A] + K_aV_2[B] + V_2[A][B] + \frac{K_qV_1[P]}{K_{app}} + \frac{K_pV_1[Q]}{K_{app}} + \frac{V_1[P][Q]}{K_{app}} + \frac{K_qV_1[A][P]}{K_{ia}K_{app}} + \frac{K_aV_2[B][Q]}{K_{iq}} + \frac{V_2[A][B][P]}{K_{ip}} + \frac{V_1[B][P][Q]}{K_{ib}K_{app}}} \quad (22)$$

$K_a$ etc. = Michaelis constants (*e. g.* [B] saturating, [P] and [Q] at zero concentration)
$V_1$ = maximum velocity ([A] and [B] saturating, [P] and [Q] at zero concentration)
$V_2$ in analogy to $V_1$ for the reverse reaction
$K_{ia}$ etc. = inhibition constants (dissociation constants of EA etc.)
All constants are in [µmole/l].

The value of $\tau_{ss}$ was obtained by applying a modification of the method of *Hammes* and *Alberty*, which is analogous to that used for the two-component reaction (see page 431). Assuming that $\Delta A \ll [\bar{A}], [\bar{B}], [\bar{P}], [\bar{Q}]$ and applying the very useful "Haldane" relationships given by *Cleland* (see [30], page 128), we obtain:

$$\tau_{ss} \cdot V_1 = \frac{K_{ia} \cdot K_b + K_b[\bar{A}] + K_a[\bar{B}] + [\bar{A}][\bar{B}] + \frac{K_a}{K_{iq}}[\bar{B}][\bar{Q}] + \frac{1}{K_{ip}}[A][\bar{B}][\bar{P}]}{[\bar{A}] + [\bar{B}] + \frac{[\bar{P}] + [\bar{Q}]}{K_{app}}} + \frac{V_1}{V_2K_{app}}\left(\frac{(K_q[\bar{P}] + K_p[\bar{Q}] + [\bar{P}][\bar{Q}] + \frac{K_q}{K_{ia}}[\bar{A}][\bar{P}] + \frac{1}{K_{ib}}[B][\bar{P}][\bar{Q}])}{[\bar{A}] + [\bar{B}] + \frac{[\bar{P}] + [\bar{Q}]}{K_{eq}}}\right) \quad (23)$$

[*] This graphic description of the reaction sequence should be read from left to right. The enzyme is represented by the horizontal line. The free substrates (A, B,...) and products (P, Q,...) lie above it and the transitory complexes beneath. The central complexes (EAB) and (EPQ) are characterized by the fact that they do not participate in bimolecular reactions with substrates or products, but can only undergo (monomolecular) cleavage or isomerization.

[48] *V. Bloomfield, L. Peller*, and *R. A. Alberty*, J. Amer. chem. Soc. *84*, 4365, 4367, 4375 (1962).

If $[\overline{P}]$, $[\overline{Q}]$, and $[\overline{A}]$, $[\overline{B}]$ are constant, then $\tau_{ss} \cdot V_1$ can be expressed as a function of $[\overline{B}]$:

$$\tau_{ss} \cdot V_1 = \frac{\alpha[\overline{B}]^2 + \beta[\overline{B}] + \gamma}{[\overline{B}]^2 + \delta[\overline{B}] + \tau_i} \text{ [µmole/l]} \qquad (24)$$

If we substitute the kinetic constants obtained in the approximation experiments using the method of *Florini* and *Vestling* [48a] and by fluorimetric titration (see Table 4), and if we consider that the terms containing $K_{ib}$ and $K_{ip}$ are sufficiently small to be neglected, then, when

$[\overline{B}] = [\overline{DAP}]$ $\qquad$ $[\overline{P}] = [\alpha\text{-}\overline{GP}] = 200$ µmole/l
$[\overline{A}] \cdot [\overline{B}] = 4$(µmole/l)$^2$ $\qquad$ $[\overline{Q}] = [\overline{DPN}] = 500$ µmole/l

$$\tau_{ss} \cdot V_1 = \frac{350\,[\overline{DAP}]^2 + 117\,[\overline{DAP}] + 80 \times 10^3}{[\overline{DAP}]^2 + 2.7 \times 10^{-2}\,[\overline{DAP}] + 4} \text{ [µmole/l].} \qquad (25)$$

It can be seen that the relaxation time increases with decreasing equilibrium concentrations of $[\overline{DAP}]$. The graph of the function resembles a hyperbola.

Table 4. Kinetic constants.

| Measured by the method of | |
|---|---|
| *Florini* and *Vestling* | Fluorimetry |
| $V_1$ = 3.8 nmole/l/h | $K_{ia}$ = 0.01 µmole/l |
| $V_2$ = 0.8 mmole/l/h | $K_{iq}$ = 2.8 µmole/l |
| $K_a$ = 2 µmole/l | |
| $K_q$ = 30 µmole/l | |
| $K_p$ = 530 µmole/l | |
| $K_q$ = 980 µmole/l | |

25 °C, 50 mmole/l of triethanolamine/HCl buffer, 5 mmole/l of EDTA, pH 7.5, $K_{app} = 2.5 \times 10^4$

Our measurements (Fig. 12) on the relationship between $\tau_{ss} \cdot V_1$ and the equilibrium concentration of dihydroxyacetone phosphate are in agreement with the theory cited above insofar as there is a large variation in $\tau_{ss} \cdot V_1$ in the range of low $[\overline{DPA}]$ concentrations. The shape of the curve also resembles that described by Equation (20). However, the numerical values of $\tau_{ss} \cdot V_1$ calculated from Equation (20) are much higher than the experimental values.

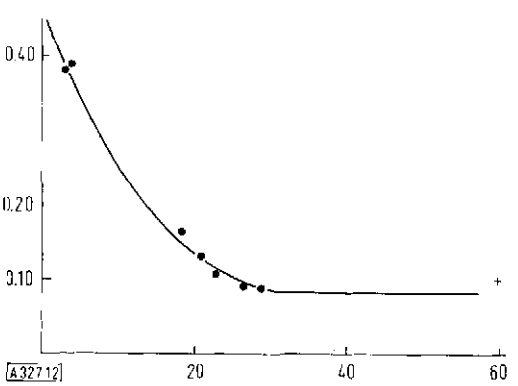


Fig. 12. Glycerophosphate dehydrogenase reaction.
Relaxation time×enzyme units per unit volume (ordinate) versus equilibrium concentration of dihydroxyacetone phosphate (abscissa).
Experiments of the type indicated in Figure 9 ($[\overline{DAP}] \times [\overline{DPNH}]$ approximately constant), but at pH 7.2 with an ionic strength $\mu = 0.1$ mM. The "plus" sign corresponds to the experiment reproduced in Figure 10.
Ordinate: $\tau_{ss} \cdot V_1$ [mmole/l].
Abscissa: $[\overline{DAP}]$ [µmole/l].

[48a] *R. Florini* and *C. S. Vestling*, Biochim. biophysica Acta *25*, 755 (1957).

In view of these discrepancies, it would be advisable, at the present state of the theory, to measure relaxation times directly and not to calculate them by using Michaelis constants (cf. [14]). The adoption of $\tau_{ss}$ as a parameter in mathematical models should prove to be advantageous for the same reason.

## 11. The Glycerophosphate Cycle

The glycerophosphate/dihydroxyacetone phosphate system cannot be treated in the same manner as the lactate/pyruvate system (see Section 9) without introducing some further considerations. First, the cellular activity of GDH is lower by at least one order of magnitude (Table 5, Column 3) than that of LDH (except in the flight muscles of insects [49,50,52]). Second, in conformance with Equation (17), $V_{st}/V_1$ is a function of $[\overline{B}]$. However, $[\overline{B}]$, the metabolite concentration, in the glycerophosphate system is considerably lower than that in the lactate system.

Third, the glycerophosphate system is not isolated in a "blind alley", but oscillates between and is coupled with two different redox systems. In the glycerophosphate cycle (Fig. 2, top right), it is coupled to the extramitochondrial DPNH/DPN system via extramitochondrial glycerophosphate dehydrogenase; in the same cycle, it is coupled to the respiratory cycle via glycerophosphate oxidase (the Meyerhof-Green enzyme). The *mitochondrial reaction*, which is unidirectional under aerobic conditions, is the *controlling reaction*.

Another fact that is also of functional importance is the redox potential of the extramitochondrial DPNH/DPN system, which is considerably more positive (about 80 mV [10,43a–46]) than the mid-potential (Fig. 8). This is indicated by the potential of the lactate/pyruvate system (see Sections 8 and 9).

We have already discussed in previous articles the differences between the redox potentials of the lactate and glycerophosphate systems, in connection with the glycerophosphate cycle [10,49,50]. In order to make use of the more extensive information now available, we have marked the ratios found in various tissues (see Table 5, Column 5) for the activities of glycerophosphate oxidase and glycerophosphate dehydrogenase by arrows at the ordinate of Figure 11 ($V_{st}/V_1$). We assume here that $V_{st}$ is proportional to the activity level of the controlling mitochondrial enzyme and that $(V_1)_{tissue}$ is proportional to the activity level of the extramitochondrial enzyme.

Table 5. On the cellular state of the lactate/pyruvate and glycerophosphate/dihydroxyacetone phosphate systems: Levels of enzyme activity in some mammalian tissues (columns 2–5), ratios of metabolite levels (column 6), and rates of flow measured *in vivo* (columns 7 and 8). The activities were measured in tissue extracts and isolated mitochondria under standard conditions (25 °C). At 37 °C, the enzyme values would be 2–2.5 times higher. The metabolic throughput was calculated from metabolite changes in ischemia experiments.

[k] Ratios in parentheses are based on the plasma value [Lac]/[Pyr] = 10.
[l] $[\overline{\text{α-GP}}]\cdot[\overline{\text{Pyr}}]/[\overline{\text{DAP}}]\cdot[\overline{\text{Lac}}] = 0.8$.
[m] Compare also [53].

Curve 2 of Figure 11 describes the system under consideration. Sections of the abscissa corresponding to the arrows opposite the ordinate would lead us to anticipate considerable deviations of $\Gamma/K_{app}$ -1 in some cases. That such deviations do indeed exist and that their interpretation can be correlated with the chain of reasoning presented here, will now be shown using liver as an example [29].

*Lardy* and coworkers discovered that the cellular activity of mitochondrial glycerophosphate oxidase is governed by the inductive action of the thyroid hormone [51]. The hormone does not affect the activity of the extramitochondrial enzyme. In fact, the ratio α-GPOX/GDH can be varied over a range of two orders of magnitude by feeding or withdrawing the thyroid hormone (Table 5, bottom of Column 5).

In order to demonstrate deviations in the metabolite ratio {α-GP}/{DAP}, we may use the {Lac}/{Pyr} ratio as an indicator for the redox potential of the extramitochondrial DPNH/DPN system (see Section 9). When the two DPN-specific systems are at equilibrium

Lactate + Dihydroxyacetone phosphate
⇅ LDH + GDH + DPN/DPNH (e)
Pyruvate + Glycerol-1-phosphate

then we have in our ionic medium

$$\frac{[\overline{\text{α-GP}}]\,[\overline{\text{Pyr}}]}{[\overline{\text{DAP}}]\,[\overline{\text{Lac}}]} = 0.8 \qquad (26)$$

and, therefore,

$$\frac{\Gamma}{K_{app}} \approx \frac{1}{0.8}\,\frac{\{\text{α-GP}\}\,\{\text{Pyr}\}}{\{\text{DAP}\}\,\{\text{Lac}\}} \qquad (27)$$

If the measured values given at the bottom of Column 6 in Table 5 are inserted, $\Gamma/K_{app}$ in the hypothyroid state becomes 1.1, in the normal state 0.8, and in the hyperthyroid state 0.4. Sections of the abscissa corresponding to the arrows on the ordinate in Figure 11 represent smaller deviations. Thus, for the hypothyroid state, we obtain from the graph: $\Gamma/K_{app} = 0.76$.

At the present state of these techniques, exact numerical agreement between the values predicted by reconstruction experiments and those measured in the organ could only be accidental. However, even an agreement between mere trends, which can be seen from examination of Figure 11 and Table 5, is already convincing evidence for the existence of the glycerophosphate cycle *in vivo* in rat liver. Besides, it should be noted that with the characterization and localization of the enzymes (see review in [50]) and with the measurement of the ratios listed in Table 5, we have gathered all the evidence which could be obtained *in vitro* to contribute to a demonstration of the existence of the glycerophosphate cycle. Irrespective of whether the results are positive [53–56] or negative [57], reconstruction experiments with homogenate fractions or isolated mitochondria

and GDH cannot yield more significant data than those obtained from the measurement of kinetic constants of the enzymes.

As shown by the data and discussion of this Section, the α-glycerophosphate/dihydroxyacetone phosphate system departs considerably from equilibrium even at low rates of flow. Exact agreement between the redox potentials for the lactate/pyruvate and α-glycerophosphate/dihydroxyacetone phosphate systems are not to be anticipated even if the liver is in a normal state. In this respect, we have to correct our previous statements [10,11].

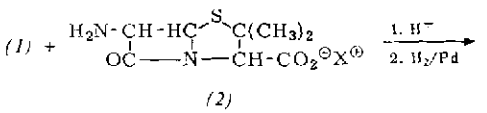
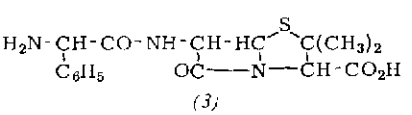
## Synthesis of 6-[(D-α-Amino-α-phenylacetyl)amino]-penicillanic Acid Using β-Dicarbonyl Compounds as Amino-Protecting Groups



By Prof. Dr. E. Dane [1] and Dipl.-Chem. T. Dockner

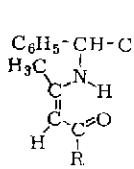
Institut für Organische Chemie
der Universität München (Germany)



*Doyle* et al. [2] prepared 6-[(D-α-amino-α-phenylacetyl)-amino]penicillanic acid [ampicillin, *(3)*], in the following way:

*(1)*

*(2)*



*(3)*

Z = $C_6H_5CH_2O$-CO- $X^{\oplus}$ = $Na^{\oplus}$

The catalytic hydrogenation required for removal of the protecting group does, however, not proceed satisfactorily because of the S-content of the compound.

We have found that it is also possible to use β-dicarbonyl compounds as amino-protecting groups in the synthesis of *(3)* [3].

D-α-Amino-α-phenylacetic acid dissolved in methanolic KOH reacts with benzoylacetone, acetylacetone, and ethyl acetoacetate to give the potassium salts *(4a)* to *(4c)*. The formation of *(4a)* requires heating at 60 °C for some hours. The reaction with acetylacetone takes some hours at room temperature, acetoacetic ester reacts when the solution is warmed briefly.

| | R | Decomp. temp. [°C] | Yield [%] |
|---|---|---|---|
| *(4a)* | $C_6H_5$ | 231–234 | 95 |
| *(4b)* | $CH_3$ | 222–224 | 80 |
| *(4c)* | $CO_2C_2H_5$ | 229–233 | 84 |

The potassium salts *(4a)–(4c)* were treated with pivaloyl chloride in tetrahydrofuran at −5 to −10 °C [*(4a)*, *(4b)* in suspension, *(4c)* in solution] giving the corresponding mixed anhydrides. To the anhydride solution was added a solution in chloroform of the triethylammonium salt *(2)*, $X^{\oplus}$ = $[HN(C_2H_5)_3]^{\oplus}$. The oily products remaining after evaporation were taken up in $NaHCO_3$ solution. The pH was gradually brought to 2 by addition of 1 N HCl with stirring. This precipitated the compound formed from *(4a)*, 6-[α-(benzoylacetonylamino) - α - phenylacetylamino]penicillanic acid, m.p. 138–147 °C, yield 63 %. The protecting group was split off by passing $CO_2$ into a solution of the compound in chloroform covered with water. We did not isolate the *N*-protected compounds from *(4b)* and *(4c)*. The protecting groups were split off in the acid solution. After extraction with ether, the pH of the aqueous phase was adjusted to 5 with $NaHCO_3$ solution. The solution was then concentrated by evaporation, and *(3)* crystallized out at 4 °C. The yield based on *(2)*, $X^{\ominus}$ = $H^{\oplus}$, was 50–60 %. Microbiological tests showed that the compound obtained from *(4c)* had the characteristic activity against *E. coli*.

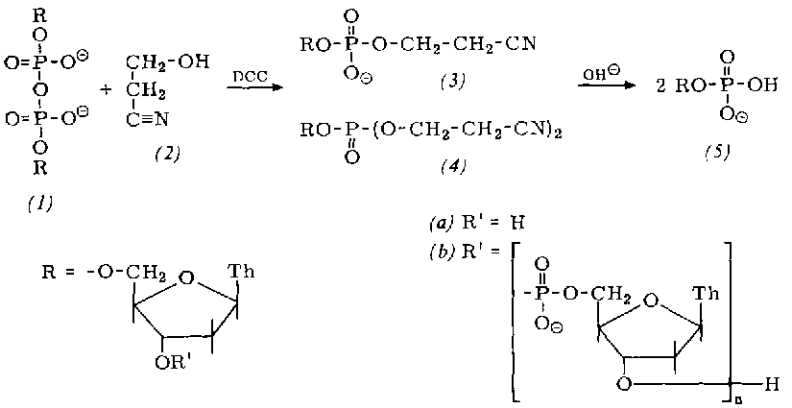
## Selective Hydrolysis of Pyrophosphate Bonds in Polynucleotides

By Dr. H. Schaller



Institute for Enzyme Research, University of Wisconsin, Madison, Wis. (U.S.A.) and Max-Planck-Institut für Virusforschung, Tübingen (Germany)

Dinucleoside pyrophosphates *(1a)* can be split to 2 moles of mononucleotide *(5a)* by reaction with dicyclohexylcarbodiimide (DCC) and 2-cyanoethanol *(2)* and alkaline hydrolysis of the phosphoric acid di- and tri-esters, *(3a)* and *(4a)*, formed [1].

This method is also suitable for the selective hydrolysis of pyrophosphate bonds in polynucleotides *(1b)*, as they are found at the end of a polymerization with DCC [2] or similar reagents. The doubly esterified phosphate groups in the polynucleotide chain are partly also esterified, but are recovered unchanged on treatment with alkali, since the β-elimination of the cyanoethyl group from the triester proceeds very rapidly [1].

To a polymerization mixture of thymidylic acid (2 mmoles) with DCC (4 mmoles) in dimethylformamide (0.9 ml) and pyridine (0.1 ml), 20 mmoles of *(2)* and 5 mmoles of DCC

were added after the end of the reaction. After 3 days the mixture was worked up in the usual way [3] and treated in addition with $NH_3$ for 10 hours at 25 °C. By chromatography on DEAE-cellulose, polythymidylic acid *(5b)*, n = 1–10, was obtained in the same yield and purity as in the procedure with acetic anhydride/pyridine [3].

*(1)* *(2)* *(3)* *(4)* *(5)*

## Determination of the Magnetic Susceptibility of Organic Compounds from Proton Resonance

By Dr. H. J. Friedrich

Chemisches Institut der Universität Würzburg (Germany)

The magnetic susceptibility effect observed in proton resonance in small cyclindrical tubes causes a shift of the resonance signal, relative to an external standard, which is proportional to the volume susceptibility of the medium [1]:

$$\Delta H/H = c \cdot \Delta\chi_v$$

Previous c-values taken from the literature (*e.g.* 2.60 [2]; 2.79 [3]; 1.57 [4]) have usually been vitiated by influences of the medium, such as magnetic anisotropy effects, van der Waals interaction, and electrical polarization effects.

Our determinations on tetramethylsilane in 35 diamagnetic media yielded the value 2.09 ± 0.1 for c, which is in agreement with the theoretical value $2\pi/3 = 2.094$. Corresponding measurements in paramagnetic media (solutions of diphenylpicrylhydrazyl) yielded c = 2.07 ± 0.1.

The method [5] was applied to the determination of the magnetic susceptibilities and spin densities of novel radicals [6] recently prepared by *Hünig* (cf. Table). We measured the shift of the $^1$H-signal of acetonitrile (10 %) in nitromethane, after the addition of about 5 mg radical/ml, at 20 °C, by means of a Varian-A60-NMR-spectrometer. The observed paramagnetism corresponds to that for monomeric radicals with a single unpaired electron ($\chi_{p,\,theor.} = 1280 \times 10^{-6}$).

| $[R{:}X{:}X{:}R]^{\oplus}\,Y^{\ominus}$ | $\chi_{mol} \times 10^6$ | $\chi_{dia} \times 10^6$ (calc.) | $\chi_{para} \times 10^6$ | spins/g $\times 10^{-21}$ |

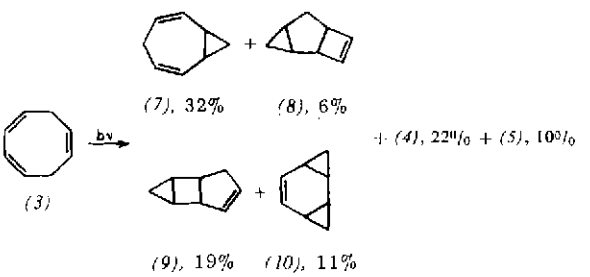
## Photolysis of Bicyclo[4,2,0]octa-2,4-diene, Cycloocta-1,3,5-triene and Cycloocta-1,3,6-triene

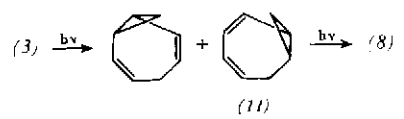
By Dr. W. R. Roth and Dipl.-Chem. B. Peltzer

Institut für Organische Chemie
der Universität Köln (Germany)



Bicyclo[4,2,0]octa-2,4-diene *(1)*, cycloocta-1,3,5-triene *(2)*, and cycloocta-1,3,6-triene *(3)*, which are in equilibrium at 200 °C [1], were photolysed (high-pressure mercury lamp, quartz apparatus) at room temperature in methanol solution and in the gas phase. Compound *(1)* was thereby isomerized to *(2)* in 40 % yield, the remainder was decomposed into benzene and ethylene. Compound *(2)* formed 68 % of bicyclo[4,2,0]octa-2,7-diene *(4)* [2] and 32 % of tricyclo-[3,2,1,$0^{2,8}$]-3-octene *(5)*. All-*trans*-octatetraene *(6)* was formed as an intermediary product and reacted further to produce *(4)* and *(5)* presumably with re-formation of *(2)*.

*(2)* *(4)* *(5)* *(6)*



The structures of *(4)* and *(5)* were deduced from the infrared and NMR-spectra, from the products of hydrogenation, *viz.* bicyclo[4,2,0]octane and bicyclo[3,2,1]octane, and from thermal reactions: *(4)* was converted at 200 °C into an

equilibrium mixture of *(1)*, *(2)* and *(3)*; compound *(5)* was rearranged, with a 1,5-homodienyl hydrogen shift [3], into bicyclo[3,3,0]octa-2,7-diene. The photolysis of *(3)* gave rise to *(4)*, *(5)*, and *(7)–(10)*.

The formation of *(4)* and *(5)* in 22 and 10 % yields indicates that they originate from *(2)* which occurs as an intermediary product. This assumption could be supported by photolysis of 5,8-dideuterocycloocta-1,3,6-triene *(3a)*. Its product of isomerisation *(4a)* showed a distribution of deuterium which corresponds to an isomerization *(3)* → *(2)*, by way of a 1,5-hydrogen shift [4].

Compound *(7)* was formed, on the other hand, without hydrogen shift: The product *(7a)* which was obtained on photolysis of *(3a)*, carries deuterium only at C-4 and C-8. It is suggested that its formation is due to a rearrangement of the santonine type [5]. The 1,2-homotropilidene *(11)*, which would also be expected, is converted to *(8)* under the conditions of experiment.

Open-chain 1,3,6-trienes can be isomerized in the same way. Thus 5,5-dimethylhepta-1,3,6-triene is readily rearranged on irradiation into a mixture of *cis*- and *trans*-3,3-dimethyl-1,2-divinylcyclopropane [6].

The structure of *(10)* was deduced from infrared and NMR spectra. The formation of *(10)* is the first example of a photochemically induced Diels-Alder reaction.

## Diastereomeric Secalonic Acids [1]

By Prof. Dr. B. Franck [*] and Dipl.-Chem. E. M. Gottschalk

Organisch-Chemisches Institut
der Universität Göttingen (Germany)

Secalonic acid, the pale yellow main pigment of ergot (*Claviceps purpurea*), was originally isolated by *Kraft* [2] and has since been investigated by several groups of workers [1,3–6]. We found that the crystalline secalonic acid obtained from a number of ergot varieties consists of a mixture of two diastereomers. Thus, secalonic acid derived from German and Austrian cultured ergot and from Spanish wild ergot could be separated chromatographically into secalonic acid A ($R_F$ = 0.42) and secalonic acid B ($R_F$ = 0.64) [7,8]. On the other hand, secalonic acid from a strongly pigmented Canadian wild ergot contained only the slow-moving component A. The mass spectra of secalonic acids A and B show the same molecular peaks (at M = 638) and the same fragmentation. Both acids have identical chemical formulae, ultraviolet spectra, functional groups, and exhibit the same reactions on degradation with alkali, but have different melting points $R_F$- values, and optical rotations (cf. Table 1). They are therefore diastereomers.

Table 1. Properties of the diastereomeric secalonic acids A and B, $C_{32}H_{30}O_{14}$ (mol. wt. 638.6).

| | A | B |
|---|---|---|
| M. p. [°C] (from $CHCl_3$) | 246–247 (decomp.) | 254–256 (decomp.) |
| $[\alpha]_D^{20}$ ($CHCl_3$) | −76 ° | −196 ° |
| $[\alpha]_D^{20}$ (pyridine) | −177 ° | +194 ° |

[8] Chrysergonic acid, which was isolated by *A. Stoll* et al. [3] and whose structure was recently investigated [6], was found as already suggested by its low rotation ($[\alpha]_D^{20}$ = −3 ° in pyridine) [3] – to be a 2:1 mixture of secalonic acids A and B.

## The Structure of Secalonic Acids A and B [1]

By Prof. Dr. B. Franck, Dipl.-Chem. E. M. Gottschalk, cand. chem. U. Ohnsorge, and Dipl.-Chem. G. Baumann

Organisch-Chemisches Institut der Universität Göttingen and Institut für Organische Chemie der Universität Kiel (Germany)

The diastereomeric secalonic acids A and B [1] were shown by degradation [1,2], spectra [1–3], and synthesis of *(1)* [3] to be symmetrical derivatives of a new type of natural product skeleton, *viz.* 5,5′-dihydroxy-8,8′-bichromonyl *(1)*. Moreover, they contain four hydroxy groups, two *C*-methyl, and two methoxycarbonyl groups [2]. *Whalley* et al. [4] recently suggested an arrangement of the substituents according to Formula *(2)*. We were able to obtain an independent confirmation of the structure of ring C in our pure, diastereomeric secalonic acids A and B by means of mass spectrometry, ring C being split off as methyl cresotinate, and by degradation with ozone to α-hydroxy-β-methylglutaric acid and methylsuccinic acid. In contrast to *(2)*, however, the β-dicarbonyl system in the secalonic acids is enolized to the vinylogous carboxylic acid *(3)* [5].

(The rings are labelled as A, B, and C from left to right.)

The relative and absolute configurations of the three centers of asymmetry at C-10, C-5, and C-6 of secalonic acid A shown in *(3)* were established as follows: The methylsuccinic acid formed by ozonolysis of secalonic acid A is dextrorotatory and has the *(R)*-configuration. It therefore follows that the center of asymmetry at C-6 of this secalonic acid – which carries the methyl group – has the absolute configuration shown in *(3)*. Since the proton on C-5 in *(3)* has a doublet at $\tau = 4.36$ with $J = 9$ cps in its NMR spectrum in pyridine, it is in *trans*-diaxial orientation relative to the methine proton on C-6. This proves that the hydroxy group is *trans*-diequatorial relative to the methyl group. The configuration of the methoxycarbonyl group follows from the mass spectrum and the optical rotatory dispersion of secalonic acids A and B. The opposite Cotton effect curves [5a] with unusually high peak values for secalonic acid A ($[\alpha]^{22}_{246} = 133000°$) and secalonic acid B ($[\alpha]^{23}_{246} = -115000°$) in chloroform show [6] that the two diastereomers differ in their configuration at one ring linkage, namely at the angular methoxycarbonyl group. In secalonic acid A *(3)*, the methoxycarbonyl group must be in the less stable position, *viz. cis*-quasiaxial relative to the neighboring hydroxy group, because it is split off more readily in mass spectroscopy [7] (the M - $COOCH_3$ fragment from *(3)* is 2.7 times more intense relative to the molecular peak than that from secalonic acid B).

## Enzymatic Reactions on Ion-Exchange Thin-Layer Plates

By Dr. K. Randerath and Dr. Erika Randerath

John Collins Warren Laboratories, Huntington Memorial Hospital of Harvard University
and
Biochemical Research Department, Massachusetts General Hospital and Harvard Medical School [*]

Mono- and oligonucleotides may be separated by anion-exchange thin-layer chromatography on cellulose impregnated with polyethyleneimine [1]. We found that enzymatic reactions may be performed directly on the ion-exchange layer. As an example, we quote the degradation of cytidine diphosphate glucose *(1)* to cytidine 5'-monophosphate and glucose 1-phosphate.

*(1)*

snake-venom phosphodiesterase ↓ pH 7.8, 45–60 min, 23°C.

cytidine 5'-monophosphate + glucose 1-phosphate

A buffered solution of the enzyme is applied to the substance spot and covered with paraffined film (Parafilm®). The degradation products are separated by thin-layer chromatography, compared with known compounds and estimated quantitatively after elution. The monophosphates can be degraded further to cytidine, orthophosphate and glucose if, after pretreatment with phosphodiesterase, a solution of prostate phosphomonoesterase is added to the substance spot:

cytidine 5'-monophosphate + glucose 1-phosphate

$$\xrightarrow[\text{pH 5–6, 60 min, 23 °C.}]{\text{prostate phosphomonoesterase}} \text{cytidine} + 2\,H_3PO_4 + \text{glucose}$$

Suitable substrates for the phosphodiesterase reaction are, in addition to nucleotide sugars, other diesters of pyrophosphoric acid, *e.g.* diphosphopyridine nucleotide as well as oligonucleotides with a free terminal 3'-hydroxy group. Oligonucleotides with a free, terminal 5'-hydroxy group may be degraded with spleen phosphodiesterase, and nucleoside 2',3'-cyclophosphates with ribonuclease on ion-exchange layers. The layer has no influence on the specificity of the enzymes investigated.

The method is suitable not only for the analysis of traces of nucleotides (quantities $< 10^{-9}$ mole), but also as a sensitive detection procedure in enzyme fractionations.

## Bicyclo[4,2,0]octa-2,4,7-triene

By Prof. Dr. Emanuel Vogel, Dr. H. Kiefer, and Dr. W. R. Roth

Institut für Organische Chemie der Universität Köln (Germany)

*Dedicated to Prof. H. Meerwein on the occasion of his 85th birthday*

*Huisgen* and *Mietzsch* [1] recently presented convincing kinetic evidence for the existence of valence tautomerism between cyclooctatetraene *(3)* and bicyclo[4,2,0]octa-2,4,7-triene *(2)*. We have now shown that bicyclo[4,2,0]octa-2,4,7-triene is produced in good yield when 7,8-dibromobicyclo-[4.2.0]-octa-2,4-diene ("cyclooctatetraene dibromide") *(1)* [2] is dehalogenated with disodium phenanthrene in dimethyl ether at −78 °C [3]. The purest sample of *(2)* prepared so far contained 95 % of the bicyclic compound; the impurity was solely *(3)*, which was obviously produced during the work-up (distillation at −20 °C) [4].

*(1)* *(2)* *(3)*

The chemical evidence for the structure *(2)* is based on its catalytic hydrogenation to bicyclo[4,2,0]octane together with its ready isomerization to *(3)*. Compound *(2)* reacts with maleic anhydride at 0 °C to give the known adduct of *(3)*. Bromination of *(2)* gives mainly tetrabromides [5]. The structure *(2)* is in complete agreement with the spectroscopic data. The NMR spectrum shows the expected signals from the four olefinic protons on the six-membered ring (multiplet centered at 4.37 $\tau$), the two protons on the double bond in the four-membered ring (singlet at 4.12 $\tau$), and the two aliphatic, doubly allylic protons (symmetrical multiplet centered at 6.68 $\tau$). The presence of the cyclobutene ring is

further deduced from the characteristic –C–H and –C=C– stretching vibrations (at 3112 and 1552 $cm^{-1}$ respectively) in the infrared spectrum determined at –20 °C [6]. The ultraviolet maxima at 273 mμ (ε = 3100) and 277 mμ (ε = 3000) correspond to those of other cyclohexadienes fused onto three- and four-membered rings [7].

The activation parameters, $E_a$ = 18.7 ± 0.8 kcal/mole and $A = 9.1 \times 10^{11}$ $sec^{-1}$, for the rearrangement of bicyclo[4,2,0]-octa-2,4,7-triene *(2)* to cyclooctatetraene *(3)*, were derived by means of the Arrhenius equation from the rate constants determined between 0 and –20 °C (5 °C intervals) by NMR spectroscopy. The half-life of *(2)* in this rearrangement at 0 °C is 14 min. We intend to determine the enthalpy of the rearrangement in order to obtain an independent estimate of the equilibrium concentration of the bicyclic isomer.

Received, March 23rd, 1964 [Z 701/531 IE]

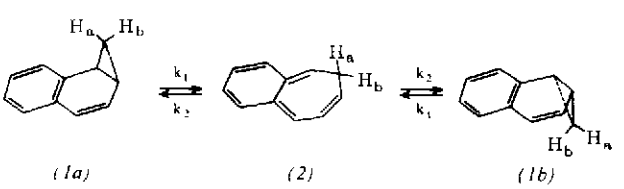
## Proof of a Norcaradiene-Cycloheptatriene Valence Tautomerism by NMR Spectroscopy



By Prof. Dr. Emanuel Vogel, cand. chem. D. Wendisch and Dr. W. R. Roth

Institut für Organische Chemie
der Universität Köln (Germany)

*Dedicated to Prof. H. Meerwein on the occasion of his 85th birthday*

The height of the energy barrier separating norcaradiene and cycloheptatriene is unknown and the assumption of a valence tautomerism between these two isomers is thus hypothetical [1]. In the case of benzonorcaradiene, the energy barrier has been determined from the temperature dependence of the NMR spectrum.

Benzonorcaradiene *(1)* is produced [2] by the addition of methylene onto naphthalene; its NMR spectrum shows, in addition to the signals due to the four aromatic protons, a doublet at 3.83 τ (two olefinic protons), a multiplet at 7.83 τ (benzyl proton), a complex multiplet at 8.33 τ (allyl proton) and multiplets at 8.70 and 10.35 τ, assigned to the two methylene protons.

*(1a)* *(2)* *(1b)*

On heating, the methylene signals first lose their fine structure; they then broaden until at 180 °C, they merge to a uniform flat absorption band which lies midway (9.54 τ) between the original signals. Further rise in temperature increases the sharpness of this new band. The other signals retain their positions.

These changes in the spectrum are completely reversible and can be explained by an equilibrium between the antipodes *(1a)* and *(1b)*, which is rapidly attained. As the protons $H_a$ and $H_b$ formally change places during this process, the positions of the NMR signals of $H_a$ and $H_b$ depend on the rate of the inversion *(1a)* ⇌ *(1b)*.

According to *Gutowsky* and *Holm* [3], the rate constant for such a proton exchange is given by the equation

$$k = \pi (\delta - \Delta) / \sqrt{2}$$

where $\delta$ is the chemical shift of the two protons at infinitely small rate of exchange, and $\Delta$ is the frequency interval between their signals at the temperature of observation; the rate constants for the isomerization *(1a)* ⇌ *(1b)* between 150 and 180 °C were determined in this way. Evaluation according to the Arrhenius equation gave the activation parameters $E_a$ = 19.4 kcal/mole and $A = 6.2 \times 10^{11}$ $sec^{-1}$ [4]. The isomerization *(1a)* ⇌ *(1b)* is considered to be a consequence of a norcaradiene-cycloheptatriene equilibrium which reveals its existence in the interconvertibility of the antipodes *(1a)* and *(1b)* [5]. With the assumption that $k_2 \gg k_1$ (the concentration of *(2)* remains below that detectable by NMR spectroscopy), the energy barrier for the norcaradiene-cycloheptatriene rearrangement *(1)* ⇌ *(2)* is 19.4 kcal/mole and the frequency factor $A = 1.2 \times 10^{12}$ $sec^{-1}$.

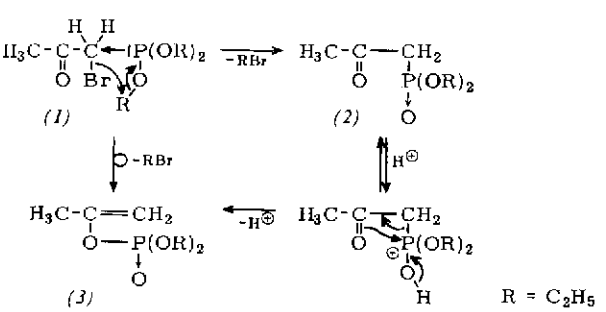
Received, March 23rd, 1964 [Z 702/523 IE]
German version: Angew. Chem. 76, 432 (1964)

[1] For the synthesis of stable norcaradienes, see: *E. Vogel, W. Wiedemann, H. Kiefer*, and *W. F. Harrison*, Tetrahedron Letters 1963, 673; *R. Darms, T. Threlfall, M. Pesaro*, and *A. Eschenmoser*, Helv. chim. Acta 46, 2893 (1963).

[2] *W. v. E. Doering* and *M. J. Goldstein*, Tetrahedron 5, 53 (1959).

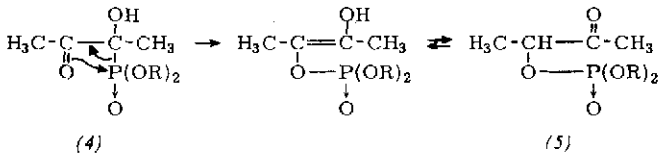
[3] *H. S. Gutowsky* and *C. H. Holm*, J. chem. Physics 25, 1228 (1956).

[4] Spin-spin interaction was not considered, although strictly speaking the above treatment is valid only if (for k = 0) coupling constants and line-widths are equal to zero; see *S. Alexander*, J. chem. Physics 37, 967 (1962).



[5] Substitution of an H-atom of the $CH_2$ group in *(1)* by another group should not significantly affect the rate of isomerization to the corresponding cycloheptatriene *(2)*. However, with such substituted benzonorcaradienes, the equilibrium concentrations of *(1a)* and *(1b)* will in general by very different since the two forms are now exo-endo isomers; the inversion of the three-membered ring can then no longer be observed by NMR spectroscopy. Thus, the NMR spectrum of benzonorcaradiene-carboxylic ester is not temperature-dependent.

## Phosphonic Ester/Enol Phosphate Rearrangement



By Dr. H. Machleidt and Dr. G. U. Strehlke

Organisch-Chemisches Institut der Universität Bonn (Germany)

The reaction of bromoacetone *(1)* with triethyl phosphite at 140–170 °C gives rise to compounds *(2)* and *(3)* [1], in the approximate ratio of 1:1. On prolonged heating, this propor-

tion changes and is displaced in favor of *(3)*. It is probable that *(3)* is partly formed by way of *(2)* [2]. This view is supported by the observation that *(2)* rearranges to an extent of 50 % into *(3)* at 170 °C in the presence of 2 % $H_3PO_4$ during 13 h. In the presence of 0.5 % $H_3PO_4$ the extent of rearrangement amounts to 12 %, and is less than 1 % in the absence of acids. Rearrangement of *(2)* into *(3)* occurs also in a 2 % solution of $H_3PO_4$ in nitrobenzene or mesitylene at 170 °C.

*(4)* *(5)*

R = $C_2H_5$

The process is an intramolecular rearrangement and not an intermolecular transphosphorylation, as shown by the fact that added 2-butanone [3 moles per mole of *(2)*] is without influence on the reaction. It is possible that the facile rearrangement *(4)* → *(5)* [3] proceeds similarly.

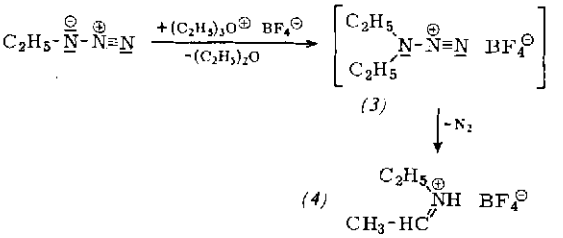
## The Reaction of Triphenylsilyl Azide with Triethyloxonium Tetrafluoroborate [1]

By Dr. N. Wiberg and cand. chem. K. H. Schmid

Institut für Anorganische Chemie
der Universität München (Germany)

The action of stoichiometric quantities of "ethyl cations" in the form of triethyloxonium tetrafluoroborate on triphenylsilyl azide in methylene chloride at 20 °C did not lead to the expected *N*-diazonium salt *(1)*. The latter is probably formed as an intermediate, but being a strong silylating agent, it removes a fluoride anion from the tetrafluoroborate to form triphenylfluorosilane *(2)*.



*(1)*

*(2)*

Excess triethyloxonium tetrafluoroborate decomposes the ethyl azide formed, with evolution of nitrogen [2].

working rapidly, however, *N*-ethyl-*N*-ethylideneammonium tetraphenylborate (m.p. 131 °C), which is resistant to hydrolysis, can be precipitated from water with $NaB(C_6H_5)_4$ [3].

*(3)* *(4)*

Since no nitrogen is evolved during the reaction of stoichiometric amounts of triphenylsilylazide and triethyloxonium tetrafluoroborate *(1)* must be more stable than *(3)* – obviously owing to the influence of its triphenylsilyl group.

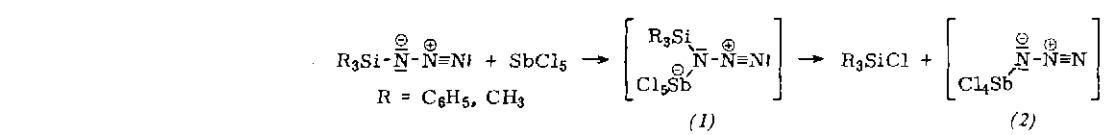
Received, March 31st, 1964 [Z 713/539 IE]
German version: Angew. Chem. *76*, 381 (1964)

[1] Communication No. 3 on Silyl Azides. – Communication No. 2: *N. Wiberg*, *F. Raschig*, and *R. Sustmann*, Angew. Chem. *74*, 716 (1962); Angew. Chem. internat. Edit. *1*, 551 (1962).

[2] The reaction of n-butyl azide with alkyl cations proceeds similarly, according to *W. Pritzkow* and *G. Pohl*, J. prakt. Chem. *20*, 132 (1963).

[3] The hydrophobic property of tetraphenylborate gives rise to immonium salts of this anion which are resistant to hydrolysis. Tetrafluoroborate and hexachloroantimonate [*J. Goubeau*, *E. Allenstein*, and *A. Schmidt*, Chem. Ber. *97*, 884 (1964)] do not display this property. We found that immonium tetraphenylborates are readily obtained from substituted ammonium tetraphenylborates $R_2NH_2^{\oplus}B(C_6H_5)_4^{\ominus}$ and ketones (aldehydes). For example, a solution of $(CH_3)_2NH_2^{\oplus}B(C_6H_5)_4^{\ominus}$ in acetone deposites crystalline $(CH_3)_2C{=}N(CH_3)_2^{\oplus}$ $B(C_6H_5)_4^{\ominus}$, m.p. 278–280 °C (decomp.), in the course of a few days.

## The Reaction of Silyl Azides with Antimony Pentachloride [1]



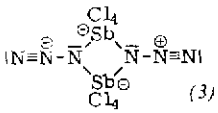
By Dr. N. Wiberg and cand. chem. K. H. Schmid

Institut für Anorganische Chemie
der Universität München (Germany)

The reaction of antimony pentachloride with triphenylsilyl azide or trimethylsilyl azide in a molar ratio of 1:1 does not stop at the stage of the addition product *(1)* [2]; instead, *(1)* decomposes instantaneously with silylation of a chloride ion from the antimony [1].

The tetrachloroantimony azide *(2)* produced thereby forms yellow crystals on sublimation *in vacuo* at 80–90 °C and melts with gradual decomposition at 126–127 °C to give a red-orange liquid. On heating further, the azide explodes. In the infrared spectrum of *(2)*, $\tilde{\nu}_{as}(N_3)$ is at 2140 $cm^{-1}$ and $\tilde{\nu}_s(N_3)$ at 1180 $cm^{-1}$.

Cryoscopic molecular-weight determinations in benzene indicated that *(2)* has twice the expected molecular weight.



*(1)* *(2)*

*N*-Ethyl-*N*-ethylideneammonium tetrafluoroborate *(4)* is thereby formed as colorless, extremely thin platelets, m.p. 140–142 °C, with $\tilde{\nu}_{C=N}$ at 1720 $cm^{-1}$. It is insoluble in common organic solvents and is hydrolysed by water. By

A plausible explanation for this lies in the dimerization via nitrogen bridges *(3)*, by means of which the strongly acidic, pentavalent antimony attains the favored coordination number of 6 [3].

As expected, as a derivative of $SbCl_6$, *(3)* is more resistant to hydrolysis than $SbCl_5$: it remains dissolved in water for a short time without decomposing.

## The Crystal Structure of Rubidium and Cesium Hexachloro-, -bromo-, and -iodorhenates(IV)

By Priv.-Doz. Dr. H. J. Berthold
and cand. chem. G. Jakobson

Institut für Anorganische Chemie und Kernchemie
der Universität Mainz (Germany)

All rubidium and cesium hexachloro-, -bromo-, and iodorhenates(IV) crystallize with the antifluorite structure of $K_2PtCl_6$ (space group $O_h^5$–Fm3m). The lattice constants (together with our values for $K_2ReCl_6$ [1–3] and $K_2ReBr_6$ [2,4]) are [5]:

| M | $M_2ReCl_6$ | $M_2ReBr_6$ | $M_2ReI_6$ |
|---|---|---|---|
| K | 9.840 ± 0.005 Å | 10.382 ± 0.005 Å | – |
| Rb | 9.974 ± 0.005 | 10.485 ± 0.01 | 11.31 ± 0.02 |
| Cs | 10.260 ± 0.005 | 10.685 ± 0.01 | 11.44 ± 0.02 |

The values for $K_2ReCl_6$ and $K_2ReBr_6$ were obtained by using film and counter diffractometer techniques. The other values were obtained by evaluation of asymmetric powder patterns (camera diameter 57.3 mm). The accuracy of the data is limited by the easily occurring partial hydrolysis of the sparingly soluble substances during their preparation or recrystallization, resulting in the inclusion of hydroxide or oxide ions in the lattice.

The compounds were prepared by boiling $Re_2O_7$ and Rb or Cs halide in concentrated solutions of the corresponding hydrohalic acids. After boiling off the halogen liberated by reduction of the rhenium the mixture was concentrated and, after crystallizing out, the complex salt was filtered off. It was freed from alkali-metal halide (and iodine) by extraction and then recrystallized from the appropriate concentrated hydrohalic acid. The iodo compound could not be recrystallized because of its poor solubility.

$Rb_2ReCl_6$ and $Cs_2ReCl_6$ like $K_2ReCl_6$ are green-yellow, $Rb_2ReBr_6$ and $Cs_2ReBr_6$ are red (somewhat lighter than the dark red $K_2ReBr_6$), while $Rb_2ReI_6$ and $Cs_2ReI_6$ are deep black like $K_2ReI_6$.

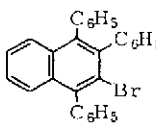
## Aryl Rearrangements in the Thermolysis of β-Arylated α-Halogenoacrylates [*]

By Doz. Dr. G. Köbrich and Dipl.-Chem. H. Fröhlich

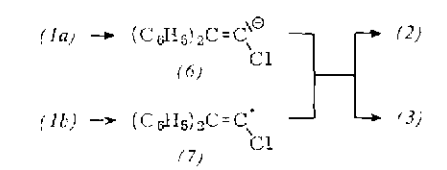


Organisch-Chemisches Institut
der Universität Heidelberg (Germany)

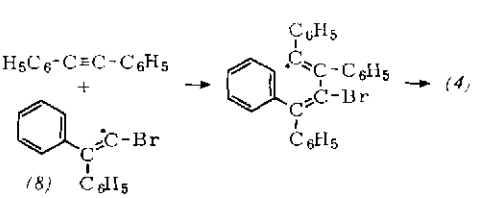
Extending research on the thermolysis of *o*-halogenobenzoates [1], we have investigated the decarboxylation of β-arylated α-halogenoacrylates *(1)* with respect to their capacity to undergo α-elimination. Dry heating of *(1a)* *(1c)* yields primarily tolane *(2)* [*(1a)*: 88 %; *(1b)*: 52 %; *(1c)*: 35 %]; *(1c)* also gave *ca.* 1 % 1,2,4-triphenyl-3-bromonaphthalene *(4)*, identified by comparison with a sample independently obtained by diene synthesis from diphenylisobenzofuran and β-bromostyrene.

*(1)* *(2)* *(3)*

*a*: M = K, X = Cl
*b*: M = Ag, X = Cl
*c*: M = Ag, X = Br
*d*: M = Ag, X = H



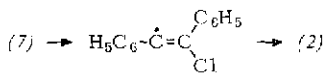
*(4)*, m.p. 245 °C



Additionally, *(1b)* and *(1c)* yield polymeric products, which are also formed (besides 21 % phenylacetylene and 3.4 % diphenyldiacetylene, $H_5C_6{-}C{\equiv}C{-}C{\equiv}C{-}C_6H_5$) in the decomposition of silver α-chloro-β-phenylacrylate.

The decomposition temperatures [*(1a)*: 325 °C; *(1b)*: 220–270 °C] are lowered to 150–190 °C by using dimethylsulfoxide (DMSO) as solvent. Under these conditions tolane and 1,1-diphenyl-2-halogenoethylene *(3)* are obtained. The proportions are influenced by the cation, which points to a different mechanism of decomposition: *(1a)* gives rise to 72 % *(3)* and 19 % *(2)*, yet *(1b)* gives 11 % *(3)* and 62 % *(2)* together with 1,1-diphenylethylene *(5)* and benzophenone in small quantities. The latter is formed from *(5)* under the reaction conditions, as was shown by a control experiment. From silver α-chloro-β,β-bis-(*p*-anisyl)acrylate [*(1b)*, *p*-$CH_3OC_6H_4$ instead of $C_6H_5$] the corresponding acetylene *(2)* is formed in 76.5 % yield; a halogenoethylene [corresponding to *(3)*] was not detectable. Styrene is polymerised during decomposition of the silver salt, but not of the potassium salt.

We conclude from this and further findings [2] that decarboxylation of the potassium salt *(1a)* gives the carbanion *(6)*, while the silver salt *(1b)* gives the radical *(7)*. Both rearrange without solvent to tolane by Cl elimination and phenyl migration. The radical *(8)* arising correspondingly from *(1c)* adds partly to the tolane already formed and cyclizes with loss of hydrogen to give the naphthalene derivative *(4)* [3].



*(6)* *(7)*

*(8)*

DMSO [4] is capable of capturing the major part of *(6)* before the elimination by protonating it to the halogenoethylene *(3)*; however, it seems to lack in saturating the radical *(7)* in corresponding amounts.

The equally conceivable phenyl rearrangement (before halogen abstraction)

can be excluded on the grounds that dry decomposition of the chlorine-free silver salt *(1d)* yields solely *(5)* (39 %) and *ca.* 1 % benzophenone and that after thermolysis of *(1b)* in DMSO no chlorostilbene is detectable.

The step *(6)* → *(2)* has a parallel in the base-initiated Fritsch-Buttenberg-Wiechell rearrangement [5]. The thermolysis of the potassium salt *(1a)* represents the only method so far of achieving this isomerisation in a non-alkaline milieu. A radical-induced aryl migration of olefines [corresponding to *(7)* → *(2)*] was hitherto unknown. Further investigations with respect to the possible appearance of an olefine carbene are in progress.

## Preparation of Fluorinated Si–N Compounds Using $SiF_4$ [1]

By Prof. Dr. U. Wannagat and Dr. H. Bürger

Institut für Anorganische Chemie
der Technischen Hochschule Graz (Austria)

$SiCl_4$ (and analogously higher silicon halides) reacts with (a) $NH_3$, (b) $RNH_2$, (c) pyridine (= Py), or (d) $(R_3Si)_2NH$ to give (a) $[Si(NH)_2]_x$, (b) $Cl_3SiNHR$, (c) $SiCl_4Py_2$, and (d) $Cl_3SiNHSiR_3$. With the same reactants $SiF_4$ yields only the adducts (a) $SiF_4(NH_3)_2$ *(1)*, (b) $SiF_4(NH_2R)_2$ [2], and (c) $SiF_4Py_2$. It does not react with $(R_3Si)_2NH$ up to 120 °C. However, it reacts vigorously with silyl-substituted alkali-metal amides (R = $CH_3$) at −78 °C:

$$2\ (C_2H_5)_3SiNHLi + 3\ SiF_4 \rightarrow Li_2SiF_6 + (C_2H_5)_3Si{-}NH{-}SiF_3 \qquad (2)$$

or

$$2\ (R_3Si)_2NNa + 3\ SiF_4 \rightarrow Na_2SiF_6 + (R_3Si)_2N{-}SiF_3 \qquad (3)$$

At room temperature *(3)* reacts further:

$$(R_3Si)_2N{-}SiF_3 + NaN(SiR_3)_2 \rightarrow NaF + (R_3Si)_2N{-}SiF_2{-}N(SiR_3)_2 \qquad (4)$$

In contrast with $SiF_4$, the solid crystalline $F_4Si(NH_3)_2$ *(1)*, the oldest known Si–N compound [3], reacts vigorously with hexamethyldisilazane at 100 °C in solution or suspension essentially according to:

$$F_4Si(NH_3)_2 + 2\ R_3Si{-}NH{-}SiR_3 \rightarrow 2\ NH_3 + 2\ R_3SiF + R_3Si{-}NH{-}SiF_2{-}NH{-}SiR_3 \qquad (5)$$

With $F_4Si(NH_2R)_2$ instead of *(1)*, $R_3SiNHR$ and $(R_3Si)_2NR$ are formed as well; apparently the $NH_3$ is not only displaced by $(R_3Si)_2NH$ from its coordinate bond with $SiF_4$.

On heating cyclosilazanes $[-R_2Si{-}NH{-}]_{3\ or\ 4}$ finely mixed with $F_4Si(NH_3)_2$, a mixture of linear silazanes $F{-}[SiR_2{-}NH]_n{-}SiR_2F$ with $n = 0$, 1 *(6)*, 2, and 3 is formed. Further products are $[-F_2Si{-}NH{-}]_x$ and $NH_3$. 1,3-Difluorotetramethyldisilazane *(6)*, $F{-}SiR_2{-}NH{-}SiR_2{-}F$, is much less reactive than its 1,3-dichloro analogue [4]; the other newly prepared F/Si/N compounds are also remarkable for their thermal and hydrolytic stability.

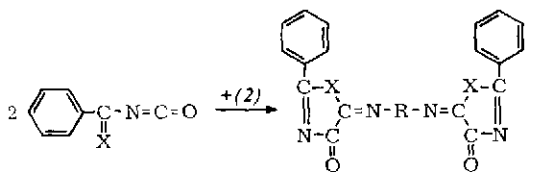
## 1,4-Dipolar Cycloaddition onto Diisonitriles

By Doz. Dr. R. Neidlein

Institut für Pharmazeutische Chemie und Lebensmittelchemie
der Universität Marburg/Lahn (Germany)

With the exception of 1,1-diisonitrilomethane [1], 1,4-diisonitrilobenzene [2], and xanthocilline [3], diisonitriles have previously not been described. By passing equimolar quantities of phosgen [4] into a suspension of *N,N'*-bisformyldiamines *(1)* in methylene chloride/triethylamine (250:35) at −10 to −30 °C diisonitriles *(2)* are obtained:



*(1)* *(2)*

| *(2)*, R | M.p. [°C] (decomp.) | Yield [%] |
|---|---|---|
| *m*-Phenylene | 106–107 | 83 |
| *p*-Phenylene | 165–166 | 75 |
| 1,4-Cyclohexylene | 108–109 | 96 |

In anhydrous ether/benzene (1:1), diisonitriles react at room temperature with 1,4-dipolar compounds, *e.g.* benzoyl isocyanate *(3)*, to yield heterocyclics *(4)*.

Equimolar quantities of thiobenzoyl isocyanate *(5)*, obtained from 2-phenyltbiazoline-4,5-dione [5] by elimination of

(3), X = O
(5), X = S

(4), X = O; R = *p*-phenylene
75 %, m.p. 174–175 °C (decomp.)
(6), X = S; R = 1,4-cyclohexylene
92 %, m.p. 213–214 °C (decomp.)

carbon monoxide in boiling xylene, react with diisonitriles in xylene at ca. 150 °C to yield derivatives, *e.g. (6)*, of *N,N'*-bis-(4-oxothiazolinylidene)diamines.

## Preparation of Polymethylene by the Reaction of Diazomethane with Diborane

By Dr. G. H. Dorion, S. E. Polchlopek [*], and E. H. Sheers

American Cyanamid Company, Stamford, Conn. (U.S.A.)

We have synthetized polymethylene at room temperature by addition of 1 mmole of diborane in 0.8 ml of anhydrous tetrahydrofuran[1] to a solution of 16 mmole of diazomethane in 80 ml of ether. An almost quantitative yield was obtained. The polymer was highly crystalline when studied by microscopy, melted at 136 °C, and was estimated by infrared spectroscopy to contain less than 1.0 methyl group per 1000 methylene groups. A typical sample contained 1.02 % boron and had a molecular weight (ebulliometry, toluene) greater than 20000.

The significance of this rather simple room-temperature synthesis is that it affords a highly linear polymer. Polyethylenes show $CH_3$:$CH_2$ group ratios of 2:1000 to 33:1000 [2].

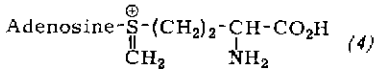
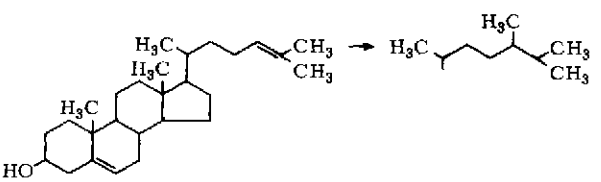
# CONFERENCE REPORTS

## Federation of European Biochemical Societies



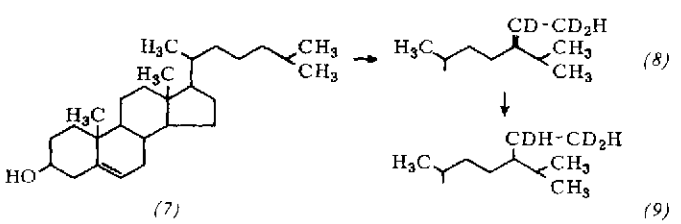
The first meeting of this federation, which was founded in January 1964, took place in London from March 23rd to 25th, 1964. The agenda included colloquia on "The Biochemistry of Chloroplasts" and on "Inborn Errors of Metabolism", a symposium on "The Structure and Activity of Enzymes", and 139 short papers.

The program on the first day included the Jubilee Lecture of the British Biochemical Society. *E. Lederer*, Gif-Sur-Yvette (France), spoke on the origin and function of some methyl groups in branched-chain fatty acids. In general, the methyl groups are derived by direct *C*-methylation of preformed molecules, or from propionic acid, isoleucine, or mevalonic acid. During the biosynthesis of tuberculostearic acid *(3)*



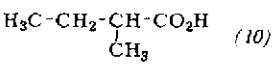
*(1)*
*(2)*
*(3)*

from the corresponding unsaturated acid *(1)*, the possible occurrence of a cyclopropane type intermediate *(2)* was envisaged. However, the bacillus was unable to convert a synthetic sample of this compound into tuberculostearic acid. Cyclopropanecarboxylic acids may be biosynthetized from an unsaturated acid and *S*-adenosylmethionine. When the methyl group of the methionine used is fully deuterated, two of the deuterium atoms are retained in the cyclopropane ring, suggesting the conversion of active methionine into a methylene-donating molecule *(4)*



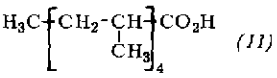
*(4)*

Similarly, methylation of C-24 in desmosterol *(5)* to give ergosterol *(6)* proceeds with retention of only 2 hydrogen atoms.



*(5)* *(6)*

The ethylation of cholesterol *(7)* that occurs at C-24 to give β-sitosterol *(9)* appears to be in fact a form of double methylation. Biological deutereomethylation gave an intermediate *(8)* which was isolated and which on ozonization gave acetaldehyde deuterated on both carbon atoms.



*(7)* *(8)* *(9)*

In *Ascaris lumbricoides*, condensation of acetate and propionate moities gives a branched fatty acid *(10)*, and in the preen

*(10)*

*(11)*

gland of the goose, the long chain fatty acid *(11)* is built up entirely from propionic acid units.

The methyl group of coenzyme Q is known to be derived from mevalonic acid: this methyl group may play an important part in oxidative phosphorylation via a quinone methide.

In the symposium, *F. M. Richards*, New Haven, Conn. (U.S.A.) listed some chemical modifications made at specific sites in ribonuclease in order to study the contribution made by its various constituent amino acids to the activity of the whole molecule. Thus, dinitrophenylation of lysine 41 results in complete loss of enzymatic activity; this in turn affects the reactivity of lysine 7 towards fluorodinitrobenzene. Mutually exclusive carboxymethylation of histidines 12 or 119 with iodoacetic acid also results in marked loss of ribonuclease activity. It was noted as illustrative of the effect of the tertiary structure on the chemical reactivity of constituent amino acids that three of the tyrosine residues do not ionize in the usual pH range, only 4 out of 6 of these residues react with iodine, and methionines 13, 29, 30, and 79 do not react with iodoacetic acid.

During recombination of the terminal peptide containing 20 amino acids (S-peptide) with the protein part of the molecule (S-protein) to give ribonuclease-S, residues 3–13 in the peptide are crucial for enzymatic activity in the newly formed complex. Recombination with S-protein of an S-peptide in which methionine 13 has been oxidized to the sulfone gives a catalytically active complex. However $\Delta S$ for this reaction is −100 e.u. compared with −150 e.u. when the recombination is carried out with unoxidized S-peptide. It was pointed out that this methionine is adjacent to position 12 which is implicated in the enzymatic activity of the molecule and yet it can be changed by 50 e.u. (conformational entropy) without changing the enzyme's activity.

*S. Moore*, New York (U.S.A.) gave evidence that the dimer of ribonuclease which is enzymatically active and which is obtained by lyophilization of a 50 % acetic acid solution of ribonuclease consists of a head-to-tail fit of two partially uncurled molecules. By carboxymethylation of the dimer with 2 moles of iodoacetic acid, he obtained a new dimer consisting of 1 molecule of a hitherto inaccessible ribonuclease which is carboxymethylated at positions 12 and 119, and one molecule of active ribonuclease.

Substances which inhibit enzymatic hydrolysis of cytidine 2′,3′-phosphate and protect the enzyme against alkylation were reported by *A. P. Mathias*, London (England). In general, there is good agreement between the $K_i$ values obtained for each compound in both reactions. The pH activity curves in organic solvents, the variation with pH of the rate of hydrolysis of cytidine 2′,3′-phosphates, and the results of spectrophotometric and kinetic examinations of the inhibition of ribonuclease by $Zn^{2+}$ ions all imply that there are two histidines in the active site. It was suggested that a protonated imidazole group interacts with the 2′-oxygen of the substrate and another imidazole in its basic form is hydrogen-bonded to the attacking water molecule. This view was contested by *H. Witzel*, Marburg (Germany) in the resulting discussion and in a short paper. This worker postulated that the binding of the enzyme to the substrate involves only the phosphate group in dianionic form, the two concomitant positive charges being supplied by a triprotonated diimidazole system and the ε-ammonium group of lysine 41.

One-hundredfold purification of an enzyme from pig pancreas which catalyses the reactivation by oxygen of reduced ribonuclease was described by *P. Venetianer*, Budapest (Hungary). This enzyme requires a thermostable dialysable cofactor which can be replaced by dehydroascorbic acid.

Amino acid sequences for beef chymotrypsinogen arrived at by *B. Keil*, Prague (Czechoslovakia), and *B. S. Hartley*, Cambridge (England), differ, but both are in agreement over the relative positions of all five disulfide bridges. Serine 195 and histidine 57 probably constitute the active site. The catalytic activity also depends on the *N*-terminal isoleucine as was shown by *B. Labouesse*, Orsay (France). *J. Kraut*, La Jolla (U.S.A.), and *D. M. Blow*, Cambridge (England), reported progress on X-ray crystallographic analyses of chymotrypsinogen and α-chymotrypsin, respectively. Both agree that neither of these molecules contains an α-helix. *R. A. Oosterbaan*, Rijswijk (Holland), described the incubation of chymotrypsin with its substrate (*N*-acetyltyrosine ethyl ester) in the presence of $H_2^{18}O$. Subsequent acetylation of the protein and isolation of the tetrapeptide Gly-Asp(Ac)-Ser-Gly showed that it contained no $^{18}O$. Thus it appears that ring structures involving serine and a neighboring aspartic acid are not involved in the active site.

*J. I. Harris*, Cambridge (England), compared some aspects of the structure and mode of action of yeast and muscle glyceraldehyde-3-phosphate dehydrogenases (GAPDH). Inactivation of GAPDH by iodosobenzoate is due to formation of an intra-chain S–S bridge between two cysteines in the "active-center" peptide. Yeast alcohol dehydrogenase contains four identical polypeptide chains each with a molecular weight of 36 000. Treatment of the enzyme with [1-$^{14}$C]iodoacetic acid leads to complete loss of its activity, and the resulting *S*-carboxymethylcysteines occur in the same sequence of amino acids in the enzyme protein. Some peptide sequences in dehydrogenases are the same as some in haemoglobin.

*M. F. Perutz*, Cambridge (England), described the isolation of a new form of reduced haemoglobin from horse which, when subjected to two-dimensional X-ray crystallographic analysis, showed an increase of 7 Å in the distance between its reactive SH groups (loaded with Hg) compared to the oxidized form. Hence the difference between horse oxyhaemoglobin and human reduced haemoglobin is not a species difference but is due to a large change in the shape of the molecule on uptake of oxygen. In a short paper, *D. Labie*, Paris (France), described a new normal human haemoglobin, haemoglobin $A_4$.

In the colloquium on the biochemistry of chloroplasts, the isolation of these particles in mixtures of hexane and carbon tetrachloride was described by *R. Leech*, London (England). High-speed centrifugation between sucrose densities of 1.29 and 1.36 gave particles which were morphologically closer to those in the leaf than chloroplasts isolated by aqueous methods. However, some lipids, *e.g.* carotenoids and plastoquinones, had been removed; this presumably accounts for the fact that these particles did not give the Hill reaction.

## Reactions of Compounds with Electropositive Chlorine

*K. Dehnicke* [1], Stuttgart (Germany)

*Reactions with ClF:* $SbCl_5$ reacts with ClF at 5 °C to form $SbCl_4F$. Infrared and Raman spectra show that the compound occurs undissociated as trigonal bipyramids in the molten state and as ions $[SbCl_4]^+ + F^-$ in the solid state [2]. The force constant of $[SbCl_4]^+$ corresponds with that of the isoelectronic $SnCl_4$. – $AsCl_3$ reacts with ClF as follows:

$$2\ AsCl_3 + 6\ ClF = [AsCl_4]^+[AsF_6]^- + 4\ Cl_2.$$

[1] In collaboration with *K.-U. Meyer*, *J. Weidlein*, *J. Strähle*, and *U. Müller*.

[2] *Cf. L. Kolditz*, Z. anorg. allg. Chem. *289*, 128 (1957).

The vibration spectrum demonstrates that the ionic form is present exclusively [3]. The force constant of $[AsCl_4]^+$ is somewhat higher than that of the isoelectronic $GeCl_4$.

*Reactions with $Cl_2O$:* Oxide chloride syntheses with $Cl_2O$ are already familiar. $ZrOCl_2$ has now been prepared at −15 °C in $CCl_4$:

$$ZrCl_4 + Cl_2O \rightarrow ZrOCl_2 + 2\,Cl_2.$$

According to the infrared spectrum, $ZrOCl_2$ is a zirconyl tetrachloro-oxozirconate $[ZrO]^{2+}[ZrOCl_4]^{2-}$ with a chain-form anion polymerized via the oxygen atoms.

*Reactions with $ClNO_3$:* By the method of *Schmeisser* [4], the anhydrous nitrates $Co(NO_3)_2$ ($\mu$ = 4.85 B.M.) and $Mn(NO_3)_2$ ($\mu$ = 5.48 B.M.) result from $CoCl_2$ and $MnCl_2$ with chlorine nitrate. $Co(NO_3)_2$ forms a solvate with $N_2O_4$, which according to spectral and magnetochemical data is a nitrosyl trinitratocobaltate $NO^+[Co(ONO_2)_3]^-$ ($\mu$ = 5.19 B.M.) with the nitrato group as a bidentate ligand.

From the chloride fluorides $SbCl_4F$ and $[AsCl_4]^+[AsF_6]^-$ the complex nitrates $[Sb(ONO_2)_4]^+F^-$ and $[As(ONO_2)_4]^+[AsF_6]^-$ are obtained with chlorine nitrate. $SbF_3Cl_2$ yields an unstable $SbF_3(ONO_2)_2$, which is stabilized by rearrangement at 40 °C:

$$SbF_3(ONO_2)_2 \rightarrow NO_2^+\,[SbOF_3(ONO_2)]^-.$$

Thermal decompositon of the fluoride nitrates leads to the formation of definite oxide fluorides, *e.g.*

$$[As(ONO_2)_4]^+[AsF_6]^- \rightarrow 2\,AsOF_3 + 4\,NO_2 + O_2.$$

*Reactions with $ClN_3$:* $SbCl_5$ reacts with chlorine azide to form $SbCl_4N_3$, which splits off $N_2$ and $Cl_2$ and is thereby converted into polymeric $SbNCl_2$. An unstable chloride azide $VCl_4N_3$ is formed from $VCl_4$ and $ClN_3$. In solution it splits off $N_2$ spontaneously:

$$VCl_4N_3 \rightarrow [Cl_4V{-}\bar{\underline{N}}] + N_2$$

The radical is stabilized by anionotropy yielding an *N*-chlorovanadium imide:

$$[Cl_4V{-}\bar{\underline{N}}] \rightarrow Cl_3V{=}N{-}Cl.$$

This compound is monomeric, sublimes readily and melts at 132 °C in a sealed tube. The V–N double bond absorbs in the infrared at 1110 $cm^{-1}$.

[Inorganic Chemistry Colloquium, Technische Hochschule Aachen (Germany), February 18th, 1964] [VB 798/140 IE]

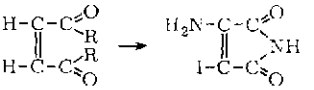
## Recent Investigations of Inorganic Nitrogen-Halogen Compounds

*J. Jander* and *V. Engelhardt*, München (Germany)

When $I_2$ disproportionates in excess liquid $NH_3$ a red N-I compound precipitates [5]. The tensimetric analysis of its degradation shows a nitrogen:iodine ratio of 2:1, *i.e.* $NH_2I{\cdot}NH_3$. Chemical evidence for this formula includes:

1. $NH_2I{\cdot}NH_3$ is converted into a black compound with a nitrogen:iodine ratio of 1:1 ($NH_2I$) by careful removal of $NH_3$ at −90 °C.

2. $NH_2I{\cdot}NH_3$ results also from ammonolysis of ICl, IBr, $INO_3$, pyridine, or $IClO_4$·pyridine in liquid $NH_3$ at −75 °C, *e.g.*



$$ICl + 3\,NH_3 \rightarrow NH_2I{\cdot}NH_3 + NH_4Cl$$

3. $NH_2I{\cdot}NH_3$ corresponds in color completely with the sparingly soluble $(CH_3)_2NI{\cdot}NH_3$ formed from $(CH_3)_2NI$ and liquid $NH_3$ at −75 °C.

4. $NH_2I{\cdot}NH_3$ is also formed when pale yellow, saturated solutions of $NI_3{\cdot}3\,NH_3$ in liquid $NH_3$, which contain dissolved $NH_2I$ (as shown by the Equation), are cooled with liquid air:

$$NI_3{\cdot}3\,NH_3 \rightleftharpoons NHI_2 + NH_2I + 2\,NH_3 \rightleftharpoons 3\,NHI_2 + NH_3$$

5. $NH_2I{\cdot}NH_3$ in liquid $NH_3$ has the properties of an iodinating agent, *e.g.*

The infrared spectrum of the solid red substance at −90 °C displays band groups at 3000 $cm^{-1}$ (N–H stretching vibrations), 1600 $cm^{-1}$ (N–H–N bending vibrations) and 1100 $cm^{-1}$ ($H_2N$–H rocking vibrations) which are typical of compounds containing $NH_3$ and $NH_2$. The black $NH_2I$ shows the two bands in the NH stretching region to be expected. On pumping off more $NH_3$ *in vacuo* at higher temperature a black substance with only one NH stretching band is obtained and at the same time the intensities of the bands at 1600 and 1100 $cm^{-1}$ decrease considerably. These changes are to be expected for the transition $NH_2I \rightarrow NHI_2$. The end product of the decomposition *in vacuo* is a black substance which displays no absorption in the three frequency regions mentioned. This is $NI_3$ which can be decomposed and removed without hazard in high vacuum at room temperature.

## The Biological Utilization of Lactose

*K. Wallenfels*, Freiburg/Breisgau (Germany)

1. As far as we know, lactose occurs in the free form only in milk. It may be considered, therefore, as a product of the evolution of mammals. Its controlled use as a carbon source for *Coli* bacteria appears then as a consequence of the process of adaptation of a symbiont to its host. One can assume that lactose is utilized by the higher organism according to the same principles as by bacteria.

2. The utilization of lactose by *Coli* bacteria is controlled genetically and determined by the constitution of the lac-region in the chromosome of the bacterial cell. This region consists of the sections i o z y A, of which z, y, A represent structural genes [2] and cause the synthesis of enzymatically active proteins. Until now, only the products of the z- and A-genes, β-galactosidase and galactoside transacetylase, have been isolated and crystallized. The locus i controls the synthesis of the repressor. Suitable galactosides (inducers) abolish repression of the o-, z-, y-, and A-activities and therefore induce the enzyme synthesis. By changes in structure, inducers can be inactivated or even converted into very active inhibitors of the induction.

3. (with *H. V. Rickenberg* and *B. Müller-Hill*): Each product of a gene of the lac-region has its own specificity for galactosides of different chemical constitution. All specificities are relative, but markedly different from each other, *i.e.* good inducers can be, for example, no or poor substrates for galactosidase or transacetylase. The combined action of these relative specificities leads to an extremely high specificity of the lac-system, since only very few compounds are simultaneously substrates for all activities.

4. (with *H. Sund*, *K. Weber*, *B. Müller-Hill*, *Ch. Streffer*, and *R. Weil*): The product investigated in the greatest detail hitherto of the lac-region of the *Coli* chromosome is the β-galactosidase (molecular weight: 520000). It may be split by different methods into 4 large sub-units (mol.wt. 130000). Treatment with performic acid yields 12 smaller sub-units (mol.wt. 43000). The sulfur balance shows the presence of 84–88 half cystine residues, 46 reacting as free SH-groups in the denatured state. Twelve free SH-groups per molecule of galactosidase can be alkylated or mercurated, without the activity decreasing. Further substitution of 6–8 SH-groups leads to complete inactivation.

[3] Cf. *L. Kolditz*, Z. anorg. allg. Chem. *280*, 313 (1955).

[4] *M. Schmeisser* and *K. Brändle*, Angew. Chem. *73*, 388 (1961).

[5] *J. Jander*, *U. Engelhardt*, and *G. Weber*, Angew. Chem. *74*, 75 (1962); Angew. Chem. internat. Edit. *1*, 46 (1962).

5. (with *P. Schädel, E. Schillinger*, and *W. Hengstenberg*): The specificity of β-galactosidase is largely known. Both the structure of the aglycone as well as that of the glycone determine the substrate quality. The β-linked galactoside residue is up to now the optimal glycone structure. Substitution at one of the hydroxyl groups, replacement of an OH-group by H, or epimerisation decrease the cleavability considerably. With the aglycone, a strong electronic influence on cleavability is shown: nitrophenyl is better than phenyl and this is better than alkyl. Replacement of the glycosidic oxygen by sulfur so reduces the cleavability, that thiogalactosides with an unsuitable aglycone are practically not cleaved. Nitrophenyl thiogalactoside, however, is cleaved. Further nitro groups increase the cleavability considerably. 2,4,6-Trinitrophenyl β-D-thiogalactoside is the second best substrate after *o*-nitrophenyl galactoside. It is slowly hydrolysed non-enzymatically at pH 7.6 to picric acid and thiogalactose, whereas enzymatic fission at the same pH yields only galactose and thiopicric acid. Enzymatic cleavage proceeds therefore in the manner expected for a proton-catalysed reaction.

6. (with *G. Kurz*): By enzymatic oxidation of the liberated galactose with DPN and galactose dehydrogenase (*Ps. saccharophila*), it can be shown that the direct product of the enzymatic hydrolysis of lactose is β-galactose.

7. (with *K. Herrmann*): In the biochemical utilization of lactose, phosphorylation by galactokinase to α-galactose 1-phosphate follows hydrolysis. The substrate of this enzyme is α-galactose. When it was investigated, whether in the case of galactose utilization the speed of mutarotation can likewise be regulated enzymatically, a high aldose-1-epimerase activity (A-1-E) was discovered in *Coli* bacteria. The enzyme accompanies β-galactosidase in the purification up to high degrees of purity and can be separated by recrystallization.

8. (with *G. Seeler* and *K. Herrmann*): Estimations of A-1-E activity in different *E. coli* mutants ($i^-z^+y^+$; $i^-z^+y^-$; $i^+z^+y^+$ with and without methyl thiogalactoside as inducer of the lac-region) show that the enzyme is determined not in the lac-region of the *E.coli* chromosome and probably also not in the gal-region.

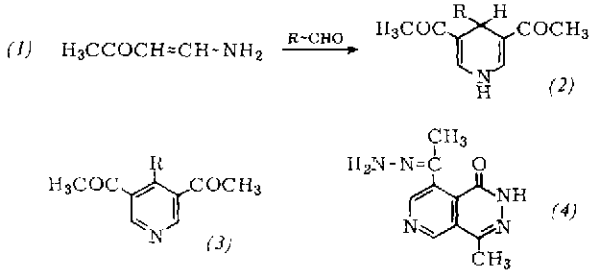
# SELECTED ABSTRACTS

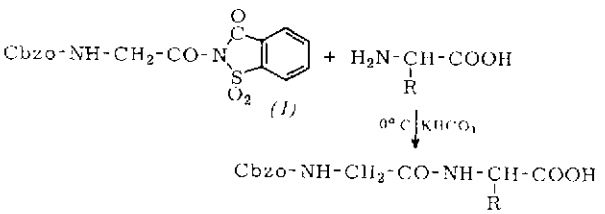


**The synthesis of polyunsaturated fatty acids in microorganisms** has been investigated by *J. Erwin* and *K. Bloch*. *Euglena gracilis* produces large amounts of linolenic acid in light but only traces of other polyunsaturated acids. About 85 % of the α-linolenic acid is contained in the chloroplast lipids of the green cells. Cells grown in the dark and many colorless mutants of *Euglena* synthetize only small amounts of α-linolenic acid, although the cells' content of $C_{20}$, $C_{22}$ and $C_{24}$ polyene acids is considerably increased. In [$^{14}$C]acetate media with and without Hill-reaction inhibitors, cell growth was stimulated by brief illumination. Incorporation of acetate into unsaturated acids was reduced by Hill-reaction inhibitors, but its incorporation into saturated acids was unaffected. / Biochem. Z. *338*, 496 (1963) / – De. [Rd 837/229 IE]

**A new synthesis of secondary and tertiary amines** was discovered by *K. A. Schellenberg*. Primary or secondary amines were treated with carbonyl compounds and $NaNH_4$ in a neutral aqueous solution at 0 °C. The Schiff bases or tertiary immonium salts produced as intermediates were presumably reduced by the $BH_4^{\ominus}$. A typical example is the reaction of $N^2$-carbobenzoxy-L-lysine with acetone and $NaBH_4$. Subsequent treatment with methanolic HBr leads to esterification and hydrolysis of the protecting groups. $N^6$-Isopropyl-lysine methyl ester dihydrobromide is produced in 53 % yield, m.p. 156.5–157.5 °C. In an analogous manner $N^2$,$N^6$-diisopropyl-lysine methyl ester hydrobromide (m.p. 186.5–188.5 °C) is formed from L-lysine hydrochloride in 4 % yield. Further examples: *N*-isopropylbutylamine, m.p. 197–197.8 °C, yield 63 %; *N*-ethylpiperidine, m.p. 225 to 227 °C, yield 53 %. / J. org. Chemistry *28*, 3259 (1963) / – Kr. [Rd 845/231 IE]

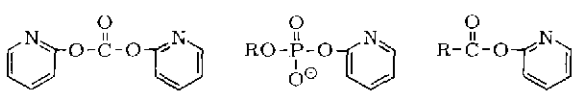
**Chinese iatrochemists in the middle ages prepared mixtures of steroid hormones** for medical purposes as *L. Gwei-Djeu* and *J. Needham* have been able to show by translations of old manuscripts from the 10th to 16th centuries. One manuscript describes the addition of bean juice from the soap bean tree *Gleditschia sinensis* to large quantities of urine. This juice contains saponins, and a precipitate was thus obtained from which the steroid conjugates were extracted with hot water. The Chinese chemists sublimated the residue from the extraction in small earthenware vessels under accurately controlled conditions. They obtained white, relatively pure, crystalline substances, which, emulsified in milk fat, were used in the treatment of hypogenitalism. / Nature (London) *200*, 1047 (1963) / –Sch. [Rd 861/230 IE]

**Hapten-binding antibodies** were obtained *in vitro* by *P. Haux, P. W. Jungblut*, and *F. Turba* by refolding of rabbit γ-globulin, in which about 5 sulfur bridges had been reduced with mercaptoethanol. On reduction, the γ-globulin unfolds. The reduced but reducing-agent-free rabbit γ-globulin was brought into contact with dinitrophenylated human albumin, which was absorbed on low-capacity DEAE-cellulose, and then oxidized with $O_2$ in tris buffer (at pH 7.0). Part of the γ-globulin refolded. The proteins were separated from the DEAE-cellulose with a solution of tris buffer and NaCl (pH 9.5) with addition of ε-DNP-lysine as dissociating hapten. The specific refolded γ-globulin was obtained from the eluate by chromatography. The "antibody" thus produced bound about 2 moles of the hapten, ε-DNP-lysine, per mole. Before refolding, the binding capacity was only about 5 % of this value. Refolded and normal γ-globulin had the same sedimentation constant. / Biochem. Z. *338*, 393 (1963 / – De. [Rd 839/228 IE]



**Syntheses of pyridine derivatives from aminobutenone and aldehydes** were reported by *F. Micheel* and *H. Dralle*. 1-Amino-1-buten-3-one *(1)* or 1-methoxy-1-buten-3-one (in the presence of $NH_3$) react with aldehydes in the presence of $H^+$ ions (glacial acetic acid) exothermically to form 3,5-diacetyl-1,4-dihydropyridine derivatives *(2)* (yields 33–57 %). On dehydrogenation with $NO_2$ and $CrO_3$, the latter give the pyridine derivatives *(3)* (yields 25–88 %).

*(a)*: R = H; *(b)*: R = $CH_3$; *(c)*: R = $C_6H_5$; *(d)*: R = $COOC_2H_5$



Oxidation of *(3a)* with $HNO_3$ gives pyridine-3,5-dicarboxylic acid; oxidation of *(3b)* and *(3d)* yields pyridine-3,4,5-tricarboxylic acid. Compound *(3d)* is converted into *(4)* with hydrazine hydrate. / Liebigs Ann. Chem. *670*, 57 (1963)/ –Ma. [Rd 899/249 IE]

**A new method of peptide synthesis using amino acid derivatives of saccharin** (*o*-sulfobenzoic imide) has been described by *F. Micheel* and *M. Lorenz*. *N*-Carbobenzoxy- (Cbzo) amino acids, whose carboxyl group is activated by condensation with saccharin, react with amino acids in tetrahydrofuran/water. The saccharin derivates are obtained from the *N*-Cbzo-amino acid and pseudosaccharin chloride by a reaction involving rearrangement in methylene chlorid at 0 °C. The *N*-Cbzo-glycine derivative *(1)*, m.p. 156–158 °C corr. (decomp.), is formed in 91 % yield. Compound *(1)* is also obtained from *N*-Cbzo-glycine and saccharin in the presence of dicyclohexylcarbodiimide in tetrahydrofuran (91 %). Examples of dipeptides and saccharin derivatives: *N*-Cbzo-glycyl-DL-phenylalanylsaccharin, m.p. 154–155 °C corr., 70 %; *N*-Cbzo-glycylglycine, m.p. 178 °C corr., 86 %; *N*-Cbzo-glycyl-L-phenylalanine, m.p. 125–126 °C corr., 93 %; *N*-Cbzo-glycyl-L-glutamic acid, m.p. 161–162 °C corr., 77.2 %.

Advantages of this method: protection of the carboxyl group of the free amino acid is not necessary, high yields, ease of separation of the saccharin, no racemization during peptide synthesis. / Tetrahedron Letters *1963*, 2119 / –Ma. [Rd 853/223 IE]

**Transacylations using α-hydroxypyridyl phosphates and carboxylates** are described by *W. Kampe*. Di-α-pyridyl carbonate *(1)* yields α-pyridyl monohydrogen phosphates *(2)*, while carboxylic acids or their amine salts yield α-pyridyl carboxylates *(3)* in very good yields. The esters *(2)* react with phosphoric acids to give pyrophosphates, with alcohols to give diesters, and with amines to give phosphoramides (yields: 70–90 %). The esters *(3)* undergo transesterification with alcohols in the presence of catalytic quantities of alkoxide or sodium α-pyridoxide, sometimes very rapidly, in 75–90 % yields. This catalysis with base probably depends on an equilibrium between α-pyridoxide anions and alcohol molecules. Furthermore, *(3)* reacts easily with amines, the

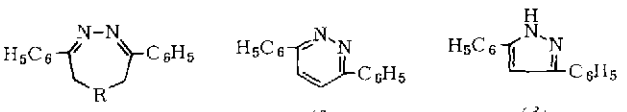
*(1)* *(2)* *(3)*

reaction rates at room temperature depending on the consitution of the reactant. / Tetrahedron Letters *1963*, 2133 / –Ma. [Rd 856/224 IE]

**Aldehyde hemihydrates** were obtained by *D. L. Klass, W. N. Jensen, J. S. Blair*, and *T. W. Martinek* by dry distillation of a mixture of the barium salts of higher fatty acids and barium formate. Using barium dodecanoate they obtained, besides the aldehyde hemihydrate, n-dodecanal, *n*-dodecanal-*n*-dodecanol hemiacetal, and n-dodecanol. Aldehyde hemihydrates are also formed from the aldehydes and stoichiometric quantities of water. The structures of the adducts

$H_3C-(CH_2)_n-CHOH-O-CHOH-(CH_2)_n-CH_3$

n = 5, m. p. 54 – 59 °C (decomp.)



n = 8, m. p. 58.5 – 63 °C (decomp.)

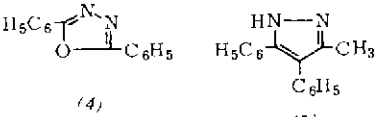
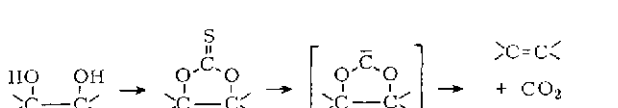
(α,α'-dihydroxy ethers) were proved by infrared spectroscopy./ J. org. Chemistry *28*, 3029 (1963) / –Kr. [Rd 844/227 IE]



**Inorganic salts have been used as the stationary phase** in gas chromatography by *J. A. Favre* and *L. R. Kallenbach*. Of 44 salts tested with a 1:1:1 mixture of *o*-, *m*-, and *p*-terphenyl, the most effective were potassium antimonate, carbonate, borate, and phosphate. The salts are suitable for the separation of very high-boiling organic substances, with operating temperatures of up to 500 °C; the maximum is about 300 °C with organic liquid phases. Retention times are of the order of a few minutes. The resolving power of a given potassium salt can be very much increased by the addition of a few per cent of KOH. The salts were applied to the support, Chromosorb P, in aqueous solution. Separation of higher polyphenyls was also investigated; for hexaphenyls, for example, lithium chloride is a very suitable stationary phase. / Analytic. Chem. *36*, 63 (1964) / –Jg. [Rd 835/232 IE]

**Ring contractions by desulfurization leading to pyridazines and pyrazoles** are described by *J. D. London* and *L. B. Young*. 2,7-Dihydro-3,6-diphenyl-1,4,5-thiadiazepine *(1a)* is converted by halogenation-dehalogenation with *N*-bromosuccinimide in $CCl_4$, by treatment with $SO_2Cl_2$ in $CH_2Cl_2$ followed by NaI in acetone, or with bromine in acetic acid (in each case under reflux) into 3,6-diphenylpyridazine *(2)*, m.p. 222 °C (yields: 83, 65, or 40 %, respectively). Compound *(2)* is also formed in 80 % yield by thermolysis in boiling ethylene glycol. The dioxide *(1b)* also undergoes thermal decomposition in boiling ethanol or acetic acid to yield 80 and 90 % *(2)*, respectively. The monoxide *(1c)*, on the other

*(1a)*: R = S
*(1b)*: R = $SO_2$
*(1c)*: R = SO



*(2)* *(3)*

*(4)* *(5)*

hand, is converted in hot acetic acid into 3,5-diphenylpyrazole *(3)*, m.p. 199 °C. When heated with hydrogen peroxide in acetic acid, *(1a)* yields 2,5-diphenyl-1,3,4-oxadiazole *(4)*, m.p. 138 °C, and *(3)* yields 1,2-dibenzoylhydrazine. Isomerization of *(1b)* with ethanolic $NaOC_2H_5$ leads to a sulfinic acid, which loses sulfur dioxide on melting to yield 3-methyl-4,5-diphenylpyrazole *(5)*. / J. chem. Soc. (London) *1963*, 5496 / –Ma. [Rd 858/225 IE]

**A new stereospecific synthesis of olefins from 1,2-diols** has been found by *E. J. Corey* and *R. A. E. Winter*. A 1,2-diol is converted, *e.g.* by means of thiocarbonyldiimidazole in boiling toluene or xylene (30 min), into the cyclic thiocarbonate *(1)*. When heated with an excess of a desulfurizing agent, *e.g.* trimethyl or triethyl phosphite (70–80 h reflux under nitrogen), *(1)* splits off $CO_2$ and S by specifically *cis*-elimination. Even highly substituted olefins are obtainable

*(1)* *(2)*

without difficulty. The reaction probably proceeds via the carbene *(2)*. Examples: *meso*-hydrobenzoin (→ thiocarbonate) → *cis*-stilbene (92 % yield); (±)-hydrobenzoin → *trans*-stilbene (87 %); *cis*-1,2-cyclohexanediol → *cis*-cyclodecene (84 %); *trans*-1,2-cyclohexanediol → *trans*-cyclodecene (81 %). / J. Amer. chem. Soc. *85*, 2677 (1963) / –Ma. [Rd 860/226 IE]

**Chemotaxonomie der Pflanzen – Eine Übersicht über die Verbreitung und die systematische Bedeutung der Pflanzenstoffe** (Plant Chemotaxonomy – A Survey of the Distribution of Plant Constituents and Their Significance for Botanical Classification). By *R. Hegnauer*. Birkhäuser Verlag, Basel and Stuttgart. Vol. I (1962): Thallophyta, Bryophyta, Pteridophyta, and Gymnospermae. Chemical Series, Vol. 14, 1st edit. 517 pp., numerous illustrs. and tables, cloth, DM 96.– (about $ 24.–). Vol. II (1963): Monocotyledoneae. Chemical Series, Vol. 16, 1st edit. 540 pp., several illustrs., numerous tables, cloth, DM 98.– (about $ 24.50).

In this work, planned to be completed in about five volumes, *R. Hegnauer*, Professor of Pharmacognosy at the University of Leiden (Holland), has undertaken to collect all the data known on phytochemical materials and to classify them according to the criteria of botanical systematics. The subject matter in these books is presented according to a single general scheme: within each family a description of the botanical characteristics and distribution of the various species and their systematic classification is followed by a description of their morphology, and finally by a detailed description of their phytochemical characteristics. Extensive literature references are given, and finally views are expounded on the significance of the constituents referred to for the classification of plants.

It is immediately apparent that while there are many structural peculiarities in the phytochemical spectra of some genera or families, only the most painstaking investigation of enough well-defined plant material would give a safe basis for a taxonomic evaluation. Many chemical investigations of plants, though useful in themselves, are useless for the purposes of systematics, because only too often the chemists have not taken the trouble to characterize their starting materials adequately. It is also obvious from this work how restricted these chemical investigations have been to date: although there are multitudinous publications referring to economically and medicinally important plants, there are whole families of plants which have never been investigated phytochemically at all.

The work is written and organized with extreme care. Printing and other errors are few. The reviewer has noticed the following: *Cedrus deodora* instead of *C. deodara*; phenoxazim instead of phenoxazine (p. 171): *Whally* for *Whalley*; telephoric acid is not a dibenzylbenzoquinone derivative, but a diphenylbenzoquinone derivative; the term isoprenoid should not be used in connection with cortisalin (p. 112); in the formula for cycasin, the representation with a pentavalent nitrogen should be replaced by the modern azoxy representation; *Missiorny* should be *Misiorny* (p. 381); in the formula for maltol, the two substituents have been interchanged; *Dietrich* should read *Dietsche* (p. 475), *Clatriau* should be *Clautriau* (p. 57); the structure of belladin given (p. 69) is not quite correct; the isoquinuclidin formula (p. 152) has an H missing; on p. 484 the reference should be to 1,8-dihydroxy-2-acetylnaphthalene or 2-acetylplumbagin and not to 1,8-dioxy-2-acetoxynaphthalene; also it would be preferable if the accepted prefix "hydroxy" were used consistently in place of the no longer official "oxy" nomenclature.

In many of the organic structural formulae, especially in the alicyclic field, there is a general neglect of stereochemistry; also some formulae are represented in such a way as to insinuate configurations, *e.g.* in the ephedrine formula, which in reality indicates ψ-ephedrine. The importance of configuration and stereoselectivity in the enzymatic synthesis of various compounds is so clearly recognized nowadays that a more thorough treatment of this aspect of structural chemistry is greatly to be desired in later volumes.

These minor objections should in no way be taken to belittle the magnificent performance of the author. The work presents a number of views that will be extremely useful to the scientist interested in phytochemistry. Through its clear exposure of the gaps in existing knowledge, it will stimulate research and open new horizons in plant chemistry.

*C. H. Eugster* [NB 138/72 IE]

**Chemie in nichtwäßrigen ionisierenden Lösungsmitteln** (Chemistry in Nonaqueous Ionizing Solvents). A series of monographs edited by *G. Jander*, *H. Spandau*, and *C. C. Addison*. Vol. I. The Chemistry of Anhydrous Liquid Ammonia. Part 2: Organic Reactions in Liquid Ammonia. By *H. Smith*. Verlag Friedr. Vieweg & Sohn, Braunschweig, 1963. 1st edit., XV, 363 pp., cloth DM 55.20 (about $14.00).

This book is the first of a series of monographs dealing with the chemistry of nonaqueous solvents which are written partly in German and partly – like the present volume – in English. This part deals with organic reactions in anhydrous liquid ammonia, whereas inorganic reactions in this solvent are to be discussed in Part 1, which will be in German but is not due to be published for some time yet. On account of this, the general problems relating to liquid ammonia and solutions of alkali and alkaline-earth metals in this solvent are discussed only briefly or not at all in Part 2. Yet it is precisely these solutions which play a very important part in certain reductions carried out in organic chemistry; in fact, they may be regarded as the most important portion of the book. Section H, which deals with these reductions, is the best chapter of the book with regard to both its concise presentation and its theoretical treatment. This conciseness is lacking in the other sections, which are mainly compilations, particularly in the introductory sections A and B: on the 'Formation of ammoniates' and 'Solubilities'. However, this is not the fault of the author since there are only unrelated observations to be found scattered widely throughout the literature and these can only be reviewed; incidentally, this remark applies not only to the subject matter of these two chapters. More coherent relationships occur apart from in section H also in section D (ionic reactions in liquid ammonia), although this subject might have been treated somewhat more fully. Greater clarity of the theoretical aspects would also be desirable for the sub-section on nucleophilic aromatic substitutions which is appended in section J. Other themes dealt with include the 'Properties of solutions of organic substances' (section C), 'Amonolytic reactions' (E), 'Electrolysis' (F), and 'Oxidation reactions' (G).

The book serves mainly as an efficient guide to the literature (1388 references). It cannot serve as a laboratory manual, for no practical hints are given, not even for reactions of a general nature.

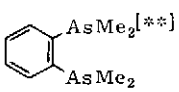
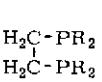
# Complexes of Tetradentate Ligands Containing Phosphorus and Arsenic [*]

BY DR. L. M. VENANZI



INORGANIC CHEMISTRY LABORATORY, UNIVERSITY OF OXFORD (ENGLAND)

*The effect of ligand shape on coordination numbers and geometry of coordination compounds has been studied using two tetradentate ligands containing phosphorus and arsenic. These tend to form five-coordinate complexes with trigonal bipyramidal structure [Fe(II), Co(I), Co(II), Rh(I), Ni(II), Pd(II), Pt(II)], but can also form six-coordinate complexes with octahedral structure [Fe(II), Ru(II), Os(II), Co(III), Rh(III), Pd(IV), Pt(IV)]. The magnetic properties and the stereochemistry of the complexes are explained by ligand field theory which predicts that, for metal ions with $d^6$-electronic configuration, a low overall field strength should favor the formation of five-coordinate paramagnetic complexes while a high overall field strength should favor the formation of six-coordinate diamagnetic complexes. – This work provides further indication that the tendency of polydentate ligands to use all the potential donor atoms is not as pronounced as is generally believed. This is shown by the isolation of chromium(III) complexes in which the tetradentate ligands are, in fact, acting as tridentate, and by the isolation of mercury(II) complexes where only two of the four donor atoms of the polydentate ligand are actually bonded to the central metal atom.*



## 1. Introduction

One of the most fruitful developments which has taken place in recent years in the field of coordination chemistry has been the investigation of the complexing properties of polydentate ligands. Most of these have been either polyamines or aminopolycarboxylic acids [1]. Recently, however, polydentate ligands containing phosphorus(III) and arsenic(III) have attracted increasing attention.

Most of the studies reported to date in the coordination chemistry of the heavy Group V donors [1a] have been carried out using bidentate ligands such as *o*-phenylenebis(dimethylarsine) or, for short, DAS *(1)* [2] and 1,2-disubstituted phosphinoethanes or DP *(2)* [3]. However, tridentate ligands such as bis-(3-dimethylarsinopropyl)arsine *(3)* [4] are being increasingly used and

DAS *(1)*

DP *(2)*

some complexes of tris-(3-dimethylarsinopropyl)arsine *(4)* have been described [5].

*(3)* *(4)*

The chemistry of complexes of the heavy Group V donors has many interesting aspects:

1. *The formation of stable complexes with the platinum metals.* Numerous complexes of P(III) and As(III) as donors with these elements are known; any attempt to

[1a] The heavy Group V donors, in this context, are phosphorus(III), arsenic(III), and antimony(III). Antimony(III) forms coordination compounds which are similar to those of arsenic(III), although the complexes of antimony(III) are less stable. As no polydentate ligands containing Sb(III) have yet been reported, only those of P(III) and As(III) will be discussed.

enumerate even only the main types would go beyond the scope of this introduction.

2. *The stabilization of low oxidation states.* Numerous complexes of metals in their low oxidation states have been prepared; a representative selection is shown in Table 1 [6]. The thermal stability of most of these complexes is fairly high, but their resistance towards oxidation by air is often lower than that of the corresponding metal carbonyls.

Table 1. Complexes of Group VB donors with metals in low oxidation states.

| Complex | M or L | Ref. |
|---|---|---|
| $[M(DP)_3]$ | V, Cr, Mo, W | [6a] |
| $[M(DP)_2]$ | Fe, Co | [6a] |
| | Ni, Pd | [6b] |
| | Pt | [6c] |
| $[M(CO)_2(DAS)_2]$ | Cr, Mo, W | [6d] |
| $[Fe(CO)(DAS)_2]$ | | [6e] |
| $[Co_2(CO)_4(Ph_3P)_4]$ | | [6f] |
| $[NiL_4]$ | $PF_3$, $PCl_3$ | [6g] |
| | $MePCl_2$ | [6h] |
| $[RhCl\{(PhO)_3P\}_3]$ | | [6i] |
| $[Re(CO)_4(Ph_3P)_2]Cl$ | | [6j] |

3. *The formation of low-spin complexes.* Practically all the complexes of the heavy Group V donors are of low-spin type. Ligands containing these donors cause spin pairing more easily than aromatic nitrogen heterocycles. The magnetic properties of some phosphine and arsine complexes and of the corresponding *o*-phenanthroline or 2,2′-bipyridyl complexes are shown in Table 2 [7].

Table 2. Comparison of the magnetic properties of phosphine and arsine complexes with those of the corresponding complexes with *o*-phenanthroline (phen) or dipyridyl (dpy).

| Complex | Magnetic properties | Ref. |
|---|---|---|
| $[Ni(DAS)_3](ClO_4)_2$ | diamagnetic | [7a] |
| $[Ni(phen)_3](ClO_4)_2$ | $\mu_{eff.} = 3.10$ B.M. | [7b] |
| $[Co(DAS)_3](ClO_4)_2$ | $\mu_{eff.} = 1.92$ B.M. | [7b] |
| $[Co(dipy)_3](ClO_4)_2$ | $\mu_{eff.} = 4.85$ B.M. | [7b] |
| $[FeBr_2(DAS)_2]$ | diamagnetic | [7c] |
| $[FeBr_2(phen)_2]$ | $\mu_{eff.} = 4.9$ B.M | [7d] |

4. *The formation of complexes with unusual coordination numbers.* Coordination numbers of 3, 5, 7, and 8 have been observed in complexes of the heavy Group V donors. A list of some of these compounds is given in Table 3 [8]. Although unusual coordination numbers have been observed with other ligands, there is often a difference in the number of bonds found in the complexes formed by, say, nitrogen donors, and those found in the complexes formed by heavy Group VB donors.

Table 3. Complexes with Group VB donors exhibiting unusual coordination numbers.

| Complex | M | Ref. |
|---|---|---|
| $[MCl_4(DAS)_2]$ | Ti, V, Zr, Hf | [8a] |
| $[MoI(CO)_2(DAS)_2]I$ | | [8b] |
| $[Mn(CO)_4(Ph_3P)]$ | | [8c] |
| $[M(DP)_2]$ | Fe, Co | [8d] |

| $[AuI_2(DAS)_2](ClO_4)$ | | [8j] |

## 2. Bonding

The unusual coordinating properties of P(III) and As(III) can be attributed to the large degree of covalence of the metal-ligand bond. This covalence is associated with a) the high polarizability of the donor atoms [9], which use hybrid orbitals of the $sp^3$-type for $\sigma$-bond formation, and b) the contribution from $\pi$-bond formation involving transfer of charge from filled d-orbitals of the metal atom to empty d-orbitals of the donor atom [10], as shown in Figure 1.

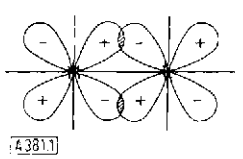

Fig. 1. Schematic representation of $\pi$-bond formation between filled metal d-orbitals and empty ligand d-orbitals.

As most of the platinum-metal atoms or ions are rich in d-electrons, they should be capable of forming strong $\pi$-bonds and therefore strong metal-ligand bonds, thus

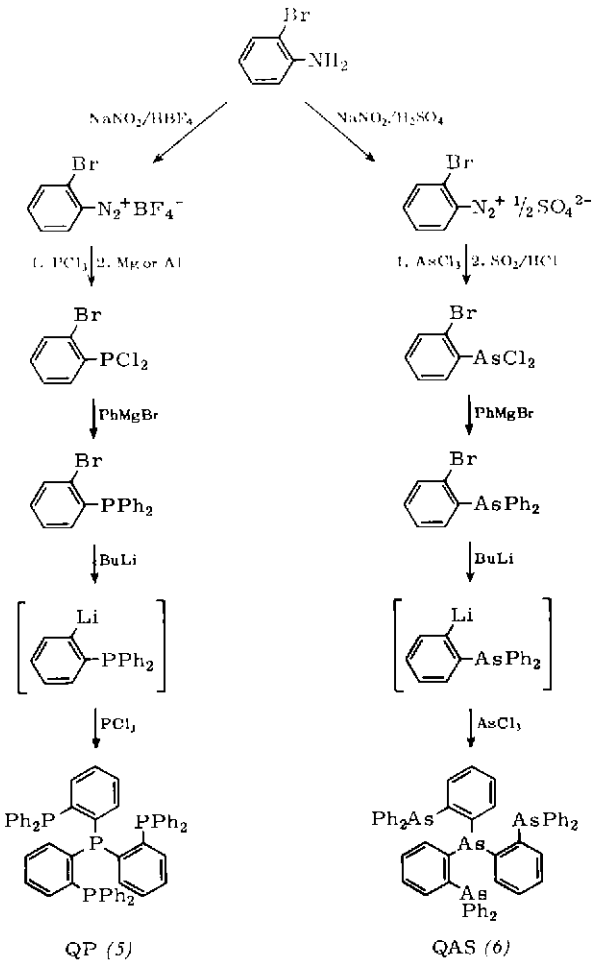
accounting for the stability of the complexes. Furthermore, since strong covalent bonding in transition metal complexes induces spin pairing [11], it is to be expected that the complexes of the heavy Group V donors should be of low-spin type.

The stabilization of low oxidation states can also be explained in terms of $d_\pi$-$d_\pi$ bonding [12]. In this respect, phosphines and arsines are similar to carbon monoxide [13]: the latter acts as an electron acceptor by using its $\pi^*$-levels, while the former use their empty d-orbitals.



Finally, although unusual coordination numbers could arise as a result of a variety of factors, it is probable that strong $\sigma$-bonding is the most important one in the formation of complexes with unusually high coordination numbers: strong mixing of metal and ligand orbitals would favor the use of all the available empty low-energy metal orbitals. On the other hand, $\pi$-bonding may be responsible for the formation of complexes with unusually low coordination numbers: hybridization of the filled (n-1)d- and empty np-orbitals of the metal ion would give better overlap with the ligand orbitals and would prevent the use of some of the metal's p-orbitals for $\sigma$-bonding.

The above considerations are certainly an over-simplification of the problem, but they provide useful working hypotheses, particularly in the chemistry of the later transition elements.

## 3. Tetradentate Ligands

In recent years, we have managed to prepare two tetradentate ligands, one containing phosphorus, *viz.* tris-(*o*-diphenylphosphinophenyl)phosphine or QP *(5)* [14], and the other containing arsenic, *viz.* tris-(*o*-diphenylarsinophenyl)arsine or QAS *(6)* [15].

These complexing agents were prepared as indicated in Scheme 1. The use of aryl-substituted compounds was dictated by practical considerations: they are easier to synthetize than the corresponding alkyl derivatives and the free ligands, once obtained, are stable in air. The complexes of these ligands proved to be of great interest.

QP *(5)* QAS *(6)*

Scheme 1. Synthesis of the tetradentate ligands QP *(5)* and QAS *(6)*.

These compounds may be easily prepared by the following routes:

$$Na_2[MX_4] + QAS \rightarrow [MX(QAS)]X + 2\,NaX;$$
(M = Pd(II) or Pt(II); X = Cl, Br, or I)

$$MX_2 + QP + NaClO_4 \rightarrow [MX(QP)](ClO_4) + NaX;$$
(M = Fe(II), Co(II), or Ni(II); X = Cl, Br, or I)

$$[Rh_2Cl_2(CO)_4] + 2\,QAS \rightarrow 2[RhCl(QAS)] + 4\,CO;$$

$$4\,[CoX(QP)]X + 5\,N_2H_4 \rightarrow 4\,[CoX(QP)] + 4\,N_2H_4{\cdot}HCl + N_2;$$
(X = Cl or Br)

A small selection of complexes of this type is shown in Table 4 [16]. The complexes of doubly charged metal ions dissociate as 1:1-electrolytes in nitrobenzene,

### a) Five-Coordinate Complexes

The largest class of compounds is of the type $[M^{n+}X(Q)]^{(n-1)+}$ (X = halogen; Q = QP or QAS).

Table 4. Colors, decomposition points (D.p.), molar conductances ($\Lambda_M$), and magnetic moments ($\mu_{eff.}$) of five-coordinate complexes of QP and QAS.

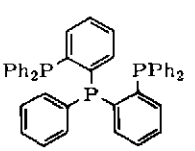
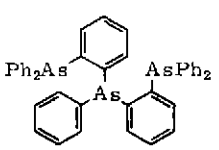
whereas those of singly charged metal ions are non-electrolytes in the same solvent (see Table 4). Thus if all the donor atoms of the polydentate ligands are bonded to the central metal atom, these complexes have a coordination number of five. This has been shown to be invariably the case as follows: tertiary phosphorus or arsenic derivatives react readily with methyl iodide to give a quaternary compound [17], but coordinated tertiary phos-



*(6a)*, L = P, As



phines and arsines do not undergo this reaction unless the complexes are appreciably dissociated in solution. The test for the presence of uncoordinated P(III) or As(III) can be carried out very simply by dissolving the complex in nitrobenzene and measuring any changes in conductivity occurring upon addition of methyl iodide when the formation of a quaternary salt leads to an increase in the number of ions.

None of the complexes of the type $[M^{n+}X(Q)]^{(n-1)+}$ (X = halogen; Q = QP or QAS) reacts with methyl iodide; thus, all the donor atoms of the polydentate ligand must be coordinated to the central metal atom, *i.e.* all the complexes of this type are five-coordinate.

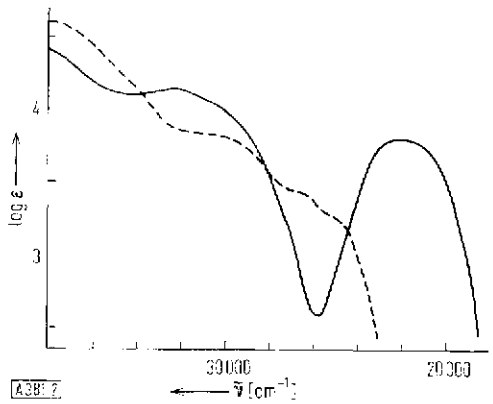
Further evidence for the unusual nature of these complexes is provided by their colors, which differ from those of complexes with similar ligands and more common coordination numbers, the general trend being a shift towards the red as compared with the corresponding four-coordinate complexes. This can be seen by comparing the spectra of the complexes of QP and QAS with those of the two tridentate ligands bis-(*o*-diphenylphosphinophenyl)phenylphosphine or TP *(7)* and bis-(*o*-diphenylarsinophenyl)phenylarsine or TAS

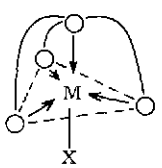
TP *(7)*

TAS *(8)*

*(8)* of the type [MI(T)] $(ClO_4)$ (M = Pd or Pt; T = TP or TAS), which have a four-coordinate square-planar structure [14, 16d, 16f] (see Fig. 2).

The magnetic susceptibilities of the five-coordinate complexes also show some unexpected features, *e.g.* they indicate the presence of two unpaired electrons in the iron(II) complexes, instead of the more usual four unpaired electrons or the diamagnetism exhibited by





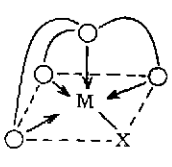


Fig. 2. The visible and ultraviolet spectra of [PtI(QAS)] $(ClO_4)$ (——) and [PtI(TAS)] $(ClO_4)$ (– – –) in methanol.

the complexes of this ion. A low magnetic moment is also observed in the cobalt(II) complexes, corresponding to the presence of one unpaired electron, instead of the more common three unpaired electrons (see Table 4).

The geometrical arrangement of the five ligands around the central metal atom can be either trigonal bipyramidal *(9)* or square pyramidal *(10)*:

*(9)*

*(10)*

X-ray structural investigation of [PtI(QAS)][$BPh_4$], showed that the coordination around its platinum atom is trigonal bipyramidal *(9)* [18].

Spectral studies have shown that this geometry prevails in all the complexes of the type $[M^{n+}X(Q)]^{(n-1)+}$. Thus, on replacement of the arsenic ligand by the phosphorus analogue or of the iodide ion by another anion in the platinum complexes, the pattern of the

absorption bands in the visible and ultraviolet spectra remains unchanged but the absorption maxima shift as predicted by ligand field theory [14, 16f]. In addition, replacement of the platinum by another metal atom results only in the band-shifts predicted by the ligand field theory [16a] (see Fig. 3).

The magnetic susceptibility of the complexes can also be accounted for in terms of the ligand field theory. The d-energy-level splitting for trigonal bipyramidal fields was worked out by *Ballhausen* and *Jørgensen* from group-theoretical considerations [19], but the effect of a field of this symmetry can be visualized in a simpler, more intuitive manner. If an electron is placed successively in each of the five d-orbitals arranged with their origin at the centre of a trigonal bipyramid (see Fig. 4), it will be

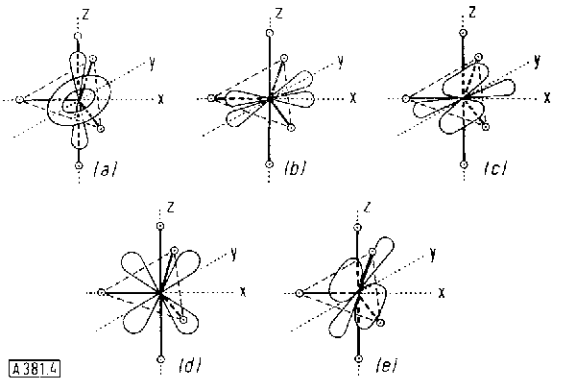

Fig. 4. The directional properties of d-orbitals relative to the ligands in a trigonal bipyramidal complex:
(a) $d_{z^2}$; (b) $d_{x^2-y^2}$; (c) $d_{xy}$; (d) $d_{xz}$; (e) $d_{yz}$.

seen that the electrostatic repulsions experienced by the electron will be of three types:

1. strong, when the electron is in the $d_{z^2}$ orbital;

2. medium, when the electron is in the $d_{x^2-y^2}$ or $d_{xy}$ orbitals;

3. weak, when the electron is in the $d_{xz}$ or $d_{yz}$ orbitals.

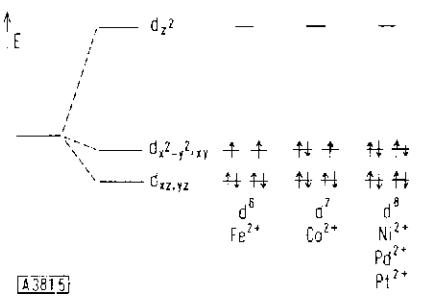
It is found that the interaction between the field of the ligands and the electron in the $d_{x^2-y^2}$ orbital is equal to that with the electron in the $d_{xy}$ orbital, and that the interaction between the external field and the electron in the $d_{xz}$ orbital is equal to that with the $d_{yz}$ orbital, although it is not possible to infer this from the diagrams shown in Figure 4. Thus, the presence of a trigonal bipyramidal field splits the five-fold degenerate d levels into three sets of orbitals. The sets with higher energy will be those where greater repulsion occurs, giving the following order of energies for the d-orbitals:

$$d_{z^2} > d_{x^2-y^2} = d_{xy} > d_{xz} = d_{yz}$$

If the magnitude of the interaction for the three groups of orbitals is taken into consideration, and if the energy of the orbitals in a spherical field is taken as the zero point for the energy scale, then the d-level splitting shown in Fig. 5 is obtained.

This splitting explains the magnetic susceptibility of the complexes: those of the $d^6$ ions show two unpaired

[19] *C. J. Ballhausen* and *C. K. Jørgensen*, Kgl. danske Vidensk. Selsk., mat.-fysiske Medd. *29*, No. 4 (1954).



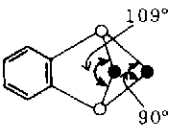


Fig. 5. Crystal field splitting and orbital occupancy in trigonal bipyramidal complexes $[M^{n+}X(Q)]^{(n-1)+}$.

electrons, those of $d^7$ ions show one unpaired electron, and those of the $d^8$ ions are diamagnetic.

The frequent occurrence of trigonal bipyramidal structures in the complexes of the tetratertiary phosphine QP *(5)* and of the corresponding arsine QAS *(6)* must be due to a large extent to the steric requirements of these ligands. After coordination, the bonds about the apical donor atom will be tetrahedral, so that the positions of the three terminal donor atoms will lie around a three-fold axis of symmetry. Given a metal ion of suitable size, the above arrangement of donor atoms could give rise to tetrahedral coordination around the central metal atom. For complexes of QP and QAS with transition metals, however, it is found that the donor-donor distances are too short for the formation of tetrahedral complexes, but are just right for the formation of trigonal bipyramidal complexes. This geometry not only preserves the trigonal symmetry of the three terminal donor atoms, but also, for a given donor-donor separation, allows a longer metal-donor bond length than does tetrahedral geometry, as shown in *(11)*.

*(11)*

Although five-coordinate complexes of many transition metal ions have been reported, the use of QP and QAS has allowed, for the first time, the preparation and the systematic study of a whole series of complexes with trigonal bipyramidal structures.

### b) Six-Coordinate Complexes

The two tetradentate ligands QP and QAS can also form six-coordinate complexes. Their preparation is often quite simple; some of the methods used are shown below.

$$[M^{n+}X(Q)]X_{(n-1)} + X_2 \rightarrow [M^{(n+2)+}X_2(Q)]X_n$$
(M = Rh, Pd, or Pt; X = Cl or Br; Q = QP or QAS)

$$Na_2[MX_5(NO)] + QAS \rightarrow [MX_2(QAS)] + 2\,NaX + NOX$$
(M = Ru or Os; X = Cl or Br)

$$[FeCl(QP)]Cl + 2\,NaX \rightarrow [MX_2(QP)] + 2\,NaCl$$
(X = $MeCO_2$, NCS, $NO_2$, or CN)

A selection of the compounds prepared to date is shown in Table 5 [20]. Conductivity measurements have shown that two of the anions are bonded to the central metal

[*] In $10^{-3}$ M solution in nitrobenzene at 20 °C.

atom (see Table 5) and, as the complexes do not react with methyl iodide, it is inferred that they are six-coordinate.

In view of the rather rigid steric requirements of the ligands, it was of interest to establish the geometry of the metal-ligand bonds in the six-coordinate complexes. An X-ray study of $[RuBr_2(QAS)]$ indicated a slightly distorted octahedron of donor atoms around the Ruthenium atom (see Fig. 6) [18]. Comparison of the visible and ultraviolet spectra of complexes of the type $[M^{(n+2)+}X_2(Q)]X_n$ showed that they are all of similar structure.

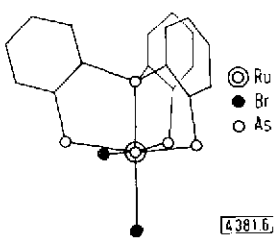

Fig. 6. Schematic representation of the geometry of the $[RuBr_2(QAS)]$ molecule.

Complexes of the above type are very resistant to oxidation. Although this may be expected for the derivatives of cobalt(III) and rhodium(III), it is somewhat surprising to find that this is also true of those of ruthenium(II) and osmium(II) in view of the observations of *Nyholm* et al. that $[RuCl_2(DAS)]$ and $[OsCl_2(DAS)]$ are oxidized by chlorine to $[RuCl_2(DAS)]^+$ and $[OsCl_2(DAS)]^+$ [22a, b] and that the osmium compound can be oxidized further to $[OsCl_2(DAS)]^{2+}$ [22b]. Even more surprising is the observation that $[ReCl_2(QAS)]$ remains unchanged in the presence of excess chlorine at room temperature, which suggests that the stabilization of the low oxidation states in these complexes is kinetic rather than thermodynamic.

The chelating agents QP and QAS do not always act as tetradentate ligands; for example, with chromium(III), tridentate complexes of the type $[CrX_3(QP)]$ may be prepared as follows [23]:

$$CrCl_3 + QP \rightarrow [CrCl_3(QP)]$$
$$[CrCl_3(QP)] + 3\ NaX \rightarrow [CrX_3(QP)] + 3\ NaCl$$
$$(X = Br, I, \text{ or } SCN)$$

These complexes are non-electrolytes in nitrobenzene (see Table 6), and react with methyl iodide. Their

limiting conductances after quaternization with MeI indicate that only three of the donor atoms of the organic ligand are coordinated to the chromium atom. Confirmation of this hypothesis is provided by comparison of the visible and ultraviolet spectra of the complexes of the tetradentate ligand QP with those of the closely related tridentate ligand TP *(7)*. TP complexes of the type $[CrX_3(TP)]$ are also non-electrolytes in nitrobenzene, but do not react with methyl iodide. The spectra of the two series of complexes are practically identical (see Fig. 7); this confirms that, in the chromium(III) complexes, the tetradentate ligand QP is in fact acting as a tridentate ligand.

[23] *D. C. Goodall* and *L. M. Venanzi*, unpublished observations.

This behavior can be rationalized by comparing the energy of a chromium-halogen bond with that of a chromium-phosphorus bond; the former is known to be a strong bond because it has, in addition to σ-character, a contribution from dative π-bonding of the type $M \xleftarrow{\pi} X$, whereas the latter bond is fairly weak because chromium(III), which is a $d^3$ ion, cannot form strong dative π-bonds of the type $M \xrightarrow{\pi} L$.

### c) Mercury(II) Complexes

The mercury(II) complexes are of the type $[HgX_2(Q)]$ (X = Cl, Br, or I; Q = QP or QAS) (see Table 7) and are prepared by reaction of the ligands with the appropriate mercury halides [24]. They are non-electrolytes in nitrobenzene and react with methyl iodide, indicating that they contain uncoordinated tertiary phosphorus or arsenic. Confirmation of this was obtained by an X-ray study of $[HgBr_2(QAS)]$ which showed that here the QAS

[*] In $10^{-3}$M solution in nitrobenzene at 18 °C.

was acting only as a bidentate ligand, using only two of its terminal donor atoms *(12)* [25]. It is presumed that the compounds of the other halides have similar structures.

Mercury(II) is a $d^{10}$ ion and tends to form four-coordinate complexes because any increase in coordination number places electrons in antibonding orbitals. These complexes have a tetrahedral arrangement of bonds [26]. As mentioned above, the two tetradentate ligands cannot use all four donor atoms to give tetrahedral complexes with transition metal ions. The mercury(II) ion is larger than most transition metal ions and a complex of the type $[Hg(Q)]^{2+}$, if it were formed at all, would have trigonal pyramidal coordination at the mercury atom *(13)*. Thus, it is not surprising to find that this geometry is not preferred in the presence of strongly coordinating anionic ligands.

*(12)*

*(13)*

[24] *G. Dyer, D. C. Goodall,* and *L. M. Venanzi,* unpublished observations.

[25] *R. H. B. Mais* and *H. M. Powell,* unpublished observations.

[26] *A. F. Wells:* Structural Inorganic Chemistry. Oxford University Press, 1962, p. 892.

It is interesting to note that the reactions of mercury(II) perchlorate with QP and with QAS give compounds of the type $[Hg(Q)](ClO_4)_2$, which are 1:2-electrolytes in nitrobenzene, which do not react with methyl iodide, and which contain ionic perchlorate, as shown by infrared spectra [24]. These compounds may well contain four-coordinate mercury with a trigonal pyramidal structure *(13)* owing to the weak coordinating properties of the anion.

### d) Iron(II) Complexes

The behavior of the iron(II) complexes with QP is of great interest. This ion gives five-coordinate complexes with a trigonal bipyramidal structure and two unpaired electrons (see Table 4) and also six-coordinate, diamagnetic complexes with an octahedral structure (see Table 5).

These stereochemical and magnetic differences can be explained in a similar way to those observed in the complexes of $d^8$ ions. The complexes of nickel(II) are normally six-coordinate and have two unpaired electrons, but many diamagnetic, four-coordinate compounds with square-planar structures are known. These differences have been associated with the effect of field asymmetry on the total energy of the complex. This relationship is shown in Figure 8 [27]. A similar diagram

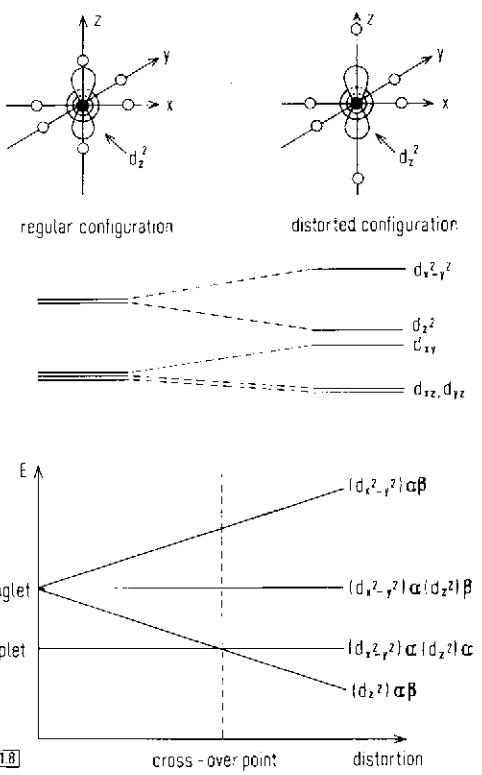

Fig. 8. The effect of distortion on the energy levels of octahedral complexes of $d^8$ metal ions.

can be constructed for the trigonal bipyramidal complexes of iron(II). The postulated distortion and a qualitative energy level diagram are shown in Figure 9.

Thus, when the overall field strength is large, one is on the right-hand side of the cross-over point and one obtains diamagnetic, octahedral complexes; when

[27] *L. E. Orgel:* An Introduction to Transition-Metal Chemistry. Methuen, London 1960, p. 63.

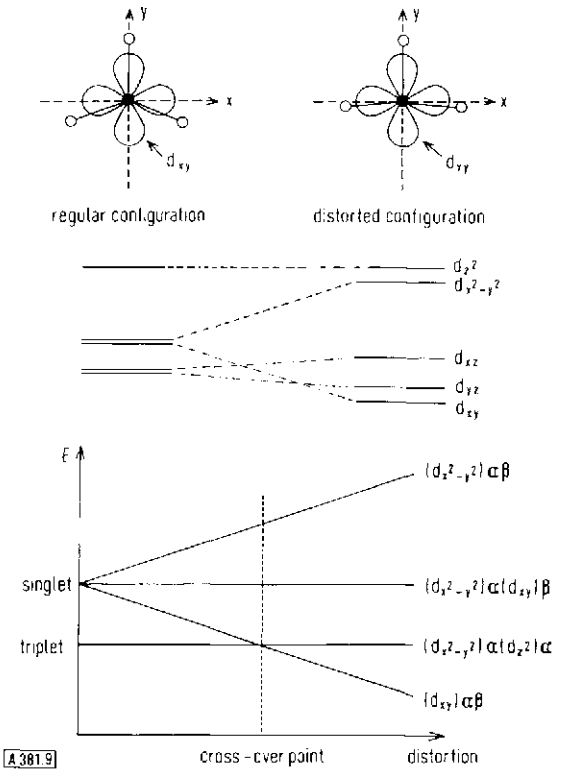

Fig. 9. The effect of distortion on the energy levels of trigonal bipyramidal complexes of $d^6$ metal ions.

the overall field strength is low one is on the left-hand side of the cross-over point and one obtains paramagnetic complexes.

This also explains the diamagnetism and octahedral structure of the QP and QAS complexes of ruthenium(II), osmium(II), and the other $d^6$ ions of higher charge, as the crystal field splitting increases with the charge on the transition metal ion, and also on passing from the first to the second and third transition series. Similar behavior is also observed in the $d^8$ complexes referred to above, where the compounds of palladium(II) and platinum(II) are almost always square-planar.

### 4. Conclusion

Ligands such as QP and QAS provide an interesting example of the interplay of electronic and steric factors in determining coordination numbers. Although these ligands tend to favor the formation of trigonal bipyramidal complexes, crystal field effects can force six-coordinate structures to occur.

Our work provides a further indication that the tendency of polydentate ligands to attach themselves to metal atoms or ions using all their donor atoms is not as pronounced as is generally believed.

A comparison between the complexing properties of QP and QAS and of similar nitrogenous ligands would be of great interest. A number of complexes of $N(CH_2CH_2NH_2)_3$ are known, but none of them appears to be five-coordinate. As the tetradentate ligand $As(CH_2CH_2CH_2AsMe_2)_3$ does not appear to form five-coordinate complexes either, it is likely that the frequent occurrence of five-coordination in complexes of QP and QAS is mainly due to the rather stringent steric requirements of these ligands.

# The Chemistry of New Heat-Resistant Films and Fibers

BY DR. F. T. WALLENBERGER [*]

PIONEERING RESEARCH DIVISION, TEXTILE FIBERS DEPARTMENT,
E. I. DU PONT DE NEMOURS & COMPANY, WILMINGTON, DEL. (U.S.A.)

*This survey is principally concerned with papers published since 1959 on hydrocarbon polymers, aliphatic poly(terephthalamide) fibers, poly(hydroxybenzoic acid) films, poly(oxadiazole) fibers, poly(benzimidazole) films, poly(phenyltriazole) films, poly(pyromellitimide) films, and fibers from cyclized poly(acrylonitrile). All these materials have extremely high melting points and satisfactory in-use characteristics at high temperatures.*

## I. Thermal Stability and Polymer Structure

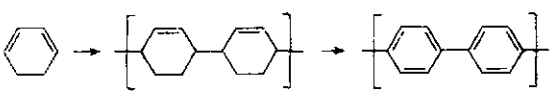
### 1. Introduction

Extreme conditions in space, *i.e.* oxidizing or reducing "atmospheres", high temperatures, magnetic belts, or radiation fluxes, demand new and heat-resistant materials. Most of the polymers, fibers, films, and elastomers [1] known today have valuable properties below 300 °C. Space flights [2] require materials which are

[*] Present address: Carothers Research Laboratory, Nylon Technical Division, Textile Fibers Department, E. I. du Pont de Nemours & Co., Inc., Wilmington, Del. (U.S.A.). - This paper represents an expanded version of a lecture given on October 9th, 1963 at Fordham University in New York, N.Y., and of a lecture given on January 29th, 1964 at the Gordon Research Conference in Santa Barbara, California.

[1] This review does not include information about commercial plastics which may be considered as forerunners of the polymers, films, and fibers discussed here.

[2] *R. Bartholmew, G. R. Eykamp,* and *W. E. Gibbs,* Rubber Chem. Technol. *32,* 1587 (1959).



thermally stable for 400 hours at up to 350 °C, or 80 hours at up to 550 °C.

Great advances have been made since about 1959 in the preparation of high-melting polymers. *Wittbecker* and *Morgan* [3] reported the interfacial polymerization technique [3, 4], and cyclopolymerization [5, 6] as well as intramolecular cyclization [7–10] of high molecular-weight compounds were developed. This new phase of polymer chemistry [1, 11] is reviewed here, with particular regard to film- and fiber-forming polymers and to the relationship between structure and heat-resistance [11a].

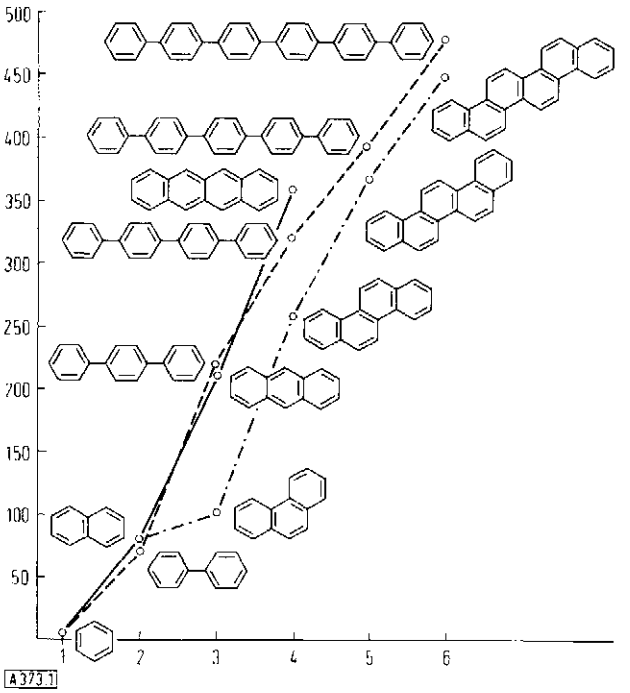
## 2. Poly-(*p*-phenylene), Polyacene, and Graphite

The melting points of *p*-phenylenes increase from *p*-terphenyl to *p*-sexiphenyl (Fig. 1) [12]. It has therefore been suggested that poly-(*p*-phenylene) would be infusible and stable up to 800 or 900 °C, whereas poly-(*m*-phenylene) would melt at a lower temperature [12a, b].

*Marvel* et al. [13, 14] prepared linear polycyclohexene *(1)*, m.p. 170 °C, with a molecular weight of 5000 to 10000, from 1,3-cyclohexadiene with coordination catalysts. Dehydrogenation with chloranil gave black,

*(1)* *(2)*

incompletely aromatized poly-(*p*-phenylene) *(2)*. *Kovacic* [9b] prepared the same polymer by low-temperature polymerization of benzene with metal halide catalysts. It is infusible, decomposes at 530 °C, and is insoluble in the conventional solvents. It is therefore unsuitable for the preparation of shaped objects, since fibers and films are either melt-spun or cast from solutions.



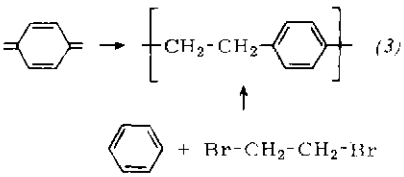


Figure 1. Melting points of polycyclic aromatics [12].
(— · · —) linearly fused
(— · — · —) angularly fused
(— — — —) not fused
Ordinate: melting point [°C]
Abscissa: number of rings

Molecular models show that poly-(*p*-phenylene) is a rigid linear polymer, and that fibers and films would be unusually brittle and almost inextensible, since the molecule cannot become bent or coiled.

The insertion of two methylene groups after every phenylene group gives the much more flexible poly-(*p*-xylylene) *(3)*. *Auspos* et al. [15], *Schaefgen* [16], and *Errede* [17] prepared this polymer by pyrolysis of *p*-xylene, as an insoluble, crystalline material which does not melt below 520 °C, and which yields optically anisotropic films.

*(3)*

*Farthing* [18] and *Vansheidt* et al. [19] used the Wurtz reaction to prepare a poly-(*p*-xylylene) which melts at 395 to 405 °C, and which is soluble in diphenyl, α-bromonaphthalene, and benzyl benzoate.

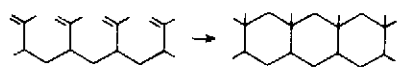
[16] *J. R. Schaefgen*, J. Polymer Sci. *15*, 203 (1955).

[17] *L. A. Errede* and *B. F. Landrum*, J. Amer. chem. Soc. *79*, 4952 (1957).

[18] *A. C. Farthing*, J. chem. Soc. (London) *1953*, 3261.

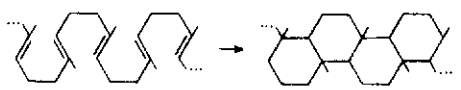
[19] *A. A. Vansheidt, E. P. Melnikova, L. V. Kukhareva*, and *M. G. Krakovyak*, Zhur. priklad. Khim. *31*, 1898 (1958).

Thus the insertion of $-CH_2CH_2$-groups in the poly-(*p*-phenylene) chain provides solubility, and hence the possibility of preparing films and possibly fibers; however it lowers the melting point and thermal stability. The insertion of two ispropylidene groups after each phenylene group *(4)* gives a crystalline polymer with improved chain flexibility, but the melting point is even lower (300 °C). *Korshak* et al. [20] have synthetized such compounds by treating diisopropylbenzene with t-butyl peroxide.



*(4)*

Films of poly-(*m*-xylylene) [21] (m.p. 60 °C) and poly-(*o*-xylylene) [22] (m.p. 110 °C) [22a] are also low-melting.



The thermal stability of graphite is very high. *Gulbrandson* [22b] has shown that carbon is even more fireproof under the conditions encountered in space than certain metals; thus in theory it should burn three times as rapidly as tungsten, but in practice it burns twelve times more slowly. This, and the increase in melting points of linearly and angularly fused polycyclic aromatics (Fig. 1), indicate that the as yet unknown linear polyacene and the angular polyphene should be as infusible and heat-resistant as graphite. "Ladder polymers", which resemble graphite in their structure, should also be stable and high-melting.

The cyclization of 1,2-polyisoprene *(5)* gives nearly quantitatively linear polycycloisoprene *(6)* with molecular weights of 15000 to 30000, which is soluble and can therefore be cast into films (m.p. 180 °C) [23, 24].

*(5)* *(6)*

The cyclization of 1,4-polyisoprene *(7)* yields segmented angular polycycloisoprene *(8)*, m.p. 80 °C [25, 26].

*(7)* *(8)*

However, aromatization of the linear or angular polycycloisoprene does not give polyacene or polyphene, but only fragments of the dimensions of pentacene or phenanthrene.

## II. Polyphenylene-Like Polymers

### 1. Polyamide Fibers

#### a) *Aliphatic Poly(terephthalamides)*

High-melting poly(terephthalamides) *(9)* with molecular weights of 15800 to 31000 have been prepared by *Shashoua* and *Eareckson* [27] from short-chain primary and secondary aliphatic diamines and terephthalyl dichloride. These polymers can be regarded structurally as poly-(*p*-phenylenes) with inserted $-CO-NH-(CH_2)_n-NH-CO$-groups. They are prepared by interfacial polymerization [3, 4], in which the acid chloride is reacted with the diamine in water at room temperature. Since the reaction takes place at the phase boundary, vigorous stirring must be maintained [28].

*(9)*

The melting points of the poly(terephthalamides) synthetized from primary and secondary amines alternate (Fig. 2) in a similar manner as the melting points of aliphatic polyamides [29].

Poly(terephthalamides) derived from primary amines are soluble only in sulfuric and trifluoroacetic acids.

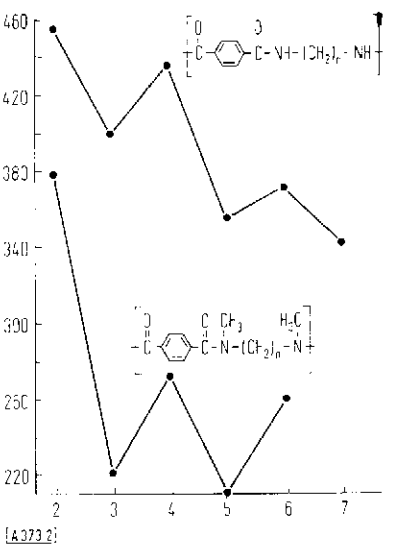

Figure 2. Melting points of secondary and tertiary aliphatic poly(terephthalamides) [27].
Ordinate: melting point [°C]
Abscissa: number of methylene groups in the aliphatic diamine.

[27] *V. E. Shashoua* and *W. M. Eareckson,* J. Polymer Sci. *40*, 343 (1959).

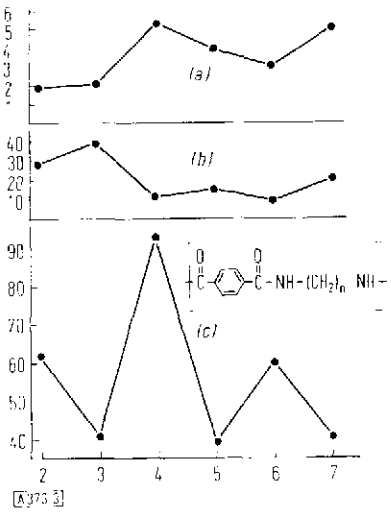
[28] *P. W. Morgan* and *S. L. Kwolek,* J. chem. Educat. *36*, 182, 530 (1959).

[29] *D. D. Coffman, G. F. Berchet, W. R. Peterson,* and *E. W. Spanagle,* J. Polymer Sci. *2*, 306 (1947).

[29a] *W. O. Statton,* Ann. N.Y. Acad. Sci. *83*, 27 (1959).

Their properties are determined by the ease of formation of hydrogen bonds, and by the rigidity of the *p*-phenylene unit. Complete *N*-methylation changes the solubility characteristics and lowers the melting point (Fig. 2), since hydrogen bonding is no longer possible in secondary terephthalamides.

Primary terephthalamide polymers are spun from trifluoroacetic acid. The fibers are strong (2 to 5 g/den) and have elongations of 10 to 40 % [27]. The initial modulus alternates and indicates a chain rigidity varying between 40 and 90 g/den [27] (Fig. 3). This alternation of the fiber properties indicates that members



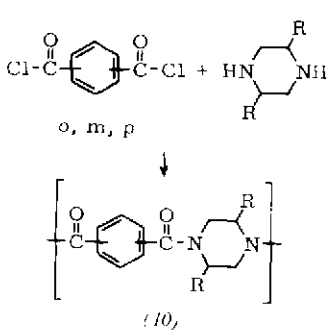


Fig. 3. Tenacity (a), elongation (b), and modulus at 1 % elongation (c) of aliphatic poly(terephthalamides) [27].

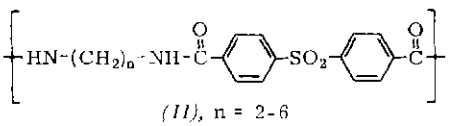
Ordinates: (a) tenacity [g/den]
(b) elongation [%]
(c) initial modulus [g/den]
Abscissa: number of methylene groups in the aliphatic diamine

with an odd number of C-atoms and with low moduli, have a less extended structure than those with an even number of C-atoms. X-ray diagrams [29a] show that members with an odd number of C-atoms possess only longitudinal lattice order. Freshly drawn poly(terephthalamide) fibers take up 8 to 20 % of water at a relative humidity of 90 %, and so lie between nylon 6-6 (7 %) and cotton (25 %).

Poly(ethyleneterephthalamide) and poly(tetramethyleneterephthalamide) fibers are among the highest-melting fibers known, with melting points of 455 and 436 °C respectively. Rigid, inflexible, cyclic diamines such as piperazine also give thermally stable poly(phthalamides), poly(isophthalamides), and poly(terephthalamides) [30].

*(10)*

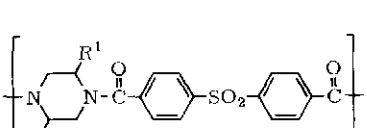


[30] *M. Katz*, J. Polymer Sci. *40*, 337 (1959).

Polyamides based on 2,5-dimethylpiperazine and phthalic, isopthalic, or terephthalic acids decompose at 467, 474, and 438 °C respectively. Fibers from these polymers have not been reported.

Aromatic polyamides have been prepared from *m*- or *p*-phenylenediamine by interfacial polymerization [30a]. They were found to melt above 360 °C. The thermally most stable aromatic polyamide [30b] was prepared from 4,4′-diaminostilbene-2,2′-disulfonic acid. It shows a weight loss of only 5.1 % after 74 hours of exposure to air at 300 °C.

b) *Aliphatic Poly-(4,4′-sulfonyldibenzamides)*



*Stephens* [31] prepared high-melting polyamides of the type *(11)* by interfacial polymerization [3, 4] of 4,4′-sulfonyldibenzoyl dichloride and certain aliphatic diamines or piperazines.

*(11)*, n = 2-6

The melting points of the polymers based on aliphatic diamines are moderately high, and exhibit the usual alternation: with ethylenediamine m.p. 380 °C, with trimethylenediamine m.p. 298 °C, with tetramethylenediamine m.p. 358 °C. These polymers are lower-melting than the corresponding terephthalamides, owing to the greater flexibility of the dicarboxylic acid components. However, this disadvantage is to some extent offset by an increase in the solubility in polar solvents; this property is attributable to the polar $SO_2$ groups [32].

The use of piperazine as the diamine component increases the melting point, since piperazine is much less flexible than the aliphatic diamines. At the same time, the polymer retains the favorable soluhility characteristics due to the $SO_2$ group. *Stephens* [31] has investigated fibers from two of these very high-melting polyamides: the polyamide *(12)* from 4,4′-sulfonyldibenzoic acid and 2,5-dimethylpiperazine, which has a water absorption of

*(12)*, $R^1 = R^2 = CH_3$
*(13)*, $R^1 = H$, $R^2 = CH_3$

11.6 %, and the related polyamide *(13)* from 2-methylpiperazine. Both fibers can be spun from *N,N*-dimethylformamide and from formic acid. Their properties are shown in Table 1.

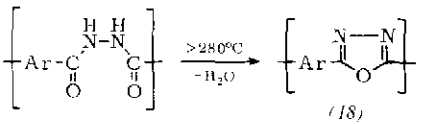
c) *Aromatic Polyhydrazides*

*Frazer* and *Wallenberger* [33, 34] have recently reported the preparation of 24 high molecular-weight aromatic and heteroaromatic polyhydrazides with melting points between 320 °C and >400 °C. These were synthetized from equimolar proportions of aromatic diacid chlorides *(14)* and aromatic dihydrazides *(15)* in hexamethylphosphoramide.



*(14)* *(15)* *(17)* *(16)*

These aromatic polyhydrazides may be regarded as polyamides with hydrazine as the diamine component. They differ from aliphatic polyhydrazides [33a] in their melting points and solubilities: aliphatic polyhydrazides melt between 200 and 300 °C and are insoluble in dimethyl sulfoxide, while aromatic polyhydrazides are normally soluble in dimethyl sulfoxide, and can thus be used for the production of fibers.

An interesting example of the close relationship between polymer structure and solubility [33] is provided by poly-(terephthalic/isophthalic dihydrazide): the regular compound *(16)* is soluble in dimethyl sulfoxide, whereas random copolymers with more than 65 % of *p*-phenylene units, as well as poly(terephthalic dihydrazide), are insoluble.

The highest-melting aromatic polyhydrazides are poly-(terephthalic dihydrazide) (>400 °C) and the alternating poly(terephthalic/isophthalic dihydrazide) (375 °C) [33, 34]. However, these temperatures are neither true melting points nor true decomposition points, since polyhydrazides liberate one molecule of water per hydrazide group at and above 280 °C to give quantitative yields of high molecular-weight poly-[2,5-(1,3,4-oxadiazoles)] *(18)*, which are even more heat-resistant (see below).

*(18)*

Polyhydrazide fibers have been spun [33] from polymers with structures *(16)* and *(17)*. Useful solvents were *N,N*-dimethylformamide and dimethyl sulfoxide. The properties of the fibers are shown in Table 2.

Table 2. Properties of fibers from the aromatic polyhydrazides *(16)* and *(17)* [33a].

| Moisture regain [%] | 4.5 | 4.3 |
| Density [g/cm³] | 1.443 | 1.452 |

[a] At 1 % elongation.

The high chain rigidity (modulus of elasticity) is attributable to the *p*-phenylene group, as in the case of the terephthalamides. A poly(isophthalic dihydrazide) fiber prepared for comparison had a lower modulus, *i.e.* a lower rigidity than the poly(isophthalic/terephthalic dihydrazide) *(16)*.

The hydrazide group is known to enolize. According to *Frazer* and *Wallenberger* [33], the color of polyhydrazides changes from white to yellow in the presence of bases. This color change is most pronounced with aromatic polyhydrazides, and particularly with poly(terephthalic hydrazide), owing to the extended conjugation and the resonance interaction with the adjacent benzene rings. Poly-(*N,N'*-dimethylterephthalic dihydrazide) [33] does not undergo this color change.

Aromatic polyhydrazides give polymeric chelates with mono- and divalent metal salts ($Ni^{2+}$, $Ca^{2+}$, $Ag^{+}$, $Pb^{2+}$) in basic media; these chelates contain one metal ion per hydrazide linkage [33b, 34]. Very tough fibers of polyhydrazide chelates *(19)* with metal ions ($Cr^{3+}$, $Co^{2+}$, $Ag^{+}$)

were prepared by passing the polyhydrazide fiber through solutions of the salts in dimethylformamide. The melting points of the chelate fibers are not higher than those of the normal polyhydrazide fibers [33b, 34], possibly because chelation was incomplete.

d) *Aromatic Polyoxamides*

Since none of the polyamides and polyhydrazides mentioned can be obtained with a sufficiently high

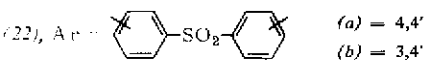
molecular weight for fiber formation by melt polymerization, *Hall* and *Berge* [35] tried to prepare polyoxamides by reacting aromatic diamines with diphenyldithiol oxalate *(20)* [36] in tetramethylene sulfone at 130 to 200 °C.



*(20)*

*(21)*, Ar =

*(22)*, Ar =

*(a)* = 4,4'
*(b)* = 3,4'

The polyoxamide from 2,2-di-(4-aminophenyl)propane *(21)* melts above 400 °C, has an intrinsic viscosity of 0.60, and gives perfectly clear, tough, and flexible films from dichloroacetic acid or *N*-methylpyrrolidone solutions. The polyamide from oxalic acid and 4,4'-diaminodiphenyl sulfone *(22a)* also melts above 400 °C, while the polyoxamide from 3,3'-diaminodiphenyl sulfone *(22b)* melts at 375 °C and is less rigid.

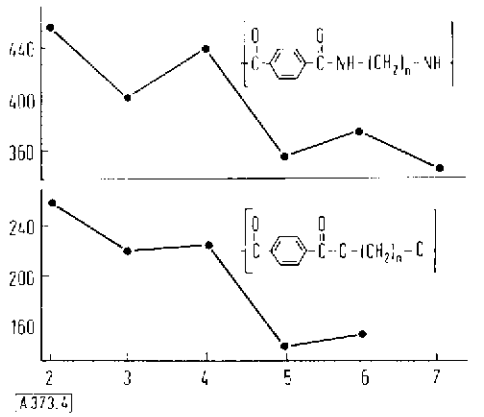
## 2. Polyester Films

### a) *Structure and Properties*

In a recent survey, *Wilfong* [37] showed that only very few polyesters have melting points above 380 °C. High melting points are generally attributed to a dipole interaction, strong intermolecular forces, molecular symmetry, or close packing of linear chains. High rigidity is primarily introduced by the *p*-phenylene unit of terephthalic acid, hydroquinone, or 4,4'-diphenylenedicarboxylic acid (cf. [38]). Owing to the absence of hydrogen bonds, polyesters melt at appreciably lower temperatures than the corresponding polyamides (Fig. 4).

Alternation of the melting points [37,40] is attributed to structural differences, since the X-ray repeat period of high-melting polyesters with an even number of C-atoms is equal to one chemical repeat unit, while that of low-melting polyesters with an odd number of C-atoms corresponds to two chemical repeat units.

Even polyesters with rigid structures [41], such as poly(ethylene 1,5-naphthalenedicarboxylate), m.p. 226 °C,



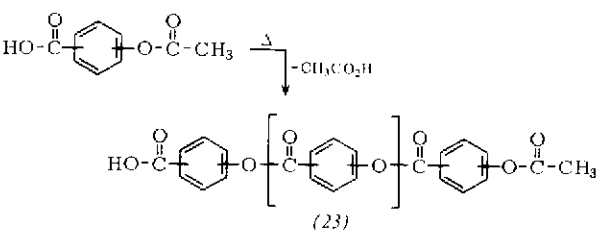


Fig. 4. Melting points of polyamides [27] and comparable polyesters [38].
Ordinate: melting point [°C]
Abscissa: number of methylene groups in the diamine and glycol.

poly(ethylene 2,6-naphthalenedicarboxylate), m.p. 255 °C, and poly(ethylene 2,7-naphthalenedicarboxylate), m.p. 260 °C, do not have particularly high melting points. Only some of the completely aromatic [42] polyesters melt above 380 °C. Poly(hydroquinone isophthalate), m.p. 385 °C [42], poly(hydroquinone terephthalate), m.p. >400 °C [42], 500 °C [39], and similar compounds [42 44] have very high melting points, surprisingly high melt viscosities, and are soluble [39], so that it might be possible to spin them into fibers.

### b) *Poly(hydroxybenzoic acids)*

Films of poly-(*p*-hydroxybenzoic acid) are as tough as some commercial polycarbonates, and melt at 380 to 450 °C [45]. They are prepared by the autocondensation of *p*-acetoxybenzoic acid. High molecular-weight poly-(*m*-hydroxybenzoic acid) and copolymers of *m*- and *p*-hydroxybenzoic acids have been prepared by a two-stage, Mg-catalyzed melt polymerization at 200 °C, followed by polymerization in the solid phase at about 300 °C [46].

*(23)*

Some of these polyesters *(23)* were reported to have molecular weights of up to 20000 [46]. They are crystalline and stable to oxidation, but sensitive to hydrolysis. The film pressing temperatures [46] (usually 10 to 15 °C above the melting point) and the flow points [46] (at which the films begin to elongate spontaneously) of

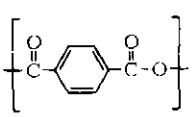
the copolymers increase with increasing content of the *p*-isomers (Table 3). At least 60 % of the *p*-isomer are required to achieve very high-melting films with a flow point of 300 °C. The melting points of the two homopolymers are given [46] as 200 °C (*meta*) and above 450 °C (*para*).

Table 3. Properties of films from poly(hydroxybenzoic acids).



| | Isomer ratio *m*:*p* | | | |

| Modulus [$10^5$ psi] | 2.8[a] | 2.7 [a] | 3.2 | — |

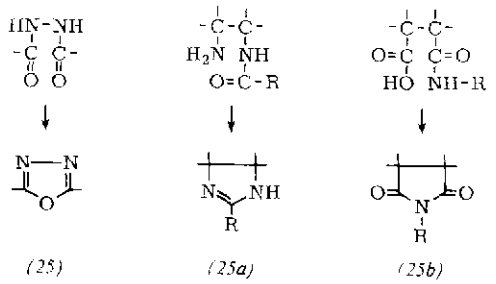
[a] Average values.

Films of hydroxybenzoic acid copolymers are tough, moderately extensible, and stiff (Table 3), and thus resemble films of poly-[2,2-di-(*p*-hydroxyphenyl)propane carbonate] [47], which are reported to posses a tear strength of 9000 to 10000 psi, an elongation at break of 60–100 %, and an initial modulus of $3.5\times10^5$ psi. Since increasing quantities of the *p*-isomer raise not only the melting point, but also the initial modulus (as a measure of stiffness) and reduce the extensibility (Table 3) there is also a resemblance between the mutual relationships of these copolymers and those of the poly-(terephthalic/isophthalic dihydrazides) as shown in Table 2 [33a].

c) *Poly(terephthalic anhydride)*

Little is known about film- or fiber-forming aromatic polyanhydrides with very high melting points. *Yoda* [48] recently reported on 24 polyanhydrides, of which only two melt above 300 °C: poly(terephthalic anhydride)

*(24)*



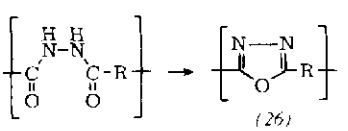
*(24)* (m.p. 400 °C) and poly(bis-*p*-carboxyphenylmethane anhydride) (m.p. 325 °C). Poly(terephthalic anhydride) [49] in particular should be of great interest in the film and fiber fields, since it is resistant to hydrochloric acid, nitric acid, and even to aqua regia [50].

## III. Structural Analogues of Polyphenylene and Polyacene

### 1. Synthesis of Heteroaromatic Polymers

A new development in polymer chemistry was due to the intramolecular cyclization of polymers. This led to film- and fiber-forming hetero-aromatic polymers.

The cyclization of a diacylhydrazine to form 1,3,4-oxadiazole *(25)* [51], the cyclodehydration of a β- (or *o*-) aminoacid amide [52a] to give imidazole *(25a)*, and the reaction of a carboxamide group with a β- (or *o*-) carboxyl group [52b] to give the imide group *(25b)* are well known.



*(25)* *(25a)* *(25b)*

The same reactions were used for the cyclization of polyhydrazides [53, 54] and poly(aminobenzamides) [10], and for the cyclodehydration of poly(amide acids) [9c, 56a, b]. High molecular-weight poly-(1,3,4-oxadiazoles) [53] and their fibers [54], poly(benzimidazoles) [10] and their films [55b], and poly(pyromellitimide) films [9, 56c] were obtained. The structure of the "prepolymers" can be chosen in such a manner that the resulting film or fiber possesses the thermal stability of poly-(*p*-phenylene), in addition to the flexibility which is lacking in the latter. Polymers and fibers were also prepared by cyclization of poly(acrylonitrile) [57] which may be regarded as heteroaromatic analogues of polyacene.

### 2. Poly(oxadiazole) Fibers

Thirteen aliphatic and aromatic polyhydrazides [33, 33a] have been converted into high molecular-weight poly-(1,3,4-oxadiazoles) *(26)* by thermal cyclodehydration at 170 to 280 °C [53].

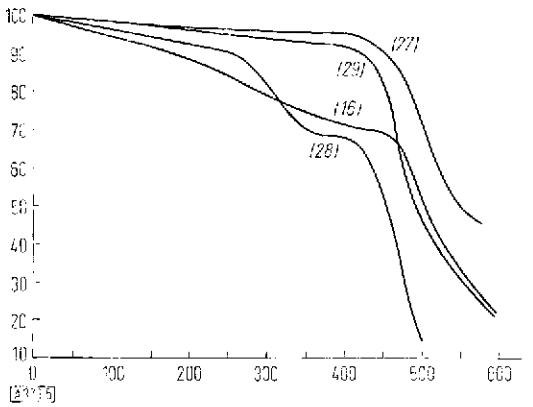
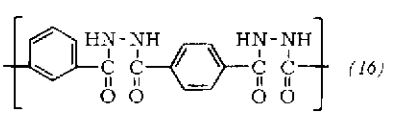
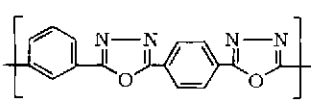
Figure 5 represents a thermogravimetric analysis of the cyclization of the polyhydrazide *(16)* from isophthalic dihydrazide and terephthaloyl dichloride. The initial weight loss is due to the loss of surface water (25 to 240 °C). The weight loss at higher temperatures (280 to







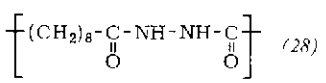


Fig. 5. Thermogravimetric analysis of componnds *(16)*, *(27)*, *(28)*, and *(29)* [53].
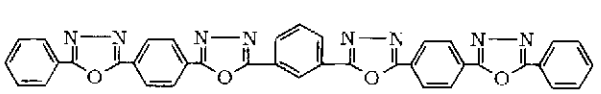
Ordinate: weight retention [%]
Abscissa: temperature [°C]



350 °C) corresponds to the conversion of the polyhydrazide to poly-(1,3,4-oxadiazole) *(27)* (calculated water loss: 11.11 %). In the cyclization of poly(octanedicarboxylic dihydrazide) *(28)* (Fig. 5) the surface water is given off between 25 and 225 °C, while the water of reaction is liberated between 250 and 350 °C. Completion of the formation of poly(octamethylene-1,3,4-oxadiazole) is indicated by constant weight.

Poly-(1,3,4-oxadiazoles) give the expected analytical results, and have a high inherent viscosity in $H_2SO_4$ [$\eta$ – 0.6 for *(27)*] and high X-ray crystallinity. The infrared and ultraviolet spectra also indicate that cyclization is complete. Films could be pressed from aliphatic poly(oxadiazoles) melting below 350 °C, while very high-melting or infusible poly(oxadiazoles) could not be

*(16)*

*(27)*

*(28)*

*(29)*

made into films or fibers. Poly(oxadiazoles), like the nine-membered model compound *(29)*, are also resistant to oxidation, and decompose between 450 and 500 °C [57a].

[57a] *F. T. Wallenberger*, unpublished work.

The thermal cyclodehydration of a fiber from poly(isophthalic/terephthalic hydrazide) *(27)* yields a polyoxadiazole fiber with outstanding thermal stability, namely poly-[*m*/*p*-phenylene-2,5-(1,3,4-oxadiazole)] *(27)* [54].

The reaction proceeds at 280 °C in a muffle furnace under positive nitrogen pressure, and is complete in 48 to 72 hours, as shown by elementary analysis. The fiber is stable to prolonged heating at 400 °C. Other properties are shown in Table 4.

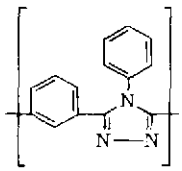
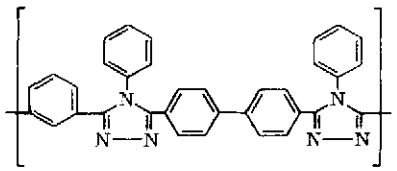
*Huisgen* et al. [57b] have recently shown that the oxadiazole ring is spectrally and electronically equivalent to a *p*-phenylene structure. Poly-(1,3,4-oxadiazole) can therefore be regarded as a pseudo-polyphenylene.



### 3. Poly(phenylenetriazole) Films

The treatment of polyhydrazides with aniline and polyphosphoric acid yields high molecular-weight poly-(phenylenetriazoles) *(30)*–*(32)* [55c]. Reaction of the polyhydrazide *(16)* proceeds in solution at 250 to 265 °C. *Lilyquist* and *Holsten* [55c] claim that the reaction is homogeneous throughout. The final viscosity depends on the molecular weight of the prepolymer.



Poly-(*m*-phenylene-4-phenyltriazole) *(31)* and alternating poly(*m*/*p*-phenylene-4-phenyltriazole) *(30)* are soluble in strongly polar solvents such as formic acid [55c]. Poly-(*m*-phenylene/*p*,*p'*-diphenylene-4-phenyltriazole) *(32)*, on the other hand, is insoluble, probably owing to the greater stiffnes of the *p*-diphenylene group.

[57b] *J. Sauer*, *R. Huisgen*, and *H. J. Sturm*, Tetrahedron *11*, 214 (1960).

(31)

(32)

Formic acid can also be used as a solvent for the casting or spinning of films or fibers from poly-(*m*/*p*-phenylene-4-phenyltriazole). The fibers can be drawn over hot surfaces (250 °C), remaining amorphous and unoriented. The films were tough, and had excellent strength and dimensional stability at high temperatures (cf. Table 5). The thermal stability is notable particularly after annealing at 290 °C: the breaking temperature with a load of 0.1 g/den is 423 °C.

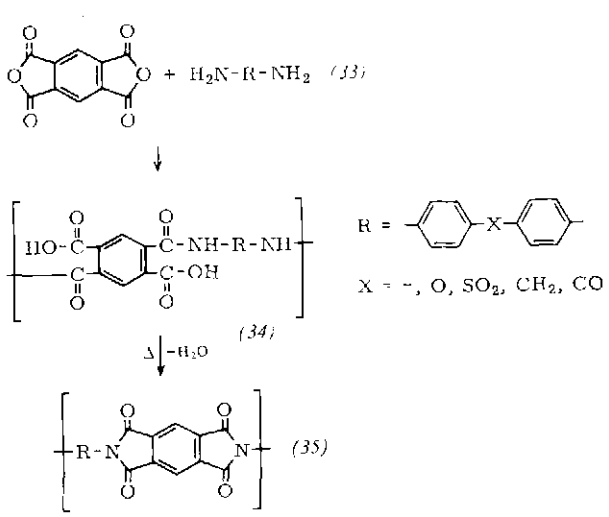


Table 5. Properties of films from the poly-(*m*/*p*-phenylene-4-phenyltriazole) *(30)* [55c].

[a] Temperature at which the film will break under a load of 20 psi.

### 4. Poly(pyromellitimide) Films

Poly(pyromellitimide) films are stable up to 800 °C, highly resistant to oxidation, extremely tough [56, 56a-c], and exhibit excellent flame and radiation resistances. They are prepared [58, 58a, f] from pyromellitic anhydride *(33)*, which reacts under mild conditions in dimethylformamide or dimethylacetamide with aromatic diamines, in the molar ratio of 1:1, to form poly(pyromellitamic acid) *(34)*. Films cast from this solution underwent cyclodehydration on heating to yield the insoluble, infusible polyimide *(35)*.

(33)

(34)

(35)

The poly(pyromellitimide) that is derived from 4,4'-diaminodiphenyl ether gives films with the best combination of mechanical, electrical, and thermal properties [58, 58c]. Polyimides based on alipbatic diamines have a lower thermal stability than aromatic poly(pyromellitimides) [56, 58e, d].

H-film derived from such a poly(pyromellitimide) *(35)* [58e] with high thermal stability and very good electrical properties resembles a ®Mylar polyester film at room temperature (Table 6), but substantially retains its strength and rigidity at much higher temperatures [56a, 58b, c]. After 1000 hours in air at 300 °C, it still retains more than half of its original tensile strength [56d]. The breaking temperature of 815 °C is unusually high. H-film does not become very brittle at low temperatures, and retains 50 % of its extensibility at room temperature even in liquid helium (4 °K) [58c].

Table 6. Properties of H-film and films from ® Mylar polyester (polyethyleneterephthalate) [56c].

[a] Temperature at which the film will break under a load of 20 psi.

### 5. Poly(benzimidazole) Films

Aliphatic and aromatic poly(benzimidazoles) *(37)* have been synthetized by *Brinker* and *Robinson* [10] and by *Vogel* and *Marvel* [55a, b]. Fully aromatic polymers with high thermal stability have been prepared by reacting aromatic tetramines with diphenyl esters of aromatic dicarboxylic acids in a melt polymerization. The reaction proceeds in two stages: initially at 220 to 260 °C, and then below 400 °C. The poly(amino amide) *(36)*, which is undoubtedly an intermediate, has not been isolated. Reactivity, polymer solubility and crystallinity of poly(benzimidazoles) are dependent upon the polymerization temperature [55d]. Mixed aliphatic-aromatic

poly(benzimidazoles) (aliphatic dicarboxylic acids) are stable up to 470 °C. Poly(benzimidazoles) from isophthalic acid and 1,2,4,5-tetraaminobenzene or 3,3'-diaminobenzidine begin to volatilize at 600 °C losing about

(36)

(37)

30 % of their weight at 900 °C. *Vogel* and *Marvel* [55a] succeeded in producing films from certain poly(benzimidazoles). The properties of a film of poly-[2,2'-(*m*-phenylene)-5,5'-dibenzimidazole] *(38)* are shown in Table 7. The thermal stability of *(38)* in the presence of oxygen is equivalent to that of a copolymer from tetrafluorocthylene and hexafluoropropylene [55].

(38) (39)

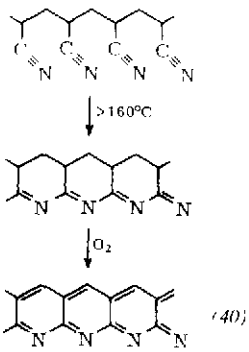

Table 7. Properties of films from the poly(benzimidazole) *(38)* [55a].

| | 25 °C | 200 °C |
|---|---|---|
| Tensile strength [g/den] | 0.7 | 0.5 |
| Elongation [%] | 7 | 9 |
| Modulus [g/den] | 35 | 15 |

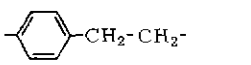
A polymer prepared from 1,3-dianilino-4,6-diaminobenzene and diphenyl isophthalate *(39)* [55b] was less stable (decomposition temperature: 400 °C) than the unsubstituted compound *(37)* (decomposition temperature: 600 °C). Poly(benzimidazoles) are soluble in dimethyl sulfoxide and formic acid, and can therefore be cast into films [55].

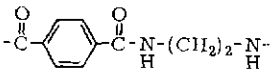
### 6. Fireproof Fiber from Cyclized Poly(acrylonitrile)

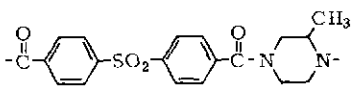
A method of preparing black, fireproof textile fibers (Fiber AF) from cyclized poly(acrylonitrile) fibers has been described by *Vosburgh* [59]. Orlon fibers or fabrics are heated in air above 160 °C. The product is probably a double-chain polymer *(40)* ("ladder" structure) [57, 59–61].

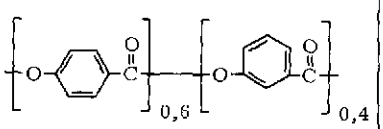
(40)

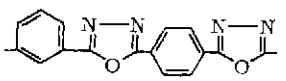
The logarithm of the reaction time is inversely proportional to the reaction temperature. *Vosburgh* found that the most important process variables were heating time and temperature, fabric structure, and reaction atmosphere. The reaction is exothermic and is accompanied by severe shrinkage. The optimum oxygen concentration is 15 to 20 %. Fiber AF is fireproof, and withstands thermal radiation 100 times more intense than the limiting radiation flux for conventional textile fabrics. It gradually loses its tensile strength on prolonged exposure to high temperatures. At 900 °C, it is completely consumed in 3 hours. Other properties are shown in Table 8. The fiber is suitable for the fabrication of fireproof clothing, and for fabrics which do not demand high abrasion resistance.

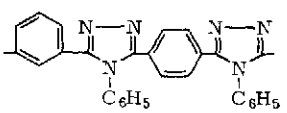


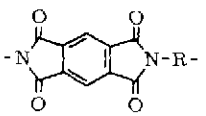


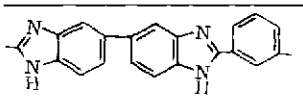












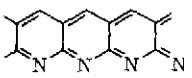


Table 8. Properties of AF-fiber and normal poly(acrylonitrile) fiber [59].

## IV. Conclusion

The properties of the high-melting fibers and films are listed in Table 9.

It is hoped that the present study, relating polymer structure with in-use properties of films and fibers, will encourage further technical development in the field of heat-resistant polymers, films, fibers, and elastomers.

# Amides of the Alkali and the Alkaline Earth Metals

BY PROF. DR. R. JUZA [1]

INSTITUT FÜR ANORGANISCHE CHEMIE DER UNIVERSITÄT KIEL (GERMANY)

*Following preparative work, the behavior of amides towards excess ammonia (ammoniate formation) and on removal of ammonia (degradation to imides) was studied particularly with regard to the solid state (crystal structure) and the transition to the liquid phase (melting point). Energy relationships are discussed on the basis of enthalpies of formation. Studies on ternary amides and imides are still in the initial stage. – Emphasis is laid here on the establishment of parallels between amides and hydroxides as well as between the aquo and ammono systems, and also on the differences between the amides with their dipolar $NH_2^-$ anion, and the halides. The results, although still incomplete, permit a survey to be given of experimental data with the aid of information obtained from the pertinent literature.*

## 1. Preparation of the Amides

Two principal methods are available for the preparation of the amides of *alkali metals*: reaction of the metal with (a) liquid or (b) gaseous ammonia.

The purest products are obtained by the long-established reaction of metals with *liquid* ammonia [2]. The alkali metals dissolve in ammonia to give the familiar intensely blue solutions. The rate of formation of the metal amide and hydrogen is slow, particularly with the lighter alkali metals. It increases appreciably with rising temperature and with increasing atomic weight of the alkali metal [3, 4]. Acceleration of the reaction by catalysts, *e.g.* iron oxide or platinized platinum, is also possible.

Lithium and sodium amides are most readily obtained by sealing the solution of the alkali metal together with the catalyst in a pressure tube, taking care to exclude air and moisture, and allowing the mixture to stand at room temperature until the deep-blue solution is fully decolorized. With potassium, rubidium, and cesium, the reaction is complete after a few hours, even at low temperatures, and it is possible to work at normal pressure, so that the hydrogen formed can escape [5]. The second method depends on the reaction of the molten metal with *gaseous* ammonia, *e.g.* at 400 °C for $LiNH_2$ or 300 °C for $NaNH_2$. With lithium, higher temperatures must be avoided as the decomposition pressure becomes too high and degradation to the imide occurs. It is advantageous to allow the very mobile molten reaction product to drain away into a cooler zone of the apparatus [6].

In addition, numerous reactions are known in organic chemistry in which alkali amides are formed as by-products. Mention may be made of the hydrogenation of conjugated double bonds by the method of *Birch* [6a], where liquid ammonia serves as solvent and often also as proton donor. Although these reactions proceed very rapidly even at low temperatures, they are mostly unsuitable for the preparation of metal amides since the organic substances are difficult to separate off. However, when the solvent and the organic compound are readily volatile, such a reaction may be preparatively useful [7]:

$$R_2NH + CH_2{=}CH{-}CH{=}CH_2 \xrightarrow[\text{n-Octane}]{\text{Na}} CH_3{-}CH{=}CH{-}CH_3 + R_2NNa$$

The following *substituted* amides have been prepared in this way: sodium diethylamide, sodium anilide, sodium *N*-ethylanilide, and sodium *N*-isopropylanilide. Little is known about the chemical and physical properties of these compounds, but studies of alkali metal methylamides have been carried out [8–10]. The latter compounds can generally be prepared from the alkali metal and methylamine, and, in the case of lithium, also from phenyl-lithium and methylamine in ether. Cesium reacts rapidly with methylamine, even at low temperatures, to form $CsNHCH_3$; the other alkali metals react too slowly under these conditions. At higher temperatures, *e.g.* 30–50 °C, only the lithium compound is obtained. Cyanides and decomposition products of the amine are formed by the other elements of this group.

The preparation of amides by sealing alkali metal dissolved in liquid ammonia in a pressure tube was also applied to the *alkaline earth metals* [11]. Products free from hydride are obtained in this way, and partial thermal decomposition is prevented; both of these side

reactions can interfere during the reaction of metals with gaseous ammonia at elevated temperatures [12, 13].

Magnesium occupies a special position. In order to obtain magnesium amide by this method, the addition of a small quantity of ammonium iodide is required [14]. This substance behaves as an acid in liquid ammonia and acts as a catalyst; it also precipitates the sparingly soluble magnesium amide:

$$Mg + 2\ NH_4^+ = Mg^{2+} + 2\ NH_3 + H_2$$
$$Mg^{2+} + 4\ NH_3 = Mg(NH_2)_2 + 2\ NH_4^+.$$

By adding alkali metal amides or halides to magnesium in liquid ammonia, *Bergstrom* obtained amidometalates, *e.g.* $Mg(NHNa)_2 \cdot 2\ NH_3$. In the case of beryllium such derivatives are the only amides known at present [15]. On the other hand, the reaction of gaseous ammonia with magnesium nitride at 350 °C under a pressure of 10 atm. for 4–6 weeks results in the formation of magnesium amide [14].

The amides of the heavier metals of both groups are clearly the ones most readily obtained. Preparation of the amides of the lighter elements sometimes requires laborious methods, and special difficulties may be anticipated in the case of beryllium amide.

## 2. Properties

Irrespective of their method of preparation, all the amides of the alkali metals are colorless, crystalline substances. They are extremely *reactive* and are rapidly attacked by moisture and atmospheric oxygen. Cesium amide is the most sensitive, and oxidizes explosively with spontaneous ignition. It is noteworthy that the decomposition in air of potassium, rubidium, and cesium amides is accompanied by the formation of an intense yellow coloration typical for the peroxides of these metals. With the exception of lithium amide, all the alkali metal amides can be heated up to their melting points in nickel, copper, or silver crucibles without appreciable decomposition. The fused amides are good conductors of electricity; this confirms the salt-like character of these compounds.

The amides of the heavy alkaline earth metals are crystalline, more or less greyish-white compounds, irrespective of their method of preparation. Magnesium amide is precipitated as a whitish-grey powder in liquid ammonia, but is amorphous as indicated by X-ray studies. Its particles are so fine that excess ammonia is adsorbed. This is similar to the adsorption of water by amorphous hydroxides [14]. A white crystalline product is obtained from the reaction between magnesium nitride and ammonia. The alkaline earth amides react less vigorously with moisture or atmospheric oxygen than the alkali metal amides, and on heating they lose ammonia and are all converted into the corresponding imides. They are only slightly soluble in liquid ammonia.

Amides of the heavier alkali metals (sodium to cesium) decompose when heated above their melting points. At 335–400 °C, two possible modes exist for the thermal decomposition of sodium amide [16], depending on the total pressure in the system. If the pressure exceeds the dissociation pressure of sodium hydride, then the reaction proceeds according to the equation

$$NaNH_2 \rightarrow NaH + 0.5\ N_2 + 0.5\ H_2.$$

If, on the other hand, the total pressure is below the dissociation pressure of NaH, the following decomposition takes place:

$$NaNH_2 \rightarrow Na + 0.5\ N_2 + H_2.$$

The gaseous mixture produced always contains ammonia together with the hydrogen and nitrogen.

The solubilities of the alkali amides in liquid ammonia differ strongly. Lithium amide is very sparingly soluble, sodamide dissolves far more readily (0.114 g of $NaNH_2$/100 g of $NH_3$ at −20 °C) and potassamide is readily soluble (65.8 g of $KNH_2$/100 g of $NH_3$ at −32.4 °C) [17]. Rubidium amide is extremely soluble – several hundred grams dissolve in 100 g of liq. $NH_3$ (cf. Section 3); the solubility of cesium amide is slightly lower.

Like the hydroxides in water, metal amides behave as solvobases in the liquid-ammonia system. The numerous reactions of these ammoniacal bases described in the literature [18] involve mostly organic compounds, but inorganic neutralization reactions are also known. In considering the use in liquid ammonia of indicators normally employed in aqueous systems, primary attention should be given to the large difference in the dissociation constants of water and ammonia:

$$[NH_4^+]\,[NH_2^-]/[NH_3] = 4.5 \times 10^{-35}\ (\text{at } -50\,^\circ C)$$

The enthalpy of neutralization, $\Delta H_N$, of liquid ammonia:

$$NH_4^+ + NH_2^- \rightarrow 2\ NH_3\ (liq.);\ \Delta H_N$$

is directly related to the dissociation constant. According to van't Hoff's reaction isochore, the dissociation constant decreases with increasing enthalpy of neutralization. Values of

$$\Delta H_N = -26.1\ kcal/mole$$

were obtained by calorimetric measurements involving the reaction of dilute solutions of $KNH_2$ with strong ammonium acids such as $NH_4I$, $NH_4NO_3$, $NH_4SCN$, and $NH_4Br$ [19]. (For water, $\Delta H_N = -13.4$ kcal/mole.) Furthermore, the *proton affinity* [*] of ammonia, 209

kcal/mole, *i.e.* the energy released when a proton becomes attached to the $NH_3$ molecule, is much greater than the proton affinity of water (182 kcal/mole) [20], so that ammonia is a solvent of pronounced basic character. For this reason, the usual indicators for aqueous systems cannot always be employed, since indicators which are weak acids are completely dissociated, while weak bases do not dissociate at all. Further difficulties are caused by poor solubilities and reaction between the indicator and the amide bases (see [18] for colors and usefulness of indicators in neutralization reactions).

## 3. Ammoniates

The reaction with liquid ammonia generally results in the formation of amides, but with heavy alkali metals ammoniates of the amides are formed [21], in analogy with the hydrate formation of alkali metal hydroxides. The relationships can be readily investigated by measuring *pressure changes*. A known amount of $NH_3$ is condensed onto the alkali metal amide, and decomposition is then conducted inside a tensioeudiometer [22] with systematic variation of the temperature. The temperature dependence of the equilibrium pressures permits calculation of the enthalpies of formation of the ammoniates by means of the van't Hoff isochore.

The simplest system is that of cesium amide and ammonia [21]. First the pressure of the liquid ammonia is measured; the value obtained lies below the saturation pressure of pure ammonia owing to dissolved $CsNH_2$. Subsequently, the dissociation pressure of the monammoniate is established. When the latter is decomposed, the $NH_3$ pressure falls to zero. The enthalpy of formation of the ammoniate $CsNH_2 \cdot NH_3$ is found to be $\Delta H_B = -10.7$ kcal/mole.

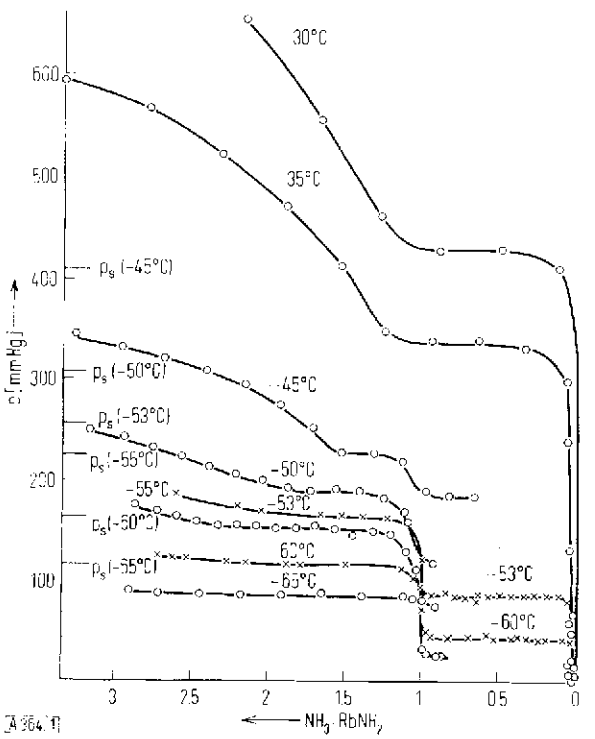

Fig. 1. Tensiometric decomposition reactions in the $RbNH_2/NH_3$ system ($p_s$ = saturation pressure of $NH_3$ at the temperature stated).

The system rubidium amide/ammonia is more complicated, in particular because of the extreme solubility of $RbNH_2$ in liquid ammonia [21]. The degradation diagram (Fig. 1) is again that of the two-phase system monoammoniate/ammonia. From the temperature coefficient of the decomposition reaction, the enthalpy of the formation of $RbNH_2 \cdot NH_3$ can be calculated as $\Delta H_B = -9.0$ kcal/mole. A cursory examination suggests that the abrupt breaks of the −30 and −35 °C curves on the right-hand side of Figure 1 are associated with the monoammoniate; in fact, they are due to a saturated solution with $RbNH_2$ as solid phase. Similar saturated solutions, with $RbNH_2 \cdot NH_3$ as the solid phase, are responsible for the breaks in curves corresponding to higher ammonia contents. The range of existence of this compound can be read off from the graph of log p versus 1/T (Fig. 2) and does not extend above −42 °C. Above this temperature, the saturated solution II with $RbNH_2$ as solid phase is present, below −42 °C $RbNH_2 \cdot NH_3$ is the solid phase of the saturated solution I.

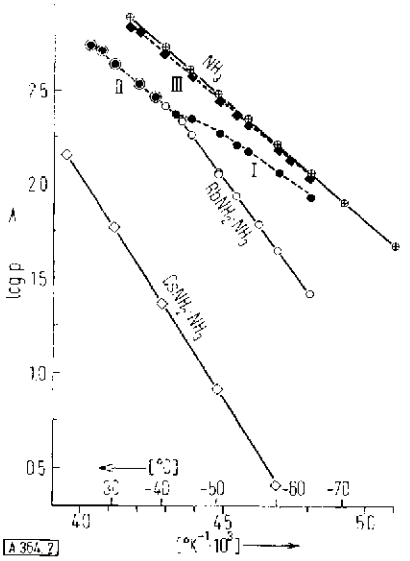

Fig. 2. Equilibrium pressures of $CsNH_2 \cdot NH_3$, $RbNH_2 \cdot NH_3$, and of their saturated solutions in liquid ammonia.

I Saturated solution in liquid ammonia with $RbNH_2 \cdot NH_3$ as the solid phase

II Saturated solution in liquid ammonia with $RbNH_2$ as the solid phase

III Decomposition pressure of $RbNH_2 \cdot NH_3$.

In the potassium amide/ammonia system [21, 23], only a diammoniate exists below −60 °C, a diammoniate and a monoammoniate coexist between −60 and −42 °C, and only the monoammoniate appears above −42 °C. The enthalpy of formation of the monoammoniate is $\Delta H_B = -7.3$ kcal/mole.

The thermal stability of the ammoniate increases from potassium to cesium, as shown by the dissociation pressures; the *enthalpies of formation* of the monoammoniates increase in the same order (see above). Consequently, sodium and lithium amides do not form ammoniates.

Similar relationships are found in the far more numerous hydrates of the alkali metal hydroxides. Here again an intermediate alkali metal hydroxide, NaOH, forms the most hydrates, and the number of water molecules attached to the hydroxides falls off in the direction to lithium and cesium hydroxides. Among the monosolvated compounds, $CsNH_2 \cdot NH_3$ and $CsOH \cdot H_2O$ have the highest thermal stabilities.

[21] *R. Juza* and *A. Mehne*, Z. anorg. allg. Chem. *299*, 41 (1959).

[22] *G. F. Hüttig*, Z. anorg. allg. Chem. *114*, 161 (1920).

[23] *R. Juza* and *H. Liedtke*, Z. anorg. allg. Chem. *290*, 205 (1957).

The construction of the phase diagram and the elucidation of the energy relationships naturally give no information about the *constitution* of these ammoniates. Two alternative structures are possible; the $NH_3$ molecule is associated with either the metallic ion or the $NH_2^-$ ion. The first alternative involves an ion-dipole bond, the second a hydrogen bond.

Determination of crystal structures should resolve this problem. The existence of a hydrogen bond would be shown by a small N–N bond length, similar to that in solid $NH_3$ [24]; the alternative structure requires a much greater N–N bond length. However, the magnitudes of the enthalpies of formation of the monoammoniates [21] give a highly probable indication of the type of bonding of the ammonia molecules. Thus, the greatest values are found for $CsNH_2 \cdot NH_3$ and the smallest for $KNH_2 \cdot NH_3$. The same conclusions can be drawn from the equilibrium vapor pressures of these compounds. If the $NH_3$ molecule were coordinated to the cation, the opposite behavior would be expected for electrostatic reasons, *i.e.* the compound with the smallest cation would have the greatest stability. On the other hand, a hydrogen bond is weakened by the counterpolarizing effect of a small cation, and this is indeed confirmed in the series Cs, Rb, K. The same reasoning explains the absence of ammoniate formation with sodium, lithium, and alkaline earth amides.

Crystal structure determinations on hydrates of alkali metal hydroxides provided information about the way in which the water is bound in these compounds. $NaOH \cdot H_2O$ [25] crystallizes in an orthorhombic layer lattice. Hydrogen bridges between the oxygen atoms are highly developed within the layers, and the O–O distance is very small (2.64 to 2.66 Å). The layers are interlinked by weak hydrogen bonds with an O–O distance of 3.11 Å, which is even less than that found in compounds containing OH groups and free from hydrogen bonds ($\approx$ 3.3 Å). Similar relationships are found in all the hydrates of alkali metal hydroxides investigated so far [26].

In general, fluorine shows the greatest tendency towards hydrogen bonding. Hydrogen bonds to oxygen are less strong, while those to nitrogen are only weak [27]. This explains why ammoniate formation is restricted to the amides of the heavy alkali metals, why only one or two ammonia molecules are attached, and why the thermal stability of these compounds is so poor.

## 4. Crystal Structures

It is now possible to correlate the crystal structures of the alkali metal amides and to discuss the crystallochemical relationships existing among the amides themselves, and among the amides, hydroxides, hydrogen sulfides, and dihydrogen phosphides.

*Lithium amide* [6] is tetragonal, the $NH_2^-$ ions being approximately cubic close-packed (Fig. 3). The lithium ions can occupy either octahedral or tetrahedral interstices; in practice, the latter are found. In effect, two deformed zinc blende unit cells are placed on top of each other. The $NH_2^-$ ions have been displaced from their ideal positions; those with $z = 1/8$ and $7/8$ are nearer the lithium ions ($z = 0$), while the others approach $z = 1/2$.

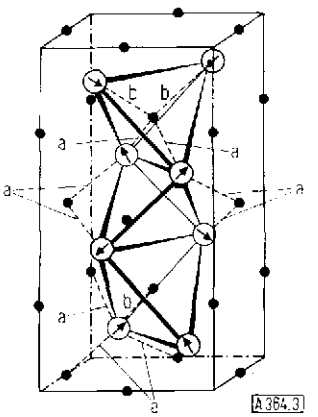

Fig. 3. Crystal structure of lithium amide. ● Li; ○ $NH_2$.

In this way, the substance acquires a slight tendency towards a layer structure. Two of the four lithium ions which surround an $NH_2^-$ ion are at a greater distance (b = 2.35 Å) than the other two (a = 2.15 Å). It is likely that the dipole of the $NH_2^-$ ion is orientated in the direction of the greater distances. This direction is indicated by the arrows in Figure 3.

It would be very interesting to determine experimentally the positions of the hydrogens here and in the low-temperature modifications of the other amides in order to obtain a reliable indication of the position of the dipoles. Appreciable difficulties are likely to be encountered in this investigation even at the preparation and handling stages.

The unit cell of *sodium amide* [28] is rhombic (Fig. 4). Here again the $NH_2^-$ ions have an approximately cubic close-packed structure. The sodium ions occupy the

[27] The bond energies of the hydrogen bonds vary markedly with the lengths of the bonds. Cf. *C. A. Coulson:* Valence. 2nd Edit., Oxford University Press, 1961.

[28] *R. Juza, H. H. Weber*, and *K. Opp*, Z. anorg. allg. Chem. *284*, 73 (1956).

tetrahedral interstices, which are surrounded by $NH_2^-$ ions in a fairly strict tetrahedral arrangement. On the other hand, the $Na^+$ tetrahedra which surround the $NH_2^-$ ions are very strongly distorted, the sodium ions being removed from the positive side of the $NH_2^-$ dipole.

The structure of sodium amide has been reinvestigated and confirmed by *Zalkin* and *Templeton* [29], who calculated the orientation of the $NH_2^-$ ions in the unit cell. The H–N–H angle (104°) [30] is known from infrared measurements, and the H–H distance in $NH_2$ (1.63 Å) from proton magnetic resonance [31]. These figures give an H–N distance of 1.03 Å. The N–N distance in sodium amide is 3.81 Å, much greater than that in solid ammonia (3.38 Å) [24]; consequently no hydrogen bonding exists between the nitrogen atoms in $NaNH_2$. In Figure 4 the positions of the hydrogen atoms of the $NH_2^-$ ions are indicated by two short lines. The *structural relationship* between lithium and sodium amides can be better appreciated if only the monoclinic unit cell (indicated on the upper base in Figure 4) is used. Figure 5 gives a schematic representation of this portion of the sodamide unit cell, and also that of lithium amide and lithium hydroxide.

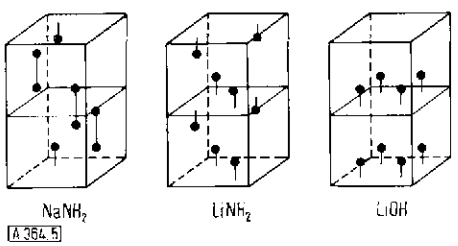

Fig. 5. Structural relationships between $NaNH_2$, $LiNH_2$, and LiOH. The anions arranged in a distorted cubic close-packed lattice are not shown.
● Cations.

The anions are always approximately cubic close-packed and are not indicated; what is shown is the position of the cations in the tetrahedral interstices. *Ernst* has demonstrated the presence of a layer lattice in lithium hydroxide [32]; the tetrahedral interstices with z = $^1/_4$ are all occupied and those with z = $^3/_4$ are all vacant. In lithium amide, as mentioned above, tetrahedral occupation of the tetrahedral interstices by lithium occurs, and a weak layer character appears owing to the displaced $NH_2^-$ ions (not shown here). In sodium amide, two superposed tetrahedral interstices are always occupied.

The picture is much simpler for the *high-temperature modifications* [21, 23, 33] with freely rotating $NH_2^-$ dipoles and quasi-spherical $NH_2^-$ ions. β-$KNH_2$ and β-$RbNH_2$ have the sodium chloride lattice (coordination number 6), and β-$CsNH_2$ crystallizes in the cesium chloride (lattice coordination number 8). The transition temperatures are low, being approximately 50, 40 and 30 °C, respectively.

The corresponding *low-temperature modifications* are much less symmetrical, but their structures are closely related to those of the high-temperature modifications.

The low-temperature modification [33] of *cesium amide* can be derived from the high-temperature form as shown in Figure 6. Below the transition temperature, relatively slight splitting of the cubic powder pattern reflections occurs due

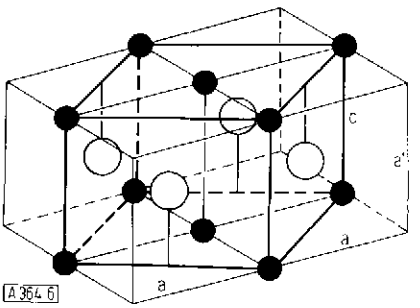

Fig. 6. Crystal structure of the low-temperature modification of cesium amide and its relation to the high-temperature modification.
● Cs; ○ $NH_2$.

to tetragonal transformation; the structure of the low-temperature modification is that of ammonium bromide, γ-$NH_4Br$. Accurate determination of the z-parameter of the $NH_2^-$ ion is not possible, but its value does not deviate markedly from z = $^1/_2$. The tetragonal deformation indicates that orientation of the $NH_2$ dipole occurs in the low-temperature modification of cesium amide; allowance for the as yet unknown positions of the hydrogens would probably reduce the degree of symmetry still further.

Investigation of the low-temperature modifications of *potassium* and *rubidium amides* [34, 34a] presented difficulties as single crystals could not at first be obtained. Crystals from the melt become opaque and polycrystalline below the transition temperature. Crystalline ammoniates are generally obtained from liquid ammonia, but after decomposition at room temperature, these also form polycrystalline $RbNH_2$. Knowledge of the $RbNH_2/NH_3$ system described above (cf. Fig. 1 and 2) showed however that $RbNH_2$ itself appears as the solid phase above −42 °C in liquid ammonia, and it was then possible to obtain single crystals by slow cooling to 15 °C of a solution saturated at + 35 °C [34a].

The unit cells of both amides are monoclinic and, according to Figure 7, are closely related to the sodium chloride lattice, *i.e.* to the high-temperature modification. The c-axis of the monoclinic unit cell is approximately equal to the edge of

the cube and (a + b) is approximately equal to the face diagonal of the cube, although a is substantially greater then b. The positions x $^1/_4$ z and $\bar{x}$ $^3/_4$ $\bar{z}$ are likewise taken from the sodium chloride lattice. The axis of the $NH_2^-$ dipole is probably contained in the two planes of symmetry of the unit cell.

*Comparison* of the structures of the alkali metal amides with those of the corresponding hydroxides, hydrogen sulfides, and dihydrogen phosphides was also of interest with particular reference to the ionic sizes and dipole moments of the anions. The size of the ions increases in the order $OH^- < NH_2^- < SH^- < PH_2^-$, and it is generally assumed that the dipole moments decrease in the same order as those of the parent molecules, *i.e.* $H_2O$ (1.84 D), $NH_3$ (1.47 D), $H_2S$ (0.93 D), and $PH_3$ (0.55 D), although they cannot be determined directly. A large dipole moment and a small ionic radius indicate a low degree of symmetry, possibly associated with a layer structure. Table 1 gives a list of crystallographic data for the four types of compounds.

*Lithium hydroxide* [32] crystallizes in the tetragonal system and, as can be seen from Figure 5, has a pronounced layer lattice, whereas the layer character in lithium amide is only weakly developed. The low-temperature modification of sodium hydroxide [35], which crystallizes in a Tl I lattice, and hence is still related to the NaCl lattice, also differs appreciably from sodamide with its (2+2) coordination. Even better agreement is obtained between the amides and hydroxides of potassium and rubidium. The low-temperature modifications [36] of these compounds also form monoclinic crystals; the monoclinic distortion is stronger in the hydroxides than in the amides. No reliable indication of the identity of the space group of these amides and hydroxides can be obtained, as a determination of the position of the hydrogen atoms is required for this purpose. The high-temperature modifications of potassium and rubidium hydroxides [37] are the same as those of the amides, all possessing the NaCl structure.

Cesium hydroxide has also two enantiotropic modifications whose structures have not as yet been determined. The existence of a high-temperature modification of sodamide corresponding to that of sodium hydroxide is to be expected, although none has yet been observed, even at only a few degrees below its melting point [14].

The *hydrogen sulfides* [38–40] present a somewhat different picture, owing to the higher degrees of symmetry of these compounds due to the lowering of the dipole moments and increase in the ionic radius in the order $OH^-$, $NH_2^-$, $SH^-$. Lithium hydrogen sulfide [41] is isotypic with lithium amide, and the layer character in LiSH is again less highly developed than in LiOH. α-Sodium, α-potassium, and α-rubidium hydrogen sulfides crystallize in a weakly rhombohedrically deformed sodium chloride lattice, which is the alternative,

frequently encountered deformed form of the NaCl lattice. Cesium hydrogen sulfide has the lattice of cesium chloride. The high-temperature modifications have exactly the same structure as the corresponding hydroxides and amides.

The structures of potassium and rubidium *dihydrogen phosphides* were recently elucidated [42] and fit readily into the series. Both compounds form crystals with the monoclinically distorted NaCl structure, but in a space group with a higher degree of symmetry than the corresponding hydroxides and amides. Both structures may also be described as approximately rhombohedral deformations of the NaCl lattice, but they have slightly different "rhombohedral angles", so that their analogy to the hydrogen sulfides is at least as pronounced as that to the amides. No high-temperature modifications of these compounds have yet been observed between 20 and 100 °C.

Calcium and strontium amides are so far the only *alkaline earth metal amides* whose structures have been determined [11]. The two substances are isotypic and form tetragonal crystals of the anatase type.

The axial ratio is exactly 2.00:1 in calcium amide, and very close to 2:1 in strontium amide. This results in an ideal position of the amide ions with $z = 0.25$. The structure (cf. Fig. 8) can be interpreted to consist of two cubic face-centered unit cells occupied by $NH_2^-$ ions. Half of the

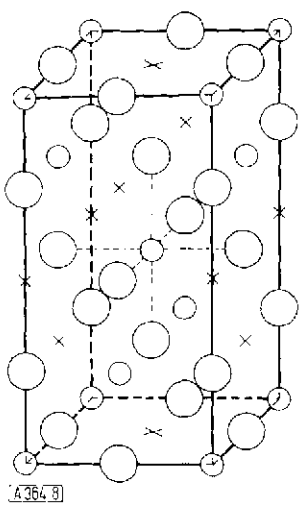

Fig. 8. Crystal structure of calcium and strontium amides.
● Ca or Sr; ○ $NH_2$; × represents lattice sites occupied by Ca in the $Ca(NH_2)_2$/CaNH solid solution.

octahedral interstices are occupied by calcium or strontium ions, *i.e.* the coordination number is 6. If the second half of the interstices indicated by crosses were also occupied, the sodium chloride lattice would result; this phenomenon will be dealt with further in Section 7 during the discussion of the thermal decomposition of these compounds.

## 5. Molecular Volumes

The comparison between the amides and hydroxides can be extended further to a discussion of their densities and molecular volumes [4, 11, 14] on the basis of known structures, allowing conclusions to be drawn about unknown structures.

In Figure 9 the molecular volumes (in the sense of *Biltz*'s volume chemistry [43]) are plotted against the molecular volumes of the alkali metal fluorides. The "standard" increase (broken line) is the rise of the molecular volume of the alkali metal fluorides, which, as is

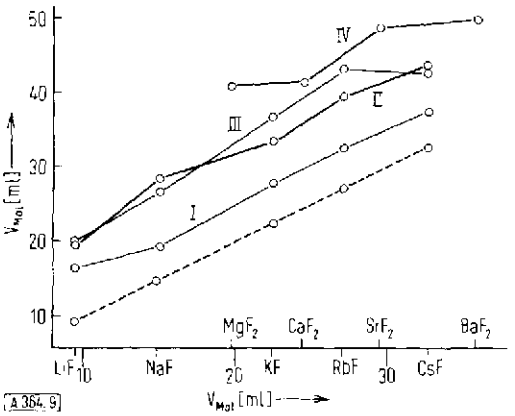

Fig. 9. Molecular volumes of the amides (II), hydroxides (I), and chlorides (III) of the alkali metals and the amides of the alkaline earth metals (IV), plotted against the molecular volumes of the corresponding fluorides.
(Broken line: Alkali fluorides *vs.* alkali fluorides).

well known, all have the same type of lattice. The corresponding curve III for the alkali metal chlorides is linear and somewhat steeper so long as they crystallize in the sodium chloride lattice. Cesium chloride with a coordination number of 6 would be very bulky, but its true coordination number of 8 leads to a smaller molecular volume. This change in coordination number thus gives rise to a break in the curve.

The molecular volume curve of the amides contains two breaks (curve II). $LiNH_2$ and $NaNH_2$, the first two amides, crystallize with a coordination number of 4. Potassium amide with a coordination number of 4 would be too bulky and no longer capable of existence. Thus a coordination number of 6 is found for both potassium and rubidium amides. For the same reason, cesium amide has a coordination number of 8.

In the hydroxides (curve I), the lithium compound has a coordination number of 5 (without allowing for the varying interatomic distances), and potassium and rubidium have a coordination number of 6.

The change in coordination number is therefore accompanied by a lowering of the molecular volume for sodium hydroxide, but no further change in coordination is observed. No information is available about the structure of cesium hydroxide.

Similar relationships are found for the alkaline earth metal amides. The abscissa in Figure 9 contains the molecular volumes of the alkaline earth fluorides; that of magnesium fluoride must be corrected for a coordination number of 6 since this compound crystallizes in the rutile lattice with a coordination number of 4. It can be concluded from Figure 9 that magnesium amide will crystallize with a coordination number of 4 [14] but it has not yet been possible to interpret its complex X-ray diagrams. Sixfold coordination has been demonstrated for both calcium and strontium amides [11], while barium amide very probably crystallizes in two modifications [44], both of which have complicated

[44] *A. Lämmke*, Diploma Thesis, Universität Kiel, 1963.

structures and, to judge from the course of the molecular volume plot, have a coordination number of 8. A calcium fluoride structure might have been anticipated; by analogy to the anatase-type structure of calcium and strontium amides, a zirconium dioxide structure is expected for barium amide.

## 6. Enthalpies of Formation, Lattice Energies, and Melting Points

The *enthalpies of formation* [4] of the alkali metal amides were determined by calorimetric determinations of the heats of solution. The values obtained are appreciably lower than those found for the corresponding hydroxides but vary in the same way with the cation in both series of compounds; the course of this variation is completely different from that observed with the halides.

The enthalpies of formation provide no direct information on constitutional problems, but by the use of the Born-Haber cycle, permit calculation of the *lattice energies*. The proton affinity of the $NH_2^-$ ion is unknown, but this difficulty can be circumvented by precise evaluation of the relative lattice energies from experimental data; the absolute values are then obtained by equating the lattice energy of potassium chloride (167 kcal/mole) to the lattice energy of the high-temperature NaCl-lattice modification of potassium amide. For this purpose, the lattice energy of potassium chloride must be corrected for the size of the $NH_2^-$ ion ($r_{Cl^-} = 1.81$ Å; $r_{NH_2^-} = 1.73$ Å), which is spherically symmetrical in the high-temperature modification [44a]; the corrected value is found to be 172 kcal/mole. Absolute lattice energies determined in this way are listed in Figure 10. Their course is practically identical with that of the lattice energies of the alkali metal hydroxides, but deviates markedly from that of the halides.

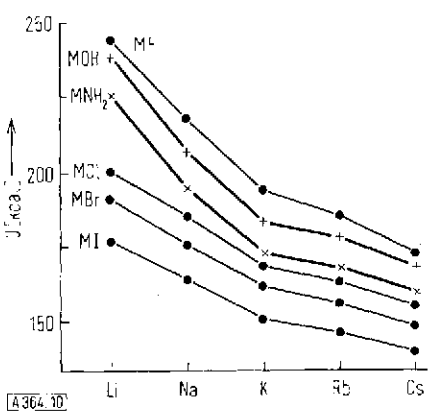

Fig. 10. Lattice energies U of the alkali metal amides, hydroxides, and halides.

The lattice energies for a given anion depend on the size of the cation and should rise from the cesium to the lithium compound, as indicated by the curve for the fluorides, the gradient being somewhat steeper at the last break, *i.e.* from the sodium to the lithium compound.

[44a] *A. Lämmke*, Universität Kiel, unpublished work.

However, the values found for the lithium halides are too low. According to *Pauling* [45, 46] and *van Arkel* [47], this is due to the fact that the distances between the lithium and halide ions in the lattices of lithium halides are larger than those calculated from the appropriate ionic radii. The cations and anions no longer come into contact inside the lattice; instead, anion-anion contact takes place and this results in a lowering of the lattice energy owing to the appearance of additional forces of repulsion. This effect is small in lithium fluoride, but increases with the size of the anion in the order LiF < LiCl < LiBr < LiI. It is also noticeable in NaBr and NaI.

No similar lowering of the lattice energy occurs in lithium hydroxide or lithium amide. These compounds crystallize with a coordination number of 4 and this lower value is responsible for the elimination of the disturbing influence of anion-anion contact. The lattice energies of these compounds are therefore higher.

The schematic energy diagram (Fig. 11) illustrates these and further energy relationships to be discussed below. Level I corresponds to isolated gaseous ions, and level VI

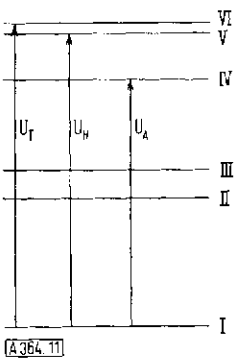

Fig. 11. Schematic representation of the energy levels of compounds with and without dipole anions.

$U_T$, $U_H$, $U_A$: Lattice energies.

I: Gaseous ions
II: Disordered melt
III: Ordered melt
IV: Anion-anion contact
V: High-temperature modification
VI: Low-temperature modification.

to the most stable modification, *e.g.* one with orientated dipoles. The transition from I to VI gives the lattice energy of this low-temperature modification: $\Delta U_{I,VI} = U_T$. In the high-temperature modification, the lattice energy $\Delta U_{I,V} = U_H$ is smaller; the lattice energy, $\Delta_{UI,IV} = U_A$, of a crystal with anion-anion contact is even smaller.

The *melting points* [3] of the alkali metal amides (in °K) are to a first approximation proportional to the enthalpies of fusion (Richards' rule). As can be seen in Figure 12, the melting points of the alkali metal hydroxides and amides are appreciably lower than those of the halides; this difference can be explained by the fact that the $OH^-$ and $NH_2^-$ ions are ion dipoles. In the solid

(M = Metal).

state, the lattice energy is only a little higher than that of a crystal built up of dipole-free ions, since the dipole forces of the anions cannot exert their full effect; the dipoles arrange in the crystal field corresponding to the coordination polyhedron (level VI). In the molten state, the association of each cation with a dipole anion is more strongly favored (level III), resulting in lowering of the enthalpy of fusion of the amides and hydroxides to $\Delta U_{VI,III}$ and hence in lower melting points, whereas the enthalpy of fusion for a non-ordered, dipole-free liquid ($\Delta U_{VI,II}$) is greater.

The course of the melting points of the amides and hydroxides from lithium to cesium differs from that of the halides. The relatively high melting points of lithium amide and lithium hydroxide deserve special attention. At this point, it should be remembered that lattice theory predicts an increase in melting point on passing to smaller cations. Thus, the low melting points of the lithium halides are anomalous, and in order to explain it we must again turn to the theory underlying the lattice energy. Repulsion forces owing to anion-anion contact arise in the lithium halides with a coordination number of 6, and the lattice energy is reduced (level IV) with a consequent fall in their enthalpies of fusion $\Delta U_{IV,II}$ and melting points. In lithium amide and hydroxide, which have a coordination number of 4, no anion-anion contact occurs, so that their lattice energies (level VI), energies of fusion $\Delta U_{VI,III}$, and melting points are high.

The initially somewhat complicated course of the melting points of the alkali metal amides can thus be explained by considering the structural and calorimetric data, but no reliable explanation can be given for the fall in melting point from potassium to sodium amide. Attempts to discover a suspected high-temperature modification with a coordination number of 6 remained unsuccessful.

## 7. Imide Formation by Thermal Decomposition

Sodium, potassium, rubidium, and cesium form no imides, although imides are readily formed by thermal decomposition of lithium and the alkaline earth amides. Investigations concerning the formation of these compounds are made difficult by the slow rates at which pressure equilibria are attained. To explain the crystallographic changes occurring during the amide-imide transformation, the degradation products were also subjected to X-ray structural analysis. It was shown that the structures of the amides and imides were markedly similar, and that during the degradation *mixed crystals* appeared which are distinguished by the simultaneous occurrence of both $NH_2^-$ and $NH^{2-}$ ions.

Lithium amide decomposes to form lithium imide at 300–400 °C [48, 49]. Initially ammonia is given off without the formation of a new phase. The mixed crystals with the amide structure exist until 25 % of the $NH_3$ has been liberated; lithium imide then appears as a new phase on removal of more ammonia.

Table 2 shows the distribution of the ions in the lattice in schematic form. The $LiNH_2$ unit cell corresponding to two deformed zinc blende cells contains $2\times4$ anions and $2\times4$ lithium ions in the tetrahedral interstices; further tetrahedral interstices are unoccupied. In the mixed crystals derived from lithium amide, the anion lattice is predominantly occupied by $NH_2^-$ and partly by $NH^{2-}$ ions. A number of lithium ions, equivalent to the additional charge of the $NH^{2-}$ ions, leave the cation lattice and enter into the unoccupied tetrahedral interstices of the face-centered cubic anion lattice [14].

The same behavior is observed during the decomposition of calcium amide to calcium imide [11] (cf. Table 2, B). However, here the cations are in octahedral instead of tetrahedral interstices of the face-centered cubic anion lattice, and the mixed crystals are based on the imide rather than on the amide.

With the alkaline earth compounds, the transformation of the mixed crystals into the imides occurs without the appearance of a new phase but with an increase in volume. Evidently, here the filling of the interstices is more important than the replacement of the amide ions by the smaller imide ions.

The magnesium amide/magnesium imide system [14] behaves crystallographically in a different manner. Amide/imide mixed crystals are again formed on thermal degradation of the amide, but other structures appear.

Since the chemical and physical properties of the amides and hydroxides have much in common, similar relationships should exist for *oxides* and *imides*. In the ammonia system, imides correspond to oxides in the aqueous system.

The imides react with ammonia at elevated temperature to form amides. The latter are not very resistant toward air and moisture, and the imides react explosively with water. Lithium nitride and the alkaline earth nitrides are much less sensitive.

One notable difference between oxides and imides is to be found in their colors. The alkaline earth oxides are all white, but magnesium imide is pale yellow. The yellow color deepens progressively in the order MgNH $<$ CaNH $<$ SrNH $<$ BaNH, barium imide being deep ochre.

[48] *O. Ruff* and *F. Georges*, Ber. dtsch. chem. Ges. *44*, 504 (1911).
[49] *R. Juza* and *K. Opp*, Z. anorg. allg. Chem. *266*, 325 (1951).

Both oxides and imides have simple crystal structures. Lithium imide [49] crystallizes in the cubic antifluorite lattice, and is isotypic with lithium oxide. Calcium, strontium, and barium imides [13], like the corresponding oxides, crystallize in the sodium chloride lattice.

Table 2. Phases occurring on thermolysis of $LiNH_2$, $Ca(NH_2)_2$, and $LiMg(NH_2)_3$.

[*] $\overline{LiNH_2}$; $\overline{NaCl}$ indicate deformed lattices with a certain breadth of phase boundary. $CaF_2$ indicates the antifluorite lattice.

$\square$ indicates vacant tetrahedral or octahedral interstices in the anion lattice.

The $NH^{2-}$ ion is isoelectronic with the $O^{2-}$ ion but, like $NH_2^-$, it must be regarded as dipole ion. Neutron diffraction experiments on calcium imide [50] have shown that the protons in the crystal are probably free to rotate about the nitrogen atom. It is possible that fixation of the $NH^{2-}$ dipole occurs in magnesium imide, which has a complicated crystal structure [14].

The enthalpies of formation and lattice energies of the imides of Ca, Sr, and Ba have been calculated [51]. Since the compounds are isotypic, the oxides with their comparatively small $O^{2-}$ ions have the greatest lattice energies, the imides have lower lattice energies, and the sulfides the lowest.

## 8. Ternary Amides and Imides

Ternary amides of the alkali and alkaline earth metals have been known for a long time in addition to the binary amides and imides.

Some of the alkaline earth metals react only very slowly with liquid ammonia to form the corresponding amides. If a solution of an alkali metal amide is added, *e.g.* $KNH_2$, then the reaction

$$2\,KNH_2 + Mg \rightarrow Mg(NH_2)_2 + 2\,K$$

occurs rapidly. The alkali metal dissolved in the ammonia can be readily detected, but its quantitative separation is hardly possible since it reacts further to reform the amide. Only rarely two separate amides are the end-products; in general, ternary amidometalates are formed, *e.g.* $BeNK\cdot 2\,NH_3$, $Mg(NHK)_2\cdot 2NH_3$, $CaNK\cdot 2\,NH_3$, $SrNK\cdot 2\,NH_3$, and $BaNK\cdot 2\,NH_3$. These metathetical reactions have been the subject of some earlier papers [52–54].

These ternary compounds used to be formulated as the ammoniates of ternary nitrides or imides, *e.g.* $BeNK\cdot 2\,NH_3$, but it is probable that they are in fact ternary amides. It cannot yet be decided whether the compounds should be represented as "double amides", *e.g.* $KBe(NH_2)_3$, or as complexes, *e.g.* $K[Be(NH_2)_3]$, potassium triamidoberyllate.

In one solitary case it has been possible to confirm the formation of a ternary compound. During the preparation of the ternary nitride LiMgN [55], it was observed that LiMgN can take up ammonia; the problem was then to decide whether the ammoniate of a ternary nitride, a ternary amide, or a ternary imide, is formed. It was found that a *lithium magnesium amide* [14], written as $LiMgN\cdot 2\,NH_3$ according to the old mode of formulation, was formed from lithium and magnesium in liquid ammonia and also during the reaction of LiMgN or of a stoichiometric $Li_3N/Mg_3N_2$ mixture at higher temperatures (350 °C) and elevated pressures of ammonia (10 atmospheres). The X-ray diagram of $LiMg(NH_2)_3$ is identical with that of $Mg(NH_2)_2$ if slight differences in intensity are disregarded. From experiments with varied Li:Mg ratios it appears that $LiMg(NH_2)_3$ is the terminal member of a series of mixed crystals starting with $Mg(NH_2)_2$. The fact that lithium and magnesium can replace each other corresponds to the similarity of their ionic radii. Since magnesium amide, whose complicated structure is still

[55] *R. Juza* and *F. Hund*, Z. anorg. allg. Chem. *257*, 1 (1948).

unknown, assumes a coordination number of 4 according to molecular volume considerations, filling of the tetrahedral interstices is indicated in Scheme C of Table 2, but no precise information on this aspect is as yet available.

Lithium magnesium amide can be degraded isothermally, reversible pressure equilibria being established. The end-product of the thermal decomposition is a new phase with the composition $LiMgN \cdot {}^1/_2\ NH_3$, which is a *lithium magnesium imide* [56] of formula $Li_2Mg_2(NH)_3$ and which is isotypic with lithium amide. When the composition deviates from the 1:1 cation ratio, X-ray reflections due to either MgNH or $Li_2NH$ appear in addition to those of the ternary imide. Accordingly, the ternary imide phase has a limited range of stability.

As shown in Table 2, the substances discussed in Sections 7 and 8 are characterized by extraordinary mutual interchangeability of their ions. During the degradation of lithium and calcium amides, $NH_2^-$ and $NH^{2-}$ ions are found together at anionic positions and one kind of metallic ions or vacancies at the cationic sites. In the ternary compounds, the anionic positions are occupied by one kind of anion, while the cationic sites are occupied by two different metallic ions or remain empty. Occupation of the lattice sites is partly ordered and partly random.

# The Chemical Composition of the Stars [*]

BY PROF. DR. A. UNSÖLD

INSTITUT FÜR THEORETISCHE PHYSIK UND STERNWARTE
DER UNIVERSITÄT KIEL (GERMANY)

*The abundances of the elements in the atmospheres, i.e. the directly observable layers, of the stars are related to the energy production by nuclear processes in the interior of the stars and to their evolutionary states. For purposes of quantitative analysis of a given stellar spectrum, several "model atmospheres" are first calculated, assuming tentative numerical values for the effective temperature $T_e$, for the gravitational acceleration g at the surface of the star, and for the relative abundances of the more important elements. The appropriate temperature distribution is obtained from the theory of radiative equilibrium in conjunction with the quantum theory of the continuous absorption coefficient; the pressure stratification is obtained from the hydrostatic equation. Evaluation of the Fraunhofer lines requires a theory of line absorption coefficients and line widths. In conclusion, the final numerical values for $T_e$, g, and the abundances of the elements in the stellar atmosphere are determined by comparison of the calculated spectra with the measured spectrum of the star. The main sequence stars and the hot supergiants, i.e. the star population I of the spiral arms and the disk population of the Milky Way, all have the same chemical composition, which coincides with that of the interstellar medium. In the old population II stars of the galactic halo (high velocity stars, subdwarfs), on the other hand, the abundance of all the heavy elements relative to that of hydrogen is reduced by a factor of as high as 200, possibly even 500; hydrogen seems to be the original material of our Milky Way. In helium stars, almost all the hydrogen has been transformed into helium even in the atmosphere; it is likely that these are well mixed stars.*

## I. Introduction [1]

Qualitative identification of many elements in the atmospheres of the sun and the stars was made possible by the laws of spectral analysis discovered by *Kirchhoff* and *Bunsen* in 1859. In addition, the relationship discovered by *Kirchhoff* and named after him between the emission and absorption of radiation under conditions of thermodynamic equilibrium became one of the most important

fundamentals for the quantitative analysis of solar and stellar spectra. However, fruitful application of these discoveries to astrophysics came only after the twenties, when quantum theory provided deeper insight into the relationships between atomic structure and spectral lines and thus led to a better understanding of the behavior and radiation of matter under cosmic conditions.

The modern theory of stellar spectra began in 1920 with *Saha*'s theory of thermal ionization. Quantitative analysis of cosmic spectra was developed in the next two decades, following the work of *K. Schwarzschild*, *Eddington*, and *Russell*. An exciting feature of this development is the fact that the abundances of the chemical elements in the various stellar atmospheres (*i.e.* in the directly observable stellar layers) can be related to recent concepts concerning the energy production in stellar interiors by nuclear processes. Hence, our data can also be applied to problems of stellar evolution, primarily in connection with the relationship between nuclear reactions and the abundance of the lighter elements. However, the heavy elements are also involved, since the arguments for abandoning the long popular "Big Bang" theory are becoming more and more convincing, and the newer theories assume the creation of the heavy elements to take place during specific phases of stellar evolution. It thus appears fitting to preface our actual subject with some remarks concerning the evolution of stars and of the Milky Way.

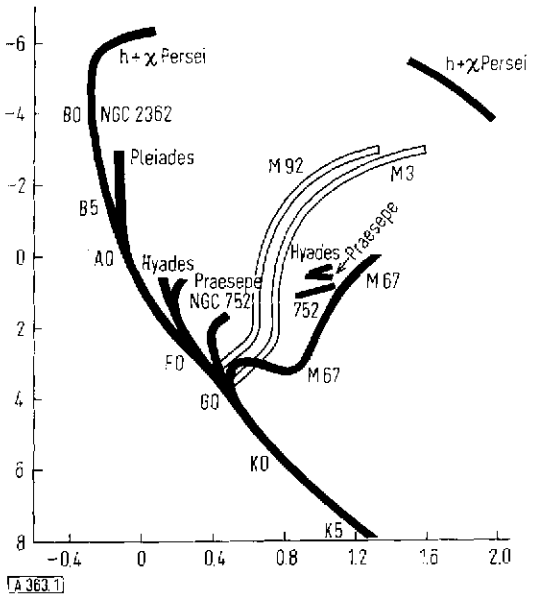

Fig. 1. Color-magnitude diagrams or Hertzsprung-Russell diagrams of the galactic star cluster h + χ Persei, NGC 2362, Pleiades, Hyades, Praesepe, NGC 752, M 67, as well as of the globular star clusters M 92 and M 3 (after [2]).

Abscissa: Color index B—V.

Ordinate: Absolute visual brightness $M_V$ (based on a distance of 10 parsec = 32.6 light years).

The spectral types S are indicated along the main sequence. The position at which the diagram of a cluster deviates towards the right from the main sequence characterizes its age. The age is only 3 million years for h + χ Persei and about 10 billion years for the oldest galactic star clusters, *e.g.* M 67 and the globular star clusters (which belong to the galactic halo).

## 1. Evolution of Stars

According to present-day concepts, the life of a star proceeds approximately as follows: Interstellar matter with a density of approx. $10^{-23}$ g/cm$^3$ gradually forms a cloud with a mass exceeding that of the sun by a factor of several hundred to thousand. This cloud then breaks up, and further localized condensation yields numerous stars, a so-called stellar association or star cluster. The evolution of these stars may be followed on the Hertzsprung-Russell diagram or its equivalent, the color-magnitude diagram (Figure 1). In such a diagram, the abscissa indicates the spectral type (color index) or temperature of the star, and the ordinate gives either its absolute brightness (based on a distance of 10 parsec = 32.6 light years) or luminosity (based on that of the sun). The changes occurring during the life-time of a star are recorded in this diagram: A young star begins on the right as a distended cool mass which heats up moving to the left during its contraction phase. Contracting stars are apparently quite unstable, like the rapidly varying T Tauri and RW Aurigae stars. The atmospheres of the latter show evidence of powerful eruptions, so-called flares, perhaps involving nuclear reactions due to high-energy particles.

At the end of a 20-million-year contraction process, a star with a mass equivalent to that of the sun is compressed to such an extent that the temperature in its interior reaches some $10^7$ °K, and the transformation of hydrogen to helium begins. In smaller stars (up to a mass slightly larger than that of the sun), this conversion proceeds by direct fusion; in heavier stars with somewhat higher central temperatures, it proceeds by the nuclear reaction cycle discovered by *Bethe* and *von Weizsäcker* in 1938:

$$^{12}C(p,\gamma)^{13}N(\beta^+\nu)^{13}C(p,\gamma)^{14}N(p,\gamma)^{15}O(\beta^+\nu)^{15}N(p,\alpha)^{12}C$$

which uses carbon and nitrogen as catalysts, so to speak. The star is now located on the main sequence of the Hertzsprung-Russell diagram. It remains there in a quasi-steady state until about 10 % of its hydrogen is fused to helium. With cooler stars (whose temperatures are, at the most, slightly higher than that of the sun), this process takes longer than the entire "history of the world" (astronomically speaking, *i.e.* about 10 billion years). On the other hand, hot stars burn their hydrogen very rapidly; *e.g.* the well-known blue stars in Orion were formed at a time at which our oldest ancestors just prepared to come down from the trees.

[2] *H. L. Johnson* and *A. R. Sandage*, Astrophys. J. *121*, 616 (1955).

At the end of this period, *i.e.* after about 10 % of its hydrogen is used up, the further development of a star depends critically on whether the burned-out matter in its interior is steadily mixed with fresh material, or whether it remains in the innermost region as a burned-out helium core. Mixing of stellar material takes place only in exceptional cases; a helium core is the rule. In the latter case, the shell in which the energy production by nuclear processes is going on in the star spreads outwards from the center; the star expands and becomes a red giant, located in the upper right portion of the Hertzsprung-Russell diagram. What happens beyond this stage has not yet been sufficiently studied. Later on the process of formation of heavy 4n-nuclei $^{12}C$, $^{16}O$, *etc.* from $^{4}He$ at even higher temperatures probably becomes the principal factor in energy supply.

The abundance distribution indicates that at some stage heavy elements may also be formed; this might occur during catastrophic processes (supernovae?) and would involve large numbers of free neutrons. During such a catastrophic process, the star gives back an appreciable portion of its material to the interstellar gas; this material has, of course, been chemically changed by the nuclear reactions. More is known about the next stage of stellar evolution; the star finally ends up as a white dwarf consisting of degenerate matter (mostly helium) of enormous density.

### 2. Evolution of the Milky Way

The evolution of stars takes place as part of the overall development of the galactic system (Figure 2). Our galaxy started – as we shall show later – as an almost spherical cloud of hydrogen, which then produced the first stars; these consisted of almost pure hydrogen.

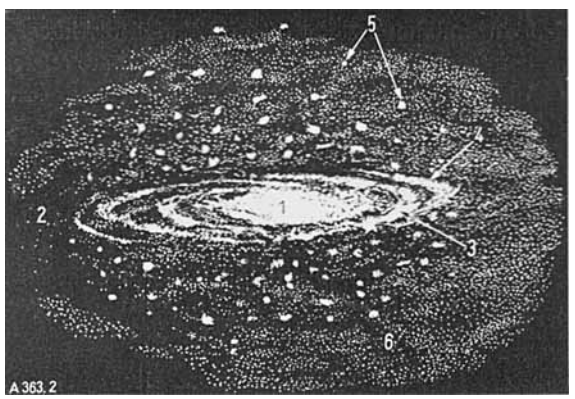

Fig. 2. Schematic diagram of the structure and population groups of the Milky Way (after [3]).
1: Nucleus; 2: disk; 3: galactic star cluster; 4: spiral arms; 5: globular star cluster; 6: halo.

These oldest stars – insofar as they still exist – constitute the Milky Way halo; they move around the galactic center in highly elliptical orbits and are recognizable as the so-called high-velocity stars and subdwarfs. The galactic disk, whose stars now execute almost circular orbits around the galactic center, was formed simultaneously with the first stellar generations, *i.e.* during a period in which more and more hydrogen was converted into helium and heavy elements; it is perpendicular to the axis of rotation of the original Milky Way. The old stars, including our sun, have all practically identical chemical compositions, namely that of the present-day interstellar gas from which they did in fact originate. Accumulations of this gas in the galactic disk later produced the spiral arms of the Milky Way. Exactly how this occurred remains a very difficult problem of magnetohydrodynamics. In these spiral arms we find *inter alia* young, bright blue stars of high mass (O and B stars), whose age cannot exceed one to ten million years, if only for reasons of energy supply.

We thus see that the various parts of our Milky Way are populated by stars of different ages and – as we would anticipate – of different chemical compositions. We speak of different star populations, of the halo population II, the disk population, and the extreme population I of the spiral arms. The classification of stellar populations by *W. Baade* was probably one of the most important discoveries of modern astronomy.

## II. Quantitative Analysis of Stellar Spectra

### 1. Observational Data; Profiles and Equivalent Widths of the Fraunhofer Lines

The spectrum of the sun can be recorded at high dispersion and a resolving power of $\lambda/\Delta\lambda \approx 10^6$. The observatories in Utrecht (Holland), Ann Arbor (Michigan, U.S.A.), Göttingen (Germany), and elsewhere have prepared photometric atlases (Figure 3), from which the intensity distribution in the lines, *i.e.* the line profiles,

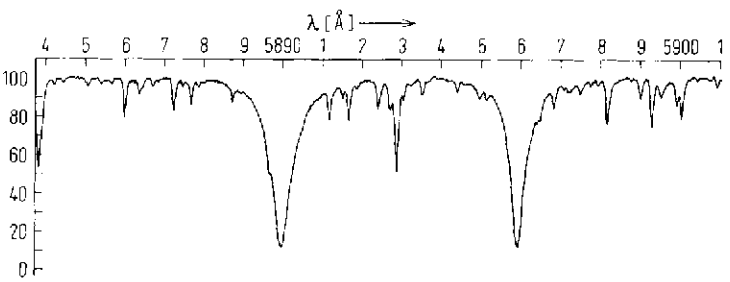

Fig. 3. Utrecht photometric atlas of the solar spectrum; sodium D-lines $\lambda$ = 5889.96 and 5895.93 Å.

can be obtained. However, while any line profile is a very sensitive function of the resolving power of the spectrograph, the energy absorbed in the line is independent thereof. It is therefore advantageous, particularly for stellar spectra of small dispersion, to measure the equivalent width $W_\lambda$ (Figure 4). The latter gives the width (in angstroms or milliangstroms) of a rectangular strip in the spectrum whose area, as a measure of the absorbed energy, is equal to that of the line profile.

The largest reflecting telescopes and spectrographs are just sufficient for obtaining suitable stellar spectra. Thanks to the cooperation of American colleagues, I was able to make use of excellent telescopes and spectrographs in American

[3] *A. Unsöld*, Naturwissenschaften *47*, 76 (1960).

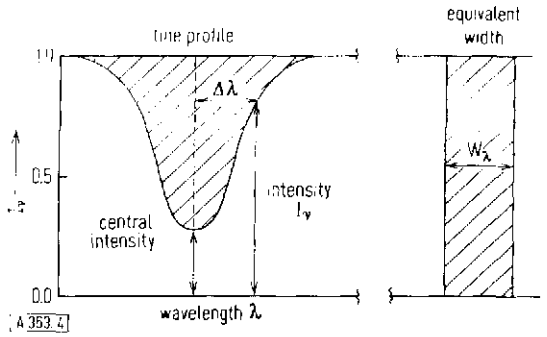

Fig. 4. Profile and equivalent width $W_\lambda$ of a Fraunhofer line.

observatories. With the 100-inch Hooker telescope of the Mount Wilson Observatory at Pasadena, Calif., one can obtain satisfactory spectra of 7th magnitude stars, *i.e.* stars just below the limit of visibility of the naked eye, in the photographic region ($\lambda$ = 3200–4900 Å) with a dispersion of 10 Å/mm and in the visual region ($\lambda$ = 4800–6800 Å) with 15 Å/mm. It is often also useful to take infrared spectra up to $\lambda \approx 8800$ Å. All the plates used are of course provided with photometric density scales so that the profiles or equivalent widths of the lines can be measured (this is best done with a directly recording microphotometer). For example, one of our recent investigations, the analysis of the A2-supergiant α Cygni (by *H. G. Groth*), is based on the measurement of some 800 lines.

## 2. Physics of Stellar Atmospheres

Measurements such as those described above serve as a basis for the determination of the parameters which characterize the atmosphere of a given star. These parameters include the effective temperature $T_e$, which is defined in conformity with the Stefan-Boltzmann radiation law, the radiant energy flux per cm² of the stellar surface being $\pi F = \sigma T_e^4$. Another essential quantity is the gravitational acceleration g (cm/sec²) at the surface of the star [4]. Last, but not least we want to determine the chemical composition of the stellar atmosphere, *i.e.* the abundance of all the elements.

It is readily appreciated that $T_e$, g, and the abundance of the elements completely determine the structure, *i.e.* the temperature and pressure distribution, of a static atmosphere. If we are dealing with stars of uniform composition, the theory of the internal constitution of the stars further requires the existence of a relationship between their mass, their luminosity, and $T_e$, *Eddington*'s well known mass-luminosity relation. If such a relationship exists, then $T_e$ and g are also related in a simple manner to the two parameters of the Hertzsprung-Russell diagram, namely $T_e$ and the luminosity L (or the absolute brightness $M_v$). For stars with the same effective temperature $T_e$, the gravitational acceleration g is related to the mass M and the radius R of the star in a simple manner. On the other hand, the luminosity L (or the absolute magnitude $M_v$) depends only on the size of the star, *i.e.* on its radius R. By using the mass-luminosity relation, we can calculate (again for stars of the same effective temperature $T_e$) the relationship between g and L (or $M_v$). Thus, $T_e$ and g determine the position of the star on the Hertzsprung-Russell diagram or – in other words – its spectral type S and its luminosity class LC. These two parameters are used in the classification of stellar spectra, for example, in the well known Morgan and Keenan classification.

However, a two-parameter classification of stellar spectra does not suffice for all stars. Apart from differences in chemical composition, we must also take into account turbulent motions, magnetic fields, rapid rotation, and possibly even further quantities, all of which must be derived from the same observational material.

The complexity of the task suggests use of a method of successive approximation. Our first question is thus: what type of spectrum (equivalent widths, intensity distribution in the continuum) would be given by an atmosphere of proposed $T_e$, g, and fixed chemical composition, according to theory? In other words, we calculate a so-called model atmosphere. We then investigate how the measured quantities (*e.g.* the $W_\lambda$ of some of the elements) and the various stages of ionization fit our calculations. Finally, the parameters are revised until as good an agreement as possible is achieved between the model atmosphere and the measured spectrum. These cumbersome calculations are greatly facilitated nowadays by electronic computers.

The temperature distribution in a stellar atmosphere is determined by the nature of the energy transfer. *K. Schwarzschild* recognized in 1905 that in stellar atmospheres energy is transported primarily by radiation; we speak of radiative equilibrium. The mathematical problem involved is simple, provided the continuous absorption coefficient $\varkappa$ is independent of frequency or can be replaced by a mean value taken over the entire spectrum – the so-called Rosseland opacity coefficient $\bar{\varkappa}$. Unfortunately, however, this approximation is mostly insufficient, and one is forced to solve an infinite system of differential or integral equations, one for each frequency; the latter are related by an integral relation expressing the constancy of the total radiative flux, *i.e.* the conservation of energy.

Several atomic processes affect the continuous absorption coefficient $\varkappa$ (Figures 5 and 6), including

1. bound-free and free-free transitions of hydrogen atoms (particularly in hot stars);

2. bound-free and free-free transitions of the negative hydrogen ions $H^-$ (in cooler stars).

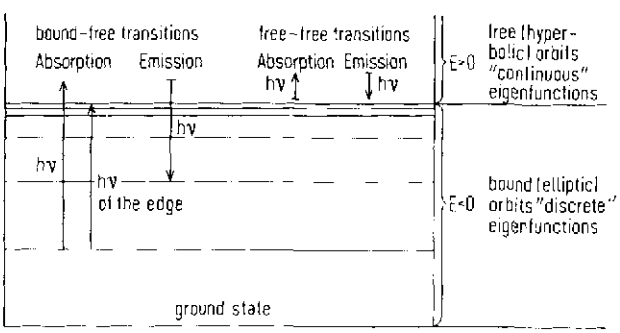

Fig. 5. Formation of continuous atomic spectra. Bound-free and free-free transitions.

[4] We can calculate the effective temperature $T_e$ for the sun directly from the solar constant, and its gravitational accelleration g from its mass and radius, and obtain $T_e$ = 5780 °K and g = $2.74 \times 10^4$ cm/sec², *i.e.* 28 times the gravitational acceleration at the earth's surface.

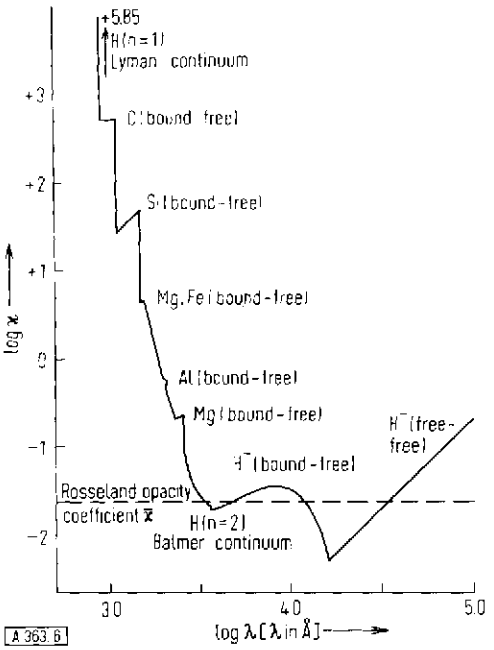

Fig. 6. Continuous absorption coefficient $\varkappa$ per gram of solar matter at $T = 5040\,^{\circ}K$ ($\Theta = 1$) and $\log P_e = 0.5$, or $P_e = 3.16$ dynes/cm² (after [5]).

In addition, smaller but still not negligible contributions are due to continuous absorption by HeI and HeII (in hot stars) and by metals (in cooler stars), and to the scattering of light by free electrons (Thomson scattering; in hot stars) and by neutral hydrogen atoms (cooler stars). Our knowledge concerning the continuous spectra of molecules in cooler stars is still rather scant.

The type of relationship existing between the elementary processes of absorption and emission is crucial for calculating the energy transfer by radiation. To start these calculations, one tries to get along with Kirchhoff's law, *i.e.* one assumes local thermodynamic equilibrium, although – strictly speaking – the existence of a radiative flux is, of course, not compatible with thermal equilibrium. In order to justify this approximation theoretically, one would have to prove that the relaxation times of all essential elementary processes are sufficiently short. So far, this has been possible only for the $H^-$-absorption prevailing in cooler stars, *e.g.* the sun. To begin with, it can be shown that despite deviation of the radiation field from Planck's formula, the electrons and heavy particles possess a Maxwellian velocity distribution, which we may then use for defining a "local temperature". Negative hydrogen ions are formed primarily by the process of "associative detachment" (*Dalgarno, Pagel*):

$$H + H^- \rightleftharpoons H_2 + e^-$$

Finally, the $H_2$ molecules, which are important despite their low concentration, are formed by three-body collisions of the many H atoms present. In this manner, local thermodynamic equilibrium is assured.

Similar theoretical treatment may also be applied to the ionization of the atoms. On the other hand, with regard to the occupation numbers of excited states (relative to the ground state), we must still content ourselves with verification of the assumption of local thermodynamic equilibrium by means of observational data.

In addition to radiative energy transfer, transport by convection plays an important role in somewhat deeper layers of cooler stellar atmospheres. Convection currents arise in the zones where the atomic hydrogen is partly ionized. If in such a hydrogen-convection zone, for example, in the solar atmosphere, a partly ionized volume element rises to cooler regions and the hydrogen recombines via the reaction $H^+ + e^- \rightarrow H$, the heat of recombination (which corresponds to about 25 kT!) is liberated, so that the temperature of the volume element remains higher than that of the surroundings. It therefore continues to rise – like a hot air balloon – and a convection current is set into motion. Incidentally, this hydrogen convection zone is essentially the cause not only of the granulation of the solar surface, but also of sunspots, of the phenomena of solar activity, and thus also of the hyperthermal phenomena (radio frequency radiation, cosmic rays) of the "disturbed sun".

A small portion of the energy flux of the sun is also emitted by the upper layers of the convection zone in the form of sonic, shock, and other waves. Slightly higher up, the dissipated energy can no longer be radiated away because the density of the matter is small. This in turn results in heating of the solar corona to the enormous temperature of about one million degrees. Similar processes probably occur to a significant degree in the outermost layers of the other cool stars.

In high temperature supergiants, *e.g.* $\alpha$ Cygni, 55 Cygni, we also encounter energy transfer through irregular oscillations of the entire star mass, a movement which in the stellar atmosphere assumes more or less the character of shock waves.

The motions in stellar atmospheres are important in our considerations, not so much because of their contribution to the energy transport as because of their direct effect on the line spectrum. We shall discuss this phenomenon later.

The calculation of the pressure distribution is much simpler than that of the temperature distribution. The increase in gas pressure $P_g$ with depth t of the stellar atmosphere can usually be computed by means of the hydrostatic equation

$$dP_g/dt = -g\rho$$

where $\rho$ is the density, and g is again the gravitational acceleration. In hot stars, we must also take the radiation pressure into account, in addition to the gas pressure. The dynamic pressure of turbulent motions is of importance in some stars. In sunspots and Ap stars, where magnetic fields of several thousand gauss exist, we must also take into account the forces generated by these fields.

For the calculation of model stellar atmospheres, extensive tables listing various data as functions of the temperature T and the electron pressure $P_e$ are of vast help. Thus, given a mixture of elements for a particular model, one is able to obtain directly from these tables the gas pressure $P_g$, the mean molecular weight $\mu$, the continuous absorption coefficients $\varkappa$ for many frequencies and their Rosseland mean value $\bar{\varkappa}$, the specific heats $c_p$ and $c_v$, as well as other thermodynamic quantities.

### 3. Quantitative Theory of Fraunhofer Lines

In practice, the problem of radiative energy transfer can be treated also for spectral lines to a considerable extent by assuming local thermodynamic equilibrium,

[5] *G. Bode*, Ph. D. Thesis, Universität Kiel 1964.

*i.e.* by applying Kirchhoff's law. An approximation, which in the limiting case reduces to local thermodynamic equilibrium, is favored precisely by the enormous variety of elementary processes possible (consider for example, the crowded energy level diagram of the iron atom). On the other hand, explicit justification of this approximation by means of kinetic calculations is so complicated that despite tremendous efforts, the calculations of theoreticians have so far produced only meager results.

If, for example, the center of the solar disk emits radiation of frequency $\nu$, its intensity $I_\nu$ in a line can be calculated by the following procedure: The emission of radiation in a layer of thickness dt, situated at a depth t, is proportional to both the Kirchoff-Planck function $B_\nu(T)$, where T is the prevailing local temperature, and the absorption coefficient, which is composed of a continuous component $\varkappa$ and of the specific line absorption coefficient $\varkappa_\nu$ for the frequency $\nu$. Up to the point where it leaves the stellar atmosphere, the intensity of the emitted radiation $(\varkappa + \varkappa_\nu)B_\nu(T)$ is reduced by an absorption factor $e^{-\tau_\nu}$, where $\tau_\nu = \int(\varkappa + \varkappa_\nu)dt$ is the so-called optical depth (for continuous absorption plus line absorption). Thus, we finally obtain an important relationship for the observed intensity distribution $I_\nu$ in a Fraunhofer absorption line:

$$I_\nu = \int_0^\infty B_\nu[T(\tau_\nu)]\, e^{-\tau_\nu} d\tau_\nu$$

This expression forms the basis for the evaluation, *e.g.* of the Utrecht photometric atlas.

The pure continuum, which is the basis of the measurements, is obtained simply by neglecting the line absorption coefficient $\varkappa_\nu$. Our formula shows that if $\varkappa$ and $\varkappa_\nu$ are the same functions of depth, then the continuum and the wings of the lines originate mainly at an optical depth of $\tau_\nu \approx 1$. On the sun, however, the concentration of the neutral metal atoms, such as FeI, TiI, decreases so rapidly with depth in the atmosphere (owing to increased ionization) that their Fraunhofer lines, which dominate the spectrum, are mainly formed at optical depths of 0.05 to 0.1 only.

Calculation of the line absorption coefficient $\varkappa_\nu$ (per atom of the element, for example) as a function of the temperature T, electron pressure $P_e$ (or gas pressure $P_g$), and the distance from the line center ($\Delta\nu$ in frequency units or $\Delta\lambda$ in wavelength units) is not quite as simple. The following effects contribute to the line absorption coefficient (Figure 7):

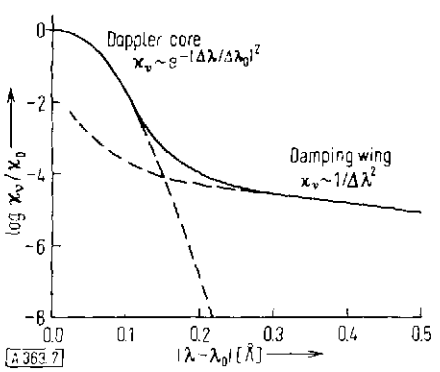

Fig. 7. Line absorption coefficient $\varkappa_\nu$ (referred to $\varkappa_0$ for the line center). Doppler core and damping wings of the sodium D-lines, calculated for T = 5700 °K and pure radiation damping.

1. The Doppler effect due to thermal velocities of particles and turbulent motions. The thermal velocities of, for example, the Fe atoms in the solar atmosphere ($T \approx 5700$ °K) amount to 1.3 km/sec, corresponding to a Doppler width $\Delta\lambda_D = 0.017$ Å in the line at $\lambda = 3860$ Å. The Doppler distribution of the line absorption coefficient, corresponding to the Maxwell velocity distribution of the atoms, is $\varkappa_\nu \sim \exp-(\Delta\lambda/\Delta\lambda_D)^2$. Turbulent motions usually give rise to similar velocities.

2. Damping. Radiation damping is always present, and in addition – at somewhat higher pressures – there is collision damping. Both effects are based on the fact that (in the language of classical theory) a sine-wave train emitted by an atom has a limited length or time of duration due to emission by the atoms themselves and possibly also to perturbations by collisions with other particles. The spectral analysis of such a wave train necessarily produces a line having a finite width in the frequency or wavelength scale. In a largely ionized gas, collisions with free electrons are an important factor; in cooler stars, line-broadening collisions with neutral H atoms usually predominate. The actual damping width is always considerably smaller than the Doppler width, but for damping in the line wings, the absorption coefficient decreases only $\sim 1/(\Delta\lambda)^2$, where $\Delta\lambda$ = distance from the line center. In effect, damping thus always predominates over the Doppler effect in the line wings (Figure 7).

The absolute magnitude of the absorption coefficient is always normalized by the quantum theoretical relationship

$$\int \varkappa_\nu d\nu = (\pi e^2/mc) \cdot N \cdot f$$

In this equation, e and m are the charge and mass of the electron, respectively, c is the velocity of light, N the number of atoms in the absorbing quantum state, and f the oscillator strength. The oscillator strengths f used here are proportional to the well-known Einstein transition probabilities. Since analysis of a spectrum thus always yields the number of atoms N only in terms of the combination N·f, the determination of exact oscillator strengths is one of the most important and complicated problems for the astrophysicist.

a) For hydrogen and HeII, the f values can be calculated exactly from quantum theoretical considerations.

b) *Bates* and *Damgaard* have developed a very useful approximation method for more or less hydrogen-like spectra (in particular, for systems with 1, 2, or 3 outer electrons).

c) For the spectra of ions and atoms with several outer electrons, so-called complex spectra, one can start by making relative measurements of line emission (*e.g.* in an electric arc or a King furnace) or absorption (King furnace) and calibrate them by measuring the absolute f values for a few selected lines of the atom or ion. The main difficulty lies in the problem of measuring directly the number of absorbing or emitting atoms. For example, a sample can be placed in a sealed quartz absorption tube in the electric furnace. Numbers of atoms have also been determined in electric arcs and in atomic beams. Most recently, direct electronic measure-

ments of the decay constants of single atomic states and hence also of transition probabilities have been accomplished. It is to be hoped that this method -- which no longer requires determination of the number of particles – will also allow measurements of transition probabilities in ionized atoms, which so far have completely eluded experimental approach.

Let us now examine the manner in which the profile or equivalent width $W_\lambda$ of a Fraunhofer line increases with the concentration of the emitting atoms N [or their product with f and with the statistical weight g of the lower atomic state, which always enters as a factor] (Figure 8). As already mentioned, in the inner part of

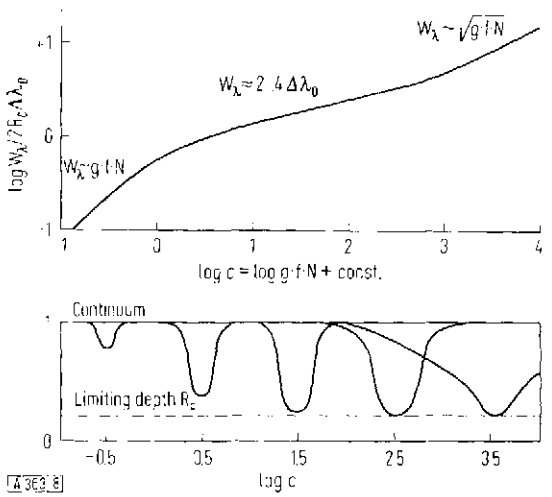

Fig. 8. Curve of growth. The equivalent width $W_\lambda$ – referred to a strip having twice the Doppler width $\Delta\lambda_D$ and a depth $R_c$ – is plotted as a function of the concentration of the absorbing atoms, *i.e.* of log (g·f·N) + const.

It was assumed that the continuous and the line absorptions depend upon depth in the atmosphere in the same way, and that the damping width is $^1/_{50}$th of the Doppler width.

The line profiles (below) illustrate the formation of the curve of growth.

the lines, the absorption coefficient is determined by the Doppler effect; further out toward the edges of the line are the damping wings, in which the damping constants $\gamma$ are determined by radiation and collision damping. Thus, we obtain the curve of growth which is very important for the evaluation of stellar spectra: Weak lines simply reflect the Doppler distribution of the absorption coefficient $\varkappa_\nu \sim \exp-(\Delta\lambda/\Delta\lambda_D)^2$ at the line center, and $W_\lambda$ is obviously proportional to g·f·N. With increasing g·f·N, the line center attains a maximum depth $R_c$. The reason for this is that the radiation received is only emitted by the uppermost layers, whose temperature (according to the theory of radiative equilibrium) approaches a certain limiting value. In addition, the line broadening by damping is not very pronounced at first; we thus obtain relatively sharp, deep lines and the curve of growth becomes rather flat.

This behavior changes only when g·f·N increases still further, *i.e.* when the line broadens into the damping wings. There the line absorption coefficient is $\varkappa_\nu \sim g \cdot f \cdot N \cdot \gamma/(\Delta\lambda)^2$. It follows that, at a fixed depth in the line (*i.e.* for $\varkappa_\nu$ = const.), the line width $\Delta\lambda$ (and thus also the equivalent width $W_\lambda$) increases proportionally with $\sqrt{g \cdot f \cdot N \cdot \gamma}$ The stronger lines of the solar spectrum, *e.g.* the sodium D-lines as well as the H- and K-lines of CaII, lie on this damping branch of the curve of growth.

The hydrogen lines are of special importance. Inasmuch as they exhibit particularly strong linear splittings in an electric field due to the Stark effect, their broadening in partly ionized gases takes place mostly through the Stark effect of the statistically distributed fields of ions. This theory, originally developed by *Holtsmark*, has recently been refined (by *Griem* and *Kolb*, in particular) by taking into account non-adiabatic effects and the collision damping of electrons, and by an improved calculation of the microfield in the plasma.

## III. Abundance of Elements in the Atmospheres of Various Stars

So far, we have tried to present the methodology of the quantitative analysis of stellar spectra, at least in crude outline; we shall now turn to the results obtained. The accuracy with which the abundance of a given element can be determined in stars of various temperatures varies, of course, from case to case; the factors determining this are the number of lines by which the element is represented in the spectrum, the region of the curve of growth in which these lines lie, and, above all, the accuracy with which the oscillator strengths are known. As a rule, it can be said that, relatively to hydrogen as the most abundant element, the abundance of helium and of the lighter non-metals, which require high ionization energies, can best be determined in hot stars; on the other hand, the more easily ionized metals are best observed in cooler stars. Careful determinations give a probable accuracy $\Delta \log N = \pm 0.3$.

In Table 1, we have collected the results of careful spectral analyses for the following main sequence O and B stars: 10 Lacertae (O9 V), $\tau$ Scorpii (B0 V), $\gamma$ Pegasi (B2.5 V). (The spectral type S and the Morgan-Keenan luminosity class LC are given in parentheses.) The effective temperature $T_e$ and the gravitational acceleration g obtained in the course of the analysis of the spectrum are also given. Table 1 contains the logarithm of the number of atoms (log N) referred, as usual, to log N = 12 for hydrogen. Helium and the lighter elements up to Si or S are represented by transitions between highly excited levels, whose f values had been calculated rather accurately (*Glennon* and *Wiese*, 1962). The heavy elements can be expected only in high stages of ionization and consequently show no lines in the accessible spectral region.

The next group of stars shown in Table 1 are the hot supergiants, $\zeta$ Persei (B1 Ib) and 55 Cygni (B3 Ia), as well as the A stars $\alpha$ Lyrae (A0 V) and $\alpha$ Cygni (A2 Ia). The He lines are extremely temperature-sensitive and weak in the last two stars; He can thus be determined only with uncertainty. Instead, the lines of the ionized and neutral metals appear in large numbers below 10000 °K. Unfortunately, the data for the ionized metals will continue to be of very limited value until a greater number of reliable absolute measurements of their oscillator strengths become available. $\alpha$ Cygni is one of the brightest supergiants; its luminosity exceeds that of the sun by a factor of about 20000.

Table 1. Abundances (log N) of the elements in various stars. The logarithms of the numbers of atoms N were referred to log N = 12 for hydrogen. For the "old" stars γ Serpentis and HD 140283, and the helium star HD 160641, log N was further reduced in such a way that the values for the heavy elements are directly comparable.

We have incomparably better and more comprehensive observational data for the sun (G2 V) than for any other star; moreover, $T_e$ and g are known from independent measurements. The right-hand part of the sun's column in Table 1 shows the most recent and probably most accurate analysis (only for the more important elements), due to *Goldberg, Müller,* and *Aller* [16]. Earlier, *Weidemann* achieved about the same accuracy for some of these elements. The possible errors in the absolute f values naturally do not show up. As far as the cooler stars are concerned, there is still no acceptably satisfactory method of analysis.

The abundances of elements manifested in the stars which we have considered up to now are denoted as "normal" by the astronomer. Comparison of these abundances shows no differences which exceed the limits of error. Moreover, this abundance distribution in turn agrees – as far as can be verified – with that in the interstellar gas and in the galactic nebulae (*e.g.* the Orion nebula). The stars listed in Table 1 belong partly to the population I of the spiral arms (10 Lac up to 55 Cyg and α Cyg) and partly to the population of the galactic disk (α Lyr, sun). The analyses thus confirm the hypothesis that these stars were formed from the interstellar gas, and that the composition of the latter has not changed essentially since the formation of the galactic disk.

This picture changes if we consider the high-velocity stars and subdwarfs, *i.e.* the old stars of population II. For example, the F6 IV–V star γ Serpentis moves at 80 km/sec relative to our galactic vicinity and is thus a star of "moderately high" velocity. An accurate analysis shows that this star has, just at the limit of accuracy of the measurement, less of all the heavy elements than the stars previously discussed (the abundance decreases by $\Delta \log N = 0.24$, *i.e.* by a factor of 1.7, relative to hydrogen).

In the appreciably faster subdwarf HD 140283 (size and temperature are approximately those of the sun; the Morgan-Keenan classification for "normal" stars loses meaning in this case), all recognizable heavy elements, *viz.* C, Na, Mg, Al, Si, Ca, Sc, Ti, Cr, Mn, Fe, Co, Ni, and Sr, are less abundant than in the sun by a factor of 200. Within the limits of error, no differences between the abundances of the heavier elements can be distinguished. Quite recently *Wallerstein, Greenstein, Parker,*

[19] *L. H. Aller*, in: Colloque International d'Astrophysique, Liège (Belgium) 1953, p. 354. Radial velocity: + 100 km/sec; $M_V$ = −3. Reduced to log $N_{He\,(from\,H)}$ = 12.00 −0.60 plus log $N_{He\,(original)}$ = 11.20: together: 11.61. Concerning helium stars, cf. *A. R. Klemola*, Astrophys. J. *134*, 130 (1961).

and *Helfer* found some red giants (HD 122563, 165195, and 221170) with probably even smaller abundances of the heavy elements relative to hydrogen, and have asserted that individual differences exist in the abundances of the various elements.

Thus, the high velocity stars are those which have been formed at the very beginning of the evolution of our galactic system. The main sequence stars $\gamma$ Ser and HD 140283 have burned up only a small part of their internal hydrogen, while the red giants have already moved a bit further on the Hertzsprung-Russell diagram. The analytical data on the subdwarf HD 140283 must probably be interpreted to mean that the abundance ratios of the heavy elements in interstellar matter have changed amazingly little during the course of the evolution of our galactic system. The formation of the heavy elements must thus always have taken place under almost the same conditions. This is by no means easy to comprehend since the various groups of elements are formed by different nuclear processes.

The helium stars present completely different and highly interesting problems. Only few examples of these are known and, judging from their high radial velocities, they seem to belong to population II. Hot stars exhibit only very weak or no hydrogen lines, but show instead a very strong and complete helium spectrum. The lines for the heavy elements are more or less normal. Quantitative analysis of the star HD 160641 indicated a temperature of 30000 °K. Its abundance distribution of the elements (Table 1) can be interpreted to mean that while the star started with the normal mixture of elements (*e.g.* that of the sun), all of its hydrogen has by now been transformed to helium. A similar star, BD + 10° 2179, has recently been investigated by *Klemola*; the ratio of hydrogen to the heavy elements in its atmosphere is almost 1000 times lower than in normal stars. In this star, the relative abundances of the heavy elements are also almost normal (there is possibly less oxygen than normal). The cool and variable star R Coronae Borealis, which is very peculiar in many respects, probably also belongs to this group.

The formation of helium stars must probably be thought of as a process in which an old star with a burned-out helium core turns inside out; the dynamic causes of this anomalous evolution are still unknown.

The final stage of stellar evolution, the white dwarfs, have recently been investigated by *Greenstein* and (quantitatively) by *Weidemann*. The key to the understanding of their peculiar spectra is provided by their enormous gravitational acceleration $g \approx 10^8$ cm/sec$^2$ (for comparison, imagine having a weight of 10000 tons suddenly placed on one's legs!), as well as their large abundance of helium. Some of the stars show almost exclusively helium lines. According to *Weidemann*, the highly broadened hydrogen lines which another group of stars exhibits almost exclusively may be due to an extremely small hydrogen abundance in their atmospheres. The stellar interior must in fact be virtually devoid of hydrogen, since otherwise the star would soon explode by nuclear fusion.

So far we have discussed groups of stars whose "normal" or "anomalous" composition can be related to their evolutionary stage. In addition, there are stars which give spectra in which some element is represented unusually strongly or unusually weakly. Among the A stars there is a subsidiary sequence of "peculiar A stars" (Ap), followed by the "metallic-line stars". *Babcock* found on their surface non-uniformly distributed magnetic fields of several thousand gauss. The problem is then whether the anomalies in their spectra can be explained by assuming an anomalous structure of the atmosphere having normal element abundances, or whether large numbers of particles of very high energy, accelerated by magnetic fields, have appreciably changed the abundance of some elements by nuclear reactions? Studies at the Max-Planck-Institut für Physik in Heidelberg (Germany) have shown that high-energy $^3$He particles are formed during large solar eruptions.

The splitting of the spectral sequence in cool stars, which is probably related to the O:C:metals abundance ratio, also deserves mention. Finally, the $C_2$ bands show that there are – in cool stars, at any rate – appreciable variations in the $^{12}C$:$^{13}C$ isotope ratio. This is the only case in which reliable statements can be made concerning the cosmic abundance of isotopes.

## IV. Terminology

Color index B–V

Difference between the apparent brightnesses of a star, measured by plates or photocells sensitive in the blue (B) and in the visual (V) spectral regions. B–V increases from negative to positive values along the sequence of spectral types as the stellar temperature decreases.

Fraunhofer lines

Absorption lines in the spectra of the sun and stars.

Brightness of stars

The apparent brightness is given in magnitudes m. A difference in magnitude $m_1 - m_2 = 1.0$ corresponds to a brightness ratio $I_2/I_1 = 2.51$, or $\log I_2 - \log I_1 = 0.400$ (*Pogson*). Negative magnitudes correspond to high brightnesses, positive magnitudes to low brightnesses. The absolute brightness is based on a standard distance (from the observer) of 10 parsec = 32.6 light years.

King's furnace

Develops temperatures of up to about 3000 °K by means of resistance heating of a carbon tube.

Luminosity

Total radiation emitted by a star, usually referred to that of the sun, which is taken as unity.

Magnetohydrodynamics

Fluid motions in media with high electrical conductivities passing through magnetic fields are greatly influenced by induction currents and the forces generated by them. These forces are important in addition to the hydrodynamic forces.

Milky Way

Our Milky Way (galaxy) is similar to the well known spiral nebula in the constellation Andromeda. It consists of a flat disk which contains a central nucleus and spiral arms. Our

sun moves around the galactic nucleus in a circular orbit whose radius is approximately 30000 light years, and completes the orbit in 200 million years. The nucleus and disk are surrounded by an almost spherical halo, which contains the globular star clusters as well as the high velocity stars and subdwarfs.

Spectral Classification

The spectra of stars are arranged according to two parameters:

a) Spectral types (S) O B A F G K M which constitute a sequence in which the effective temperature decreases from left to right.

b) Luminosity classes (LC) I–V which correspond essentially to a decreasing absolute brightness; I = supergiants; V = main sequence stars. The older Harvard classification was elaborated by *Morgan* and *Keenan* to yield the MK classification generally used today.

The relatively few stars which do not fit into the two-parameter scheme are denoted as "peculiar", *e.g.* the Ap stars with strong magnetic fields.

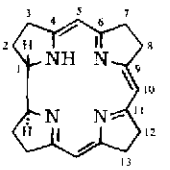
# A Synthetic Route to the Corrin System

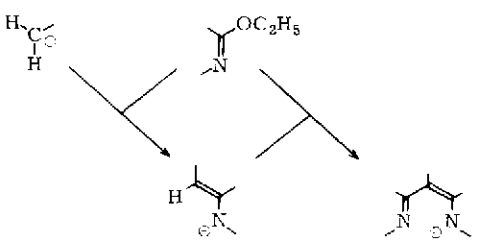
BY DR. E. BERTELE, H. BOOS [1], PROF. DR. J. D. DUNITZ [2], DR. F. ELSINGER, PROF. DR. A. ESCHENMOSER, I. FELNER, H. P. GRIBI, H. GSCHWEND, DR. E. F. MEYER [2], DR. M. PESARO, AND DR. R. SCHEFFOLD



ORGANISCH-CHEMISCHES LABORATORIUM DER EIDGENÖSSISCHEN TECHNISCHEN HOCHSCHULE, ZÜRICH (SWITZERLAND)

*Dedicated to Prof. H. Meerwein on the occasion of his 85th birthday*

*The synthesis of the nickel(II) complex of (±)-1,8,8,13,13-pentamethyl-trans-corrin illustrates a synthetic route to the corrin system. Repeated use of triethyloxonium tetrafluoroborate in this synthesis demonstrates the preparative value of the trialkyloxonium salts discovered by Meerwein et al.*



Corrin *(1)* [3] is the name given to the hypothetical parent compound of the porphyrinoid ligand system that, in the form of a cobalt complex, characterizes the vitamin $B_{12}$ structure [4]. Our knowledge of the constitution of this system stems from the now classical series of X-ray structural analyses carried out during the last 10 years by *Dorothy Crowfoot-Hodgkin* and her collaborators in Oxford (England) [5]. The consequent elaboration of the chemistry of this novel type of structure has since received additional impetus through the discovery of $B_{12}$ coenzymes [6], as manifested by the work going on at Nottingham (England) [7] and Stuttgart (Germany) [8].

This article describes the first results of investigations directed toward the development of synthetic pathways [9] to compounds with the corrin structure.

*(1)*

The concept underlying our work is patterned on a type of reaction that seems predestined for the construction of the conjugated unsaturated carbon-nitrogen chain typical of the corrin chromophore, *viz.* C→C condensation of carbanionoid carbon centers with C=N double bonds of imino ether derivatives [10] (Scheme 1). The

Scheme 1. The reaction principle used for the synthesis of the corrin chromophor.

verification of such a scheme hinges on the availability of the trialkyloxonium salts discovered by *Meerwein* et al. [11] as reagents that allow a reliable conversion of amide or lactam groups into the corresponding imino ether derivatives.

the development of a synthetic route to the corrin type of structure was inspired by the substitution pattern present in natural corrin complexes; moreover, it circumvents dangers of isomerization and dehydrogenation

Scheme 2. Synthesis of compound *(2)*. In the experimental data, Rf = boiling under reflux, RT = room temperature. Melting and boiling points are uncorrected. Physical properties of the compounds are listed in Table 1 [12].

The synthetic route is illustrated by the formulae of the bicyclic intermediates *(2)* and *(3)*; their combination in the sense shown is intended to yield a derivative of (±)-1,8,8,13,13-pentamethyl-*trans*-corrin. The choice of this polymethylated derivative as the first subject for

that might well lie along the path to the unsubstituted corrin.

Scheme 2 shows a synthesis of the left-hand structure *(2)*. The monocyclic tetraester *(4)*, readily prepared by Diels-Alder addition of tetramethyl ethylenetetracarboxylate onto isoprene, is smoothly converted into the aliphatic tetraester *(5)* by a novel reductive ring-cleavage with sodium in liquid ammonia. The position and configuration of the double bond in *(5)* is unambiguously defined by the method of formation.

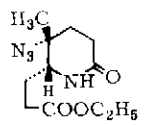
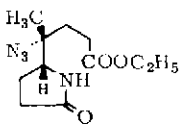
The crystalline diamide *(6)* is the starting material for a sequence of operations leading to sterospecific imination of the double bond to form the aziridine derivative *(7)*, without isolation of pure intermediates. Thus, first, reaction of *(6)* with triethyloxonium tetrafluoroborate yields the diimino diether, $\tilde{\nu}_{C=N}$ = 1642 $cm^{-1}$; secondly, careful bromination of the latter with one equivalent of bromine affords the monocyclic bromodiimino diether *(6a)*, $\tilde{\nu}_{C=N}$ = 1642/38 $cm^{-1}$; $\delta_{\rangle CHBr}$ = 4.1 ppm; thirdly, mild hydrolysis of *(6a)* with dilute sulfuric acid followed by treatment with sodium ethoxide yields *(7)*. The assignment of *cis*-configuration to the aziridine derivative *(7)* rests on the postulate of direct participation of the imino ether nitrogen in the bromination step, assuming that inversion occurs in the cyclization of the α-bromo amine *(6b)* formed during hydrolysis. This assignment is confirmed by the fact that *(7)* reacts with one equivalent of nitrosyl chloride/triethylamine at low temperature to split off $N_2O$, giving stereospecifically a high yield of diethyl *cis*-4-methyl-4-octenedioate [13].

*(6a)*

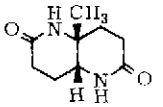


*(6b)*

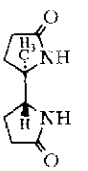


[13] We have checked that the cleavage of *N*-nitrosoaziridines to $N_2O$ and the corresponding olefins, observed by *C. L. Bumgardner, K. S. McCallum*, and *J. P. Freeman*, J. Amer. chem. Soc. *83*, 4417 (1961), and by *W. Rundel* and *E. Müller*, Chem. Ber. *96*, 2528 (1963), in the case of the unsubstituted aziridine, proceeds with retention of configuration and can therefore be used for determining the configurations of aziridines and aziridine precursors. The reaction with 1.0 mole of nitrosyl chloride/triethylamine in ether at −60 → 0 °C gave 87% *trans*-stilbene (quantitative analysis by gas chromatography) from *trans*-2,3-diphenylaziridine, and 80–86% *cis*-stilbene containing 7.5–1.7% *trans*-isomer from *cis*-2,3-diphenylaziridine.

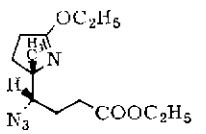
Introduction of the second nitrogen function is achieved by proton-catalysed opening of the aziridine ring of *(7)* with azide ions. The main reaction consists in the attachment of the azide group to the secondary carbon atom; a slow cyclization step then leads to the butyrolactam derivative *(8)*. The fact that the azide group in this compound is on a secondary carbon atom is shown by the NMR spectrum: the signal at 3.28 ppm, corresponding to the tertiary hydrogen, is displaced upfield by 0.8 ppm after catalytic hydrogenation of the azide group to an amino group. The configuration of *(8)* is derived by assumption of *trans*-opening [14] of the aziridine ring. This is suggested by the entry of the azide ion at the secondary carbon atom, *i.e.* at the position corresponding to an $S_N2$-type reaction.



A by-product *(8a)* [$\tilde{\nu}_{C=O}$ = 1665/1728 $cm^{-1}$, $\delta_{\rangle CH-N-CO}$ = 3.25 ppm], isolated in small yield from the reaction of *(7)* with azide ions and formed by a rapid cyclization step, originates from competitive opening of the aziridine ring at the tertiary carbon atom. Compound *(8a)* can be transformed via the isomeric lactam *(8b)*, which is formed by equilibration with sodium ethoxide (K ≈ 2 in $C_2H_5OH$, 25 °C), into the same five-membered cyclic dilactam *(8d)* as is obtained by catalytic hydrogenation and subsequent cyclization of *(8)*. This relates the configuration of *(8a)* to that of *(8)*. It is noteworthy that catalytic hydrogenation carried out immediately after the azide reaction, followed by a double cyclization leads exclusively to the six-membered bicyclic dilactam *(8c)*.

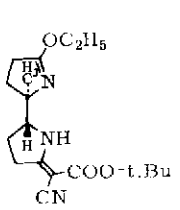


*(8a)*

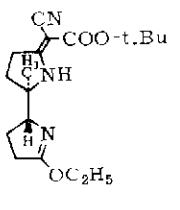


*(8b)*

*(8c)*

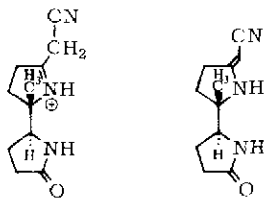


*(8d)*



*(8e)*

The system *(2)* can be constructed from the dilactam *(8d)* by a sequence of reactions analogous to the transformations *(8)* → *(9)* and *(10)* → *(2)*, but the isomeric intermediates *(10a)* and *(10b)* must be separated by chromatography. A more convenient route is described below.

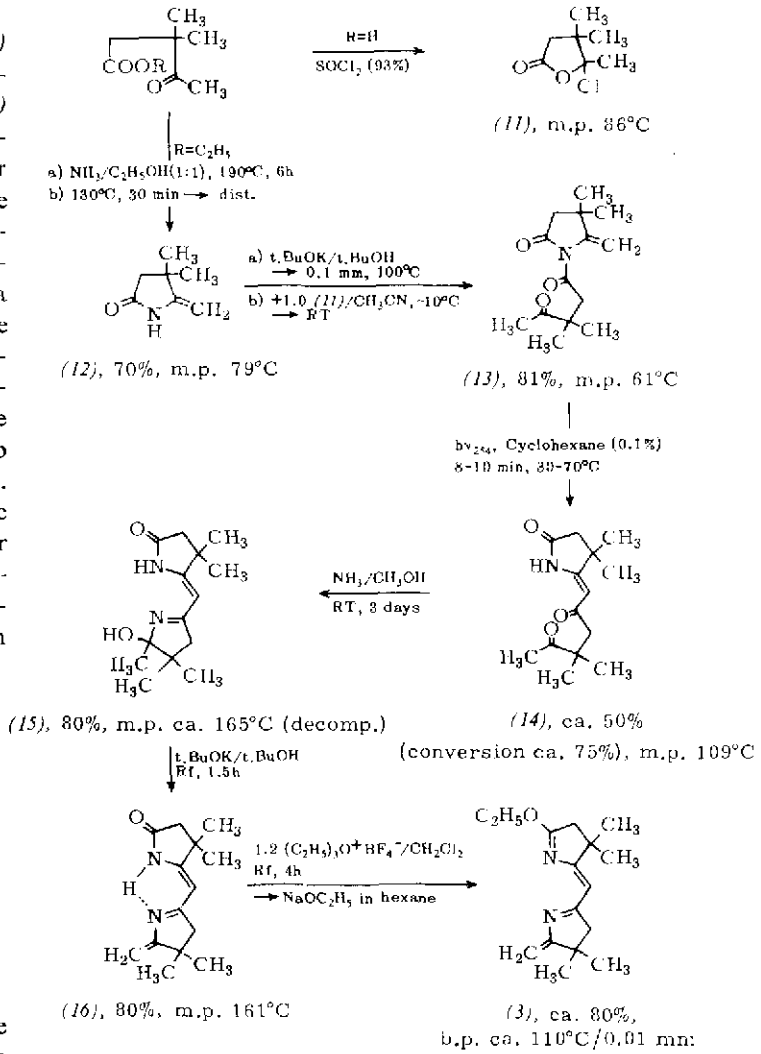


*(10a)*

*(10b)*

[14] Cf. also *F. H. Dickey, W. Fickett*, and *H. J. Lucas*, J. Amer. chem. Soc. *74*, 944 (1952); *R. Ghirandelli* and *H. J. Lucas*, ibid. *77*, 106 (1955).

The lactam group in the butyrolactam derivative *(8)* can be transformed with triethyloxonium tetrafluoroborate into the corresponding iminoether grouping *(8e)* without altering the azide function. This reaction provides, in the sense of Scheme 1, the opportunity for introducing the two-carbon chain required to complete the synthesis of *(2)*. Condensation with t-butyl cyanoacetate in the presence of catalytic amounts of triethylamine proves particularly suitable for this purpose: a uniform reaction leads to compound *(9)*, in which the arrangement of the imino and the ester groups are assumed, on the basis of infrared spectroscopic investigations on simple model systems, to be *cis*. Selective catalytic hydrogenation of the azide to the amino group proceeds readily to yield the bicyclic monolactam *(10)*. Brief treatment of *(10)* with anhydrous trifluoroacetic acid effects smooth cleavage [15] of the t-butyl ester group, together with spontaneous decarboxylation. Conversion of the lactam into the imino ether with triethyloxonium tetrafluoroborate is achieved via the immonium



*(10c)* *(10d)*

$\lambda_{max}$ = 268 mμ
(log ε = 4.3)

salt *(10c)*; neither the neutral compound *(10d)* nor the cyano ester *(10)* can be *O*-alkylated selectively on the lactam group because of interfering side reactions in the enamine region. In practice the trifluoroacetic acid is sucked off immediately after cleavage of the ester group, and the residue (log $\varepsilon_{268\ m\mu} < 3.6$ in $CH_2Cl_2$) is alkylated directly with an excess of triethyloxonium tetrafluoroborate. The crystalline product obtained in this way gives analytical and spectroscopic data that confirm the constitution of the structural formula *(2)*; its NMR spectrum indicates, however, the presence of the two possible geometrical isomers.

Scheme 3 summarizes the reaction sequence leading to the right-hand structure *(3)*. The crucial intermediate is β,β-dimethyl-γ-methylenebutyrolactam *(12)*, which can be prepared by various methods, starting from β,β-dimethyllevulinic acid. A simple and efficient process consists in the reaction of the corresponding ethyl ester with ethanolic ammonia at elevated temperature, followed by pyrolytic elimination of ammonia. *C*-Acylation of *(12)* by the acyl residue of β,β-dimethyllevulinic acid is achieved indirectly by *N*-acylation of the potassium salt of *(12)* with the pseudo-acid chloride *(11)*, followed by a photochemically induced *N*-acyl → *C*-acyl migration *(13)* → *(14)*. This last process occurs rapidly in dilute cyclohexane solution on irradiation with a low-pressure mercury vapor lamp, but is accompanied by a photochemical change of the

reaction product at about half its rate of formation; it is therefore best carried out in a continuous flow system [16].

Replacement of both carbonyl oxygens in *(14)* by nitrogen is achieved with methanolic ammonia. The initial product is compound *(15)*; its tertiary hydroxyl group can be eliminated either pyrolytically or by treatment with potassium t-butoxide. The constitution of *(16)* follows clearly from its NMR spectrum. The configuration shown is deduced from an infrared band at about 3190 $cm^{-1}$, whose position, shape, and intensity are independent of concentration (0.03–5 % solution in $CCl_4$); the band is assigned to an intramolecularly associated NH group. This internal hydrogen bond presumably contributes to the success of the subsequent reaction with triethyloxonium tetrafluoroborate, which results in a practically exclusive *O*-alkylation. With this formation of the sensitive iminoether derivative *(3)* the synthesis of the right-hand half of the corrin system is complete.

Scheme 4 shows a solution of the crucial problem of the present work, *i.e.* the combination of the two components *(2)* and *(3)* to the corrin system. Starting with the sodium salt of component *(2)* in diglyme, specific C → C condensation of the β-aminocrotonitrile system of *(2)* with the conjugated – and hence more reactive – iminoether grouping of component *(3)* is achieved; under suitable conditions the sodium salt of the condensation product *(17)* crystallizes out directly from the reaction mixture in good yield. The free condensation product is very labile and has not been obtained in crystalline form. The configurational details of formula *(17)* remain hypothetical, but the constitution is well founded on spectroscopic data, particularly on the NMR spectrum, which contains all the signals required by formula *(17)* with respect to both position and intensity. The same characteristic signals, particularly those of the three vinyl protons and of the iminoether ethoxyl group, are observed in the spectrum of the beautifully crystalline diamagnetic nickel(II) complex *(18)*, obtained by reaction of the sodium salt *(17)* with nickel(II) perchlorate in acetonitrile. The planoid structure of the ligand system in this complex now satisfies the geometrical requirements for the final ring closure to the macrocyclic corrin ligand, *i.e.* the two condensing centers are fixed close to each other. Ring closure of *(18)* can be achieved in high yield by treatment with potas-

Scheme 4. Combination of compounds *(2)* and *(3)* to the corrin system. In the experimental data, **Rf** = boiling under reflux, **RT** = room temperature. Melting and boiling points are uncorrected. The physical properties of the compounds are listed in Table 3 [12].

[16] The acyl substituent on the ring migrates to only a very small extent; in one experiment, the corresponding isomeric rearrangement product was isolated in about 1 % yield.

sium t-butoxide. The strong base undoubtedly evokes intermediate formation of a neutral complex, *e.g. (18a)*, by deprotonation of the singly positively charged complex ion *(18)*. In this intermediate, the nucleophilic reactivity of the exocyclic methylene group is greater than in *(18)* and the nickel-nitrogen bonds may be shorter. Indeed, a neutral deprotonated corrin complex ($C_{25}H_{29}N_5Ni \cdot H_2O$; m.p. $> 300\,^{\circ}C$; mol. wt. in $CH_2Cl_2$ –468; $\delta_{=CH-}$ = 5.27/5.06/4.93 (3s) ppm) can be isolated by avoiding acidic conditions during isolation. This complex has the structure *(19a)* or *(19b)*. On protonation with acids, crystalline salts of the orange-yellow, diamagnetic complex ion *(19)* are formed.

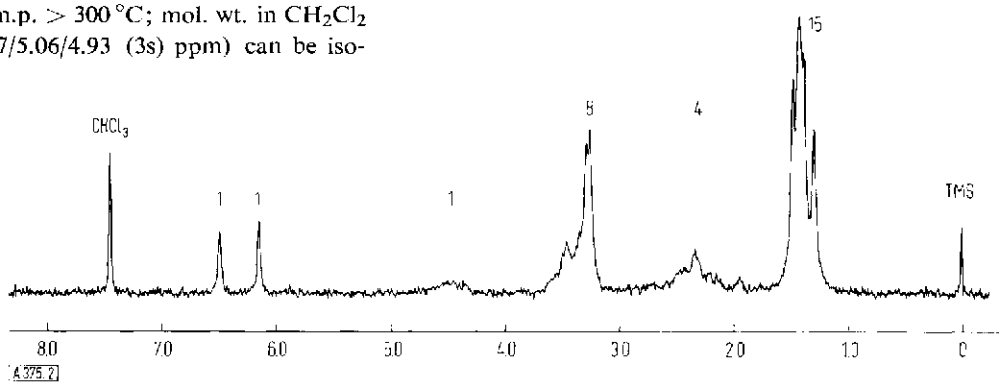

Fig. 2. NMR spectrum of compound *(19)*, R = Cl. TMS = tetramethylsilane. The numbers above the curve indicate the number of protons associated with each signal.
Abscissa: $\delta$ [ppm].

That ring closure of the open complex *(18)* does lead to the nickel(II) complex of 1,8,8,13,13-pentamethyl-5-cyano-*trans*-corrin *(19)* is supported by analytical data and by the following spectroscopic observations:

a) The ultraviolet spectrum of *(19)*, R = $ClO_4$, shows the expected bathochromic displacement of the main band at long wavelength with respect to that of the precorrinoid complex *(18)*; see Fig. 1.

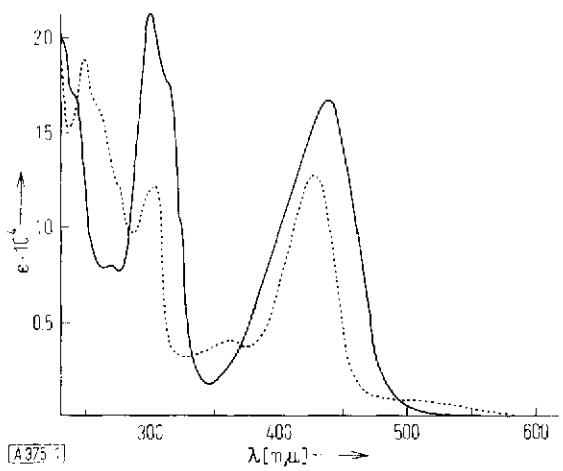

Fig. 1. Ultraviolet spectra of compounds *(18)*, R = $ClO_4$ (. . . .), and *(19)*, R = $ClO_4$ (——), in ethanol.

b) The infrared spectrum of *(19)*, R = $ClO_4$, does not show the iminoether C=N band at about 1640 $cm^{-1}$ that is present in the spectrum of *(18)*. Two intense bands appear in the C=C/C=N region at 1592 and 1508 $cm^{-1}$; two such bands characterize the same region of the infrared spectra of cobyrinic acid derivatives [17].

[17] Heptamethyl dicyanocobyrinate [cf. *F. Wagner* and *K. Bernhauer* in: Vitamin $B_{12}$ Coenzymes (Conference), New York Academy of Sciences, 1963] exhibits two prominent peaks at 1500 and 1580 $cm^{-1}$ in chloroform (experiments by Dr. *R. Keese*).

c) Comparison of the NMR spectra of *(18)* and *(19)*, R = Cl, shows the disappearance of the iminoether ethoxy and exocyclic methylidene groups, which participate in the cyclization (Fig. 2). All signals observed in the NMR spectrum of *(19)* (Fig. 2) correspond in position, structure, and intensity to the constitution shown [18].

The nickel(II)-corrin complex *(19)* is rather inert to hydrolysis, even under vigorous conditions (conc. HCl/Rf/4 h; dilute $NaOH/C_2H_5OH$/Rf/7 h); a preparative method for the hydrolysis of the cyanide group with simultaneous decarboxylation to form the nickel(II) complex of 1,8,8,13,13-pentamethyl-*trans*-corrin *(20)*, R = Cl, consists in heating *(19)* for several hours in 0.1 N hydrochloric acid at 220 °C.

The constitution of the synthetic corrin complexes is confirmed by three-dimensional X-ray analysis of the nickel(II)-1,8,8,13,13-pentamethyl-5-cyano-*trans*-corrin chloride *(19)*, R = Cl. The air-dried crystals obtained from ethyl acetate/methanol are triclinic (a = 11.10, b = 12.31, c = 10.69 Å; $\alpha = 103.9\,^{\circ}$, $\beta = 96.0\,^{\circ}$, $\gamma = 77.9\,^{\circ}$; density = 1.364 g/$cm^3$; space group $P\bar{1}$; Z = 2). The X-ray molecular weight of 566 (calc. for $C_{25}H_{30}N_5NiCl$

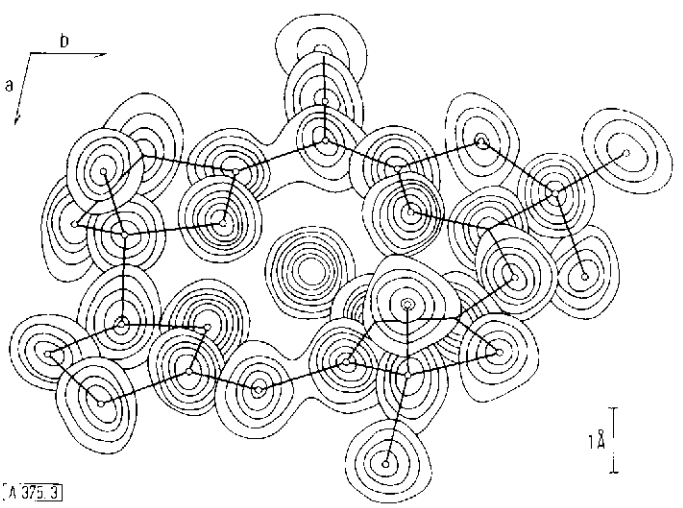

Fig. 3. X-ray analysis of nickel(II)-1,8,8,13,13-pentamethyl-5-cyano-*trans*-corrin chloride *(19)*, R = Cl.
Second electron density synthesis.

[18] $\delta_{=CH}$ of heptamethyl aquocyanocobyrinate perchlorate in deuterochloroform: 6.4 ppm (experiments by Dr. *R. Keese*).

– 494.7) indicates the presence of solvent of crystallization; the NMR spectrum of the air-dried crystals in deuterochloroform shows the presence of methanol and water. The intensities of the X-ray reflections were measured with the linear diffractometer of *Arndt* and *Phillips* [19] and converted to relative $F^2$ values. The position of the nickel atom was obtained from a three-dimensional Patterson function. The result of the second electron-density synthesis is summarized in Figure 3; it is in significant agreement with the structural formula *(19)* and, in particular, confirms the *trans*-linkage of rings A and D. Since only weak indications of the solvent molecules are present in the electron density syntheses, it seems probable that they are largely disordered in the crystal. Discussion of bond lengths and bond angles is premature, since further calculations are in progress.

The results described in this paper indicate the general direction of a route, along which the synthesis of corrin complexes with other metal ions, as well as with simpler or more complex substituents, can be attempted. With these possibilities a broader basis for studying corrin chemistry is in prospect.

## Introduction

The study of the chemical bond in solids is steadily gaining in importance [1,2]. One can expect special properties of chemical bonds to prevail at surfaces, for on one hand, free valences are available [3], and on the other, the type of bonding and hence also the arrangement of the atoms at the surface are different from those in the bulk of the crystal [4–6]. These phenomena are important not only in solid state physics but also for an understanding of the properties of materials which are involved in chemisorption and catalysis.

The quantum chemistry of surfaces is concerned with the possible states of energy of electron systems which exist on the surface of a finite crystal, as well as with the wave functions which describe the state of these electrons. From these relationships, quantum chemistry can be used to derive conclusions as to the electron distribution in the surface layers. Both a free surface and one containing adsorbed material perturb the ideal lattice periodicity. Since such perturbances bear a formal resemblance to defects within the crystal lattice, the theories evolved for the latter may be applied to surface phenomena. However, it must be noted that these theories were developed primarily for semiconductors and presuppose knowledge of the energy spectrum of a finite crystal [7–10].

One-electron approximations are particularly graphic and readily understood, although they have considerable disadvantages in quantitative computations. In the one-electron approximation it is assumed that certain definite states can be ascribed to the electrons. The

total energy of the electron system can then be expressed as the sum of the energies of the occupied states. The wave functions which describe the states of the individual electrons in the crystal can be designated as "molecular orbitals", in analogy to the terminology of quantum chemistry. It is frequently assumed that the molecular orbitals can be approximated by linear combinations of atomic orbitals, *i.e.* as linear combinations of the wave functions which describe the electron states in the single atoms (LCAO-method [*]).

If an atomic orbital, localized at an atom $\alpha$, is designated as $\chi_{\alpha i}$, then the molecular orbital assumes the following form (according to the molecular orbital method in the MO-LCAO approximation)

$$\Psi_j = \sum_{\alpha i} c_{j;\alpha i} \cdot \chi_{\alpha i}$$

where $c_{j;\alpha i}$ are the coefficients whose squares yield the probability of finding the electron with the atomic orbital $\chi_{\alpha i}$ in the state corresponding to the j-th molecular orbital. In general, we can conceive of several atomic orbitals pertaining to a single atom and can index them with subscript i. The probability that an electron will be found in the vicinity of an atom $\alpha$ is then $\sum_i c_{j;\alpha i}^2$; this probability is also designated as the electron density. The coefficients $c_{j;\alpha i}$ which, in the simplest version (the Hückel approximation), determine the solution of the quantum-mechanical problem, must satisfy the system of equations

$$(\alpha_{\alpha i} - E_j)c_{j;\alpha i} + \sum_{\gamma k} \beta_{\alpha i;\gamma k} \cdot c_{j;\gamma k} = 0$$

where $E_j$ is the electron energy; $\alpha_{\alpha i}$ is the so-called Coulomb integral, which is a measure of the energy of an electron localized at an isolated atomic orbital; $\beta_{\alpha i;\gamma k}$ is the resonance integral, which is a measure of the overlap, and hence of a possible bond between the orbitals $\chi_{\alpha i}$ and $\chi_{\alpha k}$ of the atoms $\alpha$ and $\gamma$.

The above system of equations can only be solved for definite values of energy $E_j$. The ensemble of these energies is designated as the spectrum of allowed energies. If the crystal is considered to be an assembly of unit cells, then the atoms may be indexed by the cell number (p) and by the number of the atom ($\gamma$) within the cell. The expression for the molecular orbitals can then be written in the following form:

$$\Psi_j = \sum_{p\gamma;i} c_{j;p\gamma;i} \cdot \chi_{p\gamma;i}$$

From the periodicity of the infinite crystal it follows that the expression

$$|c_{j;p\gamma;i}|^2 = |c_{j;1\gamma;i}|^2$$

must be valid, *i.e.* that equivalent lattice sites must ha vethe same electron residence probabilities (or electron densities). Since an infinite crystal contains an infinitely large number of unit cells, the probability of the occurrence of an electron in a single unit cell is infinitely small.

This approximation is justified only when the bonding of the electrons to the individual atoms is relatively strong. The great advantage of this approximation is that the theoretical results can be easily and graphically interpreted by means of chemical concepts and may then be compared with experimental data from organic or inorganic chemistry.

The objective of quantum chemistry of surfaces is therefore to find the allowed energy levels of the one-electron states for a given arrangement of the atomic nuclei in the finite crystal, as well as to determine the pertinent one-electron wave functions, *i.e.* the "molecular" orbitals.

[*] LCAO = linear combination of atomic orbitals.

## 1. Electron States in a Finite Crystal

Two kinds of states can be distinguished in a finite crystal:

a) Volume States: The energies of these states are virtually identical with those in an infinite crystal. The electrons are distributed uniformly throughout the crystal so that the effect of the surface on their energy is small. The probability of occurrence of an electron in any unit cell of a large crystal is again very low, and at large distances from the surface, it is constant for equivalent atomic orbitals.

b) Surface States: The energies of these states are determined primarily by the conditions in the neighborhood of the surface, for the probability of finding the electrons in these states at large distances from the surface is negligibly low. Nevertheless, the probability of finding an electron in the crystal's surface layers has a finite value. Such surface states [11] have been computed for various models, using the simplified one-electron approximation methods [12–14]. It has been found that surface states with diametrically different properties are possible.

### 1. Volume States

Let us consider briefly some properties of volume states which are of importance for the understanding of the nature of the surface states.

Let us imagine that a crystal is formed from single atoms which are originally at an infinite distance away from each other and which then approach to within lattice dimensions; the process of crystal formation will produce fundamental changes in the original discrete electronic energy levels of the isolated atoms. The originally discrete levels are broadened into energy bands because of overlap of the atomic orbitals. If the interaction between the atoms or ions of the crystal is sufficiently strong, these bands will overlap or even cross (Fig. 1). When, for any reasons (*e.g.* of symmetry),

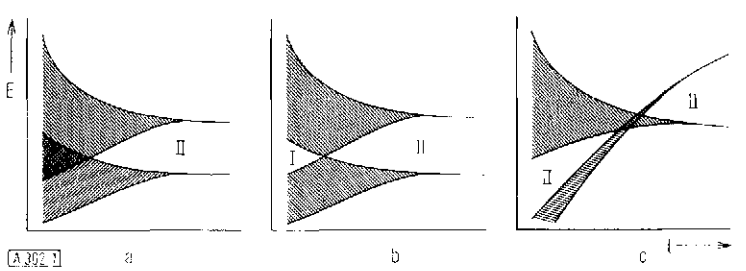

Fig. 1. Allowed energy bands of molecular orbitals.
a: overlapping of bands; b: crossing of bands;
c: overlapping of bands predominantly via a change of the Coulomb potential during crystal formation;
Abscissa: a parameter characteristic of the spacing between the electrons;
Ordinate: energy;
I: gap of the first kind;
II: gap of the second kind.

[11] *I. Tamm*, Physik. Z. Sowjetunion *1*, 733 (1932).
[12] *I. M. Lifshits* and *I. J. Pekar*, Usp. fiz. Nauk *56*, 531 (1955).
[13] *J. Koutecký*, J. physic. Chem. Solids *14*, 233 (1960).
[14] *J. Koutecký*, Physica Status Solidi *1*, 554 (1961).

the wave functions corresponding to the various atomic orbitals cannot interact, then the bands overlap and give rise to states which, although of different type, have the same energies (Fig. 1a). In such a case, the molecular orbitals may be represented as linear combinations of atomic orbitals of only one kind. The molecular orbitals will then have the form

$$\Psi_{j\,(i)} = \sum_{p,\gamma} c_{j;\,p\gamma;\,i} \cdot \chi_{p\gamma,\,i}$$

(No summation over the index i).

On the other hand, when interaction between the wave functions is possible, then the bands cross at a definite distance between atomic nuclei (Fig. 1b). Any further decrease in the atomic spacing again results in a gap between the bands. The width, position, and even the nature of the bands after such a crossing are quite different from those before the crossing at larger interatomic distances. The crossing is often an indication of localized bonds between the atoms of the crystal, the energies of the bonding and antibonding states of this localized bond being allocated to the two bands. The positions of the bands can change not only because of interaction between the orbitals – *i.e.*, for instance, because of the formation of a chemical bond – but also because of changes occurring in the Coulomb potential of an electron in a given atomic orbital during the mutual approach of the atoms (Fig. 1c).

Let us consider, for instance, a crystal composed of two different atoms, A and B. Let us suppose that the highest one-electron energy level of a free atom A partly occupied by electrons is situated lower than the corresponding level of the free atom B. The crystal may then be considered as being composed of ions, formed by transition of all the electrons from the highest partly filled level of the A atom to the highest partly occupied level of the B atom. As the ions A and B approach each other, their energies are reduced by electrostatic attraction; this manifests itself as a shift of the highest occupied band of the B ion. Thus, at small interionic distances, we find this band at a level lower than that of the empty band associated with the originally partly occupied degenerate levels of the free atom A.

The transition of an electron from the highest occupied band (which arises from the energy level of the B atom) to the empty band (which arises from the degenerate level of atom A) is equivalent to the creation of a neutral atom in a lattice composed of monovalent ions.

The gaps between the allowed energy levels of the volume states can be differentiated into gaps of the first and of the second kind. Gaps of the first kind are caused by localized bonding, although the localization need not be complete. The energy bands separated by a gap of the first kind correspond to molecular orbitals of the bonding and antibonding states. Gaps of the second kind separate bands whose molecular orbitals are produced by different atomic orbitals; in this case, there need not be any correspondence between the energy sequence of the molecular orbitals and those of the atomic orbitals in the isolated atoms; ionic crystals stand out especially in this respect.

Crystals in which there is a gap between the energy bands of the bonding and antibonding states and in which the bonding states are fully occupied (in accordance with the Pauli principle) while the antibonding states are empty are insulators or semiconductors. In the terminology of solid state physics, the highest completely filled energy band is designated as the "valence band", and the first empty band as the "conduction band". Thus, insulators and semiconductors are substances which have large or small gaps, respectively, between the valence and conduction bands.

Metals exhibit considerable broadening of the bands and correspondingly strong overlapping, but the resulting complex band is not fully occupied. The kind of gap prevailing within a given substance can be determined either by investigation of the wave functions the energies of which produce the above bands separated by the gap, or else from chemical and physical informations about properties of the bonds in the crystal. To gain a clearer understanding of the phenomena involved, we shall now proceed to examine a simple model.

## 2. Energy Spectra Corresponding to Models of Crystals with Localized Bonds

Even a simplified model, such as that of a chain of mutually interacting atoms, provides an insight into most of the typical crystal properties.

We shall consider only two atomic orbitals for each atom and shall use these to form the molecular orbitals [15–17] (Fig. 2). The first of these atomic orbitals is spherically symmetrical (the s orbital), while the second one is antisymmetrical [*] with respect to a plane

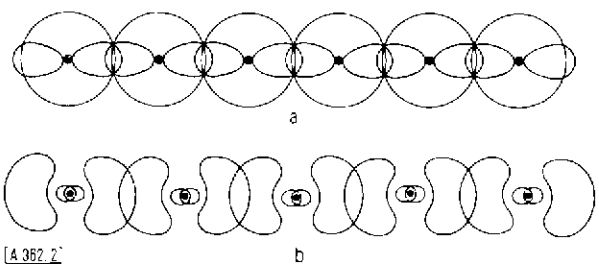

Fig. 2. Linear atomic chain.

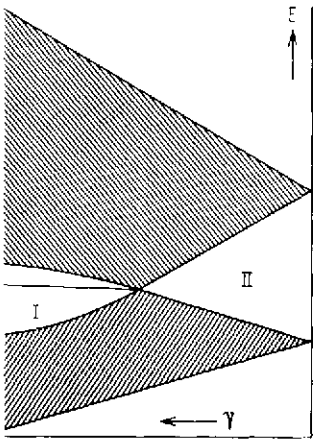
a: Atomic 2s and 2p orbitals whose linear combination according to the MO-LCAO method results in molecular orbitals;

b: 2sp hybrids which cause localized bonds at small interatomic distances.



passing through the atom and orthogonal to the atomic chain (the 2p orbital). The remaining 2p atomic orbitals are neglected. If the interatomic distance is very large, then two discrete energy levels can be distinguished; one of these corresponds to the 2s and the other to the 2p state. As the atoms approach each other, these levels give rise to bands, mostly via the separate interactions of s orbitals with each other and of p orbitals with each other. In addition, interaction between the s and p orbitals is also present and results in intermingling of 2p orbitals in the 2s orbitals and vice versa. It is only at small interionic distances that we can use the concept of a localized bond, *i.e.* we can say that 2sp hybrids (Fig. 2b) are formed between the atoms.

It is convenient to take the sp hybrids into account when the interaction between the hybrids of the same atom is smaller than that between the sp hybrids of two

[*] The notation "antisymmetrical" means that the sign of the atomic orbital considered is changed by reflection in a plane.

neighboring atoms. At a given interatomic distance, the formation of sp-hybridized bonds within an infinitely long atomic chain manifests itself via the crossing of the bands and formation of a new gap (see Fig. 3). The

γ: A parameter which is an approximately exponential function of the interatomic distance r [$\gamma \sim \exp(-kr)$]. The energy level of the Shockley surface state is shown in gap I.

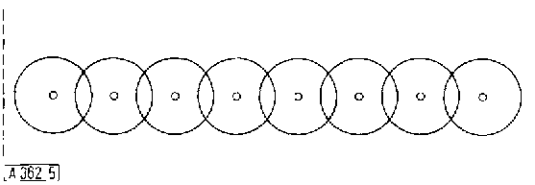
energy gap II present at large interatomic distances results mainly from the difference in the energies of the 2s and 2p atomic orbitals. The gap present at small interatomic distances is caused by localized bonding. For a concrete example, see the energy states of diamond as a function of the interatomic distances (Fig. 4 [18]).

A 362. 4

Fig. 4. The band diagram of diamond as a function of the distance r between the carbon atoms [18].

The gap II present at large spacings between the carbon atoms is caused by the energy difference between the 2s and 2p atomic orbitals. The gap I present at smaller interatomic spacings is caused by localized bonding between hybrid $sp^3$ orbitals.

### 3. Surface States

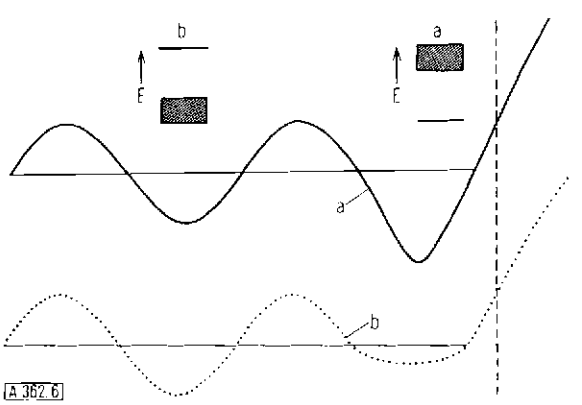


a) *When the Change of the Potential Function inside the Crystal is Sufficiently Large.*

Let us consider a simple case in which we may restrict ourselves to a single band of those volume states which are generated by atomic orbitals of a single kind. We are thus dealing with the wave function of the form

$$\Psi_j = \sum_p c_{j;p} \cdot \chi_p$$

(Indices other than those for the unit cell are superfluous). Index p is summated from $-\infty$ to $+\infty$ in the case of an infinite chain and from 1 to $+\infty$ in the case of a finite chain.



Our model is a linear atomic chain with uniform interatomic distances, in which a spherically symmetrical s-type atomic orbital is considered for each atom (Fig. 5). We thus obtain a single band of allowed volume state energies. In a real crystal, this assumption is justified to some extent when the bands of allowed volume state energies are quite far apart and are separated by wide gaps of the second kind.

A 362. 5

Fig. 5. The simplest model of a finite linear atomic chain: the atomic orbitals are combined into molecular orbitals.

The existence of the crystal surface may be related to a perturbance of the ideal periodicity of the potential function inside the crystal (Fig. 6). One measure of this perturbance of the potential is the Coulomb integral difference $(\alpha_i - \alpha)$, where $\alpha_i$ is the Coulomb integral for the i-th atom and $\alpha$ is the integral corresponding to the atom in an ideal infinite chain. When this perturbance encompasses only the surface atoms, the surface states described by *Tamm* [11] are obtained; these are characterized by an exponential decrease of the electron density with increasing distance from the surface. While this is a monotonic function, other surface states (discussed below) do not decrease monotonically. In the case of Tamm states, the potential drop at the crystal surface must be large enough [11,16,19] to force the electron to stay in the deep potential well near the

A 362. 6

Fig. 6. Tamm surface states. Schematic representation of the potential and the corresponding one-electron energies for the model shown in Fig. 5 as a function of the distance from the surface. a: Decrease, and b: rise of the potential in the region of surface atoms (perpendicular dashed line: the crystal boundary).

[18] *G. E. Kimball*, J. chem. Physics *3*, 560 (1935).

[19] *E. T. Goodwin*, Proc. Cambridge philos. Soc. *35*, 221 (1939).

surface atom and to prevent it from delocalization, the behavior favored from the energy point of view. When the potential drop at the surface is large enough, the energy level of the localized state lies below the band of allowed volume state energies (Fig. 6a). Tamm surface states also appear in the case of a rise in potential at the crystal surface (Fig. 6b), although here they are not favored because they lie above the band of allowed volume state energies. Inside the crystal, the electrons in volume states are delocalized and can avoid this unfavorable region, and have thus lower energies than electrons in surface states.

When $\alpha_j = \alpha\,(j \neq 1)$, the condition for the existence of Tamm surface states can be expressed in terms of Coulomb integrals as $|\alpha_1 - \alpha| > \beta$, where $\beta$ is the resonance integral between two neighboring atomic orbitals. The exponential decrease of the probability of finding an electron at the p-th atom is given by the equation:

$$\left|c_p/c_{p-1}\right|^2 = \left|(\alpha_1-\alpha)/\beta\right|^2 .$$

The energy of the Tamm state is

$$E = \alpha_1 + \beta^2/(\alpha_1-\alpha) .$$

If we proceed from a finite atomic chain to a semi-infinite [*] crystal, then all the qualitative deductions remain the same as those for the one-dimensional case, but the discrete energy levels corresponding to the surface states spread out into bands (Fig. 7). The number of Tamm surface states equals the number of surface atoms.

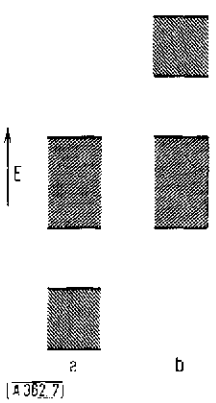


Fig. 7. Molecular orbital energies for a cubic crystal bounded by a single plane; it is assumed that only one atomic orbital of each atom may be used in the construction of the molecular orbital (the volume state bands are hatched from the upper right to the lower left, the surface state bands from the upper left to the lower right). a: Decrease and b: rise of the potential in the region of surface atoms.

If the perturbance of the potential reaches even deeper beneath the crystal surface, then states may exist having the maximum electron residence probability not only at the surface cells, but also in cells located below the surface [20]. In brief, one can say that the Tamm surface states are occasioned by local changes of potential at and immediately below the crystal surface. The mere existence of a surface is not sufficient for their occurrence.

[*] The term semi-infinite implies that the crystal is bounded by one plane and thus occupies only a half-space.

[20] *J. Koutecký*, Physic. Rev. *108*. 13 (1957).

b) *When There are Strong Bonds between the Surface Atoms and Those of the Second Layer*

Let us again consider linear atomic chains, but let us now assume that the bonds between the atoms at the surface and those immediately below them are stronger than the bonds in the bulk of the crystal [20,21]. A stronger bond indicates an electron with lower energy, *i.e.* an electron localized in a bonding state between the two atoms. Localization of the electron in an antibonding state (relative to the stronger bond) is, on the other hand, not favored. In accordance with this concept, two localized states are obtained when the strengthening of the bond between the first and the second atoms is sufficiently great: one lies below and the other above the band of allowed volume state energies (Fig. 8).

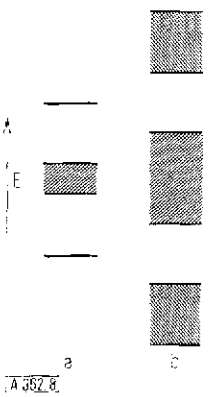

Fig. 8. One-electron energies of a semi-infinite crystal with a strengthened bond, a: between the surface atom and that immediately below it, b: between the first and second surface layers of a semi-infinite crystal (similar spectra are obtained in the case of chemisorption when the surface is completely occupied). The band marking is the same as in Fig. 7.

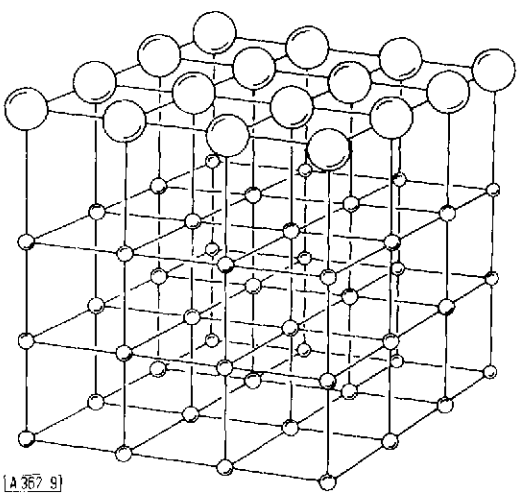
The strength of the bonds between the surface atoms and those in the second layer is not identical with the bond strengths prevailing in the bulk of the crystal. In the MO-LCAO approximation, this bond strength is expressed in terms of the difference between the resonance integrals $\beta_{1,2}$ and $\beta$ (for two neighboring atomic orbitals inside the crystal). The condition for the existence of such a surface state is:

$$\beta_{1,2}^2 > 2\,\beta^2 .$$

If the increase in bond strength of more than two atomic layers is sufficiently large, several localized states are obtained in a gap of the second kind, both below and above the band of allowed volume state energies.



If both the Coulomb potential of the surface layer and the bond strength between the atoms of the surface layers are changed, then we have an intermediate case. The drop in the Coulomb potential facilitates the occurrence of localized bonding surface states and prevents antibonding surface states. The opposite result is obtained if the Coulomb potential increases. The shift of the energy of the localized state may then be of such magnitude as to render the surface state energy identical with some volume state energy, thus leaving no basis for the independent existence of a surface state, in which case the latter disappears.

[21] *T. A. Hoffmann*, Acta physica Acad. Sci. hung. *3*, 195 (1953).

## II. Chemisorption States

### 1. Tamm Chemisorption States

Changes in the Coulomb potential and bond strengths in surface layers may be caused by the mere existence of the crystal surface. The potential in the region of surface atoms can, however, also be altered by adsorption of ions [7,8,10]. When the surface is fully occupied (formation of a monolayer), its symmetry need not be disturbed by the adsorption. If homopolar bonds are formed between the chemisorbed particles and the surface atoms [22–24] and if the surface is fully occupied, the chemisorption can also be thought of as an incorporation of the chemisorbed particles into the crystal; the bond strengths which deviate from those prevailing in the bulk of the crystal may be ascribed to the bonds formed between the chemisorbed particles and the atoms at the crystal boundary. For the above representations to hold, the chemisorbed particles must form – at least approximately – a two-dimensional network with a symmetry identical to that of the crystal surface (Fig. 9). In effect we are dealing with a perfect

[A 367 9]

Fig. 9. Chemisorption model at full coverage and preserved symmetry of the surface.

analogy to a crystal with an altered bond strength between the atoms of the surface and those in the second layer (cf. Sect. I.3b). Thus, localization of electrons in surface states may be compared with the localization of electrons in strong chemisorption bonds.

In chemisorption, bonding states may occur whose energies lie below the band of allowed volume state energies. In addition, there is a band corresponding to the antibonding states of the chemisorption bond and lying above the band of allowed volume state energies (Fig. 8). The condition for the existence of these states is again substantially greater strength of the chemisorption bond relative to the strength of the bonding of the atoms inside the crystal. If this condition is not satisfied, then the electrons participating in the chemisorption bond cannot be definitely assigned to any specific localized state. Instead, all the electrons of the crystal will participate to the same extent in the chemisorption bond, and the chemisorbed particles will appear only as an extension of the crystal itself. This chemisorption bond has a metallic character. Just as for surface states, differences between the electronegativity of the chemisorbed and of the crystal atoms may result in shifts in the localized chemisorption bands within the crystal. This shift may even lead to the disappearance of these bands, as these are merged into a volume state band.

If the surface is only incompletely covered [24–27], we are dealing with perturbed symmetry of the crystal surface. Thus, the chemisorbed layer can no longer be formally regarded as an extension of the crystal. However, the essential conclusions derived above remain valid even in this case. Because of the analogy between Tamm surface states and the localized surface states prevailing in the case of a strong chemisorption bond, these latter states are called Tamm chemisorption states.

### 2. Shockley Chemisorption States

As already mentioned, the gaps between the bands in the band diagram of allowed volume state energies may result from the existence of localized bonds between atoms of the unit cell. When the crystal surface intersects localized bonds (or at least bonds which are stronger than others), we find Shockley surface states [28–31]. These lie in gaps of the first kind. If the gap is of the second kind, then surface formation results in no localized surface states at all. Shockley surface states are thus localized free valences present in the surface of a crystal with localized bonds [13,14,32].

The formation of Shockley surface states may be explained more lucidly by means of the simple model of a linear atomic chain [17,33]. We shall consider only one 2s and one 2p orbital for each atom. In the case of the 2p orbital, the axis of maximum electron density (Fig. 2a) coincides with the chain axis. If localized bonds occur in this chain between sp hybrids and if the chain is then broken (Fig. 2b), then one of these localized sp bonds is also broken. We then have a state in which the electron is localized in the vicinity of the surface, predominantly in the sp hybrid of the broken bond. In this state, the probability of finding the electron in the sp hybrid which is oriented towards the chain break is significantly higher than that of finding it in the oppositely oriented sp hybrid of the same atom. The probability of its occurrence in the latter hybrid may even be negligibly low. This occurs when the interaction between two sp orbitals not forming a bond between two neighboring atoms is negligible. In addition, for sp orbitals of the same orientation, the amplitude of the wave function decreases with increasing distance from the chain break (Fig. 10).

Mere cleavage of the bond between the surface atoms is sufficient to create a Shockley surface state. On the other hand, change in the Coulomb potential within a finite crystal can cause the Shockley surface state to disappear. As already stated, Shockley surface states always lie in the gap between the bands of allowed

volume state energies. Specifically, they are usually found in not too wide gaps. Variation of the potential within the crystal causes a shift of the energy level of the surface state, which may then merge with the upper or lower volume state band.

When a surface atom possessing localized bonds interrupted by a crystal surface interacts with a molecule of a surrounding gaseous phase, chemisorption states of the Shockley type may be formed. These surface states, which correspond to the bonding and antibonding states of the chemisorption bond, are localized only if the chemisorption bond is not too strong. These states are called "Shockley chemisorption states" because they can be derived from the Shockley surface states.

If the strength of the chemisorption bond is of the same magnitude as that prevailing in the bulk of the crystal, then the bands of allowed volume state energies overlap the energies of the chemisorption states, and the latter are then no longer localized. When the chemisorption bond is very strong, then Tamm chemisorption state energy bands may appear below the lowest or above the uppermost band. The differences in the electronegativities of the participating atoms are also of major importance in this connection.

Shockley surface states may also appear when the crystal possesses both strong and weak bonds [32–36]. Let us consider as model an atomic chain of which it is sufficient for our purposes to take into account only a single atomic orbital, which is symmetrical with respect to the plane passing through the atom and perpendicular to the chain. The spacings between the atoms alternate in length so that a stronger bond always succeeds a weaker one in the chain. If we now form a semi-infinite chain by breaking a stronger bond, a Shockley surface state will be produced in the gap between the allowed energy bands of the atomic chain. No Shockley states would arise from the breaking of a weaker bond.

The difference in bond strength resulting from the varying bond lengths is expressed in the MO-LCAO approximation as the difference in the resonance integrals. Thus, bonds with resonance integrals $\beta$ and $\beta'$ alternate in the chain. If a $\beta$ bond is interrupted by the surface, then the condition for the existence of a Shockley surface state is

$$|\beta/\beta'| > 1$$

The energy is then given by the relationship $E = \alpha$, where $\alpha$ is the Coulomb integral of an isolated atomic orbital.

The molecular orbital for the Shockley surface state may be written in the form

$$\Psi = \sum_p c_{p;1} \cdot \chi_{p;1}$$

since $c_{p;2} = 0$. The unit cell contains two atoms.

The above model is only a mental exercise since we have not considered the possibility of change in the interatomic distances on transition from the infinite to the semi-infinite chain. If the surface atom is assigned the number 1 and the atoms succeeding it (in the direction of the crystal center) are numbered consecutively higher as the distance from the chain break increases, then the probability of finding an electron in the orbitals of even-numbered atoms is zero, provided we consider only interactions between neighboring atomic orbitals. In this case, an analogy can be drawn between the Shockley surface states and the non-bonding molecular orbitals familiar fron the theory of conjugated hydrocarbons [37].

According to the MO-LCAO theory of conjugated hydrocarbons, molecular orbitals occur in "alternant" [*] hydrocarbons containing an odd number of atoms in the conjugated system which possess the following two characteristics:

a) The energy of these molecular orbitals corresponds to that of a $p_z$-localized electron. No strengthening or weakening of the bonds between the atoms of the conjugated system is required for the electron to be in this state; hence, this state is called a non-bonding one (as distinguished from bonding and antibonding states).

b) Only for one atomic class is the residence probability of one electron greater than zero. The non-bonding orbital system is associated with the phenomenon that hydrocarbons with an odd number of carbon atoms are free radicals if each carbon atom contributes one electron to the conjugated $\pi$-electron system.

Thus, here Shockley surface states form an expression for the free radical properties of a surface in which free valences are present. It can be shown that the energy bands of the Shockley surface states are only half-filled with electrons, since the number of electrons equals the number of atomic orbitals.

We should emphasize here that results which agree qualitatively are obtained with other models using the one-electron approximation. For example, *Kronig* and *Penney* [38–43] employed a model with a constant linear potential along the interatomic bond, while the atoms themselves represented very narrow and deep potential wells. Here, too, Tamm and Shockley surface states can be differentiated. Their properties

are similar to those of states calculated by the MO-LCAO method. We may thus conclude that, provided a one-electron approximation is used, the results are qualitatively independent of the particular model employed.

## III. Surface States in Semi-Infinite Diamond-Type Crystals

### 1. Boundary Formed by the (111) Plane [44]

So far we have represented the properties of the main types of surface states by means of simplified models. However, complex spectra of allowed volume state energies may give rise to various combinations of and transitions between surface or chemisorption states.

Diamond is a real crystal with distinct localized bonds. The (111) plane intersects one of the localized bonds formed by $sp^3$ hybrid orbitals of each surface atom (Fig. 11); each surface atom is bound (by three bonds) to three atoms of the second layer. Let us then set up a

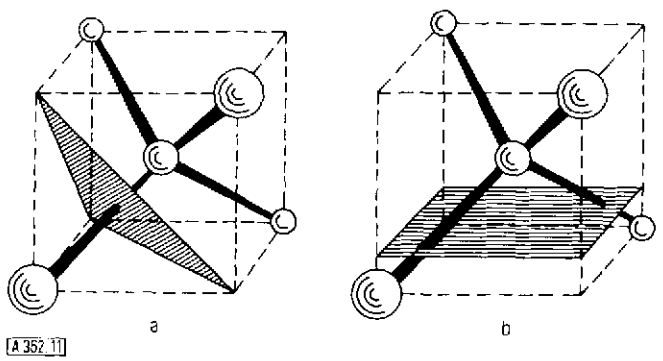

Fig. 11. Position of the $2sp^3$ orbitals of boundary atoms in diamond a: Crystal bounded by the (111) plane, b: by the (100) plane.

simple model, in which we consider the mutual interaction between such $sp^3$ hybrids of the adjacent atoms whose maximum electron density coincides with the line interconnecting them. We shall also consider the interaction between the $sp^3$ hybrids of one and the same atom (this allows shifting of an electron from one bond to another). Such a simplified model neglects a number of other interactions between various atomic hybrid orbitals, even though these undoubtedly are also of considerable importance with diamond and attain even greater importance in the case of the related silicon and germanium crystals.

We thus consider the resonance integrals $\gamma$ between the $sp^3$ hybrids of neighboring carbon atoms and the resonance integrals $\gamma'$ between $sp^3$ hybrids of one carbon atom. The relationship $\gamma'/\gamma = 0.25$ seems to be valid for diamond. This model yields two bands of allowed volume state energies (Fig. 12): one of the bands corresponds to the bonding states, the other to the antibonding states, with regard to the localized bond between the $sp^3$ hybrids of neighboring carbon atoms. The finite width of these bands is caused by the interaction between the $sp^3$ hybrids of the same atom. If this interaction were absent, the energy spectrum of diamond would consist of two discrete lines corresponding to the bonding and antibonding orbitals localized on bonds between neighboring carbon atoms.

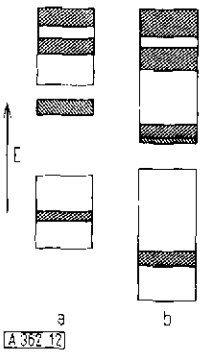

Fig. 12. One-electron energies of a diamond-type crystal bounded by the (111) plane. The bands of the surface states are hatched from the upper left to the lower right when they do not overlap with the bands of volume states. In the case of overlap, they are hatched from the upper right to the lower left). a: Weak and b: strong interaction between the $sp^3$ hybrids of the same atom.

This type of interaction also entails a complex structure of the single bands. In this case, the valence band as well as the conduction band consist of partial bands corresponding to the various possible interactions between the $sp^3$ hybrids of the same carbon atom. These partial bands overlap, since interaction between the states corresponding to them is forbidden for reasons of symmetry.

The band of Shockley surface states whose properties are due to the existence of free surface bonds is found in the gap of the first kind present between the valence and conduction bands. The Shockley band is only half-filled. An electron in a state of this energy band is localized mostly in that $sp^3$ hybrid of the surface atom which is oriented outward from the crystal surface.

Here again the typical alternating probability of occurrence of the electrons in the hybridized orbitals is encountered. The probability that an electron existing in this Shockley state will be found in the remaining $sp^3$ hybrids of the surface atoms is very small. Furthermore, in the above model, the same probability with those $sp^3$ hybrids of the second layer atoms which are oriented inward into the crystal is in fact zero.

However, additional surface states are made possible by the complex volume band structure of the valence and conduction bands. The electrons present in these states are preferentially localized in those $sp^3$ hybrids which form the bonds between the first and second atomic layers. The probability that an electron present in this state will reside in an $sp^3$ hybrid which belongs to a second-layer carbon atom and is oriented inward into the bulk of the crystal is again zero. Thus, these states again reflect the specific bond conditions between the layers of atoms near the surface. Their existence demonstrates the fact that the bonds between the first and second layers differ in character from those between the second and third layers, etc.

Interaction between an $sp^3$ hybrid of a surface atom and the atomic orbital of a chemisorbed atom may lead

[44] *J. Koutecký* and *M. Tomdšek*, Physic. Rev. *120*, 1212 (1960).

[45] *J. Koutecký*, Surface Science, in the press.

to localized chemisorption states (Fig. 13) [45]. If this interaction is significantly weaker than that between $sp^3$ hybrids of neighboring atoms inside the crystal, then Shockley bonding and antibonding states arise in the gap between the valence and conduction bands

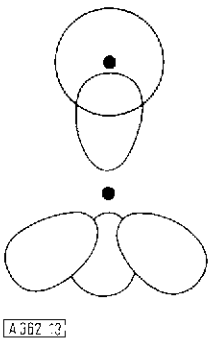

Fig. 13. Model of chemisorption at the (111) diamond surface. The atomic $sp^3$ orbitals of a surface atom of a diamond crystal and the atomic s orbital of the chemisorbed atom are shown schematically. The chemisorption bond arises from the overlap between an s and an $sp^3$ atomic orbital.

(Fig. 14a). In contrast, when the interaction is very strong, the energy levels of localized chemisorption states may be below the valence band or above the conduction band (Fig. 14b). These energy bands are of the Tamm type.

In addition, the model also yields chemisorption bands whose localized surface states fall within the conduction and valence bands of the volume states. These surface states characterize the bonding conditions between the first and second layers below the surface.

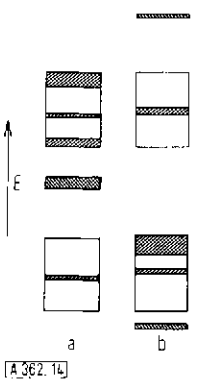

Fig. 14 Allowed one-electron energies for chemisorption at the (111) diamond surface in accordance with the model of Fig. 13. a: Weak and b: strong chemisorption bond. (The band marking is the same as in Fig. 12).

If we assume a large difference between the energy of that surface atom $sp^3$ hybrid which is oriented toward the vacuum and the energy of the $sp^3$ hybrids in the bulk of the crystal, then we obtain Tamm surface states. Such a change in energy leads to the formation of bands situated below the valence band or below (according to the sign of this energy change) the conduction band of the volume state (Fig. 15). In addition, the bands of the surface states lie within the bands of the volume states.

A small change in the energy of a vacuum-directed $sp^3$ hybrid of a surface atom (relative to an atom in the bulk of the crystal) causes only a shift of the band of the Shockley surface states.

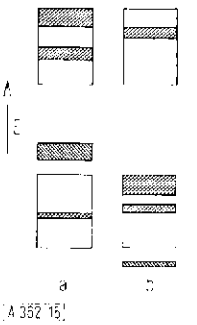

Fig. 15. Allowed one-electron energies for a: a small and b: a large change in the potential of the outward-directed $sp^3$ hybrid of a surface atom of the (111) diamond plane. (The band marking is the same as in Fig. 12).

### 2. Boundary Formed by the (100) Plane [46]

The (100) plane cuts through two bonds of each surface carbon atom in the crystal (Fig. 11). Interaction between these two free $sp^3$ hybrids produces rehybridization of the hybrid orbitals. The spectrum of allowed surface state energies (Fig. 16) exhibits a band I between the

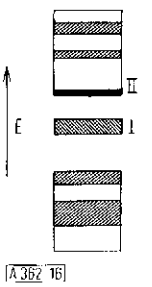

Fig. 16. Allowed one-electron energies in a diamond crystal bounded by the (100) plane. (The band marking is the same as in Fig. 12).

valence and conduction bands. This band is situated at a lower level than that of the semi-infinite diamond crystal bounded by the (111) plane, and is fully occupied. In addition, there is also a band II situated in the vicinity of the lower edge of the conduction band. In our model, band II degenerates to a single energy level and is empty in the ground state. There are no free valences here, only a lone electron pair belonging to the surface atom. Thus, while the (111) surface is characterized by a polyradical, the (100) surface is characterized by lone electron pairs which tend to form donor-acceptor bonds with gas molecules. Naturally other valence states, permitting other bonds, may arise by excitation.

## IV. Electronic States in Crystals Containing Heterogenous Atomic Species

Our discussion thus far was concerned with crystals composed of atoms of the same kind. The problem then arises whether the results derived will still hold when atoms of various kinds are present in the unit cell, or whether the presence of two kinds of atoms will not result in a new kind of surface state.

[46] *J. Koutecký*, Czechoslov. J. Physics *B 12*, 184 (1962).

The simple model of a chain whose unit cell contains two different atoms A and B was studied by means of the MO-LCAO method [47,48]. It was found that the volume states form two energy bands separated by a gap of the second kind. A finite chain is again produced by bond rupture. Let an atom of species A then be situated at the surface and that of species B below it. The atomic orbitals of atoms A and B will then be characterized by differing Coulomb integrals $\alpha_A$ and $\alpha_B$, where $\omega = \alpha_A - \alpha_B$ is the gap width between the two energy bands of volume states. It turns out that the fact that the chain is finite, *i.e.* that the bond is ruptured at the surface, is not sufficient to produce Shockley surface states. As for a chain of identical atoms, bond alternation and the formation of a finite crystal by rupture of the stronger bond is the prerequisite for the appearance of Shockley surface states. The condition for Tamm surface states – a sufficiently large change of the Coulomb potential in the vicinity of a surface atom – is qualitatively similar to the requirements imposed on a chain of identical atoms.

The condition for the existence of Tamm surface states is

$$\delta^2 + \delta\omega/2 > \beta$$

where the variation of the Coulomb integral of a surface atom is expressed by

$$\delta = \alpha_1 - \alpha_A$$

$\beta$ being the resonance integral. The occurrence of Tamm surface states is facilitated by an increase in the potential difference between the surface atom and its neighbors.

However, here we encounter not only the surface states already discussed, but also some characteristic new phenomena. We can, for instance, stipulate that the potential of an electron localized in the orbital of the atom A shall be smaller than that in the orbital of atom B. Thus, if the surface causes a rise in the potential near the surface atom A, then the latter acquires greater similarity to the B atoms within the chain than it has to an identically situated A atom. Within the gap between the energy bands of the volume state, we then find one surface state energy level which is characteristic of chains containing various atomic species. A similar result is obtained when the potential of an electron localized in the orbital of atom A is intrinsically higher than the corresponding potential of a B atom, but is reduced because of surface formation. Here again, the A atom at the surface acquires greater similarity to a B atom than it has to the A atoms within the chain. The condition for the existence of this surface state is $\delta\omega < 0$.

## V. Concluding Remarks

From the above arguments it can be seen that it is possible for an electron to become localized in various states near the surface, depending on the physical and chemical causes of this localization. Surface atoms generally exhibit properties different from those of free atoms or of atoms bound in the crystal bulk. The nature of the surface states, especially the extent of localization, is an indication of the extent to which the properties of the atoms within the crystal have been retained by the surface atoms.

In spite of the variety of the surface states, there are still some common characteristics among them, so that a theory accounting for all the phenomena may be developed.

Knowledge of the degree of filling of the one-electron energy spectra is a prerequisite for obtaining some information about the effect of the surface states on surface behavior. *Volkenshteyn*'s concept [9] of the occurrence of a chemisorption bond at the surface of ionic crystals might serve as an example. According to it, a localized state of the Tamm type arises during chemisorption. The pertinent wave function may be formed by linear combination of the orbitals of excited atoms. In addition, linear combination of the same atomic orbitals produces also the conduction band of the volume state of an ionic crystal. This chemisoption surface state may localize either a single electron provided by the chemisorbed atom (weak bond) or two electrons (strong bond). Another model used in the theory of chemisorption and catalysis is the concept already mentioned of ionosorption [10].

No fixed free surface valences have thus far been considered in the chemisorption theory. We have seen, however, for an ideal diamond surface created by the (111) plane, that the Shockley state band in the gap between the conduction and valence bands is only half-filled; this phenomenon is a characteristic indication of the existence of fixed free valences at the surface. The surface state corresponding to these valences can easily disappear when a bond formed with a chemisorbed substance is stronger. This is in agreement with the fact that the concentration of surface states on impure germanium surfaces is very low.

As shown by the examples, the present-day theories of chemisorption and catalysis are tailored to special cases. Quantum chemistry shows that multifarious states may exist at surfaces; electrons may be localized in these states and this localization explains the vast differences in surface properties observed. Thus, three basic problems remain to be solved by the quantum chemistry of surfaces:

1. The theoretical basis for surface states in electrically conducting and in salt-like crystals remains to be worked out. First steps have already been taken in this direction [49,50]. These classes of substances do not lend themselves too readily to interpretation by the MO-LCAO method, since the latter yields only crude and not entirely reliable approximations.

[50] *D. A. Dowden* and *D. Wells*: Actes du II-ème congrès international de catalyse 1960. Ed. Technip, Paris 1961, p. 1499.

2. A semiquantitative calculation of the surface states should be executed for at least a few simple substances; this will allow quantitative predictions to be made about the strengths of bonds between surface atoms or of the chemisorption bonds. In order to achieve this aim it will of course be necessary to take into account the small changes in volume states due to surface formation, for their total effect is not negligible [51].

3. The qualitative and quantitative theoretical results should be utilized in surface chemisorption, in semiconductor electrochemistry [52], and in the clarification of the effect of surfaces on semiconductor properties. Quantum chemistry can be used not only to explain the properties of pure surfaces but also of surface compounds, that is, the problems of real surfaces.

## Synthesis of Alkynylamines by Nucleophilic Substitution of Halogenoalkynes [*]

By Dr. H. G. Viehe and M. Reinstein

Union Carbide European Research Associates, Brussels (Belgium)

We recently reported [1] the synthesis of diethyl(phenylethynyl)amine *(1)*, the first representative of this class of compounds. Fluorophenylacetylene was formulated as a hypothetical intermediate in the reaction

$$C_6H_5-CH=CClF \xrightarrow[86\,\%]{2\ LiN(C_2H_5)_2} C_6H_5-C\equiv C-N(C_2H_5)_2 \quad (1)$$

because the occurrence of chlorophenylacetylene was unlikely according to the literature [2].

However, we have now obtained dimethyl(phenylethynyl)amine *(2)* in 87 % yield by condensation of chlorophenylacetylene with lithium dimethylamide in ether in a molar ratio of 1.1:1; the temperature during addition of the alkyne was −80 °C; the reaction mixture was then allowed to warm up to room temperature, the total reaction time being one hour.

$$C_6H_5-C\equiv C-Cl \xrightarrow[87\,\%]{LiN(CH_3)_2} C_6H_5-C\equiv C-N(CH_3)_2 \quad (2)$$

The ease of substitution of the chlorine may be due to the activating phenyl residue [3,4]. This is reconcilable with the fact that t-butylchloroacetylene does not react with lithium dimethylamide under the same conditions. On the other hand, t-butylethynyldimethylamine *(3)* is readily formed from t-butylfluoroacetylene [5] and lithium dimethylamide. It is more advantageous in practice not to use t-butylfluoroacetylene as such, but instead to treat its "dihydrobromide", *i.e.* 1,2-dibromo-1-t-butyl-2-fluoroethane, with excess amide (molar ratio 1:4, ether as solvent, temperature of addition −80 °C followed by warming to room temperature, reaction time about 1 hour).

$$(CH_3)_3C-CHBr-CHBrF \xrightarrow{LiN(CH_3)_2} [(CH_3)_3C-C\equiv C-F] \quad \text{(not isolated)}$$

$$\xrightarrow[\text{overall } 48\,\%]{LiN(CH_3)_2} (CH_3)_3C-C\equiv C-N(CH_3)_2 \quad (3)$$

t-Butylethynyldimethylamine *(3)* is also formed in 44 % yield from t-butylchloroacetylene when the latter is heated with trimethylamine for 60 hours at 135 °C.

$$(CH_3)_3C-C\equiv C-Cl \xrightarrow[44\,\%]{N(CH_3)_3} (3)$$

Starting from 1,1-dichloro-2-fluoroethylene and lithium diethylamide in a molar ratio of 1:3.3 in ether (addition temperature −80 °C followed by warming to room temperature, reaction time 1.5 hours) bisdiethylaminoacetylene *(4)* is obtained.

$$Cl_2C=CHF \xrightarrow[57\,\%]{LiN(C_2H_5)_2} (C_2H_5)_2N-C\equiv C-N(C_2H_5)_2 \quad (4)$$

The reaction products were isolated and characterized by elementary analysis, infrared spectra, and hydration to the corresponding amides.

## 1,3,4-Triaza-2,5-diborolidines

By Dr. K. Niedenzu, Dr. P. Fritz, and Dr. H. Jenne

Department of Chemistry, Duke University, Durham, N.C. (U.S.A.)

Recently, *Nöth* and *Regnet* [1] described the first derivative of 1,3,4-triaza-2,5-diborolidine. This five-membered boron-nitrogen heterocycle was obtained by aminolysis of 1,2,4,5-tetraza-3,6-diborine. We have now found that hydrazinolysis of bis(aminoboryl)amines *(1)* [2] also affords triazadiborolidines.

*(1)* *(2)*

For instance, when stoichiometric amounts of *N,N'*-dimethylhydrazine and bis(dimethylaminophenylboryl)amine are refluxed in ether for 1 h, 3,4-dimethyl-2,5-diphenyl-1,3,4-

triaza-2,5-diborolidine *(2)*, $R^2 = C_6H_5$, $R^3 = CH_3$, b.p. 180–182 °C/3 mm, m.p. 106–108 °C (sealed tube, uncorrected), precipitates out on cooling. Concentration of the mother liquor yields a second crop of crystals; the overall yield is about 85 %.

1,3,4-Triaza-2,5-diborolidines appear to be stable to heat. For example, when *(2)*, $R^2 = C_6H_5$, $R^3 = CH_3$, is heated to 225 °C *in vacuo*, no signs of decomposition are found. This behavior seems to indicate the existence of resonance stabilization of the ring by participation of BN double bonds.

This assumption is supported by the presence of a peak in the infrared spectrum of *(2)* near 1400 $cm^{-1}$; this region is normally assigned to BN double bonds [3]. In addition, the chemical reactions of *(2)*, *e.g.* with metal carbonyls, indicate a strong similarity between triazadiborolidines and the cyclopentadiene system.

However, the heterocycle *(2)* is not stable to hydrolysis. Traces of moisture first attack the B–N–B bridge to yield 3,4-dimethyl-2,5-diphenyl-1,3,4-oxodiaza-2,5-diborine, m.p. 202–204 °C [4]; this is followed by ring cleavage to afford dihydroxyphenylborane and *N,N'*-dimethylhydrazine.

## Diethylselenothiophosphinic Acid Derivatives

By Doz. Dr. W. Kuchen and Dipl.-Chem. B. Knop

Institut für Anorganische Chemie und Electrochemie der Technischen Hochschule Aachen (Germany)

Sodium diethylselenothiophosphinate *(1a)* has been obtained both in the fused state according to the equation:

$$(C_2H_5)_2P(S)-P(S)(C_2H_5)_2 + Na_2Se + Se \xrightarrow[2\ h]{\approx 200\ ^\circ C} 2\ (C_2H_5)_2P(S)SeNa \qquad (1a)$$

and in absolute alcohol by the reaction:

$$(C_2H_5)_2P(S)Cl + NaSeH \xrightarrow{0\ ^\circ C} (C_2H_5)_2P(S)SeNa + HCl \qquad (1a)$$

It was isolated as its crystalline dihydrate $(C_2H_5)_2P(S)SeNa \cdot 2H_2O$ *(1b)*, m.p. 124–125 °C. This is isomorphous with $(C_2H_5)_2P(S)SNa \cdot 2H_2O$ [1], which also melts at 124–125 °C.

Aqueous solutions of diethylselenothiophosphinic acid $(C_2H_5)_2P(S)SeH$ *(2)* were obtained from *(1b)* using a strongly acidic cation exchanger (*Ionenaustauscher I, from* E. Merck, Darmstadt, Germany). The acid gradually decomposes on standing for a few hours at room temperature in diffuse daylight, its solutions turning yellow.

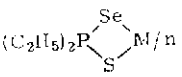
The anion *(3)* derived from the thiol form of *(2)* according to the equilibrium

$$(C_2H_5)_2P(S)Se^{\ominus} \rightleftharpoons (C_2H_5)_2P(Se)S^{\ominus} \qquad (3)$$

is presumably practically the only species present in aqueous solutions of *(1b)* and *(2)* [2]. Hence the intensely yellow, crystalline product, m.p. 56.5 °C, which is formed in water by the reaction:

$$2\ (C_2H_5)_2P(S)SeNa \cdot 2\ H_2O + KI_3 \rightarrow (C_2H_5)_2P(Se)-S-S-P(Se)(C_2H_5)_2 + 2\ NaI + KI \qquad (1b)$$

is most probably bis(diethylselenophosphoryl)disulfane, especially since the infrared spectrum of the yellow compound in the KBr region is practically the same as that of $(C_2H_5)_2P(S)-S-S-P(S)(C_2H_5)_2$ [1].



Diethylselenothiophosphinic esters, *e.g.* $(C_2H_5)_2P(S)SeC_2H_5$, b.p. 135 °C/10 mm, $n_D^{20} = 1.5854$, and $(C_2H_5)_2P(S)Se\text{-}n\text{-}C_3H_7$, b.p. 86–87 °C/0.06 mm, $n_D^{20} = 1.5738$, were obtained smoothly by refluxing *(1b)* with alkyl bromides.

$$(C_2H_5)_2P(S)SeNa \cdot 2\ H_2O + RBr \rightarrow (C_2H_5)_2P(S)SeR + NaBr \qquad (1b)$$

The structures proposed for the esters are supported by the separation of diethylphosphinothioic bromide from the products of the reaction of any one of them with 1 mole of bromine, the main reaction probably being the following:

$$(C_2H_5)_2P(S)SeR + Br_2 \rightarrow (C_2H_5)P(S)Br + RSeBr.$$

Compound *(1b)* reacts with metals to form non-electrolytic inner complexes of the type:

*e.g.* bis(diethylselenothiophosphinato)zinc(II), m.p. 157 °C; -cadmium(II), m.p. 160 °C; -nickel(II), olive-green, decomp. >142 °C; -lead(II), green-yellow, m.p. 132 °C; orange-red tris(diethylselenothiophosphinato)bismuth(III), m.p. 94 °C. The zinc and cadmium complexes, like the corresponding dialkyldithiophosphinato complexes *(4)* of these two metals, are associated in benzene [3]. The thermal and chemical stabilities [3] of the compounds *(4)* are not attained by their seleno analogues.

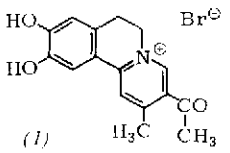
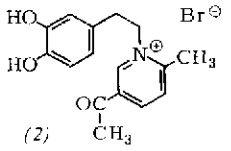
## Benzo[a]quinolizinium Salts from 3,4-Dihydroxyphenethylamine Hydrobromide and Acetoacetaldehyde, a Possibly Biogenetic-Type Cyclization



By Prof. Dr. H. J. Teuber and Dipl.-Chem. D. Laudien

Institut für Organische Chemie der Universität Frankfurt/Main (Germany)



3,4-Dihydroxyphenethylamine (dopamine) hydrobromide reacts in hot glacial acetic acid with 2 moles of either acetoacetaldehyde dimethylacetal or 1-methoxy-1-buten-3-one, analogously to tryptamine [1], to yield 40 % of the benzo[*a*]quinolizinium salt *(1)* and 31 % of the pyridinium salt *(2)* [2]. In aqueous solution at 20 °C, only about 13 % of *(1)* is obtained. Product *(1)* can be separated from *(2)* as a red anhydro base $C_{16}H_{15}NO_3$.

Pure *(1)* was characterized as its oxime, 2,4-dinitrophenylhydrazone, and diacetyl derivative as well as by the mono-

methyl ether formed on reaction with methyl iodide. On reduction with sodium borohydride, *(1)* is converted into the corresponding bright yellow secondary alcohol.

*(1)*

*(2)*

The 60 Mc proton resonance spectrum [3] of the anhydro base of *(1)* in trifluoroacetic acid ($\delta = 0$ for tetramethylsilane) shows 4 one-proton singlets at $\delta = 9.1$, 8.2, 7.7, and 7.1. They correspond to the isolated protons of the pyridine and benzene rings and prove that double ring closure has occurred.

This novel synthesis leads in one step beyond the isoquinoline ring closure [4] obtained hitherto with monocarbonyl compounds to the ring system of protoemetine [5] with side chains in the "natural" positions.

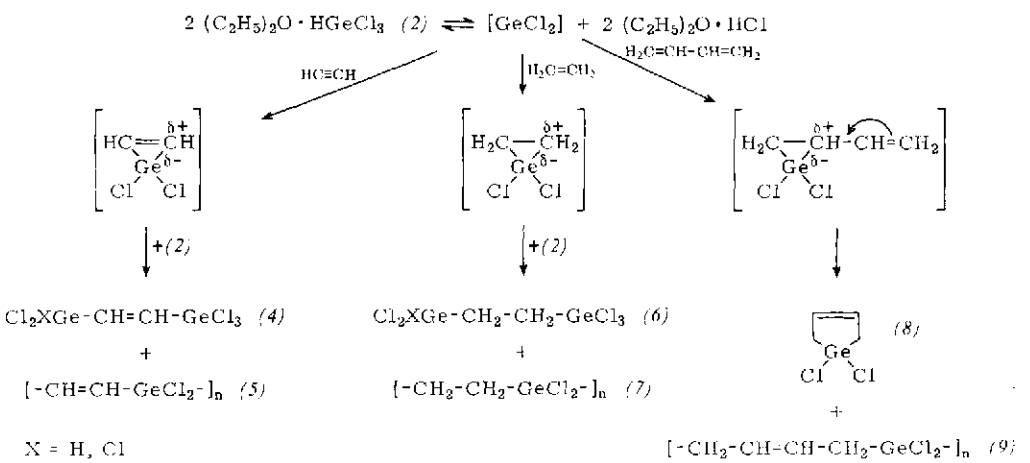
## Structure and Properties of Trihalogenogermane Etherates



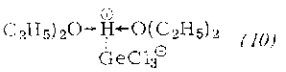
By Dr. O. M. Nefedov, cand. chem. S. P. Kolesnikov, and Dipl.-Chem. V. I. Sheichenko

N. D. Zelinskij Institute for Organic Chemistry, Academy of Sciences of the U.S.S.R., Moscow (U.S.S.R.)

$HGeCl_3$ *(1)* associates with diethyl ether to forme an etherat $2(C_2H_5)_2O \cdot HGeCl_3$ *(2)*, a bright yellow oil which is insoluble in excess diethyl ether, but which dissolves *(1)*. The infrared spectrum of *(2)* does not contain a Ge–H band, which would be expected to occur between 2000 and 2200 $cm^{-1}$. The NMR spectrum of *(2)* [60 Mc, tetramethylsilane as internal standard] shows only the signals of the $CH_2$ and $CH_3$ groups of the ether ($\delta = -1$ to $-4$ ppm) plus a singlet at $\delta = -14.7$ to $-14.5$ ppm. Comparison of this figure with the values for $HGeCl_3$ ($-7.6$ ppm) and dilute hydrochloric acid ($-16.6$ ppm) shows that the H–Ge bond in $HGeCl_3$ is strongly polarized, hence the proton attaches itself to the lone electron pairs of the ether's oxygen atoms.

Other similar etherates are formed by *(1)*, *e.g.* with di-n-butyl ether and with tetrahydrofuran ($\delta_{Ge-H} = -14.2$ ppm); the etherate with tetrahydrofuran is soluble in tetrahydrofuran and diethyl ether. After standing for 1–2 days, *(2)* dissolves in ether. At the same time, a new NMR signal appears at about $-11$ ppm, because the etherate has partly decomposed into $C_2H_5OH$ and $C_2H_5GeCl_3$. Etherates of other trihalogenogermanes, *e.g.* $HGeI_2Cl$, are formed when $GeI_2$ is dissolved in strong hydrochloric acid/ether $[2(C_2H_5)_2O \cdot HGeI_2Cl$ *(3)*, $\delta_{Ge-H} = -12.1$ ppm]. $2(C_2H_5)_2O \cdot HSnCl_3$ ($\delta_{Sn-H} = -11.8$ ppm) is formed from $SnCl_2$ under the same conditions. The etherates of trihalogenogermanes differ strongly in their chemical behavior from the trihalogenogermanes themselves: the etherates act as sources of $GeHal_2$, *i.e.* germanium analogues of dihalogenocarbenes [1]. The reaction diagram shows the reactions of *(2)* with acetylene, ethylene, and butadiene (ca. 20 °C, normal pressure). The other etherates *(3)* react analogously. Compounds *(4)* and *(6)* react with $CH_3MgBr$ to yield the hexamethyl derivatives, and *(8)* gives rise to the dimethyl derivative. Yields: *(4)* 50–60 %; *(5)* 20–30 %; *(6)* 50–60 %; *(7)* 20–25 %; *(8)* 60–65 %; *(9)* ca. 30 %. Both RMgHal and RLi cause *(2)*, *(3)*, $GeI_2$, other etherates of *(1)*, and also the complex compound formed from *(1)* and pyridine to undergo telomerization of the $GeCl_2$ or of the $GeR_2$ formed from it – a property characteristic of carbenes and their analogues; $R-[GeR_2]_n-R$ (n usually $\geq 2$) and small quantities of cyclopolymers $[-GeR_2-]_n$ with n = 4 or 6 are formed.

Like $HGeCl_3$ and the stable compounds $GeHal_2$ and $SnHal_2$ [2], the etherates of $HGeHal_3$ are strong reducing agents, being oxidized to $GeHal_4$ or $SnHal_4$. For example, *(1)* and



*(2)* reduce $ArN_3$ to $ArN_2NH_2$, and $ArNO_2$ to $ArNH_2$. Cautious evaporation of the etherate *(2)* leaves a residue of $GeCl_2$ (probably polymeric $[GeCl_2]_n$) in 50–60 % yield as an amorphous or finely crystalline bright yellow to red powder. This is soluble in acetone but insoluble in diethyl ether and hydrocarbons, and decomposes at 140 °C. Atmospheric moisture hydrolyses it to GeO; it reacts with benzyl chloride to form $H_5C_6-CH_2-GeCl_3$.

The structure *(10)* proposed for the etherate *(2)* explains the ease of formation of $GeCl_2$ by the dissociation:

$$GeCl_3^{\ominus} \rightleftharpoons GeCl_2 + Cl^{\ominus}$$

and also its greater reactivity, compared with that of the stable compounds $GeI_2$ and $SnHal_2$ [3].

*(10)*

$HCCl_3$ scarcely reacts with diethyl ether ($\Delta\delta_{C-H} \approx 0.5$ ppm), and $HSiCl_3$ not at all ($\Delta\delta_{Si-H} = 0$ ppm). The difference in behavior of $HGeCl_3$ and $HSiCl_3$ can probably

be explained by the difference in direction of their polarizations ($H^{\delta+}Ge^{\delta-}Cl_3$ and $H^{\delta-}Si^{\delta+}Cl_3$ [4]).

## Compounds Containing the Si—N—B Linkage [1]

By C. R. Russ and Prof. Dr. A. G. MacDiarmid

John Harrison Laboratory of Chemistry
and Laboratory for Research on the Structure of Matter
Philadelphia, Penn. (U.S.A.)

*Geymayer, Rochow*, and *Wannagat* [2] recently prepared the compounds $[(R_3Si)_2N]_2BF$ *(1)*, $(R_3SiNBCl)_3$ *(2)*, and $[R_3SiNBN(SiR_3)_2]_2$ *(3)*, where R = $CH_3$. We have also obtained *(1)* and *(3)* by somewhat different synthetic methods, and have prepared $[(CH_3)_3Si]_2NBF_2$ *(4)* by two different types of reaction.

$BF_3$ was passed through a solution of $[(CH_3)_3Si]_2NLi$ [3] in pentane/hexane; subsequent distillation at reduced pressure afforded good yields of *(1)*, m.p. 18 °C, b.p. 63 °C/0.5 mm. Its structure was confirmed by elementary analysis, infrared and $^1H$—NMR spectra (dioxane as internal standard; $\delta = 0.21$ ppm relative to low field of tetramethylsilane); mol. wt. found 350, calc. 348. The reverse order of mixing of the reactants did not result in the formation of *(4)*, even at −78 °C. However, when *(1)* was heated with $BF_3$ at 95 °C for several hours, good yields of *(4)*, m.p. −37.6 °C, b.p. 21 °C/5.2 mm, were

$$\underset{(1)}{[(CH_3)_3Si]_2N-B(F)-N[Si(CH_3)_3]_2} + BF_3 \rightarrow 2\,\underset{(4)}{[(CH_3)_3Si]_2NBF_2} \quad (a)$$

obtained. Compound *(4)* is a colorless liquid. Its structure was confirmed by elementary analysis, and infrared and mass spectra.

Solutions of $[(CH_3)_3Si]_3N$ [4] in pentane do not react with $BF_3$ at room temperature. However, on heating the reactants in the absence of solvent at 130 °C for several hours, large amounts of *(4)* were obtained.

$$[(CH_3)_3Si]_3N + BF_3 \rightarrow \underset{(4)}{[(CH_3)_3Si]_2NBF_2} + (CH_3)_3SiF \quad (b)$$

When *(4)* was heated in a sealed tube at 200 °C for several hours, no $BF_3$ was evolved. This indicates that reaction (a) is not reversible. Instead, $(CH_3)_3SiF$ was eliminated from *(4)*, and it appears that the *B*-fluoroborazine analogous to *(2)* was produced.

When *(1)* was heated at 200 °C for 36 h in a sealed tube, $(CH_3)_3SiF$ was eliminated, and ca. 75 % of *(3)* were obtained.

$$2\,\underset{(1)}{[(CH_3)_3Si]_2N-B(F)-N[Si(CH_3)_3]_2} \longrightarrow \underset{(3)}{[(CH_3)_3Si]_2N-B\langle N(Si(CH_3)_3)-B-N(Si(CH_3)_3)\rangle B-N[Si(CH_3)_3]_2} + 2\,(CH_3)_3SiF \quad (c)$$

The structure of *(3)*, m.p. 208 °C, was confirmed by elementary analysis, and infrared and $^1H$—NMR spectra (dioxane as internal standard; $\delta[(CH_3)_3Si]_2N$ − 0.19 ppm and $\delta(CH_3)_3SiN$ = 0.15 ppm relative to low field of TMS); mol. wt. found 520, 511, calc. 517. The NMR signals were in the ratio 1.96:1. The NMR data indicate that the nitrogen atoms of the ring system are less effective in withdrawing electrons from the protons than the exocyclic nitrogen atoms. This suggests that delocalization of the lone pairs of electrons on the nitrogens in the ring is not extensive. A similar conclusion, based on different experimental evidence, has been reached regarding electron delocalization in the ring system of $[t\text{-}C_4H_9(H)NBN(t\text{-}C_4H_9)]_2$ the only other dimeric borazine derivative known [5].

## Iron Carbonyl Complexes of the Dimers of Cyclooctatetraene and Bullvalene

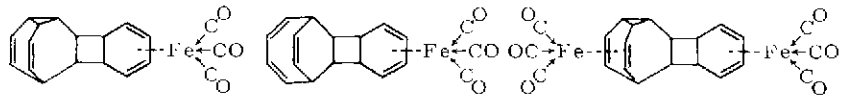
By Priv.-Doz. Dr. G. N. Schrauzer and Dipl.-Chem. P. Glockner

Institut für Anorganische Chemie
der Universität München (Germany)

and by Dipl.-Ing. R. Merényi

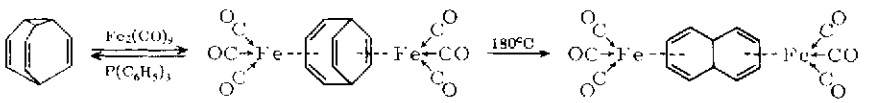
Union Carbide European Research Associates,
Brussels (Belgium)

Light-induced addition of cyclooctatetraene onto cyclooctatetraeneiron tricarbonyl [1] leads to two isomeric complexes, *viz.* $C_{16}H_{16}Fe(CO)_3$ *(1)*, m.p. 118 °C, and $C_{16}H_{16}Fe(CO)_3$ *(2)*, m.p. 172 °C (decomp.).



Compound *(1)* is also formed directly by the reaction of $Fe_2(CO)_9$ with the dimer of cyclooctatetraene $C_{16}H_{16}$ *(3)*, m.p. 76 °C [2]. *(1)* is a π-complex whose organic ligand undergoes fast and reversible valence isomerization; its NMR spectrum is strongly temperature-dependent. However, the structure of *(2)* does not "fluctuate".

The reaction of *(3)* with $Fe(CO)_5$ at 160–170 °C gives besides *(1)*, another $C_{16}H_{16}Fe(CO)_3$ isomer *(4)*, m.p. 175–180 °C (decomp.), a binuclear complex $C_{16}H_{16}Fe_2(CO)_6$ *(5)*, m.p. 191 °C, and a trinuclear complex $C_{16}H_{16}Fe_3(CO)_9$ *(6)*, m.p. 170 °C (decomp.) [3].



Complex *(5)* is also formed by the reaction of *(1)* with $Fe(CO)_5$ at 180 °C, as well as by heating *(6)* in a sealed glass tube to 180 °C. The complicated NMR spectra of *(4)*, *(5)*, and *(6)* are not temperature-dependent; thus, the reversible valence isomerization of the parent hydrocarbon is suppressed by complex formation. The structures of *(4)* and *(6)* are still unknown [4]. The proposed structure for *(5)* is not in contradiction to its NMR spectrum.

The reaction of tricyclo[3,3,2,$0^{4,6}$]deca-2,7,9-triene (bullvalene) *(7)* [2,5] with $Fe_2(CO)_9$ in boiling benzene affords the complex $C_{10}H_{10}Fe_2(CO)_6$ *(8)*, m.p. 120 °C; when heated to 140 °C in the presence of excess triphenylphosphine, *(8)* decomposes into bullvalene *(7)* and $Fe(CO)_3 \cdot 2P(C_6H_5)_3$; at 180 °C in an autoclave, it is transformed into the known complex 9,10-dihydronaphthalenediiron hexacarbonyl *(9)*, m.p. 195–197 °C (decomp.) [6]. The NMR spectra of *(8)*

and *(9)* support the proposed structures; unlike to that of bullvalene *(7)*, they are not temperature-dependent. Thus, it is possible to stabilize the intermediates of the transformation of bullvalene into naphthalene [2] as *(8)* and *(9)* by complex formation, although these intermediates were

*(1)* *(2)* *(5)*

*(7)* *(8)* *(9)*

not isolated in their non-complexed form. This transformation is favored by the presence of the $Fe(CO)_3$ groups and takes place at a much lower temperature than with free bullvalene; bullvalene *(7)* therefore loses its "fluctuating" structure on $\pi$-complex formation.

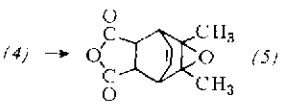
## Synthesis of an Oxepin Derivative

By Prof. Dr. E. Vogel, Dipl.-Chem. R. Schubart, and Dr. W. A. Böll



Institut für Organische Chemie der Universität Köln (Germany)

Oxepins are of theoretical interest on account of their cyclic 8-$\pi$-electron system, and several attempts at their synthesis have been made [1]. 2,7-Dimethyloxepin *(4)* is the first simple representative [2] of this class of compounds to be prepared. It is obtained in 60 % yield as a stable yellow liquid, b.p. 51 °C/14 mm, $n_D^{20} = 1.5045$, when the dibromo compound *(2)*, m.p. 85–86 °C (derived from the unsaturated epoxide *(1)* [3]) is dehydrobrominated with potassium t-butoxide in ether at 0 °C. The epoxide *(3)* is a likely intermediate.

*(1)* *(2)* *(3)* *(4)*

The proof of the structure of *(4)* is based mainly on its NMR spectrum, which has a singlet at 8.1 $\tau$ (6 methyl protons) and two multiplets centered at 4.1 and 4.7 $\tau$ (two protons each). The olefinic region in the NMR spectrum is similar to that of 1,6-dimethylcycloheptatriene [4]. In the infrared spectrum a band at 1660 $cm^{-1}$ (C=C), typical of enolic ethers, appears. The yellow color of *(4)* is due to the long-wave end of a broad ultraviolet absorption band with $\lambda_{max} = 297$ m$\mu$ (log $\varepsilon$ = 3.25). On standing for some time with maleic anhydride, *(4)* reacts to form the adduct *(5)*, m.p. 235 °C (decomp.), derived from *(3)* [5].

*(4)* → *(5)*

The synthesis of *(4)* instigated reinvestigation of the dehydrobromination of 1,2-epoxy-4,5-dibromocyclohexane [1b, 1c]. Previously only phenol had been isolated from this reaction. When 1,5-diazabicyclo[3,4,0]non-5-ene [6] is used as dehydrohalogenating agent, a yellow elimination product, b.p. 27 °C/14 mm, was obtained in good yield in 95 % purity; it is assumed to be oxepin. The product began to rearrange into phenol above 70 °C, and its catalytic hydrogenation yielded mainly oxepane. Maleic anhydride added onto it fairly rapidly, even at 20 °C; the adduct melts at 264 °C (decomp.). Finally, the NMR spectrum shows absorptions only in the olefinic range (three multiplets with relative intensities of 1 : 1 : 1, centered at 3,9 $\tau$, 4.4 $\tau$, and 4.7 $\tau$) which suggest that the product is actually oxepin [7].

[2] 3-Benzoxepin and some of its derivatives were described by *K. Dimroth* et al., Angew. Chem. *69*, 95 (1957); Chem. Ber. *90*, 1623 (1957); Angew. Chem. *73*, 436 (1961); 1-Benzoxepin was recently obtained in our laboratories (unpublished).

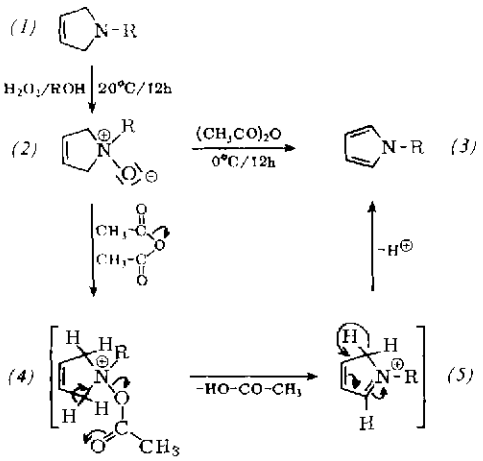
[3] *W. Hückel* and *U. Wörffel*, Chem. Ber. *88*, 338 (1955).

[4] Unpublished experiments with *H. D. Roth*.

[5] The kinetic and thermodynamic relationship between oxepins and the valence-bond isomeric aromatic oxides has still to be investigated.

[6] *E. Truscheit* and *K. Eiter*, Liebigs Ann. Chem. *658*, 65 (1962).

[7] Note added in proof (May 25th): Oxepin has now been prepared in pure form, b.p. 38 °C/30 mm, $n_D^{25} = 1.5162$, broad ultraviolet absorption band with $\lambda_{max} = 271$ m$\mu$ (log $\varepsilon$ = 3.15), in cyclohexane. The compound appears to exist in equilibrium with its valence tautomer benzene epoxide.



## A New Synthesis of N-Alkylpyrroles

By Dr. R. Kreher and cand. chem. H. Pawelczyk

Institut für Organische Chemie der Technischen Hochschule Darmstadt (Germany)

*N*-Alkylpyrroles *(3)* are formed in 50–60 % yield by the action of acetic anhydride at 0 °C [1] on *N*-alkyl-$\Delta^3$-pyrroline-*N*-oxides *(2)*, which are in turn obtained in almost quanti-

tative yields by oxidation of *N*-alkyl-$\Delta^3$-pyrrolines *(1)* [2] with 30 % hydrogen peroxide.

*(a)*: R = $C_6H_5$-$CH_2$-$CH_2$-
*(b)*: R = $C_6H_5$-$CH_2$-
*(c)*: R = n-$C_4H_9$-

To account for the formation of the pyrrole derivatives, we assume that, by analogy to the Polonovski reaction [3], the *N*-oxide is acetylated by the acetic anhydride at the oxygen. The intermediate *(4)*, which cannot be isolated, loses a molecule of acetic acid with formation of a pyrroleninium cation *(5)*, which is converted with loss of a proton into the mesomerically stabilized pyrrole system [4].

Received, May 6th, 1964 [Z 734/560 IE]
German version: Angew. Chem. *76*, 536 (1964)

[1] Thermal decomposition of the *N*-oxides *(2)* at 120–140 °C occurs differently in part (cf. *H. Pawelczyk*, Diploma Thesis, Technische Hochschule Darmstadt, 1964).

[2] We succeeded in preparing *N*-alkyl-$\Delta^3$-pyrrolines *(1)* from *cis*-1,4-dichloro-2-butene and primary amines, and in characterizing them by analysis of their picrates; cf. the preparation of *N*-phenyl-$\Delta^3$-pyrroline according to *G. Wittig* and *H. Sommer* [Liebigs Ann. Chem. *594*, 10 (1955)] and *J. M. Bobbitt, L. H. Amundsen*, and *R. I. Steiner* [J. org. Chemistry *25*, 2230 (1960)].

[3] *R. Huisgen, F. Bayerlein*, and *W. Heydkamp*, Chem. Ber. *92*, 3223 (1959).

[4] The removal of the acetoxy group together with a hydrogen atom from the alkyl group, occurs only to a very small extent in the reaction of *N*-benzyl-$\Delta^3$-pyrroline-*N*-oxides *(2b)*, in which the $\alpha$-hydrogen atoms of the benzyl residue are activated by the phenyl group; this side-reaction leads, after hydrolysis, to benzaldehyde and $\Delta^3$-pyrroline.

## New Modifications of $Nb_2O_5$ [*]

By Prof. Dr. H. Schäfer, Dr. F. Schulte, and Dr. R. Gruehn

Anorganisch-chemisches Institut der Universität Münster (Germany)

$Nb_2O_5$ migrates towards the coldest part of a temperature gradient during the endothermic equilibrium reaction [1]

$$Nb_2O_5\,(s) + 3\,NbX_5\,(g) \rightleftharpoons 5\,NbOX_3\,(g) \qquad (X = Cl, Br, \text{or } I).$$

By variation of temperature and pressure, especially in the system X = Cl, three new modifications, *viz.* P-, B-, and N-$Nb_2O_5$ [2,3], result as well-formed crystals besides the forms known earlier, *viz.* H-$Nb_2O_5$ and M-$Nb_2O_5$. The transport conditions were for example 850→750 °C, $p(NbOCl_3)$ ≈ 5 atm. To ensure that the Nb was present to a very high extent in the oxidation state 5, chlorine was filled into the reaction tube (1 atm at room temperature).

All the $Nb_2O_5$ modifications transported in this way were colorless, with the exception of the B-form, which was obtained under these conditions with a pale blue color and a composition corresponding to $NbO_{2.496}$ [4]. These new Modifications are mostly formed simultaneously, but usually apart from each other and in such large crystals that they can be easily isolated.

P-$Nb_2O_5$ forms colorless prisms or plates; it contains < 0.01 % Cl.

Its d-values [**] [Å] (estimated intensities in brackets) are: 6.37 (5); 3.85 (10); 3.54 (4); 3.18 (7); 3.10 (7); 2.76 (2); 2.70 (7); 2.66 (7); 2.31 (4); 2.29 (2); 2.12 (4); 2.09 (2); 1.99 (2); 1.95 (5); 1.93 (2); 1.87 (3); 1.77 (2); 1.75 (5); 1.74 (6).

On annealing amorphous $Nb_2O_5 \cdot nH_2O$ containing 8 % HCl X-ray crystalline P-$Nb_2O_5$ (+ T-$Nb_2O_5$) resulted.

B-$Nb_2O_5$ can be separated as pale blue or colorless plates which are often over 5 mm in size and contain < 0.01 % Cl.

Its d-values [Å] (estimated intensities in brackets) are: 6.15 (5); 3.63 (10); 3.31 (10); 3.07 (10); 2.96 (10); 2.73 (1); 2.68 (6); 2.50 (6); 2.44 (6); 2.34 (3); 2.26 (1); 2.22 (3); 2.19 (2); 2.16 (2); 2.05 (3); 1.91 (6); 1.88 (2); 1.82 (1); 1.80 (7).

*Laves* et al. [5] have also meanwhile, obtained the B-modification using the same transport method.

B-$Nb_2O_5$ (+ T-$Nb_2O_5$) was obtained from $NbO_2$ crystals with a small iodine content by igniting them in air; no macroscopically recognizable B-crystals resulted, however.

N-$Nb_2O_5$ occurs as colorless crystalline needles with 0.1 % Cl. The product contained appreciable amounts of $SiO_2$, but whether this is included in the lattice is not yet known.

Its d-valnes [Å] (estimated intensities in brackets) are: 7.17 (2); 6.89 (2); 4.78 (3); 4.73 (3); 3.73 (10); 3.58 (10); 3.56 (10); 3.33 (1); 3.16 (3); 2.87 (1); 2.77 (9); 2.67 (1); 2.53 (1); 2.50 (1); 2.43 (1); 2.39 (1); 2.37 (1); 2.30 (7).

Nothing is yet known about the thermodynamic stability of the new modifications. The T-modification [6] and its precursor [7], designated by us as TT-$Nb_2O_5$, were also obtainable by transport, but not yet as perfect crystals.

We will gladly respond to requests for prints of Guinier photographs, crystal photographs, and limited samples of substances.

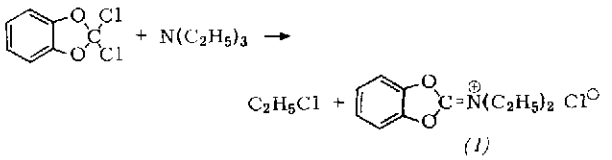
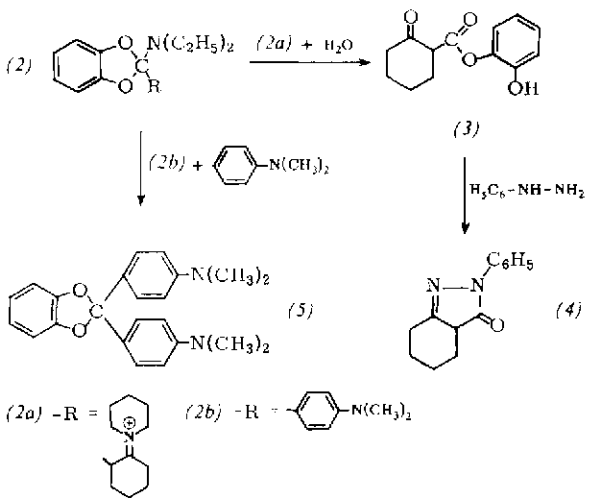
## Synthesis and Reactions of Benzodioxolone-N,N-diethylimidinium Chloride



By Doz. Dr. H. Gross and Dipl.-Chem. J. Rusche

Institut für Organische Chemie der Deutschen Akademie der Wissenschaften, Berlin-Adlershof (Germany)

*Dedicated to Professor H. Bredereck on the occasion of his 60th birthday*



Benzodioxolone-*N*,*N*-diethylimidinium chloride *(1)*, the postulated primary product of the interaction of triethylamine and catechol dichloromethylene ether [1], has now been iso-

lated in pure form by heating the reactants for 3 h at 130 °C and recrystallizing the product from acetonitrile/ether. Its polar character follows from its high melting point (decomp.

*(1)*

above 176 °C) and its behavior towards polar and non-polar solvents. Its infrared spectrum features a strong band at 1730 $cm^{-1}$, which is attributable to the C=N bond [2, 3]. On treatment with *N*-cyclohexenylpiperidine, *(1)* yields presumably first *(2a)*, which is hydrolysed smoothly to *o*-hydroxyphenyl cyclohexanone-2-carboxylate *(3)*, m.p. 98–99 °C; yield: 71 % [4]. Alkaline hydrolysis of *(3)* gave cyclohexanone, carbon dioxide, and catechol; treatment of *(3)* with phenylhydrazine gave the expected 2-phenyl-4,5-tetramethylenepyrazol-3-one *(4)*. *N*-Cyclopentenylpiperidine reacted similarly with *(1)* to give *o*-hydroxyphenyl cyclopentanone-2-carboxylate, m.p. 153–154.5 °C, in 76 % yield. Neither

*(2b)* nor a hydrolysis product thereof could be isolated from the reaction of *(1)* with dimethylaniline; nascent *(2b)* immediately reacts further with dimethylaniline to form the *o*-phenyleneketal of Michler's ketone *(5)*, m.p. 156–158 °C, in 65 % yield; this could be hydrolysed almost quantitatively to the ketone.

## The Absolute Configuration of 1,2-(α-Oxotetramethylene)ferrocene

By Doz. Dr. K. Schögl and cand. chem. H. Falk

Organisch-Chemisches Institut der Universität Wien (Austria)

Ferrocene derivatives with at least two different substituents on one ring are asymmetric and can thus be resolved into optical antipodes [1–3]. We have now succeeded in ascertaining the absolute configuration of (+)-1,2-(α-oxotetramethylene)ferrocene, *i.e.* (+)-*(1)*.

The latter ($[\alpha]_D = +510°$ in ethanol, *i.e.* 87 % optical purity) was reduced with $LiAlH_4$ to a mixture of the epimeric *endo*- and *exo*-alcohols. The mixture of acetates obtained therefrom could be hydrolysed stereoselectively with aqueous acetone (owing to neighboring group effect of the iron) [4] to the dextrorotatory *exo*-alcohol *(2)* ($[\alpha]_D = +113°$ in ethanol). The reaction of (+)-*(2)* with racemic α-phenylbutyric anhydride in pyridine according to *Horeau* [5] liberated α-phenylbutyric acid which was optically active ($\alpha_D = -0.79°$, l = 1 dm, in 2 ml of benzene) on account of the asymmetric esterification. Since 550 mg of (+)-*(2)* yielded 230 mg (= 27 %) of the phenylbutyrate *(3)* (isolated by preparative

(+)-*(1)* (+)-*(2)*

thin-layer chromatography, identified by infrared spectroscopy), the optical yield amounted to 20 %. As expected, saponification of *(3)* then yielded an excess of the (+)-acid. The asymmetric carbon atom in (+)-*(2)* thus has the (*S*)-configuration [5], which determines the absolute configuration of (+)-*(2)* to be (*R*)-1,2-(α-oxotetramethylene)ferrocene [6]. Also the absolute configurations of all optically active ferrocenes derived from *(1)* have thereby been established [7].

Since other methods for determining the configurations of the ketone *(1)* and of the alcohol *(2)*, *e.g.* asymmetric Meerwein-Ponndorf reduction or *Prelog*'s method [8], proved to be unsuitable, we checked *Horeau*'s method with several examples, including ( )-α-methylbenzyl alcohol, quinine, quinidine, and cinchonidine, in which an aromatic ring system is also present next to the asymmetric carbon atom, before applying it to the ferrocene derivative *(2)*. Correct results with very satisfactory chemical and optical yields were invariably obtained regarding the configuration of the carbon atom in question.

The result of this chemical determination of the configuration of *(2)* – and with it of *(1)* – corresponds with the absolute configuration of (+)-*(1)* postulated by us earlier [7] on the basis of the octant rule [8].

## The Reaction of Alkylidenetriphenylphosphoranes with Acetylenedicarboxylic Esters

By Prof. Dr. H. J. Bestmann and Dipl.-Chem. O. Rothe

Institut für Organische Chemie der Technischen Hochschule München (Germany)

A recent communication [1] on the reaction of triphenylphosphineimines with acetylenedicarboxylic esters prompts us to publish some results of our experiments on the reaction of alkylidenetriphenylphosphoranes *(1)* and dimethyl acetylenedicarboxylate *(2)*.

The reaction of *(1)* with *(2)* proceeds extremely readily. The product is not that of a Michael addition *(4)* [2], but an ylide *(6)*, which is very stable. It is assumed that the betaine *(3)* initially formed rearranges to *(6)* via *(5)*.

| | R′ | R¹ | M.p. [°C] | Yield [%] |
|---|---|---|---|---|
| *(6a)* | $CH_3$ | H | 174—176 | 77 |
| *(6b)* | $CH_3(CH_2)_2$— | H | 133—137 | 47 |
| *(6c)* | $C_6H_5$ | H | 182—184 | 72 |
| *(6d)* | $C_6H_5$—CH=CH— | H | 173—178 | 48 |
| *(6e)* | $C_6H_5$ | $CH_3$ | 213—216 | 60 |
| *(6f)* | $C_6H_5$ | $C_6H_5$ | | |

The structure *(6)* was derived:

a) By degradation reactions: Hydrolysis of *(6c)* led to benzylidenesuccinic acid and triphenylphosphine oxide; oxidative cleavage gave benzaldehyde.

b) From infrared spectra: The spectra of all the compounds *(6)* contain two carbonyl bands, one of which appears at 6.15–6.20 μ; this is characteristic of alkylidenephosphoranes with an ester group at the carbon atom of the C=P double bond [3].

c) From NMR spectra: The signal of the olefinic proton at 4.4 τ in the NMR spectrum of *(6a)* is split into a quadruplet (J = 3.9 cps). For the methyl group, two doublets appear at 8.4 τ and 8.25 τ (J = 3.9 cps); one can be assigned to the *cis*- and one to the *trans*-form.

Starting from *(2)* and α-methylbenzylidenetriphenylphosphorane, $(C_6H_5)_3P{=}C(C_6H_5)(CH_3)$, which cannot undergo Michael addition to give *(4)*, we obtained a compound *(6e)* whose constitution has been established by oxidative cleavage to acetophenone and by its infrared spectrum. These findings support the supposition [1] that the yellow compound formed from diphenylmethylenetriphenylphosphorane, $(C_6H_5)_3P{=}C(C_6H_5)_2$, and *(2)* is *(6f)*.

## Dichloromethyl-lithium and Trichloromethyl-lithium [*]

By Doz. Dr. G. Köbrich, Dipl.-Chem. K. Flory, and W. Drischel

Organisch-Chemisches Institut der Universität Heidelberg (Germany)

We have obtained solutions of the title compounds *(1a)* and *(1b)* by treating respectively methylene dichloride and chloroform with n-butyl-lithium in tetrahydrofuran/ether/petroleum ether (4:1:1) [1] at ca. −110 °C.

These compounds react with benzophenone to give good yields of the known alcohols *(2)*; with mercuric chloride, they give respectively bisdichloromethylmercury *(3a)* [97 % yield, m.p. 154–155 °C (decomp.)] and bistrichloromethylmercury *(3b)* [91 % yield, m.p. 146.5–148.5 °C (decomp.)].

*(a)* X = H; *(b)* X = Cl

The following experiments give an indication of the stability of the organo-lithium compounds *(1)*: if *(1b)* is allowed to warm up in the above solvent mixture to −60 °C during 12 min and is kept at this temperature for further 25 min, treatment with $HgCl_2$ gives 50 % *(3b)*. Unlike *(1b)*, *(1a)* can be prepared in tetrahydrofuran at −65 °C; reaction with $HgCl_2$ after 30 min gives 91 % *(3a)* and, even after 11 h, the yield of *(3a)* is still ca. 75 %.

The greater stability of *(1a)* relative to *(1b)* thus established is unexpected since the inductive effect of an additional α-halogen atom should stabilize the carbanionoid state further; it is, however, consistent with the assumption [2] that α-elimination of LiCl occurs more readily from *(1b)* than from *(1a)* since the carbene produced from the former (dichlorocarbene) is more stable than that formed from the latter (chlorocarbene [3]). Further investigations of the organo-lithium compounds *(1)* and related substances are in progress.

## Alkyl(Aryl)dialkylaminotrifluorophosphoranes and -fluorophosphines [*]

By Dr. R. Schmutzler

University Chemical Laboratory, Cambridge (England)

We have found that, like chlorophosphines $R_nPCl_{3-n}$ [1], several dialkylaminochlorophosphines $RPClNR_2'$ react with Group V trifluorides in accordance with the following equation:

$$3\,RPClNR_2' + 3\,MF_3 \rightarrow 3\,RPF_3NR_2' + 2\,M + MCl_3$$
(M = As or Sb)

$CH_3PF_3N(CH_3)_2$ *(1)*, b.p. 85 °C, $C_6H_5PF_3N(CH_3)_2$ *(2)*, b.p. 88 °C/6.5 mm, and $C_6H_5PF_3N(C_2H_5)_2$ *(3)*, b.p. 81–82 °C/2 mm, were readily accessible by this route. Compound *(2)* and several other aryldialkylaminotrifluorophosphoranes were previously prepared in a three-step reaction [2].

The $^{19}F$-NMR spectra (Table 1) of *(1)–(3)* consist of a pair of doublets (a) and a double triplet (b), the doubling arising from P–F spin-spin splitting. An intensity ratio a:b = 2:1 was found. These data are consistent with trigonal-bipyramidal geometry, as in trifluorophosphoranes $R_2PF_3$, with a fluorine atom in each apical position and one occupying an equatorial site. The phosphorus-fluorine coupling constants $J_{P-F}$ and the chemical shifts $\delta_F$ are consistently larger for

Table 1. Chemical shifts $\delta$ [ppm] and spin-spin coupling constants $J_{P,F}$ [cps] for *(1)*–*(5)*.

| | *(1)* | *(2)* | *(3)* | *(4)* | *(5)* |
|---|---|---|---|---|---|
| $^{19}$F-NMR spectra [a] | | | | | |
| $\delta_{Fa}$ [b] | 27.6 | 40.6 | 43.5 | | |
| $\delta_{Fb}$ | 69.0 | 68.5 | 66.5 | | |
| $J_{P-Fa}$ | 808 | 818 | 823 | | |
| $J_{P-Fb}$ | 965 | 959 | 966 | | |
| $J_{Fa-Fb}$ | 53 | 54 | 55–56 | | |
| $\delta_F$ | | | | 117.9 | 128.5 |
| $J_{P-F}$ | | | | 920 | 989 |
| $^{31}$P-NMR spectra [c] | | | | | |
| $\delta_P$ | | | | −168.9 | −159.8 |
| $J_{P-F}$ | | | | 917 | 985 |

[a] $CFCl_3$ as internal standard.
[b] $F_a$: F atom at apex, $F_b$: F atom at base of trigonal bipyramid.
[c] 85 % $H_3PO_4$ as external standard.

equatorial than for apical fluorine atoms both in dialkylaminotrifluorophosphoranes $RPF_3NR'_2$ and in other trifluorophosphoranes $R_2PF_3$ [3]. Thus, there is sufficient evidence that the stereochemical conclusions put forward for $R_2PF_3$ also hold for *(1)*–*(3)*.

Fluorination of $RPClN(CH_3)_2$ with NaF in tetramethylene sulfone (as a polar medium, preventing oxidation-reduction reactions) led to $CH_3PFN(CH_3)_2$ *(4)*, b.p. 85–86 °C, and $C_6H_5PFN(CH_3)_2$ *(5)*, b.p. 88–90 °C/15 mm.

Both *(4)* and *(5)* are distinguished by very large negative chemical shifts in their $^{31}$P-NMR spectra, which are indicative of fluorides of trivalent phosphorus (cf. for instance: $[(CH_3)_2N]_2PF$, $\delta_P$ = −151.4 ppm; $C_6H_5PFN(CH_3)_2$, $\delta_P$ = −159.8 ppm; $ClCH_2PF_2$, $\delta_P$ = −201.8 ppm; $C_6H_5PF_2$, $\delta_P$ = −208.3 ppm; based on 85 % $H_3PO_4$ as an external standard).

## Addition of Secondary N-Trimethylsilylamides onto Aldehydes [1]

By Prof. Dr. L. Birkofer and Dipl.-Chem. H. Dickopp

Institut für Organische Chemie der Universität
Köln (Germany)

Secondary *N*-trimethylsilylamides such as *N*-trimethylsilyl-*N*-methylformamide, *N*-trimethylsilyl-*N*-methylacetamide, or *N*-trimethylsilyl-2-pyrrolidone react without a catalyst with aliphatic or aromatic aldehydes to give the *N*-alkyl-*N*-(α-trimethylsiloxyalkyl)amides *(1)*–*(6)* in 80–90 % yield. To our knowledge, the reaction of free secondary amides has previously been achieved only with formaldehyde to give *N*-hydroxymethyl derivatives [2].

*N*-Trimethylsilyl-*N*-methylformamide reacts exothermally with aldehydes at room temperature; the other silylamides react only when heated. The products *(1)*–*(6)* may be purified by vacuum distillation. They are colorless, oily liquids which are relatively insensitive to water and alcohol at room temperature. However, they are hydrolysed in the presence of $H^+$ ions, and the intermediate hydroxy compounds decompose to the corresponding amides and aldehydes.

$$R^1{-}CHO + R^2{-}CO{-}N{-}R^3 \xrightarrow[Si(CH_3)_3]{} R^1{-}CH{-}O{-}Si(CH_3)_3 \quad R^2{-}CO{-}N{-}R^3$$

*(1)*–*(6)*

| | $R^1$ | $R^2$ | $R^3$ | B.p. [°C/mm] | $n_D^{20}$ |
|---|---|---|---|---|---|
| *(1)* | $C_6H_5$– | H– | $CH_3$– | 156–157/12 | 1.4973 |
| *(2)* | $C_6H_5$– | $CH_3$– | $CH_3$– | 154.8–155/12 | 1.4941 |
| *(3)* | *p*-$CH_3OC_6H_4$– | $CH_3$– | $CH_3$– | 125–126/0.02 | 1.5012 |
| *(4)* | $CH_3{-}CH_2{-}CH_2$– | H– | $CH_3$– | 109.8–110/12 | 1.4357 |
| *(5)* | $CH_3{-}CH_2$– | $CH_3$– | $CH_3$– | 97.8–98/12 | 1.4324 |
| *(6)* | $C_6H_5$– | $-(CH_2)_3$– | | 174.5–175.5/12 | 1.5056 |

The structures *(1)*–*(6)* were established by analysis and NMR and infrared spectra.

The mechanism of formation is assumed to be an addition of Si–N onto the carbonyl double bond, for which a cyclic transition state is probable because of the availability of the silicon 3d-orbitals, into which an electron pair from the carbonyl oxygen can be donated. The reaction appears to be generally applicable. Thus, *N*-trimethylsilyl-*N*-alkylamides react with epoxides in the presence of basic catalysts to give *N*-alkyl-*N*-(β-trimethylsiloxy)alkylamides.

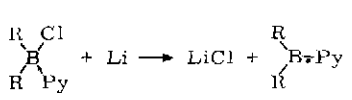
## Stable Free Radicals with B-N and Al-N Bonds



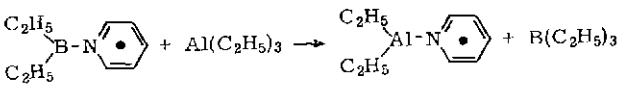
By Dr. R. Köster, Dr. G. Benedikt, and Dr. H. W. Schrötter

Max-Planck-Institut für Kohlenforschung,
Mülheim/Ruhr (Germany)

On dehalogenation of alkylchloroboranes (*e.g.* $R_2BCl$, $RBCl_2$, or *B*-chloroborolanes) with alkali metals (*e.g.* K/Na alloys), compounds containing B–H bonds are obtained (*e.g.* 1-diethylborylalkyldiboranes or 2-borolanylborolanes [1]), which originate from the extremely unstable primary dialkylboryl or borolanyl radicals as a result of hydrogen migration and subsequent combination (*e.g.* with another boryl or borolanyl radical). Thus, for example:

The intermediate free radicals may be trapped in the form of stable compounds if the dehalogenation is carried out in the presence of a suitable base (*e.g.* pyridine, quinoline, or isoquinoline). Intensely colored free radicals can be produced in high yield from the resultant addition compounds. Lithium in suitable solvents (*e.g.* diethyl ether or tetrahydrofuran) has proved particularly valuable for effecting dehalogenation.

R = $C_2H_5$, $C_6H_5$



In ether, the diethylborylpyridine radical is deep-green. After storage for several days at room temperature, the compound separates out as a dark-blue precipitate. Both the solid and its

solution (*e.g.* in diethyl ether) give a strong ESR signal (g = 2.003). With low concentrations of the compound (approximately $10^{-3}$ mole/l), the signal (total width ca. 28 Gauss) shows hyperfine structure (ca. 50 lines), which could not however be fully resolved on further diluting or on cooling to ca. −70 °C.

Interaction of the unpaired electron with the atomic nuclei of the pyridine ring alone would theoretically give rise to 54 lines. With the resolution attained (smallest interlinear distance ca. 0.3 Gauss), these could certainly not all be observed because of overlapping. The unpaired electron may therefore also interact with the boron nucleus (nuclear spin = 3/2 for $^{11}B$), the number of hyperfine structural lines being then increased to 216.

The diethylborylquinoline radical (g = 2.003) is yellow, the corresponding isoquinoline radical (obtainable analogously by reduction with lithium in tetrahydrofuran) is red. The diphenylborylpyridine radical (unresolved ESR signal, g = 2.003), which is isoelectronic with the triphenylmethyl radical, is deep-blue to violet in tetrahydrofuran and can be prepared in the solid state in 86 % yield; cryoscopic molecular-weight determinations in benzene indicated about 1.1 times the simple formula weight. The B—N radicals react with triphenylmethyl with simultaneous decolorization. They are also extremely sensitive towards oxygen.

The corresponding Al—N radicals are formed analogously by dehalogenation. Starting from diethylaluminum chloride pyridinate, a red-violet compound (ESR signal, g = 2.003) is obtained with lithium in ether at 0 °C. The Al—N radical is also accessible by an exchange reaction of the corresponding boron radical with triethylaluminum.

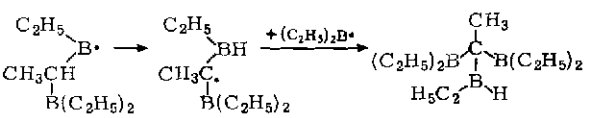
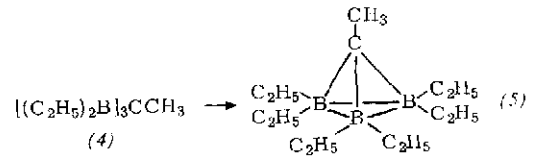
## The Formation of Organic Carboranes

By Dr. R. Köster and Dr. G. Benedikt



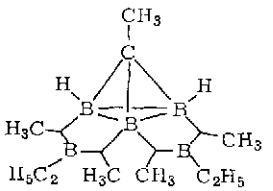
Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany)

The B-H compounds of type *(1)* derived from alkylboranes by way of free radicals [1] may be subjected to H/Cl exchange [2] and then dehalogenated further by means of lithium (*e.g.* in tetrahydrofuran) according to the reaction sequence:



*(1)* *(2)*

As a result of migration of the α-hydrogen of the ethylidene group to the boron atom, *(2)* gives rise to radicals, from which tris(ethylboryl)alkanes *(3)* may be formed by combination with a dialkylboryl radical.

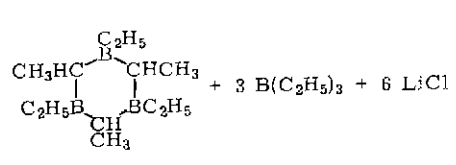


*(2)* *(3)*

Starting from these or from the homologous compound 1,1,1-tris(diethylboryl)ethane *(4)* — formed analogously by H/R exchange [2] — organoboron compounds with the carborane structure are obtained *(5)* [3].

*(4)* *(5)*

It can be demonstrated by mass spectrometry [5] that the reaction mixture contains *inter alia* a compound of molecular formula $C_{14}H_{31}B_5$ [4]. Its structure *(6)* follows from its mode of preparation, its infrared spectrum, its $^{11}B$ nuclear magnetic resonance spectrum (3 signals at δ = −3.4, −9.2, and −25.4 ppm, referred to δ = 0 for $^{11}B$ in $Ca[B(C_2H_5)_4]_2$), and its chemical degradation (BH content by alcoholysis, reaction with ethylene, transalkylation with aluminum trialkyl, followed by deuterolysis → $D_3CCH_3$, $D_2CHCH_3$ together with $DCH_2CH_3$).



*(6)*

The mixtures also contain compounds with four and six boron atoms.

Preparation of $C_{14}H_{31}B_5$ *(6)*: 200 g of diethylchloroborane are added dropwise with cooling to 13.8 g of lithium chips in 300 ml of tetrahydrofuran. After all the metal has been consumed, the LiCl is filtered off, and the solvent and the triethylborane are removed under reduced pressure (15 mm). Subsequent vacuum distillation affords 50.5 g of a colorless liquid, b.p. 30—100 °C/$10^{-3}$ mm, and 15.7 g of a non-volatile viscous residue. Fractionation yields 14 g of a liquid, b.p. 40—60 °C/$10^{-3}$ mm, consisting principally of $C_{14}H_{31}B_5$ (intensive absorption band, with $\tilde{\nu}_{max}$ (BH) = 2570 $cm^{-1}$); mass-groups found in the mass-spectrometric analysis: 252—254, 224—226, 117—119. A second fraction (9 g), b.p. 60 to 85 °C/$10^{-3}$ mm, contains, in addition to a little $C_{14}H_{31}B_5$, boron compounds of higher molecular weight; mass-groups found: 318—321, 303—308, 291—294, 263—266.

If the nascent BH compounds formed during the dehalogenation (*e.g.* of diethylchloroborane by lithium) are removed by means of ethylene as ethylboranes (hydroboration), no C—$CH_3$ groups are formed. The organoboron compounds then contain, apart from ethyl groups, only ethylidene groups. The main product (over 50 % yield) is 1,3,5-triethyl-2,4,6-trimethyl-1,3,5-triboracyclohexane *(7)*, b.p. 70—71 °C/0.01 mm.

*(7)*

The $^{11}B$ nuclear magnetic resonance spectrum of this compound exhibits only a single broad signal (width ca. 37 ppm), with δ = −99.8 ppm. This position thus corresponds to the $^{11}B$ signal of the trialkylboranes and to those of other known organoboron heterocyclics.

## Equilibriation of Cyclic Silazanes and Isolation of a Linear Polysilazane

By Dr. G. Redl and Prof. Dr. E. G. Rochow

Department of Chemistry, Harvard University, Cambridge, Mass. (U.S.A.).

Hexamethylcyclotrisilazane *(1)* and octamethylcyclotetrasilazane *(2)* can be polymerized by heating them with ammonium halides [1]. Ammonia is split off and a crosslinked polymer containing tertiary nitrogen atoms is obtained. We wished to study the kinetics of this reaction by measuring the rate of evolution of ammonia volumetrically in a closed system. It was found that under these circumstances hardly any evolution of ammonia was observable, and the polymer obtained was less crosslinked than that obtained in the open system.

The extent of crosslinking was estimated from NMR spectra. The spectra of the cyclic silazanes *(1)* and *(2)* consist of a single peak at $\delta = 0.06$ ppm due to the methyl protons. The azo-proton peak is extremely broad and can hardly be detected. The spectra of the crosslinked polymers contain several peaks because of the different methyl proton environments. A peak at $\delta = 0.09$ ppm is assigned to methyl protons attached to a silicon atom between secondary nitrogen atoms *(3)*. In a perfectly linear polymer, only this peak should be present.

*(3)*

The product obtained by heating *(1)* with $NH_4Br$ at 130 to 140 °C under 4 atm of ammonia for 80 h was an equilibrium mixture containing approximately 55 % *(1)* and 20 % *(2)*. After removal of all the volatile products by distillation, a colorless viscous residue (20 %) was obtained which was shown to be a linear silazane polymer with an average molecular weight of 1200.

The proton resonance spectrum of this polymer had only a single methyl proton peak at $\delta = 0.09$ ppm and a broad but well-defined azo-proton peak at $\delta = 0.50$ ppm. Integration of the peaks could be carried out only approximately because of slight overlap, but the methyl-proton peak area was found to be 6.0–6.5 times larger than that of the azo-protons. The intensity of the NH stretching and deformation bands at 3399 and 1159 $cm^{-1}$ in the infrared spectrum of *(1)* [2] is unchanged in that of the polymer. This is further evidence for the linear structure of the new polymer since the intensity of these bands is strongly reduced in the infrared spectrum of the crosslinked polysilazane.

It was found that, although $NH_4Br$ is slightly soluble in liquid or molten cyclic silazanes at 140 °C and atmospheric pressure, it is insoluble in the reaction mixture under 4 atm of ammonia, and that the reaction proceeds in exactly the same way with omission of the $NH_4Br$. However, when an inert gas (nitrogen) was used instead of ammonia, no reaction was observed. The catalyst must therefore be ammonia or some ion derived from it. We believe that the reaction is similar to the base-catalysed polymerization of cyclic siloxanes [3], with $NH_2^-$ ions acting as chain initiators, and that the chains are terminated by reaction with $NH_4^+$ ions. The linear polymer then would have the structure:
$NH_2\text{-}SiMe_2\text{-}(NH\text{-}SiMe_2\text{-})_nNH_2$.

The compositon calculated with $n = 15.2$ (corresponding to an average molecular weight of 1200) agrees well with its analysis.

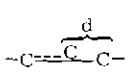
# CONFERENCE REPORTS

## Modern Problems of Stereochemistry

On February 29th, 1964 the annual meeting of the Schweizerische Chemiker-Verband took place in Bern (Switzerland).

*A. Dreiding* (Zürich) chose for his opening paper two subjects of current importance: conformational analysis and stereoelectronics. In the first part of his account he dealt with the methods of calculating intramolecular strains. For the four types of intramolecular interaction the following expressions give satisfactory results:



*Bayer strain* (deformation of bond angles)

$E = K \cdot \alpha^2$

*Bond strain* (change of bond length)

(to be ignored in calculations owing to the steep rise in potential)

$E = k \cdot d^x$

*Pitzer strain* (torsion of staggered arrangement)

$E = 1.40\,(1 + \cos 3\,\omega)$

*Prelog strain* (intramolecular van der Waals forces)

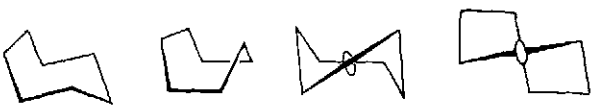
$E = 10^4 \times e^{-4.6r} - \frac{49}{r^6}$

With these equations the energy contents of the conformations of simple molecules, *e.g.* cyclohexane, can be calculated with the aid of electronic computers [1]. These calculations lead to qualitatively satisfactory results, which, however, are not yet sufficiently quantitative in most cases owing to the inexactness of the primary equations.

Newer results of conformational analysis in simple ring compounds were dealt with in detail and the growing importance of the molecular topological approach was alluded to [*]. In the case of cyclohexane, the twist form (symmetry $D_2$) is second in stability to the "rigid" chair form. It has the lowest energy content of all "mobile" conformations, the boat (symmetry $C_{2v}$) being the transition form between two twist forms.

The findings of conformational analysis stimulated the synthesis of the hydrocarbon "twistane" *(2)* (an isomer of

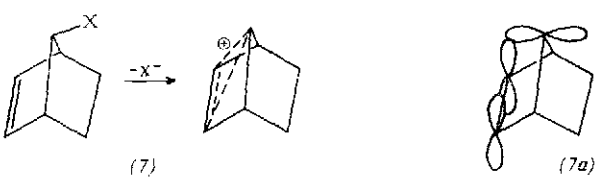
[1] *J. B. Hendrickson*, J. Amer. chem. Soc. *83*, 4537 (1961).



[*] By this term the speaker apparently understands a purely geometrical approach, not at all as closely related to the current concept of topology in mathematics as the use of the same name by *Wassermann* for a somewhat different concept in chemistry [J. Amer. chem. Soc. *83*, 3789 (1961)] (Abstractor's note).

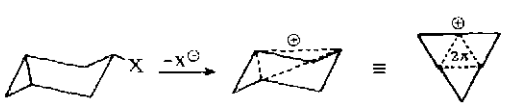
adamantane). It consists of four fused six-membered rings, all of which are in the twist form [2].

(1) (2)



First results have recently been obtained in the conformational analysis of the saturated seven-membered ring. As in the case of the six-membered ring there are two forms, chair *(3)* and boat *(4)*; in contrast to the situation in the six-membered ring, however, both forms of the seven-membered ring are flexible (flexomers) and can assume a large number of conformations, of which the twist boat *(6)* and the twist chair *(5)* are the most stable ones. The twist chair is more stable than the twist boat by about 2.5 kcal/mole and is thus the most stable conformation of cycloheptane [1].

(3) (4) (5) (6)



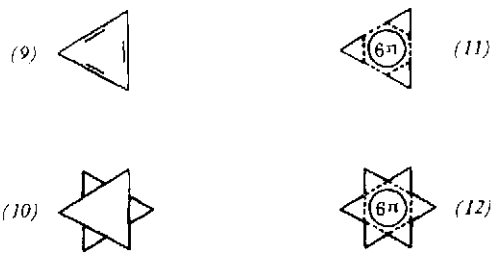
A new branch of stereochemistry is *stereoelectronics*. This concept collects together those phenomena which result from the interaction of electron orbitals suitably arranged sterically. It was illustrated by two examples, *homoaromaticity* and *valence tautomerism*.

Anti-7-norbornenyl derivatives *(7)* solvolyse up to $10^{11}$ times faster than the corresponding saturated compounds. Because of their favorable steric position *(7a)* the π-electrons of the double bond can delocalize the positive charge of an incipient C-7 carbonium ion.

(7) (7a)

A similar delocalization of charge is possible when the double bond is replaced by a cyclopropane ring *(8)*.

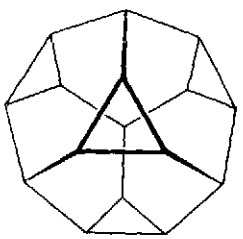
(8)



Systems that can be regarded [like the symmetrical cation *(8)*] as being formed from aromatic compounds through replacement of the groupings

and

are termed, after *Winstein* [3], homoaromatic; *(8)* is accordingly the trishomocyclopropenyl cation. By synthesis of the hydrocarbons cyclonona-1,4,7-triene *(9)* [4] and tetracyclo[9,1,0,$0^{3,5}$,$0^{7,9}$]dodecane *(10)* [5] it could however be shown that "homoaromatic" delocalization of the electrons with formation of trishomobenzene *(11)* or hexakishomobenzene *(12)* [*] does not occur in these systems.



(9) (11)

(10) (12)

*Valence tautomerism* as a stereoelectronic problem was illustrated by Cope's rearrangement. This takes place only when sterically specific interactions of the electron orbitals of the participating bonds are possible.

The speaker ended his paper with a reference to his own work, not yet concluded, on the synthesis of a spheroidal polycyclic system "chemophane" *(13)*, for which interesting properties may be expected because of the possible homoaromatic delocalization of the bonds.

(13)

*R. F. Zürcher* (Ciba AG, Basel) gave a paper on "Determination of configuration and conformation by means of proton spin resonance". The speaker illustrated the principles of such investigations by examples drawn from the steroids, in which structure and configuration often can be determined only from the position of the proton signals of the two angular methyl groups. Substituents on the basic skeleton alter the magnetic shielding of the methyl protons and shift their signals. This "additional chemical shift" Δδ is characteristic for the type and the position of the substituent in the molecule [6]. Substituents in equivalent positions relative to a methyl group shift the signal of this methyl group to about the same extent. With several substituents the effect is approximately additive.

An alteration in the configuration of the basic skeleton also leads to an additional chemical shift. For example, the difference between *trans*-fusion of rings A and B (in 5α-steroids) and *cis*-fusion (in 5β-steroids) is noticeable in the NMR spectrum by the different positions of the C-19 methyl signals. The methyl group C-19 is axial to both rings in the first case, but equatorial to ring A in the second.

By use of Karplus' equation, which gives for vicinal protons the relationship between the angle of torsion ω and the coupling constant J, information about the conformation of steroids can be obtained in some special cases, *viz.* when the proximity of substituents leads to substantial alterations in the chemical shifts of certain protons, so that the splitting of their signals can be estimated. It was found in this manner, for example, that ring C in 11β-bromo-12-keto steroids is practically not deformed.

[6] *R. F. Zürcher*, Helv. chim. Acta *44*, 1380, 1755 (1961).

*G. Schetty* (Geigy AG, Basel) reported on the steric configuration of 1:2 metal-dye complexes [7].

*o,o'*-Disubstituted azo dyes and the trivalent metals Cr and Co form 2:1 complexes, in which a dye molecule occupies three of the six coordination sites.

*(14)* *(15)* *(16)*

With octahedral coordination of the ligands two basically different arrangements of the dye molecules in the complex result, namely:

1. the "Drew-Pfitzner" arrangement with the dye molecules perpendicular to each other *(14)*,

2. the "Pfeiffer" or "sandwich" arrangement in which the two dye molecules lie parallel to each other *(15)*. In this rraangement five forms are possible [*].

The azo dye obtained from anthranilic acid by diazotization and coupling with β-naphthol forms with trivalent Cr a 2:1 complex *(16)*, which can be separated into four fractions by chromatography on $Al_2O_3$. This indicates that the complex has the "sandwich" arrangement. The fractions can easily be isomerized by heating in water. The ratio of isomers depends on the pH.

Systematic investigations of complexes of different azo dyes, including those with pyrazolone derivatives as coupling components, showed that the "Drew-Pfitzner" arrangement occurs as well as the "sandwich" arrangement. The type of complex formed is determined by the size of the dye molecules and particularly by the spacing of those atoms which serve as ligands in the complex.

# Raman Colloquium

About 100 scientists from 9 countries took part in the symposium held in Freudenstadt (Germany) from March 10th to 13th, 1964. Recent results in Raman spectroscopy were reported in 28 lectures.

The recording of Raman spectra within frequency ranges of about 1000 $cm^{-1}$ is possible, according to *M. Delhaye* et al., within tenths of a second, if image converters or image amplifier tubes are used. In this way, cinematographs of a test sample may be taken in the course of a chemical reaction. The same authors reported on the use of lasers for exciting Raman spectra. A single laser flash sufficed to produce a complete Raman spectrum of $PBr_3$. Similarly, *B. Schrader* and *M. Stockburger* showed Raman spectra of colored crystalline powders (*p*-nitraniline and *p*-nitro-*p*-dimethylaminostilbene) with a ruby laser as source of radiation. These authors also explained new testing arrangements permitting the recording of Raman spectra even of substances with slight scattering, with a test sample of only 0.07 ml, by using low-pressure mercury arcs with a contraction, a condenser, and interference filters.

The emission of Raman lines from nitrobenzene stimulated by a ruby laser beam was treated by *G. Rivoire* and *R. Dupeyrat* who investigated, among other things, the dependence of intensity on direction and put forward quantum-mechanical equations for interpreting the stimulated emission.

For the further improvement of the photographic technique used for intensely colored substances a helium lamp was constructed by *Mecke*, *Schühly*, and *Stammreich*, and a Raman set-up, equipped with it, was described.

*J. Behringer* lectured on an expansion of the theory of the resonance Raman effect on molecules with more than two atoms. A point on the potential hyperplane in the excited state is ascribed to the equilibrium configuration of the nuclei in the ground state. The gradient of the plane at this point and the symmetry characteristics of the overlap integrals of the vibration eigenfunction determine the selection rules of the resonance Raman effect. A qualitative interpretation of the experimental results is made possible by this approach.

*H. Hacker* reported on recent resonance Raman measurements. Investigations were carried out on azobenzenes and azonaphthalenes in solution. The N–N frequency was found to lie between 1380 and 1440 $cm^{-1}$. The scattering coefficients of various Raman lines and the factors determining intensity were discussed.

Further lectures dealt with the measurement of intensities, which presents great difficulty, especially in the case of crystalline powders. *H. Moser* reported on the determination of relative scattering coefficients, independent of the apparatus used. The Raman spectra were recorded according to the pellet method of *Schrader* and *Kresze* and the intensities extrapolated from several determinations with varying pellet thickness to infinitely thin pellets. So far, such intensity measurements have been carried out on naphthalene, benzoic acid, tetracyanoethylene, $KNO_3$, $K_2SO_4$ and $KBrO_3$.

*E. Steger* reported on the determination of the scattering coefficients of inorganic anions (*e.g.* $PO_4^{3-}$, $SO_4^{2-}$, $ClO_4^-$) in aqueous solution and discussed the assumptions, on the basis of which the derivations of the bond polarizability can be calculated from these values. Relationships between changes in intensity of characteristic Raman vibrations and bond characteristics in silicon and tin compounds were discussed by *H. Kriegsmann*. *H. Gerding* and *C. C. Smitskamp* examined changes in intensity, caused by intermolecular forces, in the Raman spectra of mixtures of $POCl_3$ or $PSCl_3$ with $CCl_4$ or $GeCl_4$, in which maximum values may occur at certain mixing ratios.

*G. Matz* reported on the efficiency of Raman spectroscopy in routine application to problems of qualitative and quantitative analysis in an industrial laboratory and on an apparatus set up for such measurements. According to this report, Raman spectroscopy is frequently not inferior to other spectroscopic methods as regards rapidity and accuracy.

Complete assignment of the ground vibration spectra of symmetrical molecules is normally possible only if the Raman spectra, too, are taken into consideration. Examples for the assignment of vibrations and structural conclusions resulting therefrom were contributed in reports by *Stammreich* (*p*-benzoquinone), *Lippert*, *Moser* et al. (tetracyanoethylene), *Schrötter* and *Hoffmann* (trimeric dialkylaluminum hydrides), *Ziegler* (determination of the constitution of perchlorinated hydrocarbons $C_6Cl_8$, $C_6Cl_6$, and $C_8Cl_8$) as well as *Gerding* and *Smitskamp* ($SeO_3$).

Calculation of the force constants from completely assigned vibration spectra was treated in the lectures by *Duinker* and *Mills*, by *Sawodny*, and by *Strey*. The latter reported on computations of force constants, according to an iteration method, for the molecules $H_2O$ and $C_2H_4$ as well as their isotopic deuterium and $^{18}O$ derivatives. *Duinker* and *Mills*

worked out a new set of valence force constants from the vibrations of benzene and from the Coriolis zeta-coefficients, in which a limited number of interaction constants were considered on the basis of a hybrid orbital field of force. The resulting force constants agree closely with theoretical expectations and may be applied to halogenated benzene derivatives as well as pyridine and its deuterium derivatives, with only minor modifications. – From the ground vibrations of molecules with a known geometrical arrangement *Sawodny* computed complete series of force constants of the general valence force model, by ascribing the vibrations, regarded as uncoupled, to individual internal coordinates and thus obtaining solutions for the force constants, which are improved by gradual introduction of kinetic coupling according to the Newton method. This method yields good results if the normal vibrations are predominantly determined by single symmetry coordinates. [VB 812/144 IE]

## Recent Investigations into the Structures of Noble-Metal Compounds

*K. Brodersen*, Aachen (Germany)

Iridium(III) chloride occurs as two modifications which differ in crystal form, color, and magnetic properties. Its monoclinic modification forms platelets with the lattice constants: a = 5.99 Å, b = 10.36 Å, c = 5.98 Å, and β = 109°27′. The arrangement of atoms in the unit cell corresponds to that in aluminum(III) chloride, the parameters of the chlorine atoms being slightly different.

Platinum(II) chloride crystallizes in needle-like hexagonal prisms. Its rhombohedral unit cell has dimensions a = 8.09 Å and α = 108°15′ and consists of six formula units. The lattice sites can be found from Weissenberg and precession photographs; space group: $D_{3d}^5$–C $\bar{3}$ m,

lattice sites: 6 Pt on 6 (h): x = 0.079 and z = 0.333
6 Cl on 6 (h): x = 0.583 and z = 0.825
6 Cl on 6 (f): x = 0.258.

The six platinum atoms are arranged octahedrally with Pt-Pt distances of 3.32 Å or 3.40 Å. Each platinum is surrounded nearly quadratically by four chlorine atoms with Pt-Cl distances 2.34 Å or 2.39 Å. The 12 chlorine atoms are situated in front of the 12 edges of the $Pt_6$ octahedron. Accordingly, platinum(II) chloride has a structure with $Pt_6Cl_{12}$-complexes and with weak metal-metal bonds.

## Size of the Solvation Sheath of Poly(vinyl alcohol) in Aqueous Solutions

*S. Peter*, Hannover (Germany)

The rheological properties of aqueous solutions of poly(vinyl alcohol) with molecular weights of 20000 or 85000 and 180000 were examined at 20–50 °C and at concentrations up to about 10% by weight, using a Couette viscometer. The degree of hydrolysis of the products prepared by alkaline saponification of poly(vinyl acetate) was 98 %.

The activation energy for the flow process was determined from the temperature depence of the viscosity in the absence of forces of interaction between the dissolved particles. At low concentrations, it corresponds to the activation energy for the flow of pure water. With increasing concentration, the activation energy rises and appears to approach a limiting value of about 6.2 kcal/mole.

The effective, rheologically immobile volume proportion in the solution was determined using an expression proposed by *Franck*. With increasing dilution, the effective, rheologically immobile volume corresponding to unit weight of solute (denoted by $\varphi_{sp}$) tends to a limiting value $\varphi^0_{sp}$ which is proportional to the intrinsic viscosity $[\eta]$ (cf. Table 1).

Table 1. Limiting values $\varphi^0_{sp}$ for $c \to 0$, at 20 °C.

| Molecular weight | $\varphi^0_{sp}$ [cm³] | Immobile water [mole/mole of monomer] [a] | $[\eta]$ [cm³/g] |
|---|---|---|---|
| 20000 | 14.7 | 36 | 44.1 |
| 85000 | 27.5 | 67 | 82.5 |
| 180000 | 39.8 | 97 | 117.4 |

[a] Determined assuming the density of water in the solvation sheath to be equal to that of pure water.

The assumption that large solvation sheaths occur in aqueous solutions of poly(vinyl alcohol) is confirmed by the fact that $[\eta]$ and $\varphi^0_{sp}$ decrease with increasing temperature, whereas $[\eta]$ should increase with temperature if the solvent flows more or less freely through the poly(vinyl alcohol) coils. Thus, for polyisobutylene (mol. wt. 180000) in benzene, $[\eta]$ has a value of 35.2 cm³/g at 24 °C and 76.5 cm³/g at 60 °C; poly(vinyl alcohol) with the same molecular weight, on the other hand, gave $[\eta]$ = 119.4 cm³/g in water at 20 °C, and 99.0 cm³/g at 50 °C.

## Experiments with Potassium Needles

*K. Neumann*, Gießen (Germany) [1]

When potassium is sublimed onto wires of metals such as silver, gold, and platinum, moderate supersaturation leads to the formation of very fine needles with a thickness of a few hundred Å and a length up to 1 mm. With suitable illumination, their diffraction diagrams can be observed as bright lines under the microscope, and their growth can be followed. At first, their length increases exponentially with time until a maximum constant rate of growth has been attained. This exceeds the value calculated for direct condensation of the vapor on the growing tip by several powers of ten. Actually, potassium condenses on the long mantle faces and migrates from there along to the tip. Finally, the rapid lengthwise growth stops suddenly, and the needles begin instead to increase gradually in thickness, making it possible to recognize their shape: hexagonal (rarely quadratic) prisms with a roof formed from three or four (011) rhombs. The three long lateral faces are likewise (011) faces. The unimpeded growth at the tip is probably due to a spiral dislocation terminating at this position.

Observation of the rate of growth (or evaporation) as a function of the degree of supersaturation (or unsaturation) in the vapor phase also provides important information on the selfdiffusion of the K adatoms. Furthermore, the increase in vapor pressure of the needles owing to their low thickness is readily determined and from this in turn, the free surface energy of the (011) faces can be obtained, a magnitude which otherwise cannot be determined experimentally for solids. Its value is 170 ± 15 erg/cm² at 25 °C.

With about 15-fold supersaturation in the vapor phase, rapid lengthwise growth stops as a result of two-dimensional nucleus formation on the side faces. If the supersaturation is reduced after some time, the needles again increase in length, but at a slower rate, because they have meanwhile become thicker. In this manner, the thickening can be followed in the critical region in which nucleus formation on the surface is

[1] Based on work carried out by *F. Hock*, *W. Dittmar*, *H. D. Meissner*, and *A. Köhler*.

rate-determining. With a crystal temperature of 25 °C and sixteenfold supersaturation, a rate of thickening of $10^{-9}$ cm per sec was observed, corresponding to a condensation coefficient of 0.2 or the origination of about one crystallization nucleus per minute on every prism surface. The same value is derived from the nucleation theory of ideal crystals by taking a value of 167 erg/cm² for the free surface energy when calculating the atomic deposition work functions.

A critical value for the degree of unsaturation was likewise observed. If the pressure in the vapor phase decreases beyond this, rapid evaporation at the tip ceases because the side faces begin to evaporate, starting from the top edges. When the pressure is not far from that of the saturated state, these edges are protected by a diffusion stream from the neighboring roof faces, the dislocation stage of which has a slightly higher vapor pressure. According to theory, this protection may be effective down to extremely low pressures so that a critical degree of unsaturation need not necessarily occur with all needles.

# The Structure of Glass

The Fourth Interunion Conference on the Vitreous State took place in Leningrad (U.S.S.R.) from March 16th to 21st, 1964. It was again held under the patronage of the Nestor of Soviet glass science, Prof. *A. A. Lebedev* and was organized by the U.S.S.R. Academy of Sciences, the Grebenstshikov Institute of Silicate Chemistry, the Leningrad Chemical Mendeleev Society, and the State Optical Institute in Leningrad. Most of the lectures dealt with investigations into the microheterogeneities in glass. While during the Third Conference on the structure of glass the main topic of discussion was the contrast between the crystallite and the network theories, during this year's session the crystallite theory was acknowledged by most participants.

*E. A. Poray-Koshits*, Leningrad (U.S.S.R.), reported on crystallochemical aspects of the structure of inorganic glasses. The properties of quartz glass, whose structure corresponds most closely with the concepts of the network theory, can be described satisfactorily in terms of the vitron theory (*Tilton*). $Si_2O_7$ groups with Si–O–Si angles of 143 ± 17° and interatomic distances of 1.60 Å for Si–O and 3.0 Å for Si···Si, are supposed to be the basic units. He then compared results of electron-optical investigations with those of small-angle X-ray scattering on multicomponent glasses; both methods lead to the concept of a microheterogeneous structure.

*V. A. Florinskaya*, Leningrad (U.S.S.R.), investigated the structure of glass by various physical methods, *e.g.* infrared spectroscopy and electron microscopy. Investigations of the system $Li_2O$–$SiO_2$ have shown that above 20 mole-% $Li_2O$, segregation phenomena decrease, but increase again with $Li_2O$ contents exceeding 33 mole-% (glasses with less than 20 mole-% $Li_2O$ were not examined). This is consistent with the results of *Vogel* and coworkers. In the melt, inhomogeneities are already present in the form of extremely stable silicates. On cooling a melt, several new structural units become superimposed on each other. The microheterogeneous character of glass is determined by the most stable compounds. Microheterogeneities often have dimensions of 100 Å and exhibit higher order than their surroundings. By studying the variation of crystal equilibria with temperature it was shown that the crystallization times required for equilibrium to be reached at room temperature and at very high temperatures amounted to about 30 years.

*O. K. Botvinkin*, Moscow (U.S.S.R.), gave an account of the diversity in glass structures. Although there are examples to be found which conform to each of the various concepts of glass structure, the properties of most complex glasses can only be understood in terms of a microheterogeneous structure. In an experiment to study the canal system in leached out borosilicate glasses, the pores were filled with a liquid organic resin which was then solidified; the $SiO_2$ framework was then dissolved away. *Botvinkin* proposed that in future studies, special attention should be given to nucleation and crystallization in combination with the formation of ion clusters and segregation phenomena.

*A. A. Appen*, Leningrad (U.S.S.R.), considered glass formation as the overlapping of bilateral processes. The attainment of diverse equilibria in glasses, is important *e.g.* in the processes:

$$\text{association} \rightleftharpoons \text{dissociation}$$

or

$$\text{dissolution} \rightleftharpoons \text{crystallization.}$$

*Appen* suggested that the fundamental investigations of *Lebedev* and *Stocharov* into states of equilibrium by refractive-index and viscosity measurements be taken up again. As a supporter of the network theory even for complex glasses, he was of the opinion that experimentally detectable microheterogeneities probably result from insufficient homogenization of the melt and should be regarded as defects in glass. *D. A. Goganov* and *E. A. Poray-Koshits*, Leningrad (U.S.S.R.), investigated sodium borosilicate glasses by X-ray scattering methods using small angles of incidence to surfaces which had been subjected beforehand to different thermal treatments. Droplet-shaped regions of phase separations with uniform dimensions or volumes are formed. *N. S. Andreyev* and *V. J. Averyanov*, Leningrad (U.S.S.R.), also observed phase separation with sodium silicate glasses in the metastable liquation region. These results were obtained from light scattering and electron-optical investigations. *V. J. Averyanov* and *E. A. Poray-Koshits*, Leningrad (U.S.S.R.), investigated the segregation of $Li_2O$–$SiO_2$ glasses with increasing $Li_2O$ content by electron microscopy. The dimensions of the regions of segregation reach a maximum and then – above 29 mole-% – a minimum, as found by *W. Vogel* and *H. G. Byhan*.

According to *A. B. Shatilov*, Leningrad (U.S.S.R.), an accuracy of ± 10 % is attainable in the determination of the size of microheterogeneities in glass by X-ray small-angle scattering. Regions 0.25 μ in diameter can be detected by infrared scattering. The results are dependent on the wavelength of the radiation. Microliquation of $K_2O$–$SrO$–$SiO_2$ melts and $K_2O$–$BaO$–$SiO_2$ melts has been studied by *F. I. Galakhov*, Leningrad (U.S.S.R.). Secondary segregation processes occur in these glasses which lead to a three-phase glass. Two different droplet-shaped microphases are embedded in a homogeneous base glass. Hence further evidence for the occurrence of secondary segregation phenomena has been obtained.

According to *N. M. Weisfeld* and *V. I. Shelyubski*, Moscow (U.S.S.R.), unambiguous results can be obtained with Class 2 electron microscopes (resolving power 20–30 Å) only for the identification of structural elements larger than 500 Å (all samples were prepared as replicas in the presence of air). Direct specimen irradiation, vacuum preparation, and decoration techniques have not been used hitherto.

*Aniuta Winter-Klein*, Paris (France), dealt with glass formation from the viewpoint of the arrangement of electrons in the atoms. Compounds of elements with 4p electrons in the outer

shell are the best glass formers. The derivation of further regularities of vitrification was attempted by consideration of the electron configurations of the elements. Within the four characteristic temperature ranges of glass (1. glass as a highly viscous liquid, 2. glass as a supercooled liquid, 3. glass in the state of transformation, 4. glass as a solid), the physical properties undergo various profound changes.

*P. J. Bray*, Providence, R.I. (U.S.A.), investigated the structures of vitreous and crystalline boric acid, of lithium borate glasses, of lead silicate glasses, of glasses of the systems $NaF-B_2O_3$ and $CaO-Al_2O_3-B_2O_3$, and of phosphate glasses by NMR measurements. Even small amounts of $Li_2O$ suffice to convert boron ions (coordination number = 3) into a state of tetrahedral coordination. The change in coordination (from coordination number $> 4$ to $= 4$) of lead ions in binary silicate glass in the region of higher PbO concentrations was definitely detected. The proportion of boron ions with a coordination number of 4 can be found in the system $CaO-Al_2O_3-B_2O_3$ (Cabal glass). Even small amounts of fluorine in the system $NaF-B_2O_3$ cause 3-coordinate boron ions ($[BO_3]$ planar triangles) to be converted into 4-coordinate ($[BO_4]$ tetrahedra) ions. With phosphate glasses, similarity between the structural elements in the glass and in the corresponding crystalline compounds was demonstrated.

*O. L. Anderson*, Murray Hill, N.J. (U.S.A.), divided the lattice properties of glasses into three classes: 1. properties corresponding to those of a single crystal, 2. properties like those of a liquid, and 3. properties similar to those of common solids, but not like those of single crystals, which are simple functions of pressure, volume, and temperature and dependent on heat pretreatment. These three classes of properties were derived using a linear-chain model of a dynamic lattice under the assumption that non-harmonic forces exist between the atoms of the chains, which are assumed to be diatomic, with small disturbances of the vibrational energies.

*R. D. Maurer*, Corning, N.Y. (U.S.A.), investigated the effect of temperature and time on the growth of crystal nuclei in glass by small-angle scattering of X-rays. The differences in the refractive indices were measured and calculated for scatterings of various strengths.

The mobility of ions in glass was ascertained by *K. Kühne*, Berlin (Germany), from electrical-potential measurements. Measurements on electrical potential cells consisting of two different glasses allowed conclusions to be drawn concerning defects due to bubble formation at the metal-glass interface on melting-in a metal.

*W. Vogel*, Jena (Germany), reported on the microheterogeneous structure of glasses in the system $Li_2O-SiO_2$. Electron microscopy of direct samples or replicas revealed a segregation maximum in the range from 0 to 33 mole-% $Li_2O$. Although extensively microheterogeneous structures are present in the middle ranges, glasses with about 33 mole-% $Li_2O$ are homogeneous in the sense of an infinitely large drop. Special hydrofluoric-acid treatment isolated either drop-like regions or the glass phase encompassing the drop-like regions and thus permitted separate examination of these microphases. The composition of the drops approaches that of lithium disilicate; at 16–17 mole-% $LiO_2$, secondary segregation into $SiO_2$ and a metasilicate phase occurs.

The dependence of the turbidity of optical glass on heat treatment was investigated by *H. Besen*, Jena (Germany). On slow cooling of fluorosilicate glasses, turbidity occurs which gives rise to characteristic color effects due to Rayleigh scattering at submicroscopic droplets. The droplets result from phase separation. The color effects were produced during systematic thermal-treatment experiments and were investigated by measuring the spectral transmittance of specimens 100 mm thick. Samples heated at 950 °C and cooled at a constant rate in order to remove their turbidity were used as specific, reproducible starting material. The very sharply defined region of turbidity for each glass examined was determined by annealing for 24 hours while cooling. Annealing for various times at the turbidity maximum during cooling or reheating showed that turbidity developed about seven times faster during reheating than during cooling [1].

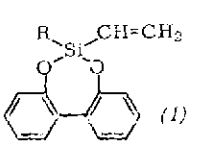
# SELECTED ABSTRACTS



**The synthesis of trithiones from enamines, carbon disulfide and sulfur** is described by *R. Mayer, Peter Wittig, J. Fabian*, and *H. Heitmüller*. Trithiones *(2)* are formed exothermically at room temperature in 30–60% yield by reacting enamines *(1)*, $CS_2$ and sulfur in a polar solvent, such as dimethylformamide. Mono- or 4,5-disubstituted derivatives are obtained according to the type of enamine used. The amine which is split off is bound as the ammonium salt of dithiocarbamic acid. The enamines of cyclic ketones react particularly well.

The reactions of enamines of substituted acetaldehydes are of special preparative value, since they lead to trithiones substituted only in the 4-position. Trithione itself is made from the enamine of acetaldehyde. The syntheses probably proceed by nucleophilic addition of the β-carbon atom of the enamine to a $CS_2$ double bond, followed by sulfuration and cyclization. Ketimines *(3)* react with $CS_2/S$ to give trithiones and 1,2-thiazoline-5-thiones *(4)*, a new heterocyclic system. Anils give *(4)* exclusively. / Chem. Ber. *97*, 654 (1964) / –Ma. [Rd 898/248 IE]

**New types of cyclic silicon compounds** were synthetized by *R. M. Ismail*. Vinyltrichlorosilane, or organovinyldichlorosilanes, react with 2,2'-dihydroxydiphenyl and aliphatic or aromatic hydroxy compounds to give compounds of type *(1)* in 60–87% yield. They show high thermal stability and are suitable comonomers in the production of heat-resistant plastics.

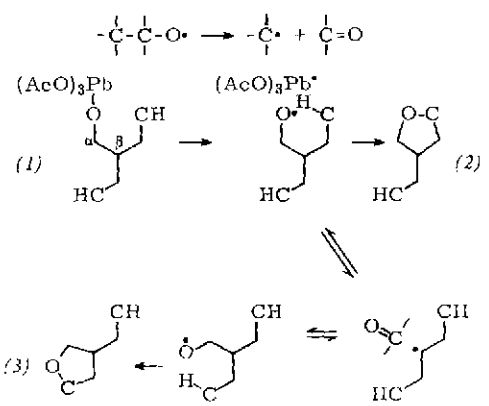
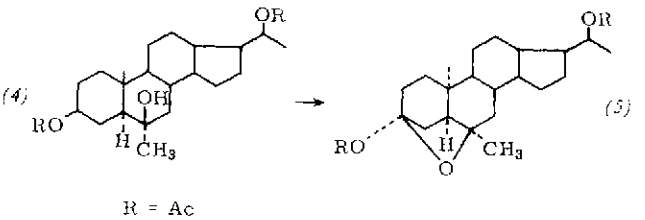
**An improvement of the Friedländer synthesis** was achieved by *G. Kempter, P. Andratschke, D. Heilmann, H. Krausmann,* and *M. Mietasch.* Friedländer synthesized substituted quinolines by condensing *o*-aminobenzaldehyde with compounds containing a $-CO-CH_2-$ group. The authors replaced the difficultly available and unstable *o*-aminobenzaldehyde with the easily obtainable *o*-aminoacetophenone hydrochloride *(1)*. By reacting *(1)* with cyclanones – in the



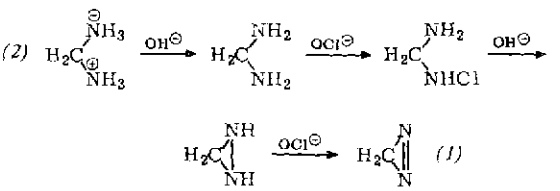
absence of solvents – one obtains, for example, *(2)*, b.p. 119 °C/4.5 mm, in 65 % yield, or *(3)*, m.p. 62.5–64 °C, in 75 % yield. Both $-CO-CH_2-$ groups of 2-acetylcyclohexanone can take part in the reaction. With 2 moles of *(1)* it forms *(4)*, m.p. 85–86 °C, in 32 % yield. / Chem. Ber. *97*, 16 (1964) / –Kr. [Rd 894/247 IE]

**A new synthesis of *N*-alkylisoindoles** *(1)* by pyrolysis of *N*-oxides of *N*-alkylisoindolines *(2)* was discovered by *J. Thesing, W. Schäfer,* and *D. Melchior. N*-Methyl-, *N*-ethyl-, and *N*-butylisoindole were obtained as the oxalates or trinitrobenzoates in 40–65 yield. If the alkyl group is adjacent to a conjugated system, as in *N*-(β-phenethyl)isoindoline *N*-oxide, the yield falls to 8–11 %, with simultaneous production of



44 % *N*-hydroxyindoline and styrene. The yield of *N*-(β-phenethyl)isoindole is raised to 38 % if the *N*-oxide is decomposed in refluxing butanolic potassium hydroxide solution. / Liebigs Ann. Chem. *671*, 119 (1964) / –W. [Rd 892/245 IE]

**A homolytic hydrogen transfer in a cyclohexane ring** is reported by *K. Heusler* and *J. Kalvoda.* The fragmentation of alkoxyl radicals into a CO-compound and a C-radical can be reversible. For example, two isomeric tetrahydrofuran derivatives, *(2)* and *(3)*, which differ in the configuration at the α- and β-carbon atoms, are formed from the Pb derivative *(1)* of a secondary alcohol. It is assumed that there is an intermediate stage in which the asymmetry of the α- and β-positions is eliminated. The indicated C-atoms are part of a steroidal skeleton.



The tertiary steroidal alcohol 3β,20β-diacetoxy-6α-methyl-6β-hydroxy-5α-pregnane *(4)* undergoes a homolytic fission of the 5,6-bond with lead tetraacetate. This is followed by a transannular homolytic 1,5-hydrogen transfer, rotation of ring A around the (C-9)–(C-10) bond, and recyclization to

a pregnane *(5)*, m.p. 112–114 °C. The 6β,19-oxide is formed as a by-product. The carbon atom 10 of *(5)* is epimerized. The course of the reaction was followed by specific deuteration. / Helv. chim. Acta *46*, 2732 (1963) / –Ma. [Rd 900/250 IE]

**A simple synthesis of cyclodiazomethane** was achieved by *R. Ohme* and *E. Schmitz.* Cyclodiazomethane *(1)*, the parent compound of the diazirines, is formed when methylenediammonium salts *(2)* are added with stirring to a solution of NaOCl at 0–5 °C. Compound *(1)* is carried away in a stream of nitrogen, washed with strong sodium hydroxide solution, dried over soda lime and absorbed in absolute ether at

–50 °C. The melting point of *(1)* (from ethanol/water) is 134–136 °C; the compound is formed in 26 % yield. Cyclodiazomethane is explosive and should never be handled in an undiluted form. / Chem. Ber. *97*, 297 (1964) / –Kr. [Rd 893/246 IE]

**Reactions of sulfides in molten salts** were studied by *M. Feld, S. Sundermeyer,* and *O. Glemser.* They dissolved 20–30 % by weight of $K_2S$ in a LiCl/KCl eutectic melt and at 380–400 °C passed in phosgene. Carbonyl disulfide was formed in 75 % yield according to the reaction

$$COCl_2 + K_2S \rightarrow COS + 2\,KCl$$

The remainder of the $COCl_2$ was converted into $CO_2$. On passing in trimethylchlorosilane hexamethyldisilthiane, $(CH_3)_3Si-S-Si(CH_3)_3$, was formed in 81 % yield based on reacted chlorosilane. / Chem. Ber. *97*, 620 (1964) / –Kr. [Rd 897/253 IE]

**Hexaalkylplumbosiloxanes** were synthetized for the first time by *H. Schmidbaur* and *H. Hussek.* The hexamethyl derivative is formed even at room temperature in ether according to the reaction

$$(CH_3)_3SiONa + (CH_3)_3PbBr \rightarrow NaBr + (CH_3)_3SiOPb(CH_3)_3$$

in 76 % yield (b.p. 172 °C/720 mm in a dry, inert atmosphere). Both trimethyltriethyl derivatives and the hexaethyl derivative were analogously prepared. The alkylplumbosiloxanes are colorless, very mobile liquids of intolerable odor and high toxicity. In the presence of $O_2$ they explode at about 140 °C with evolution of black clouds (Pb). They react very rapidly with agents containing active protons but also with acid anhydrides and halides. Anhydrous $AlCl_3$ reacts explosively under normal conditions but at very low temperatures $(CH_3)_3PbCl$ as well as some $(CH_3)_3SiCl$ and AlOCl can be isolated. / J. organometallic Chem. *1*, 257 (1964) / –Kr. [Rd 895/255 IE]

**The properties of alkylstannosiloxanes, alkylsiloxanes and alkylstannoxanes** were compared by *H. Schmidbaur* and *H. Hussek*. They prepared, for example, hexamethylstannosiloxane (m.p. −59 °C, b.p. 141 °C/720 mm) in 78 % yield according to the reaction

$(CH_3)_3SiOLi + ClSn(CH_3)_3 \rightarrow LiCl + (CH_3)_3Si{-}O{-}Sn(CH_3)_3$

The simplest distannosiloxane (b.p. 77 °C/1 mm) is formed in 86 % yield according to the reaction

$2\ (CH_3)_3SnOLi + Cl_2Si(CH_3)_2 \rightarrow 2\ LiCl + [(CH_3)_3SnO]_2Si(CH_3)_2$

The analogous stannodisiloxane was also prepared.

The alkylstannosiloxanes are colorless, highly toxic compounds mostly with an unpleasant odour. They are thermally not so stable as the alkylsiloxanes and -stannoxanes. The majority of the compounds decompose above 150 °C into siloxanes and stannoxanes. The alkylstannosiloxanes exist in monomeric form; they are very reactive towards electrophilic and nucleophilic agents. In this respect they resemble the (even more reactive) alkylstannoxanes. The NMR spectra show the gradual change of the bond properties in siloxanes, stannosiloxanes and stannoxanes. / J. organometallic Chem. *1*, 244 (1964) / −Kr. [Rd 896/254 IE]

# BOOK REVIEWS

**Vitamin-Bestimmungen. Erprobte Methoden** (Determination of Vitamins. Approved Methods). By *R. Strohecker* and *H. M. Henning*. Published for E. Merck AG., Darmstadt by Verlag Chemie, GmbH., Weinheim/Bergstr. 1963. 1st edit., 365 pp., 42 illustr., 8 color plates, linen, DM 42.– (about $ 10.50) [*].

This comprehensive, excellently produced and illustrated book by two experienced analysts provides a collection of reliable methods for estimating the 15 most important vitamins, applicable primarily to pharmaceuticals and concentrates, but also to foods and animal feedstuffs. Almost all the currently known chemical, physico-chemical, and microbiological methods of liberation, extraction, separation, and assay are used and described in a readily intelligible manner. The relevant literature could not be completely reviewed, but on the other hand, the reader is familiarized with valuable analytical information as yet unpublished elsewhere, *e.g.* the extensive use of thin-layer chromatographic procedures, which also provide simple tests for the specificity of the reactions.

The authors very correctly emphasize that there are no generally applicable analytical methods. The appropriate combination of procedures for extraction, purification, and determination must be selected critically and adapted to the specific properties and composition of each individual sample, even in the case of relatively simple pharmaceutical preparations. In this regard, thorough study of the introductory chapter, which provides a wealth of basic information and guidance, is indispensible.

The proposed methods have proved their reliability in the reviewer's laboratory, where the details of the methods were sometimes altered in a few points. For colorimetric measurements, we generally use a reagent blank rather than an empty cuvette. The vitamin D determination by direct spectrophotometry or colorimetric measurement gives correct values only with pure crystalline vitamin D, and gives high results for all other forms of the vitamin owing to interfering impurities. It is also useful to dissolve materials for separation by thin-layer chromatography either in the mobile phase or in one of its components in order not to influence the separation by the presence of an extra solvent. Although it is stated that relatively large errors are inherent in several methods, more details would occasionally be desirable.

This valuable book is recommended to all engaged in the analysis of vitamins. *B. Schmidli* [NB 181/75 IE]

**Kurzes Lehrbuch der Biochemie für Mediziner und Naturwissenschaftler** (Concise Textbook of Biochemistry for Medical and Science Students). By *P. Karlson*. Georg Thieme Verlag, Stuttgart 1962. 3rd edit., XVI, 360 pp., 63 illustrations, linen DM 31.– (about $ 8.00).

In recent years it has become clear that a modern introduction to biochemistry is necessary, not only for medical students, but for all scientists. *Karlson*'s book, now appearing in its third edition, fulfils this need.

The arrangement of the first edition is unchanged except for a new chapter, twelve pages long, in which mineral metabolism, physico-chemical aspects of water as a solvent, osmosis and active transport, are discussed.

It seems desirable, even in a book for beginners, to consider basic physico-chemical concepts, such as equilibria, in an introductory chapter. There should be also fuller discussion about the fundamentals of macromolecular chemistry, so that problems of molecular biology can be understood in the further course of studies. The reviewer has observed again and again that even those students, whose grasp of the subject is not very great, approach the physico-chemical fundamentals of biochemistry with enthusiasm.

The manner in which the author has mastered the wealth of material, so that the most recent developments are discussed without noticeable omission, fascinates the reader throughout the book. Naturally, the reader's knowledge of organic chemistry is assumed.

Mistakes or misprints have been almost eliminated in this edition. A trivial mistake: diesterase cleaves the O–P bond (p. 121).

The book will keep its important place in biochemical teaching.

*F. Cramer* [NB 180/78 IE]

**Altamira und die Urgeschichte der chemischen Technologie.** (Altamira and the Prehistory of Chemical Technology). By *E. Pietsch*. German Museum – Transactions and Reports – Volume 31, No. 1. R. Oldenbourg Verlag, Munich, 1963. 1st Edit., 68 pp., 35 illustr., 12 color plates, 1 chronological table, brochure DM 4.80 (about $ 1.25).

This brochure reports a veritable masterpiece accomplished for the German Museum by the author and his assistants. It consisted of a reproduction, faithful almost even to the very materials used, of a section 9.5 m by 4.6 m from the ceiling in the "Cave of Bulls" at altamira in Spain. This portion shows a typical selection of the masterly animal portraits created by our ancestors in the period from the Aurignacian to the Magdalenian culture phases 30000 to 10000 years ago, in younger Palaeolithic times. Since the roof of the cave, for obvious reasons, could not be touched, it had to be photographed by stereophotography for mensuration. The resulting plan served as basis for a plaster of Paris pattern which was given a plasticine skin in order to reproduce the fine structure in all details. From this pattern a mold was made in silicone rubber which was itself supported in a bed of plaster of Paris. The reproduction of the roof was finally cast in this mold and, in order to reproduce the limestone in the cave as faithfully as possible, a mixture of chalk from Solnhofen and white cement (Dyckerhoff) was used. Only iron oxide pigments and charcoal were used for painting, just as in the original. The fixative for the paint had to be Mowilith [*] instead of the natural calcium bicarbonate contained in the moisture on the roof. Even the illumination in the exhibition room has been arranged to approximate the tallow lamps of the Palaeolithic period.

[*] An English edition will appear by the end of 1964.

[*] Mowilith is the German trade name for synthetic drying oils containing polymerized vinyl and acetylenic compounds.

Accompanying the brochure is a condensed survey giving the development of technology from the preparation of flint cells 600000 years ago to the development of the art of tanning and pottery and up to the beginning of the Bronze Age (4000 B.C.).

The text is supplemented by a host of instructive illustrations. Only with the colored plates of the animal pictures would one have wished for something more impressive.

*U. Hofmann* [NB 179/74 IE]

**Enzyme im Blutplasma** (Enzymes in Blood Plasma). By *B. Hess*. Biochemistry and the Clinic – Monographs edited by *G. Weitzel* and *N. Zöllner*. Georg Thieme Verlag, Stuttgart 1962. 1st. edit., VIII, 142 pp., 33 illust., 13 tables, stiff covers DM 29.70 (about $ 7.50).

The measurement of enzyme activities in serum has acquired great interest in clinical diagnosis within the last decade. *Hess* gives an excellent summary of the results to date in this field in a text intended primarily for the orientation of the clinician. However, the biochemist also receives a very lucid survey of the vast possibilities for applying enzyme assays in clinical practice. The most important items are selected from the glut of literature available and presented in concise form, so that the book provides at the same time a valuable approach to the literature. The value of this undertaking is all the greater, because the non-specialist is no longer able to survey the literature in this field on his own, and a similar concentrated exposition of recent information does not exist in the German language. The book contains about 600 references, unfortunately quoted without titles, as is usual in the series "Biochemistry and the Clinic."

The book deals with fundamentals (systematics of plasma enzymes; identification methods; isozymes, enzyme patterns; mechanism of enzyme liberation; origin, synthesis, and breakdown of plasma enzymes; *etc.*), and then with the pathology and clinical implications of serum enzymes, arranged according to disease groups. The last section deals summarily with questions of method: theoretical bases of activity tests, definitions of units, assay conditions. The author's clear, concise style has resulted in a presentation, which remains fluently readable, despite the large number of facts communicated in relatively small space, so that the outsider is presented with a valuable survey; at the same time, the expert finds an abundance of information on details of clinical enzyme diagnostics. *D. Busch* [NB 177/79 IE]

**Synthetic Methods of Organic Chemistry.** By *W. Theilheimer*. Yearbook 1963. Vol. 17 (with a key to the subject index, etc. in German). Verlag S. Karger AG., Basel-New York 1963. 1st Edit., XVI, 507 pp., clothbound DM 150.–.

When leafing through Volume 17 of "Synthetic Methods", one again finds a wealth of original reactions, many of which can be applied more generally. The whole field of organic chemistry is covered by 955 examplex. The syntheses extend over numerous types of compounds, including the carbon compounds of hetero-elements (particularly phosphorus, sulfur, and boron). Reagents and methods (photochemical reactions, for instance) are classified seperately and also cover a wide field. Chemists working on synthetic problems can again find constant help in this selection. This presupposes, however, adeptness in the use of the logically arranged subject index, although the extensive list of terms included gives a great deal of information. Because this yearbook is so valuable, an additional punched card index should be issued at least every five years to facilitate literature screening.

Once again the binding and print are excellent.

*S. Hünig* [NB 137/69 IE]

**Grundlagen der Arzneimittelforschung und der synthetischen Arzneimittel** (Fundamentals of Drug Research and of Synthetic Drugs). By *J. Büchi*. Chemical Series Volume 15. Textbooks and Monographs from the Realms of the Exact Sciences. Birkhäuser Verlag, Basel, Stuttgart 1963. 1st edit., 744 pp., numerous figs., tables, and formulae, linen DM 96.– (about $ 24.00).

Drug research, in the author's opinion, includes all fields which are involved in the development of new pharmaceuticals. These include problems in the chemical and physicochemical fields, such as the synthesis, analytical characterization, and conversion of drugs into a suitable form for administration. In addition, there is pharmacological testing on animals and also clinical evaluation. The aims of systematic drug research include appraisal of the relationships between the pharmacological action and chemical constitution or physico-chemical properties of drugs as well as their mode of action and their biochemical transformations in organisms.

Of a book that, according to the introduction, is intended "to provide the basic principles of this field of knowledge for students and professionals who wish to be trained or informed in some branch or other of drug research" one can scarcely demand that all the aspects mentioned should be treated exhaustively; this would ask too much of a single author. The same is true of one reviewer. The chemist will be primarily interested in the chapters dealing with preparative and analytical problems, which constitute about one-third of the volume. The work contains no information on syntheses, but the structural formulae of very many substances are given; they serve as examples of the connections between chemical variation and parallelism or modification of activity, which are organized into more or less firm rules. One must admire the author's familiarity with the literature and one is amazed at the predictions to which the principle of chemical similarity can occasionally lead. Of course, most of the rules are the result of postexperimental interpretation, and for most of them, contrary examples are also indicated or are not difficult to find. The purely pharmaceutical chapters, *e.g.* that on the influence on activity of different modes of application or that on the conversion of drug substances into drug forms, are valuable and illustrated with many examples. The characterization of chemical analytical testing methods is also comprehensive and thorough.

The reading of the book, the title of which is somewhat unhappily chosen, will no doubt be stimulating to any chemist interested in pharmaceuticals, but an uncritical reader may possibly be led to believe that new drugs will very soon be developed "by constructive planning" on the basis of theoretical speculations. Up to now, the discovery of new kinds of drugs has been due, at all events, quite predominantly to empiricism, *i.e.* either to schematic pharmacological testing of innumerable chemical compounds or to chance observations, which were then developed systematically with due regard to all previous experiences.

# Intramolecular Free-Radical Reactions

BY DR. K. HEUSLER AND DR. J. KALVODA

CIBA AG., BASEL (SWITZERLAND)

*In the present article an attempt is made to summarize the steric requirements and the influence of neighboring groups which determine the course of intramolecular radical reactions. Steroids are used as substrates for these reactions, since here the spatial arrangement of the ring members and the distances between substituents are largely fixed. Furthermore, intramolecular free-radical reactions are of practical importance in steroid chemistry in connection with substitution at non-activated carbon atoms. Almost all the reactions discussed begin with the formation of an oxygen radical by oxidation of an alcohol with lead tetraacetate or by homolysis of the corresponding hypoiodite.*

## A. Introduction

Although a large number of free-radical reactions is known, the steric requirements for the attack of free radicals on saturated compounds, the nature and geometry of the transition state, the influence of neighboring functional groups and the reaction medium on the course of the reaction have been far less thoroughly studied than for heterolytic reactions. For example, the free-radical substitution at a carbon atom, corresponding to an $S_N2$ reaction, has not yet been detected with certainty [1], and the cases in which neighboring groups are definitely known to participate in homolytic reactions are very few [2].

Knowledge regarding the course of free-radical reactions in solution is mainly derived from investigations on bimolecular homolytic processes, frequently chain reactions, and has been reviewed by *Walling* [3]. It is the aim of the present survey to point out certain new aspects of free-radical reactions in solution – particularly stereochemical problems, the influence of neighboring groups, and new possibilities of substitution reactions – the understanding of which is important for the preparative use of such reactions.

For our investigations, we have chosen *intramolecular* free-radical reactions, since these are particularly well suited to the study of the steric requirements and the influence of neighboring groups. Moreover, reactions whose intermolecular analogues are unfavorable owing to entropy considerations, can gain importance in intramolecular processes.

The relative positions of reaction centers are very easily assigned in the case of fused-ring cyclohexane derivatives, since the spatial arrangement of the ring members and the distances between substituents are fixed in these compounds. Furthermore, hydroxylated cyclohexanes with known configurations and conformations, which can be used to obtain oxy-radicals, are readily available. Examples are found particularly among alicyclic natural products, such as steroids or terpenoids, whose skeletons exhibit considerable rigidity owing to the fused rings. Fortunately, intramolecular free-radical reactions have

[1] It is, however, not impossible that the reactions described by *R. A. Ogg* and *M. Polanyi*, Trans. Faraday Soc. *31*, 482 (1935), *R. A. Herrmann* and *R. M. Noyes*, J. Amer. chem. Soc. *78*, 5764 (1956), *J. N. Pitts*, *R. S. Tolberg*, and *T. W. Martin*, ibid. *79*, 6370, (1957), *J. N. Pitts*, *D. D. Thompson*, and *R. W. Woolfolk*, ibid. *80*, 66 (1958), and *J. E. Bujake*, *M. W. T. Pratt*, and *R. M. Noyes*, ibid. *83*, 1547 (1961), are substitutions of this type.

also achieved practical importance [4] in steroid chemistry, and this has been decisive in promoting more thorough investigations.

In the following parts of this paper we shall be concerned mainly with intramolecular reactions initiated by the formation of an *oxy-radical*, and only in this connection shall we examine the reactions of nitrogen and carbon radicals in any detail. Carbenes and nitrenes, which may be regarded as diradicals, will not be considered.

We shall begin by discussing the attack of an oxy-radical on a carbon-hydrogen bond, *i.e.* the abstraction of hydrogen, laying particular emphasis on the spatial requirements of these reactions. Two types of intramolecular free-radical reactions, namely the oxidation of monohydric alcohols with lead tetraacetate [5] and the hypoiodite reaction [6], will then be examined in greater detail. Finally, in this connection, steric effects, participation of neighboring groups, and fragmentation reactions are discussed.

## B. The Intramolecular Abstraction of Hydrogen

Intramolecular abstraction of hydrogen corresponds to the transfer of a hydrogen atom to an attacking free radical in the same molecule, and hence to a hydrogen shift. The most frequently observed intramolecular hydrogen transfers are 1,5-shifts. They can be generally represented by Scheme 1 [7].

Scheme 1. Free-radical induced intramolecular 1,5-hydrogen shifts.

The reaction is initiated by thermal or photolytic homolysis of the A–X bond in *(1)*, and this is followed by the hydrogen shift from C-δ to A. The resulting carbon radical *(3)* finally reacts with a free radical X'•, which may be identical with X•. Besides certain hydrogen transfers from carbon to carbon [8] [*(2)* → *(3)*, A = C], it is in particular the Hoffmann-Löffler-Freytag reaction [9] (A = N) which, being initiated by the homolysis of *N*-chlorides, proceeds according to this Scheme. The most important reactions of this type are those in which A is an oxygen atom [10]. Oxygen radicals may be produced by conventional methods [11], *e.g.* by the photolysis of nitrites [12] (A = O; X = NO) or by cleavage of hypochlorites [13] (A = O; X = Cl).

Two further methods have recently been described for the production of oxygen radicals, namely the oxidation of monohydric alcohols with lead tetraacetate [5] and the cleavage of alkyl hypoiodites [6]. The advantage of these methods over the photolysis of nitrites and hypochlorites is that the unstable product *(1)* does not have to be formed and isolated in a separate step from the alcohol *(1)*, A = O, X = H. Instead, the cleavable product *(1)*, A = O, X = $Pb(OAc)_3$ or I, is produced from the alcohol in the same solution in which the oxy-radical is generated.

The following general rules apply to intramolecular hydrogen abstractions:

1. The most favorable transition state for the hydrogen transfer is that of a 6-membered ring in the chair form. Consequently, hydrogen is preferentially abstracted from the δ-carbon atom. The steric requirements for this reaction are more important than the energetic ones; thus, for example, hydrogen on a non-activated δ-carbon atom is removed in preference to a more weakly bonded hydrogen in the ε-position [12, 14a]. In the formation of bridged systems, the reaction centers can also assume positions which favor abstraction of hydrogen from the ε-carbon atom [9, 14b]. Hydrogen shifts corresponding to 1,2- and 1,3-hydride shifts observed with (carbonium and) oxonium ions [15] do not occur with oxy-radicals.

[7] This principle was formulated for the first time by *D. H. R. Barton, J. M. Beaton, L. E. Geller,* and *M. M. Pechet,* J. Amer. chem. Soc. *82,* 2640 (1960).

[8] *De Los F. De Tar* and *E. I. Relyea,* J. Amer. chem. Soc. *78,* 4302 (1956); *C. A. Grob* and *H. Kammüller,* Helv. chim. Acta *40,* 2139 (1957), where previous publications are quoted.

[9] *M. E. Wolff,* Chem. Reviews *63,* 55 (1963).

[10] As has recently been shown, the hydrogen transfer occurs in a similar 6-membered cyclic transition state, even if the oxygen radical is formed not by homolysis of an O-X bond, but by photochemical excitation of a C=O group. The reaction probably proceeds in *two* stages. – *N. C. Yang, A. Morduchowitz,* and *D. H.*

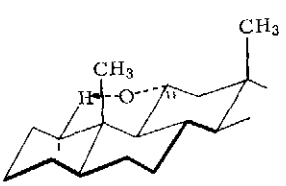
2. As expected, the reactivity of the hydrogen atoms decreases in the order tertiary > secondary > primary [16]. For example, if two δ-carbon atoms at the same distance from the radical center carry a tertiary and a secondary hydrogen atom respectively, the tertiary hydrogen will be preferentially attacked.

Formulae *(5)–(10)* illustrate these general rules and demonstrate the importance of steric requirements for successful intramolecular radical reactions.



Certain assertions can also be made regarding the favorable distance between the O-radical and the hydrogen atom for the intramolecular abstraction of hydrogen and regarding the orientation of the C–H bond attacked with respect to the attacking oxy-radical [for references, see under formulae *(5)* to *(10)*]. Since the conformations of the methyl groups in steroids of the type *(5)* in the transition state cannot be ascertained, the internuclear distances between the oxygen atoms and the carbon atoms carrying hydrogen were determined from Dreiding models of the compounds *(5)* to *(10)*. These values are greater than the internuclear distance between the oxygen radical and the hydrogen to be abstracted in the starting material which, for a C–O distance of 2.6 Å and for normal bond angles, is at least 2.1 Å. This minimum distance is realized when the C–O and the C–H bonds lie in the same plane. For the reactions indicated by arrows in formulae *(5)–(10)*, Dreiding models give values of 2.5 to 2.7 Å for the C O distances, corresponding very closely to the O–O distances in compounds of the type O–H···O, *i.e.* in compounds with hydrogen bridges [27]. For intramolecular hydrogen bridges between C–H groups and oxygen atoms, the C–O distances have been found to be 2.6 to 3.0 Å [28].

The distance between the 20-oxygen atom and the 18-carbon in *(5)* can be reduced to about 2.0 Å, depending on the configuration of the side chain. The distances marked in the formulae can be varied to some extent by changes in the basic skeleton, *e.g.* by the introduction of trigonal centers or the formation of bridged systems.

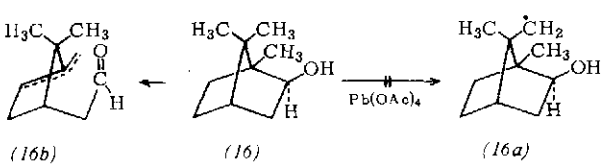
[26] Lead tetraacetate and hypoiodite reaction: unpublished work from the laboratories of ETH Zürich and CIBA AG, Basel.

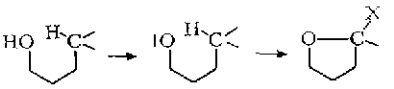
Thus the distance between 11β-O and C-18 in *(11)* and *(13)* is 2.65 Å, but the distance between 11β-O and C-19 is 2.5 Å in *(11)* and 2.9 Å in *(13)*. It is now interesting



to compare the reactions of *(11)* and *(13)*: A C–H bond on an oxygen-bearing C-atom is weaker than a C–H bond in a $CH_3$ group. This appears to be the deciding factor when the C···O distance is less than 2.70 Å, since despite the shorter distance between 11β–O and C-19, compound *(11)* yields predominantly the 11β,18-ether *(12)*. In compound *(13)*, on the other hand, the distance to the oxygen-bearing C-19 is too great (2.9 Å) compared with the distance to the unsubstituted C-18 (2.65 Å), so that the latter is substituted, although the reaction in this position is less favored energetically.

Finally, no intramolecular abstraction of hydrogen occurs after the production of the O-radical *(15)* by means of the hypoiodite reaction [31, 32]. In this case the distance between

the 6β-oxygen and C-19 is over 3 Å, owing to the deformation of ring B caused by the cyclopropane ring. The distance be-



tween the methyl groups and the oxygen atom in *(16)* [33] is also greater than 3 Å, so that here again the oxygen radical fails to attack the methyl group.

It can be concluded from these experiments that the activation energy for the intramolecular abstraction of hydrogen reaches a minimum in fixed systems with an O···C distance of 2.5 to 2.7 Å in the starting material, but that for distances exceeding 2.8 Å, the rate of this reaction becomes smaller than those of intermolecular hydrogen abstraction or fragmentation reactions. Intramolecular reactions in compounds in which the O···C distance is 2.5 to 2.7 Å are so much more rapid than intermolecular free-radical reactions, that they can even be carried out in solvents, such as cyclohexane, which are readily susceptible to free-radical attack.

The experiments referred to also give some indications regarding the geometry of the transition state in the hydrogen shift. Although the reactions on the angular methyl groups indicated in *(5)* do not yield accurate conclusions, owing to the free rotation of these groups, the hydrogen transfers illustrated in *(6)*, *(7)*, and *(9)* are significant. The fact that these reactions, in which all reacting centers are fixed as constituents of a six-membered chair-like ring, proceed with good yield, confirms the general rule regarding the geometry of the transition state [34]. The linearity of the C, H, and O atoms taking part in the reaction, which was postulated for himolecular hydrogen transfers (from C to halogen) [35], is practically impossible in these cases.

### C. The Hypoiodite Reaction

The term "hypoiodite reaction" is used here to denote the homolytic cleavage of alkyl hypoiodites *(17)*, which leads to an intramolecular substitution on non-activated carbon atoms. The end-products of the reaction are generally tetrahydrofuran derivatives *(18)*.

Alkyl hypoiodites have never yet been isolated in the pure state, but are readily prepared in solution by the action of *N*-iodosuccinimide or acyl hypoiodites, *e.g.* acetyl hypoiodite, on alcohols [6]. Acetyl hypoiodite can be obtained from silver acetate, mercury(II) acetate, or particularly advantageously, from lead tetraacetate and iodine in non-polar solvents such as cyclohexane. Alkyl hypoiodites prepared in this way decompose homolytically above 60 °C into iodine atoms and oxy-radicals. This decomposition is accelerated by iodine atoms. An adequate concentration of iodine atoms is ob-

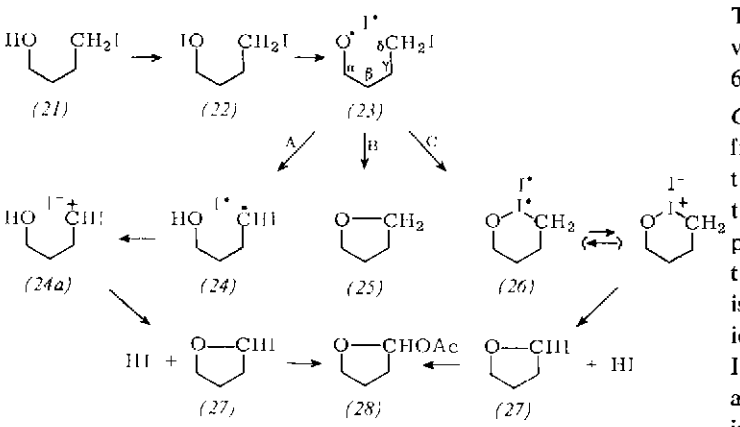
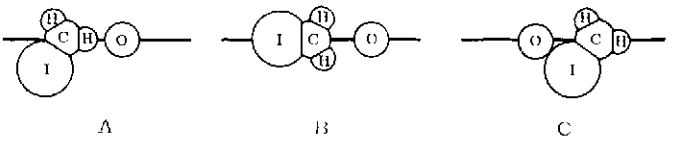
tained, *e.g.* by irradiation of dissolved iodine with light of a wavelength between 500 and 550 mμ, *i.e.* in the region of the principal absorption band of iodine (522 mμ in saturated hydrocarbons, and 512 mμ in halogenated hydrocarbons [36]). For this reason, the reaction proceeds well in non-polar solvents, in which iodine is normally soluble, while in aromatic solvents, such as benzene, in which charge-transfer complexes are formed with iodine, the concentration of free iodine atoms formed on irradiation is not sufficiently large. Although the photolysis of nitrites is similar in many respects, the hypoiodite reaction [36a] exhibits special characteristics connected with the method of preparation of the alkyl hypoiodites, and with the bulk and the oxidation potential of the iodine atoms. Since the course of the reaction also depends on the degree of substitution of the attacked center, substitutions on methyl, methylene, and methine groups will be treated separately.



### 1. Substitution on Methyl Groups

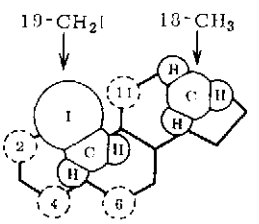
The first stages of the hypoiodite reaction with alcohols in which the δ-carbon is a methyl group *(19)* correspond exactly to the general scheme *(1)* → *(4)*. In the same manner as the hypoiodite *(20)* formes from *(19)*



*(19)* *(20)* *(21)*

in the reaction mixture, the resulting alcohol *(21)* is converted to a hypoiodite *(22)*, and this undergoes homolysis to yield *(23)*.

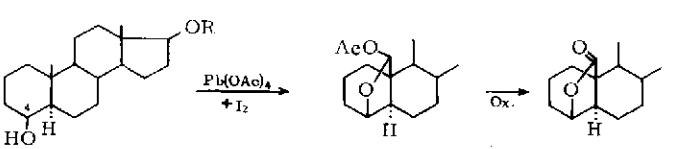
*(21)* *(22)* *(23)* *(24a)* *(24)* *(25)* *(26)* *(27)* *(28)* *(27)*



Subsequent reactions are determined by the steric arrangement of the reaction centers in *(23)*, if the C(α)–O and the γ,δ-bonds are fixed. There are three possible orientations, A, B, and C, for the oxygen atom with respect to the $CH_2I$ group, which arise by rotation of the $CH_2I$ group about the γ,δ-bond [37].

A B C

In Case A, the oxygen, hydrogen, and carbon lie in a straight line when projected on a plane perpendicular to the C(α)–O bond. This orientation definitely favors the abstraction of hydrogen. In Case B, the hydrogens are turned around, and the oxygen, carbon, and iodine are now situated in a straight line when projected. This position fulfils the requirement for a replacement of the iodine by oxygen with reversal of the configuration. Finally, in Case C, the arrangement is suitable neither for a hydrogen abstraction nor for a substitution. In this case, an interaction probably arises between the oxygen radical and the iodine atom.



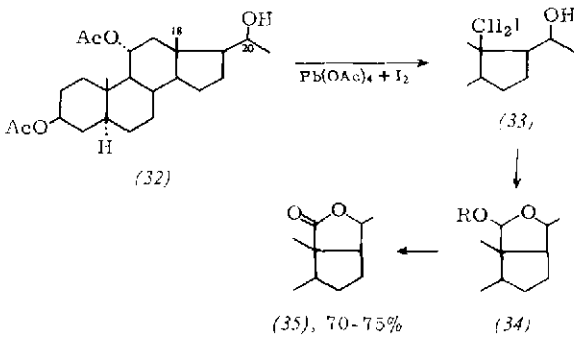
These three possibilities can be easily realized in the steroid series, for example in the substitution at the 19-methyl group. A 19-iodomethyl group, formed according to *(19)* → *(21)* by the attack of a neighboring oxygen radical, is fixed between the axial 2β- and 11β-hydrogen atoms *(29)*, so that the power of free rotation is lost.

*(29)*

The three orientations A, B, and C can be experimentally verified by the introduction of oxygen atoms in the 4β-, 6β-, and 2β-positions [37].

*Case A*: This corresponds to the intermediate product from a 4β-hydroxysteroid [18a] which, by normal abstraction of hydrogen, yields the C-radical *(24)*. Since substitution by a second iodine atom in the 19-position is not possible in steroids owing to steric factors, electrons are transferred to the iodine atom, and the iodo ether *(27)* is formed through a carbonium ion (stabilized by the iodine atom on C-19) by elimination of hydrogen iodide. If the reaction is carried out in the presence of lead tetraacetate or mercury (II) acetate, the hemiacetal acetate is formed. Acid oxidation of *(27)* and *(28)* with chromium trioxide yields the corresponding lactone. This reaction sequence is illustrated by the example *(30)* → *(31)* [17b] and in the 20-hydroxy series by *(32)* → *(35)* [21d].

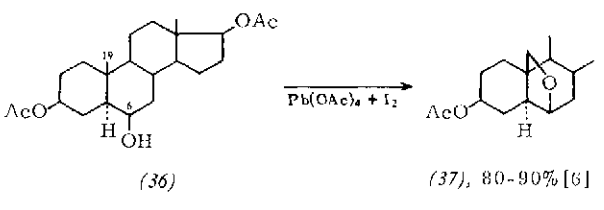
*(30)* *(31)*, ca. 78%



[36] *H. Tsubomura* and *R. P. Lang*, J. Amer. chem. Soc. *83*, 2085 (1961).

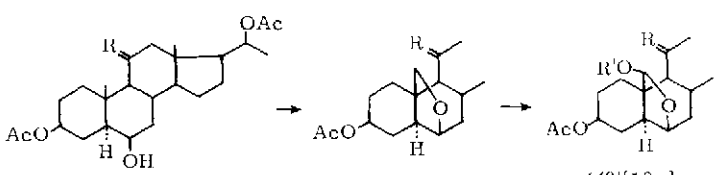
[36a] The homolytic cleavage of *N*-iodoamides, which leads to γ-iodoamides and, by intramolecular substitution via an iminolactone, to γ-lactones [*D. H. R. Barton* and *A. J. L. Beckwith*, Proc. chem. Soc. (London) *1963*, 335], is an interesting extension of the hypoiodite reaction and a parallel to the Löffler-Freytag reaction [9].

[37] Review: *J. Kalvoda*, *K. Heusler*, *P. Wieland*, *G. Anner*, and *A. Wettstein*, Gazz. chim. ital. *93*, 140 (1963).



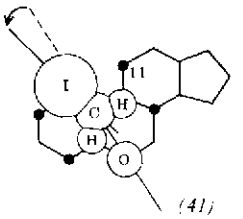
Thus a *double* substitution of the methyl group takes place. However, iodosuccinimide, silver acetate and mercury(II) acetate in the presence of iodine also yield *singly* substituted products, *i.e.* 4β,19- and 18,20-ethers respectively, since the hypoiodite is more slowly formed from the alcohol with these reagents than with lead tetraacetate and iodine, so that the ether *(25)* is formed from part of the iodohydrin *(21)* by an ionic reaction, before a hypoiodite is formed again.

Using a 20-hydroxysteroid as starting material, the iodohydrin intermediate *(33)* can be isolated under suitable conditions.

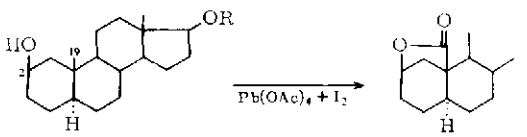


*(32)* *(33)* *(34)* *(35)*, 70-75%

*Case B*: This case merits special attention, since a second hydrogen abstraction does not occur, although a hypoiodite is again formed, at least in part, from the iodohydrin intermediate of type *(21)*. This appears to be one of the few cases of homolytic substitution at carbon by attack of an oxygen radical with displacement of an iodine atom [38] ($S_H2$ reaction [39]). This reaction only occurs when the "linear" arrangement B of the O, C, and I atoms prevails, as it is found in 6β-hydroxy-19-iodides. The transition state for the $S_H2$ reaction thus appears to correspond substantially to that of the bimolecular nucleophilic substitution ($S_N2$). The sensitivity of this reaction to steric effects is shown by the examples *(36)* → *(37)* and *(38)* → *(40)*.



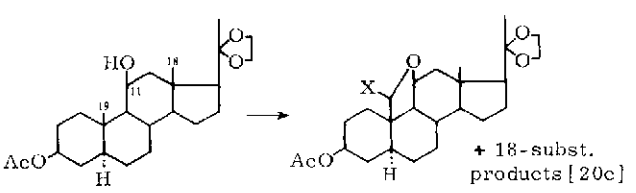
*(36)* *(37)*, 80-90% [6]



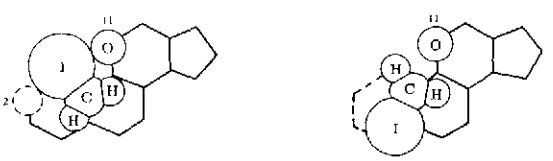
*(38)* *(39)*, R = H, OAc or O, yield ca. 60% *(40)* [19e], yield ca. 7%

At the same time, these examples prove that the iodohydrin intermediate *(21)* does again form an oxygen radical *(23)* through a hypoiodite *(22)*. Thus on introduction of an 11-substituent, the pseudo-linearity of 6β-O, C-19, and I is somewhat disturbed on steric grounds, and, as indicated in *(41)*, the orientation of the reaction centers approaches Type A. In fact, mixtures of singly *(39)* and doubly *(40)* substituted products are obtained with lead tetraacetate and iodine.

*(41)*



*Case C*: Here the oxygen radical appears to attack the most closely positioned iodine atom; the iodo ether *(27)* is formed through an intermediate *(26)* of the iodonium type [40], and the methyl group is doubly substituted, as in Case A. This reaction course has been observed with 2β-hydroxysteroids (the crude product was converted directly to the lactone by mild oxidation).



*(42)* yield 54% [18b] (no 2β,19-ether)

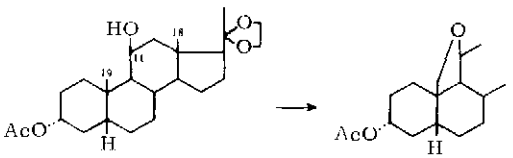
The mode of reaction of 11β-hydroxysteroids, *e.g. (43)* and *(45)*, is of interest in this connection, although these do not yield uniform products owing to the simultaneous attack on C-18 and C-19.

In compounds of the 5α-series, the spatial arrangement of the 11β-oxygen atom in the intermediate product, with respect to the $CH_2I$ group on C-10, which has a fixed conformation, is analogous to that of the 2β-oxygen atom in *(42)* [cf. *(43a)*]. Nevertheless, 11β,19-ethers (in addition to 18-substituted compounds) are found in this case besides the hemiacetals expected from the Type C orientation.

*(43)* *(44)*, X = H, OAc

*(43a)*, 5α-H(A/B-trans) *(45a)*, 5β-H(A/B-cis)

The formation of the 11β,19-oxido compound *(44)*, X = H, with no substituents in the 19-position could be due

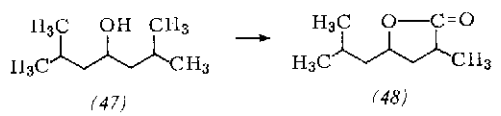


[38] This reaction is energetically favorable: the dissociation energy of a C–I bond is 49–55 kcal/mole, while ca. 77 kcal/mole are liberated in the formation of a C–O bond. *E. W. R. Steacie:* Atomic and Free Radical Reactions. Reinhold Publishing Corp. New York 1954; *P. Gray*, Trans. Faraday Soc. *52*, 344 (1956).

[39] For nomenclature, see *E. L. Eliel* in *M. J. Newman:* Steric Effects in Organic Chemistry. Wiley, New York 1956, p. 143; see also [1].

[40] See [2a] and *J. E. Leffler* and *J. S. West*, J. org. Chemistry *27*, 4191 (1962).

to steric hindrance of the formation of the second hypoiodite: the ether would then be formed in an ionic reaction from the corresponding iodohydrin.

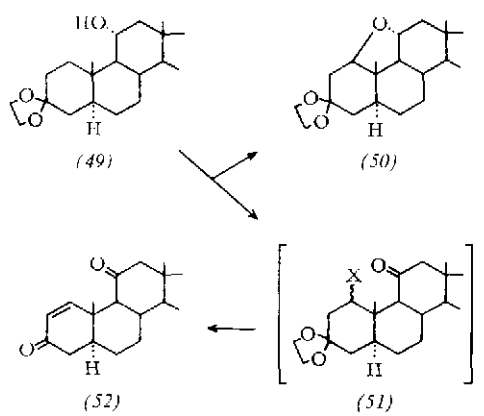


In the 11β-hydroxysteroids of the 5β-series *(45)*, the $CH_2I$ group in the intermediate product is not fixed. The iodine atom can rotate freely above ring A, which is folded downwards [cf. *(45a)*]. The principal product is the 11β,19-ether *(46)*. It appears that the $S_H2$ reaction

*(45)* *(46)*[20c]

gains in importance in this case. This would mean that the $CH_2I$ group preferentially assumes the "linear" arrangement B.

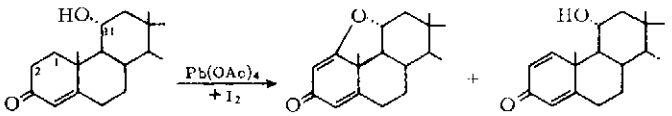
However, intermolecular $S_H2$ reactions of this type do not occur [41]. Preliminary experiments with the aliphatic alcohol *(47)* show that the "double" substitution of one of the four methyl groups is preferred in this case, although the "linear" arrangement B could be realized. After oxidation of the reaction mixture with chromium(VI) oxide the lactone



*(47)* *(48)*

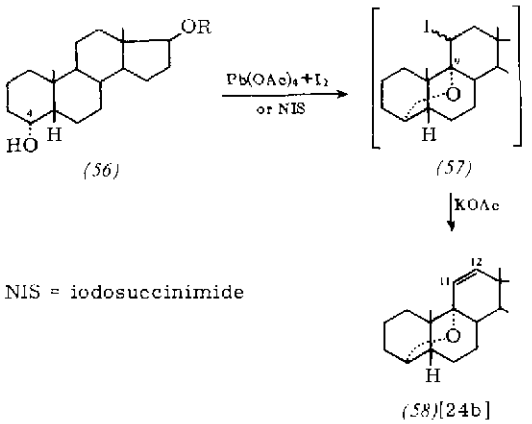
*(48)* can be isolated (as a mixture of the two stereoisomers) as the principal product (ca. 37 %) by preparative gas chromatography [42].

## 2. Substitutions on Methylene and Methine Groups



Substitutions on secondary and tertiary carbon atoms by the hypoiodite reaction are less numerous. The abstraction of secondary hydrogen atoms was investigated for 11α-hydroxy- and 19-hydroxysteroids [cf. *(6)*, *(7)*, and *(10)*]. The course of the hypoiodite reaction with 11α-hydroxysteroids depends on the nature of the substituent on C-3. For example, the principal product from a 3,3-ethylenedioxy-11α-hydroxy compound *(49)*

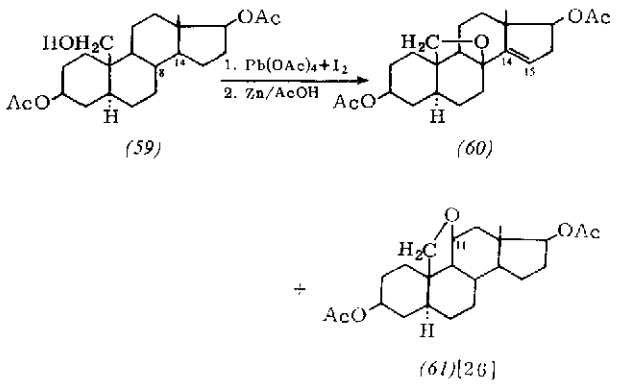
*(49)* *(50)* *(52)* *(51)*



is the saturated 1,11α-ether *(50)*. 1-Iodo- or 1-acyloxy-11-oxosteroids *(51)* occur as by-products; on acid and base hydrolysis they are probably converted to 3,11-dioxo-$\Delta^1$-steroids *(52)*, but these were not isolated in pure form.

This behavior differs from that of the 3-oxo-11α-hydroxysteroids, *e.g.* *(53)*, the hypoiodite reactions of which yield 1,2-unsaturated 1,11α-ethers *(54)* as the principal products, together with the corresponding 1-dehydro compounds *(55)*.

*(53)* *(54)* *(55)*[22b]

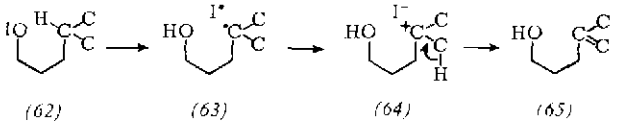


In 4α-hydroxysteroids of the 5β-H series (A/B-cis) *(56)*, the 7α- and 9α-hydrogen atoms are equidistant from the 4α-oxy-radical; of these two atoms, the latter is almost exclusively attacked.

*(56)* *(57)* *(58)*[24b]

NIS = iodosuccinimide

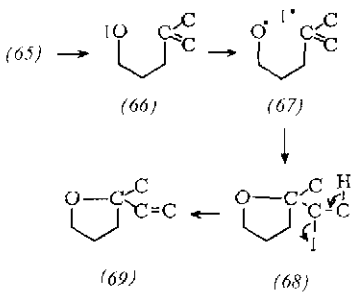
In the 19-hydroxysteroids, *e.g.* *(59)*, on the other hand, both the tertiary 8β- and the 11β-hydrogen are attacked, probably because the approach of the oxygen radical to



*(59)* *(60)* *(61)*[26]

the 8β-hydrogen atom is more difficult than to the 11β-hydrogen atom owing to steric factors. The first stages of the radical chain-reaction are the same in substitution on a methylene or methine group as in the attack on a methyl group. However, in the substitution at a tertiary carbon atom, the iodination of the C-radical *(63)* by an iodine atom is impossible or very difficult for steric

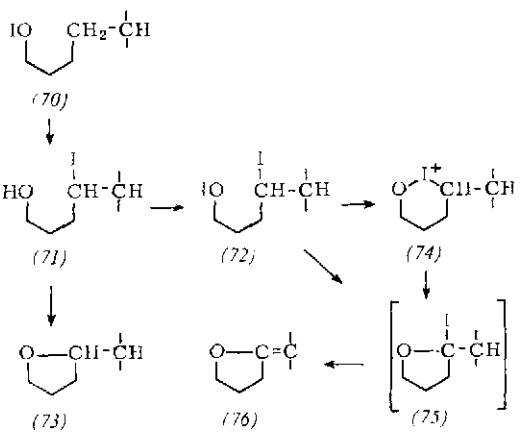
[41] *L. H. Slaugh*, J. Amer. chem. Soc. *83*, 2734 (1961).



[42] Unpublished work. The constitution of *(48)* follows from the infrared, NMR, and mass spectra.

reasons. Therefore, an electron displacement, *i.e.* an oxidation to the carbonium ion *(64)*, occurs as in the conversion *(24)* → *(27)*. The ion pair *(64)* corresponding to the radical pair *(63)* is stabilized by release of a

*(62)* *(63)* *(64)* *(65)*

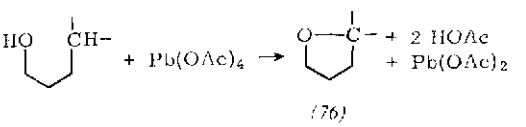


proton to form *(65)*. The double bond in the intermediate of type *(65)* is situated in the 9,11-position in the reaction *(56)* → *(57)*, and in the 8,14-position in the reaction *(59)* → *(60)*. Since *(65)* is again an alcohol, a hypoiodite is formed once more and, on homolysis, the O-radical and an iodine atom are added to the double bond *(68)*. Hydrogen iodide is finally split off by the action of a base and the allyl ether *(69)* is formed.

*(65)* *(66)* *(67)* *(69)* *(68)*

The iodo ether intermediate of type *(68)* was not isolated, but its formation was indirectly verified in the case of the 4α,9α-ether. Thus, if the crude product of the hypoiodite reaction is oxidized with chromium trioxide/silver chromate, instead of the potassium acetate treatment, a 4α,9α-oxido-11-ketone is obtained [23b].

In the formation of the 1,11α-ethers *(50)* und *(54)*, the reaction does not appear to proceed through the 1,2-olefin of type *(65)* which has been isolated in some cases as a by-product [cf. *e.g.* *(55)*], since the hypoiodite reaction with an 11α-hydroxy-$\Delta^1$-3-oxosteroid yields a complex mixture, containing no $\Delta^1$-1,11α-ether. Nevertheless, it must be assumed that an iodohydrin of type *(71)* [analogous to *(21)*] is also formed initially.



*(70)* *(71)* *(72)* *(74)* *(73)* *(76)* *(75)*

Since the formation of the second hypoiodite *(71)* → *(72)* is difficult owing to steric factors, part of the iodohydrin *(71)* can undergo an ionic reaction, eliminating HI, to form the saturated ether *(73)*.

Depending on the configuration of the 1-iodine atom and the conformation of ring A in the iodohydrin of type *(71)* formed from *(53)*, a spatial arrangement of oxygen and iodine similar to that in Case A or C in the attack on a methyl group (cf. above) is possible, so that after the second hypoiodite formation, the enol ether *(76)* is finally produced. From the ketal *(49)*, the ether *(50)* could be formed directly through a carbonium ion in the 1-position, as in the substitution of tertiary hydrogen atoms, since the approach of the iodine atom is sterically hindered.

## D. The Oxidation of Monohydric Alcohols with Lead Tetraacetate [5]

The oxidation of monohydric alcohols to tetrahydrofuran derivatives *(76)*, is stoichiometrically a simple oxidation. However, the course of the reaction is

*(76)*

divided into three stages, namely the formation of a lead alkoxide from the alcohol and lead tetraacetate, the formation of the oxy-radical, and the formation of the ether.

### 1. Lead Alkoxide Formation

Since the homolytic cleavage of an O–H bond is almost impossible owing to the high bond energy [43], it must be assumed that a readily cleavable derivative is first formed in the lead tetraacetate reaction. It is reasonable to assume that this initial product is a lead alkoxide, although such a compound has never been isolated [44]. In the exchange of an acyloxy group on the tetravalent lead for an alkoxy group, the equilibrium

$$ROH + Pb(OAcyl)_4 \rightleftharpoons RO-Pb(OAcyl)_3 + HOAcyl$$

is displaced to the left on the addition of acid [44]. This exchange should proceed in the same manner and at roughly the same rate as the exchange of acyl groups on tetravalent lead [45a]. On the other hand, it also depends on the steric effect in the alcohol part. Tertiary [21b, 25] or strongly hindered secondary alcohols [18b] react only slowly.

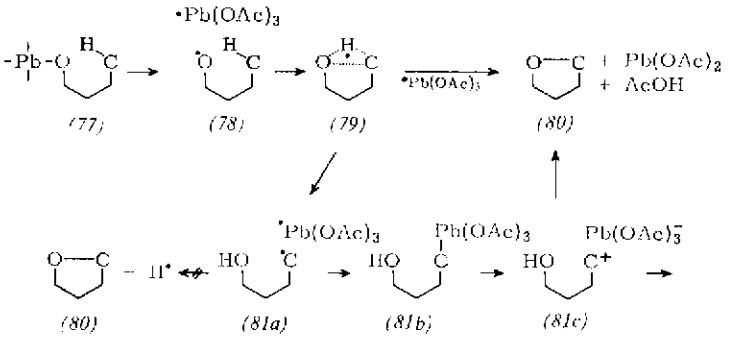
### 2. Cleavage of the Pb–O Bond in Oxygen Compounds of Tetravalent Lead

Both heterolytic and homolytic cleavages of Pb–O bonds are known [45b]. The cleavage of glycols in polar media at low temperatures should mainly proceed

[43] The bond energy of a O–H bond is ca. 102 kcal/mole; see *T. L. Cottrell:* The Strengths of Chemical Bonds. Butterworths, London 1954.

[44] *R. Criegee, L. Kraft,* and *B. Rank,* Liebigs Ann. Chem. *507*, 159 (1933), isolated a crystalline product of the formula $Pb(OAc)_2(OH)(OCH_3)$ from lead tetraacetate and incompletely anhydrous methanol, and referred to the different rates of cleavage of glycols in benzene and acetic acid.

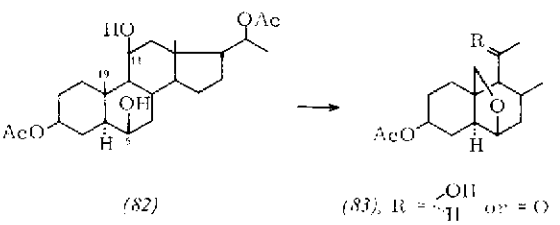
[45a] *E. A. Evans, J. L. Huston,* and *T. H. Norris,* J. Amer. chem. Soc. *74*, 4985 (1952).



[45b] According to infrared measurements the Pb–O bonds in lead(IV) acylates exhibit ionic character. Nevertheless we shall use the terms homolysis and heterolysis of the Pb–O bond although in fact a single or double electron transfer from oxygen to lead is involved.

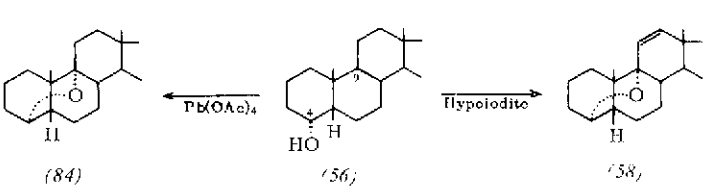
heterolytically [46], while in methylation with lead tetraacetate [47] in non-polar solvents at elevated temperatures, methyl radicals are formed by decarboxylation of the acetoxy-radicals produced by homolysis of the lead(IV) salt. The homolysis of lead(IV) acylates of primary, secondary, and tertiary carboxylic acids can also be carried out photolytically [48a]. At very low temperatures, the carbon radicals produced by decarboxylation can be detected directly by ESR measurements [48b].

The cleavage of the Pb–O (alkyl) bond in lead alkoxides of the type $(RCOO)_3Pb-OR'$ appears to be similar to, but considerably easier to effect than, the cleavage of a Pb–O–(Ac) bond in lead tetraacylates: the alkoxylead triacetates are thermally decomposed at temperatures as low as 70 to 80 °C (boiling benzene or cyclohexane), while lead tetraacetate (in the absence of a "catalyst" [47]) is only decomposed above 140 °C. The fact that the above-mentioned lead alkoxides can also be decomposed by irradiation at low temperatures to yield tetrahydrofuran derivatives [49] also indicates a homolytic cleavage of the R'O–Pb bond. The fragmentation reactions summarized in Section F particularly show that the cleavage of the R'O Pb bond yields products with the character of an alkoxy-radical (R'O·). The heterolytic decomposition into $R'O^+$ and $Pb(OAc)_3^-$ repeatedly discussed in connection with the oxidation of monohydric alcohols with lead tetraacetate, is not compatible with the experiments described below [50].



### 3. Ether Formation

The steric requirements for the tetrahydrofuran formation from alcohols with lead tetraacetate are substantially the same as for the abstraction of hydrogen in the homolysis of nitrites, hypochlorites and hypoiodites, and have been discussed in detail in Section B. Thus the cleavage of the lead alkoxide *(77)* again leads, through the oxy-radical *(78)* [51], to a transition state *(79)* which can undergo hydrogen abstraction *(81a)*. However, the direct formation of an ether from *(81a)* by ejection of a hydrogen atom is energetically unfavorable. There must therefore be another route available for the ring-closure to form *(80)*.



Nothing can be said at present regarding the importance of the transition state symbolized by formula *(79)*. In particular, it is not known whether, and to what extent, the indicated bond between oxygen and carbon in *(79)* exhibits bond character; however, it does not appear to be impossible that the three bonding electrons which are available for the three dotted bonds are approximately symmetrically distributed in certain cases. It is interesting to note that even the degree of conformational mobility of the reaction centers in the starting material yields information about the course of the reaction.

If the relative positions of the oxygen radical and the δ-carbon atom in *(78)* are fixed, direct oxidation of *(79)* to the ether *(80)* occurs – probably with the aid of a lead triacetate radical – without the intervention of a free carbonium ion as an intermediate. This was demonstrated for the example of a 6β,11β-dihydroxysteroid *(82)* [52], in which lead tetraacetate predominantly attacks the 6β-oxygen owing to steric factors. Although the C-19

methyl group is equidistant from the 6β- and 11β-oxygen atoms, the only product of the reaction is the 6β,19-ether *(83)*; an intermediate of the type *(81)* is therefore unlikely.

The behavior of 4α-hydroxy-5β-steroids *(56)* is particularly interesting in this connection. Whereas lead acetate yields only the saturated 4α,9α-ether *(84)* [18b], a $\Delta^{11}$-4α,9α-ether *(58)* is formed in the hypoiodite reaction, which proceeds through an intermediate 9-carbonium ion (cf. Section C. 2).

[46] *R. Criegee*, Angew. Chem. *70*, 173 (1958). The formation of aldehydes [*V. M. Micović* and *M. Lj. Mihailović*, Recueil Trav. chim. Pays-Bas *71*, 970 (1952)] and ketones (cf. [18b, 20a, 24h]) from primary and secondary alcohols by means of lead tetraacetate should also be classified as heterolytic reaction.

[47] *L. F. Fieser* and *F. C. Chang*, J. Amer. chem. Soc. *64*, 2043 (1942); *L. F. Fieser*, *R. C. Clapp*, and *W. H. Daudt*, ibid. *64*, 2052 (1942); *L. F. Fieser* and *A. E. [48a] *V. Franzen* and *R. Edens*, Angew. Chem. *73*, 579 (1961), have investigated the decomposition of lead(IV) salts on irradiation with ultraviolet leight.

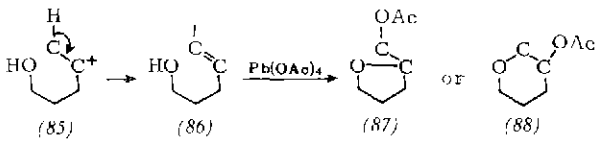
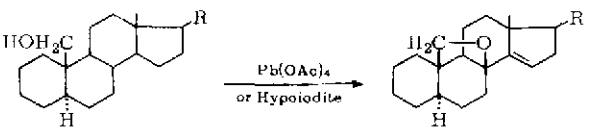
[48b] *K. Heusler*, *H. Labhart*, and *H. Loeliger*, unpublished work.



[49] *J. Kalvoda* and *K. Heusler*, Chem. and Ind. *1963*, 1431.

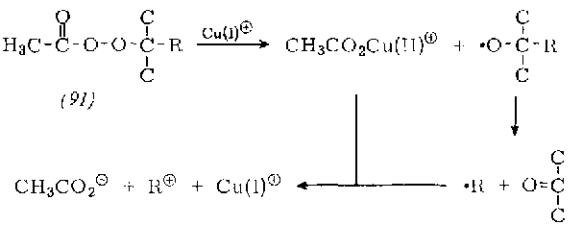
[50] In this connection, it should be mentioned that in no case to date has it been possible to isolate rearrangement products which might have been expected if an alkoxy cation occurred as an intermediate in the lead tetraacetate oxidation. It is particularly significant that, in the reaction of lead tetraacetate with 3β-hydroxycholestane, which does not contain a hydrogen atom in the δ-position relative to the hydroxy group favorably situated for abstraction, practically pure starting product is recovered together with a little 3-ketone, even after prolonged reaction.

[51] This statement does not imply that free oxy-radicals are produced. It seems probable that the lead atom remains somehow associated with the reaction complex during the transition *(77)* → *(80)*. Cf. the discussion in Section F.



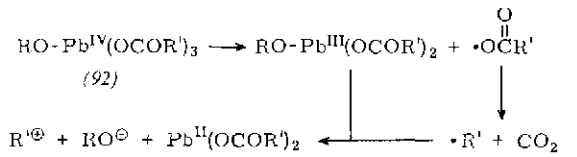
[52] Unpublished results.

However, when the centers in *(78)* are not fixed (especially in aliphatic compounds), the reaction leads to a radical pair *(81a)*, which is transformed into the ion pair *(81c)*, either by direct electron transfer or via the organolead compound *(81b)* [53a]. In addition to the formation of the ether *(80)*, a proton may be eliminated from *(81c)* with formation of a double bond *(86)*; a newly formed oxy-radical can finally add to this double bond to form the 5- or 6-membered cyclic ethers *(87)* and *(88)* [53b–e].



*(85)* *(86)* *(87)* *(88)*

It can be seen from the oxidation of 19-hydroxysteroids *(89)* that the ability to rotate freely about *one* C–C bond is sufficient for the formation of a carbonium ion as an intermediate. In this case unsaturated ethers *(90)* are formed, not only in the hypoiodite reaction, but also with lead tetraacetate.

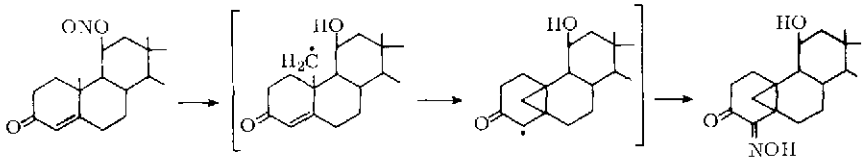


*(89)* *(90)*[26]

The cleavage of a lead alkoxide such as $R'O-Pb(OCOR)_3$ may be compared to the copper-catalysed decomposition of a peroxyester [54]. In the cleavage of peroxyacetates *(91)* in the presence of copper salts, the only products which have so far been observed are acetate ions and derivatives of alkoxy-radicals.

*(91)*

It is quite possible that the carbonium ions formed in the oxidation of free radicals with lead triacetate behave in a similar manner to those from the oxidation with copper ions. In the copper-catalysed decomposition of peroxyesters, the alternative mode of cleavage into an alkoxide-copper complex and acyloxy-radicals has not so far been observed [54]. However the alternative cleavage of the lead alkoxides *(92)* may possibly occur in the treatment of alcohols with lead salts of tertiary carboxylic acids. In any case, no 6β,19-ether



*(92)*

is formed in the reaction of lead tetrapivalate with a 6β-hydroxysteroid, although the lead(IV) salt is completely decomposed on heating. However, this result could also be explained by steric hindrance in the formation of the lead alkoxide. The copper-catalysed decomposition of tertiary peroxyesters has not as yet been described.

Other peculiarities of the lead tetraacetate oxidation of monohydric alcohols will be discussed in Section F.

## E. Participation of Neighboring Groups

In most of the examples described so far, the abstraction of hydrogen by an oxy-radical is followed by a direct

*(93)* *(94)*

substitution (*e.g.* by NO or iodine) on the carbon atom from which the hydrogen has been removed. This Section will deal with reactions in which this is not the case. Reactions of this kind always involve the addition of a carbon-free radical to unsaturated systems, namely C=C, C=O, and C≡N.

The participation of a neighboring double bond [*(93)* → *(94)*] has been described by *Barton* [20d].

The conversion to the dienone *(99)*, observed by *Barton* [55] in the photolysis of the nitrite *(95)*, can also be formally interpreted as the addition of a carbon-free radical *(96)* to an unsaturated system, followed by fragmentation to form a carbonyl compound [*(97)* → *(98)*].

[53a] The carbonium ion character of this intermediate is strongly supported by the results of the oxidation of 4,4-dimethylpentan-1-ol with lead tetraacetate which produces in addition to the 3,3-dimethyltetrahydropyrane (3–4%) 1–2% of 2-methyl-2-ethyltetrahydrofuran formed by rearrangement of the neopentyl-type carbonium ion generated as an intermediate. (95) (96) (97) (99) (98)

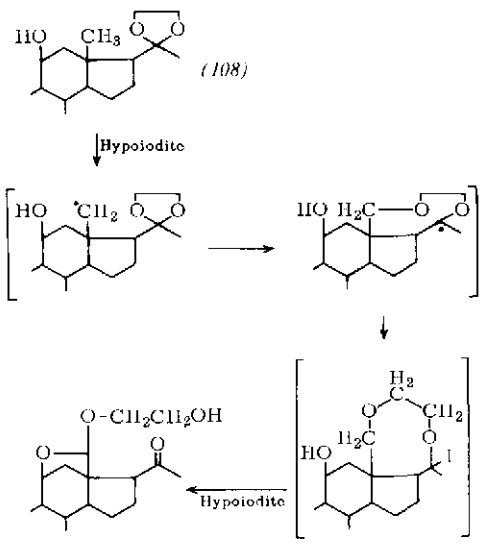
Ester carbonyl groups can also combine with carbon-free radicals. Evidence for this is found in the hypoiodite reaction of 6β-hydroxy-11β-acetoxysteroids. As described in Section C.1 (Case B), the hypoiodite reaction of a 6β-hydroxysteroid with a substituent in the 11-position should in part lead to the formation of hemiacetal-like compounds, with double substitution on the C-19 methyl group. However the 11β-acetoxy compound *(100)* yields only the simple 6β,19-ether *(101)* [52].

The angular substituent is so strongly hindered by the 11β-acetoxy group (as shown by a molecular model) that the formation of a 19-iodide is practically excluded. The course of the reaction can be best explained by assuming the intermediate addition of the initially formed carbon radical *(102)* to the acetate carbonyl group *(103)* [56]. The arrangement of

(102) (103) (104) (100) (101) (105)

yield 85%

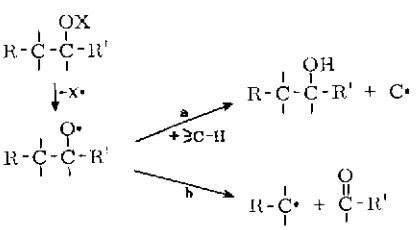


(106) (107)

[56] Similar addition products have been postulated by *J. C. Martin* and *E. H. Drew* [2b] to explain the cleavage of peroxides induced by cyclohexene.

the reactive centers (·O → C–O) in the intermediate *(105)* again favors a homolytic substitution ($S_H2$). Preliminary results with 4β-hydroxy-11β-acetoxysteroids appear to confirm the existence of this intermediate in the hypoiodite reaction (but not in the lead tetraacetate reaction) [52].

Finally, let us turn our attention to the remarkable case of the participation of a C≡N group [57]. The hypoiodite reaction with 20-hydroxy-20-cyanosteroids *(106)* yields 18-cyano-20-ketones *(107)* [6].



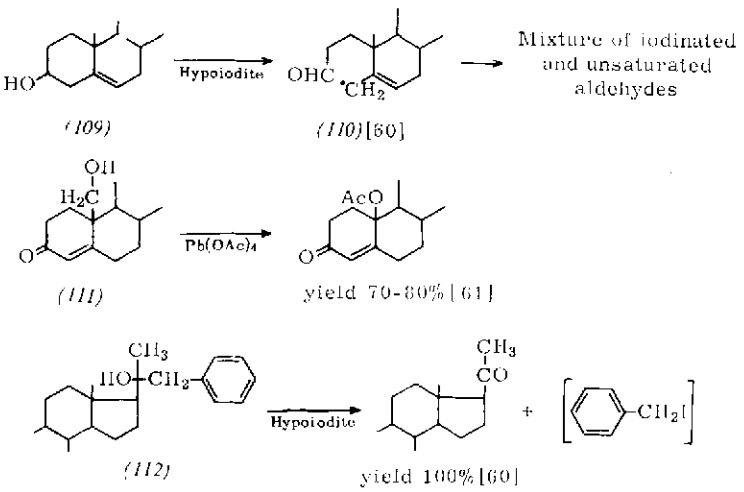
The participation of a neighboring ketal group was observed with an 11β-hydroxy-20-ethylenedioxysteroid *(108)* [20c], but an ionic mechanism cannot be definitely excluded in this case.

(108)

## F. Fragmentation Reactions

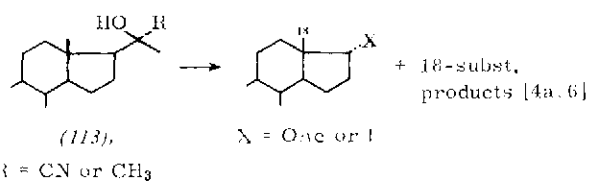
So far, we have discussed only the reactions of oxy-radicals which commence with an (intramolecular) abstraction of hydrogen (a) and have given no attention to the carbonyl-forming fragmentations (b), which are also energetically favored [11].

The rate $k_b$ of the cleavage reaction increases with the stability of the product of cleavage, R–$\dot{C}$– [58, 59]. Besides this, other factors must play a part: the stability of the ketone formed, the decrease in strain by ejection of bulky groups [59], polar structures in the transition



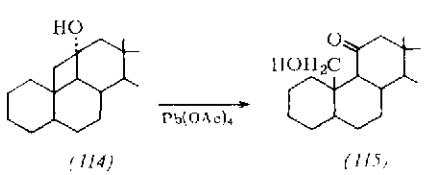
[57] *J. Kalvoda, K. Heusler, Ch. Meystre, G. Anner,* and *A. Wettstein,* IUPAC-Congress, London, July 1963.

[58] *J. K. Kochi,* J. Amer. chem. Soc. *84,* 1193 (1962).



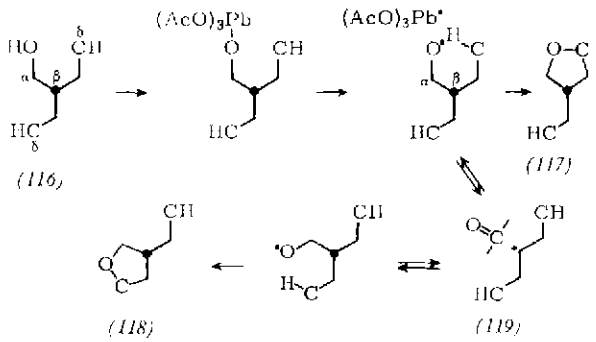
[59] *Ch. Walling* and *A. Padwa,* J. Amer. chem. Soc. *85,* 1593 (1963).

state stabilized by polarizing groups in R, entropy factors in the resonance stabilization of the radical formed by cleavage (*e.g.* R = benzyl), and, in cyclic compounds (particularly with small rings), the decrease in strain as a result of ring opening.

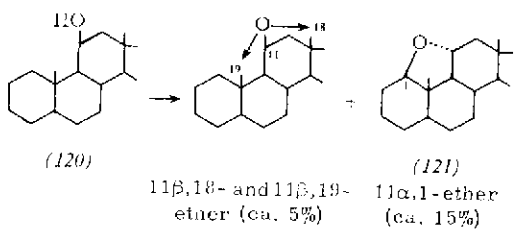


These factors also determine the outcome of the competition between intramolecular hydrogen abstraction and fragmentation. Particularly when the cleavage gives rise to an allyl or benzyl radical or to a radical adjacent to an oxygen function (especially a hydroxy, acyloxy or ketal group), the hydrogen abstraction can be entirely suppressed. This is exemplified by the reactions of *(109)*, *(111)* and *(112)*.

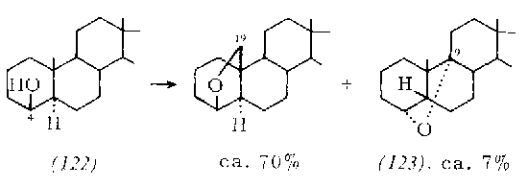
With tertiary 20-hydroxysteroids *(113)*, in contrast to the reaction of secondary 20-hydroxysteroids, the hydrogen abstraction from C-18 is distinctly suppressed in favor of the fragmentation, although the carbon radical formed is not appreciably stabilized. This is true of both the reaction with lead tetraacetate and the hypoiodite reaction.



The influence of ring strain on the ease of fragmentation is shown by the reaction *(114)* → *(115)*, investigated by *Jeger* et al. [61].



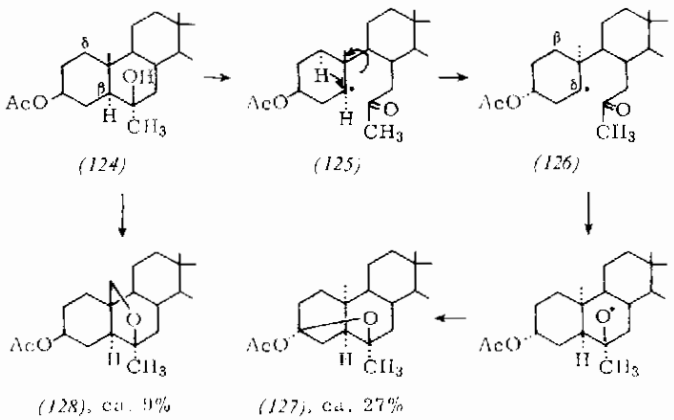
Fragmentation reactions are by no means restricted to tertiary alkoxy-radicals, but have also been observed with secondary alkoxy-radicals, particularly in the photolysis of nitrites [12] and in the oxidation with lead tetraacetate [61].



The peculiar character of the fragmentations in the lead tetraacetate reaction deserves special mention: In the oxidation of various steroid alcohols which exhibit exclusively hydrogen abstraction in the hypoiodite reaction, a novel mode of reaction, namely a *reversible* fragmentation, is observed. This is recognized from the fact that a sterically homogeneous alcohol *(116)* with

two δ-CH groups, and in which all C–C bonds lie in a rigid, polycyclic system and are therefore fixed in their orientation, yields two isomeric ethers *(117)* and *(118)*. These differ from the starting material in the stereochemistry of the α- or of the α- and β-carbon atoms. The isomerization is possible owing to the fact that the centers α and β in the (hypothetical) cleavage product *(119)* are trigonal [62]. An inversion on the α-carbon atom *(121)* takes place with 11β-hydroxysteroids *(120)* [18b, 62a].

The configurations of the α- and β-carbon atoms *(123)* are found to change with 4β-hydroxy-5α-steroids *(122)* [18b].



The example of a 6α-methyl-6β-hydroxysteroid *(124)* [25] shows that the bond between C-α and C-β is completely broken. The recombination in this case does not occur with C-β, but with a new C-radical *(126)*, which is formed by a homolytic hydrogen shift *(125)* from a δ-carbon atom to C-β.

[60] Unpublished work; see also *F. A. Braude* and *O. H. Wheeler*, J. chem. Soc. (London) *1955*, 320 (in particular p. 326).

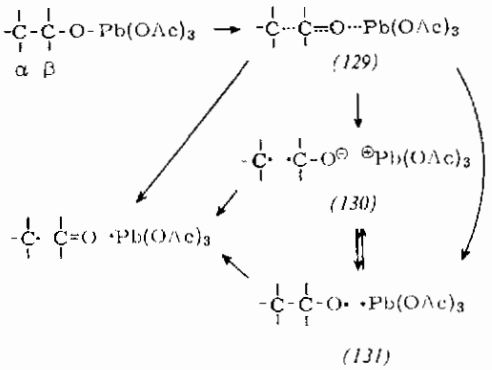
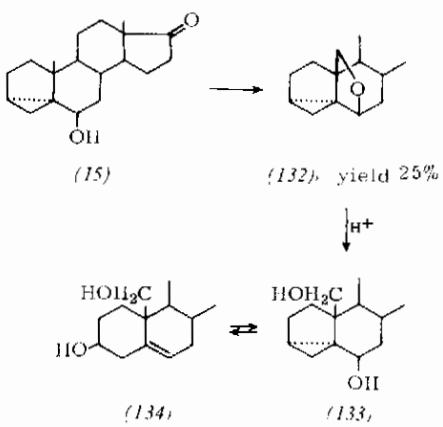
[62a] *G. B. Spero, J. L. Thompson, W. P. Schneider*, and *F. Kagan*, J. org. Chemistry *28*, 2225 (1963).



(124) (125) (126)

(128), ca. 9% (127), ca. 27%

The fact that, in the β,δ-hydrogen shift [63], the hydrogen atom from C-1 is displaced and not that from C-3, which is probably more weakly bound, indicates that the homolytic hydrogen shift in the ring is coupled with etherification of the 6-oxygen to C-3 *(127)* and occurs only when the hydrogen atom at position 3 already lies within bonding distance of the 6β-oxygen atom.



Finally, we shall attempt to explain why the reversible cleavage is principally observed in the oxidation with lead tetraacetate. Hydrogen abstraction (a) and fragmentation (b) are unimolecular processes, and the ratio of the reaction rates $k_a/k_b$ should therefore be independent of the solvent [64]. This has been confirmed by the investigation of the reaction *(124)* → *(128)* in benzene and in cyclohexane [25]. On the other hand, if the hypoiodite and hypochlorite as well as the lead tetraacetate reaction proceed through the same free oxy-radical, the ratio $k_a/k_b$ should also be independent of the method of production of this radical. This is obviously not the case, as is shown by a comparison of the hypoiodite and lead tetraacetate reactions with the starting materials *(124)* and *(122)* [or *(30)*]. The change in the ratio $k_a/k_b$ in the oxidation with lead tetraacetate can be caused by a retardation of the abstraction reaction ($k_a$) or an acceleration of the fragmentation reaction ($k_b$). Considering the strong dependence of the rate $k_a$ on the geometry of the transition state as discussed in Section B, it appears to be possible that the lead tetraacetate reaction gives rise to an intermediate product or transition state *(129)* which differs in the geometry of its basic skeleton from that of the free oxy-radical formed in the photolysis of hypoiodites and nitrites [65]. This could be due to an appreciable contribution from structures, possibly with polar character, in which the α,β-bond is already distinctly stretched.

An intermediate product of type *(130)*, in which the carbonyl group has a ketyl character [66], could also explain the isomerization and recyclization. A structure of type *(131)* would finally lead to hydrogen abstraction and ether formation. The elongation of the α,β-bond could slow down the hydrogen abstraction by increasing the O–C distance (which, even in alcohols with a C O

(129) (130) (131)

distance of 2.5 to 2.7 Å in the ground state, can lead to mixtures of abstraction and fragmentation products). On the other hand, in cases where the O–C distance in the ground state is too large for a hydrogen abstraction, the elongation could cause acceleration of this reaction to the point where it becomes observable, particularly when the fragmentation is energetically unfavorable owing to structural factors. An example of this might be the oxidation of 3,5-cyclo-6β-hydroxysteroids as mentioned in Section B [Formula *(15)*]. Thus, despite the considerable O–C distance of more than 3 Å, the 6β,19-ether *(132)* [23, 67] is formed with lead tetraacetate [68] but only in benzene, and not in cyclohexane, where the intermolecular hydrogen abstraction predominates [69].

(15) (132), yield 25%

(134) (133)

[63] The hydrogen shift can be regarded as a 1,3- or as a 1,5-migration. For homolytic 1,5-shifts, see [8]; however, 1,3-shifts are also known: cf. *O. A. Reutov*, Record of Chemical Progress (Kresge Hooker Sci. Library) *22*, 1 (1961); *O. A. Reutov* and *T. N.* Shatkina, Tetrahedron *18*, 305 (1962).

[64] *Ch. Walling* and *P. Wagner*, J. Amer. chem. Soc. *85*, 2333 (1963).

[65] The occurrence of free NO radicals (and hence also more or less free oxy-radicals) has been definitely established in the photolysis of nitrites [*M. Akhtar* and *M. M. Pechet*, J. Amer. chem. Soc. *86*, 265 (1964)].

[66] Ketyl-containing complexes are also discussed in a different connection by *Ch. Walling* [59] and by *V. Franzen*, Liebigs Ann. Chem. *633*, 1 (1960).

[67] The structure and stereochemistry of *(132)* was established by a synthesis of *(133)* from authentic *(134)*.

[68] Cf. [31]. Since *(15)* is a secondary alcohol and the cyclopropyl radical expected in the fragmentation is not stabilized, the fragmentation must be slower in this case. In the example *(16)* mentioned at the beginning, the fragmentation to the tertiary carbon radical with opening of the strained ring system is energetically favored.

[69] The hydrogen atoms in benzene are about 670 times less reactive towards the attack of alkoxy radicals at 135 °C than those in cyclohexane: *A. L. Williams*, *E. A. Oberright*, and *J. W. Brooks*, J. Amer. chem. Soc. *78*, 1190 (1956). Cyclohexyl ethers are sometimes formed as by-products in oxidations of alcohols with lead tetraacetate in cyclohexane as solvent [14b].

## G. Closing Remarks

The intramolecular substitution reactions of oxy-radicals may be summarized as follows:

In the photolysis of *nitrites* and *hypochlorites* only ligand transfers have been observed as primary processes (formation of 1,5-nitroso alcohols or 1,5-chlorohydrins).

In the *hypoiodite reaction*, the principal process besides the ligand transfer (formation of 1,5-iodohydrins, which can then undergo intramolecular solvolysis, in the same way as the chlorohydrins, to yield tetrahydrofuran derivatives) is the oxidation of carbon radicals to carbonium ions. In contrast to the photolysis of nitrites and hypochlorites, in which only a single intramolecular substitution is possible, the same carbon atom may be doubly substituted in the hypoiodite reaction. The reason for this difference is that the hypoiodites are prepared from alcohols and split homolytically *in situ*, so that both the initially formed (monoiodinated) alcohols and the regenerated starting material can react further. The yields in the hypoiodite reaction are therefore generally higher than those of the analogous photolyses of nitrites or hypochlorites.

The course of the reaction can be influenced by special steric relationships. If the reaction centers are suitably situated, the hypoiodite reaction can lead to a homolytic substitution of iodine on the carbon by an oxy-radical.

The action of *lead tetraacetate* on alcohols leads directly to high yields of tetrahydrofuran derivatives, without the formation of a "free carbonium ion", when all the participating centers are fixed in the arrangement which favors hydrogen abstraction. In the lead tetraacetate oxidation of alcohols in which the hydroxy groups and the attacked C–H bond are not fixed, acetoxylated or unsaturated 5- or 6-membered cyclic ethers can be formed through intermediates with a carbonium character.

Easily cleavable derivatives of homoallyl and homobenzyl alcohols are not suitable as starting materials for intramolecular substitution reactions, since in such cases the carbonyl-forming fragmentation competes successfully with the intramolecular hydrogen abstraction. This side reaction occurs in general when the carbon radical produced is stabilized. In the presence of acylates of tri- and tetravalent lead, the carbonyl-forming fragmentation may be reversible.

The course of the intramolecular free-radical reactions can be changed by the addition of intermediately formed carbon radicals onto neighboring unsaturated systems such as C–C, C=O, or C≡N groups.

## Introduction

Ever since the discovery of the inert gases [1] in the period from 1892 to 1897 [2] by *Ramsay* and *Lord Rayleigh* [3], various workers have attempted to prepare compounds of these elements. No genuine valence compounds were obtained until 1962, although substances which might be termed "compounds" in a wider sense of the word have been known for some time.

For example, the charged particle $He_2^+$ is thermodynamically stable against decomposition into the components $He + He^+$. The energy of dissociation of $He_2^+$ is 108.4 kcal/mole [4], the normal value of the free enthalpy of decomposition thus being strongly positive. Molecules like HHe and $He_2$ are spectroscopically known in activated states. Their electronic ground states, however, are instable, *i.e.* they contain terms of repulsion [6]; this has been confirmed by theoretical considerations [5].

[1] Cf. Gmelins Handbuch der Anorganischen Chemie. 8th Edit. Springer, Heidelberg 1926, System No. 1.

[2] Helium was detected as early as 1868 in the solar spectrum; cf. [1].

[3] Radon was first recognized to be an inert gas by *Soddy* and *Rutherford*; the various emanations were characterized from 1899 onward, cf. [1].

[5] See, for example, *C. A. Coulson:* Valence. Clarendon Press Oxford 1952.

[6] Further data on molecules of this kind are to be found in *Landolt-Börnstein:* Zahlenwerte und Funktionen aus Physik, Chemie, Astronomie, Geophysik und Technik. Springer, Berlin 1951, Vol. I, parts 2 and 3.

"Compounds" in the form of volatile molecules may be formed by a spark discharge in inert gases (almost always He) in the presence of certain metals, *e.g.* Hg [7] but these are detectable only by spectroscopy. Substances such as $WHe_2$ [8] and $Pt_{3.3}He$ [9] have been obtained in the solid state. However, in these cases the helium appears to be merely adsorbed on the highly divided metals. It is significant that the Debye X-ray pattern of $Pt_{3.3}He$ closely resembles that of colloidal platinum [9, 10].

Inert gas clathrates [11] are the substances which most closely resemble conventional chemical compounds. The inert gas hydrates [12, 13], which were first described in 1896, form members of this group; these have the remarkable composition $G_{5.75} \cdot H_2O$ (G = Ar, Kr Xe, or Rn, but not He or Ne!) governed by their crystal structure [14]. In addition, double hydrates $R \cdot 2\,G \cdot 17\,H_2O$ [15], *e.g.* with $R = CH_3COOH$, $CH_2Cl_2$, $CHCl_3$, or $CCl_4$, of argon, krypton, and xenon are known. Mention may also be made of the interesting inclusion compounds of hydroquinone, $G \cdot 3C_6H_4(OH)_2$ (G = Ar, Kr, or Xe), which are usually a little deficient in inert gas, *e.g.* 0.88 Xe [16].

"Compound formation" in all these clathrates is governed only by van der Waals forces, the neutral inert gas atoms lying in the interstices of these cage structures.

## I. Early Experiments

Numerous attempts have been made to prepare genuine inert gas compounds [1], although many were probably never published; of those reported, experiments which might have led to the formation of halides are particularly interesting.

According to *Ruff* [17], fluorine does not react with argon and krypton when subjected to an electrical discharge; *Yost* [18] stated that attempts to obtain chlorides or fluorides of xenon from a mixture of both gases by excitation with ultraviolet irradiation or electric sparks were unsuccessful. Postulates concerning the existence of krypton chloride or bromide [19] could not be confirmed.

The range of interhalogen compounds, examples of which – ICl and $ICl_3$ – were known as early as 1814 [22], has grown markedly since the discovery of $IF_5$ [20] in 1902 and that of $BrF_3$ [21] in 1905/1906. After the preparation in 1931 of $IF_7$ [23], $BrF_5$ [24], and $ClF_3$ [25], it became clear that xenon, radon, and perhaps even krypton might be able to form fluorides.

This explains why the experiments mentioned above were carried out just after 1931. *Yost* [18], despite his lack of success, emphasized that the non-existence of xenon fluorides had by no means been proved.

In addition to these experimental results, the success of the concept of "filled shells" in the electronic configuration of the inert gases [26] contributed considerably to the general assumption that compounds of this kind could not exist.

Attempts were made to calculate the heats of formation of such compounds. By applying the Born-Haber cycle, it was shown [27], that a hypothetical neon(I) chloride $Ne^+Cl^-$ made up of ions and crystallizing in the NaCl lattice would be thermodynamically unstable and would decompose into its elements. However, it is quite clear that this compound, made up of two non-metals, would not be salt-like in structure, and would not be isotypical with NaCl. If compound formation were to occur at all, neon should form a dichloride $NeCl_2$, or perhaps $NeCl_4$, and even more probably $NeF_2$ or $NeF_4$. Finally, the interhalogen compounds mentioned above show that the existence of neon halides is particularly improbable.

The heats of formation of the halides of the heavy inert gases Xe and Rn cannot be calculated with sufficient reliability to allow a prognosis regarding their possible existence, even though the Born-Haber cycle can be used – despite its fundamental drawbacks – to calculate the heats of formation of covalent halides of light elements such as $CCl_4$ or $CF_4$ [28].

## II. The Discovery of the First Inert Gas Fluorides

The first inert gas fluoride, xenon difluoride $XeF_2$, was prepared in Germany in the last week of July, 1962 [29]. The first corresponding experiment in the United States was carried out on August 2nd, 1962 [30], and resulted in the preparation of xenon tetrafluoride

The results on $XeF_2$ were obtained in July but were submitted for publication only on October 8th, 1962, since it seemed necessary to confirm the chemical analysis by a mass-spectroscopic investigation. The American authors published their results on August 20th, 1962.

[30] See *H. H. Claassen, J. G. Malm*, and *H. Selig* in: Noble-Gas Compounds. The University of Chicago Press, Chicago 1963, p. 31.

$XeF_4$ during the following few days [31 31b]. This independent and practically coincident work represents the starting point of modern developments in this field. The excellent and numerous American experiments were initiated by *Bartlett* [32].

In his initial attempts to prepare $PtF_5$, *Bartlett* had obtained a by-product thought to be $PtOF_4$ [33] but subsequently shown to be a new type of complex, $O_2^+[PtF_6]^-$ [34]. Since the ionization potentials of oxygen (12.2 eV) and xenon (12.13 eV) are very similar, a prepartion of $Xe[PtF_6]$ was attempted and met with success [32]. Publication of these results stimulated the work subsequently carried out at National Argonne Laboratories.

Our research group in Münster had already deliberated upon the possibility of formation and the properties of xenon fluorides in 1949/1950 [35], and, from 1951 onwards, we were convinced that $XeF_4$ and $XeF_2$ must be thermodynamically stable to decomposition into their elements.

The enthalpy of formation of $IF_5$ was determined by *Woolf* [36] in 1951. Using his value and the value previously obtained for $TeF_6$ [37], it was possible to calculate the mean thermochemical bond energies of $Te^{VI}$-F and $I^{V}$-F. Extrapolation of these values demonstrated that the bond energy of $Xe^{IV}$-F is probably greater than 20 kcal/val, and hence over half the dissociation energy of the $F_2$ molecule: $XeF_4$ would thus be stable [43].

Projected experimental investigations at Münster University encountered the major difficulty that at first xenon of adequate purity and, up to 1963, cylinders containing compressed fluorine were not obtainable in Germany. Judging from the experiments of *Ruff* and *Yost*, the high-pressure synthesis originally appeared to be the most promising method [35]. Model experiments carried out for the preparation of compounds with extremely anomalous valencies such as $K_2Au^{IV}F_6$ [38, 39], $K_2AgF^{IV}_6$ [39], and $KHg^{III}F_4$ [40, 41] by direct fluorination at a fluorine pressure of 1 atm, can merely be mentioned in passing.

The first krypton fluoride $KrF_4$ was prepared by *von Grosse*, also in 1962; this compound is unstable under normal conditions [42].

## III. The Preparation of Inert Gas Compounds

Several limiting cases can be distinguished. The first group consists of compounds which are thermodynamically stable under normal conditions and do not decompose into their components or into other compounds. Fluorides are the only known compounds of this type. The reaction

Inert gas + fluorine = inert gas fluoride

is therefore so to speak "exothermic" and takes place when sufficient excitation energy is supplied to the mixture of the elements, *e.g.* thermally by electric discharge or by exposure to ultraviolet light or $\gamma$- or $\beta$-rays. Sometimes unstable fluorides (*e.g.* $KrF_4$) are also obtained in this way.

A second group of inert gas compounds can be obtained from these fluorides under more or less mild conditions. This long-established method of preparation leads mostly but not invariably (*e.g.* $XeOF_4$) to compounds which are thermodynamically unstable, and decompose into their components or other substances.

Methods of preparation in which the starting point is the inert gas and a fluorine compound, rather than fluorine itself, naturally deserve special attention. A few examples of such methods have been described.

## IV. Xenon Difluoride $XeF_2$

Xenon difluoride $XeF_2$ was first obtained by subjecting xenon/fluorine mixtures to electric spark discharges ($Xe:F_2$ = 1:1 to 1:3, generally 1:2; $p_{tot.}$ = 700–800 mm, room temperature, cold finger at −78 °C) [43]. $XeF_2$ is also formed as the primary product in the high-pressure synthesis of $XeF_4$ [44], during pumping of an $Xe/F_2$ mixture ($Xe:F_2$ = 1:4) through a zone heated to 400 °C [45], and on irradiating xenon and fluorine with $\gamma$-rays below −35 °C [45a]; above this temperature $XeF_4$ is also formed.

Photosynthesis of $XeF_2$ [46] can be carried out in nickel vessels fitted with sapphire windows; quartz is attacked during the reaction ($\lambda$ = 2500–3500 Å; the maximum of the continuous absorption of gaseous fluorine in the ultraviolet region occurs at 2900 Å).

It must be assumed that the initial reaction is dissociation of the $F_2$ molecule into F atoms [47], which then form XeF as an intermediate according to the equation

$$F + Xe + F_2 = XeF + F_2,$$

or the equation

$$F + Xe + Xe = XeF + Xe.$$

The existence of XeF as an intermediate was confirmed by other authors [47a]. The formation of $XeF_2$ can then be pictured according to the reactions

$$XeF + F = XeF_2$$

and

$$XeF + XeF = XeF_2 + Xe \text{ [47]}.$$

It is of interest to note that $XeF_2$ can be prepared even without the use of elementary fluorine. It is formed together with organic products by the action of electrical discharges on mixtures of xenon and carbon tetrafluoride [48] ($Xe:CF_4 = 1:1$), and also when xenon is heated in the presence of $CF_3OF$ ($CF_3OF:Xe = 2.2:1$; 250 atm, 500 °C) and $SO_3F_2$ ($SO_3F_2:Xe = 2.2:1$; 150 atm, 450 °C) [49].

Xenon difluoride is a colorless substance which forms magnificently lustrous crystals [29] of characteristic odor [43]. It forms tetragonal crystals with a = 4.315 Å and c = 6.990 Å, with two linear F–Xe–F structural units (Xe–F = 2.00 Å) per unit cell [50–53].

Neutron diffraction data [52] and X-ray structural analysis [51] indicate the space group $D_{4h}^{17}$–I4/mmm with 2Xe in 2(a), 4F in 4(e) and $z_F = 0.2837$ [neutron diffraction] or, less reliably, 0.306 [X-ray analysis]. The given parameter indicates a Xe–F distance of 1.98$_3$ Å [or 2.14 Å, a value not taken into consideration in this paper]. As a result of precession of the rigid $XeF_2$ dumb-bell molecules about [001] (7°) or vibrations normal to the molecular axis, the actual Xe–F distance is probably 2.00 ± 0.01 Å. This distance is in accordance with the distance I–Cl in the isoelectronic $ICl_2^-$ group (I–Cl = 2.36 Å), taking into consideration the differences between Cl and F, *etc.*, although according to *Smith* [45], the bonding relationships in $XeF_2$ are appreciably different from those in the structural unit $ICl_2^-$. The infrared spectrum of $XeF_2$ [52a] exhibits no Q branch due to the asymmetric stretched vibrational band, showing that the $XeF_2$ molecule is also linear.

The unexpectedly high melting point of xenon difluoride (140 °C) [54] is noteworthy, as are its low vapor pressure (3.8 mm at 25 °C) [54] and its large heat of sublimation ($\Delta H_{subl}$ = 12.3 kcal/mole [55]).

According to calculations performed by *Jortner* [56], only about 2 kcal/mole of the heat of sublimation can be ascribed to dispersion forces. Approximately 11 kcal/mole are thus due to electrostatic interchange effects between adjacent molecules. The linear $XeF_2$ units are considered by *Jortner* to have an appreciable polarity, and the effective charge of the F atoms [57] may be as much as −0.5 to 0.7 units, in agreement with spectroscopic findings [45].

$XeF_2$ is diamagnetic [43]. $\chi_{mol} = -50\times10^{-6}$, the expected value, but, in contrast to $XeF_4$, its susceptibility is not significantly dependent on the temperature [43]. The nuclear magnetic resonance of the F atoms in $XeF_2$ has also been measured (cf. page 545).

Xenon difluoride is decomposed by water. At 0 °C a yellow solution is first formed at the surface, but the color disappears when the ice melts, and complete evolution of xenon occurs at slightly higher temperatures [55a]. At lower temperatures, the xenon is not always completely liberated [43]. Decomposition also takes place with alcohol or with water containing ammonia or hydrazinium hydroxide. A violent reaction accompanied by ignition occurs with methanol [43].

$XeF_2$ is remarkably soluble in anhydrous hydrogen fluoride (*e.g.* 7.82 moles of $XeF_2$ in 1000 g of HF at 12.25 °C). The conductivity of such solutions is not higher than that of pure HF, so that apparently no dissociation or any other reaction takes place [55b].

The heat of formation estimated from spectroscopic data is $\Delta H_{250}^{\circ}(XeF_2, gas) = -19.4$ kcal/mole [69]; $XeF_2$ is thus thermodynamically stable. It may be stored without decomposition in glass or quartz vessels, provided moisture is excluded.

Double fluorides with $SbF_5$ and $TaF_5$ are discussed on p. 543.

## V. Xenon Tetrafluoride

Colorless crystals of xenon tetrafluoride $XeF_4$ were first prepared by heating a mixture of the approximate composition $Xe + 5\ F_2$ under pressure in a nickel vessel [31, 31a].

The compound is also formed when a mixture of xenon and fluorine is passed through a red-hot nickel tube [58], as well as by the action of electric discharges on similar mixtures of the gases at −78 °C [59].

$XeF_4$ is thermodynamically stable, (cf. p. 544) and can be stored in glass vessels at room temperature; samples kept at −25 °C exhibit no decomposition or reaction with the glass after long periods [58]. Its specific heat has been measured as a function of temperature: $C_p$ = 28.334 cal/deg/mole at 298 °K. The molecular lattice (5 atoms, 6 degrees of freedom) leads to an expected value of 30 cal/deg/mole [60a]. Its melting point of 114 °C [61] is astoundingly high, while its low vapor pressure (3 mm at 25 °C) [61] and large heat of sublimation ($\Delta H_{subl}$ = 15.3 kcal/mole [55]) are due, as for $XeF_2$, to an appreciable polarity of the Xe–F bond, possibly $Xe^{+2.0}(F^{-0.5})_4$. $XeF_4$ crystallizes in the monoclinic system [50, 51, 62–66] in the space group $C_{2h}^5$-$P2_1n$.

With regard to the structural parameters of $XeF_4$, the reader is referred to the original literature cited. Two molecules are contained in the unit cell. The structure contains well-defined, planar, practically square $XeF_4$ units with an Xe–F distance

of $1.96_5 \pm 0.02_2$ Å: this bond is thus slightly shorter than that in $XeF_2$. The gaseous molecule also has the square structure [67].

$XeF_4$ is diamagnetic, and below 0 °C its susceptibility varies with temperature in agreement with measurements of the nuclear magnetic resonance of the fluorine [68].

$XeF_4$ is hydrolysed in water, $XeO_3$ or the corresponding oxoxenates being obtained by disproportionation (cf. p. 543) [55c].

$XeF_4$ dissolves in anhydrous HF to the extent of 0.18 moles per 1000 g at 20 °C, and 0.73 moles at 60 °C. As with $XeF_2$, the conductivity of the HF remains unaltered, and no indication of any other reactions between the solvent and the solute has been obtained [55b].

$XeF_4$ reacts with $SF_4$ to form $SF_6$, with complete reduction to Xe, and $XeF_6$ is formed with $O_2F_2$ [60]. It is noteworthy that $XeF_4$ reacts neither with $BF_3$ nor with NaF or KF up to 200 °C [68a, 81].

## VI. Higher Fluorides and Oxide Fluorides of Xenon

Xenon hexafluoride $XeF_6$ occurs under equilibrium conditions in the $Xe/F_2$ system at 250 °C and represents the highest stable fluoride of xenon [69]; it was prepared as such by heating mixtures of $Xe/F_2$ (Xe:Fe = 1:4 to 1:20; $p_{tot}$ = 25–250 atm, T = 250–500 °C and higher) [70–73], and also by the action of electric discharges [60] on such mixtures (Xe:Fe = 1:3) at −78 °C. It is also formed when $XeF_4$ reacts with $O_2F_2$ [60].

$XeF_6$ forms colorless crystals at room temperature, and melts at 46 °C to form a pale yellow liquid, b.p. 87 °C. The gas is yellow-green.

The vapor pressure of solid $XeF_6$ is given to be 6–7 mm at 0 °C [60, 70, 71] and 30 mm at 25 °C [70]. Its heat of sublimation is about 9.1 kcal/mole [60, 61]. The strongest, unusually broad absorption band of $XeF_6$ in the infrared spectrum occurs at 610 $cm^{-1}$; a second, weaker band of normal width appears at 520 $cm^{-1}$ [75].

$XeF_6$ is a stable compound: $\Delta H^{\circ}_{298}$ ($XeF_6$, gas) = −79 kcal/mole [74]. At room temperature, it hardly attacks glass and quartz, but in the molten state reacts rapidly with both, with initial formation of $XeOF_4$, and finally of an explosive solid, presumably $XeO_3$ [76].

The solubility of the compound in anhydrous hydrogen fluoride is high (3.16 moles of $XeF_6$/1000 g of HF at 15.8 °C, and 19.4 at 30.2 °C). Its solutions exhibit appreciable molar conductivity [0.024 moles of $XeF_6$/l: 147 mho/cm²] and, like liquid $XeF_6$, are pale yellow, becoming colorless on cooling. Nuclear magnetic resonance studies also indicate marked changes in the character of $XeF_6$ on dissolution, *e.g.* in the sense of a dissociation [55b].

The Yugoslavian research group has also reported that $XeF_8$ is formed in traces as a by-product in the high-pressure synthesis of $XeF_6$ (Xe:$F_2$ = 1:16) at 620 °C and 200 atm as a yellow compound which remains undecomposed only at very low temperatures (77 °K). Details have not yet been given [77, 78].

Three oxide fluorides are known, *viz.* $XeOF_4$, $XeO_2F_2$, and $XeOF_2$.

$XeOF_4$ is the initial product of the reaction of $XeF_6$ (at 50 °C) with quartz vessels, and is also formed during the hydrolysis of $XeF_6$ with the calculated quantity of water [76]. It is a colorless liquid which sets at −28 °C [76, 79]; its vapor pressure (8 mm at 0 °C and 29 mm at 23 °C) is approximately equal to that of $XeF_6$ [76].

The strongest infrared absorption band of $XeOF_4$ occurs at 608 $cm^{-1}$ and thus overlaps that of $XeF_6$. On the other hand, $XeOF_4$ shows practically no absorption at 520 $cm^{-1}$ [75].

$XeO_2F_2$ is formed as a further intermediate during the hydrolysis of $XeF_6$ to $XeO_3$ [80].

A colorless compound, m.p. 90 °C, b.p. ca. 115 °C, which according to *Peacock* is formed from Xe and $F_2$ in the presence of $O_2$ or air is regarded as $XeOF_2$ [81]. Oxide fluorides are also formed during the reaction of Xe with $O_2F_2$ at 300–400 °C as stable, colorless products of overall composition $Xe_{1.2}O_{1.1}F_{3.0}$ or under the influence of electric discharge ($XeOF_2$) [60].

In conclusion, it may be mentioned that the existence of $XeF_5$ is suspected [69] (this would be extremely surprising) and that an X-ray structural analysis carried out on the so-called "dense" modification of $XeF_4$ suggests that this is actually an adduct $XeF_2 \cdot XeF_4$ and not $XeF_4$ [82–84]. Since no confirmatory analytical data are available, the validity of this interpretation remains an open question.

## VII. Fluorine Compounds of Krypton

The first krypton fluoride prepared was krypton tetrafluoride $KrF_4$, which was obtained in the form of colorless, transparent crystals from the elements under the influence of an electric discharge at 84–86 °K and 7–12 mm total pressure [42, 60].

This substance decomposes into its elements at room temperature but can be sublimed at −40 to −30 °C, or even at 0 °C if the process is carried out rapidly. Its sublimation point was determined by extrapolation to be about 70 °C; its heat of sublimation is 8.8 kcal/mole [60].

Mixtures of Kr and $F_2$ do not react when excited by exposure to ultraviolet light, by heating to 400–500 °C (nickel vessels), or on irradiation with a beam of electrons at −130 °C [46, 60, 45a].

Recently, krypton difluoride $KrF_2$, whose formation in minute amounts had previously been deduced from spectroscopic observations [85,86], was prepared from a mixture of Kr and $F_2$ at −150 °C in a beam of electrons, being obtained in the form of a colorless substance which sublimed unchanged at lower temperatures (p ≈ 2 mm at −40 °C) but which decomposes into its elements at room temperature [87].

A colorless substance which is obtained in small quantities from $Kr/F_2$ mixtures under the influence of an electric discharge at −130 °C decomposes rapidly at room temperature but can be maintained unchanged at 77 °K, and is presumably also $KrF_2$ [43, 88].

No well-defined fluorides of other inert gases have so far been prepared, although the formation of radon fluorides has been claimed [31a, 89].

## VIII. Fluorine Compounds of Higher Order

The first inert gas compound in the narrower sense of the word, $Xe[PtF_6]$, was obtained by *Bartlett* in the summer of 1962 [32]. This compound is formed on reaction of gaseous $PtF_6$ and Xe as an orange solid insoluble in carbon tetrachloride. Its vapor pressure is negligible at room temperature but it is possible to sublime the substance *in vacuo*. It decomposes with water:

$$XePtF_6 + 3\,H_2O = Xe + {}^1/_2\,O_2 + PtO_2 + 6\,HF$$

This compound is analogous to the $O_2^+[PtF_6]^-$ previously prepared [34]. Further investigations of this class of compounds by *Bartlett* et al. have so far resulted in no clarification of their structures, but rather introduced new complications [90]:

Xe and $PtF_6$ interact at room temperature to form red products whose composition lies between the limiting forms $Xe[PtF_6]$ and $Xe[PtF_6]_2$. Xenon tetrafluoride is evolved when the platinum-rich products, *e.g.* $Xe[PtF_6]_{1.8}$, are heated. The brick-red diamagnetic (!) residue left after thermal decomposition has the composition $XePt_2F_{10}$. Analogous deep-red substances are obtained with rhodium and have compositions close to $XeRhF_6$. Krypton forms no compounds with either $PtF_6$ or $RhF_6$.

According to *Peacock*, xenon tetrafluoride is reduced by tantalum pentafluoride, and also by antimony pentafluoride, with formation of addition compounds of $XeF_2$ [81]. The straw-yellow adduct $XeF_2 \cdot 2\,SbF_5$ melts at 63 °C and can be sublimed unchanged *in vacuo*.

## IX. Oxygen Compounds of Xenon

No oxides of xenon have so far been obtained from the elements. However, oxides or their derivatives are formed when xenon fluorides reacts with water or alkaline or acid solutions.

a) Xenon difluoride is decomposed by water [55c] or aqueous solutions above 0 °C, giving oxygen and elementary xenon. An intermediate yellow coloration is observed at the surface at 0 °C. Derivatives of "hypoxenic acid" $Xe(OH)_2$ have not yet been prepared.

(b) Xenon tetrafluoride reacts with water with initial formation of a brilliant canary-yellow color at the surface of the colorless $XeF_4$ crystals [55c].

The yellow solid formed in this way is of unknown composition and decomposes rapidly between −5 and +5 °C in NaOH solution, but somewhat more slowly in pure water or 9 M $H_2SO_4$, and after 20 minutes in 3 M $H_2SO_4$. Bubbles of gas are generated during the decomposition; the supernatant liquid remains colorless.

The overall reaction proceeds according to the equation:

$$6\,XeF_4 + 12\,H_2O = 4\,Xe + 3\,O_2 + 2\,XeO_3 + 24\,HF$$

The form in which $XeO_3$ is present in the solution has not yet been elucidated. Compounds such as $Xe(OH)_6$ [91], $H_4XeO_6$ [55c], and $H_2XeO_4$ [92] have been proposed.

According to a different source [55a], formation of the yellow substance during the hydrolysis of $XeF_4$ with NaOH is not transient, but a pale-yellow solution is formed which retains its color for several days.

No matter what the composition of the yellow substance may be, evaporation of the solution yields colorless xenon trioxide $XeO_3$ [93–96]. This strongly endothermic compound ($\Delta H^\circ_{298}$ ($XeO_3$, solid) = +96 kcal/mole) [97] detonates readily.

The crystal structure of $XeO_3$ has been elucidated by X-ray studies on single crystals [98]. $XeO_3$ crystallizes in the rhombic system, with a = 6.163 Å, b = 8.115 Å, and c = 5.234 Å, in the space group $D_2^4$–$P2_12_12$, with 4 molecules per unit cell. Its structure is closely related to that of $HIO_3$ [99–101]. The structural group $XeO_3$ is present in the crystal as a closed "shallow" pyramidal group; the Xe–O distances are 1.74 to 1.77 Å, and the O–Xe–O angles lie between 100 and 108°; the corresponding values for $HIO_3$ are 1.78–1.90 Å and 94 to 100°. With regard to the individual parameters of the occupied point sites, reference should be made to the original literature [98].

Oxoxenates(VI) of the alkali metals have been described, but their compositions have not yet been established [102]. Barium xenate $Ba_3XeO_6$ was recently prepared as a white precipitate, which is sparingly soluble in water; its thermal decomposition into BaO, Xe, and $O_2$ commences at 125 °C and is complete at 250 °C [102].

The thermal stabilities of alkali metal xenates are said to be higher [102]. Xe(VI) solutions oxidize acidified bromide and iodide solutions to $Br_2$ and $I_2$, respectively [103].

(c) Xenon hexafluoride forms perxenates in alkaline solutions by disproportionation. These perxenates have the general formula $M^I_{2n}XeO_{4+n}$ and, in general, contain water of crystallization [92, 55a]. Analytical data for the substances obtained from NaOH indicate compositions lying between the limiting formulae $Na_4XeO_6 \cdot 2\,H_2O$ and $Na_6XeO_7 \cdot H_2O$ [55a]. The existence of heavy metal perxenates has also been claimed [104]. Xe(VIII) solutions, which slowly decompose into Xe(VI) solutions and oxygen, have been studied in somewhat greater detail [105]. Recently, $Na_4XeO_6 \cdot 8H_2O$ was isolated and its structure determined: the perxenate anion $[XeO_6]^{4-}$ is an almost regular octahedron. The Xe–O distance of 1.875 Å is longer by 0.12 Å than that in $XeO_3$. Correspondingly, the I–O bond length of 1.93 Å in the $[IO_5]^{5-}$ anion is greater by 0.11 Å than that in the $IO_3^-$ anion (1.81 Å). The $[XeO_6]^{4-}$ anion is isoelectronic with the long familiar $IO_6^{5-}$ ion; it is likely that all the 5s and 5p as well as the 5d orbitals participate in the bonds in both ions [105a].

Recently, barium kryptate, apparently $BaKrO_4$, was prepared from $KrF_4$, as a colorless compound with no tendency to decompose up to 0 °C [106].

## X. Thermochemistry and Bonding Relationships

According to the investigations carried out so far, the following compounds are formed exothermically:

Xenon difluoride $XeF_2$. The enthalpy of formation was determined from spectroscopic measurements and estimated to be $\Delta H^\circ_{298}(XeF_2, \text{solid}) = -20$ kcal/mole [69].

Xenon tetrafluoride $XeF_4$. Two calorimetric determinations have so far been reported. In one, the reaction

$$XeF_4 + 4\,I^- = 2\,I_2 + Xe + 4\,F^-$$

was utilized, although a small portion of the $XeF_4$ reacts [107] according to

$$XeF_4 + 2\,H_2O = Xe + O_2 + 4\,HF.$$

In the other, gaseous $XeF_4$ was reduced with $H_2$ to Xe and gaseous HF [74]. $\Delta H^\circ_{298}$ ($XeF_4$, solid) was found to be −60 kcal/mole [107], whence it follows that $\Delta H^\circ_{298}$ ($XeF_4$, gas) = −48 kcal/mole, with $\Delta H_{subl}$ ($XeF_4$) = 12 kcal/mole; in the other estimation $\Delta H^\circ_{298}$ ($XeF_4$, gas) = −55 kcal/mole [74]. The entropy at 298.16 °K is 35.0 ± 1.0 e.u. Consequently, the free enthalpy of formation $\Delta F^\circ$ = −29.4 kcal/mole, with $\Delta H^\circ_{298}$ ($XeF_4$, solid) = −60 kcal/mole.

Xenon hexafluoride $XeF_6$. Reduction of gaseous $XeF_6$ with $H_2$ to Xe and gaseous HF was also utilized here. A calorimetric value of $\Delta H^\circ_{298}$ ($XeF_6$, gas) = −79 kcal/mole was found [74].

These thermochemical values for the xenon fluorides were as expected [43]. The values listed in Table 1 were obtained by calculating the mean thermochemical bond energy E(Xe–F) from the enthalpies of formation, and comparing it with the corresponding values for halogen fluorides [108, 109].

Table 1. Mean thermochemical bond energies for halogen fluorides, halogen chlorides, and inert gas fluorides.

| Halogen fluorides | | | | | Halogen chlorides | | | Inert gas fluorides | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | I | III | V | VII | | I | III | | II | IV | VI |
| F | 36.7 | | | | | | | | | | |
| Cl | 60.7 | 40.9 | | | Cl | 58.0 | | Ar | | | |
| Br | 63.4 | 49.6 | 48.4 | | Br | 55.9 | | Kr | ≈16 | ≈16 | |
| I | 73.9 | (69) | 63.9 | 55.1 | I | 57.9 | (40?) | Xe | ≈30 (46?) | 30–≈32 | 31.5 |

The results listed in this table lead to the following conclusions.

1. Thermochemically, $XeF_4$ and $XeF_6$ closely resemble the corresponding bromine compounds $BrF_3$ and $BrF_5$ (diagonal relationship), insofar as their respective bond energies are roughly equal: the bond energies of the bromine compounds are about 16 kcal/mole higher than those of the xenon compounds.

2. The bond energy of $XeF_2$ is probably greater than the value derived from the enthalpy of formation estimated from spectroscopic data. A value of 40–45 kcal/mole is to be expected.

If a parallel is now drawn analogously between $KrF_2$ and ClF and between $KrF_4$ and $ClF_3$, then it can be estimated tentatively that the bond energies in both $KrF_2$ and $KrF_4$ are about 16 kcal/mole. However, at least 18.3 kcal per F atom [= 1/2 $D_0(F_2)$] are required to obtain an "exothermal" compound, so that these compounds lie at the border of thermodynamic instability, as is actually observed in practice.

Comparison of the bond energies of ICl and $ICl_3$ with those of IF and $IF_3$ on the one hand and those of $XeF_2$ and $XeF_4$

[108] The values used were taken from *E. H. Wiebenga* et al., Advances inorg. Chem. Radiochem. *3*, 133 (1961).

[109] National Bureau of Standards Circular No. 50.

on the other hand shows that all xenon chlorides are probably unstable; $XeCl_2$ is the one most likely to be capable of "preparation", analogously to $KrF_2$ and $KrF_4$, but it has not so far been obtained.

Finally, the enthalpy of formation of solid xenon trioxide $XeO_3$ was determined as $\Delta H^{\circ}_{298}$ ($XeO_3$, solid) = 96 + 2 kcal/mole [97]. This value fits conveniently into the series $Sb_2O_3$, $TeO_2$, $I_2O_5$ when the values for the latter are converted for their formation from gaseous atoms.

The nature of the bonds in inert gas compounds has been the subject of much discussion. Let us recall that $Te^0$, $I^I$, $Xe^{II}$, and $Te^{II}$, $I^{III}$, $Xe^{IV}$ represent an isoelectronic series. The bonds in the xenon fluorides (*e.g.* in $XeF_2$) are almost certainly neither purely covalent (*i.e.* F–Xe–F) nor purely ionic (*i.e.* $F^-Xe^{2+}F^-$). If an ionic structure (*e.g.* $I^{3+}Cl_3^-$) is taken for a start and the true nature of the bonds is then approached by superimposing covalent bonds, it becomes clear that since the discovery of compounds such as ICl, $ICl_3$, $IF_5$, and $IF_7$, no fundamental objections could be raised against the existence of inert gas compounds (as had been previously because of the "filled" electron configurations of the inert gases).

Despite numerous theoretical calculations [75, 110–121], spectroscopic investigations, and measurements either of the nuclear magnetic resonance of the fluorine atoms or of the Mössbauer effect, no quantitative description of the character of the bonds in, for example, the xenon fluorides has yet been made. On the basis of theoretical calculations, it can be taken as certain that [owing to the unusually high heats of sublimation of $XeF_2$, $XeF_4$, and $XeF_6$, as well as from the extent of the chemical shift in their F–NMR spectra, which lies between the limiting values for $F_2$ (purely covalent bond) and $F^-$ in HF (practically pure ionic bond)] the effective charge per fluorine atom in $XeF_2$ and $XeF_4$ is about −0.5. The effective charge on the xenon atom is therefore about +1 in $XeF_2$ or +2 in $XeF_4$. It becomes clear that $XeF_2$ cannot therefore be strictly compared with the $ICl_2^-$ ion, although the latter is also linear, because the bond character of $ICl_2^-$ can be described quite well by resonance between the two limiting forms Cl–I $Cl^-$ and $Cl^-$ I–Cl.

It is also certain that there are no pure σ-bonds, although a certain π-bond character is present. In addition an increasing number of authors postulate that the 5d-orbitals of xenon also participate in the bond.

It should be remembered that detailed interpretation of chemical shifts in nuclear magnetic resonance measurements is difficult, and that uncertainties always remain in any interpretations.

## XI. Conclusions

From our present knowledge, several reasons can be proposed to explain the failures of earlier attempts to prepare inert gas compounds, and why it was widely assumed that compounds of this type could not exist:

a) Firstly, before 1950 experimental difficulties were encountered.

Above all, fluorine-resistant "greases" (for example Hostaflon of appropriate softening point) became available only after 1950. All earlier authors experienced appreciable difficulties in this respect.

b) In addition, successful application of the concept of the special stability of completed electron shells (*e.g.* in carbonyls and complex compounds of the transition metals, particularly for the interpretation of their magnetic behavior caused the fact to be overlooked that the well-known and long-established interhalogen compounds were necessarily close neighbors of possible valence compounds of the inert gases.

c) Finally, the view was widely held that any possible inert gas compounds would be thermodynamically unstable and would tend to decompose into their elements so that they could only be prepared and handled with particular experimental skill.

The following-up of a chance observation by *Bartlett* led in a remarkable fashion to the preparation of $XePtF_6$ and stimulated the high-pressure synthesis of $XeF_4$, whereas the determination of the heat of formation of $IF_5$ led our research team in Münster to the assurance that $XeF_4$ and $XeF_2$ must be exothermal compounds and initiated, although with some delay, experiments resulting in the preparation of $XeF_2$. Starting from different observations independently and at the same time, a new field of inorganic chemistry was opened up which in reality presents no particular experimental difficulties. Inert gas compounds readily fit the periodic system (with the inert gases considered as Group 8 elements). Severe limitations are placed upon the range of thermodinamically stable compounds only by the fact that no other nonmetal has such a low dissociation energy and at the same time such a high mean thermochemical bond energy as fluorine.

The formation of $XeO_3$, of salts of corresponding acids, and of double fluorides, shows that although there are probably not very numerous stable binary compounds of the inert gases, a number of additional derivatives may become accessible by using sufficiently mild conditions, *e.g.* by working in solution. Preparation of helium, neon, and even argon compounds is nevertheless unlikely.

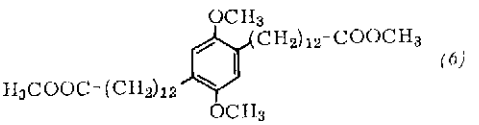
# The Preparation of Catena Compounds by Directed Synthesis [1]

BY DR. G. SCHILL AND PROF. DR. A. LÜTTRINGHAUS

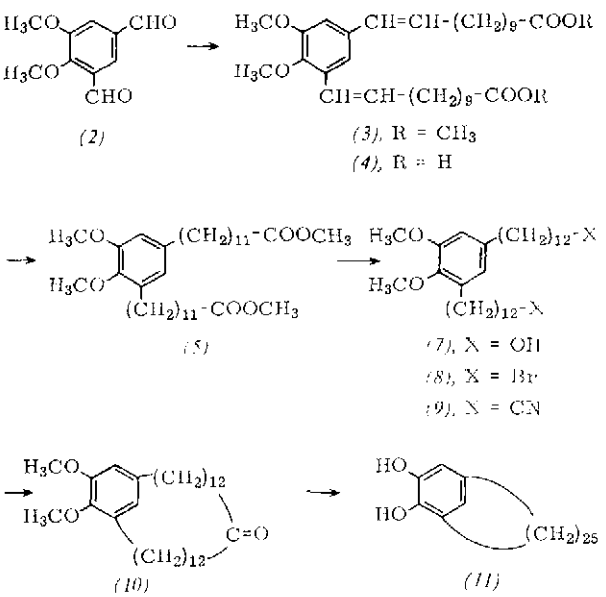
CHEMISCHES LABORATORIUM DER UNIVERSITÄT FREIBURG/BREISGAU (GERMANY)

Six years ago [2] we discussed some of the principles involved in the synthesis of catena compounds, a new class of substances consisting of rings, which are not chemically combined but which are held together like the links of a chain *(1)*, and began some experimental work on such systems [2, 3].



*(1)*

As the reactions we envisaged were of statistical character, only very poor yields were to be expected. Our experimental results [3] were even more disappointing than expected although they gave valuable information about the behavior and morphology of long-chain and macrocyclic compounds in solution.



On the other hand, *Wasserman* [4] claimed to have obtained yields of approximately 1 % (relative to the entire mixture isolated) using one of these methods. Later on he modified this statement to a claim [5] of having obtained by chromatography yields that were several powers of ten less than those previously reported, namely a few milligrams of an oil which was thought to be a catenane. The new principle of the directed synthesis which we have now applied proved successful. By steric control it avoids the extra-annular ring closures which always occur predominantly in statistical cyclization methods.

4,5-Dimethoxyisophthalaldehyde *(2)* [6] was converted into the dicarboxylic ester *(3)* by Wittig reaction with an excess of 10-methoxycarbonyldecylidenetriphenylphosphorane [7]. Hydrolysis gave the crystalline dicarboxylic acid *(4)* (m.p. 67–71 °C, after sintering) in 52–58 % yield based on *(2)*. Catalytic hydrogenation and esterification of *(4)* gave *(5)*. Surprisingly, this ester could not be cyclized by the acyloin ring closure method of *Hansley*, *Prelog*, and *Stoll*, but remained unchanged, whereas the dicarboxylic ester *(6)* of a hydroquinone ether was cyclized readily.

*(6)*

The diester *(5)* was therefore reduced to the diol *(7)* with $LiAlH_4$, and *(7)* was converted into the dinitrile *(9)* via the dibromide *(8)*. The cyclic β-imino nitrile obtained from *(9)* by ring closure according to the method of *Ziegler* was hydrolysed and remethylated to give the ketone *(10)*, m.p. 45–47 °C. Reduction of *(10)* using the method of *Huang-Minlon* [8] and subsequent demethylation afforded 3,5-pentacosamethylenecatechol *(11)*, m.p. 100–102 °C.

*(2)*; *(3)*, R = $CH_3$; *(4)*, R = H; *(5)*; *(7)*, X = OH; *(8)*, X = Br; *(9)*, X = CN; *(10)*; *(11)*

Ketal formation from the *ansa*-catechol derivative *(11)* with 1,25-dichloropentacosan-13-one *(12)* according to the method of *Salmi* [9] yielded the 1,3-benzo[*d*]dioxole derivative *(13)*, m.p. 48–50 °C.

We obtained the ketone *(12)* from 13-chlorotridecanoyl chloride by ketene dimerisation [10] with triethylamine. $Cl-(CH_2)_{12}-COCl \rightarrow Cl-(CH_2)_{12}-CO-(CH_2)_{12}-Cl$ *(12)*

Nitration of *(13)* with copper nitrate in acetic anhydride [11] afforded the nitro compound *(14)*, which on catalytic hydrogenation gave the amine *(15)*, m.p. 56–57.5 °C. Cyclization of *(15)* with potassium carbonate in amyl alcohol by the method of *Lüttringhaus* and *Simon* [12] in

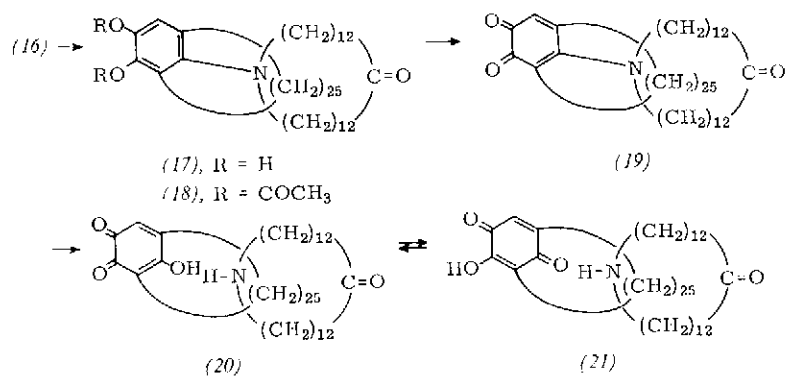
the presence of alkali iodide gave a 29.7 % yield [based on *(14)*] of crystalline 2,2,*N*,*N*-bisdodecamethylene-4,6-pentacosamethylene-5-amino-1,3-benzo[*d*]dioxole *(16)*, m.p. 121–125 °C, which is linked intra-annularly and in which the chains of the double ansa-system are situated on opposite sides of the benzene ring.



*(13)*, R = H
*(14)*, R = $NO_2$
*(15)*, R = $NH_2$

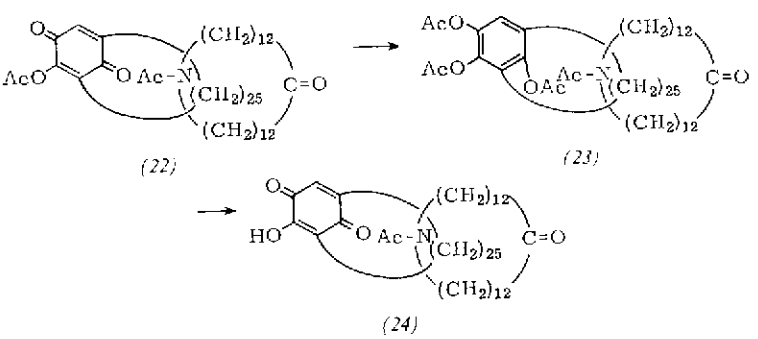
*(16)*

Formation of the isomer of *(16)* with extra-annular attachment of the rings (both chains of the double ansa-system on the same side of the benzene ring) can be excluded. In *(13)*, the chain derived from *(12)* which becomes attached to the benzene ring is fixed at right angles to the plane of the ring on account of the tetrahedral structure of the aliphatic carbon. The side reaction which would lead to an isomer of *(16)* is suppressed for this reason and on account of the chain-length of 12 methylene groups.

Cleavage of the ketal linkage in *(16)* with HBr in acetic acid gave the intra-annularly linked catechol derivative *(17)* which was characterized as its crystalline diacetate *(18)*, m.p. 104–106 °C. Dehydrogenation of *(17)* with ferric sulfate gave the amino-*o*-quinone *(19)*. Hydrolysis of *(19)* with acid afforded the desired catena compound *(20)*, which rearranged to the tautomer *(21)*. The reactions leading from *(16)* to *(21)* are nearly quantitative.

*(17)*, R = H
*(18)*, R = $COCH_3$

*(19)*

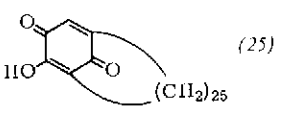


*(20)*

*(21)*

Acetylation of *(21)* with acetic anhydride/sodium acetate gave the *O*,*N*-diacetate *(22)*, which was characterized by analysis and its infrared spectrum, which showed the carbonyl band of the *O*-acetyl group at 1779 $cm^{-1}$, that of the keto group at 1717 $cm^{-1}$, and the coinciding carbonyl bands of the quinone and of the *N*-acetyl group at approximately 1650 $cm^{-1}$.

Reductive acetylation of *(22)* gave the tetraacetate *(23)* which was also identified by analysis and infrared spectroscopy. It showed the band of the *O*-acetyl group at 1786 $cm^{-1}$, that of the keto group at 1715 $cm^{-1}$, and that of the *N*-acetyl group at 1650 $cm^{-1}$. Molecular-weight determination by isothermal distillation [13] gave the figures 960 and 995, which are in good agreement with the value of 1022.5, calculated for the combined weight of the two chemically unconnected parts of the molecule.



Alkaline hydrolysis of the tetraacetate *(23)* followed by dehydrogenation yielded the *catena*-hydroxy-*p*-quinone *(24)*, which in alcoholic solution gave alkali salts with the mauve color characteristic of 2-hydroxy-3,5-dialkylbenzoquinones [14]. C, H, and N determinations of *(24)* gave the expected values; its infrared spectrum showed the expected carbonyl bands. The ultraviolet spectrum of *(24)* had maxima ($\lambda_{max}$ = 266 mμ, log ε = 3.97; 406 mμ, log ε = 2.87 in alcohol) similar to those of the "simple" hydroxyquinone *(25)*,

*(22)*

*(23)*

*(24)*

*(25)*

m.p. 64–67 °C ($\lambda_{max}$ = 269 mμ, log ε = 4.02; 413 mμ, log ε = 2.90 in alcohol).

The catena compound *(24)* was homogeneous on paper chromatograms, except for a very small amount of impurity which remained at the start. The hydroxyquinone *(25)*, which would have been formed from the isomer of *(16)* with extra-annular linking of the rings during the reaction sequence quoted, could not be detected.

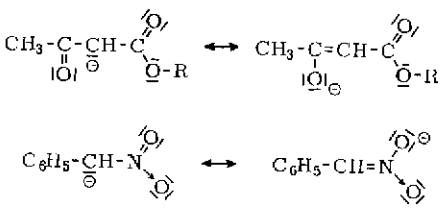
# The Modes of Reaction of Ambident Cations

BY PROF. DR. S. HÜNIG



CHEMISCHES INSTITUT DER UNIVERSITÄT WÜRZBURG (GERMANY)

*Dedicated in gratitude and admiration to Prof. Hans Meerwein on the occasion of his 85th birthday*

*The effect of the nature of the coreactants and the reaction conditions on the ability of certain mesomeric cations to react with nucleophilic reagents to form isomeric products has been studied. The structures of the products isolated are determined by competition between a kinetically controlled but reversible reaction and a thermodynamically controlled reaction.*

## 1. Comparison of Ambident Anions and Cations

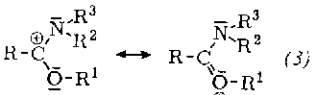
The mesomeric anions derived from β-dicarbonyl compounds and nitroalkanes, *e.g. (1)* and *(2)*, can react with electrophiles at either the oxygen or the carbon atom.

*(1)*

*(2)*

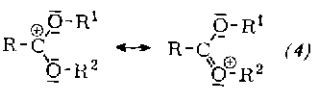
This ambident character [1] is of great significance from both the preparative [2] and theoretical [3] points of view. Systematic investigations carried out over the past few years have revealed that the relative proportions of products resulting from the two possible reaction paths depend on numerous, frequently still unclarified factors. One of the principal difficulties encountered in their elucidation is that the electrophilic partner of these anions becomes available as a free cation only in the case of the solvated proton, with which the anion simply undergoes association. All other reagents (*e.g.* methyl iodide) must react by substitution. Consequently, the result of the reaction is governed in a complicated manner by both the ambident anion and the electrophilic reagent. In addition, the cation associated with the anion frequently exerts a decisive effect [4], which is also dependent upon the solvent used.

The reaction between ambident cations and nucleophilic reagents might be expected to proceed in a more straightforward manner. In the following, such cations will comprise mainly types *(3)* and *(4)*, derived from amides and esters of carboxylic acids.



[1] *N. Kornblum* et al., J. Amer. chem. Soc. *77*, 6269 (1955).

[2] Cf., for example, *H. Henecka:* Chemie der β-Dicarbonylverbindungen. Springer, Berlin 1950.



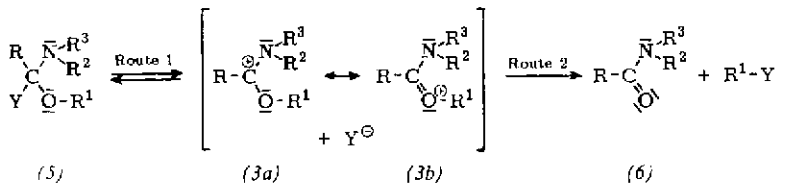
[3] Cf., for example, *J. Hine:* Physical Organic Chemistry. McGraw-Hill, New York 1962, pp. 233–244.

[4] *N. Kornblum* and *P. Pink*, Tetrahedron Letters *1963*, Suppl. I, 17; *H. E. Zaugg* et al., J. org. Chemistry *26*, 644 (1961); β-Diketones: *H. Stetter*, Angew. Chem. *67*, 769 (1955).

Even when they are strongly electrophilic, these cations can be conveniently isolated if the anions are stable complexes (*e.g.* $BF_4^{\ominus}$, $SbCl_6^{\ominus}$, or $ClO_4^{\ominus}$) and if the solvent is only slightly nucleophilic (*e.g.* $CH_2Cl_2$). This principle was developed and used with great success by *Meerwein* [5], and has been employed for the preparation of most of the complex cations described here.

*(3)*

*(4)*



Numerous anions may be used as the attacking nucleophile (*e.g.* $Cl^{\ominus}$, $C_2H_5O^{\ominus}$), but uncharged bases can also be used (*e.g.* $C_2H_5OH$, $HNR_2$). These entities can attack *(3)* or *(4)* at two points (see below). The reaction invariably begins with an addition to the lone pair of electrons on the nucleophile. The influence of the nucleophile on the formation of products with ambident cations should therefore be more straightforward than that of an electrophile with ambident anions. Since the effect due to the complex anion can be neglected, it should be possible to recognize the factors which essentially govern the result of the reaction.

## 2. General Reaction Scheme

The ambident cation *(3)* is used as an illustration, since the reactions with *(4)* proceed in an analogous manner. The nucleophile $Y^{\ominus}$ rapidly adds on at the position of lowest electron density, *i.e.* at the carbon atom in *(3)*, to form *(5)* (Route 1). If the energy released on formation of the new bond is large, *(5)* can be considered as a kinetically controlled product. On the other hand, if an equilibrium *(5)* ⇌ *(3)* is set up, then $Y^{\ominus}$ effects slow dealkylation of *(3)* (Route 2) to form the thermodynamically stable compound *(6)* and $R^1$–Y [6].

[5] *H. Meerwein* et al., Angew. Chem. *67*, 374 (1955).

[6] Cf., for example, analogous considerations by *S. Winstein* and *E. M. Kosower*, J. Amer. chem. Soc. *81*, 4399 (1959); *J. Miller*, J. Amer. chem. Soc. *85*, 1628 (1963).

(5) (3a) (3b) (6)

The relative importance of reaction routes 1 and 2 is essentially dependent on
the nature of the nucleophilic reagent,
the stability of the ambident cation,
the temperature and duration of the reaction, and
the solvent.

These factors influence the energy profile of the overall reaction (Fig. 1) [6]:

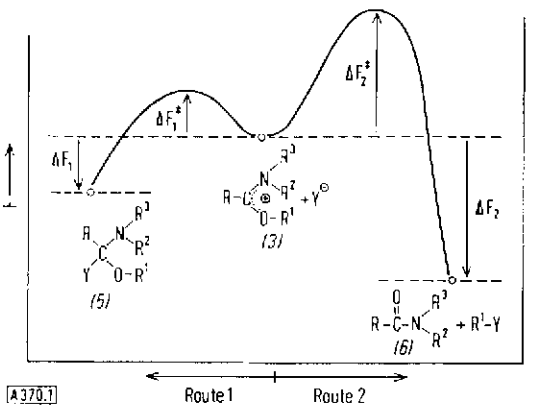


Fig. 1. General energy profile of the system (5) ⇄ (3) → (6); schematic.

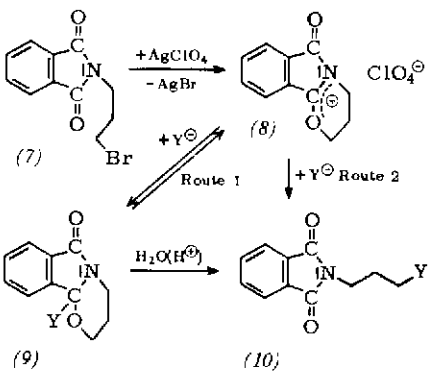
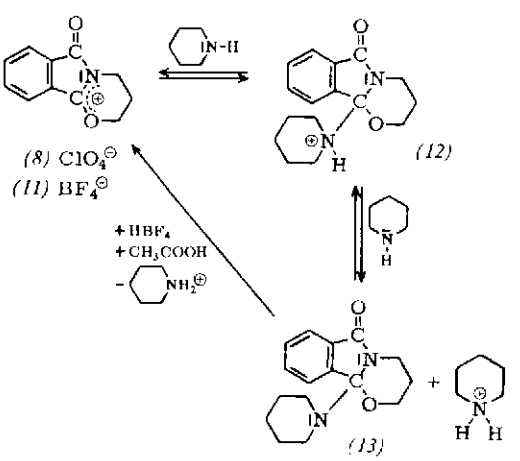
a) The primary ratio of the reaction products from (3) is mainly determined by the ratio of the free activation energies $\Delta F_1^{+}$ and $\Delta F_2^{+}$ associated with Routes 1 and 2. Since only Route 1 corresponds to a simple association of ions, $\Delta F_1^{+}$ is always less than $\Delta F_2^{+}$. Moreover, it may be assumed that $\Delta F_1^{+}$ is small, and variations in the ratio $\Delta F_1^{+}/\Delta F_2^{+}$ due to changes in the reaction conditions and the nature of the nucleophile can, to a first approximation, be ignored, except for steric factors.



b) The position of the equilibrium between (3) and (5) in Route 1 depends on the difference in energy $\Delta F_1$ between (3) and (5), *i.e.* on their relative positions in the energy diagram.

c) Since the transformation (3) → (6) results in release of the mesomeric energy of the amide as well as the energy of charge neutralization, (6) must be the thermodynamically stable product, *i.e.* $\Delta F_2 > \Delta F_1$. Both $\Delta F_2$ and $\Delta F_2^{+}$ may assumed to be so large that the reaction (3) → (6) can be regarded as irreversible. The energy profile shown in Figure 1 is repeated in subsequent illustrations in order to show the changes more clearly.

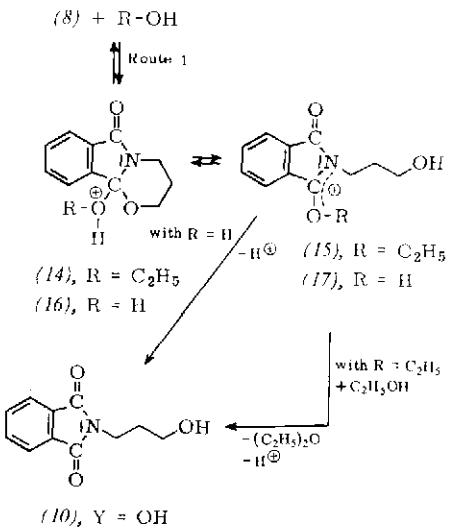
## 3. The Influence of the Nucleophile on the Course of the Reaction



So far, investigations into the above factors have involved exclusively the nature of the nucleophilic reagent.

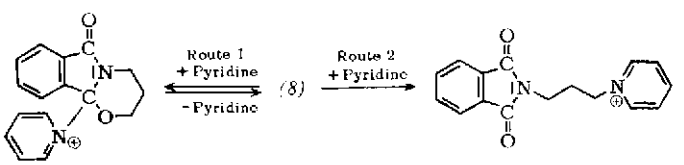
A compound particularly suitable for study is the strong electrophile *N,O*-trimethylenephthalimidium perchlorate (8), which is formed smoothly from (7) and silver perchlorate [7].

| | Route 1 | Route 2 |
|---|---|---|
| $Y = O_2N{-}CH_2^{\ominus}$ | Piperidine | Pyridine |
| $CN^{\ominus}$ | $C_2H_5OH$ | $I^{\ominus}$ |
| $C_2H_5O^{\ominus}$ | $H_2O$ | $C_6H_5SO_2^{\ominus}$ |



This energy-rich tricyclic compound (8) reacts with nucleophiles to form (9) or (10) according to whether Route 1 or Route 2 is followed. The differences in the infrared and ultraviolet spectra of the two products permit unambiguous assignment of their structures [7]. Whereas the phthalimide derivative (10) represents the stable end-product, the adducts (9) are readily hydrolysed to form γ-hydroxypropylphthalimide (10), Y = OH. The reactions of (8) with piperidine, ethanol, and water occupy a special position, since here the adduct (9) can be formed only by release of a proton. The synthesis of (13) therefore requires the use of excess piperidine. Water rapidly transforms (13) into γ-hydroxypropylphthalimide (10), Y = OH. Undoubtedly, the first step of the reaction entails protonation of the base (13) to

[7] *L. Geldern*, Ph. D. Thesis, Universität Marburg, 1962; *S. Hünig* and *L. Geldern*, J. prakt. Chem., in the press.



give *(12)*, which is in equilibrium with the ambident cation *(8)*. The rapid hydrolysis of the latter to form γ-hydroxypropylphthalimide has already been mentioned. Exclusion of a nucleophilic solvent should prevent this last step. The fluoroborate *(11)* of the ambident cation can in fact be obtained from *(13)* and excess fluoroboric acid in glacial acetic acid, *i.e.* the reaction sequence *(8)* → *(12)* → *(13)* can be completely reversed.

The reaction of the cation *(8)* with alcohol also leads to γ-hydroxypropylphthalimide *(10)*, Y = OH, when water is carefully excluded; diethyl ether is formed at the same time. This result excludes Route 2. Instead, Route 1 must result in the formation of adduct *(14)*, which undergoes prototropy to form *(15)*, an open-chain,

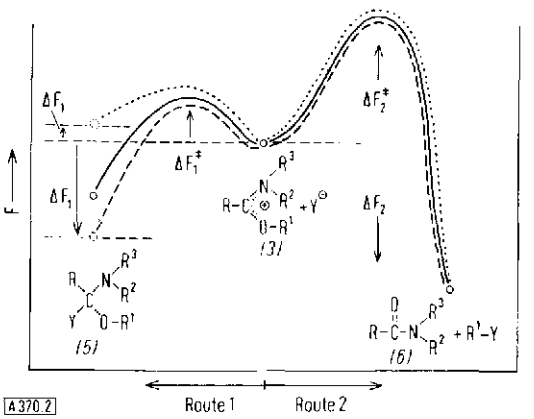
ambident phthalimidium cation. This substance is then dealkylated by excess ethanol to form *(10)* and diethyl ether, by analogy with Route 2. Water probably reacts in the same way with the ambident cation *(8)* by Route 1 [*(8)* → *(16)* → *(17)* → *(10)*]. Although this problem can be resolved only by the use of $H_2{}^{18}O$, findings with related cations support this course of reaction [*(21)* → *(20)*; *(71)* → *(76)*].

No similar stabilization of the adduct formed by Route 1 occurs during the reaction of *(8)* with pyridine. Here, the adduct *(18)*, which has not been isolated, is still positively charged. The small gain in bonding energy rapidly drives the reaction forward with formation, via *(8)*, of the more stable phthalimide derivative *(19)*.

In the case of the iodide ion, which is a good leaving group [8], it is doubtful whether the reaction with *(8)* results in formation of a covalent bond in the sense of *(9)* at all. When the components are mixed in acetonitrile, an intense red color develops, similar to that of

[8] *J. Mathieu, A. Allais*, and *J. Valls*, Angew. Chem. *72*, 71 (1960).

quaternary, aromatic-heterocyclic iodides [9]. Thus, at least an internal ion pair associated with a charge-transfer band [10] is initially formed. Since the solution is almost instantaneously decolorized again, only the γ-iodopropylphthalimide *(10)*, Y = I, formed by Route 2, can be isolated.



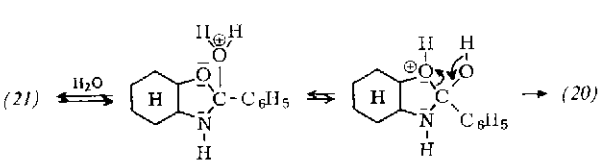


Fig. 2. The influence of the nucleophile on the position of *(5)* in the energy profile (schematic).
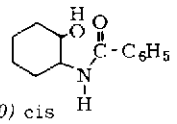
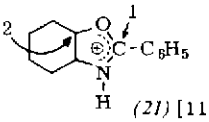
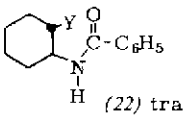
..... Y = *e.g.* $I^{\ominus}$
----- Y = *e.g.* $CN^{\ominus}$
——— General curve (cf. Fig. 1).

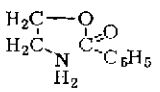
These examples show that the effect of the nucleophile on the course of the reaction depends predominantly on the position of *(5)* in the energy diagram, *i.e.* on the magnitude of $\Delta F_1$ (Fig. 2). Since the small free activation energy $\Delta F_1{}^{+}$ changes only slightly with the nature of the nucleophile, the product formed by Route 1 can be isolated only for low energy levels of *(5)*, *i.e.* for large values of $\Delta F_1$. Naturally, the nucleophile also produces changes in $\Delta F_2{}^{+}$ and $\Delta F_2$, but to a first approximation this effect can be neglected.

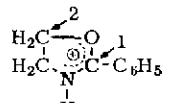
The same reasoning may explain the similar behavior of nucleophilic reagents towards a large number of ambident cations. Table 1 contains characteristic examples; only ambident cations which have been isolated are listed. The arrows show the possible points of attack for reactions by Routes 1 and 2, while the outer columns contain the products isolated.

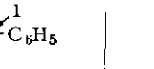


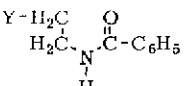


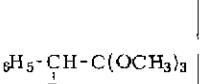


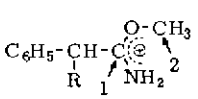


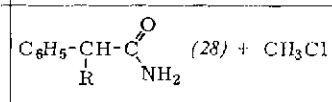


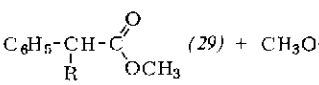


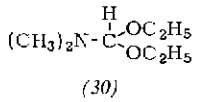


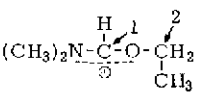


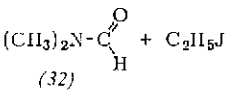


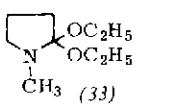


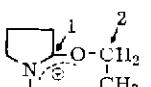


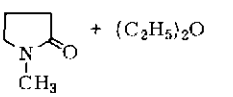


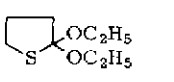


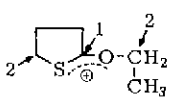


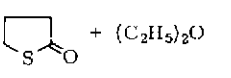


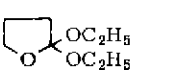


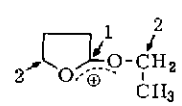


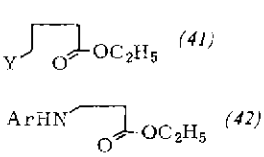


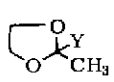


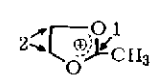


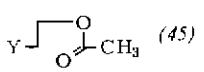


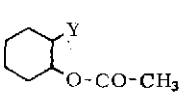


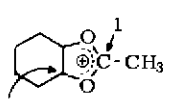


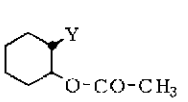


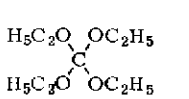


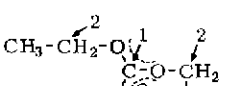












Examination of Table 1 reveals that here again the kinetically controlled products of Route 1 can be isolated only where strongly nucleophilic reagents such as $C_2H_5O^{\ominus}$ and $CN^{\ominus}$ are used. The only exception is that of $H_2O$ in *(21)*. Here the stereochemistry of the product *(20)* shows that the cleavage of the ring is introduced by the conversion of the kinetic adduct *(51)* into *(52)* by prototropy [11].

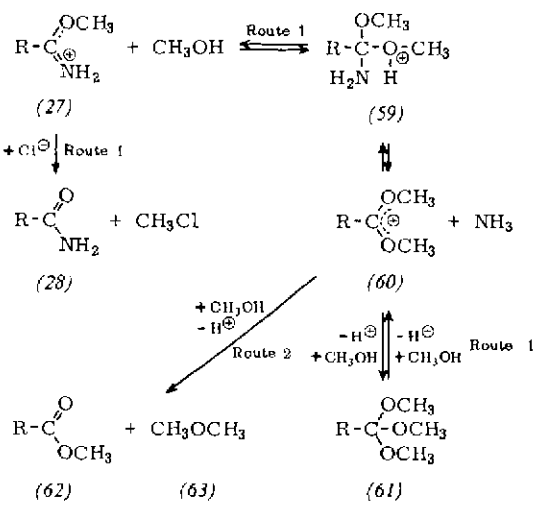
Results obtained with *N*-alkyloxazolinium salts have shown that the hydrolysis of oxazolines to esters of aminoethanol [*(24)* → *(23)*] can be interpreted as proceeding by Route 1 [20]. Thus it is doubtful whether the hydrolytic cleavage of the ion *(44)* to form *(45)* [18] proceeds by Route 2.

The ambident character of the oxazolinium ions was observed by *Gabriel* and *Heymann* [12] as long ago as 1890. An explanation for this repeatedly confirmed behavior [21] was first given by *Fry* [13] in 1950 when he postulated a reversible nucleophilic attack at C-2 and an irreversible attack at C-5, but made no comment on the nature of the nucleophilic reagent. The opening of the 2-phenyloxazoline ring by acid chlorides was explained in the same way, the intermediate ion, *e.g. (53)*, which resembles the phthalimidium ion *(8)*, reacting by Route 2, *e.g.* to form *(54)* [14]. The attack of thiocarboxylic acids [22] [*(24)* → *(25)*] can be used in the synthesis of optically active cysteine starting from optically active 5-carboxy-2-phenyloxazoline [23]. Since

*(55)* *(58)* *(56)* *(57)*

factory yields are often obtained during the preparation of orthoesters [14] from imino ether hydrochlorides and alcohols by the method of *Pinner* [25]. This reaction is



*(53)* *(54)*

thiophenols also open the oxazoline ring at the bond between O-1 and C-5 [24a], β-acylaminothioaryl ethers, *e.g. (58)*, can be obtained from carboxylic acids, β-amino alcohols, and thiophenols in a single-stage synthesis [24b].

The amide *(55)* initially formed undergoes ring closure to form the basic oxazoline *(56)* which then reacts as a cation with the thiophenoxide ion to form the thioether *(57)*. The steps A + B twice repeated finally lead to the product *(58)*.

Oxazolines may be regarded as cyclic imino ethers; accordingly the cations of imino ethers also exhibit ambident characteristics and it is not surprising that unsatisfactory yields are often obtained during the preparation of orthoesters [14] from imino ether hydrochlorides and alcohols by the method of *Pinner* [25]. This reaction is always accompanied by the well-known Pinner cleavage [26], which proceeds by Route 2 to form an amide and an alkyl chloride [*(27)* → *(28)*]. The primary adduct *(59)* formed by Route 1 is stabilized in the form of the ambident carboxonium ion *(60)*.

*(27)* *(59)* *(28)* *(60)* *(62)* *(63)* *(61)*

In the presence of ammonia as a base, it is possible to isolate the orthoester *(61)* as the kinetically controlled product from the reaction with alcohol. However, the ammonium ion formed catalyses the attainment of the equilibrium *(61)* ⇌ *(60)* so strongly that the concurrent reaction to form the thermodynamically stable products, *viz.* the carboxylic ester *(62)* and the ether *(63)*, cannot be prevented. This hypothesis is based on

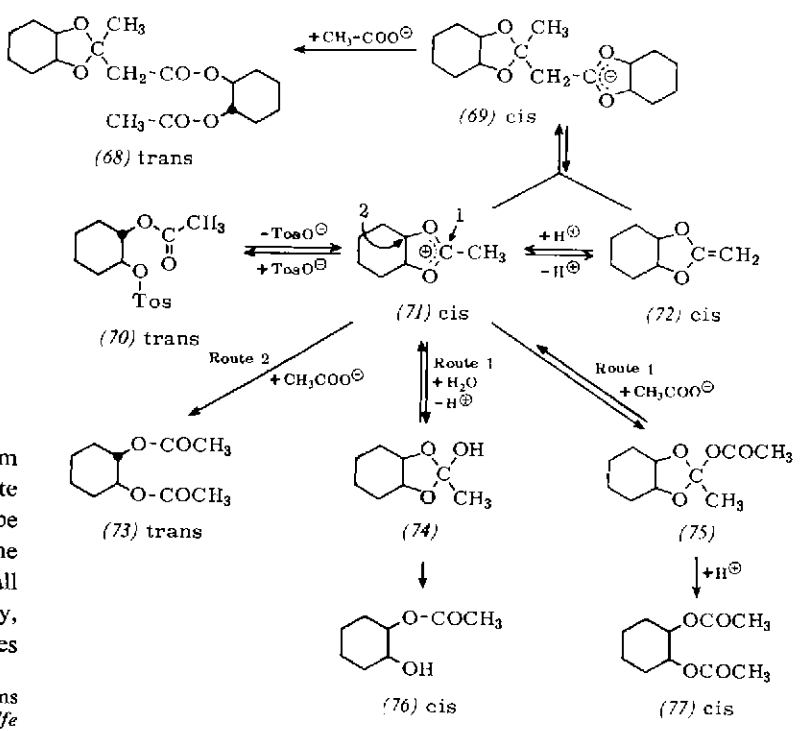
[26] See [25], p. 700, and [14]. – This reaction is suitable for the direct preparation of labile alkyl chlorides from imide chlorides and alcohols; *H. Eilingsfeld*, *M. Seefelder*, and *H. Weidinger*, Angew. Chem. *72*, 836 (1960); Chem. Ber. *96*, 2671 (1963).



the argument advanced by *McElvain* [28] and was confirmed by investigations carried out by *Meerwein* (see below).

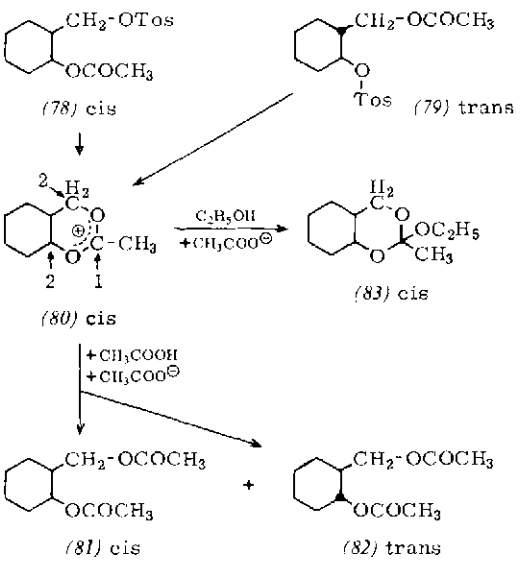
Apart from the hydrolysis products *(20)* and *(23)*, so far only thermodynamically controlled products, *e.g.* *(22)*, *(25)*, *(28)*, *(29)*, *(54)*, and *(58)*, have been isolated from reactions involving ambident cations, *e.g.* *(21)*, *(24)*, and *(27)*. Synthesis of peralkylated imino ether cations, *e.g.* *(31)* and *(34)*, finally enabled *Meerwein* et al. [17, 18] to isolate highly reactive amide acetals *(30)* and lactam acetals *(33)* as the kinetically controlled products obtained by Route 1 from the reaction with alkoxide [29]. As expected, the analogous thiocarboxonium salts [16–18], *e.g.* *(37)* or *(40)*, *(44)*, *(47)*, *(50)*,

are converted into orthoesters. While with the lactam acetals the reversible character of the reaction by Route 1 is apparent from the low conductivity [16], it can be detected with the orthoesters *(39)* and *(43)* by the irreversible rearrangement induced by acid or small quantities of boron trifluoride [16, 18]. Undoubtedly, the cations *(40)* and *(44)* are formed as intermediates en route to the alkoxycarboxylates *(41)* and *(45)*. This is confirmed by the rapid interchange of the alkoxy groups; for example, the difficultly soluble fluoroborate of the cation *(64)* can be isolated with isopropanol, being then "dealkylated" by Route 2 to form *(65)*, *(66)*, and *(67)*. The assumption of a reversible and an irreversible mode of reaction with nucleophiles, which has particularly been emphasized by *Meerwein* [16], simultaneously explains the long-known decomposition of orthoesters into esters and ethers [27] [cf. *(61)* → *(62)* and *(63)*]. The cations *(34)*, *(37)*, and *(40)* show the effect of the hetero-atom. Only in the last case is the five-membered ring opened with ethanol, but even here, as with *(64)*, a side-reaction involving substitution of the side-chain, *i.e.* the formation of butyrolactone and diethyl ether, must be assumed.

The isolation of carboxonium ions of this type supports the views of *Winstein* and *Boschan* [11], who postulated the existence of the intermediate ion *(71)* from the stereochemistry of the solvolysis of *(70)* in acetic acid/water with formation of *(73)* and *(76)*. The kinetically controlled adduct *(75)* expected in acetic acid cannot be isolated in the reaction between the ketene acetal *(72)* and glacial acetic acid [30]. Nevertheless, it must be present in equilibrium, since in the presence of a strong acid it is possible to isolate the *cis*-diacetate *(77)*, the formation of which can be attributed to an acid-catalysed rearrangement of *(75)* [11]. The cation *(71)*, recently isolated as the fluoroborate by the same group of workers [19], does in fact exhibit the expected properties. Furthermore, it was found that *(71)* reacts with acetate ions in glacial acetic acid to form about 50 % of the dimer *(68)*.

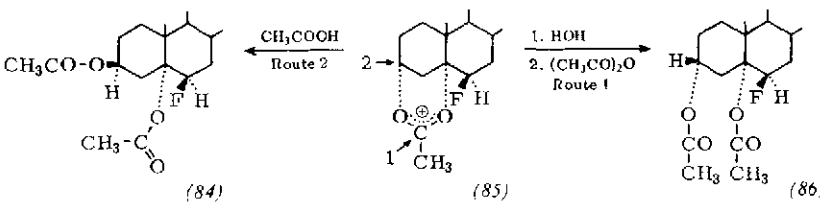
Evidently, *(71)* has been partly deprotonated to form the ketene acetal *(72)*, which then undergoes nucleophilic addition onto excess *(71)* to form *(69)*. Finally, *(68)* is formed from *(69)* and acetate.

Similarly, the ambident cation *(80)* must be assumed to be an intermediate in the solvolysis of the isomeric *p*-toluene-



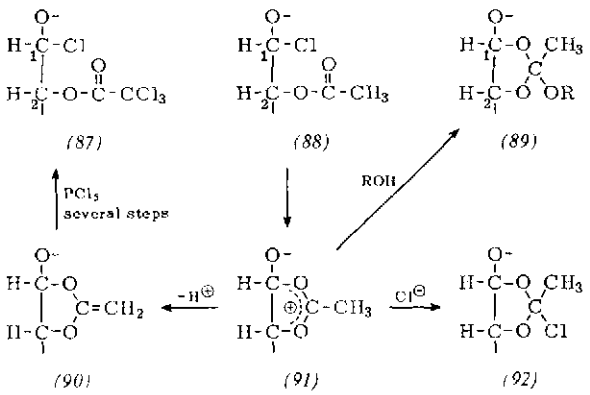
[27] The fast, acid-catalysed hydrolysis of orthoesters also gains from the formation of the carboxonium ion. Cf. *R. H. DeWolfe* and *J. L. Jensen*, J. Amer. chem. Soc. *85*, 3264 (1963). – According to *J. Hine*, J. Amer. chem. Soc. *85*, 3239 (1963), the behavior of acetals and orthoesters is determined by an increase in the heat of formation through double-bond no-bond resonance.

[28] *S. M. McElvain* and *C. L. Stevens*, J. Amer. chem. Soc. *69*, 2663 (1947).

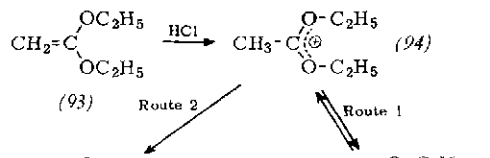


[29] *N,N*-Dialkylamide acetals from imide chlorides: Cf. *H. Eilingsfeld*, *M. Seefelder*, and *H. Weidinger*, Angew. Chem. *72*, 836 (1960); Chem. Ber. *96*, 2671 (1963); *Z. Arnold*, Collect. czechoslov. chem. Commun. *26*, 723 (1961); *H. H. Bossard*, *E. Jenny*, and *H. Zollinger*, Helv. chim. Acta *44*, 1204 (1961).

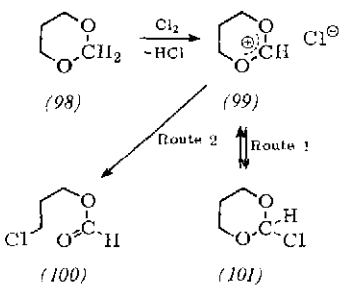
[30] This presumably explains the basic properties of orthoesters in the presence of acetic anhydride, which were observed by *F. Kröhnke* and *W. Weiß*, Liebigs Ann. Chem. *669*, 52 (1963).



sulfonates *(78)* and *(79)* [31]. Ethanolysis in the presence of sodium acetate therefore stops at the labile orthoester stage (Route 1). In glacial acetic acid/sodium acetate, on the other hand, a mixture of the stable diacetates *(81)* and *(82)*, formed by Route 2, is isolated.



Carboxonium ions and products therefrom can be expected to be formed during the acylation of 1,2- and 1,3-glycols. Thus, the ambident cation *(85)* was recently isolated in the cholestane series. This reacts with acetic acid to form the 3β,5α-di-*O*-acetate *(84)*, while hydrolysis and subsequent esterification produce the isomeric 3α,5α-diacetoxy derivative *(8b)* [32].



The results of this mode of reaction have been known much longer in the chemistry of carbohydrates [33]. Here, extra isomers were observed during the normal synthesis of glycosides from peracetylated α-halogeno sugars *(88)*, silver carbonate and an alcohol; as early as 1930, these were recognized by *Freudenberg* [34] as orthoesters *(89)*. This author even succeeded in isolating the extremely reactive isomeric hepta-*O*-acetyl-α-maltosyl chloride containing the grouping *(92)*. It is not known why the orthoester chloride can be isolated in this particular case [35]. *Freudenberg* considered the possibility of intermediate formation of ketene acetals *(90)*, which could serve as the preliminary stage in the formation of 3,4,6-tri-*O*-acetyl-2-*O*-trichloroacetyl-β-D-glucosyl chloride from penta-*O*-acetylglucose and phosphorus pentachloride [36], for it is otherwise difficult to explain.

Since halide ion is a better leaving group than acetate, reactions in which α-halogeno-α,α-dialkoxy compounds, *e.g. (97)*, *(101)*, *(105)*, should normally lead to the thermodynamically stable products via the intermediate carboxonium ion *(94)*, *(99)*, *(103)*. This is true of the addition of HCl onto ketene acetals, *e.g. (93)* → *(95)* + *(96)* [37], and also for the halogenation of acetals, *e.g. (98)* → *(100)* [38]. The suggested course

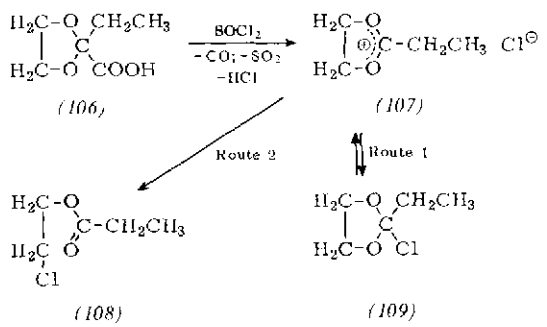
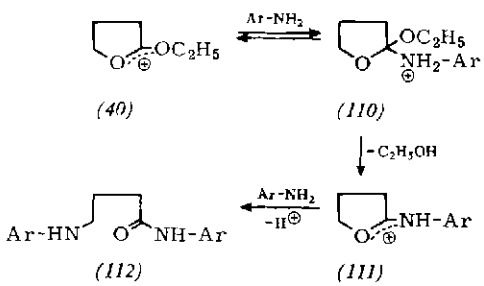
[37] *S. M. McElvain* and *D. Kundiger*, J. Amer. chem. Soc. *64*, 254 (1942); *S. M. McElvain* and *M. J. Curry*, ibid. *70*, 3781 (1948); for the assumption of carboxonium ions, see [41].



[38] *L. A. Cort* and *R. G. Pearson*, J. chem. Soc. (London, *1960*, 1682, where intermediate *(99)* is mentioned. Cf. the analogous result obtained by *H. Baganz* and *L. Domaschke*, Chem. Ber. *91*, 653 (1958), in the chlorination of 1,3-dioxolane.

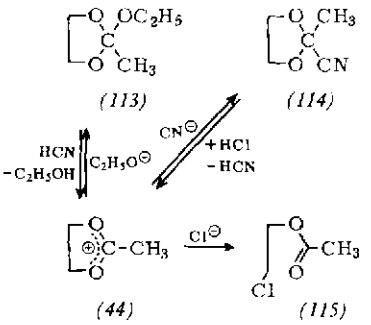
of the reaction is confirmed by the formation of *trans*-2-bromocyclohexyl benzoates during the free-radical bromination of *O,O'*-benzylidenecyclohexane-*cis*-1,2-diol *(102)* [39]. For the same reasons, the halogen



*(102)* cis *(103)* cis *(104)* trans *(105)* cis

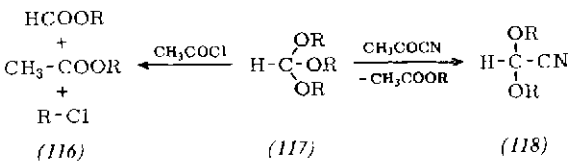
compound obtained from the carboxylic acid *(106)* and thionyl chloride, which is stable towards cold water, has the structure *(108)* [41] and not *(109)* [40].

*(106)* *(107)* *(108)* *(109)*



A variant of the reaction scheme is provided by the attack of excess aromatic amines on the carboxonium ion *(40)*. Here the kinetically controlled primary adduct

*(40)* *(110)* *(112)* *(111)*



*(110)* is stabilized by forming the imino ether cation *(111)*, which is then split open by Route 2 to form the γ-arylaminobutyric arylamide *(112)* [17].

The following example gives a particularly clear illustration of the effect of the nucleophilic component on the course of the reaction: As shown in Table 1, the carboxonium ion *(44)* adds on cyanide and alkoxide ions by Route 1 to form the unstable compounds *(113)* and *(114)* [18]. Even hydrocyanic acid is able to split off alcohol from the orthoester *(113)* to reform the ambident ion *(44)*, which is immediately trapped in the form of *(114)* [42]. The proton-active hydrogen chloride

*(113)* *(114)* *(44)* *(115)*

again displaces hydrogen cyanide from *(114)* so that the ion *(44)* can now react to form the stable β-chloroethyl acetate *(115)*. This explains why the orthoformate *(117)* reacts directly with acetyl chloride to form the stable products *(116)* [43], whereas acetyl cyanide produces α,α-dialkoxyacetonitrile *(118)* by Route 1 [44].

*(116)* *(117)* *(118)*

## 4. The Effect of the Ambident Cation on the Course of the Reaction

As shown in Figure 1, the effect of the ambident cation in system *(3)* is determined by its energy content as compared with those of the two possible reaction products *(5)* and *(6)* [45]. If *(3)* is very rich in energy, $\Delta F_1$ becomes so large, even when a weak nucleophile is used, that isolation of a kinetically controlled product formed by Route 1 becomes possible (Fig. 3). If, on the

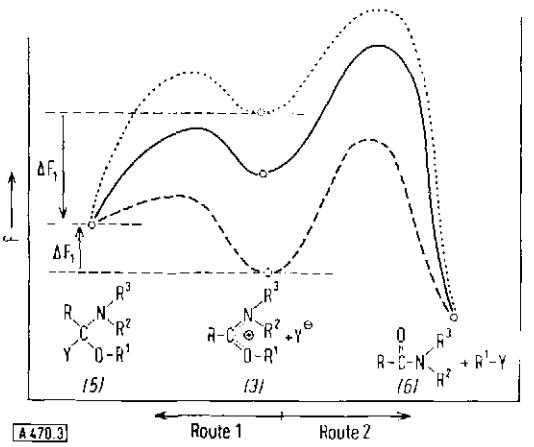


Fig. 3. Effect of the ambident cation on the position of *(3)* in the energy profile diagram.
—— General curve (Fig. 1);
..... *(3)* rich in energy;
- - - - - *(3)* poor in energy.

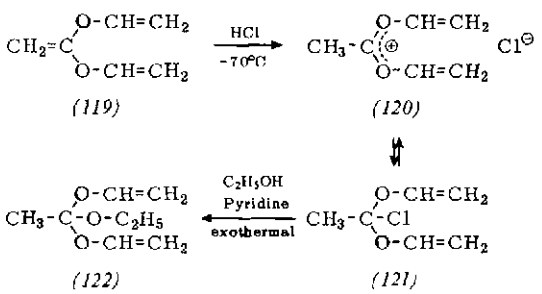
[39] *A. Rieche, E. Schmitz, W. Schade*, and *E. Beyer*, Chem. Ber. *94*, 2926 (1961).

[40] *E. Vogel* and *H. Schinz*, Helv. chim. Acta *33*, 116 (1950).

[41] *S. M. McElvain* and *A. N. Bolstad*, J. Amer. chem. Soc. *73*, 1988 (1951).

[42] *I. G. Erickson*, J. Amer. chem. Soc. *73*, 1338 (1951).

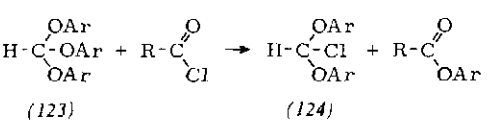
[43] *H. Post*, J. org. Chemistry *1*, 231 (1937).



[44] *H. Böhme* and *R. Neidlein*, Chem. Ber. *95*, 1859 (1962).

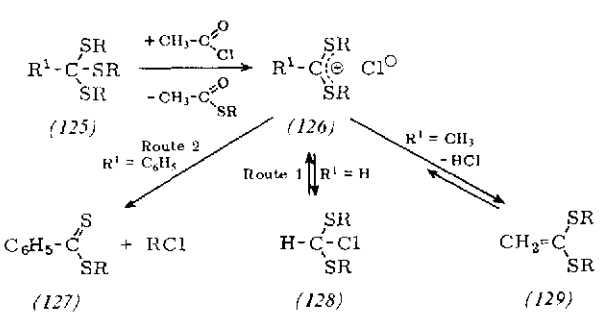
[45] Strictly speaking, the energy content of *(3)* is that of the system $Cat^{\oplus}$ + $Y^{\ominus}$. Since, however, the nucleophile remains constant, this energy depends practically only on the energy of dissociation of *(5)* (Cat-Y), which in turn is determined solely by the nature of $Cat^{\oplus}$.

other hand, *(3)* is strongly stabilized by mesomerism, so that $\Delta F_1$ is very small or, in extreme cases, has its sign reversed, then even strongly nucleophilic reagents lead only to the thermodynamically stable *(6)* via Route 2 (Fig. 3). Examples of both alternatives are known.



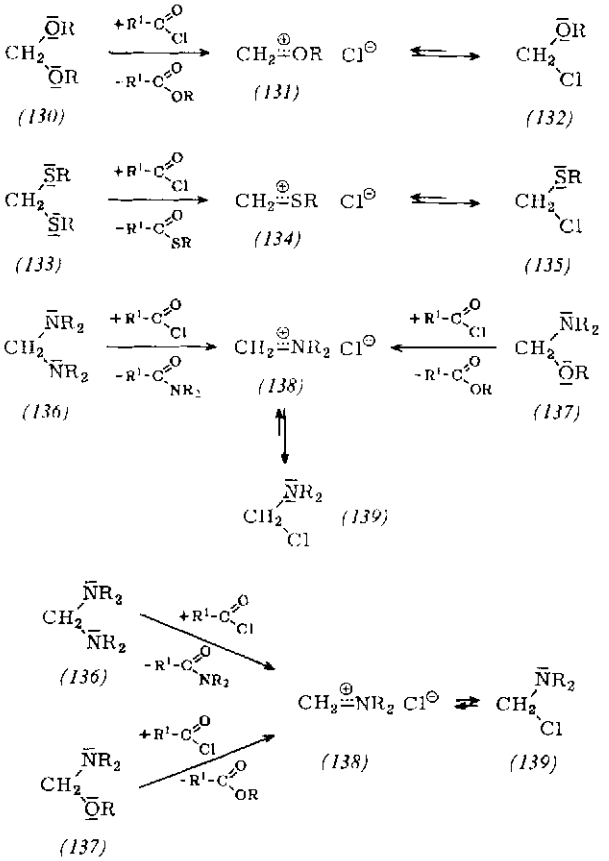
### a) Energy-Rich Ambident Cation

As described above, the addition of HCl onto ketene acetals produces ambident cations which do not add on the weakly nucleophilic $Cl^{\ominus}$ ion to form the kinetically controlled α-chloro-α,α-dialkoxy compound [*(93)* → *(97)*]. However, this metastable adduct can be isolated when divinylketene acetal *(119)* is used [41].



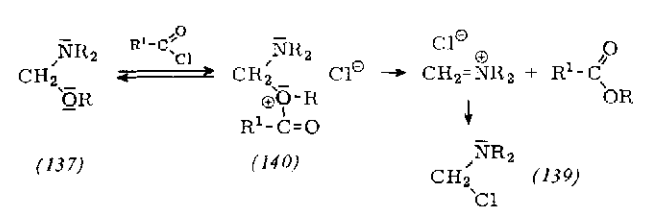
*(119)* *(120)* *(122)* *(121)*

Owing to the *O*-vinyl mesomerism (= strengthened O–C vinyl bond) the ambident cation *(120)* is so rich in energy that it adds on chloride ions to form *(121)*. The constitution of this compound follows from its vigorous reaction with alcohol containing pyridine to form mixed orthoesters *(122)* [41]. Analogously, it is possible to obtain the distillable, readily hydrolyzable compound diphenoxymethyl chloride (formyl chloride diphenylacetal) *(124)* from phenyl orthoformate *(123)* and acyl chloride [44].



*(123)* *(124)*

The extent to which the reaction is affected by the substituent on the carbon atom of the ambident cation is shown by the cleavage of trithio-orthoesters *(125)* with acid chlorides [46]. Here the dithiocarboxonium ion *(126)* must be an intermediate, but it forms the unstable, rapidly hydrolysed formyl chloride mercaptal *(128)* only when $R^1 = H$. In *(126)*, $R^1 = C_6H_5$, the ambident ion evidently contains so little energy that only the stable products *(127)* can be isolated. Finally, when $R^1 = CH_3$, the ion *(125)* loses a proton to form the ketene mercaptal *(129)*.



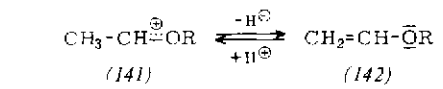
*(125)* *(126)* *(127)* *(128)* *(129)*

Cations in which the positive charge is distributed between only one hetero-atom and the carbon atom are naturally much richer in energy. For this reason, they are able to take up even the weakly nucleophilic chloride and bromide ions exclusively by Route 1 to form the labile adduct. This postulate is confirmed without exception by the numerous reactions of acetal-like compounds with hydrogen halides or with inorganic or organic acid chlorides. Examples are the reactions of acyl chlorides with formaldehyde acetal *(130)* [43], mercaptal *(133)* [46], aminal *(136)* [47], and α-aminomethyl ethers *(137)* [47]. α-Chloro ethers *(132)* [43],

*(130)* *(131)* *(132)* *(133)* *(134)* *(135)* *(136)* *(138)* *(137)* *(139)*

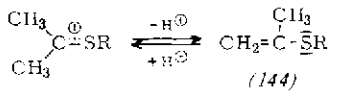
α-chloro thioethers *(135)* [46], and α-chloroamines *(139)* [47] are formed. The reaction must always begin with reversible addition of the acid chloride, the adduct then decomposing exothermically to form the ambident cation. This explains why, in the case of the aminoethyl ether *(137)*, the reaction proceeds via the adduct *(140)*, as is shown by the predominant formation of α-chloroamines *(139)* [47,48].

*(137)* *(140)* *(139)*



[46] *H. Böhme* and *J. Roehr*, Liebigs Ann. Chem. *648*, 21 (1961).

[47] *H. Böhme* and *K. Hartke*, Chem. Ber. *93*, 1305 (1960).

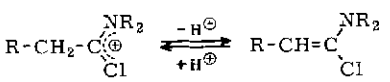


[48] *H. Meerwein*, Angew. Chem. *67*, 374 (1955).

Since α-chloroamines *(139)* are sparingly soluble in nonpolar solvents, it may be assumed that they are in equilibrium with their ions *(138)*. Both *(138)* [47] and *(131)* [48] have been isolated with complex anions.

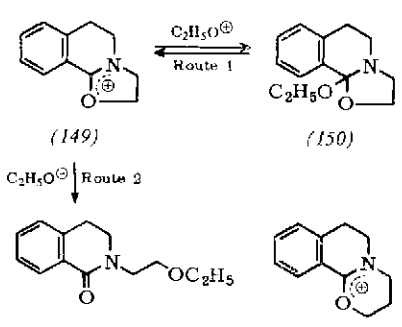
It should be noted that the reactions proceed smoothly only with derivatives of formaldehyde, tertiary aldehydes, or corresponding ketones. In other cases the energy-rich ions are stabilized even more readily than the carboxonium derivatives mentioned above, with loss of a proton [*(71)* → *(72)*; *(126)* → *(129)*]. The electrophilic character of the cations *(141)* [48], *(143)* [47], and *(145)* [49] then changes to nucleophilic character [*(142)*, *(144)*, and *(146)*], so that these partners, which are interrelated by addition or subtraction of a proton, often undergo aldol-type condensations. This explains

*(141)* *(142)*



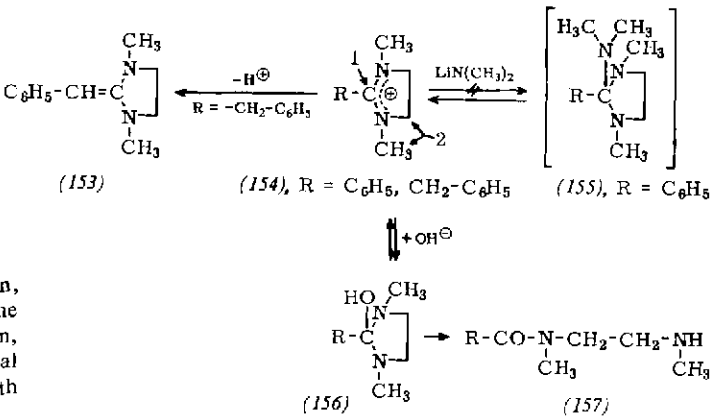
*(143)* *(144)*

*(145)* *(146)*



the favored position of formaldehyde in the Mannich reaction, which proceeds via *(138)* [50], and also the limitation of the Vilsmeier reaction to formylamines. If in the latter reaction, the intermediate *(147)* contains an alkyl group, partial deprotonation again occurs and hence dimerization of both partners takes place [29].

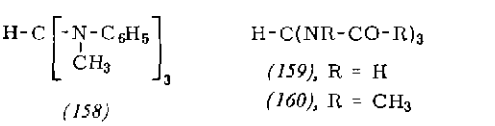
*(147)* *(148)*



### b) Low-Energy Ambident Cation

Although simple trialkylimino ether cations, *e.g. (31)* and *(34)* in Table 1, add on alkoxide ions smoothly to form the corresponding amide acetals, *e.g. (30)* and *(33)* in Table 1, the ion *(149)* yields only the stable ether *(151)* [51]. Neither the transition to the less strained dihydrooxazine system *(152)* [52] nor the use of cyanide ions [53] or of a lower temperature alters the course of the reaction [52]. Since the perchlorates of the ambident cations *(149)* and *(152)* can be recrystallized unchanged from water, these ions are so stable that it is impossible to isolate them in the form of the amide acetal, *e.g. (150)*.

*(149)* *(150)* *(151)* *(152)*



By comparison with all the ambident cations discussed so far, the amidinium ions have appreciably less energy, as is manifest in the unusual basicity of the amidines. Nevertheless, it is surprising that the amidinium ion itself *(154)* is not attacked by lithium dimethylamide in boiling ether [55]. Trisdialkylaminomethanes such as *(155)* cannot be isolated, in agreement with other attempts of synthesis [56, 57], because the resonance energy of the amidinium ions is too great.

*(153)* *(154)*, R = $C_6H_5$, $CH_2$-$C_6H_5$ *(155)*, R = $C_6H_5$ *(156)* *(157)*

If R contains a methyl group, then the cation can again react by loss of a proton, but only with alkoxide as the base [55, 57]. Ketene aminals, *e.g. (153)*, are formed. The occurrence of reversible addition onto *(154)* by Route 1 is shown by the exothermic reaction of the ketene aminal *(153)* with water. Here the ion *(154)* must be an intermediate; the adduct of this ion with hydroxyl ions *(156)*, even if present in very small concentrations, initiates opening of the ring to give *(157)*. The question whether the decomposition of the ion on fusion of the iodide *(154)* involves dealkylation (Route 2), as with other ammonium ions [58], remains to be resolved.

If the energy content of the amidinium ion is increased by weakening the basicity of the nitrogen atom, trisaminomethanes, *e.g. (158)* [59], *(159)* [60], and *(160)* [61], can be prepared [55].

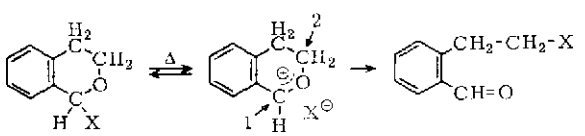
## 5. Influence of Temperature on the Course of Reaction



With suitable co-reactants, the isolated kinetically controlled product can be cleaved again by increasing the temperature to such an extent that a "rearrangement" with formation of the stable end-product occurs.

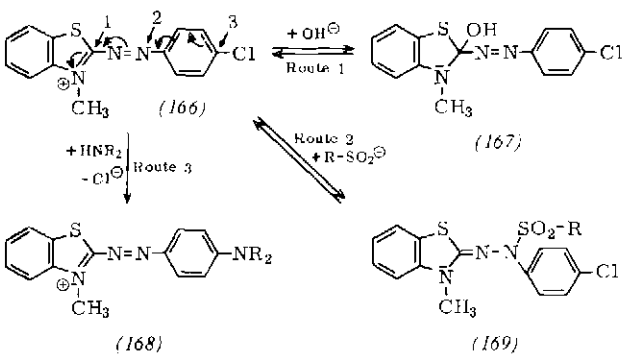
(8) (161) (162)

For example, the phthalimidium ion *(8)* combines instantaneously with the yellow *p*-nitrophenoxide ion in acetonitrile to form the colorless adduct *(161)*, from which the nitrophenoxy group can be easily split off by hydrolysis. If *(161)* is heated for about 2 hours at 130 °C, then the ether *(162)*, which is resistant to hydrolysis and which has the typical phthalimide structure, is obtained in quantitative yield [8].

The same process occurs during the thermal rearrangement of the 1-halogenoisochromanes *(163)* [54], which are very sensitive to hydrolysis. The ambident cation *(164)* formed as an intermediate takes up halide ion

*(163)* *(164)* *(165)*, X = Cl, Br

by Route 2 to form the stable *o*-halogenoethylbenzaldehyde *(165)*. In agreement with this mechanism, the optimum reaction temperature is appreciably higher (180 °C) for *(163)*, X = Cl, than for *(163)*, X = Br, (130 °C).

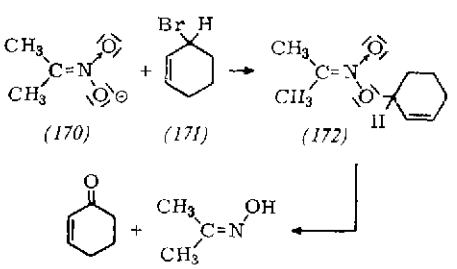


## 6. Effect of Solvent on the Course of Reaction

The ionizing effect of the solvent plays a decisive part in solvolysis reactions. This is also true for compounds which ionize to form ambident cations. A study of the solvent effect when solvolysis is excluded, *i.e.* the rate of rearrangement of the kinetically controlled product to form the thermodynamically controlled product, does not appear to have been undertaken so far. Experiments in this direction are being carried out at present in our laboratory.

## 7. Concluding Remarks

The examples given so far have all involved cations with a three-atom mesomeric system containing two points of attack for nucleophilic reagents. However, ambident behavior by a compound is not confined to a mesomeric three-atom system, and hence to two points of attack, nor to cations, nor indeed to ions. The sole criterion is the existence of an electron system which can be attacked at several points and in which reaction at one point eliminates the potential reactivity at the other sites. This general principle will now be illustrated by several examples.



a) Heterocyclic quaternary azo salts of type *(166)* have three sites capable of being attacked by nucleophilic reagents, corresponding to the mesomerism indicated by bent arrows [62]. Hydroxide ions add on reversibly to form a pseudo-base *(167)* [62], while sulfinate ions are

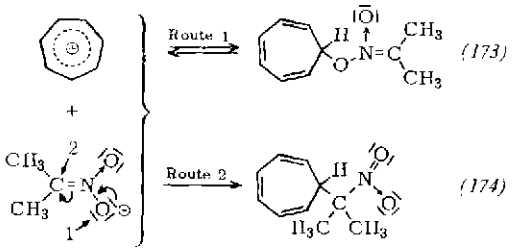
*(166)* *(167)* *(168)* *(169)*

also taken up reversibly by the azo group to form *(169)* [62]. On the other hand, amines react irreversibly by additive substitution [63] in the phenyl nucleus to form colored salts of type *(168)* [62,64]. Apart from steric factors, the course of the reaction is influenced primarily by the gain in bonding energy.

b) As mentioned above, reactions of ambident anions often take place in heterogeneous phase, so that their course is difficult to follow [5]. The reaction of the ambident 2-nitropropane anion *(170)* with carbonium ions of different energy contents [65] is a favorable exception.

*(170)* *(171)* *(172)*

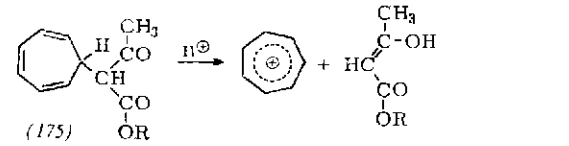
[62] *W. Kniese*, Ph. D. Thesis, Universität Marburg, 1963.



[63] Cf. *J. Sauer* and *R. Huisgen*, Angew. Chem. *72*, 294 (1960).

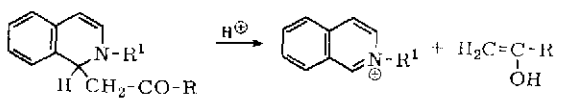
[64] *S. Gabriel* and *T. Heymann*, Ber. dtsch. chem. Ges. *23*, 2493 (1890); *Th. Wagner-Jauregg* and *M. Roth*, Chem. Ber. *93*, 3036 (1960); *L. J. Bellamy*: The Infrared Spectra of Complex Molecules. Methuen, London 1958, pp. 179, 209, 162, 205.

[65] *M. Bersohn*, J. Amer. chem. Soc. *83*, 2136 (1961).



If the highly reactive carbonium ion obtained from 3-bromocyclohexene *(171)* is used, the reaction takes place irreversibly at the position of highest electron density [66], *viz.* at the oxygen atom. The primary product *(172)* decomposes by a conventional redox reaction.

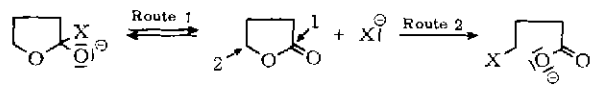
With the tropylium ion, however, which is low in energy, *O*-alkylation proceeds reversibly to form *(173)*, so that the thermodynamically more stable *C*-alkylated product *(174)* can be formed [65].



*(173)* *(174)*

It should be noted that even *C*-alkylated products of type *(175)* [67] or *(176)* [68] are readily cleaved again

*(175)*

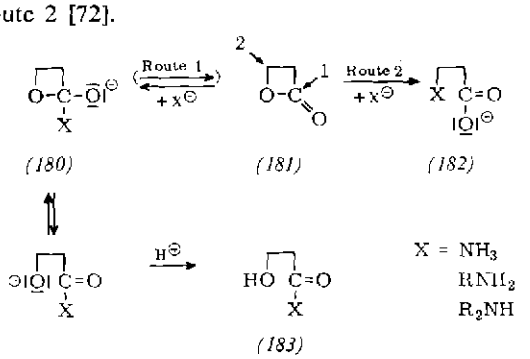


*(176)*

on protonation, if the ambident cation is strongly stabilized by mesomerism. The reactions correspond to a Grob fragmentation [69].

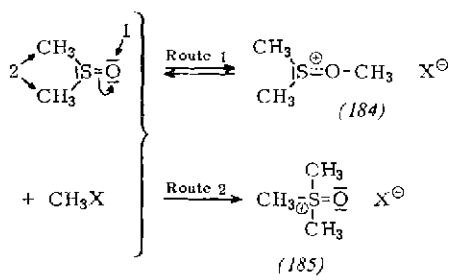
As to ambident neutral compounds, these must be differentiated according to their nucleophilic or electrophilic character.

c) A typical example of an electrophilic ambident neutral compound is γ-butyrolactone *(178)*. The ring is opened between the γ-carbon atom and the lactone oxygen by numerous nucleophiles under more or less drastic conditions [70].



*(177)* *(178)* *(179)*

| | | | |
|---|---|---|---|
| $X = C_2H_5O^{\ominus}$ | $CH_3S^{\ominus}$ | $CN^{\ominus}$ | $(NH_2)_2\overset{\oplus}{C}\text{-SH}$ |
| $C_6H_5O^{\ominus}$ | $CH_3\text{-}C(=O)\text{-}S^{\ominus}$ | $R\text{-}SO_2NH^{\ominus}$ | HCl |
| $S_2^{2\ominus}$ | $SO_3^{2\ominus}$ | $H_2N\text{-}R$ | HBr |
| | | $P(OR)_3$ | $SOCl_2$ |



The labile adduct *(177)*, which was isolated with X = $SCH_3$ [71], generally cannot become stabilized, so that the ring eventually opens to form *(179)*. If proton rearrangement is possible, as in the reaction with primary amines in alcohol, then γ-hydroxybutyramides are formed from *(177)*. Butyrolactams are formed [70] only at higher temperatures and in the absence of solvent. The greater ring strain of β-propiolactone *(181)* permits it to be attacked in accordance with Route 2 by almost all the nucleophilic reagents mentioned for butyrolactone (generally even at room temperature) to form β-substituted propionic acids *(182)*. Only alkoxide ions add on by Route 1 to form β-hydroxypropionates *(183)*, X = OR.

Ammonia and primary or secondary amines, whose primary adducts *(180)* can themselves become stabilized by prototropy, lead to β-hydroxypropionamides and also to β-aminopropionic acids. With tertiary amines, on the other hand, the adduct *(180)* cannot become stabilized, so that only betaines of β-alanine are formed by Route 2 [72].

*(180)* *(181)* *(182)* *(183)*

d) Dimethyl sulfoxide is an example of a nucleophilic neutral ambident compound [73]. Kinetically controlled alkylation results in attack on its oxygen atom. The instability of *(184)* is shown not only by its rapid hydrolysis but also by the retro-alkylation of $X^{\ominus}$, depending

*(184)* *(185)*

on its nucleophilic character: $I^{\ominus} > NO_3^{\ominus} > Tos^{\ominus}$. This explains why, under the same conditions, methyl *p*-bromobenzenesulfonate forms 94 % of the *O*-sulfonium salt *(184)*, whereas methyl iodide forms 93 % of the *S*-methylsulfonium salt *(185)* [73, 74]. Only in the latter reaction can the reversible nature of Route 1 become effective, the thermodynamically stable end-product *(185)* being formed.

Aromatic amines also appear to be ambident, in the sense that they react with electrophilic reagents, *e.g.* diazonium ions, both at the $NH_2$ group and in the aromatic ring. However, here both primary reaction products *(187)* and *(188)* must be stabilized by deprotonation. Since this sequence of reactions is reversible with the diazoamino compound *(186)*, the kinetically controlled product can be converted into the azo compound *(189)*. All migrations of *N*-substituents into the aromatic ring should be considered on this basis, provided cleavage with reformation of aromatic amine occurs.

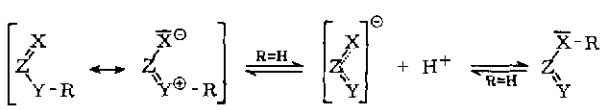
# Relations between Structure and Reactivity of Ambifunctional Nucleophilic Compounds

BY DOZENT DR. R. GOMPPER



INSTITUT FÜR ORGANISCHE CHEMIE UND ORGANISCH-CHEMISCHE TECHNOLOGIE DER TECHNISCHEN HOCHSCHULE STUTTGART (GERMANY)

*Dedicated to Professor Hellmut Bredereck on the occasion of his 60th birthday*

*Theoretical considerations and recent experimental results have added greatly to our knowledge of the structures and reactivities of ambifunctional nucleophilic compounds during the last few years. In the present work an attempt is made to present a survey of the theories which have been developed to explain the behavior of these compounds towards electrophilic reagents, and to formulate rules which may serve as guides for carrying out new reactions.*

## A. Introduction

The investigation of the structure and reactivity of tautomerizable compounds [general formulae *(1)* or *(3)* and *(4)* or *(6)*, R = H] belongs to the classical field of organic chemical research. However, while the problem of tautomerism [*(1)* ⇌ *(3)* and *(4)* ⇌ *(6)*] may now be regarded as being largely settled (cf. [1–4],

*(1)* *(2)* *(3)*

*(4)* *(5)* *(6)*

among others), the same cannot be said of the alkylation and acylation of *(1)* and *(3)* and of *(2)* and *(5)*. In the systems *(1)*, *(3)*, *(2)*, and *(5)*, partly also in *(4)* and *(6)*, resonance interaction occurs between atoms X and Y or X and N. Compounds of this type therefore differ in many respects from normal difunctional substances. *Kornblum* [5] has termed anions of formula *(2)* "ambident anions"; by analogy with the nomenclature used by *Pfrommer* [6], we generally speak of "ambifunctional nucleophilic compounds". In this context, "ambifunctional" refers to systems containing two centers

susceptible to electrophilic or nucleophilic attack, but in which only one of these centers can take part in one transition state (ambifunctional electrophilic compounds are not considered in the present work).

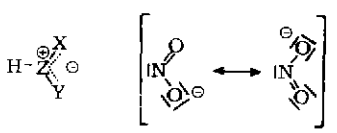

Table 1 gives a survey of the most important ambifunctional nucleophilic compounds. The need to differentiate between two types A and B arises from

Table 1. Ambifunctional nucleophilic systems.

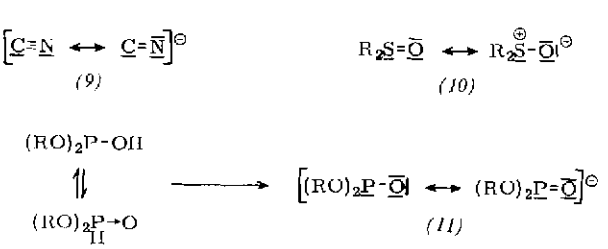
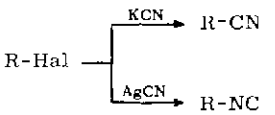
[*] And their anions.



the fact that compounds with Z = N, S, or P can react, not only through the terminal atoms X and Y of *(1)*, *(2)*, and *(5)*, but also through the central atom Z. However, the free electron pair on Z does not take part in the resonance in the sense of formulae *(1)* and *(2)* [cf. for example, the nitrite anion *(7)*].

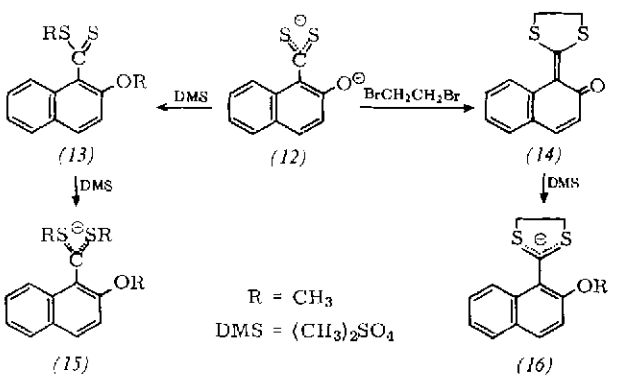
*(8)* *(7)*

Therefore, if X and Y are different, compounds of type B have three possibilities of reaction, and a third resonance form *(8)* must be formally considered in addition to *(1)* and *(3)*.



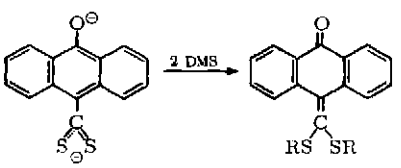
In group B, the cyanide ions *(9)*, the anions *(11)* of the phosphorous acid diesters, and the sulfoxides *(10)* are special cases, in which the resonance systems embrace only two atoms.

*(9)* *(10)* *(11)*



Before we examine the laws underlying the reactions of ambifunctional nucleophilic compounds, let us first recall the factors which affect the course of the reaction:

1. *Nature of the cation (for anions)*



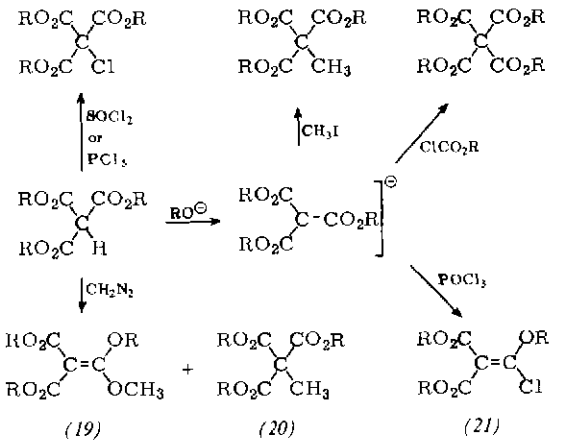
It has long been known (cf. [7]) that alkyl halides react with alkali metal cyanides to form nitriles, with, at most, traces of isonitrile, whereas with silver cyanide, at least below 100 °C, the formation of isonitrile is predominant.

2. *Nature of the resonance system and the degree of resonance*

*(13)* *(12)* *(14)* *(15)* *(16)*

Methylation of the disodium salt *(12)* of 2-hydroxynaphthalene-1-dithiocarboxylic acid leads to the formation of the methoxydithioester *(13)* [8]. The same reaction in the anthracene series yields the quinone methide derivative *(18)*. The greater nucleophilic character of the sulfur in *(17)* is explained by the

*(17)* *(18)*

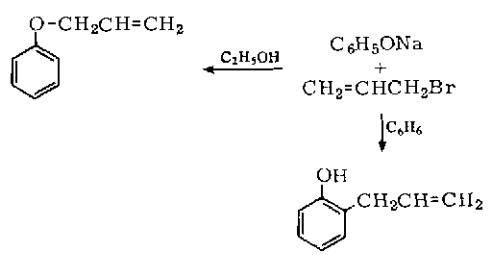


weaker aromatic character of anthracene. If the dithioester *(13)* is heated with dimethyl sulfate, the dithiocarboxonium salt *(15)* is formed. A related product *(16)* results from the analogous reaction of the quinone methide derivative *(14)*, but in this case owing to electrophilic attack on the oxygen atom. Thus the nucleophilic reactivity of the oxygen and sulfur depends very strongly on the resonance system in which they are incorporated.

[7] *Houben-Weyl:* Methoden der organischen Chemie. Thieme, Stuttgart 1952, Vol. 8, pp. 290, 352.

[8] *R. Gompper* and *R. Schmidt*, Angew. Chem. *74*, 780 (1962); Angew. Chem. internat. Edit. *1*, 596 (1962); *R. Schmidt*, Ph. D. Thesis, Technische Hochschule Stuttgart, 1962.

3. *Nature of the electrophilic reagent*



Alkylation and acylation of the alkali metal salts of carboxylic acid esters generally proceed by *C*-substitution. This is also apparent in the reactions of sodium methanetricarboxylic acid ester with methyl iodide [9] or chlorocarbonic acid ester [9]. Only on reacting

*(19)* *(20)* *(21)*

methanetricarboxylic acid ester with diazomethane, *O*-methylation to the ketene acetal *(19)* [yield 80 %, together with 20 % of *(20)*] has been observed [10] (the only other example so far of the conversion of a carboxylic acid derivative to a ketene acetal was the reaction of 7-nitrofluorene-1,9-dicarboxylic acid anhydride with diazomethane [11]). Whereas the action of $PCl_5$ [12] or $SOCl_2$ [13] on a methanetricarboxylic acid ester yields only a chloromethanetricarboxylic acid ester, the ketene acetal derivative *(21)* is formed in good yield by the reaction of its potassium salt with $POCl_3$ [12] (salts of other carboxylic acid esters undergo similar reactions).

4. *Nature of the solvent*

The reaction of sodium phenoxide with allyl bromide is a most impressive example of the solvent effect; according to *Claisen* [14], it leads to the formation of allyl phenyl ether in ethanol or acetone, but to *o*-allylphenol in benzene.

[9] *R. Scholl* and *W. Egerer*, Liebigs Ann. Chem. *397*, 358, 361 (1913).

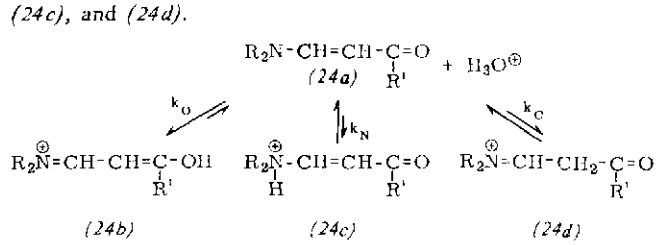
[14] *L. Claisen*, *F. Kremers*, *F. Roth*, and *E. Tietze*, Liebigs Ann. Chem. *442*, 210 (1925).

5. *Reaction temperature*

*(22)* *(23)* *(24)*

The reaction of imidazoles with phenyl isocyanate at 20 °C yields ureas *(22)* [15, 16], which regenerate isocyanate on heating. However, if 4,5-disubstituted imidazoles are heated to boiling with excess phenyl isocyanate [16], imidazole-2-carboxylic acid anilides *(23)* and imidazohydantoins *(24)* are formed.



## B. Theoretical Foundations

In all attempts to explain the reactions of ambifunctional nucleophilic compounds with electrophilic reagents (for a review and discussion of earlier literature, see [17]), it is necessary to differentiate between kinetically and thermodynamically controlled reactions.

### I. Thermodynamically Controlled Reactions

Since in equilibrium reactions the logarithm of the equilibrium constant K is proportional to the change in free energy $\Delta F$, the end product to be expected is the compound most stable under the prevailing conditions, independently of the reaction mechanism. The stability is determined by the bond energy and the resonance energy. However, since in many cases these two quantities cannot be determined with sufficient accuracy, conclusions drawn on this basis are generally only of value for the reaction of *(1)* or *(3)* to form onium salts.

An example is the protonation of α,β-unsaturated β-aminocarbonyl compounds *(24a)* [17a], which can form *(24b)*, *(24c)*, and *(24d)*.

*(24b)* *(24c)* *(24d)*

The greatest number of limiting structures can be given for *(24b)*, so that *O*-protonation should predominate. The infrared spectra of solid salts of *(24a)* do indeed point to the

[15] *H. A. Staab*, Liebigs Ann. Chem. *609*, 83 (1957).

[16] *R. Gompper*, *E. Hoyer*, and *H. Herlinger*, Chem. Ber. *92*, 550 (1959).

[17] *W. Hückel* [2], pp. 321–359.

[17a] *H. E. A. Kramer* and *R. Gompper*, Tetrahedron Letters *1963*, 969.

structure *(24b)*. NMR spectra [17a] show that the principal constituent of aqueous solutions is also *(24b)*. However, *N*- and *C*-protonation was also observed to a lesser extent [*(24b)* is not only the most stable of the three salts, it is also the one most rapidly formed].

Thus if equilibrium (a), whose constant $K_H$ is a measure of the affinity of Y and X for hydrogen, *i.e.* of their

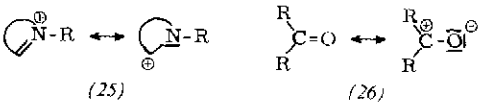
(a) $H-X + Y^{\ominus} \rightleftharpoons H-Y + X^{\ominus}$

"hydrogen basicity", is set in parallel with equilibrium (b), whose constant $K_Z$ corresponds, *e.g.*, to the "carbon" [17b–20], "halogen", "sulfur" [21] and "nitrogen basicities", then it should be possible on the

(b) $Z-X + Y^{\ominus} \rightleftharpoons Z-Y + X^{\ominus}$

$Z = R_3C$, RCO, Hal, RS, $RSO_2$, $RN_2$, NO
$Y = R_3C$, $R_2N$, RO, RS

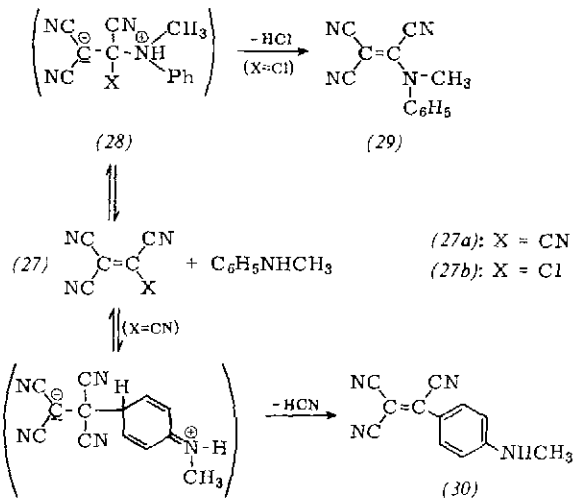
basis of the hydrogen basicity, to predict the course of the thermodynamically controlled reactions of Y, *i.e.* in our case of *(1)* to *(6)*. Although the analogy between (a) and (b) can only be formal (*e.g.* affinities for $Ag^{\oplus}$ are significantly different from affinities for $H^{\oplus}$ [22]), the resulting predictions are nevertheless fulfilled in the majority of cases (the respective reactions with formaldehyde may be regarded as models of thermodynamically controlled reactions). On extending the range of the acids and bases considered, the following rule for the stability of the end product is established [23]: "Hard", *i.e.* difficultly polarizable, acids combine particularly firmly with "hard" bases. "Soft", *i.e.* easily polarizable, acids form particularly strong bonds with "soft" bases.



It might also have been expected that the position of the tautomeric equilibrium between *(1)*, *(3)*, and *(8)*, and between *(4)* and *(6)* would yield information as to the likely products of thermodynamically controlled reactions. The picture is however influenced by solvent and chelation effects, so that correct conclusions can be drawn only in exceptional cases.

When should thermodynamic control be expected? This question is more difficult to answer than that of the reaction product. However a few rules of thumb can be stated. Thermodynamically controlled reactions are always to be expected when the temperature is so high that the products of kinetically controlled reactions can decompose again to yield the starting materials or otherwise rearrange. The temperature threshold is particularly low when:

a) stable cations are used or relatively stable cations occur as intermediates, or



b) electrophilic reagents with multiple bonds are added.

The stable cations include, for example, the triarylcarbonium ions, the carbonium-immonium ions of the Mannich reaction, and the aryldiazonium ions. Electrophilic reagents with multiple bonds include aldehydes and ketones, carboxylic acids and their derivatives, and quaternary salts of *N*-heterocyclics. However, no sharp boundary can be drawn between the two groups. Thus, a glance at the resonance structures of the quaternary cyclimmonium salts *(25)* or the carbonyl compounds *(26)* shows that these compounds can also be regarded as very stable carbonium ions.

*(25)* *(26)*

The reagents included under (a) and (b) can be further subdivided according to their reactivity, *i.e.* their "electrophilicity". The less reactive they are, the greater in general is the tendency towards thermodynamically controlled reactions at a given temperature. This is illustrated by the reactions of *N*-methylaniline with tetracyanoethylene *(27a)* and tricyanovinyl chloride *(27b)*. With *(27a)*, the product is *N*-methyl-*p*-tricyanovinylaniline *(30)* [24], while the more reactive *(27b)* yields *N*-methyl-*N*-tricyanovinylaniline *(29)* [25]. Whereas $Cl^{\ominus}$ is rapidly liberated from the adduct *(28)*, $CN^{\ominus}$

remains bound owing to its stronger nucleophilic character. Thus in the case of *(27a)*, the formation of *(28)* is reversible, so that the thermodynamically controlled reaction to form *(30)* becomes possible.

## II. Kinetically Controlled Reactions

The "dynamic basicity" of compounds with free electron pairs is termed "nucleophilicity", and is measured by the rate constant of the reaction. The main problem in predicting the course of kinetically controlled reactions of ambifunctional nucleophilic compounds is to determine the nature of the factors on which the nucleophilicity depends. If the ease with which an atom of a nucleophilic group makes electrons available for bond-

[25] *C. L. Dickinson*, *D. W. Wiley*, and *B. C. McKusick*, J. Amer. chem. Soc. *82*, 6132 (1960).

ing corresponded to the tendency of this atom to take part in nucleophilic substitutions, the basicity would provide a convenient expedient for the determination of the nucleophilicity. However, all attempts to demonstrate such a relationship have shown (cf. [26–30]) that it exists, at best, in series of similar compounds (alcohols, amines). Thus no direct parallel exists between basicity as a thermodynamic and nucleophilicity as a kinetic quantity.

However, the attempt to derive the nucleophilicity from a property of the atom which is independent of the type of compound ("sulfur is more nucleophilic than nitrogen") was also unsuccessful. Not only do the bonding conditions have a great influence, but the nucleophilicity is found to depend very strongly on the electrophilic reagent (alkylating agents [31–33], carboxylic acid derivatives [34–37], arylating agents [38–42], phosphorus compounds [43–46], and disulfides [47]; for other examples cf. [33, 35]).

The solvent also plays an important part (cf. [48]). Particularly impressive is the finding [49] that the "normal" order of nucleophilicity observed in water $I^{\ominus} > Br^{\ominus} > Cl^{\ominus}$ is reversed in the case of tetraalkylammonium halides in acetone, *i.e.* chlorides become more nucleophilic than iodides. Thus it appears that the more weakly solvated is an atom in an anion or even in a molecule, the more strongly nucleophilic it becomes. Strong solvation probably creates a sheath of solvent, which wards off the electrophilic attack in many cases.

*Streitwieser* [28] has assumed that nucleophilicity is determined by the energy of solvation of the base, the strength of its bond with a 2p-orbital of the carbon, its steric effect, and the electronegativity and polarizability of the reacting atom. *Edwards* and *Pearson* [33] have named the basicity, the polarizability and the α-effect (presence of free electron pairs on the atom adjacent to the nucleophilic center) as the most important factors. Surprisingly, electrostatic attraction is only rarely mentioned. Only *Hudson* [50, 51] centers his interpretation of nucleophilic reactivity around this factor. That an essential function must be assigned to the electrostatic attraction between the reactants (cf. also [52]) is clearly shown by, among other things, the difference in the orders of nucleophilicity observed with non-polar alkylating agents and polar acylating agents. The discovery [37] that anions react more rapidly with the acetylimidazolium cation than with *p*-nitrophenyl acetate, and only slowly or not at all with the acetyl phosphate anion, is very informative (for the effect of electrostatic interactions on the saponification of esters, cf. [53]). The calculated gain in energy when the two hydrogen atoms or a hydride ion and a proton approach each other [54–57] points in the same direction (cf. kinetic investigations [58]).

Good agreement with epxerimental results is obtained if it is assumed that the polarizability and the electrostatic attraction together constitute the phenomenon of nucleophilicity, the relative contributions of the two effects varying from one case to another.

Polarizability gives rise to the London and Van der Waals dispersion forces which lead to stabilization of the transition state [52, 59–62] (however, a clear distinction between London forces and polar forces is not always quite simple [61, 63]. The α-effect is probably related to the polarizability and electrostatic attraction. It is certainly not fortuitous, on the one hand, that it is associated with a particularly high polarizability of the nucleophilic reactant, and on the other, that it makes its appearance mainly with polar electrophilic reagents [36].

These considerations lead to the following basic principles for the behavior of ambifunctional nucleophilic compounds towards electrophilic reagents:

1. Owing to Coulomb attracting forces, a polar electrophilic reagent combines preferentially with the atom of an ambifunctional nucleophilic compound which bears

the highest electron density. The rate of this reaction increases with the difference in the charges of the positively and negatively charged centers, while reactions with other nucleophilic centers are suppressed in a similar measure.

2. If the electrophilic reagent carries no significant positive charge, or none at all, a covalent bond is preferentially formed to the most easily polarizable atom of the ambifunctional system.

*Birch* and *Dewar* [64] had already reached a similar conclusion. These authors worked on the assumption that, in the collision, an electrophilic reagent perferentially strikes the atom bearing the largest negative charge in a nucleophilic system. If it is also assumed that, for example in the reaction of an enolate anion, the transition state resulting from an attack on the C atom is poorer in energy than that resulting from an attack on the O atom, then it follows from the collision theory that *O*-substitution should predominate with energy-rich electrophilic reagents, and *C*-substitution with energy-deficient reagents. This can be verified by several examples [3]. *Brändström* [65] has criticized and improved upon this theory.

## Alkylation of Metal Nitrites

Some of the strongest evidence for the basic principles advanced above are the results obtained by *Kornblum* [5, 66] in his investigations on the action of alkyl halides on metal nitrites. These results can be summarized (Table 2) by saying that the course of the reaction – formation of alkyl nitrite or nitroalkane – depends on whether the transition state possesses a stronger or weaker $S_N2$ character, *i.e.* on whether, in the extreme case, the reaction is truly $S_N2$ or $S_N1$. In the first case the product is predominantly or exclusively nitroalkane, and in the second the alkyl nitrite. A strong $S_N1$ character results from the ability of the alkyl halide to dissociate into ions; this dissociation occurs more readily as the carbonium ion formed becomes more stable (*e.g.* $p\text{-}CH_3OC_6H_4CH_2^{\oplus} > p\text{-}O_2NC_6H_4CH_2^{\ominus}$), and as the halide anion is more readily detached. For this reason, the $S_N1$ character is more pronounced in the reaction with silver nitrite (association of $Hal^{\ominus}$ with $Ag^{\oplus}$ to form AgHal) than in the reaction with sodium nitrite; a suitable model for the $S_N2$ scheme is the reaction of α-halogenocarboxylic acid esters with sodium nitrite in dimethylformamide [67], which gives the α-nitroesters in high yields:

$$R\text{–}CH(Hal)\text{–}CO_2R' + NaNO_2 \xrightarrow[\text{(DMF)}]{} R\text{–}CH(NO)_2\text{–}CO_2R' + NaHal.$$

In the nitrite anion *(7)*, the negative charge is distributed over the two oxygen atoms. In agreement with the above principles, the greater the positive charge on the C atom of the alkylating agent in the transition state, the greater is the yield of alkyl nitrite (the extent to which the course of the reaction is affected by the arrangement of the atoms in crystalline $AgNO_2$ – Ag lies closer to the N-atom and Na to the O-atom [68] – must remain unsettled for the present). The fact that the molecular refractions of the alkyl nitrites are greater than those of the nitroalkanes [69] is an indication of the greater polarizability of the N-atom, which determines the course of the $S_N2$-type reaction.

*Kornblum* [5] has concluded that alkylation of ambifunctional anions always occurs on the atom with the greatest electron density when the $S_N1$ character is dominant. In reactions with a strong $S_N2$ character, on the other hand, the alkylation should occur on that atom of the mesomeric anion which the electronegativity scale shows to have the lower electron density. Even if this formulation remains unsatisfactory insofar as it gives no explanation of the course of the $S_N2$ reactions (no conclusion on the electron density can be drawn, strictly speaking, from electronegativity), it can nevertheless explain the alkylation of, *e.g.* the cyanide, thiocyanate, cyanate, amide, thioamide, and nitrosamine anions. It agrees only in part with the results obtained with enolate and phenoxide anions, and largely fails with the anions of the nitroalkanes, oximes, and enthiols. However, its chief drawback is that it is valid only for anions and alkylating agents.

Table 2. Reaction of benzyl bromides with silver nitrite.

$$p\text{-}R\text{–}C_6H_4\text{–}CH_2Br + AgNO_2 \xrightarrow[\text{(ether)}]{0\,^{\circ}C} Ar\text{–}CH_2\text{–}ONO + Ar\text{–}CH_2\text{–}NO_2$$

| R | Half-time of the reaction [min] | Yield [%] | |
|---|---|---|---|
| | | Nitrite | Nitroalkane |
| $O_2N$ | 180 | 16 | 84 |
| H | 16 | 30 | 70 |
| $CH_3$ | 1 | 48 | 52 |
| $CH_3O$ | very small | 61 | 39 |

## Cation and Solvent Effects

It only remains to be settled whether cation and solvent effects can also be explained with the aid of the principles discussed above. In reactions of ambifunctional anions, the reactants include not only the electrophilic reagent, but also the cations and the solvent molecules. Thus in nonpolar solvents, the electrostatic attraction originating from an anion takes effect mainly on the cation. This is why, in organic solvents such as benzene, even strong electrolytes are associated in ion pairs or higher aggregates (cf. [70]).

The degree of proximity or the strength of "bonding" [71] in the ion pair depend on the negative and positive charge densities of the two ions, on the concentration, and on the ability of the solvent to sol-

vate ions [48,70,72–74]. Owing to the electrostatic orientation of the ions, it is to be expected that the atom of the mesomeric anion system which has the greatest electron density will lie nearest to the cation (cf. [75], among others). The electron density depends on the resonance of the system and on the radii of atoms taking part in the resonance. Apart from certain exceptions [76], the result of the interaction between anions and cations is a reduced reactivity of ion pairs and similar aggregates as compared with the free ions [49,17b,77–90]. Deviations which are often observed with $Li^{\oplus}$ are associated with the solvation of $Li^{\oplus}$, which may simulate a larger ionic radius [91]; as expected, ion pairs of Li salts are particularly unreactive (cf. [92,93] among others).

As an example of the cation and concentration effects, consider the reaction of methyl iodide with lithium, sodium, potassium, and bis-piperidinium salts of 3-hydroxybenzofuran-2-carboxylic acid ester, which is strictly of second order [94]. The rates of the ionic and ion pair reactions increase with increasing radius of the cation; however, the ionic reaction is favored in dilute solutions and the ion pair reaction in concentrated solutions.

Anions have an effect on solvent molecules similar to that on cations. The solute-solvent interaction is determined by ion-dipole and dipole-dipole attraction, $\pi$-complex formation, and hydrogen bonding [48,95].

Most anions are much more weakly solvated in aprotic dipolar solvents [48] (*e.g.* dimethylformamide, dimethylsulfoxide, actone, acetonitrile, nitrobenzene) than in protonic; the reverse is true of polarizable, charged transition states [96]. Solvation of anions in protonic solvents depends primarily on ion-dipole interactions and on the formation of strong hydrogen bridges (*e.g.* [97–99]), an effect which is most pronounced with small anions. The ion-dipole interaction also plays a part in dipolar aprotic solvents. It is overlaid, particularly with large anions, by attraction due to mutual polarization.

As a result of the anion-solvent interaction, the electron-rich center in the ambifunctional anion is shielded by solvent molecules; this result is particularly important in protonic solvents, and *Kornblum* [100] has coined the name "selective solvation" to describe it. As in the occurrence of ion pairs, it leads to a shielding of the atoms with higher electron density against attack by electrophilic reagents. This explains, *e.g.*, the above-mentioned reversal of the order of nucleophilicity of the halide anions in changing from water to acetone as the solvent.

The shielding of the atom with the highest electron density by cations and solvent molecules affects not only the "specific" reactivity of this atom, but also, as a result of the demands on the free electron pair, the reactivity of the whole resonance system. The reactivity of the shielded anion therefore approaches that of the free compound, and consequently the substitution, even on the center which is not blocked, requires a greater activation energy.

*Brändström* [65,84] has tried to explain the alkylation of β-dicarbonyl compounds in a somewhat different form, but one which nevertheless, in its essence, corresponds to the view expounded above. Starting from the observation that the alkali metal salts of β-dicarbonyl compounds partly exhibit the properties of covalent compounds rather than those of the salts (cf. also [101]), the formation of chelate-alkali metal compounds such as *(31)* and that of β-dicarbonyl compounds fixed in the *trans*-configuration of the type *(33)* are assumed (Solv = solvent molecule) (cf. [102]). On addition of alkyl halide (RX), this occupies one coordination site; the *C*-alkylation is then induced in *(32)* and *(34)* by polarization of the C-Hal bond by the metal ion, and proceeds as a multi-center process. Since *(33)* is less stable than *(31)*, free enolate ions are formed relatively readily in this case; if these satisfy the condition of high charge density on the oxygen, they are then alkylated to form enol ethers. *Brändström* has quoted numerous examples in support of his theory (cf. also [103]). However, he leaves undecided, among other things, the question of the *O*-acylation of sodium acetoacetate with carboxylic acid chlorides in ether suspension.

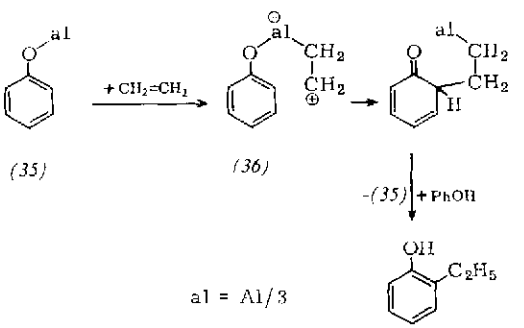
*(31)*

*(32)*

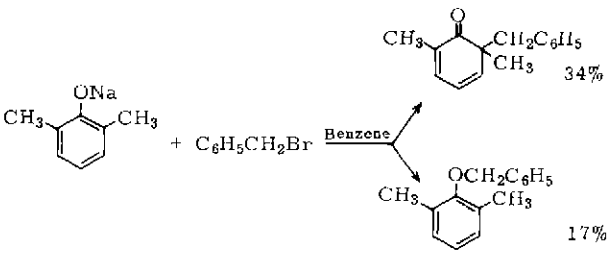
*(33)*



*(34)*

Investigations on the alkylation of metal salts of the phenol and dihydroresorcinol series have played an important part in the development of the theory of the cation and solvent effects. These will therefore be discussed below, together with a few other results.

## Alkylation of Metal Phenoxides



As an example of the action of chelation in organic reactions [105], let us examine the *o*-alkylation of phenols with olefins, with aluminum phenoxide as catalyst [106–108], for which the following mechanism is assumed: The olefin, *e.g.* ethylene, reacts with *(35)*

*(35)* *(36)*

to form the complex *(36)*, in which the electrophilic attack of the ethylene is directed towards the *o*-position. The reaction ends with the reformation of *(35)* by proton exchange with excess phenol.

According to *Claisen* [14], the reaction of metal phenoxides with particularly reactive alkyl halides (allyl bromide, benzyl bromide) in non-polar solvents (benzene, toluene, etc.) yields *o*-alkylphenols. More recent investigations [109–122] have confirmed that, apart from a few exceptions [119,123], in addition to *O*-alkylation, *o*-substitution occurs practically exclusively. Moreover, certain preparative improvements have been discovered and the range of application of the reaction has been extended. Thus, for example, it is advantageous to prepare the sodium phenoxide in toluene, in which the reaction is also carried out, with sodium hydride [110]; the yields of *o*-benzylphenols are between 80 and 90 %. The use of *o,o'*-dimethylphenols permits the synthesis of dienones [111–117]:

Dienones are also formed with α-naphthol, β-naphthols [122] and anthrone, even when methyl iodide is used.

Particular theoretical significance is attached to *Kornblum*'s discovery [118] that only *C*-alkylation occurs in completely heterogeneous reactions, and only *O*-alkylation in homogeneous reactions (on the question of the "heterogeneity factor", see also [94,103,112,117, 121,122,124,125]). The preparative result (Scheme 1), that only 19 % of *p*-(t-octyl)-*o*-allylphenol is formed in the heterogeneous reaction in ether while 96 % of *p*-t-octylphenyl allyl ether is formed in the homogeneous reaction in ethylene glycol dimethyl ether (EGDE), appears at first to contradict this statement. However,

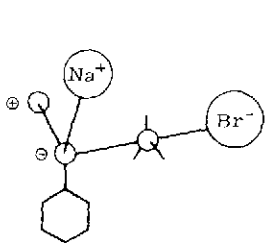
Scheme 1. Homogeneous and heterogeneous alkylation of potassium *p*-t-octylphenoxide.

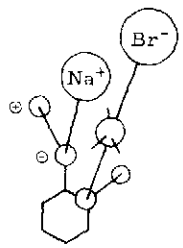
if the course of the reaction of potassium *p*-t-octylphenoxide with allyl chloride is followed, taking into account that the reaction mixture becomes homogeneous after 50–60 % conversion; it becomes clear that only the dissolved portion of the phenoxide is *O*-alkylated. This portion obviously increases as the reaction proceeds.

Table 3. „Heterogeneous" reaction of allyl chloride with potassium *p*-t-octylphenoxide in toluene at 25 °C.



| Conversion [%] | *O*-allylation [%] | *C*-allylation [%] |
|---|---|---|
| 10 | 1 | 99 |
| 22 | 11 | 89 |
| 34 | 44 | 56 |
| 100 | 81 | 19 |

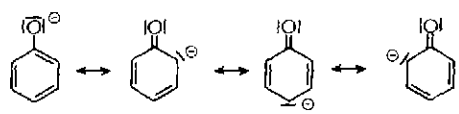
Since *o*-alkylation of the phenoxide requires a considerably greater activation energy than the *O*-alkylation, owing to the removal of the aromaticity in the transition state, it is to be expected that the former is possible only when the ions are particularly strongly bound together. As can be seen from Table 3, this type of bonding is exhibited by metal phenoxides only in the crystalline state, but not by ion pairs in solution.



It should be pointed out that, under conditions (ether as solvent) in which the Na salt of 2,6-dimethylphenol reacts with allyl bromide to the extent of 55 % (C–R/O–R = 0.5), no reaction occurs with the Li salt [112].

The reaction mechanism which thus suggests itself for the Claisen *o*-alkylation of the phenols [118] corresponds to *Brändström*'s views [65], expressed in formula *(34)* (cf. also [126]): *O*-Alkylation requires the linear transition state *(37)*. In a non-polar solvent, however, the halide ion may be poorly solvated, and furthermore, the electrostatic equilibrium between cations and anions in the crystal is disturbed by withdrawal of the negative charge from the oxygen. These difficulties do not occur in the *C*-alkylation with the transition state *(38)*. The outgoing halide anion can be solvated by ion pair formation with the sodium ion, and, in addition, the reduction of the negative charge on the oxygen is compensated for by the transfer of a sodium ion to the halide ion so that, unlike in *(37)*, Coulomb repulsion forces occur between the sodium ions.

In the *O*-alkylation in homogeneous solution, which contains relatively unstable (since non-chelated) ion pairs or dissociated ions, the deciding factor is that, as a result of the aromatic character of the ring, the limiting structure *(39a)* is more important then the



*(37)*

*(38)*

limiting structures *(39b)* to *(39d)*. The oxygen is therefore more nucleophilic than the *o*- and *p*-C-atoms.

*(39a)* *(39b)* *(39c)* *(39d)*

The picture given by the transition state *(38)* does not quite tally, inasmuch as it gives the impression that a bond is first formed between th *o*-C and the allyl-C, and only subsequently does the $Na^+$ ion promote liberation of the halide ion. However, the Claisen *o*-alkylation proceeds preferentially with those alkyl halides which tend towards $S_N1$-type reactions (cf. [127, 128]). The observation that sodium 2,6-dimethylphenoxide with methyl *p*-bromobenzenesulfonate [114] and sodium β-naphthoxide with dimethyl sulfate [122], in contrast to the reactions with methyl iodide, yield only the methyl ethers, also supports *Brändström*'s assertion [65] that the *C*-alkylation must be induced by polarization of the C-Hal bond of the alkylating agent by the metal cation. This agrees with the fact that, in the alkylation of metal β-naphthoxides, the proportion of the *C*-substitution product increases with the reactivity of the halide and with the electropositive character of the metal [117].

The material available [117, 118, 120, 129] on reactions with typical carbonium ion formers (trityl chloride, benzhydryl chloride) is too sparse to lead to definite conclusions. In this case, *p*-alkylation appears to occur in addition to *O*-alkylation and *o*-*C*-alkylation (for the formation of *o*-tropylphenol from sodium phenoxide and tropylium bromide [120], cf. [129a]).

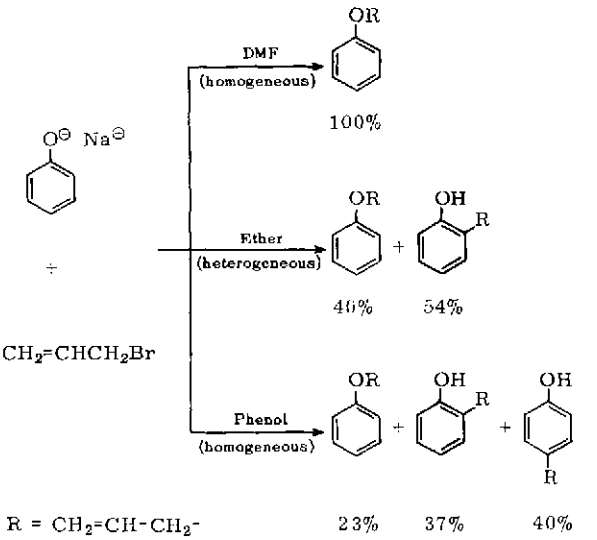
[129] *M. Busch* and *R. Knoll*, Ber. dtsch. chem. Ges. *60*, 2249 (1927).

[129a] *Ch. Jutz* and *F. Voithenleitner*, Chem. Ber. *97*, 31 (1964).

While the solvent-dependence of the reaction of sodium 2,6-dimethylphenoxide with perchloryl fluoride [130] is the same as in alkylation, no corresponding influence is known in the reaction of metal phenoxides with acid halides. The *O*-acylation appears to have precedence under all circumstances. Sodium 2,6-di-t-butylphenoxide reacts with benzoyl chloride to form 4-hydroxy-3,5-di-t-butylbenzophenone (24 %) and its enol benzoate [131] (on the question of steric hindrance, cf. [132]), but it yields phenyl urethane with phenyl isocyanate. Potassium 2,5-di-t-butylphenoxide reacts with cyanogen chloride to form 2,6-di-t-butylphenyl cyanate [133].



Thus it appears that the strongly polar acylating agents are capable of overcoming the insufficient solvation of the outgoing halide anion. This may be assumed to be due to the strong electrostatic attraction between the carbonyl or cyanide carbon atom and the phenoxide oxygen.

It should be noted that, in non-polar solvents, alkali metal salts of β-dicarbonyl compounds are also *O*-acylated by carboxylic acid chlorides [65].

So far, the solvent has been examined in connection with the Claisen *o*-alkylation only from the point of view of the heterogeneous or homogeneous reaction. However, what is the nature of its influence when separately solvated ions are present? The answer to this question, and hence a further possibility of verifying the theoretical considerations discussed here, is given by investigations of *Stetter* [134], *Zook* [103, 135], *Zaugg* [125, 136, 137], *H. Schmid* [121, 124], *Kotlyarevskii* [138], and particularly *Kornblum* [139–141] (cf. also [142–144]).

The great importance of the "selective solvation" of the atom with the greatest electron density is shown by the fact that even the little favored *C*-alkylation of phenols can be forced [139, 140] (Scheme 2). It should be remembered that *O*- and *C*-alkylations in protonic solvents are $S_N2$ processes.

Scheme 2. *O*- and *C*-alkylation of sodium phenoxide.

As shown by Table 4, the selective solvation becomes more evident as the tendency of the solvent towards H-bonding is increased; however, the acidity of the solvent is not a reliable measure of this effect. Finally, it is remarkable that, with sodium β-naphthoxide, which has a greater "carbanion activity" than the phenoxide, *C*-alkylation is possible even in more weakly H-bonded solvents, and the same result can be achieved with tetrahydrofuran, in which H-bonding is impossible. In the non-polar tetrahydrofuran, however, the transition state *(38)* is favored; correspondingly, exclusive *O*-substitution is again found in the polar dimethylformamide or dimethyl sulfoxide.

Table 4. Reaction of sodium phenoxide with allyl bromide at 27 ° [139].

| Solvent | *O*-allylation [%] | *C*-allylation [%] |
|---|---|---|
| Methanol | 100 | 0 |
| tert-Butanol | 100 | 0 |
| Water | 51 | 38 |
| Phenol | 23 | 77 |
| 2,2,3,3-tetrafluoropropanol | 58 [*] | 37 [*] |
| 2,2,2-trifluoroethanol | 37 | 42 |

[*] With allyl chloride.

The selective solvation in the reaction of phenols with acid chlorides in aqueous alkali [145] is unable to prevent the exclusive *O*-acylation. Also, in the amination of potassium phenoxide in water with hydroxylamine-*O*-sulfonic acid, *O*-phenylhydroxylamine is formed [146].

$$C_6H_5\text{-}O^{\ominus}\ K^{\oplus} + H_2N\text{-}O\text{-}SO_3H \xrightarrow[100°C]{(H_2O)} C_6H_5\text{-}O\text{-}NH_2 \quad 15\%$$

## C. Summary

The ideas developed in Section B of the course of the reactions of ambifunctional compounds with electrophilic reagents can be summarized in the following rules:

I. Thermodynamically controlled reactions

a) Thermodynamic control of electrophilic substitution is always observed when the temperature is so high that the products of kinetically controlled reaction steps can decompose to give the starting components or otherwise rearrange.

The temperature threshold is particularly low when

α) stable cations are used or relatively stable cations occur as intermediates, or

β) electrophilic reagents with multiple bonds are added.

b) The cationic residue of the electrophilic agent is generally bonded to the atom of the ambifunctional compound which has the greatest hydrogen basicity (C > N > O > S).

II. Kinetically controlled reactions

a.α) Strongly polar electrophilic reagents preferentially attack the atom of the ambifunctional system which exhibits the greatest electron density.

a.β) Weakly polar electrophilic reagents favor the most easily polarizable atom of the ambifunctional system.

b) Ambifunctional compounds of type *(1)* or *(3)* always add electrophilic reagents in such a way as to maintain maximum resonance in the transition state.

c) For the reactions of ambifunctional anions of type *(2)* and *(5)* with weakly polar electrophilic reagents it holds, in addition to a.β), that

α) the nucleophilicity of the atoms of the first short period of the periodic system decreases with increasing atomic number: C > N > O > F;

β) the nucleophilicity of the atoms of the higher periods is always greater than that of atoms of the first short period;

γ) the graduation of the nucleophilicity given by rules c.α) and c.β) is displaced in favor of the atom which carries the negative charge when one resonance structure contributes particularly heavily.

d.α) The atoms with the greatest electron density are shielded against the attack of nucleophilic reagents by cations and polar solvents. Solvents which can form hydrogen bridges are particularly effective.

d.β) Cations and, in part, solvent molecules which are particularly firmly bound to an atom of an ambifunctional anion give rise to multi-center processes in which the electrophilic reagent is directed towards the "other" atom of the anion or into the *o*-position.

Owing to the variety of compounds listed in Table 1 and to the immense number of possible combinations of reactants, solvents, catalysts, and temperature conditions, "ad-hoc assumptions" cannot be entirely avoided in the discussion of special reactions. However, a glance at the great body of facts shows that the rules given here provide a useful basis for preparative and theoretical investigations. It should be mentioned that the reactions of ambifunctional electrophilic reagents can be regarded from similar points of view.

# The Phenomenon of Phototropy [*]

BY DR. W. LUCK AND DR. H. SAND

HAUPTLABORATORIUM DER BADISCHEN ANILIN- & SODA-FABRIK
LUDWIGSHAFEN/RHEIN (GERMANY)

*Dedicated to Professor Gustav Kortüm on the occasion of his 60th birthday*

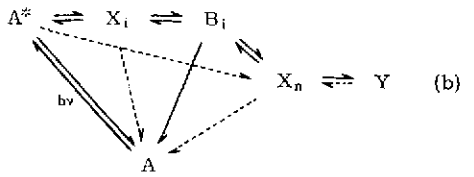
*A short survey of the present status of our knowledge in the field of "phototropy" is presented. The laws which govern this phenomenon are described, taking parafuchsin and N,N'-dimethyl-1,4-diaminoanthraquinone as examples. Phototropy and thermotropy are related. The acceleration of the regression of phototropically induced states by irradiation with light is discussed in some detail. An understanding of phototropy promises insight into the mechanisms of photochemical reactions and into the prerequisites for the preparation of light-fast dyes.*

## I. Introduction

The general Scheme (a) is assumed [1] for photochemical reactions.

$$A \rightleftharpoons A^* \rightarrow X \rightarrow B \qquad (a)$$

A = starting material; A* = optically excited A
X = a non-isolable intermediate
B = the first well-defined product capable of detection.



*Marckwaldt* observed that reversible color changes occurred with certain substances on exposure to light [2] and designated this phenomenon as phototropy.

[*] Reported in part at the II. International Dyestuff Symposium in Schloß Elmau (Germany), April 1964.

[1] *O. Kling, E. Nikolaiski,* and *H. L. Schläfer,* Ber. Bunsenges. physik. Chem. 67, 883 (1963).

[2] *W. Marckwald,* Z. physik. Chem. 30, 140 (1899).

For this case, Scheme (a) must be extended into Scheme (b)

Y = the photochemical end-product (the indices $i$ and $n$ indicate that various phototropic states B and different intermediate states X can occur).

The term phototropy [**] may be defined as follows:

*Phototropy is a reversible process which is produced by light absorption and leads to a quantum-mechanically stable but thermodynamically unstable state.*

The limitation "quantum-mechanically stable" is intended to indicate that because of the short life of the optically excited states A*, the simplest case of phototropy in the original sense of the word, *viz.* the optical transition $A \rightleftharpoons A^*$, is excluded. In the same way, transitions into quantum-mechanically metastable states with longer life-times are excluded. This means that fluorescence and phosphorescence are not included among phototropic phenomena. The limitation "thermodynamically unstable" was chosen to differentiate phototropy from photochemical reactions in general. A phototropic process is represented by the transitions

$$A \rightarrow A^* \rightarrow X_i \rightarrow B_i \rightarrow A$$

in Scheme (b). In many examples of phototropy, photochemical reactions with formation of Y compete with the reversible reaction leading from $B_i$ back to A; in these the equilibrium lies well towards Y, *i.e.* favors the thermodynamically stable or metastable states. It follows that "irreversible" photochemical reactions can emanate from phototropic states B. As a result, phototropic processes are also of interest in industrial technology.

The occurrence of this phenomenon of phototropy makes it possible to investigate the mechanism of the photochemical reactions which cause fading when dyes are exposed to light. Phototropic dyes in which the reverse reaction to reform A is slow are usually considered to be fugitive and undesirable. On the other hand, short-lived phototropic states may even enhance the light-fastness of dyes by stepwise transformation of their excitation energies. Fluorescence is associated with a relatively long life of A* (cf. the high dipol moments of A*), and many fluorescent dyestuffs are fugitive. Thus, when A* is chemically reactive, shortening of its life-time is desirable. Insofar as phototropy reduces the life-time of A*, and B does not give rise to additional "irreversible" transitions to Y, it may under certain conditions enhance light-fastness.

The definition of phototropy cannot be very precise. In particular, close distinction between $X_i$ and $B_i$ in Scheme (b) cannot be made. As in Scheme (a), the sensitivity of the method of measurement adopted will determine whether a substance is recognized as phototropic or not. The life-time of B again plays a decisive part. Phototropic reactions with life-times of milliseconds can be detected by means of flash spectroscopy [3a]; at the other extreme, reactions with half-lives of several days are known [3b].

Two examples will serve to illustrate the most important phototropic phenomena.

## II. The Phototropy of Parafuchsin

Following the work of *Frankenburger*, *Hammerschmidt*, *Heyde*, and *Zimmermann* [8–10], the old IG-Farbenindustrie works in Ludwigshafen developed an ultraviolet dosimeter. This instrument was based on the phototropic behavior of triphenylmethane dyes; changes in the dyestuff solutions were measured by comparison with suitable filters under standard conditions. Such dosimeters were successfully used for some years to measure atmospheric ultraviolet radiation [4]. *Lifschitz* [5] and *Holmes* [6,6a] proposed the reaction scheme *(1)* ⇌ *(2)* for the phototropy of alcoholic

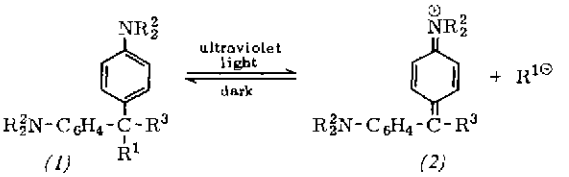


Table 1. Substituents of compounds *(1)* and *(2)*.

| $R^1$ | $R^2$ | $R^3$ | Compound |
|---|---|---|---|
| CN | H | $p$-$C_6H_4$—$NR^2_2$ | Pararosaniline; Parafuchsin (pararosaniline hydrochloride) |
| OH, CN | $CH_3$ | $C_6H_5$; $p$-$C_6H_4$—$NR^2_2$ | Crystal violet; Malachite green |
| CN | $CH_3$ | 4-$C_{10}H_6$-1-NH-$C_6H_5$ | Victoria blue (for T > 35 °C) |

solutions of triphenylmethane dyes, for ions were detected by conductivity and e.m.f. measurements on exposed and unexposed solutions [5,7].

[**] In biology, the term "phototropism" denotes "growth movement under the effect of light". For this reason, it would be better to designate the reversbile photochemical changes as photochromism, an expression common in German terminology. Nevertheless, in the present article, the English term "phototropy" is used throughout. Phototropic and photochromic processes are thus synonymous. It is also possible to use the term "phototropy" in the generic sense, and to limit "photochromism" to the sub-group involving visible color changes.

[3a] For example: *R. Livingston* and *V. A. Ryan*, J. Amer. chem. Soc. *75*, 2176 (1953).

[3b] *H. Waibel*, Melliand Textilber. *36*, 737 (1955).

[4] *H. Israel-Köhler*, Meteorol. Z. *54*, 138 (1937); *L. Schulz*, ibid. *52*, 266 (1935); *F. W. P. Götz*, ibid. *54*, 189 (1937); *H. Ungeheuer*, Bioklim. Beiblätter 66 (1935).

[5] *S. Lifschitz* and *Ch. L. Joffé*, Z. physik. Chem. *97*, 426 (1921); *S. Lifschitz* and *G. Girbes*, Ber. dtsch. chem. Ges. *61*, 1463 (1928); *S. Lifschitz*, ibid. *52*, 1919 (1919); *58*, 2434 (1925).

[6] *E. O. Holmes*, J. Amer. chem. Soc. *44*, 1002 (1922).

[6a] *L. Harris*, *J. Kaminsky*, and *R. G. Simard*, J. Amer. chem. Soc. *57*, 1151 (1935).

[7] *V. de Gaouck* and *R. J. W. Le Fèvre*, J. chem. Soc. (London) *1939*, 1457.

According to *Frankenburger, Weyde, Robl, Heyde,* and *Zimmermann* [8–10], the phototropic quantum yield of crystal violet in alcohol is equal to 1, and this value was subsequently found for malachite green as well [6a]. This means that the direct transitions A* → A can be neglected, and that the phototropic transitions A* → B are by far the predominant ones. Addition of water prevents the dark reaction B → A* [11,12]; addition of potassium cyanide accelerates it, but at the same time promotes formation of Y in photochemical reactions [11]. While the forward light reaction A → A* → B is only very slightly temperature-dependent between −6 and +40 °C, the reverse dark reaction B → A is accelerated by a rise in temperature (about fivefold for a temperature increment of 10 °C [11]). The establishment of a stationary concentration of *(2)* depends on the rates of the forward (light) reaction A → B and of the back (dark) reaction B → A, and may take up to one hour, depending on the concentration of dyestuff and the light intensity [8].

Unlike leuco-cyanides, the leuco-sulfites of triphenylmethane dyes are phototropic in aqueous media, and can be used in concentrated solutions [13], *e.g.* parafuchsin leuco-sulfite was used in the dosimeter in the following concentrations [13,14]: $1.235\times10^{-3}$ mole parafuchsin/l; $7.6\times10^{-4}$ mole $K_2S_2O_5$/l; $5.21\times10^{-3}$ mole HCl/l; 1.34 mole KCl/l.

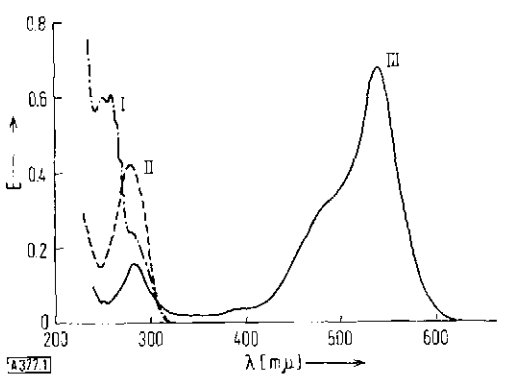

Fig. 1. Absorption spectra (E = optical density) of parafuchsin in aqueous solution at room temperature.

Curve I: c = $1.23\times10^{-3}$ M parafuchsin + $7.6\times10^{-4}$ M $K_2S_2O_5$ + $5.21\times10^{-3}$ M HCl + 1.34 M KCl (c·d = 0.2 [g·cm/l]; d = 0.5 cm).

Curve II: c = $7.6\times10^{-4}$ M $K_2S_2O_5$ + $5.21\times10^{-3}$ M HCl + 1.34 M KCl (d = 0.5 cm).

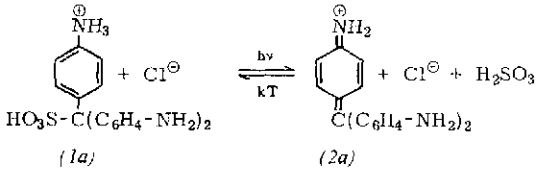
Curve III: c = $1.23\times10^{-6}$ M parafuchsin + $1.0\times10^{-3}$ M HCl + 1.34 M KCl (c·d = 0.008 g·cm/l). The absorption is due to *(2a)*.

The band at 280 mμ of Curve I corresponds to the temperature-dependent absorption of $H_2SO_3$ (see Curve II). Aqueous parafuchsin solutions without $H_2SO_3$ form insoluble products when irradiated with ultraviolet light, but not with visible light.

[8] *E. Weyde* and *W. Frankenburger*, Trans. Faraday Soc. *27*, 561 (1931).

[9] *E. Weyde, W. Frankenburger,* and *W. Zimmermann*, Naturwissenschaften *18*, 206 (1930).

[10] German Pat. 489471 (June 10th, 1927), inventors: *E. Weyde, R. Robl,* and *W. Zimmermann.*



[11] *E. Weyde,* internal report of the IG-Farbenindustrie, Dec. 17th, 1931.

[12] *G. Rößler, W. Zimmermann,* and *E. Weyde,* internal report of the IG-Farbenindustrie, March 26th, 1928

[13] *E. Weyde,* internal report of the IG-Farbenindustrie, Dec. 11th, 1928.

[14] *H. Hammerschmidt* and *W. Frankenburger,* internal report of the IG-Farbenindustrie, Febr. 2nd, 1938.

In aqueous medium, the mechanism *(1a)* ⇌ *(2a)* is suggested [5,6]. Figure 1 shows the spectra of *(1a)* and *(2a)*.

The above parafuchsin solution exhibited strong thermotropic [*] properties, *i.e.* its color changed with temperature (cf. [6]). This phenomenon contributes to clarification of that of photochromism, so that description of some of its properties is pertinent.

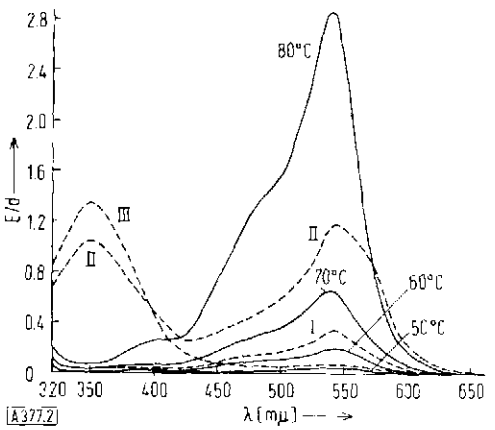


Fig. 2. Thermotropy (continuous curves) and phototropy (dotted curves) of an aqueous parafuchsin solution.

c = $1.23\times10^{-4}$ M parafuchsin + $7.51\times10^{-3}$ M $K_2S_2O_5$ + $5.21\times10^{-3}$ M HCl + 1.34 M KCl.

Curves I, II, and III after short, medium, and long (345 sec) periods of ultraviolet irradiation, respectively.

Figure 2 shows the growth of the absorption band of the quinonoid form *(2a)* of parafuchsin with increasing temperature. The absorption band (maximum at 540 mμ) appears also after brief exposure of *(1a)* to ultraviolet radiation. A further, unidentified absorption band (maximum at about 350 mμ) [**] appears on prolonged irradiation. Reaction Scheme *(b)* should therefore be extended to include further phototropic B-stages, which may be designated as $B_1$, $B_2$, $B_3$, *etc.* In the present case, $B_1$ absorbs at 540 mμ, $B_2$ at 350 mμ.

When unirradiated, heated solutions of *(1a)* are cooled, a new equilibrium concentration of *(2a)* is set up (Curve I in Fig. 3). The rate at which equilibrium is established rises with increasing concentration of $H_2SO_3$, the latter being determined by the amount of $K_2S_2O_5$ added. After brief exposure to light, the intensity of the band due to *(2a)* falls to the value determined by the respective temperature, at a rate similar to that found after heating. The long half-lives for the formation of the phototropically induced states $B_1$ by the

[*] In German, the term "thermochromism" and in English, the term "thermotropy" are generally used.

[**] The shoulder at 570 mμ of the 540 mμ band appears at the site of the parafuchsin absorption in conc. HCl without addition of $H_2SO_3$.

reverse reaction therefore obey general kinetic laws, as is shown by comparison with the thermotropic behavior. The formation of the second phototropic stage $B_2$ by the back reaction proceeds much slower (several hours, cf. Curve IV in Fig. 3). After prolonged irradiation, the dark-phase reverse reaction to reform *(1a)* therefore proceeds via two steps of different rates.

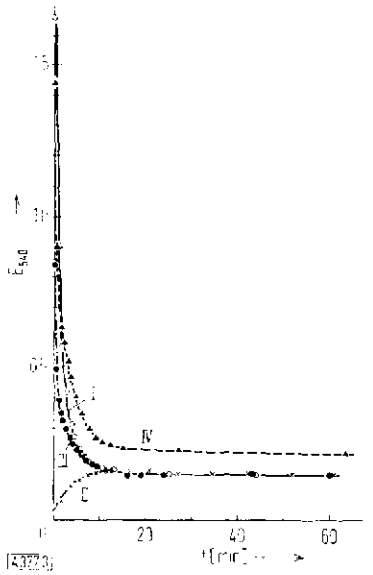

Fig. 3. Thermotropy and phototropy of a parafuchsin solution (solution as in Fig. 1); rate of attainment of equilibrium *(1a)* ⇌ *(1b)*.

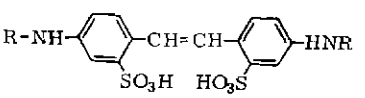
Thermotropy: Curve I: quenching from 80 to 50 °C;
Curve II: heating from 20 to 50 °C.

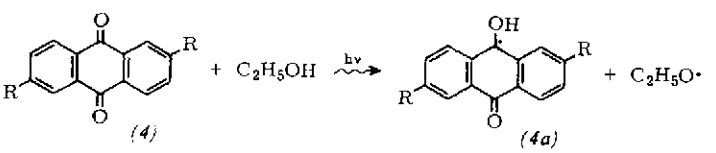
Phototropy: Curve III: dark reverse reaction at 50 °C after ultraviolet irradiation;
Curve IV: dark reverse reaction at 50 °C after ultraviolet irradiation for a longer period than with Curve III.



Phototropic and thermotropic processes in parafuchsin are thus closely allied. In the first case, a shift to the right of the equilibrium A ⇌ B [*(1a)* ⇌ *(2a)*] is produced by exposure to light, in the second, the same shift is produced by a rise in temperature. The dark-phase reverse reaction of *(2a)* proceeds in a kinetically similar fashion in both cases.

Thermodynamically unstable states induced by phototropy may be stable in other regions of temperature. This explains why many substances, *e.g.* spiropyrans [18, 19] and dianthrone [20, 21], exhibit both phototropic and thermotropic behavior [15–22]. *Stobbe*'s postulate that both phenomena must always appear together seems unfounded and is not mandatory [16]. Where thermotropism has been demonstrated, phototropy may be regarded as temporary partial "heating" of individual molecules. For this reason, *Holmes* termed this phenomenon "cold heat" [6].

Acceleration of the dark reaction by rise in temperature has frequently been demonstrated, but the light reaction is understandably little affected by temperature. For this reason, certain substances have a critical temperature at which the dark (back) reaction is as fast as the light (forward) reaction, *i.e.* no phototropy is observed above these threshold temperatures [17,22].



## III. Phototropy of Carbonyl Compounds, Particularly Anthraquinone Dyestuffs

Phototropy has been observed in numerous classes of chemical compounds [17,23–24b]. It is noteworthy that most phototropic organic substances contain carbonyl groups, *e.g.* quinoquinoline hydrochloride [5], 2,3,6,7-tetrachloro-1-oxodihydronaphthalene [5,25], acetanilides [26], fulgides [27], anthraquinone derivatives, thioindigo [28,29], and aminocamphor derivatives [30]. For stilbene derivatives *(3)*, phototropy is known only where R = X–CO– but not where R = H [17,30].

*(3)*

Anthraquinone and its derivatives may serve here as typical examples of carbonyl compounds. *Bellard* and *Cooper* [31] were able to show that on illumination in the presence of disodium anthraquinone-2,6-disulfonate *(4)*, R = $-SO_3Na$, ethyl alcohol is oxidized to acet-

aldehyde and acetic acid. The formation of semiquinone radicals *(4a)* by dehydrogenation of the alcohol is proposed.

*Bridge* and *Porter* were able to detect these semiquinone radicals *(5)* and, in alkaline media, also semiquinone radical ions *(5a)* by flash spectroscopy; both had half-lives of the order of milliseconds [32].

*(5)* *(5a)*

*Dörr* [33] and *Bridge* [34] suggested that the primary step *(6)* ⇌ *(6a)* during excitation of the keto group represents an $n \rightarrow \pi$ transition of a non-bonding n electron from the oxygen's lone electron pairs into an antibonding $\pi$ state. A long time ago, *Schenk* postulated

*(6)* *(6a)*

such diradicals during the primary photochemical reaction of quinones, and termed them phototropically isomeric diradicals [35]. Semiquinone radicals as the primary products in the photoreaction of ketones were also found by *Bäckström* [35a].

$n \rightarrow \pi$ transitions of this type can also be influenced by substituents [33, 34, 36]. Electron donors such as amino or hydroxyl groups impart negative character to the ring system and inhibit the transfer of a free electron from the carbonyl oxygen. In addition, these substituents displace the much more intense $\pi \rightarrow \pi$ bands toward longer wavelengths [33, 34], so that irradiation by light may produce a reduction in the proportion of $n \rightarrow \pi$ transitions. The differences in the action of various anthraquinone derivatives on the photo-oxidation of alcohols are explained in this way. While anthraquinone and its sodium 2-sulfonate, disodium 2,6-disulfonate, and 1-methyl and 1-chloro derivatives are active, the disodium 1,5-disulfonate as well as 2,6-dihydroxyanthraquinone, 2-aminoanthraquinone, and anthracene are inactive [32]. Accordingly, flash spectroscopy showed radicals only in the active group of substances. *Schwab* and *Dörr* [36] similarly found radicals in 2-methyl- and 1-chloroanthraquinone (only a few for 1-hydroxyanthraquinone) but none in 2-amino-, 1-amino-, and 1,5-diaminoanthraquinone. *Dörr* pointed out the parallel occurrence of fiber damage with the appearance of these radicals [36a].

Numerous general properties of phototropic substances can be demonstrated using a solution of anthraquinone in dioxane. On exposure to light, a pale-yellow substance is formed, with an absorption maximum at 373 mμ (Fig. 4), which slowly disappears again in the dark (Fig. 5). This phototropically induced absorption band is substantially similar to the absorption band of the leuco-form (Fig. 4). The reverse reaction in the dark

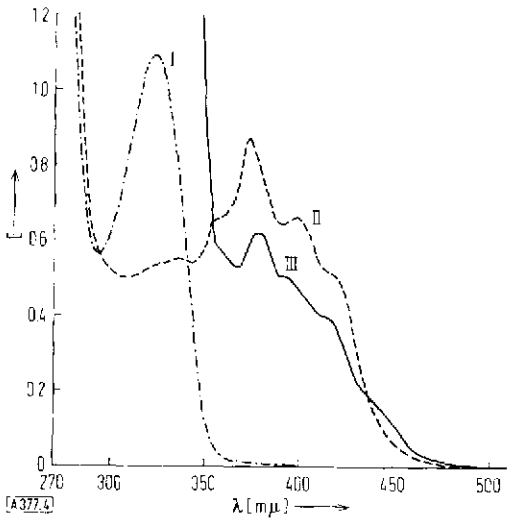

Fig. 4. Absorption spectra of anthraquinone solutions at room temperature.

Curve III: ether extract of an anthraquinone vat.

depends on the oxygen content of the solution. As in many phototropic reactions, the reverse process is accelerated with rising temperature (Fig. 5). A second photo-product is formed from the primary photo-product of the reaction, being characterized by its substantially slower reverse reaction. For this reason, the plot of the concentration of the primary product (the leuco-form), against the time of irradiation passes through a maximum.

When intermittent irradiation is used, a "stationary" terminal value is slowly established, which falls off only slightly during the dark reaction. Under these conditions of irradiation, the kinetics of the photo-

chemical reaction depend on the duration of the light and dark periods. Light-fastness is therefore a function of the irradiation conditions. Figure 6 shows the behavior of 2-aminoanthraquinone as an example. The

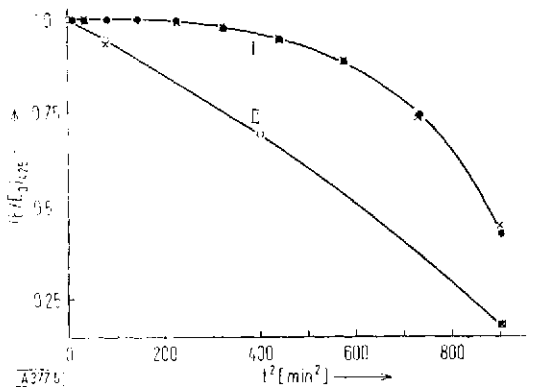

Fig. 6. 2-Aminoanthraquinone in dioxane at 30 °C. Disappearance of the long-wave extinction maximum (425 mμ) on intermittent ultraviolet irradiation (dark period = 2 min).
Curves I and II: light intervals 3 and 10 min.

importance of the dark reaction is well-known from the assimilation of $CO_2$ by plants. The promotion of plant growth by intermittent illumination may be as efficient as that obtained with continuous exposure to light [36b].

The influence of substituents and the surrounding medium on the light reaction can be readily demonstrated using the aminoanthraquinone derivatives. When the primary step leads to the formation of a phototropic diradical as formulated by *Dörr* and *Bridge*, inhibition of the photochemical reaction is to be expected if there is hydrogen bonding at the lone electron pair of the carbonyl oxygen [34]. In dioxane, the light reaction of 2-aminoanthraquinone does indeed proceed more rapidly than that of 1-aminoanthraquinone, but the rates become equally slow when 20 % water is added to the dioxane. The *N*-benzoylamino derivatives behave in the same way as the free amines (cf. Fig. 7).

Since it often happens in solution that the activated electron rapidly attains the potential minimum of the excited state, phototropy might be expected to be in-

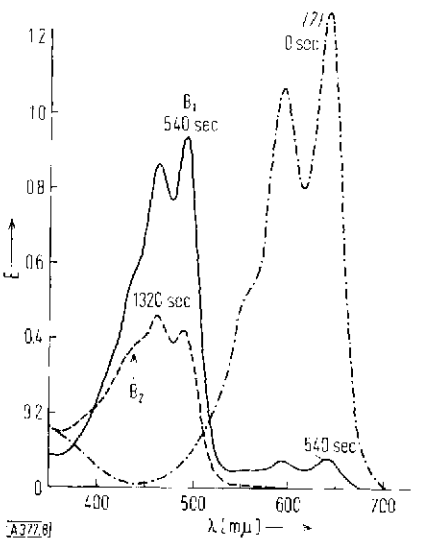
dependent of the wavelength of the irradiation absorbed. However, *N,N'*-dimethyl-1,4-diaminoanthraquinone *(7)* is an exception. *Dörr* suspected that only

*(7)*

irradiation in the n → π band wavelengths (which are normally at about 250–350 mμ) leads to photochemical reactions. Figure 8 shows the long-wave absorption band (maxima at 595 and 640 mμ) and the long-wave shoulder of the ultraviolet band of *(7)*. No evidence of



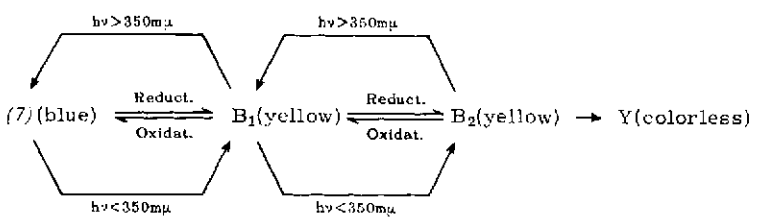


Fig. 8. Absorption band of *N,N'*-dimethyl-1,4-diaminoanthraquinone and phototropically induced bands $B_1$ and $B_2$ after 0, 540, and 1320 sec of ultraviolet irradiation in absolute ethanol.

a photochemical reaction was found on irradiation of *(7)* for 20 min at the long-wave absorption band (using a mercury immersion lamp with a ferric sulfate ultraviolet filter which absorbs strongly below 400 mμ). The reaction proceeded immediately on removal of the filter.

Irradiation of *N,N'*-dimethyl-1,4-diaminoanthraquinone in the absence of oxygen obeys the following complex reaction scheme:

$B_1$ is formed on irradiation with ultraviolett light, and $B_2$ appears after prolonged exposure (cf. Fig. 8). In the dark, *(7)* is reformed after some hours, the rate depending on the temperature and the amount of oxygen present. $B_1$ is identical with the first reduction product obtained with zinc dust in glacial acetic acid and is soluble in water, alcohol, and most organic solvents. On

prolonged reduction or heating of the reaction solution, $B_2$ is formed (Fig. 9). In air, $B_1$ is rapidly, and $B_2$ slowly, oxidized back to the original dye *(7)*. When illuminated, $B_2$ is fairly quickly transformed back into *(7)* via $B_1$ (Fig. 10), but on prolonged irradiation with ultraviolet light, decomposition of *(7)* takes place.

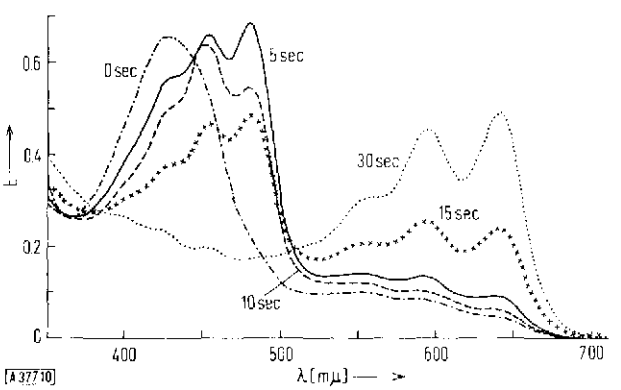

Fig. 10. The reaction $B_2 \rightarrow$ *(7)* in ultraviolet light. $B_2$ was obtained by reduction with Zn/glacial acetic acid in glacial acetic acid at room temperature.

Figure 11 shows the chronological steps involving $B_2$, $B_1$, and *(7)* when $B_2$ is irradiated.

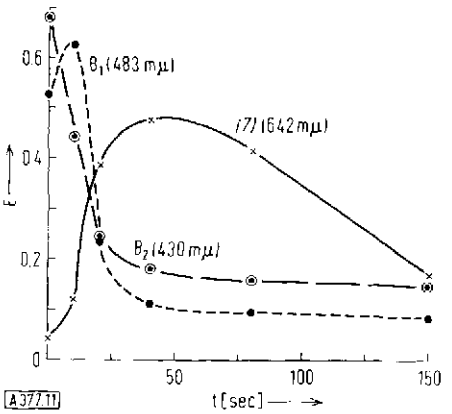

Fig. 11. The reaction $B_2 \rightarrow$ *(7)* accelerated by ultraviolet irradiation; in ethanol. $B_2$ was obtained by reduction with Zn/glacial acetic acid. The extinctions for $B_2$, $B_1$, and *(7)* were recorded for each respective maximum (cf. Fig. 8).

It is clear that the reverse reaction leading to reformation of *(7)* proceeds via the yellow stage $B_1$. When $B_2$ is illuminated with visible light only, *(7)* is reformed quantitatively and does not decompose, but in the absence of an ultraviolet filter *(7)* is formed again first and is then transformed into $B_1$ and the other stages by the ultraviolet light.

An interesting photochemical cycle is thereby established: the reduced stages $B_1$ and $B_2$ are oxidized to *(7)* by light of long wavelength, and are reduced again by light of short wavelength, part being transformed into a colorless substance Y, which has not yet been closely examined. Formation of phthalic acid as end-product via the diimine of *(7)* has occasionally been postulated. According to *Quinkert*, saturated cyclic ketones split to give high yields of carboxylic acids [37] on exposure to ultraviolet light.

The same reactions take place in dioxane, tetrahydrofuran, and dimethylformamide, but at different rates. An example of the effect of the medium on the rate of the light reaction of *(7)* is shown in Figure 12; in one experiment *(7)* was dissolved in alcohol and in the other dyed onto polyamide (on polyester the reaction is even slower than on polyamide).

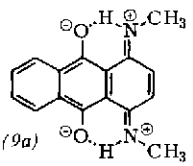
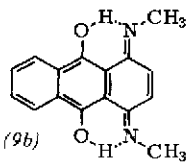
Work on the interpretation of the nature of the intermediates $B_1$ and $B_2$ is not yet complete [*]. In contrast to the photochemical products of anthraquinone, this product is not the leuco-form of *(7)*, whose absorption spectrum is shown in Figure 9, Curve V. Structures *(8a)* or *(8b)* were proposed for the leuco-form of anthraquinone derivatives with proton-donating substituents at the 1- and 4-positions [39–41].



*(8a)*



*(8b)*

With the aid of the polarographic half-wave potentials of *(7)* in a 0.1 M LiCl solution in 30 % water/70 % ethanol, it was shown that in the first stage of the reaction, one electron and one proton are taken up. On electrolysis under the same conditions in ethanol, *(7)* exhibits a spectrum identical with that of $B_1$, whereas on electrolysis in aprotic solvents such as acetone or acetonitrile, it gives rise to a long-lived free radical whose electron resonance spectrum exhibits a simple band (half-width ~ 12 gauss) with no fine structure. This radical has an absorption band with a simple maximum at 540 mμ (Curve VI of Fig. 9). According to *Dörr* and *Schwab* [36], its spectrum is similar to that of 1-chloroanthraquinone. It is probable that a semiquinone radical *(7)*-H· is involved, which reacts further in protonic solvents to form $B_1$. *Moran* and *Stonehill* postulated the formation of anthranone from the photoreactions of anthraquinone derivatives [38]. In the case of 1,4-bis-*N*-benzoylaminohydroquinone, *Coffey* [39] prefers the oxanthrone form to the anthrahydroquinone form, in contrast to the results with anthraquinone [42]. 1,4-Diamino-1-(*N*-methylamino)anthraquinone and 2-(*N*-methylamino)anthraquinone behave similarly on exposure to light. In these derivatives, as well as in *(7)*, the enolic forms *(9a)* or *(9b)* participate, so that their related behaviors, which differ

*(9a)*

*(9b)*

from that of anthroquinone, become plausible. *Couper* [43] concluded that successive decomposition of the methylamino groups occurs in *(7)* dyed on acetate. In our method, such reactions occurred to only a very slight extent. The same author found a yellow substance in solutions in ethyl acetate after the latter had been exposed to light, but this could not be detected on acetate fibers. *Couper* had previously suggested that a reduction step was involved and that the effect of light on the fiber and the solution leads to different decomposition products.

The results obtained with *(7)* may be summarized briefly as follows: the compound is stable in visible light but phototropic on exposure to ultraviolet light. When oxygen is excluded, *(7)* is ultimately reduced in two stages to a stable colorless substance. The "damage" caused by ultraviolet irradiation when *(7)* is transformed into $B_1$ and $B_2$ can generally be reversed by irradiation in its absorption band in the visible region, or the reverse reaction (oxidation) can be speeded up. This behavior was also observed in, for example, 2,2,6,7-tetrachloro-1-oxodihydronaphthalene, fulgides, stilbenes [44], anils [44], spiranes [45], *etc.* [24a, 25, 46 to 49].

Cellulose nitrate films undergo yellowing – presumably because of traces of impurities they contain – when irradiated by short-wavelength light ($\lambda < 300$ mμ), but are bleached again [50] by radiation of longer wavelength (300 mμ $< \lambda <$ 450 mμ). Aminoazo dyestuffs dyed on acetate are reported to exhibit the rare phenomenon of phototropy produced by longer-wavelength radiation ($\lambda = 400$ mμ); shorter-wavelength energy ($\lambda = 350$ mμ) has no effect, even though light of both spectral regions is absorbed to approximately the same extent [50]. It is probably not incorrect to assume a similar dependence on the wavelength of the radiation to explain the "irreversible" decolorization of dyes by light, although little information on this topic has so far been reported. As early as 1919, *Perrin* collected these observations in a general reaction scheme [50a]:

$$A_1 + h\nu_1 \rightleftharpoons A_2 + h\nu_2$$

The above behavior therefore effectively amounts to phototropically induced secondary phototropy, which may enhance the fastness of dyestuffs. For the frequency $\nu_1$ of most primary phototropy effects studied so far, $\nu_1 > \nu_2$. The absorption band induced by primary phototropy has generally a longer wavelength than that of the original compound. Our observations of a short-wave induced band of *N,N'*-dimethyl-1,4-diaminoanthraquinone *(7)* represent a rare exception. *Hirshberg* [19] found that for spiropyrans, $\nu_2$ does not lie in the region of the induced absorption band of long wavelength, but in the region of the long-wave ultraviolet band used as the source of radiation.

## IV. Phototropy of Miscellaneous Compounds

Several hundred phototropic substances have now been discovered, but indications of the type of structures necessary for phototropy are not yet available. So far, the mechanism of phototropy has been completely explained for only a few compounds. Early purely chemical investigations on phototropic solids brought little information and failed largely because the phototropically induced substance is present in only small amounts.

[*] It seemed more important to us to demonstrate the basic principles of phototropy with the aid of model experiments.

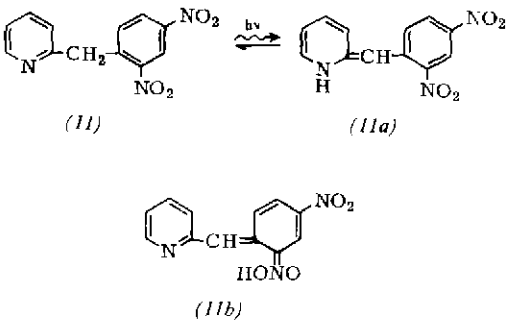
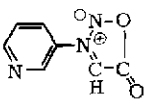
In addition to transformations into quinonoid structures, *e.g.* in triphenylmethane dyes and camphor derivatives [51], we have mentioned induced reduction and oxidation processes. Phototropically induced isomerizations have also often been reported. Phototropic transformations from the more stable *trans*- into the less stable *cis*-form were studied by *Brode* and *Wyman* using thioindigo and hydroxyazo dyes [52]. Other phototropic *trans-cis* transformations were studied by *Klotz* and *Horowitz* [53] and by *Hartley* [53a]. The back reactions in these *trans-cis* rearrangements are kinetically of first order with respect to the phototropic substances [50, 53], while the back reactions of other phototropic systems may be of second order [53b].



In model experiments designed to interpret the mechanism of vision, *Yoshizawa* and *Wald* [53c] found a phototropic reaction of rhodopsin to form *all-trans*-vitamin A-aldehyde + opsin. Secondary phototropy can cause 11-*cis*-vitamin A-aldehyde and opsin to be reformed, and these then recombine to form rhodopsin. *Gaouck* and *Le Fèvre* proposed the reaction scheme *(10a)* ⇌ *(10b)* [7] for the phototropy of anils, which occurs only in their solid form and which is considered

*(10a)* *(10b)*



to involve exchange of protons between adjacent molecules. The two forms appear isomorphous on X-ray analysis. If the hydroxyl group in *(10a)* is methylated, phototropy is no longer observed. *Cohen*, *Hirshberg*, and *Schmidt* [54, 54a] observed phototropy of anils in "rigid solvents" and therefore suspect intramolecular proton transitions. In polar solvents, the phototropically induced form *(10b)* occurs in the dark, but in paraffin oil it appears only on exposure to radiation.

For 2-(2′,4′-dinitrobenzyl)pyridine *(11)*, a phototropic mechanism to form *(11a)* or *(11b)* is proposed [55]: *(11)* adsorbed on NaCl exhibits the same phototropic changes into *(11a)* or *(11b)*, but *(11)* adsorbed on MgO does not [55a].

*(11)* *(11a)* *(11b)*

In the case of spiranes [45] and spiropyrans [56, 57], the formation of phototropically induced isomers by opening of the ring has been reported. Phototropically induced free radicals from anthraquinone derivatives have been mentioned above; free radicals have been detected by electron-spin resonance in the phototropic reactions of solid *N*-3′-pyridylsydnone *(12)* [58, 59] and

*(12)*

of an imidazole derivative [60]. Oxygen-free methanolic solutions of chlorophyll also exhibit phototropy with the formation of free radicals [61] [*]. Formation of radicals is also postulated on exposure of malachite green leuco-cyanide in cyclohexane to light [62]. According to *Feichtmayr* and *Scheibe* [63], naphthoxy-radicals arise by phototropy of 2,3,6,7-tetrachloro-1-oxodihydronaphthalene. Phototropically induced free radicals or triplet states have been detected by their paramagnetism [64], but they do not always arise [58].

Some substances are phototropic only in the crystalline state or in the form of a particular modification, *e.g.* 2,3,6,7-tetrachloro-1-oxodihydronaphthalene [65]. Where pleochroism is present, *i.e.* where the absorption depends on the crystal's orientation, phototropic behavior may also be anisotropic and apparently reinforces the pleochroism.

[*] Phototropy can play a role in biochemistry (cf. the postulates concerning the mechanism of vision. During natural growth processes, hydrogen bonds must be opened and closed. Keto-enol tautomerism of the anils [7] indicates that phototropy may be capable of effecting this (cf. also [61a]).

The first inorganic substance found to be phototropic was lithopone ZnS, which exhibits this phenomenon in the presence of moisture and oxygen; generally, such substances are solids [66]. Solutions of certain inorganic substances also exhibit phototropy [67].

Sensitized phototropy was observed in aqueous potassium ferrocyanide solutions to which phenolphthalein had been added. Here reversible color changes take place on exposure to light [68]. It is noteworthy that, as for phosphorescence, traces of activators may be responsible for the manifestation of phototropy by inorganic substances [67]. An example of this type in organic chemistry is acetanilide-*p*-disulfoxide, in which phototropy appears only in the presence of 0.1–1.0 % 1-acetanilide-*p*-disulfide [69].

Vat dyes can acquire phototropic properties by aftertreatment on the fiber, *e.g.* after impregnation [70]. The dark reverse reactions of phototropic dyes on dyed fibers may take several days to reach completion [70].

Phototropy thus plays a part both in the light-fastness of dyes and in biochemical processes. *Hirshberg* [19] has recommended the use of phototropic dyes with short-wave induced primary phototropy that is extinguished by long-wave induced secondary phototropy as high-speed memory elements for computers. Phototropic dyes have also been proposed as light filters which adapt themselves to match any given light intensity [24b], and phototropically formed dyestuff radicals may be employed as polymerization initiators [71].

The known behavior of phototropic systems can be summarized by the qualitative energy diagram shown in Figure 13; kT with an arrow pointing downwards denotes an exothermic process, one pointing upwards an endothermic process or one requiring an activation energy. On absorption of light by a species A, an activated quantum-mechanically unstable or metastable

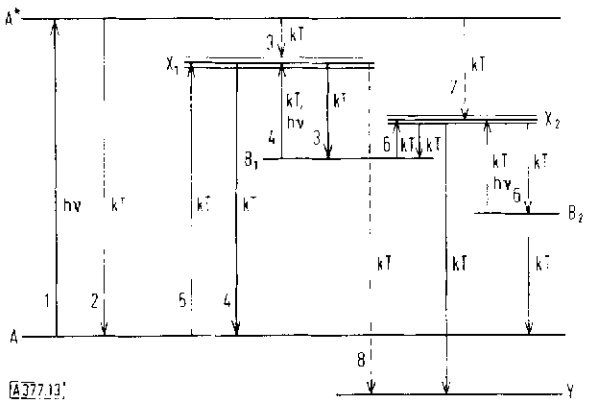

Fig. 13. Qualitative energy diagram for phototropic and photochemical processes.

state A* is produced (Process 1); A* can return to state A by giving off thermal energy (Process 2). If phototropy is involved, transformation into a quantum-mechanically stable but thermodynamically unstable state $B_1$ occurs via an intermediate state X (Process 3). Little is known about the positions and number of the intermediate states $X_1$ and $X_2$. The phototropically induced state $B_1$ can be transformed back into state A (Process 4) either thermally by using an activation energy, or by secondary phototropy using light energy. Here again the reaction proceeds via a largely unknown state $X_1$. At high temperatures, more molecules with adequate thermal energy kT are available, so that the reverse reaction $B_1 \rightarrow X_1 \rightarrow A$ (Process 4) is accelerated.

Again, at high temperatures, more molecules with higher thermal energies are available in the starting state A and thus more molecules can attain the state $B_1$ via $X_1$ by thermal means. The thermal equilibrium $A \rightleftharpoons B_1$ is consequently displaced towards $B_1$. When $B_1$ can be identified optically, this process is described as thermotropy or thermochromism (Process 5). Under certain conditions, adsorption causes the state $B_1$ to become energetically more favorable than state A; such a process is termed metachromatism [72]. Sometimes various unstable states $B_2$, $B_3$, *etc.*, can exist; $B_2$ may then be reached via $B_1$ (Process 6) or directly via A* (Process 7). Transformation of $B_2$ back into A may occur directly via $X_2$ or via $B_1$ and $X_1$. In addition to the phototropic and thermotropic states $B_1$, $B_2$, *etc.*, an end-product Y, which is energetically more favorable than A, may be formed directly by photochemical reactions from all the intermediate states. Naturally, here too normal, thermally activated chemical reactions leading to Y via any of the intermediate states X (Paths 5–8) are possible. The fact that the light-induced deterioration of dyes frequently occurs with rather low quantum yields probably means that here the intermediate state X in the reaction A* →X→Y is energetically higher than A*. A physical interpretation of this phenomenon would be that, although the excited molecule is high in energy, the more polar structures, which are necessary for the reaction with neighboring molecules, are in a rather deep potential well owing to Coulomb forces.

The relative positions of the levels in the above purely qualitative and heuristic energy scheme (Fig. 13) can of course vary from system to system. We found the energy difference between A and $B_1$ for parafuchsin-$H_2SO_3$ to be about 30 kcal/mole. For the activation $A \rightarrow A^*$ in the absorption maximum, a value $h\nu \cdot N_L$ = 105 kcal/mole is required, so that the transformation $A^* \rightarrow X_1 \rightarrow B_1$ liberates about 75 kcal/mole.

For the phototropic *cis-trans* rearrangement of 4-(*p*-dimethylaminobenzazo)phenylmercury(II) acetate, $\Delta F$ was found to be 22.5 kcal/mole, and $\Delta H$ = 19.6 kcal/mole [53]. $\Delta H$ for the phototropy of a 2,4,5-triphenylimidazole derivative was given as 5 kcal/mole, and the

activation energy for $B_1 \rightarrow X_1$ as 14 kcal/mole [73]. The activation energy for the dark reverse reaction of salicylidene-*m*-toluidine was found to be 25 kcal/mole [73], and that for the phototropic *cis-trans* rearrangement of the methinecyanines was 8 kcal/mole [74].

## V. Closing Remarks

In 1899, in the first publication dealing with phototropy, *Marckwald* concluded that "the action of light described here is a purely physical phenomenon; my reason for describing it is to encourage, physicists to investigate the matter further". In 1929, *Chalkley* [17] declined to differentiate between purely physical or chemical explanations for phototropy.

Today it is clear that phototropy mostly represents transformations into thermodynamically unstable, chemically still partly unknown states of molecules. Owing to the revolution in physico-chemical techniques, the study of phototropy has recently received great impetus and may substantially help to clarify the reaction mechanisms of photochemical processes. Its general laws are today fairly well understood; what is still lacking is a larger amount of evidence to help to explain the dependence of the mechanism on chemical constitution. Just as the list of stable atomic nuclei has been complemented by unstable nuclei, photochemistry will enrich the number of thermodynamically stable compounds with thermodynamically unstable species. In 1964, it is therefore reasonable to alter *Marckwald*'s words as follows: "My reason for describing this phenomenon is to encourage chemists to investigate the matter further".

*The authors wish to express their thanks to their colleagues, particularly Mr. W. Ditter, for assistance with the measurements and their evaluation, to Dr. Beck (Ludwigshafen), who carried out the polarographic measurements, and to Dr. Schlag (Ludwigshafen) for the electron spin resonance studies.*

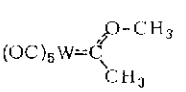
## On the Existence of a Tungsten Carbonyl Carbene Complex

By Prof. Dr. E. O. Fischer and Dipl.-Chem. A. Maasböl

Institut für Anorganische Chemie der Universität München (Germany)

When $W(CO)_6$ is treated with $LiC_6H_5$ in ether under nitrogen, nucleophilic addition takes place without elimination of CO to yield an orange-yellow, water-soluble, diamagnetic anion, which can be precipitated as its tetramethylammonium salt. This orange, finely crystalline derivative has the composition $[N(CH_3)_4][W(CO)_5COC_6H_5]$ and melts at 102.5 °C (decomp.). The anion can be protonated by acids. On attempting to isolate the free "hydride" resulting from acidification by extraction with ether, only $W(CO)_6$ and benzaldehyde were found after removal of solvent from the extract. In dilute solution, the protonated product can be methylated in good yields using diazomethane. After chromatography and sublimation *in vacuo* at 45–50 °C, orange-red, diamagnetic crystals, m.p. 59 °C, which are very soluble in organic media, can be isolated. Analysis and molecular-weight determinations indicate that their composition is $W(CO)_5(COC_6H_5)(CH_3)$.

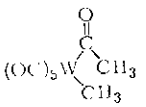
Yellow diamagnetic crystals of $[N(CH_3)_4][W(CO)_5COCH_3]$ m.p. 143 °C, can be obtained in an analogous manner by addition of $LiCH_3$ to $W(CO)_6$ in ether and precipitation of the salt from aqueous solution. On protonation and subsequent methylation with $CH_2N_2$, the anion gives yellow, diamagnetic, volatile $W(CO)_5(COCH_3)(CH_3)$ *(1)*, m.p. 52 °C.



The nature of the bonding of the methyl group introduced into the complex *(1)* by $CH_2N_2$ could not be settled by infrared spectroscopy. The spectrum of $W(CO)_5(COCH_3)(CH_3)$, the compound which has so far been more thoroughly investigated, shows two strong, somewhat broadened bands at 1252 and 1167 $cm^{-1}$ (Nujol/Hostaflon). While the band at 1252 $cm^{-1}$ can be attributed quite plausibly to a C–O single bond, that at 1167 $cm^{-1}$ may be due to either a C O bond or a $CH_3$–W group, as a comparison with the spectrum of $C_5H_5W(CO)_3CH_3$ [1] shows, in which the $\delta(CH_3-W)$ vibration appears at 1179 $cm^{-1}$ [2].

More reliable information on the structure of *(1)* was obtained from comparison of the proton magnetic resonance spectra [3] of $W(CO)_5(COCH_3)(CH_3)$, $C_5H_5W(CO)_3CH_3$, and $C_5H_5W(CO)_3COCH_3$ [4].

| Compound | Chemical shift τ referred to $C_6H_6$ (relative to TMS at τ = 2.88) [ ] = relative intensities Concn.: 1 mmole/ml $C_6H_6$ | |
|---|---|---|
| *(1)* $W(CO)_5(COCH_3)(CH_3)$ | 6.17[3] | 7.69[3] |
| *(2)* $C_5H_5W(CO)_3COCH_3$ | 5.23[5] | 7.50[3] |
| *(3)* $C_5H_5W(CO)_3CH_3$ | 5.45[5] | 9.55[3] |



We assign the peak at τ = 7.69 for *(1)* to the methyl group introduced by $LiCH_3$ addition. If it is assumed that this is present as a W–$COCH_3$ grouping, the value agrees well with that of the peak for the acetyl group bound to tungsten in *(2)* [τ = 7.50]. The fact that the other $CH_3$ proton peak for compound *(1)* occurs at τ = 6.17 and that of a $CH_3$ group bound directly to tungsten only appears at much higher fields, *e.g.* τ = 9.55 for *(3)*, leads to the conclusion that no $CH_3$–W grouping is present in *(1)*.

We believe therefore that a structure such as

may be assumed for $W(CO)_5(COCH_3)(CH_3)$. This corresponds to a "methoxymethylcarbene" bound to $W(CO)_5$ and

would thus represent the first transition-metal complex of a carbene. X-ray investigations currently in progress are expected to show that the alternative structure

does not occur. We are of this opinion because of the evidence already cited and also because of the absence of any characteristic >C=O vibrations in the infrared spectrum between 1500 and 1800 $cm^{-1}$.

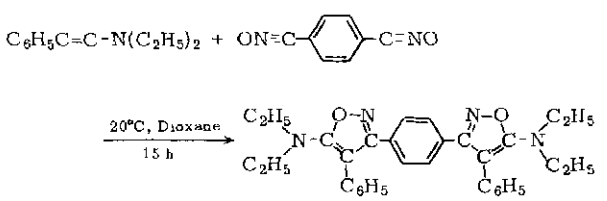
## Addition Reactions of Alkynylamines [1]

By Dr. H. G. Viehe, Dr. R. Fuks, and M. Reinstein [1a]



Union Carbide European Research Associates,
Brussels (Belgium)

Many compounds react with alkynylamines [2] by addition to their nitrogen-polarized triple bond, mostly under very mild conditions. Examples are given in the following equations. The tendency of alkynylamines (which can be considered as intramolecular anhydrides of carboxamides) to combine with water is so strong that they promise to become dehydrating agents of general importance. For example, the formation of anhydrides from carboxylic acids occurs more rapidly with alkynylamines than with dicyclohexylcarbodiimide or ethoxyacetylene.

## The Rearrangement of 9-Azabicyclo[6,1,0]-nonatriene to 4-Azabicyclo[5,2,0]nonatriene

By Dr. S. Masamune and N. T. Castellucci

Mellon Institute, Pittsburgh, Pennsylvania (U.S.A.)

We have investigated the thermal rearrangement of the adduct of ethoxycarbonylnitrene onto cyclooctatetraene.

The generation of ethoxycarbonylnitrene, $C_2H_5OCON$, from *N*-(*p*-nitrobenzenesulfonoxy)urethane and triethylamine [1] in cyclooctatetraene afforded this adduct *(1)* in 35–40 % yield. The NMR spectrum of *(1)* is very similar to that of cyclooctatetraene epoxide [2] and shows a singlet at $\tau = 6.90$ (two allylic protons), a multiplet at $\tau$ -- 3.95–4.15 (six olefinic protons), and signals for an ethyl group. This spectrum and the elemental analysis support the assignment of structure *(1)* to this adduct.

*(1)* *(2)*

Although cyclooctatetraene epoxide is stable at 120 °C for a few hours, adduct *(1)* rearranged readily within 30 minutes at 80 °C to afford an isomer *(2)*, b.p. 65–67 °C/0.07 mm, $\lambda_{max} = 228$ mμ ($\varepsilon = 1.23 \times 10^4$) in isooctane, $\lambda_{max} = 5.81$, 6.02 μ, in chloroform. The NMR spectrum of this isomer exhibited signals at $\tau = 6.23$ (H-4) [*], 4.83 [*] and 5.00 (H-3) [*], 3.77 (sharp singlet, H-5), 3.08 [*] and 3.25 (H-2) [*] in addition to a typical ethyl-group absorption. The spectral evidence permits us to assign structure *(2)* to the rearranged compound. The coupling constants [J(H-4)–(H-5) = 0, J(H-2) (H-3) = 10.5 cps] are in agreement with the stereochemistry expected for this molecule.

The valence-bond rearrangement of *(1)* to *(2)* presents a striking contrast to the thermal behavior of cyclooctatetraene [4], its epoxide [3], and its carbene adducts [5].

## Peptide Syntheses with Alkynylamines [1]

By Dr. R. Buijle and Dr. H. G. Viehe

Union Carbide European Research Associates, Brussels (Belgium)

Alkynylamines are excellent dehydrating agents [2]. One of the reactions which can be readily carried out with these reagents is the synthesis of amides from amines and carboxylic acids. As the following examples show, peptides are obtained in almost quantitative yield by this method.

1. A solution of 1 g of dimethylaminophenylacetylene or dimethylamino-t-butylacetylene in 25 ml of tetrahydrofuran is added at 35–40 °C over 1 h to a solution of 1.27 g of bis-carbobenzoxy-L-cystine and 0.8 g of dimethyl-L-aspartate in 30 ml of tetrahydrofuran. Dimethyl bis-carbobenzoxy-L-cystinyl-bis-L-aspartate, m.p. 82 °C from ether/petroleum ether, is formed in 99 % yield (1.95 g).

2. Under identical conditions, the reaction of 1.50 g of γ-methylcarbobenzoxy-L-glutamate with 0.80 g of dimethyl-L-aspartate gives 2.1 g (97 %) of the corresponding peptide.

Received, May 11th, 1964 [Z 747/578 IE]

## Alkynylamines from Halogenoalkynes and Tertiary Amines

By Dr. H. G. Viehe [1]

Union Carbide European Research Associates, Brussels (Belgium)

and Prof. S. I. Miller and J. I. Dickstein

Illinois Institute of Technology, Chicago, Ill. (U.S.A.)

Until recently, alkynylamines (amino acetylenes) were almost unknown but some have now become readily accessible [3] either via nucleophilic substitution of halogen at the acetylenic triple bond [1] or by elimination of hydrogen halide from suitable halogenated amines [2].

Following the synthesis of dimethylamino-t-butylacetylene *(1)* from t-butylchloroacetylene and trimethylamine, it appeared desirable to determine the structure of the *N*-phenylethynylammonium salts *(2)* [4] obtained in 35 % yield on treating triethylene diamine with phenylhalogenoacetylenes in benzene at room temperature, by analogy to the reaction of halogenoacetylenes with triphenylphosphine [4,5].

$$(CH_3)_3C\text{-}C{\equiv}C\text{-}Cl + 2\ N(CH_3)_3 \longrightarrow (CH_3)_3C\text{-}C{\equiv}C\text{-}N(CH_3)_2 + (CH_3)_4N^{\oplus}Cl^{\ominus}$$

*(1)*

$$C_6H_5\text{-}C{\equiv}C\text{-}Cl + 2\ N\langle\rangle N \longrightarrow C_6H_5\text{-}C{\equiv}C\text{-}N\langle\rangle N\ {}^{\oplus}N\langle\rangle N \quad Cl^{\ominus}$$

*(2)*

$$\xrightarrow{H_2O} C_6H_5\text{-}CH_2\text{-}\overset{O}{\overset{\|}{C}}\text{-}N\langle\rangle N\ {}^{\oplus}N\langle\rangle N \quad Cl^{\ominus}$$

*(3)*

The salt *(2)* which separates out slowly from the benzene solution of the components is very hygroscopic; its triple bond apparently becomes hydrated with formation of *(3)*, for its infrared spectrum subsequently shows an amide band at 6.12 μ. The elemental composition and molecular weight of *(3)* indicate combination of 2 moles of triethylene diamine with 1 mole of phenylchloroacetylene. The NMR spectrum of *(3)* shows a ratio of 5 phenyl protons (–2.6 ppm in relation to $H_2O$) to about 26 alkyl protons (ca. 2 at 0.45 ppm, ca. 16 at 1.1–1.2 ppm, ca. 2 at 1.85 ppm, and ca. 6 at 2.2 ppm).

Quaternary alkynylammonium salts appear to be unstable (like quaternary cyanoammonium salts) and to undergo Hofmann degradation with loss of alkane to yield alkynylamines;

the latter are only weakly basic owing to the electron attraction of the triple bond. The quaternary *N*-alkynylammonium salt which is presumably initially formed from triethylene diamine and phenylchloroacetylene can condense in a subsequent reaction with a further mole of tertiary amine [6] to form *(2)*.

## A New Synthesis of Dibenzo[b,g]-[1,8]-naphthyridones

By Dr. A. K. Mallams [*]

Department of Chemistry, University of the Witwatersrand, Johannesburg (South Africa)

*Dziewoński* and *Dymek* [1] isolated the dibenzo[*b,g*]-[1,8]naphthyridone *(4)* from the mixture of compounds obtained by heating acetanilide with diphenylurea. The present new synthesis gave excellent yields of dibenzo[*b,g*]-[1,8]naphthyridones without any by-products.

When 2 g of ethyl α-(*N,N'*-diphenylguanyl)acetoacetate *(1)* [2] were heated with 20 g of polyphosphoric acid at 140 °C for 1 h, a 94 % yield of 11-methyldibenzo[*b,g*]-[1,8]naphthyrid-12(5*H*)-one *(3)* was obtained as yellow needles from aqueous acetic acid, m.p. 304–308 °C (decomp.). The use of smaller amounts of polyphosphoric acid gave lower yields of *(3)*. The latter was insoluble in hot dilute alkali but soluble in hot mineral acids. Ethanolic solutions of *(3)* exhibit yellow-green fluorescence.

*(1)*: $R^1 = CH_3CO$
*(2)*: $R^1 = COOC_2H_5$

*(3)*: $R^2 = CH_3$
*(4)*: $R^2 = OH$
*(7)*: $R^2 = Cl$

*(5)*: $R^2 = OH$
*(6)*: $R^2 = Cl$

When 2 g of ethyl *N,N'*-diphenylguanylmalonate *(2)* [2,3] were heated with 20 g of polyphosphoric acid at 140 °C for 1 h, a quantitative yield of 11-hydroxydibenzo[*b,g*]-[1,8]-naphthyrid-12(5*H*)-one *(4)* was obtained as yellow needles from acetic acid, m.p. > 400 °C. Smaller amounts of polyphosphoric acid (10 g) resulted in lower yields of *(4)*. When the reaction was stopped after 20 min by pouring the reaction mixture into 80 ml of cold water, the insoluble product *(4)* was obtained in 20 % yield. Neutralization of the acidic filtrate gave a 35 % yield of ethyl 4-hydroxy-2-phenylaminoquinoline-3-carboxylate *(5)* as pale yellow needles from dilute ethanol, m.p. 185–187 °C.

Treatment of 0.2 g of *(5)* with 2 g of polyphosphoric acid at 140 °C for 1 h afforded a quantitative yield of *(4)*.

Ethyl 4-chloro-2-phenylaminoquinoline-3-carboxylate *(6)* was prepared in 94 % yield by refluxing 0.1 g of *(5)* with 2 ml of redistilled phosphorus oxychloride for 10 min; colorless needles from dilute ethanol, m.p. 62–63 °C.

11-Chlorodibenzol[*b,g*]-1,8]naphthyrid-12(5*H*)-one *(7)* was obtained analogously in 65 % yield on refluxing 0.1 g of *(4)* with 6 ml of redistilled phosphorus oxychloride for 3 h; pale yellow needles from ethanol, m.p. > 400 °C.

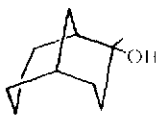
## Bicyclo[3,3,1]nonan-2-ol from 4-Cyclooctenylmethyl Toluenesulfonate

By Doz. Dr. M. Hanack and Dipl.-Chem. W. Kaiser



Chemisches Institut der Universität Tübingen (Germany)

2-Acetoxybicyclo[3,2,1]octane is formed by acetolysis of 3-cycloheptenylmethyl *p*-bromobenzenesulfonate [1]. 4-Cyclooctenylmethyl derivatives also give rise to bicyclic reaction products by transanular participation of the double bond during solvolysis.

4-Cyclooctenylmethanol (m.p. of *p*-nitrobenzoate 52–53 °C) is readily obtained from 4-cyclooctenecarboxylic acid [2]. The alcohol was converted into the tosylate *(1)* (Tos = $SO_2C_6H_4CH_3$), m.p. 29–30 °C, which was solvolysed at 60 °C for 48 hours in glacial acetic acid plus sodium acetate. The acetate obtained was reduced with $LiAlH_4$ to give some unidentified hydrocarbons and 60 % of an alcohol fraction which consisted predominantly of bicyclo[3,3,1]nonan-2-ol *(2)* [3]. Oxidation of the alcohol gave bicyclo[3,3,1]nonan-2-one [3,4] plus 18 % of another ketone, presumably bicyclo-[4,2,1]nonan-2-one. The participation of the double bond is

*(1)*

*(2)*

also shown by the rate of acetolysis of *(1)*. The reaction proceeds fifty times as fast as acetolysis of cyclooctanylmethyl toluenesulfonate.

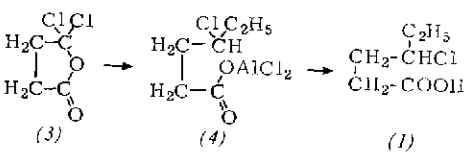
## Conversion of Succinyl Dichloride into γ-Chlorocaproic Acid

By Dr. H. Reinheckel

Institut für Fettchemie der Deutschen Akademie der Wissenschaften, Berlin-Adlershof (Germany)



The dichlorides of higher α,ω-dicarboxylic acids are alkylated by $Al_2(C_2H_5)_3Cl_3$ to give diketones [1], by analogy to the reaction of the ω-carbonyl chlorides of carboxylic esters or of normal acyl chlorides. However, succinyl dichloride reacts in a different manner, as it yields only traces of octane-3,6-dione *(2)*, being mainly converted into γ-chlorocaproic acid *(1)*. This product is formed by alkylation and reduction of one carbonyl group, the second carbonyl group remaining unchanged.

The yield of *(1)* depends on the reaction conditions. Ethane is evolved as a by-product; ethylene is formed only in small amounts.

$$ClCO-(CH_2)_2-COCl \rightarrow \underset{\underset{Cl}{|}}{C_2H_5-CH-(CH_2)_2-COOH} + C_2H_5-CO-(CH_2)_2-CO-C_2H_5$$

*(1)*, 50–75 % *(2)*, 3–5 %

The reaction must start from the unsymmetrical cyclic form of succinyl dichloride, *viz.* γ,γ-dichloro-γ-butyrolactone *(3)*. One of the two carboxyl groups is converted into the aluminum salt *(4)* which cannot react further, even in the presence of a large excess of the ethylaluminum compound.

*(3)* *(4)* *(1)*

Under the same conditions, γ-chlorocaproyl chloride reacts in the normal way to give 6-chloro-3-octanone.

Reducing properties of ethylaluminum compounds other than dialkylaluminum hydrides are known only for triisobutylaluminum [2]. Triethylaluminium only rarely shows any reducing effects [2, 3]. Halogenated hydrocarbons [4] or ketones [5] can be reduced by triethylaluminum and, to a small extent, by diethylaluminum chloride. The reaction described here is, as far as we are aware, the first example of the reducing effect of $Al_2(C_2H_5)_3Cl_3$ on organic compounds in stoichiometric proportions.

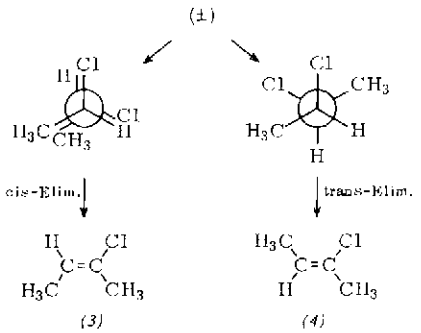
## Elimination of HCl from Gaseous 2,3-Dichlorobutane on $CaCl_2$, CaO, and $Al_2O_3$ [1, 2]

By Priv.-Doz. Dr. H. Noller, Dipl.-Phys. H. Hantsche, and Dr. P. Andréu



Physikalisch-Chemisches Institut der Universität München (Germany)

Compounds incorporating two asymmetric carbon atoms offer a possibility of deciding whether the atoms eliminated in elimination reactions are removed from *cis*- or *trans*-positions. In the elimination of HCl from 2,3-dichlorobutane, *cis*-elimination must give rise to *trans*-2-chloro-2-butene *(1)* from the *meso*-form, *trans*-elimination to *cis*-2-chloro-2-butene *(2)*.

*(1)* *(2)*

With the (±)-form, *i.e.* the racemate, *cis*-elimination yields the *cis*-olefins *(3)*, while *trans*-elimination yields the *trans*-olefin *(4)*.

*(3)* *(4)*

By varying the time of contact with the catalyst, it could be demonstrated that the above olefins are primary products, *i.e.* they do not arise by isomerizations under the experimental conditions.

Surprisingly, on $CaCl_2$ or CaO, the *meso*- and (±)-forms both afford the same ratio of *trans*-: *cis*-olefin (cf. Table).

| Catalyst | *trans*-2-Chloro-2-butene: *cis*-2-chloro-2-butene | | Temp. [°C] |
|---|---|---|---|
| | from *meso*-form | from (±)-form | |
| $CaCl_2$ | 4.4 | 4.4 | 188 |
| CaO | 1.95 | 2.0 | 217 |
| $Al_2O_3$ (basic) | 1.2 | 3.3 | 216 |
| $Al_2O_3$ (acidic) | 0.52 | 21 | 177 |

This agreement between the *meso*- and (±)-forms is maintained over the entire temperature range (170–350 °C) examined. With increasing temperature, there is merely a diminishing preponderance of the *trans*-olefin.

These results can be accounted for if a two-stage mechanism is envisaged. The carbonium ion formed as an intermediate possesses free rotation, a fact that was hardly to be predicted. Its lifetime is apparently longer than the time required for several rotations.

With $Al_2O_3$, on the other hand, the elimination proceeds in part stereospecifically (cf. Table), *i.e.* surprisingly in favor of *trans*-elimination. The lifetime of the carbonium ion relative to the time required per rotation is thus smaller on $Al_2O_3$ than on CaO or $CaCl_2$, being apparently of the order of magnitude of one rotation on $Al_2O_3$, so that the initial configuration retains an influence on the nature of the products. With increasing temperature, the stereospecificity diminishes.

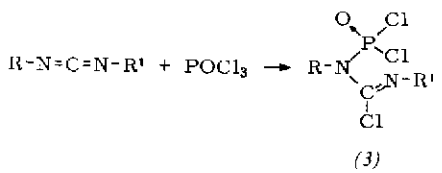
## 2-Phospha-1,3-diazetidinones, a New Class of Compounds

By Dr. H. Ulrich and Dr. A. A. R. Sayigh

The Carwin Co., Division of The Upjohn Company, North Haven, Conn. (U.S.A.)

The reaction of 1,3-disubstituted ureas with phosphorus pentachloride yields in addition to the known chloroformamidine hydrochlorides *(2)* [1] 1,3-disubstituted trichloro-2-phospha-1,3-diazetidinones *(1)*. The distribution of the reaction products depends predominantly on the nature of the substituents and to a minor degree on the polarity of the solvent. Primary alkyl groups favor attack on the nitrogen with formation of *(1)*; secondary alkyl groups react almost exclusively on the oxygen with formation of *(2)*. Similar results have been observed by us in the reaction of 1,3-disubstituted ureas with phosgene [2].

*(1a)* R = R' = $CH_3$; b.p. 78–79 °C/1.5 mm; Yield: 71.9 %



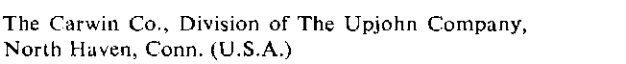
*(1b)* R = R' = $(CH_2)_3CH_3$; b.p. 105–108 °C/0.3 mm; Yield: 71 %

*(1c)* R = $C_6H_5$, R' = $(CH_2)_3CH_3$; non-distillable oil

The reaction proceeds on mild warming of the components in carbon tetrachloride and is accompanied by vigorous evolution of HCl.

The structures of the trichloro-2-phospha-1,3-diazetidinones obtained were elucidated by elementary analysis and infrared and NMR spectroscopy.

The carbonyl absorption at 5.6 μ is in agreement with the strained four-membered ring structure postulated. The isomeric compounds *(3)*, which were obtained from *N,N'*-dialkylcarbodiimides and phosphorus oxychloride, show as expected a C=N absorption at 6.0 μ.



*(3)*

In the $^1$H-NMR spectrum (Varian A 60) of *(2b)* and *(2c)*, the $CH_2$ group next to the nitrogen is not only coupled with the neighboring methylene group, but also with the phosphorus nucleus. The chemical shifts for the pairs of triplets of equal intensity in carbon tetrachloride are 192 cps [3.2 ppm; $J_{PH}$ = 28 cps] for *(1b)* and 215 cps [3.6 ppm; $J_{PH}$ = 34 cps] for *(1c)*, relative to tetramethylsilane.

In the dimethyl derivative *(1a)*, two pairs of doublets at 198 cps [3.3 ppm; $J_{PH}$ = 20 cps] and 173 cps [2.9 ppm; $J_{PH}$ = 21 cps] were observed; these are presumably due to geometrical isomers, *i.e.* the methyl groups are respectively either both above or alternately above and below the plane of the four-membered ring. Geometrically isomeric phosphazene dimers were already reported by *Trippett* [3].

When the 2-phospha-1,3-diazetidinones are heated above 100 °C in an inert solvent, disproportionation occurs as expected with formation of trichlorophosphazene *(4)* and isocyanate ($\nu_{N=C=O}$ = 4.42 μ). The cleavage products thus obtained react with each other to form a carbodiimide *(5)* ($\nu_{N=C-N}$ = 4.7 μ) and phosphorus oxychloride [4]:

## Stable Aromatic Nitrile Oxides [1,2]

By Prof. Dr. Ch. Grundmann and Judith M. Dean

Mellon Institute, Pittsburgh, Pa. (U.S.A.)

All the aromatic nitrile oxides *(2)* known so far are unstable and dimerize within hours or days to the corresponding furoxans *(3)* [3].

However, studies of Stuart-Briegleb models indicate the possibility of substituting the *o,o'*-positions with substituents of critical spatial requirements in order to block the dimerization to furoxans without impairing the ability of the nitrile oxide function to add onto other unhindered systems. The preparation of the nitrile oxides *(2a)–(2d)* has confirmed our anticipations. Compound *(2c)* is the first known individual bifunctional nitrile oxide [4]. All four preparations *(2a)–(2d)* are crystalline compounds which are stable at room temperature as well in solution as in the solid state. Their dimerization to furoxans cannot be enforced; on prolonged heating above 120 °C, *(2a)* and *(2b)* rearrange slowly to the corresponding isocyanates *(4)*, which were characterized by their reaction with aniline to give substituted phenylureas *(7)*. *(2a)–(2d)* react very easily with aniline or phenylacetylene to form hydroxamanilides *(5)* or 5-phenylisoxazoles *(6)*. Hydrogen chloride adds onto *(2a)–(2d)* to yield hydroxamyl chlorides *(8)*.

The usual route for the synthesis of nitrile oxides, *viz.* chlorination of the oximes *(1)* to afford the hydroxamyl chlorides *(8)*, followed by dehydrohalogenation of *(8)* with base, was found totally unsuitable for the preparation of *(2a)–(2d)*, since chlorine always substituted simultaneously in the group R. However, the alkali salts of the oximes *(1a)–(1d)* were readily dehydrogenated with alkyli hypobromite at 0–10 °C to afford the nitrile oxides *(2a)–(2d)* in excellent yields. The melting points and yields of compounds *(2)* and *(5)–(8)* are given in Table 1.

Table 1. Melting points and yields of the nitrile oxides *(2)* and their reaction products *(5)–(8)*.

[*] Melts with decomposition.

Aliphatic nitrile oxides are by far more transient than their aromatic counterparts; their most stable representative seems to be t-butylnitrile oxide [7], but even this compound dimerizes completely to the furoxan within 2–3 days [3]. To obtain really stable aliphatic nitrile oxides, even bulkier groups will be required next to the $-C\equiv N\rightarrow O$ grouping. We are at present engaged in preparing such compounds.

## Preparation of Anhydrous Potassium Hexathiocyanatoaluminate and Its Behavior in Liquid Ammonia

By Prof. Dr. O. Schmitz-DuMont and Dipl.-Chem. B. Ross

Anorganisch-Chemisches Institut der Universität Bonn (Germany)

When 1 mole of anhydrous aluminum chloride is added to a solution of 6 moles of potassium thiocyanate in acetonitrile, potassium chloride is precipitated. If the potassium chloride is filtered off and the filtrate evaporated to dryness *in vacuo* at room temperature with exclusion of moisture, a pale pink, crystalline thiocyanato complex $K_3[Al(SCN)_6]\cdot CH_3CN$ *(1)* is left as residue. The compound $K_3[Al(SCN)_6]$ *(2)* is obtained free from acetonitrile by heating *(1)* at 140 °C in a stream of nitrogen.

Both *(1)* and *(2)* dissolve in water to give a clear, colorless solution with an acidic reaction, and in liquid ammonia to give a bright yellow solution. On evaporation of the ammonia, a mixture of an ammonate of aluminum thiocyanate and potassium thiocyanate results. Accordingly, *(1)* and *(2)* behave like potassium hexathiocyanatotitinate(IV) [1].

The reaction of 3 moles of potassium thiocyanate with 1 mole of anhydrous aluminum chloride in acetonitrile leads to precipitation of only 2 moles of potassium chloride with formation of a solution of the complex $K[Al(SCN)_3Cl]$ *(3)*. This complex is stable only in solution. It is assumed that the complex ion still retains acetonitrile as a ligand bound to the $Al^{3+}$, *e.g.* as $[Al(SCN)_3Cl(NCCH_3)_2]^-$. The residue obtained after evaporation of the acetonitrile consists of a mixture of potassium chloride and an adduct of acetonitrile and aluminum thiocyanate. On adding this mixture to acetonitrile, it dissolves to reform complex *(3)*.

## A New Synthesis of Germylsilane [*]

By R. Varma and A. P. Cox

Mallinckrodt Chemical Laboratory, Harvard University, Cambridge, Mass. (U.S.A.)

Previously, silylpotassium $H_3SiK$ [1] has been used to only a limited extent in inorganic synthesis. Silylpotassium was prepared by the reaction (a) of disilane $Si_2H_6$ with a slight excess of potassium hydride in 1,2-dimethoxyethane over a period of 24 hours at room temperature. After removing volatile products – mainly monosilane, monoglyme, some hydrogen, and a very small quantity of disilane – an excess of germyl chloride was distilled in and allowed to react with the $H_3SiK$ at room temperature for 15 minutes (b). The germyl-

$$Si_2H_6 + KH \rightarrow H_3SiK + SiH_4 \quad (a)$$

$$H_3SiK + GeH_3Cl \rightarrow GeH_3SiH_3 \quad (b)$$

silane $GeH_3SiH_3$ [2] produced was purified by fractionation on a low-temperature column kept at approximately −115 °C in order to separate it from $Si_2H_6$ and $Ge_2H_6$, and was obtained in ca. 20 % yield.

Its infrared and mass spectra agree with those cited in reference [2] for $GeH_3SiH_3$. In addition, its microwave spectrum [3] strongly supports this identification.

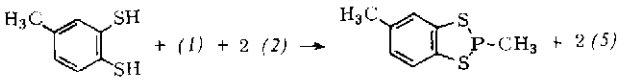
## Condensation of Methyldichlorophosphine with Dithiols

By Dr. M. Wieber, Dipl.-Chem. J. Otto, and Prof. Dr. Max Schmidt

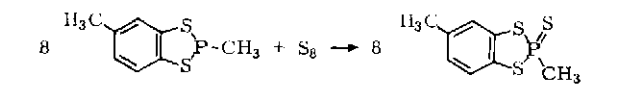
Institut für Anorganische Chemie der Universität Marburg/Lahn (Germany)

Methyldichlorophosphine *(1)* reacts in ether in the presence of triethylamine *(2)* with dithioglycol or 3,4-dimercaptotoluene in very good yields to form 2-methyl-1,3,2-dithia-



phospholane *(3)* or 2,7-dimethylbenzo[*d*]-1,3,2-dithiaphospholane *(4)*, and triethylammonium chloride *(5)*.

*(1)* *(2)* *(3)*



+ 2 $(C_2H_5)_3N \cdot HCl$,

*(5)*

*(4)*

Analogously, propane-1,3-dithiol produces the six-membered heterocycle 2-methyl-1,3,2-dithiaphosphane *(6)*, but only in moderate yield (ca. 30 %), the remainder forming a polymer of the same composition. All three derivatives [*(3)*, m.p. −5 °C, b.p. 90 °C/5 mm; *(4)*, b.p. 110–114 °C/2 mm; and *(6)*, b.p. 102 °C/5 mm] distil undecomposed and are oils of unpleasant odor; they are readily soluble in organic solvents, and easily hydrolysed by water. As nucleophilic reagents, they react with sulfur and selenium, yielding cyclic esters of methyltrithiophosphonic or methyldithioselenophosphonic acid, *e.g.*

*(4)* *(7)*

Thus, *(3)* and S afford 2-sulfo-2-methyl-1,3,2-dithiaphospholane, m.p. 74 °C, b.p. 132–134 °C/2 mm; *(3)* and Se form the corresponding selenophospholane, m.p. 68 °C, b.p. 148 °C/2 mm; *(4)* and S or Se yield the sulfophospholane *(7)* or selenophospholane respectively; but neither can be distilled unchanged. Finally *(6)* and S produce the corresponding sulfophosphane, m.p. 121 °C.

An attempt to oxidize *(3)* to the dithiophosphonic ester with oxygen at room temperature failed; warming led to a violent explosion.

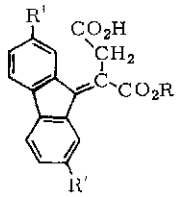
## The Synthesis of Fluoranthene Derivatives from Monoethyl 4,4-(*o*,*o*'-Biphenylene)itaconate

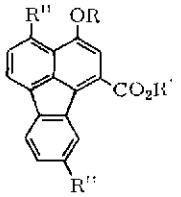
By Prof. Dr. A. Sieglitz and Dipl.-Chem. P. Böhme

Institut für Chemische Technologie der Farbstoffe und Kunststoffe, Technische Hochschule München (Germany)

Some time ago, *Borsche* [1] obtained 1-hydroxy-4-phenyl-3-naphthoic acid *(2b)* from the ester *(2a)*, which was synthetized by cyclizing monoethyl 4,4-diphenylitaconate *(1)* with acetic anhydride and sodium acetate; *(1)* was derived in turn from benzophenone by Stobbe condensation [2].



*(1)*



*(2a)*: R = $COCH_3$; R' = $C_2H_5$
*(2b)*: R = R' = H

Numerous derivatives of *(2b)* can be prepared by this route. 3-Hydroxyfluoranthene-1-carboxylic acid *(4a)* [3] should be accessible by a similar route from fluorenone via the monoethyl ester *(3a)* of 4,4-(*o*,*o*'-biphenylene)itaconic acid *(3b)*.

However, attempts by *Campbell* and *Fairful* [4] to close the fluoranthene ring by reaction of *(3a)* with acetic anhydride/sodium acetate, and by treatment of *(3b)* with aluminum chloride in nitrobenzene or with concentrated sulfuric acid were unsuccessful. When the ester *(3a)* was boiled with acetic anhydride/acetic acid/zinc chloride, only the anhydride of *(3b)* was formed.

*(3a)*: R = $C_2H_5$; R' = H
*(3b)*: R = R' = H
*(3c)*: R = $C_2H_5$; R' = Cl
*(3d)*: R = H; R' = Cl

*(4a)*: R = R' = R'' = H
*(4b)*: R = $COCH_3$; R' = $C_2H_5$; R'' = Cl
*(4c)*: R = R' = H; R'' = Cl

We have now found that the reaction of *(3a)* with acetic anhydride and aluminum chloride gives an uncharacterized intermediate which is converted into *(4a)* in good yield with alkali. Halogeno derivatives of *(3a)* can be cyclized with acetic anhydride/acetic acid/zinc chloride. Thus, for example, the monoethyl ester *(3c)* obtained from 2,7-dichlorofluorenone by Stobbe condensation gives, in addition to the anhydride of the dicarboxylic acid *(3d)*, the intermediate *(4b)*, which on hydrolysis yields 4,9-dichloro-3-hydroxyfluoranthene-1-carboxylic acid *(4c)*, a compound we had already prepared by another route [3].

## Non-Enzymatic Reduction of Methylene Blue and 2,6-Dichlorophenolindophenol by Reduced Di- and Triphosphopyridine Nucleotides

By Dipl.-Chem. F. Wagner, Prof. Dr. J. Convit, E. Bernt, and Dr. M. Nelböck

Escuela José Vargas, Hospital Vargas, Caracas (Venezuela), and Biochemische Abteilung, C. F. Boehringer & Soehne GmbH, Tutzing (Germany)

Contrary to expectations, methylene blue (MB) is stoichiometrically decolorized to leuco-methylene blue ($MBH_2$) by the reduced di- and triphosphopyridine nucleotides DPNH and TPNH on irradiation with light without addition of enzymes. The most effective wavelengths are those between 600 and 700 mμ.

The DPN or TPN thereby formed is fully active in enzymatic reactions, *e.g.* with the DPN-dependent enzymes lactic dehydrogenase and alcohol dehydrogenase, and the TPN-dependent enzymes glutathione reductase and glucose-6-phosphate dehydrogenase.

2,6-Dichlorophenolindophenol is similarly reduced, but triphenyltetrazolium chloride is not.

The same reactions were carried out with absolutely pure DPNH and TPNH. Traces of proteins were removed by dialysis, and possible traces of enzymatic activity were destroyed by heating the coenzyme solutions at 100 °C. Any enzymatic reaction (*e.g.* of diaphorase) was thus excluded.

Flavin adenine dinucleotide ($4 \times 10^{-5}$ M) accelerates the reoxidation of $MBH_2$ to MB by atmospheric oxygen, and thus leads to a faster oxidation of DPNH. Glutathione ($10^{-4}$ M) and ferric chloride ($3 \times 10^{-5}$ and $3 \times 10^{-4}$ M) did not affect the reaction rate.

Since DPNH and TPNH do not react with MB in the absence of light, dehydrogenase substrates can be oxidized with DPN or TPN in the dark in the presence of MB. Subsequently, in the presence of light, MB is hydrogenated to $MBH_2$ by the DPNH or TPNH, and DPN or TPN is regenerated. Aeration reoxidizes the autoxidizable $MBH_2$, and the chain of processes can be repeated by renewed reaction in the dark. By this means, catalytic (instead of stoichiometric) quantities of the expensive coenzymes suffice even for preparative aerobic oxidation of, for example, glucose 6-phosphate to 6-phosphogluconate.

## Superconductivity in $In_3SbTe_2$

By Priv.-Doz. Dr. A. Rabenau, Dr. K. Deneke, and M. M. van der Meij

Philips Zentrallaboratorium GmbH, Laboratorium Aachen (Germany) and Philips Research Laboratories, Eindhoven (Holland)

The ternary phase $In_3SbTe_2$ with the NaCl structure [1] (a = 6.13 Å), which lies on the pseudobinary section InTe–InSb, is closely related to the high-pressure phase InTe(II) [2], which also crystallizes with the NaCl structure [3] (a = 6.16 Å). This correspondence manifests itself in the physical properties: InTe(II) is a metallic conductor which becomes superconducting at ca. 3.45 °K [3,4]. We have found from resistivity measurements that $In_3SbTe_2$ is also a metallic conductor exhibiting transition to superconductivity.

The resistivity decreases linearly with temperature from $7.2\times10^{-4}$ ohm·cm at room temperature to $3.6\times10^{-4}$ ohm·cm at 4.2 °K. The very sharp transition to superconductivity points to a critical temperature of 1.06 °K.

Within the range of homogeneity of the phase $In_{1-x}Te(II)$ (where $0\leqslant x\leqslant0.18$), the value of the critical temperature varies according to the formal valence of the indium [5]. It decreases from ca. 3.45 °K for $In_{1.00}Te$ to ca. 1 °K on the tellurium-rich side ($In_{0.82}Te$), while the formal valence of the indium increases from 2.00 to 2.44. Bearing in mind that the formal valence of indium in $In_3SbTe_2$ is 2.33, we find the level of the critical temperature of the ternary phase to correspond to the situation in InTe(II).

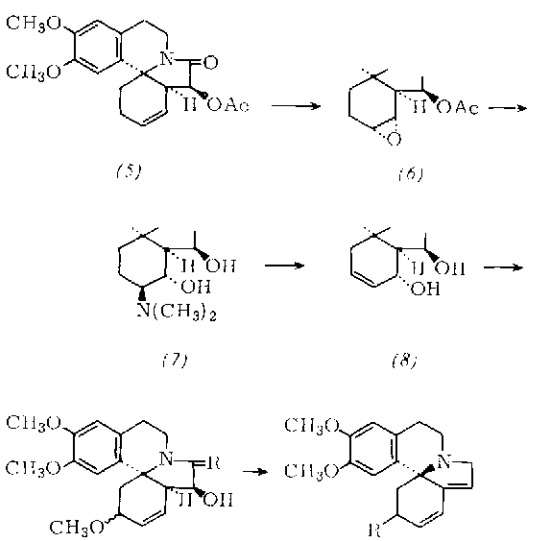
## The Total Synthesis of Erysotrine

By Prof. A. Mondon and Dipl.-Chem. H. J. Nestler

Institut für Organische Chemie der Universität Kiel (Germany)

Although compounds incorporating the erythrinan skeleton have been accessible for some time [1–4], the synthesis of an aromatic *Erythrina* alkaloid has so far not been achieved. We have now achieved a total synthesis of erysotrine *(1)* [5,6].



*(1)*, $R^1 = CH_3$; $R^2 = CH_3$
*(2)*, $R^1 = H$ ; $R^2 = CH_3$
*(3)*, $R^1 = CH_3$; $R^2 = H$
*(4)*, $R^1 = H$ ; $R^2 = H$

Although this compound has not yet been found in nature, it occupies a key position as the product of methylation of the phenolic alkaloids erysodine *(2)*, erysovine *(3)*, and erysopine *(4)*.

On treatment with peroxybenzoic acid, the unsaturated α-acetoxy-γ-lactam *(5)* [7] gave the α-epoxide *(6)*, which is cleaved by dimethylamine to give *(7)*. Degradation according to *Cope* via the *N*-oxide affords the unsaturated diol *(8)*, the structure of which was confirmed by its conversion into known erythrinan derivatives. Methanolic hydrochloric acid converts *(8)* into a mixture of the epimeric 3-methyl ethers *(9a)* and *(9b)*. After chromatographic separation, each methyl ether is reduced by lithium aluminohydride to the bases *(10a)* or *(10b)*, from which the two doubly unsaturated bases *(11a)* and *(11b)* are obtained by way of the mesylates. The overall yields, based on *(5)*, amounted to 1.8 and 2.4 %, respectively.

The infrared spectrum of the picrate of the base *(11a)* in chloroform is identical with that of erysotrine picrate, and thus justifies assignment of the racemic base *(11a)* to the naturally occurring 3β-series, and of *(11b)* to the 3α-series.

*(5)* *(6)* *(7)* *(8)*

*(9a)*,*(9b)*, R = O (±)-*(11a)*, R = $\alpha$-$OCH_3$
*(10a)*,*(10b)*, R = $H_2$ Picrate, m.p. 198 °C
(±)-*(11b)*, R = β-$OCH_3$
Picrate, m.p. 175 °C

Compound *(11a)* was resolved into its optical antipodes with dibenzoyl-(+)-tartaric acid. The less soluble salt yields a dextrorotatory base, whose picrate (m.p. 161 °C, $[\alpha]_D^{25} = +140°$ in ethanol, c = 0.23) is identical with erysotrine picrate obtained from natural sources [8]. After decomposition of the picrate and distillation of the free base, the synthetic erysotrine was obtained as crystals, m.p. 97 °C ([6] gives m.p. 97–98 °C).

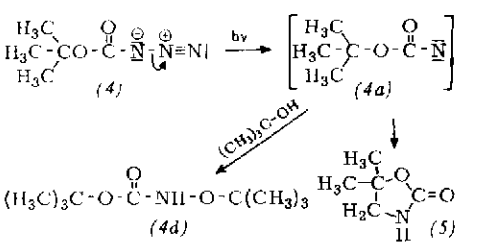
## The Photochemical Decomposition of Alkyl Azidoformates in Aliphatic Alcohols

By Dr. R. Kreher and Dipl.-Ing. G. H. Bockhorn

Institut für Organische Chemie der Technischen Hochschule Darmstadt (Germany)

*Dedicated to Professor C. Schöpf on the occasion of his 65th birthday*



Ethyl azidoformate *(1)* loses nitrogen during its photochemical decomposition [1] in t-butanol, and reacts with the tertiary alcohol to yield ethyl *N*-t-butoxycarbamide *(2d)*, b.p. 97–98 °C/13 mm, in 60 % yield; *(2d)* is also obtained from t-butoxyamine and ethyl chloroformate in the presence of triethylamine. On photolysis in methanol, ethanol, or isopropanol, *(1)* is chiefly reduced to ethylcarbamide *(3)*, with simultaneous loss of nitrogen; according to gas chromatography, ethyl *N*-alkoxycarbamates *(2a)–(2c)* are also formed in small quantities.

*(1)*

*(1a)*

| | | | |
|---|---|---|---|
| *(2a)*, R = $CH_3$- | 28% | *(3)*, | 52% in methanol |
| *(2b)*, R = $CH_3$-$CH_2$- | 3% | | 97% in ethanol |
| *(2c)*, R = $(CH_3)_2CH$- | 10% | | 90% in isopropanol |
| *(2d)*, R = $(CH_3)_3C$- | 60% | | |

*(4)* *(4a)* *(4d)* *(5)*

The photochemical decomposition of *(1)* presumably proceeds by way of the reactive ethoxycarbonylazene *(1a)* [2]. In methanol, ethanol, and isopropanol, *(1a)* apparently dehydrogenates the solvent to give the corresponding carbonyl compound, being thereby reduced to *(3)* [3].

On photolysis of the t-butyl ester *(4)* in t-butanol, the t-butoxycarbonylazene *(4a)* initially formed reacts not only with the tertiary alcohol to yield t-butyl *N*-t-butoxycarbamide *(4d)*, m.p. 70–71 °C, in 29 % yield, but preferentially tends to undergo an intramolecular reaction to yield 60 % 5,5-dimethyloxazolid-2-one *(5)*, m.p. 80–82 °C [4]; in this reaction, the azene group is apparently inserted into a C–H bond of the t-butyl group.

Received, July 3rd, 1964 [Z 770/591 IE]
German version: Angew. Chem. 76, 681 (1964)

[1] Refluxing alcoholic solutions of *(1)* were illuminated by means of a high-pressure ultraviolet lamp [Type S 81, Quarzlampengesellschaft Hanau (Germany)]. Comparable results were obtained by using a low-pressure ultraviolet lamp (Type NK 6/20, same source) at room temperature.

## Determination of the Sequence of a Code Triplet

By Prof. Dr. F. Cramer, Dr. H. Küntzel, and Dr. J. H. Matthaei [*]

Medizinische Forschungsanstalt der Max-Planck-Gesellschaft, Göttingen (Germany)

Up to the present, only polyribonucleotides with a statistical distribution of their bases were available for deciphering the genetic code; hence only the overall composition of most of the code triplets could be determined [1,2]. Recently, we have indicated possibilities for further analysis of the genetic code using oligonucleotides and polynucleotides with definite base sequences [3].

An enzymatic method was used to obtain coding polynucleotides with definite 3'-terminal base sequences. As expected [4], these polynucleotides effect specific adsorption of aminoacyl-RNA onto ribosomes in a simplified cell-free system derived from *Escherichia coli* [4]. This enabled us to carry out the first determination of the base sequence of a coding triplet. This finding also demonstrates that the RNA template is read off starting from the 3'-terminal end.

The following polynucleotides were prepared using a partially purified polynucleotide phosphorylase from *Micrococcus lysodeikticus* [5]: poly-pApC 50:1 *(1)*, poly-pApU 50:1 *(2)*, poly-pApG 100:1 *(3)*, poly-pUpG 100:1 *(4)*, and poly-pCpG 100:1 *(5)*. Polynucleotides *(1)* and *(2)* were hydrolysed with pyrimidine-specific ribonuclease from pancreas, and *(3)*, *(4)*, and *(5)* with guanine-specific ribonuclease $T_1$ from takadiastase. The 3'-phosphate residues were removed from the cleavage products using bacterial alkaline phosphatase.

For the polynucleotide Ap···ApApC obtained from *(1)* the 3'-terminal nucleotide was determined as follows (this polynucleotide contains an average of 50 nucleotides per chain): Samples of the polynucleotide were labelled in the cytosine moiety with tritium, and the [$^3$H]cytosine was liberated by oxidation with periodate and subsequent treatment with cyclohexylamine [6]. Equilibrium dialysis for 6 h against water showed that all the radioactivity had been liberated in the form of dialysable nucleobase, while the remainder of the ultraviolet-absorbing material retained by the dialysis membrane. Examination of the product obtained from the treatment with periodate and amine by paper chromatography revealed cytosine and no adenine.

About 150 μμmoles of ribosomes [8] were incubated for 60 sec at 36 °C with 300 μμmoles of polynucleotide and 1 mμmole of aminoacyl-RNA in 350 μl of standard buffer [7]. The aminoacyl-RNA was charged with one labelled and 19 non-labelled amino acids; all the 20 amino acids normally occurring in proteins were tested. Each incubate was then diluted with 30 times its volume of ice-cold 0.01 M tris-HCl buffer (pH 7.2)/0.01 M magnesium acetate and centrifuged at 150000 g for 60 min. The precipitate obtained was taken up in 0.1 M triethylammonium hydrogen carbonate (pH 7.6), applied to fibre glass paper (Whatman GFA), and dried for liquid scintillation counting. Comparison of the coding properties of poly-Up···UpUpG and poly-Up···UpU indicates that *UpUpG* is the coding sequence for *leucine*. However, valine and cysteine, having also codons consisting of one guanylic and two uridylic acid residues [2], are not coded by this sequence (see Table; the values given are the mean from two experiments).

| Amino acid | Aminoacyl-RNA bound [nμmoles] | | |
|---|---|---|---|
| | without polynucleotide | with poly-Up···UpU | with poly-Up···UpUpG |
| [$^{14}$C]Val | 139 | 125 | 350 |
| [$^{35}$S]Cys | 482 | 465 | 480 |
| [$^3$H]Leu | 780 | 788 | 716 |
| [$^3$H]Phe | 64 | 174 | 70 |

Hydrolysis at pH 9 of the complex of ribosomes, polynucleotide, and aminoacyl-RNA obtained by centrifugation, and subsequent high-voltage paper electrophoresis in 2 M acetic

acid showed that no labelled amino acid is linked by a peptide bond in the complex. Electron-microscopic investigations [9] of fractionated polyuridylic acid (average chain length 750 Å) indicated that 30-S- and 50-S-subunits of the ribosomes add onto one end of this nucleic acid more than 12 times as much as onto the rest of the chain. The above observations suggest that this end is the 3'-terminal one.

## Coding with Mono- and Polytrinucleotides

By Dr. J. H. Matthaei, Dr. H. Kleinkauf, and Prof. Dr. G. Schramm [*]

Medizinische Forschungsanstalt der Max-Planck-Gesellschaft, Göttingen, Botanisches Institut der Technischen Hochschule Braunschweig, and Max-Planck-Institut für Virusforschung, Tübingen (Germany)

Polytrinucleotides ought to act as templates in the biosynthesis of poly(amino acids) [1], whereas isolated trinucleotides lead only to a more or less specific binding of aminoacyl-RNAs onto ribosomes [1–3]. Trinucleotides which would be inactive in a homopolymer because of its tertiary structure might be active in a copolymer with a second trinucleotide [1]. We have therefore started to prepare homopolytrinucleotides by chemical synthesis and to test their coding properties. We have found that ApGpC and ApGpU are coding sequences for asparagine.

A mixture of trinucleotides was secured by complete degradation of a commercial sample of yeast RNA with pancreatic ribonuclease (RNase) followed by five extractions with phenol, threefold extraction with ether, and lyophilization. Individual mono-, di-, and trinucleotides were separated from 6.5 g of the crude mixture of degradation products by chromatography on four columns (6 cm in diameter, 2 m long) of DEAE-Sephadex (A-25 coarse) connected in series. Movable pistons fitted with a sintered-glass filter were inserted into the columns from beneath in order to keep the Sephadex together even on shrinkage. The elution was carried out upwards (against gravity) using 4×2 channels of a Durrum elastic-tubing pump, which pumped 165 l of ammonium carbonate solution (pH 8.7, concentration increasing linearly from 0.1 to 1.0 M) from one column to the next within six days. Each trinucleotide fraction contained 100 to 300 mg. They were diluted tenfold with $H_2O$ and purified and desalted in four stages by sorption on DEAE-cellulose filters of decreasing diameter (each 4 cm in height) and desorption with about 1 M ammonium hydrogen carbonate (pH 7.8). The solutions of oligonucleotides were concentrated, acidified with cellulose phosphate (P-cellulose, p.a., from Serva, Heidelberg), filtered, centrifuged, and lyophilized. The sequence of each trinucleotide was determined by high-voltage paper electrophoresis of the products obtained from it by hydrolysis either at 37 °C with 0.5 N KOH or with $T_1$-RNase.

75 mg of ApGpCp (or 60 mg of ApGpUp) were dissolved by ultrasonic agitation in 1.1 (0.9) g of ethyl tetrametaphosphate [4a] plus 0.125 (0.10) ml of anhydrous trisdimethylamino phosphate and polymerized by rotating at 60 °C for 48 h in a sealed tube [4b]. Dialysis of the products overnight gave a loss of 44 % (45 %) of the ultraviolet-absorbing material. The solution retained by the dialysis membrane was concentrated and separated on a column (3 cm in diameter, 150 cm long) of Sephadex G-75 into fractions of various chain-lengths.

The coding properties of fractions with a chain length of about 18 nucleotides was investigated using our previously published method [5]; however, for the purpose of peptide synthesis, a complete protein-synthetizing system [6], including the supernatant from 100000 g centrifugation of an almost ribonuclease-free extract of *Escherichia coli*, was used. The mixtures were incubated for 3 min at 0 °C and then for 7 min at 36 °C. Most of the experiments with poly-ApGpUp and poly-ApGpCp gave a specific increase in the incorporation of asparagine. In some experiments with poly-ApGpUp also methionine was incorporated, but this was presumably due to cleavage of the terminal nucleotide. These findings agree well with the observation that the trinucleotides ApGpC and ApGpU, which have been freed from the 3'-terminal phosphate, effect specific attachment of asparaginyl-RNA onto ribosomes following the method described in the previous communication [5].

The polynucleotide-dependent incorporation was about 20 times as high in the complete protein synthetizing system as in the simplified system for amino acid adaptation [2, 5]. The peptides presumably formed will be investigated.

## A New Type of Phosphorus-Nitrogen Compound with Pentavalent Phosphorus

By Prof. Dr. M. Becke-Goehring and L. Leichner

Anorganisch-chemisches Institut der Universität Heidelberg (Germany)

Following the interaction of $PCl_5$ with amines, products of type *(1)* or *(2)* have previously been obtained [1]. Compound *(2)* is formed in the reaction of $[(CH_3)NH_3]Cl$ with $PCl_5$. If methylammonium chloride containing a few percent of water

*(1)* *(2)* R = $CH_3$ *(3)*

is employed in this reaction, in addition to *(2)*, a brown oil is obtained which slowly deposits crystals that are recrystallizable from benzene. According to analysis and molecular-weight determinations (ebullioscopically in dichloroethane), the pure compound has the formula $P_4[N(CH_3)]_6Cl_8$. The $^{31}P$-NMR-spectrum shows only one signal at +74.3 ppm (referred to 85 % phosphoric acid). The phosphorus atoms in the compound are thus pentavalent and chemically equivalent; this is shown particularly by comparison with the chemical shift of +78.2 ppm observed with *(2)*. The cage-structure *(3)* may therefore be considered for the compound. The compound is stable in sealed tubes up to 400 °C without melting.

# CONFERENCE REPORTS

## Immunochemistry

This year, the 15th Moshach Colloquium of the Gesellschaft für Physiologische Chemie (German Society for Physiological Chemistry) was held from April 22nd to 25th. It was devoted to immunochemistry. *O. Westphal*, Freiburg (Germany), who was chairman of the symposium, and *M. Heidelberger*, New Brunswick (U.S.A.), pointed out that immunochemistry deals not only with chemical and biochemical mechanisms of immunity processes. The high specificity of antibodies towards their inducing antigen often makes them ideal and as yet unsurpassed reagents for complex structures in natural products. In this context, immunochemistry is also an important branch of analytical natural-product chemistry. The many variants of serological precipitation in gels are of increasing importance, in particular for the analysis of complex protein mixtures. This was discussed by *Ö. Ouchterlony*, Göteborg (Sweden), *P. Grabar*, Paris (France), and *G. Schwick*, Marburg (Germany).

*W. T. J. Morgan*, London (England), reported on the structures of human blood-group substances of the A, B, O(H), and $Le^a$ system. The blood-group specific substances on erythrocyte surfaces are glycolipids, but little is known of their chemical structures. In many humans they also occur in secretions and body fluids. They are mucopolysaccharides containing about 20 % protein and about 80 % carbohydrate. The carbohydrate portion consists of L-fucose, D-galactose, *N*-acetyl-D-glucosamine, and *N*-acetyl-D-galactosamine. In addition, *N*-acetylneuraminic acid occurs in very variable amounts. The chemical structures responsible for the four specificities (A, B, O(H), $Le^a$) were elucidated a) by means of immunochemical methods, b) by stepwise enzymatic degradation, and c) from the structure of the oligosaccharides obtained on hydrolysis with acids (mineral acids and polystyrenesulfonic acid) and bases (*e.g.* triethanolamine). The results led to the following tentative sequences for the first five sugar units in each individual glycolipid [1]:

A substance
1) α-GalNAc-(1-3)-β-Gal-(1-3)-β-GNAc-(1-3)-β-Gal-(1-3)-GalNAc
2) α-GalNAc-(1-3)-β-Gal-(1-4)-β-GNAc-(1-3)-β-Gal-(1-3)-GalNAc

B substance
1) α-Gal-(1-3)-β-Gal-(1-3)-β-GNAc-(1-3)-β-Gal-(1-3)-GalNAc
2) α-Gal-(1-3)-β-Gal-(1-4)-β-GNAc-(1-3)-β-Gal-(1-3)-GalNAc

O(H) and $Le^a$ substances
1) β-Gal-(1-3)-β-GNAc-(1-3)-β-Gal-(1-3)-GalNAc
2) β-Gal-(1-4)-β-GNAc-(1-3)-β-Gal-(1-3)-GalNAc

Each substance therefore contains at least two different serologically active carbohydrate chains. These are probably anchored to a common peptide skeleton, which itself has no serological significance. L-Fucose and neuraminic acid are presumably attached to the sugar chain as acid-labile, non-reducing groups.

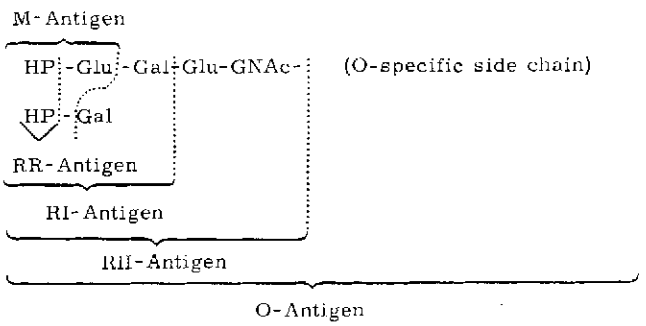
Some oligosaccharides containing fucose were obtained by alkaline hydrolysis of the group-specific substances. In these, fucose is linked 1→2-glycosidically to galactose and also (very probably) 1→4-glycosidically to *N*-acetylglucosamine. These results give an indication of the positions of attachment of fucose in the total structure of the specific mucopolysaccharides. It thus appears that relatively small regions in the polysaccharide portion of the mucopolysaccharide are responsible for the characteristic serological properties of the blood-group specific substances.

*G. F. Springer*, Evanston (U.S.A.), dealt with the "relation of blood-group active substances to bacteria, higher plants, and viruses". Blood-group active substances represent a structural principle, that is widespread in nature, being encountered in the cells of the most primitive as well as the highest forms of life.

Numerous bacteria (*e.g. Escherichia coli* O 86) have high blood-group B activity. Oligosaccharides of high B-specificity were isolated from the serologically active polysaccharide of *E. coli* O 86. One is a heptasaccharide consisting of 4 galactose molecules, 1 fucose, 1 glucose, and 1 hexosamine molecule. A galactose is at the reducing end. B-specific haptenes from *E.coli* O 86 are very similar to human glucose-free blood-group substances.

Polysaccharides with high blood-group O(H) activity were found in two higher plants (*Taxus* and *Sassafras*). Neither polysaccharide contains fucose, whereas α-linked L-fucose is present in human O(H) substance and is serologically essential. In contrast, the *Taxus* polysaccharide contains 2-*O*-methylfucose, and the *Sassafras* polysaccharide 3-*O*-methylfucose. On the basis of immunochemical investigations of synthetic methyl glycosides of fucose ethers, it was concluded that the O(H)-complementary structure of the antibody (eel serum) is smaller than a monosaccharide that requires a *C*- or *O*-methyl group in an equatorial position adjacent to an ether oxygen. Enantiomorphic isomers can possess quantitatively equal activities.

Some viruses (*e.g.* influenza virus or fowl pest virus) have high blood-group A specificity. This cannot be separated from the virus and increases with its purification.



*O. Lüderitz*, Freiburg (Germany), spoke about the somatic antigens of *Salmonella* S and R forms. *Salmonella* O antigens are obtained by extraction with phenol/water as high molecular-weight, branched lipopolysaccharides, in the structures of which various monosaccharides participate in varying number and attachments. Some O antigens contain up to 8 different sugar units, and all the *Salmonella* O antigens investigated up to now contain at least the following 5 monosaccharides (basic sugars): heptose, galactose, glucose, 2-oxo-3-deoxyoctanoic acid, and glucosamine. From structural analyses it appears that oligosaccharidic structures correspond to the specificities of the O factors of an O antigen. On transformation from the morphologically smooth S forms into the morphologically rough R form, *Salmonella* germs lose their O specificity. The R mutants synthetize only a relatively unspecific R antigen that is also a lipopolysaccharide. R antigens contain only the basic sugars; they are deficiency mutants of

[1] Gal = galactose, GalN = galactosamine, G = glucose, GN = glucosamine, Ac = acetyl.

the wild form. On careful chemical degradation of O antigens, structures with R specificity could occasionally be liberated. Hence it is concluded that R antigens are the basic structures of O antigens. Accordingly, R antigens may be regarded as intermediates of O antigen synthesis, which accumulate in R cells, because an enzyme (or several enzymes) needed for the synthesis of the complete S form is (are) missing. R antigens were differentiated by means of serological methods into two R serogroups (RI and RII). In contrast to the RII mutants, the RI mutants have a polysaccharide fraction which contains the specific sugars of the S form in addition to the typical R lipopolysaccharide. In RI mutants, therefore, the S specific sugars are synthetized but not incorporated into the lipopolysaccharide. In contrast, analysis of representatives of the serotype RII showed that here the synthesis of an S-specific sugar is blocked. Two further R mutants in *Salmonellas* are the M mutants and the RR mutants. The former cannot synthetize galactose; its lipopolysaccharide consists of glucosamine, 2-oxo-3-deoxyoctanoic acid, heptose, and glucose. When grown on fructose, the RR mutant forms no glucose; its RR antigen consists essentially of poly(heptose phosphate). The following path for the biosynthesis of the O antigen was suggested.

$$RR \rightarrow M \rightarrow RI \rightarrow RII \rightarrow O$$

From the results of chemical analyses, the following tentative scheme might be derived:

"The capsulate antigen of mucoid strains of *Escherichia coli*" was the subject of the lecture by *W. F. Goebel*, New York (U.S.A.). Under certain cultural conditions, many *Enterobacteriaceae* grow in mucoid form, *i.e.* they surround themselves with a mucous layer, which consists of M antigen. Acidic polysaccharides were isolated from two strains of *E.coli* (*E. coli* K235 and *E.coli* K12 infected with T6 phage); these proved to be identical. The substance was called colanic acid. The acidic polysaccharide isolated from *E. coli* K235 was found to be antigenic in rabbits. Colanic acid consists of glucuronic acid (17.9 %), galactose (33 %), glucose (16.3 %), and fucose (32.7 %). It is presumably identical with M antigen. *K. Jann*, Freiburg (Germany), reported on "immunochemical investigations of the K antigens of *E.coli*". Coli bacteria often possess K antigens as surface antigens in addition to the somatic O antigen. These occur especially in pathogenic coli bacteria and form a kind of natural protecting wall against the defence mechanisms of higher organism (*e.g.* against phagocytosis). Chemical investigations of a large number of *E.coli* species with different K antigens showed that these bacteria frequently have acidic polysaccharides containing hexuronic acid in addition to lipopolysaccharides (O antigens). After extraction from the bacteria with phenol/water, these polysaccharides were isolated in purified form by fractionation with cetyltrimethylammonium bromide and analysed. In 4 instances it could be clearly shown by means of immunochemical methods that these were the K antigens of the bacteria concerned. These acidic polysaccharides have the following compositions:

| | |
|---|---|
| from *E.coli* 08:K42(A):– : | galacturonic acid:galactose:fucose = 1:1:1 |
| from *E.coli* 09:K30(A):H12: | glucuronic acid:galactose:mannose = 1:1:1 |
| from *E.coli* 059:K(B):H19: | galacturonic acid:glucosamine:mannose = 1:1:3 |
| from *E.coli* 0141:K85(B):H4: | glucuronic acid:glucosamine:mannose: rhamnose = 1:1:2:1 |

In order to elucidate the serologically active groups, oligosaccharides were isolated from partial hydrolysates of the acidic polysaccharides and examined for their inhibitory effect in the homologous serological system. It was shown that the serological specificity of the K antigens is mainly caused by structures containing hexuronic acid. A trisaccharide was isolated from the acidic polysaccharide of *E.coli* O8:K42(A):– and the structure galactosyl-(1-3)-galacturonic acid-(1-2)-fucose was proposed for it on the basis of chemical investigations. Analytical and serological findings permit the conclusion that this trisaccharide is the repeating structural unit of the acidic polysaccharide.

*F. A. Anderer*, Tübingen (Germany), reported on the "Chemical basis of antigenicity in globular proteins". The protein of tobacco mosaic virus (TMV) is globular; the primary structure of its subunits is known and so is the spatial arrangement of the protein in the virus. All the polypeptide chains in the virus are arranged structurally identically, so that the virus has a periodically repeating surface structure. For the determination of the serologically determinant amino-acid sequences, 20 peptides were examined which, taken as a whole, contain the entire amino acid sequence of the virus protein. Only 4 partial sequences (15–25 % of the polypeptide chain) proved to be serologically active. From the results of the serological investigations it was concluded that the specific TMV-antibodies are directed against definite regions of the protein. Since the surface structure of the TMV arises from the tertiary structure of the protein, its antigen specificity should also depend on the tertiary structure. Preliminary experiments have shown that the C-terminal hexapeptide from the virus protein forms antibodies in the rabbit which react with TMV and neutralize its infectivity.

*K. Rajewsky*, Frankfurt (Germany), spoke about "immunological studies of lactic dehydrogenases". When enzyme proteins are used as antigens, advantage is taken of two characteristic properties of the proteins: 1. their enzymatic activity, 2. their capacity to take part in immunological reactions. Enzymes are mostly inhibited by their antibodies (antienzymes). The serological reaction can be followed by measurement of the enzyme activity in the immune precipitate and in the supernatant. Such investigations with lactic dehydrogenase (LDH) were easy to perform since there is a simple assay method and also a sensitive specific stain for this enzyme. In the region of the maximum of the precipitation curve (LDH-anti LDH), enzymatic activity begins to become detectable in the supernatant. Even with excess antibody, the immune precipitates show distinct, albeit reduced, activity. The 5 LDH-isoenzymes of higher organisms were investigated by gel diffusion and immuno-electrophoresis. In two samples (heart and muscle isoenzymes), a serological relationship was established between the LDH isoenzymes of ox, pig, and man.

"Synthetic polypeptides as model antigens" was the topic of the lecture by *E. Rüde*, Freiburg (Germany), who first gave a survey of the work of *M. Sela*, Rehovoth (Israel). The main theme was the question of the relationship between chemical structure and antigenicity, *i.e.* the ability of a macromolecular substance to induce the formation of antibodies in higher organisms. Investigations of this kind were conducted with synthetic polypeptides or poly-(α-amino acids) prepared by polymerization or copolymerization of different *N*-carboxyamino acid anhydrides with basic starters. Both linear and branched poly-(α-amino acids) were synthetized by this method; some products were antigenic. It was shown that 1. the presence and 2. the steric accessibility of certain amino acids (*e.g.* tyrosine, cyclohexylalanine, or phenylalanine) or amino-acid combinations (*e.g.* lysine and glutamic acid) in the macromolecules are prerequisites for their antigenicity. The shape of the macromolecule appears to be relatively unimportant in determining antigenicity. The molecular weight can also vary within wide limits; polypeptides of suitable composition with molecular weights of only 4000 can even be antigenic.

The lecturer reported finally on work intended to evaluate the influence of sugars on the antigenicity of synthetic polypep-

tides. Serine glucoside was synthetized and incorporated into synthetic polypeptides via the corresponding *N*-carboxy-amino acid anhydride. Serine glucoside alone did not suffice to convert a non-antigenic polymer into an antigen. When introduced into an already antigenic polypeptide, however, serine glucoside conferred a new specificity on same thus acting as a determinant group. In this connection, serine-*N*-acylglucosamides were also synthetized and incorporated into polypeptides. Serine glycosides are also of interest as model substances for a possible type of linkage between carbohydrate and protein in natural glycoproteins.

*M. Eigen*, Göttingen (Germany), gave an introduction to the physical chemistry of antigen-antibody reactions.

The present theories of antibody formation were reviewed by *F. Haurowitz* (Bloomington, U.S.A.) following a survey on the chemistry of antibodies (structural analysis of $\gamma$-globulins). The importance of the so-called natural antibodies (opsonins) for the fate of infectous agents (phagocytosis, intracellular killing) was discussed by *D. Rowley* (Adelaide, Australia).

*H. Fischer*, Freiburg (Germany), pointed out that complement takes part in immunological cytolysis to a much larger extent than was previously assumed. Following a discussion of the mechanisms of complement action, *H. J. Müller-Eberhard* (La Jolla, U.S.A.) reported on the isolation of complement factors and opened new aspects for the biochemical analysis of complement and its reactions. Five out of the ten hitherto known factors of human complement were obtained in highly purified form. Three factors were characterized as $\beta$-globulins and as $\beta_{1c}$, $\beta_{1E}$, and $\beta_{1F}$ represent the third, fourth, and fifth complement components respectively. The other isolated proteins were identified as 11S-component and C'1-esterase and are assigned to the first complement component.

The cytolytic reaction of the complement begins with the adsorption of the first complement component (C'1), which by enzymatic activity causes addition of the fourth complement component ($\beta_{1E}$). In the course of the reaction, addition of the second complement component then occurs; this is only possible with the aid of the first component. After fixation of the second complement component to the cell membrane, the sensitized cell can "react" numerous molecules of the third complement component ($\beta_{1c}$). The $\beta_{1F}$ globulin and the sixth component follow the $\beta_{1c}$ in the complement reaction chain. Afterwards the cell membrane is in an irreversible condition of susceptibility to attack by the seventh and eighth components, which brings about an irreparable permeability defect. *P. Klein*, Mainz (Germany), dealt with the characterization and the reaction mechanism of the factors of the third complementary component. The third component, identical with $\beta_{1c}$, is determined by its ability of lysing the sensitized erythrocyte-$C'_{1,2,4}$($EAC'_{1,2,4}$) complex. It was shown that the factors $C'_{3a}$ and $C'_{3b}$ can be added onto $EAC'_{1,4,2}$ cells. The $EAC'_{1,4,2,3a,3b}$ cell formed can be brought to lysis by complement treated with cobra toxin or by pseudoglobulin (both free from $C'_{3a}$ and $C'_{3b}$). Chromatographic and electrophoretic methods separated the lytic principle into 3 subfactors ($C'_{3\beta}$, $C'_{3c}$, $C'_{3d}$), which are different from $C'_{3a}$ and $C'_{3b}$. The subfactors act on the $EAC'_{1,4,2,3a,3b}$ cell in a characteristic sequence.

In two special sessions *M. Hasek* (Prague, Czechoslovakia) reported on immunological tolerance, and *G. F. Springer* (Evanston, U.S.A.) gave a survey on aspects of germ-free life.

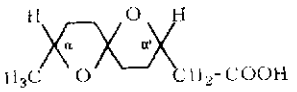
# Plant Products

The 12th Meeting of the Deutsche Gesellschaft für Arzneipflanzenforschung (German Society for Medicinal Plant Research) was held in Berlin from May 19th to 23rd, 1964. It consisted of a symposium on advances in the field of psychotropically active drugs and of individual reports on the analysis of secondary plant products.

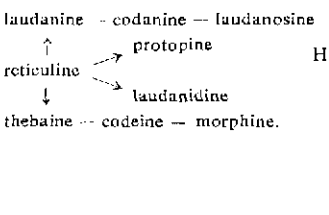
*U. Beiss*, Göttingen (Germany), described a procedure for separating lipids. The material is subjected to preliminary purification by elution through Sephadex with $CHCl_3$/methanol/water. The lipids pass through the column while contaminants are adsorbed. Subsequently, they are chromatographed with two-dimensional development on paper impregnated with kieselgel. The solvents used are 1. tetrahydrofuran/diisobutyl ketone/water (45:9:4) and 2. diisobutyl ketone/methyl isobutyl ketone/methyl ethyl ketone/$CHCl_3$/formic acid/glacial acetic acid /water (10:8:8:100:10:10:1). In this way, a mixture of plant lipids was separated into more than 20 components.

*K. Egger*, Heidelberg (Germany), demonstrated the possibilities of partition chromatographic separations of flavones on polyamide with lipophilic eluants such as $CHCl_3$/methanol/methyl ethyl ketone (5:2:1). In the swollen state, Perlon functions as polar stationary phase. Groups of substances such as the 3-rhamnosides of myricetin, quercetin, and kaempferol, which have nearly identical $R_F$-values with dilute alcohol on Perlon, are sharply separated from each other. This led to a two-dimensional chromatographic technique on Perlon: in the one direction, with alcohol/water, separation depends largely on the type of glycosidation, and in the other direction, with $CHCl_3$/methanol/methyl ethyl ketone, it depends on the aglycone. The free aglycones, too, can be characterized in this manner.

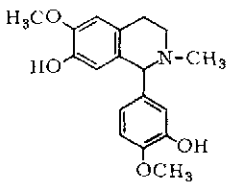


*L. Pallos*, Budapest (Hungary), elucidated the constitution of some naturally occurring aurone glycosides by synthesis. He employed *Geissmann*'s synthesis via coumaranone and benzaldehyde leading to benzylidenecoumaranone = aurone. Subsequent glycosidation yields glycoside mixtures, however. The reaction partners must therefore be glycosidated prior to the aldol condensation. Under these circumstances, alkali can no longer be employed for the condensation, but can be replaced by acetic anhydride, peracetylated substances then being obtained. These can be saponified in the cold with Na methoxide in absolute methanol. In this way it was shown that sulfurein is 6,3',4'-trihydroxyaurone 6-glucoside and that palasitrin is 6,3',4'-trihydroxyaurone 6,3'-diglucoside. For the synthesis of this latter compound, protocatechualdehyde had to be partially acetylated in the 3'-position and the 4'-hydroxy group protected with $H_3C{-}SO_2Cl$. Deacetylation and reaction with acetobromoglucose then followed. In the direct reaction, the 4'-glucoside would have been formed. It was possible to confirm that the structure of bractein is that proposed by *Hänsel (1)*.

(1)



*E. Graf*, Tübingen (Germany), spoke about exogonic acid, a compound found in the resin of *Exogonium purga* (Resina Jalapae) and *Ipomea operculata* (Resina operculina). On saponification with alkali, the ether-insolubles from the resins yield acidic oligosaccharides (including purginic acid) plus a mixture of simple carboxylic acids. The crude exogonic acid which can be recovered from this mixture contains a contaminant which can be largely separated off by freezing the solution. The contaminant was identified as 4-oxocaprylic acid. After methylation with diazomethane, the remaining mixture can be fractionated by gas chromatography into five components A–E, the relative proportions of which are A:B:C:D:E = 6:1:11:41:41. A is 4-oxocaprylic acid, which had not been completely removed. The main components D



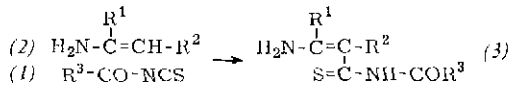
and E were taken together for structural determinations. Their reactions indicated a masked keto group (ketal). Only unbranched acids are obtained by $KMnO_4$ degradation. Finally, analytical data, including NMR-spectra, showed that exogonic acid is a derivative of oxetone, namely α-methyl-α'-carboxymethyloxetone *(2)*, a diketal with an unbranched carbon chain.

*(2)*

*E. Brochmann-Hanssen*, San Francisco, Calif. (U.S.A.), succeeded in isolating a new phenolic base from opium alkaloids and elucidating its structure. This base is apparently of great importance in the biosynthesis of the other alkaloids. Firstly, the alkaloid extract was adjusted to pH 1 and was then extracted with $CHCl_3$. The aqueous epiphase was mixed with dichloroacetic acid and again shaken with chloroform. The extract is then evaporated to dryness, and the residue subsequently dissolved in dilute sodium hydroxide and treated once more with chloroform. Only phenolic substances, including the new alkaloid, termed reticuline, remain in the aqueous phase. Reticuline can be converted into (±)-laudanosine with diazomethane, thus establishing its basic structure. The substance possesses two methoxy groups and two phenolic hydroxy groups. Comparison of its NMR-spectrum with those of some synthetically available partial methyl ethers with laudanosine structure made it possible to establish the position of the substituents, resulting in structure *(3)*. The compound is probably an intermediate in the biogenesis of the other opium alkaloids:

*(3)*

According to *T. Hartmann*, Bonn (Germany), the biogenesis of volatile amines can be formally represented as the decarboxylation of the corresponding amino acids. Additions of leucine to mycelial cultures of *Claviceps purpurea* do indeed lead to the formation of isoamylamine. However, until now, no amino acid was known which could be responsible for the abundant occurrence therein of n-hexylamine. Accurate analyses of the mycelia, which accumulate n-hexylamine, have now demonstrated the presence of an amino acid which is chromatographically identical with synthetic α-aminoheptanoic acid. The acid is readily identifiable in young mycelia. Its presence could not be demonstrated in *Secale cornutum*, however. It was not possible to show that other volatile amines arose by direct decarboxylation of amino acids. This concept should not, therefore, be generalized. For identification, the amines were treated with dinitrofluorobenzene and separated by partition chromatography on paper impregnated with paraffin oil using methanol/water (10:6) as eluant.



*R. Tschesche*, Bonn (Germany), spoke on the constitution of saponins, their hemolytic activity, and their ability to form complexes with sterols. An elegant method was elaborated for examining their complexing ability. The saponin is transferred to a paper strip, together with $^{14}C$-labelled cholesterol, and the paper developed with carbon tetrachloride. If a complex has been formed, the total radioactivity, or at least most of it, remains with the saponin at the start. If complex formation does not occur, however, the cholesterol is eluted by the carbon tetrachloride. In this way it was possible to determine whether there is a connection between hemolytic index and complex formation. This seems to be the case to only a very limited extent. Rather, the hemolytic index seems to depend in equal proportions on complex formation, detergent character, and protein association. [VB 826/152 IE]

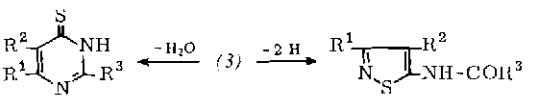
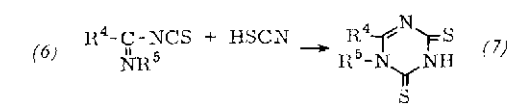
## New Observations on Acylheterocumulenes



*J. Goerdeler*, Bonn (Germany)

Acyl isothiocyanates *(1)* add onto C-2 of 1-alkoxy-1-amino- or 1,1-diaminovinyl ketones *(2)* or analogously substituted acrylic esters *(2)* [1] to form compounds *(3)*. Cyclization of *(3)* can be induced by alkali or occurs spontaneously and yields 4-mercaptopyrimidines *(4)* with amino or alkoxy groups in the 6-position. Alternatively, dehydrogenative cyclization leads to 3,5-diaminoisothiazoles *(5)* or 3-alkoxy-5-aminoisothiazoles *(5)* (experiments with *U. Keuser*).

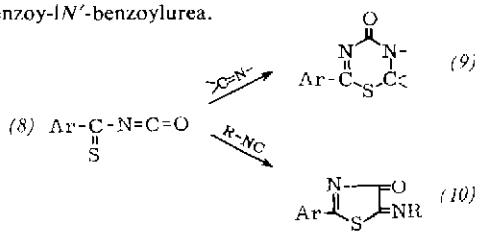
*(2)* $R^1 = H_2N$, $R^2 = H$; *(1)* $R^3 = R$, $R^3 = OR$



*(3)*

*(4)* *(5)*

$R^1$ = OR, $NH_2$; $R^2$ = COR, COOR



Monomeric *N*-substituted α-iminoalkyl isothiocyanates *(6)* are readily converted into dimers (α-iminoalkyltriazinedithiones) [2]. On the other hand, they are easily cyclized to 1,3,5-triazine-2,4-dithiones *(7)* by thiocyanic acid. This confirms the hypothesis of *I. Ugi* and *F. Rosendahl* [3] that an α-iminoalkyl isothiocyanate is formed as an intermediate when

*(6)* *(7)*

HSCN adds onto an isonitrile. It should be mentioned, however, that methyl and phenyl isothiocyanates do not add onto monomeric α-iminoalkyl isothiocyanates.

Thermal decomposition of 2-arylthiazoline-4,5-diones yields arylthioacyl isocyanates *(8)* [4]; phenylthioacyl isocyanate was isolated as red crystals, m.p. 16.5 °C. Additions of aromatic and heterocyclic amines onto *(8)* yield thioacylated ureas; in the aliphatic series, side reactions occur. Thiobenzoylurea can, however, be readily obtained by hydrolysis of *N*-thiobenzoyl-*N'*-benzoylurea.

*(8)* *(9)* *(10)*

1,4-Cycloadditions onto *(8)* with morpholinohexene, *N,N'*-dicyclohexylcarbodiimide, *N*-benzylideneaniline, and phenyl isocyanate afford thiazine or thiadiazine derivatives *(9)*; the corresponding reaction with isonitriles affords 2-aryl-4-oxo-5-alkyliminothiazolines *(10)*. Benzoyl isocyanate reacts in an analogous manner [5]. These cycloadditions are reversible and can be carried out in most cases with the precursors of the thioacyl isocyanates (experiments with *H. Schenk*).

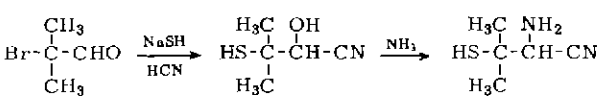
[5] *R. Neidlein* has independently observed the same isonitrile reaction with benzoyl and thiobenzoyl isocyanates [Angew. Chem. 76, 596 (1964)].

# SELECTED ABSTRACTS

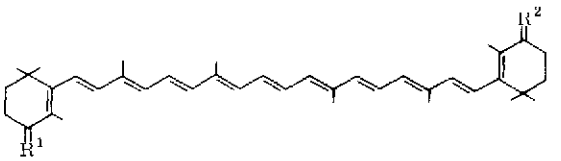


**Bis-(4-hydroxyiminomethylpyridinio)methyl ether dichloride** *(1)*, a drug which reactivates acetylcholine esterase inhibited by phosphoric esters, has been developed by *A. Lüttringhaus* and *I. Hagedorn*. According to clinical investigations carried out by *W. D. Erdmann* and *H. Engelhard*, *(1)* acts as an antidote to poisoning with esterase-blocking alkyl phosphates and has a high therapeutic index. It shows

*(1)*

considerable superiority over reference substances and, when given in greater doses, is capable of passing the blood-brain barrier. It is obtained in 95 % yield by reacting pyridine-4-carboxaldoxime with α,α'-dichlorodimethyl ether, and can be obtained in the form of the *syn*- and the *anti*-oxime, m.p. 235 °C and 220 °C, respectively. Aqueous solutions of *(1)* are stable and can be injected intramuscularly. / Arzneimittelforsch. *14*, 1, 5 (1964) / –De. [Rd 907/258 IE]

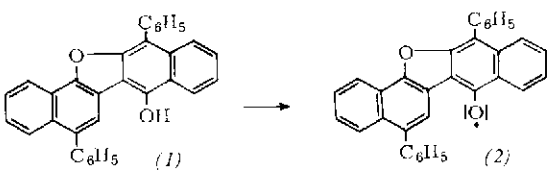
**Penicillamine nitrile** was synthetized for the first time by *I. Ugi* and *E. Böttner*. α-Bromoisobutyraldehyde was treated with NaSH and HCN in methanol. Subsequent addition of $CH_2N_2$ and 85 % phosphoric acid gave α-hydroxy-β-mercaptoisovaleronitrile *(1)* in 88 % yield; b.p. of the hydrochloride 92–94 °C/4 mm.



*(1)* *(2)*

Reaction of *(1)* with liquid $NH_3$ gave penicillamine nitrile (α-amino-β-mercaptoisovaleronitrile) *(2)* in 75 % yield; m.p. of the hydrochloride: 181–182 °C. Compound *(2)* reacts with aldehydes and ketones to form 4-cyano-5,5-dimethylthiazolidines. / Liebigs Ann Chem. *670*, 83 (1964) / –Ma. [Rd 901/251 IE]

**The synthesis of substituted benzoic acids, benzonitriles, and benzaldehydes** is reported by *F. Effenberger* and *R. Gleiter*. These substances can be prepared from *p*-substituted *N*-alkyl- and *N*-arylbenzamides, the starting materials being readily obtained in good yield by Friedel-Crafts reaction of isocyanates and benzene derivatives. Hydrolysis of *N*-substituted benzamides, *e.g. p*-chlorobenzanilide, with alcoholic KOH gives rise to *p*-substituted benzoic acids, *e.g. p*-chlorobenzoic acid (yield = 91 %). Von Braun degradation of *N*-substituted benzamides, *e.g. N*-cyclohexyl-*p*-toluamide, leads to nitriles, *e.g. p*-toluonitrile (yield = 100 %). Sonn-Müller aldehyde synthesis via the imidochlorides, which are reduced to Schiff bases with $SnCl_2$ and subsequently converted into aldehydes by hydrolysis with acid, was used to prepare some aromatic aldehydes, especially ones that cannot be obtained by direct formylation, *e.g. p*-fluorobenzaldehyde and 2,4-dichlorobenzaldehyde (obtained in 83 % and 61 % yield, respectively). / Chem. Ber. *97*, 480 (1964) / –Ma. [Rd 5/282 IE]



**Keto-carotenoids in crustacea** were detected by *H. Thomman* and *H. Wackernagel*. Flamingo feathers contain canthaxanthin as coloring matter; the carotenoid source is considered to be their food, particularly small crustacea such as water-fleas (*Daphnia*). β-Carotene *(1)*, echinenone *(2)*, and canthaxanthin *(3)* were isolated from various *Daphnia* species,

*(1)*: $R^1 = H_2$, $R^2 = H_2$; *(2)*: $R^1 = O$, $R^2 = H_2$; *(3)*: $R^1 = O$, $R^2 = O$

*(2)* and *(3)* in large quantities. It is presumed that water-fleas oxidize β-carotene and accumulate *(2)* and *(3)*. The astaxanthin from flamingo feathers may be derived from *(3)*. / Naturwissenschaften *51*, 87 (1964) / –De. [Rd 906/257 IE]

**5,12-Diphenyl-7-oxyldinaphtho[1,2-*b*:2',3'-*d*]furan** *(2)* a new, stable aroxyl radical has been described by *D. Schulte-Frohlinde* and *F. Erhardt*. Oxidation of *(1)* (obtained from 1-hydroxy-4-phenylnaphthalene) with $PbO_2$ in benzene yields the aroxyl radical *(2)*, which is green in solution and forms black crystals, m.p. above 192 °C, in 50 % yield. According to measurements of their paramagnetic spin resonance, the crystals contain about 15 % free radical, the solutions about 90 %. Solid *(2)* is stable to oxygen. Its degree of dissociation

*(1)* *(2)*

and its sensitivity towards oxygen lie between those of triphenylphenoxyl and tri-t-butylphenoxyl. It is somewhat superior to α,α-diphenylpicrylhydrazyl for trapping other free radicals. / Liebigs Ann. Chem. *671*, 84, 88 (1964) / –Ma. [Rd 903/256 IE]

# BOOK REVIEWS

**Newer Methods of Preparative Organic Chemistry,** Volume II, edited by *W. Foerst*, translated from the German into English by *F. K. Kirchner*. Academic Press, New York and London. 1963. XV + 417 pp. Cloth-bound S 14.50.

Some 50 years ago, the editors of the 4th edition of *Beilstein* had to acknowledge that it was impossible to encompass the whole field of organic chemistry in a handbook of reasonable timeliness. The past decade brought the same realization in the much more restricted field of preparative organic chemistry. *Houben-Weyl* mushroomed from a modest handbook of 4 volumes (4th edition, 1925) into a grandiose compendium of the size of *Beilstein* and with all its merits, but also with the inevitable disadvantage of staying hopelessly behind the rapidly advancing improvement of classical procedures and the steady development of novel techniques. Nonetheless, for generations to come, this impressive work will still remain the starting point for any systematic search for the best solution of problems in preparative organic chemistry. The referee doubts, however, if future generations will ever dare to compile another edition. Like *Beilstein*, which covers the progress of organic chemistry in series of supplements, even in this restricted field, the only possible solution providing a steady, timely source of information is the publication of specialized monographs by experts in individual fields. Long before a new edition of *Houben-Weyl* could even be visualized,

this approach has been chosen all over the world and has resulted in a large number of surveys and progress reports of this kind.

A highly successful attempt in this direction was the innovation of "Neuere Methoden der Präparativen Organischen Chemie" edited by *W. Foerst*, the first volume of which appeared during World War II as a collection of verbatim reprints of articles originally published between 1940 and 1942 in "Die Chemie". Thus, a unique combination of timeliness and competence with a minimum of time-consuming editorial work was achieved which resulted in enthusiastic acceptance of this volume everywhere. Its importance was immediately recognized by the Allies who had it translated into English and reprinted in several editions in the United States.

After the war, as editor of "Angewandte Chemie" *W. Foerst* resumed publication of this popular series and presents in the present volume authentic English translations of the fourteen articles comprising Volume II of the original German edition, which appeared in 1960.

The contributions are again written by recognized authorities in their fields. The selection of the individual chapters resulted both from the personal interest of the editor and from the availability of German specialists. A book of this kind can hardly satisfy everybody, and what is missing from this volume may reasonably be expected in future issues of this series. However, even the highly critical reader, will have to admit that all the articles are well-presented, interesting, exhaustive reports of the progress in their respective field. Contrary to Volume I, which covered also mere techniques such as chromatography and vacuum distillation, Volume II is strictly oriented towards the preparation of definite classes of compounds. However, sometimes the impression is obtained that too much has been included; procedures such as the continuous preparation of phenylsodium and the alkylation of phenols with low molecular-weight olefins under pressure which require specialized expensive equipment will rarely appeal to the average laboratory worker for the occasional preparation of a compound. The individual chapters deal mainly with the principles of various types of syntheses and with their variations and applications. Reaction mechanisms are occasionally discussed, especially where their understanding may allow the experimenter to extend the scope of the reaction or vary its conditions rationally rather than by intuition alone. Each chapter includes a generous supply of detailed preparative directions for actual examples in the style of *Houben-Weyl*; these are adequate for reproduction without recourse to the original literature. The book contains the following contributions, which have been brought up to date by the authors: Syntheses with Acetoacetaldehyde (*W. Franke, R. Kraft, K. Kossing*); Preparation of Peptides and Ureas Using Reactive Amides or Imides (*St. Goldschmidt, H. L. Krauss*); The Preparation of Long-Chain Carboxylic Acids from 1,3-Cyclohexanediones (*H. Stetter*); Ethyl 2-Cyclopentanonecarboxylate and Its Importance in Syntheses (*R. Mayer*); Ketene in Preparative Organic Chemistry (*G. Quadbeck*); Preparative and Analytical Importance of Phosphines and Related Compounds (*L. Horner, H. Hoffmann*); Reduction of Carbonyl Compounds with Complex Hydrides (*H. Hörmann*); Alkylation of Aromatic Amines (*R. Stroh, J. Ebensberger, H. Haberland, W. Hahn*); Chemical Synthesis of Intermediates of Carbohydrate Metabolism (*H. O. L. Fischer*); Amidomethylation (*H. Hellmann*); Selective Catalytic Oxidations with Noble Metal Catalysts (*K. Heyns, H. Paulsen*); Alkylation of Phenols with Alkenes (*R. Stroh, R. Seydel, W. Hahn*); Continuous Preparation of Phenylsodium (*H. Ruschig, R. Fugmann, W. Meixner*); Newer Investigations on Oxidations with Lead Tetraacetate (*R. Criegee*).

The author and subject indices compensate to a large extent the lack of systematic arrangement of the information presented. Like its predecessor, the above volume will extend the use of these extremely valuable monographs to chemists not conversant with German. The organic chemist may rightfully consider this book indispensable, but any member of the profession who is occasionally concerned with problems of organic preparations will derive ample benefits from it.

*Ch. Grundmann* [NB 182/86 IE]

**Zwischenprodukte-Tafeln.** (Intermediates Tables), by *O. Horn*. Carl Hanser Verlag, München 1963. 1st Edit., 20 tables, paperback, DM 7.80 (about $ 2.00).

The number of organic intermediates has grown enormously in the past decades. These compounds, in addition to their original application as dyestuff components, are meanwhile used in many other fields. Petrochemistry has made it possible to develop new syntheses of intermediates from cheap raw materials so that the whole field is now extremely difficult for the non-specialist to comprehend.

The present "Intermediates Tables", based on lectures by the author, render a valuable service in view of this situation. In twenty tables, the essential routes of syntheses for the manufacture of intermediates are clearly presented in the form of family trees. Starting from the raw materials methane, acetylene, olefins, benzene, toluene, xylene, naphthalene, and anthracene, the more important derivatives and their respective genetics are evolved. Thus, the entire range from classical dyestuff intermediates to modern processes of olefin chemistry is embraced. The reagents and characteristic reaction conditions are not always given for the individual process stages but could perhaps have been mentioned without any great loss in clarity.

The "Intermediates Tables" is a kind of "organic chemical technology without words" and will probably not only facilitate students' understanding of the subject but will always be of service when a survey on this complex field is sought. *W. Hahn* [NB 185/81 IE]

**Anabole Steroide** (Anabolic Steroids). By *H. L. Krüskemper*. Biochemie und Klinik, monographs edited by *G. Weitzel* and *N. Zöllner*. Georg Thieme Verlag, Stuttgart 1963. 1st edit., VIII, 166 pp., 14 illustr., 14 tables, cardboard DM 38.– (about $ 10.00).

With this monograph, the author presents a book, to which one may ascribe the highest praise because of its potential to induce the production of new works on this subject. His exhaustive survey of the abundance of experimental results is supported by 1108 literature references. After a review of the nomenclature, chemistry, and metabolism of anabolic steroids (19 pp.), their effects are described in detail (49 pp.). In a further chapter (9 pp.) the effect of anabolic steroids is compared with that of other anabolic hormones. The most important results on the problem of the structure and activity of anabolic steroids as well as on their clinical use, contraindications, and side-effects are presented in detail and in review, so that the book will be of great use equally to biochemists, experimental clinicians, and physicians. The author indicates numerous questions which still remain open. The reviewer is certain that the book deserves a mark of thanks in many future publications on this subject. *E. Gerhards* [NB 187/82 IE]

# The Structure of the Proton and the Neutron

BY PROF. DR. H. SCHOPPER

INSTITUT FÜR EXPERIMENTELLE KERNPHYSIK DER TECHNISCHEN HOCHSCHULE UND DES KERNFORSCHUNGSZENTRUMS KARLSRUHE (GERMANY)

*A short survey is given of the present state of our knowledge of the structure of the proton and the neutron. The results so far obtained have been derived from studies of the scattering of fast electrons.*

## I. Introduction

In the exploration of the macrocosm, attempts are being made to probe ever farther into the universe. The most remote objects known at present, *e.g.* the radio source 3C/295, are some $10^{27}$ cm distant from the earth. Conversely, penetration into the microcosm has now proceeded down to dimensions of about $10^{-14}$ cm.

The ultimate aim of the exploration of space, at least as far as basic research is concerned, is an attempt to comprehend the structure and origin of the universe. In contrast, elementary particle physics attempts to elucidate the structure of matter and its constituents. Ideas concerning the origin and transformations of elementary particles are closely related to theories concerning the creation and development of the cosmos. Progress in these fields keeps demanding increasingly costly instruments: on the one hand, giant optical and radio telescopes and satellite observatories, and on the other, particle accelerators of ever increasing dimensions.

Some decisive steps in the elucidation of the structure of elementary particles have been achieved in recent years. It was shown for the first time that the fundamental building blocks of matter, the proton and the neutron, have structures of their own and are not elementary in the strict sense [1]. Although the problems and methods of elementary particle physics are far removed from those of classical chemistry, it may still be of interest to chemists to find out about the present state of our knowledge in this field. After all, chemists such as *Dalton* and *Avogadro* were the first to produce experimental evidence for the atomic structure of matter.

However, physicists soon discovered that the atoms discovered by the chemists were indivisible only with respect to chemical methods. The golden era of physics followed, with its atomic shell theory and the simultaneous development of quantum mechanics, resulting in complete understanding of the structure of atomic shells and of the forces which hold them together. However, this did not provide an answer to the question of the fundamental nature of matter, since the classical experiments of *Rutherford* demonstrated that almost the entire mass of the atom resides in its nucleus. The by no means complete studies of nuclear physics had shown that all atomic nuclei are made up of protons and neutrons, and it seemed that these particles, the nucleons, represent the ultimate building blocks of matter. Doubts were first raised when it was discovered that the free neutron was not a stable particle but had a half-life of 12 minutes, decaying into a proton, with emission of an electron and a neutrino [2]. The situation became even more complicated when, after 1945, numerous short-lived new elementary particles were discovered (mesons, K-mesons, and other strange particles) [3].

For a variety of reasons, it was suspected that all these particles too were not elementary, but had also composite structures. Detection of the structure of these elementary particles was first achieved with the help of scattering very fast electrons by protons and neutrons [1]. Although the results obtained to date are not final, one important fact has been established: in the past, penetration into new orders of magnitude of smaller dimensions, led to the discovery of new building blocks of matter (atoms, electrons, protons, neutrons); now this no longer seems to be the case. Although the study of nucleons did lead to the discovery of new particles –

[3] *W. S. C. Williams:* Introduction to Elementary Particles. Academic Press, New York 1961.

as discussed below – these were in no way more elementary than the previously known ones They are also extremely short-lived and, for this reason, certainly cannot be regarded as the ultimate, indivisible constituents of matter. The question "What is matter?" therefore seems more complicated than ever.

## II. Indirect Evidence for the Structure of Nucleons

The discovery that the neutron has a magnetic moment of $-1.91\ \mu_K$ ($\mu_K$ – Bohr magnetons; the negative sign indicates that the spin and magnetic moment have opposite directions) was initially very surprising, since in classical physics a magnetic moment was always associated with circular currents. Since the neutron is electrically neutral, generation of a magnetic moment in the absence of an electric charge seemed incomprehensible.

An anomalous magnetic moment was discovered also for the proton. The total magnetic moment of this particle is $+2.793\ \mu_K$, whereas *Dirac*'s theory implies a value of only $+1\ \mu_K$. It should be noted that the anomalous part, $1.79\ \mu_K$, with respect to its absolute value is roughly equal to the magnetic moment of the neutron. The occurrence of normal Dirac magnetic moments of electrons and protons is interpreted in terms of relativistic quantum mechanics by assuming that even when the particle is not subject to external forces, it executes microscopic vibrations which on the average generate small circular currents. Such moments do not therefore presuppose the presence of a complex structure within the particles; as in classical physics, these can be regarded as point particles.

An explanation of the anomalous moments seems possible only by postulating that protons and neutrons are not genuine elementary particles but have internal circular currents [4]. However, the carriers of this current cannot be electrons, since for a variety of reasons, which are described in any book dealing with the subject of β-decay electrons cannot exist within the atomic nucleus. No other stable carriers of electric charges are known. According to the main concept of *Yukawa*'s meson theory [5], the structure of protons and neutrons cannot be explained on the basis of stable particles, but is due to unstable particles, which circulate for extremely brief periods within the interior of protons and neutrons and which are soon recaptured. π-Mesons were the first type of particles to be considered. These exist in three differently charged states, *viz.* positive, negative, and neutral. As will be seen later, other particles may contribute to the structure of nucleons.

In the simplest case, a proton can dissociate into a $\pi^+$-meson and a neutron. Similarly, a neutron may dissociate into a π-meson and a proton. The π-mesons produced surround the "bare" nucleons in the form of a cloud (Fig. 1) [4]. Theory predicts that the mesons are generated in orbits of finite angular momentum [4], *i.e.* they rotate about the remainder of the nucleon. Circular currents are thereby formed and give rise to the anomalous magnetic moments. The opposite charges of the

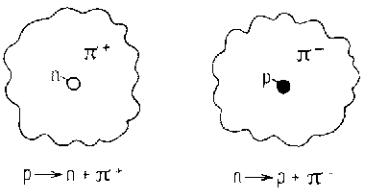

Fig. 1. Virtual dissociation of the nucleons into a meson cloud and a "bare" nucleon.

mesons in protons and neutrons explain the different signs of the anomalous moments. In addition, it has been known for some time that the nuclear forces between the nucleons and mesons are independent of the electrical charge. For this reason, the probability of meson emission is identical for protons and neutrons; this explains the approximately equal absolute values of the anomalous magnetic moments.

In addition to the intermediate states with one meson with there are likely to be others into which two or more mesons are emitted. Other "virtual" particles may appear, *e.g.* K-mesons or proton-antiproton pairs. It has not yet been possible to derive from theory a quantitative prediction of the contribution of the various virtual states to the total structure of the nucleons [4].

If this explanation of the anomalous magnetic moments is correct, then it follows directly that the nucleons must have a spatially extended distribution of electrical charge. It is to be expected that the center contains an approximately point-size bare nucleon with one or more clouds or shells of virtual particles surrounding it. Naturally, structural details cannot be derived from the magnetic moments alone, but the expected spatial extension of the structure can be at least roughly estimated from *Heisenberg*'s uncertainty principle.

The time which elapses before an emitted meson is recaptured is given by $\Delta t \cdot \Delta E = h/2\pi$. In order to determine the greatest possible time $\Delta t$, the least possible energy $\Delta E$ must be substituted in the equation. This is given by the mass m of the virtual particle at rest as $E = mc^2$. The greatest distance which a particle moving with the speed of light can cover in the time $\Delta t$ is given by the so-called Compton wavelength $\lambda/2\pi = \Delta t \cdot c = (h/2\pi)\,mc$. For a π-meson, $\lambda/2\pi = 1.4\times10^{-13}$ cm. This value gives an indication of the expected dimensions of nucleons.

## III. Investigation of the Structure of Nucleons by Electron Scattering

It is possible to determine the structures of crystals and molecules indirectly by electrons or X-ray diffraction. From the angular distribution of the diffracted electrons the spatial arrangement of the diffracting centers can be

[4] *D. R. Yennie, D. G. Ravenhall,* and *M. M. Levy,* Rev. mod. Physics *29*, 144 (1957).

[5] *H. Yukawa,* Proc. physico-math. Soc. Japan *17*, 48 (1935).

inferred. The method of electron diffraction can be applied directly to the investigation of the structure of nucleons, but the wavelength of the electrons must be of the order of $10^{-13}$ cm, since a structure can be resolved only when its details are comparable with the wavelength of the radiation used.

One additional difficulty that arises is that not only are the electrons scattered by the electrical charge of the proton, but an interaction also occurs between the magnetic moment of the electron and that of the proton. These two effects must be separated by a suitable mathematical analysis. For this purpose, a theoretical relationship between the observed scattering pattern and the spatial distribution of the scattering centers must be known [6].

The scattering cross-section for the deflection of an electron by a point proton can be readily calculated [4]. If the value of this "point scattering cross-section" is known, the scattering of a spatially extended proton can be derived by regarding the proton as being composed of numerous point charges. It is then only necessary to add together the scattering waves due to each individual center of scattering. Since coherent scattering is involved, the individual partial waves must be added with proper phases. Such a procedure is well known from X-ray diffraction. On investigating crystals one has to do with scattering centers arranged in a regular lattice, whereas in nucleons, a continuous density distribution must be expected. The conditions are therefore more akin to those encountered in X-ray diffraction by gaseous molecules or liquids.

It is expedient to derive the so-called form factor first from the measured scattering intensities instead of calculating the spatial distribution of the scattering centers directly. This form factor is a function of the recoil momentum q transferred to the scattering particle [4]. Mathematically, the form factor and the density distribution of the scattering particles behave like Fourier transforms [*].

The mathematical derivation cannot be given here; instead, the principal characteristics of the form factor are discussed with the aid of Figure 2, to enable us to interpret the experimental results later.

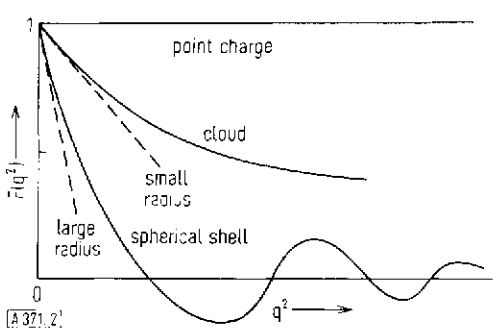

Fig. 2. Schematic representation of the form factor F as a function of the recoil momentum q for various charge distributions. A steeper slope (dotted line) corresponds to a greater mean radius.

A point charge has an associated constant form factor (Fig. 2). If the scattering centers are spread out in space, then the form factor decreases as $q^2$ increases, the slope being steeper the greater the mean radius. The tangent at $q^2 = 0$ gives directly the value of the mean radius $\bar{r}$, since $(\vartheta F/\vartheta q^2)_{q_2=0} = -\bar{r}/6$. The shape of the form factor at high q-values provides information on structural details. Thus, a diffuse distribution gives a steadily decreasing form factor, while density distributions with sharp edges or lattice-like arrangements lead to oscillations of the form factor. It can also be shown readily that the value of the form factor at $q^2 = 0$ is proportional to the total charge which it describes. Thus, the form factors shown in Figure 2 each describe an elementary charge. A density distribution composed of a diffuse cloud and a point-like nucleus is characterized by the form factor shown in Figure 3.

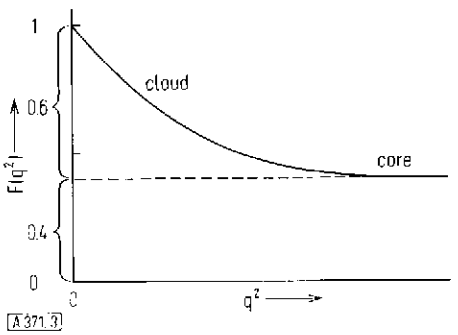

Fig. 3. Schematic representation of the form factor F as a function of the recoil momentum q for a combined charge distribution: 40 % of the charge is concentrated at a point core, and 60 % is distributed over a diffuse cloud.

Two form factors must be derived from the scattering experiments: one describing the distribution of the electrical charge, and the other the distribution of the magnetic dipole moments. Determination of both form factors is possible when the scattering is studied not only as a function of the scattering angle, but also as a function of the energy of the incident electrons. Since "electric" and "magnetic" scattering exhibits different relationships with respect to angle and energy [4], separation of the two effects is possible.

## IV. Experimental Procedure

As explained above, the electrons used must correspond to a wavelength of about $10^{-13}$ cm to be capable of resolving details of the structure of nucleons: the electrons must therefore have energies of several hundred MeV. For this reason, the structure of nucleons can be studied only with the aid of large electron accelerators.

The pioneer experiments were carried out by *Hofstadter* et al. in Stanford (U.S.A.) about seven years ago, using a linear accelerator with an initial maximum energy of about 500 MeV [1]. About two years ago, *Wilson* et al. carried out investigations at Cornell University, Ithaca (U.S.A.) using a synchrotron, *i.e.* a circular accelerator, with a maximum energy of about 1400 MeV [7]. Very

[6] *R. Hofstadter:* High-Energy Electron Scattering Tables. Stanford University Press, 1960.

[*] In X-ray diffraction terminology, this is called transformation to the reciprocal lattice.

[7] *D. M. Olson, H. F. Schopper,* and *R. R. Wilson,* Physic. Rev. Letters 6, 286 (1961); *R. M. Littauer, H. F. Schopper,* and *R. R. Wilson,* ibid. 7, 141 (1961); *K. L. Berkelman, M. Feldman, R. M. Littauer, G. Rouse,* and *R. R. Wilson,* Physic. Rev. *130*, 2061 (1963).

recently, a linear accelerator in Orsay near Paris [8], with a maximum energy of about 1000 MeV, and a synchrotron at Cambridge (U.S.A.) with 6000 MeV, have been put into operation. Fortunately, it will soon be possible to carry out similar experiments in Germany; work has just started with the DESY synchrotron in Hamburg (Germany), which has a maximum energy of 6000 MeV.

As an example of the experimental method, the set-up used at Cornell – where I had the privilege of working [7] – will be described. The arrangements employed at Cambridge and Hamburg are entirely analogous.

Figure 4 shows the arrangement in a schematic form. Straight sections are arranged between the magnets of

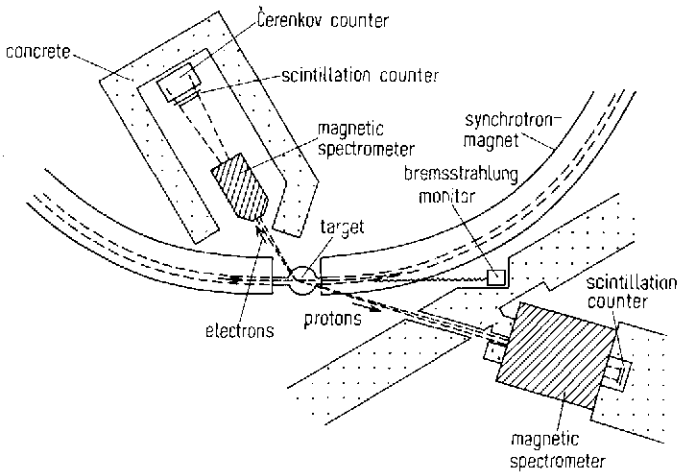

Fig. 4. Diagram of the experimental arrangement for measuring electron scattering by nucleons used at Cornell University, Ithaca, N.Y. (U.S.A.).

the synchrotron, which maintain the electrons in their circular orbit. In one of these sections, there is a scattering chamber with a hydrogen target in its center. The use of a target inside the machine has the advantage that, after a single passage through the target, any non-scattered electrons continue to orbit in the machine and will strike the target several times. Up to 100 such multiple traversals can be obtained. The scattered electrons are analyzed with a magnetic spectrometer, in order to separate elastically and inelastically scattered electrons. The electrons are detected by means of two scintillation counters and a so-called Čerenkov counter, which enables them to be differentiated from accompanying $\pi$-mesons. A second spectrometer is installed at the outside of the synchrotron for detecting protons recoiling from the scattering in coincidence with the electrons. In this way, the reliability and accuracy of the measurements can be appreciably increased.

Substances containing hydrogen (*e.g.* polyethylene) or liquid hydrogen are used as targets for the study of protons. Since, unfortunately, no pure neutron targets are available, deuterium, preferably in the liquid form, is used for the investigation of neutrons. Here however, scattering by protons naturally occurs at the same time as scattering by the neutrons. It can be shown that for high electron energies, the binding between the neutron and the proton in the deuteron can be neglected to a first approximation. Consequently, the known scattering for the proton can simply be subtracted from the scattering by the deuteron, to give the scattering due to the neutron. The magnitiude of the error introduced in this way has not yet been theoretically established; for this and several other reasons, the results for scattering by neutrons are substantially less reliable than those for protons [4].

The main difficulty encountered in carrying out the measurements is the low probability of scattering at high energies and large scattering angles. Counting rates of only a few particles per hour are obtained; thus, very long measuring times are incurred, and the elimination of systematic experimental errors is very difficult.

## V. Results and Their Interpretation

The form factors for the electric and magnetic density distributions in the proton derived from the measurements carried out to date [9] are shown in Figure 5. Certain qualitative conclusions can be drawn directly from these results without having to go into a detailed evaluation. First, it is obvious that the form factors are not constant, and consequently the proton is not a point-like particle. The slopes at $q^2 = 0$ determine the mean radii and for the electric charge distribution of the proton one obtains $r_{Ep} = 1.0\times10^{-13}$ cm, and for the magnetic moment of the proton $r_{Mp} = 1.0\times10^{-13}$ cm.

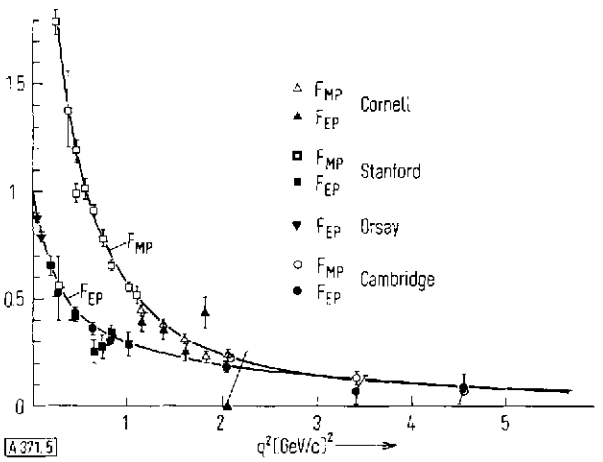

Fig. 5. Experimental form factors F of the proton as a function of the recoil momentum q. $F_{Ep}$ = form factor for the electric charge distribution; $F_{Mp}$ = form factor for the magnetic dipole moment distribution.

Surprisingly, the radii for the two distributions agree to within 10 %. Moreover, the most recent measurements at very high $q^2$ values seem to indicate that the two form factors decrease monotonically, with no indication of their reaching a constant value [9]. According to the arguments presented in Section II, this implies that the proton does not have a point nucleus.

[8] *P. Lehmann, R. Taylor,* and *R. W. Wilson,* Physic. Rev. *126,* 1183 (1962).

[9] *K. W. Chen, A. A. Cone, J. R. Dunning, S. G. Frank, N. F. Ramsey, J. Walker,* and *R. Wilson,* Physic. Rev. Letters *11,* 561 (1963).

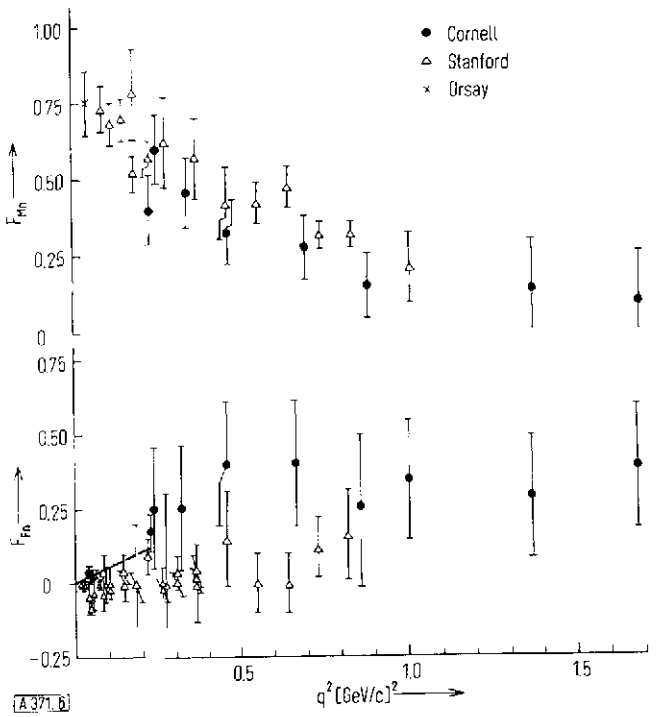

Fig. 6. Experimental form factors F of the neutron as a function of the recoil momentum q. $F_{En}$ = Form factor for the electric charge distribution; $F_{Mn}$ = Form factor for the magnetic dipole moment distribution.

The results of measurements on neutrons (see Fig. 6) [7, 8, 10] are much less reliable than those for the proton. Since the neutron has no resultant electric charge, the form factor for the distribution of electric charge begins at zero. The initial slope of the form factor, and thus the radius of the charge distribution, has been known for some time from the scattering of thermal neutrons by atomic electrons [4]. A value of $r_{En} = 0.4\times10^{-13}$ cm was found. The form factor at higher q-values is as yet uncertain since partly conflicting results have been obtained. Local deviations from electrical neutrality within the neutron are nowhere very large, as is shown by the invariably small values of the form factor. In contrast, the course of the magnetic form factor of the neutron is very similar to that of the proton. The mean radius $r_{Mn} = 1.0\times10^{-13}$ cm found agrees within experimental limits with that found for the proton.

The elucidation of additional details concerning the structure from the shape of the form factors requires complicated theoretical considerations; a final interpretation is not as yet possible. However, certain important and surprising consequences do result from such studies.

All theoretical attempts to explain the experimentally found radii of about $10^{-13}$ cm by postulating that the nucleons consist essentially of clouds of $\pi$-mesons have so far remained unsuccessful [4]. In every case, these $\pi$-mesons produce too large values for the radius. In the face of this situation, the daring idea that as yet unknown particles are responsible for the structure of the nucleons was tentatively suggested some years ago (cf. [11]). Since the radii are directly related to the mass of the particles (cf. Section II), it was possible to predict the mass of these new particles from the measured radii. A figure approximately three to four times that of the mass of the $\pi$-mesons was obtained. Particles with approximately the right mass were observed shortly afterwards in various processes, *e.g.* during the annihilation of antiprotons by protons [12]. The particle can be considered as consisting of two $\pi$-mesons. It was therefore initially designated as a dipion, but is today generally termed a $\rho$-meson. Subsequently, another particle was discovered which also contributes to the structure of the nucleons, but is composed of three mesons. It was initially called a trimeson but is now referred to as an $\omega$-meson. Both particles have extremely short lives of about $10^{-21}$ seconds. In the meantime, numerous further mesons have been discovered, which appear to form a family with those previously known [12]. The nature of the symmetry structure of this family is one of the most interesting problems facing modern elementary particle physics.

To summarize, it can be said that the structure of protons and neutrons consists of several clouds with radii of about $10^{-13}$ cm. These clouds are made up of virtual $\rho$- and $\omega$-mesons and, perhaps, of other unknown particles. The term "virtual" signifies that these particles exist in the cloud for only very brief periods, being constantly annihilated and recreated. This concept is the only one which can explain the contribution of such short-lived particles as the $\rho$- and $\omega$-mesons to the structure of the nucleons. The distribution of the electrical charges and magnetic dipole moments in the individual clouds has not yet been elucidated in detail.

The discovery of these novel mesons during the study of the structure of nucleons has led to new concepts in the interpretation of nuclear forces and of the binding of protons and neutrons inside the atomic nucleus. Further developments cannot as yet be foreseen.

The investigations carried out so far have given no indication of the existence of any ultimate, indestructible particles. Rather, on penetrating into regions of ever smaller dimensions, everything seems to resolve itself into abstractions. This result is one which must surely be of philosophical interest.

# Free Radicals and Free-Radical Reactions of Monovalent and Divalent Sulfur [*]

BY PROF. DR. ULRICH SCHMIDT

CHEMISCHES LABORATORIUM DER UNIVERSITÄT FREIBURG/BRSG. (GERMANY)

*Organic free radicals of monovalent sulfur have not been hitherto observed in solution or in melts. Steric hindrance and resonance stabilization, which are responsible for the stability of the triarylmethyl, diphenylnitrogen, and phenoxyl radicals, are apparently insufficient to stabilize the organic free radicals of monovalent sulfur in such concentrations that they can be detected by current physical methods. – It was only in 1963 that aminopolysulfur radicals ($R_2N-S_n-S\cdot$) were detected in solution, and arylsulfur radicals ($Ar-S\cdot$) and phenylselenium radicals were isolated at ca. −180 °C. – Organically bound sulfur can be stabilized in the free-radical state if association of the radicals is prevented by fixing in a crystal lattice ("cystine radical"), by repulsion between radical ions (sulfinium salts), or by freezing-in (arylsulfur radicals).*

## I. Introduction

The discovery of aryl-substituted carbon, nitrogen, and oxygen radicals had a decisive influence on our views concerning the chemical bond, and, together with the discovery of short-lived alkyl radicals, provided a basis for discussion of free-radical reaction mechanisms. Although numerous reactions are known in the organic chemistry of silicon, phosphorus, and sulfur [**] which certainly proceed by a free-radical mechanism, no free radicals of trivalent silicon and germanium, divalent phosphorus and arsenic, or monovalent sulfur and selenium have as yet been observed. Trivalent radicals of the higher elements of Group IV have been sought in vain by *Krause*, *Schlenk*, *Gilman*, and *Selwood* [1]. Earlier evidence for the existence of trivalent tin and lead radicals, obtained by molecular-weight measurements, requires confirmation by ESR spectroscopy [2]. *Kuchen* [3] was unable to detect the formation of diphenylphosphorus radicals from tetraphenyldiphosphine, in analogy with the decomposition of tetraphenylhydrazine into diphenylnitrogen radicals. Despite many investigations [4–12], in particular by *Lecher*, *Schönberg*, *Selwood*, *Pearson*, *Dimroth*, and *Rundel*, the formation of monovalent sulfur radicals from disulfides was shown, prior to 1963, only in the case of cystine on irradiation with X-rays [13].

The factors stabilizing free radicals such as triphenylmethyl, diphenylnitrogen, and aroxyl, *i.e.* steric hindrance of dimerization and resonance of the radical, are apparently no longer sufficient in the case of the elements of the second and third periods. Owing to the greater covalent radii of these elements, the accumulation of phenyl groups or other bulky substituents does not prevent dimerization. Furthermore, resonance stabilization of the radical is more difficult, owing to the greater distance between the hetero-atom and the phenyl group [1b].

We succeeded recently in isolating several arylsulfur radicals by photolysis of aromatic disulfides or mercaptans in the gaseous state, followed by quenching at 77 °K [13a–13c]. By the same method the diphenylphosphorus [14], diphenylarsenic [15], phenylselenium

[*] Free-radical reactions of tetra- and hexavalent sulfur are not considered in this work. For a survey of these reactions, see [16], p. 326.

[2] In hexamesityldiplumbane – which *M. Lesbre*, *J. Satge*, and *D. Voigt* [C. R. hebd. Séances Acad. Sci. *246*, 594 (1958)] believed to dissociate into free radicals, on the basis of molecular-weight determinations – no dissociation into free radicals could be detected by ESR spectroscopy [*E. Müller*, *F. Günter*, *K. Scheffler*, and *H. Fettel*, Chem. Ber. *91*, 2888 (1958)]. It has been also shown by magnetic measurements that the hexaryl compounds of digermane, diplumbane, and distannane, whose dissociation into free radicals had been assumed from cryoscopic measurements, are diamagnetic [*P. W. Selwood* et al., J. Amer. chem. Soc. *61*, 3168 (1939); *62*, 2765 (1940); *63*, 2509 (1941); *64*, 1727 (1942)]. *W. V. Farrar* has concluded from light-absorption measurements that diphenyl ditelluride dissociates completely in 1% solution to form phenyltellurium radicals [Research *4*, 177 (1951)]. Our own ESR measurements on diphenyl ditelluride solutions at room temperature gave no evidence of free radicals.

[15] *U. Schmidt*, *A. Müller*, and *K. Markau*, unpublished work. Diphenylarsenic radical: $g_{\parallel} = 2{,}034$; $g_{\perp} = 2{,}004$; diphenyltellurium radical: $g_{\parallel} = 2{,}0342$; $g_{\perp} = 2{,}002$.

[13a, 13b], and phenyltellurium radicals [15] were isolated by photolysis of tetraphenyldiphosphine, diphenylarsine, diphenyl diselenide, and diphenyl ditelluride, and were characterized by ESR spectroscopy. The thermal stability can be determined from the rate of recombination on heating, which is measured optically by the fading of the free-radical color. It is greater for the diphenylarsenic and phenylselenium radicals than for the diphenylphosphorus and phenylsulfur radicals.

Since in these radicals steric hindrance of dimerization probably no longer plays an important part, their stability must be due to the weak bonding between the hetero-atoms in the dimer. The bonding between elements of the fourth period (As and Se) is weaker than between elements of the third period (P and S), owing to the greater distance between the atoms and the consequently smaller overlap of the electron orbitals.

Among the radicals mentioned, organic sulfur radicals are of particular interest, since they are assumed to be intermediates in important technical and physiological-chemical processes, *e.g.*:

α) The vulcanization of rubber has been often interpreted as proceeding via organic sulfur radicals [16]. Attempts have been made to detect the benzothiazolyl-sulfur radical, probably because of the accelerating action of benzothiazolyl mercaptan.

β) The regulating action of many disulfides on vinyl polymerization depends on a free-radical displacement on the sulfur of the disulfide by the macroradical, according to Equation (a) [17, 18]. The liberated organic sulfur radical adds onto the monomer M, with formation of a carbon radical [Equation (b)], which starts a new chain.

$$(M)_n\text{—}M\cdot + R\text{—}S\text{—}S\text{—}R \rightarrow (M)_n\text{—}M\text{—}S\text{—}R + R\text{—}S\cdot \quad (a)$$

$$R\text{—}S\cdot + M \rightarrow R\text{—}S\text{—}M\cdot \quad (b)$$

γ) The primary process in the denaturation of proteins by ionizing radiation is probably free-radical formation on the protein sulfur [19]. Numerous investigations on the action of ionizing or ultraviolet radiation on proteins containing sulfur have demonstrated the formation of sulfur radicals which are stable in the crystalline state.

## II. Free-Radical Reactions of Organic Sulfur Compounds

Although there is no compelling evidence for the formation of monovalent sulfur radicals (sulfenyl or thiyl radicals) RS· in solution [*], many free-radical reactions of mercaptans and organic disulfides are known which occur on heating, irradiating, or in the presence of free-radical formers, *e.g.*:

a) The disproportionation of a mixture of symmetrical disulfides in the molten state to form unsymmetrical disulfides, and the reverse process, can be plausibly interpreted by means of a homolytic dissociation (c) into organic sulfur radicals which react with the disulfide in a displacement reaction (d) [20].

$$R\text{—}S\text{—}S\text{—}R \rightleftarrows 2\ R\text{—}S\cdot \quad (c)$$

$$R\text{—}S\cdot + R'\text{—}S\text{—}S\text{—}R' \rightarrow R\text{—}S\text{—}S\text{—}R' + R'\text{—}S\cdot \quad (d)$$

b) The reactions of disulfides or mercaptans with phosphites and free-radical formers to form hydrocarbons and thioethers [20a, b], have been explained by *Walling* by the radical chains (e), (f), (g) and (e), (f), (h) [21]:

$$R\text{—}S\cdot + P(OR')_3 \rightarrow R\text{—}S\text{—}\dot{P}(OR')_3 \quad (e)$$

$$R\text{—}S\text{—}\dot{P}(OR')_3 \rightarrow R\cdot + S{=}P(OR')_3 \quad (f)$$

$$R\cdot + RSH \rightarrow RH + RS\cdot \quad (g)$$

$$R\cdot + R\text{—}S\text{—}S\text{—}R \rightarrow R\text{—}S\text{—}R + RS\cdot \quad (h)$$

c) In the addition of mercaptans to double bonds, which is induced by free-radical formers or by light [22] and is often used in preparative work, an organic sulfur radical adds onto the C=C bond. The resulting carbon radical dehydrogenates the mercaptan to form a sulfur radical which propagates the chain according to (i) and (k):

$$R\text{—}S\cdot + R'HC{=}CHR'' \rightarrow R'HC(SR)\text{—}\dot{C}HR'' \quad (i)$$

$$R'HC(SR)\text{—}\dot{C}HR'' + R\text{—}SH \rightarrow R'HC(SR)\text{—}CH_2R'' + R\text{—}S\cdot \quad (k)$$

d) Dehydrogenation or oxidation of mercaptans in the presence of styrene or dienes leads, after addition of an organic sulfur radical to a double bond, to co-oxidation, telomerization, or polymerization [23].

e) When a mixture of a disulfide and a hydrogen donor is heated, considerable quantities of mercaptan are formed [24] until equilibrium is attained [Equations (l) and (m)].

$$R\text{—}S\text{—}S\text{—}R \overset{h\nu}{\rightleftharpoons} 2\ R\text{—}S\cdot \quad (l)$$

$$2\ R\text{—}S\cdot + H_2\text{—}Don \rightleftharpoons 2\ R\text{—}SH + Don \quad (m)$$

Harris* in Organic Reactions. Wiley, New York 1963, Vol. XIII, p. 185 et seq.

Characteristic reactions proceeding via organic radicals of monovalent sulfur may be summarized as follows:

α) Initiation of free-radical reactions of mercaptans and disulfides by light or free-radical formers (peroxides, azo-compounds) [*e.g.* initiation according to reactions (a), (c), (e), (i), or (l)].

β) Free-radical displacement reactions on the sulfur of mercaptans or disulfides [*e.g.* according to (a), (d), (g), (h)].

γ) Recombination of the short-lived, and so far not physically detected, organic sulfur radicals formed according to α) or β), to yield disulfides [Equations (c) or (l)].

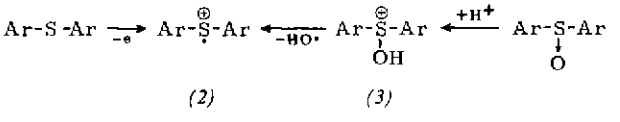
δ) Addition of sulfur radicals to C=C bonds [*e.g.* (b), (i)].

ε) Dehydrogenation of aliphatic and hydroaromatic compounds by thermally or photolytically formed organic sulfur radicals [*e.g.* Equation (m)]. Analogous behavior is shown by the polysulfur radicals formed by fission of $S_8$ rings: they react with aliphatic and hydroaromatic compounds with dehydrogenation [25], substitution [26], or trithione formation [27a, b], and induce the Willgerodt reaction possibly by α-substitution of ketones via N–S radicals [27b, 28].

## III. Attempts to Detect Organic Sulfur Radicals

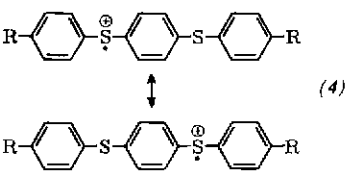
Earlier attempts have been already reported [4]. The evidence for the dissociation of disulfides into monovalent sulfur radicals, based on determinations of molecular weight, light absorption, and magnetism, has been either refuted by ESR spectroscopy [29] or is not convincing [30]. The methods are much too inaccurate to detect the expected small amounts of free radicals, but nevertheless are often quoted, even in recent textbooks and monographs. The strong thermochromism of many disulfides, which is often quoted as an argument in favor of dissociation, can be plausibly explained by thermal broadening of the absorption bands [31].

The stabilization of arylsulfur radicals by steric hindrance of dimerization appears to be possible only with very large substituents in the *ortho*-positions. Experiments with diaryl disulfides which were hexasubstituted by phenyl [10], iso-propyl [11], or t-butyl groups [12] gave no indication of dissociation into radicals. Since the phenoxyl radical has been recently shown by ESR spectroscopy [32] to occur during dehydrogenation of phenol, similar experiments with mercaptans in solution seem promising [33].



### 1. The "Cystine Radical" [13]

Irradiation of cystine crystals with X-rays produces radicals which remain stable for years in the solid state. *Gordy* has established the structure of the radical *(1)* by ESR hyperfine structural analysis of irradiated single crystals of cystine dihydrochloride. After homolytic cleavage of the S–S bond, rotation about the $C_2$–$C_3$ bond gives rise to an arrangement with widely separated radical groups, which is stable in the crystal. The free-radical state disappears immediately when the crystal is dissolved.



$$HOOC{-}HC(NH_2){-}CH_2{-}S\bullet \qquad (1)$$

### 2. Diarylsulfinium Salts [34, 35]

Oxidation of aromatic thioethers in concentrated sulfuric acid yields deeply colored solutions of divalent radical ions (sulfinium salts) *(2)*, some of which are stable for several days. The state of oxidation of the radical ion is between those of the thioether and the sulfoxide. The same radical ion is formed from aromatic sulfoxide on dissolution in sulfuric or polyphosphoric acid, probably by the removal of an OH radical from the cation *(3)* of the sulfoxide salt. Diarylsulfinium salts are stable only if substituted in the *p*-positions with electron-donating groups. Sulfur radical ions of the type of *Wurster*'s salt *(4)* are especially stable, and are formed even in the oxidation of nitro-substituted *p*-phenylene-dithiodiaryl ethers.

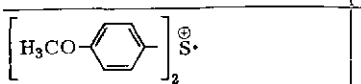
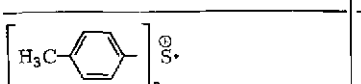
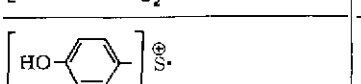
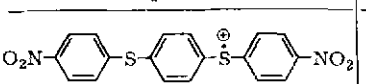
The tetraarylthiophenium salts *(7)* may be classified as sulfur-containing members of the series of stable five-membered cyclic radicals, such as pentaphenylcyclopentadienyl [36] *(5)* and pentaphenylpyrrolium salts [37] *(6)*. They are formed from tetraarylthiophenes in concentrated sulfuric acid.

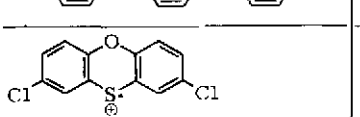
*(5)* *(6)* *(7)*

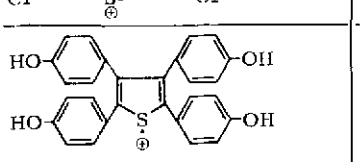












The sulfinium hexachlorostannates, which are stable in the solid state but are very sensitive to moisture, react rapidly in suspension in benzene with phenols or phenolethers to form sulfonium salts:

(n)

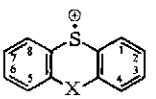
The reaction between sulfoxides and phenols or phenol ethers in concentrated acid to form sulfonium salts, which was discovered by *Smiles* [38] and which *Lüttringhaus* [39] has formulated, in the case of phenol/HCl, as passing through a sulfoxide salt, probably proceeds via a sulfur radical ion in many cases, and certainly in sulfuric acid. The radical ion is formed by removal of an OH radical from the initially produced sulfoxide salt.

Table 1. Data from the ESR spectra and colors of some sulfinium cations in $H_2SO_4$.

| Radical cation | Color | g Value | Band width [Gauss] | Number of lines |
|---|---|---|---|---|
|  | Blue-violet | 2.0078 | 10.7 | 9 |
|  | Red | 2.0091 | 12.8 | 7 |
|  | Blue | 2.0071 | 10.1 | 5 |
|  | Green | 2.0086 | 11.6 | 1 |
|  | Blue | 2.0072 | 9.3 | 3 |
|  | Red | 2.0030 | 9.6 | 5 |

Strong ESR signals were recorded with solid and dissolved sulfinium salts (cf. Table 1). The repeatedly observed fine structure of the spectra could be interpreted, *e.g.* the seven lines of the ditolylsulfinium salt by coupling of the six methyl protons. On passing from the methoxyl-substituted compounds (dianisylsulfinium salt: 9 lines; tetraanisylthiophenium salt: 13 lines) to the corresponding hydroxyl compounds, the number of lines in the spectra decreases [4,4′-dihydroxydiphenylsulfinium salt: five lines, due to coupling of the four *o*-protons; 4,4′-dihydroxy-2,2′,5,5′-tetrachlorodiphenylsulfinium salt: three lines, due to coupling of the two *o*-protons; tetra-(4-hydroxyphenyl)thiophenium salt: five lines, due to coupling of a group of four protons, probably the four *o*-protons of the phenyl groups at positions 2 and 5.

The transfer of electrons between N-and S-compounds is of interest with regard to the denaturation of proteins by radiation. For example, diarylsulfinium salts and triarylamines momentarily yield the nitrogen radical ion, which is strongly stabilized by resonance owing to its three aryl groups:



(o)

### 3. Thianthrene and Phenoxathiin (Phenoxthin) Radical Ions

High concentrations of free radicals *(8)* have been detected in the deep-blue solutions of thianthrene in concentrated sulfuric acid, by *Hirshon, Gardner,* and *Fraenkel* [40], using ESR measurements. *Wertz* and *Vivo* [41] recorded a five-line spectrum. *Shine, Davis,* and *Small* [42] as well as *Rundel* and *Scheffler* [43] deduced from the fine structure of substituted thianthrene radical ions that, in addition to the sulfur atoms, carbon atoms 2, 3, 6, and 7 possess high spin densities.

High free-radical concentrations have been also observed by ESR spectroscopy in the deep-blue solutions of chlorinated phenoxathiin *S*-oxides in sulfuric acid [44]. *Lamotte, Rassat,* and *Servoz-Gavin* [45] later recorded the ESR spectrum of the blue-violet solution of unsubstituted phenoxathiin in sulfuric acid [radical *(9)*]. However, the number of lines in the hyperfine structure cannot be established with certainty. Moreover, the spectrum is unsymmetrical and hence cannot be explained unambigously. Systematic investigation of the solutions of substituted phenoxathiin *S*-oxides yielded simpler symmetrical spectra with fine structure, which allowed conclusions to be drawn regarding the position probability of the single electron [46] (*e.g.* 1,3,4,5,6,8-hexachlorophenoxathiin radical ion: three lines, due to coupling of the two protons *para* to the free-radical sulfur).

*(8)*: X = S
*(9)*: X = O

### 4. Sulfur-Containing Oxygen and Nitrogen Radicals with High Spin Density on the Sulfur

Di-(*o*-nitrophenylsulfenyl)hydrazine *(10)* dissociates reversibly in solution above 50 °C to form *o*-nitrophenylsulfenylimine radicals *(11)* [47]. The triplet structure of the ESR

[45] *B. Lamotte, A. Rassat,* and *P. Servoz-Gavin*, C. R. hebd. Séances Acad. Sci. *225*, 1508 (1962).

[46] *U. Schmidt, K. H. Kabitzke,* and *K. Markau*, Chem. Ber. *97*, 498 (1964).

[47] *U. Schmidt, K. H. Kabitzke,* and *K. Markau*, Angew. Chem. *76*, 376 (1964); Angew. Chem. internat. Edit. *3*, 373 (1964).

spectrum shows a certain spin density on the nitrogen. However, since the equal distances between lines of equal intensity are only half as great (11 gauss) as for a comparable nitrogen radical (diphenylpicrylhydrazyl), high spin density must be assumed at an atom without nuclear spin, such as sulfur. A considerable contribution from limiting structures with free-radical sulfur *(11a)* is also indicated by the high g value (2.0076), which is within the range of the values found for sulfinium salts [$CH_3O-C_6H_4-\overset{\oplus}{S}-C_6H_4-OCH_3$: g = 2.0079] and outside that for pure N-radicals [diphenylpicrylhydrazyl: g = 2.0036]. Above about 80 °C, considerable evolution of $N_2$ occurs in toluene solution. The sulfenylimine radical *(11)* then decomposes according to Equation (r), presumably forming the arylsulfur radical – which recombines to give the disulfide *(12)* – and nitrene, which reduces the N–S radical to the sulfenamide *(13)*; compounds *(12)* and *(13)* have been detected as products. Only *(12)*, $N_2$, and $NH_3$ are formed in glacial acetic acid and in the dry decomposition of *(10)*; the $N_2$ and $NH_3$ probably result from the disproportionation of NH. When *(10)* decomposes in acrylonitrile solution, the solvent is rapidly polymerized.

$$\underset{(10)}{ArS-HN-NH-SAr} \rightleftharpoons 2\ \underset{(11)}{ArS-NH} \leftrightarrow 2\ \underset{(11a)}{Ar\overset{\oplus}{S}-\overset{\ominus}{N}H}$$

$$2\ \underset{(11)}{ArS-\dot{N}H} \rightarrow 2\ ArS\cdot + 2\ NH \qquad (r)$$

$$2\ ArS\cdot \rightarrow \underset{(12)}{ArS-SAr}$$

$$2\ ArS-\dot{N}H + 2\ NH \rightarrow 2\ ArS-NH_2 + N_2 \quad (13)$$

Aroxyls with thioether groups in the *p*-position have been studied by *Müller*, *Stegmann*, and *Scheffler* [48]. An ESR spectrum with nine lines was recorded for *p*-methylthio-*o*,*o'*-di-t-butylphenoxyl, and was explained by participation of sulfur free-radical structures. No coupling of the protons of the *p*-phenylthio group was however observed in the spectrum of the *p*-phenylthio compound, in which even stronger participation of sulfur free-radical structures should be expected (cf. the stability of the diarylsulfinium salts [34,35]).

## 5. Aminopolysulfur Radicals

By means of ESR measurements *Hodgson*, *Buckler*, and *Peters* [49] have found recently that solutions of sulfur in amines contain stable polysulfur radicals *(14)* at room temperature. These radicals probably result from the dissociation of the diaminopolysulfane *(15)*, and are possibly responsible for the catalytic action of amines in numerous reactions of sulfur [*].

## 6. Arylsulfur and Aryldisulfur Radicals

Attempts to produce monovalent organic sulfur radicals in the gaseous state by exposure of disulfides to light, followed by mixing with a hydrogen donor to detect radicals by mercaptan formation, and to determine their lifetimes by varying the distance between the zone of irradiation and the point of entry of the hydrogen donor, were successful only with aromatic disulfides [13a]. When a condenser, covered with cumol as the hydrogen donor and cooled with liquid nitrogen, was fitted past the irradiation zone, a red condensate precipitated in the photolysis of diphenyl disulfide; the red color faded on thawing. The red substance separates out on the condenser in a higher concentration when the disulfide is vaporized with accurate temperature control, and irradiated.

The red product of the photolysis of diphenyl disulfide was identified as the phenylsulfur radical by recombination to form the colorless diphenyl disulfide, by reaction with cumol to form thiophenol, and by paramagnetic resonance spectroscopy [13a–13c]. The red radical is stable at the temperature of liquid nitrogen but recombines within a few minutes even at 165 °K. The ESR signal is very strong (Fig. 1); the strong anisotropy and the high g-value indicate a phenylsulfur radical with the single electron largely localized on the sulfur atom [50].

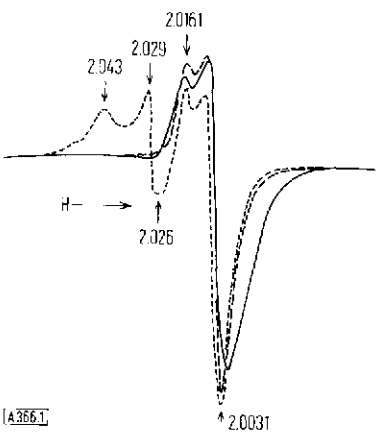

Fig. 1. ESR spectra of aromatic sulfur radicals. The measurements were recorded at 77 °K with a Varian V 4500 spectrometer with 100 kc/sec modulation. The g values were determined by measurement of the microwave frequency and of the magnetic field with a nuclear resonance probe. Frequency 9500 Mc/sec.
– – – – Phenylsulfur ($C_6H_5-S\cdot$); ——— *p*-xenylsulfur ($p$-$C_6H_5-C_6H_4-S\cdot$); ------ photolysis product of dixenyl disulfide.
Abscissa: Field strength.
Ordinate: d(absorption) d(field strength).

[50] *J. D. Michaelsen* [Ph. D. Thesis, Catholic University, Washington, 1955] has observed colored coatings on a very low-temperature condenser in the pyrolysis of aromatic disulfides. However, the free-radical nature of the colored condensate was not proved, and the results have not been published. Three weeks after the publication (March 21st, 1963) of our first communication [13a] on the isolation of the phenylsulfur radical and the detection of its free-radical nature by ESR spectroscopy, *P. J. Zandstra* and *J. D. Michaelsen* published [J. chem. Physics *39*, 933 (1963); received on April 11th, 1963] a paper describing ESR measurements on the pyrolysis products of diphenyl disulfide and β,β-dinaphthyl disulfide; the products were obtained by methods described by *Michaelsen* in his thesis. Besides a g value of 2.000, these authors found g = 2.1246 for the pyrolysis product of the disulfide. They constructed the spectrum of the phenylsulfur

A few substituted arylsulfur radicals were isolated by the same method, and the effect of the substituent on the recombination temperature was investigated [13b, 13c]. Table 2 shows that electron-donating groups, or a phenyl group in the *p*-position, stabilize the radicals and displace their light absorption towards longer wavelengths. Similarities can be recognized between the stability of the sulfur radicals and the free-radical cleavage of the corresponding disulfides by cyanoisopropyl radicals or the macroradicals in the vinyl polymerization (Table 3): with unstrained disulfides, the ease of the free-radical cleavage increases with increasing stability of the corresponding sulfur radical.

Table 2. Color and stability of monovalent organic sulfur radicals.

| Radical | Stability | Color | Color of disulfide |
|---|---|---|---|
| $C_6H_5-S\cdot$ | [a] | Red | Colorless |
| $p$-$CH_3O\ C_6H_4-S\cdot$ | [a] | Red | Colorless |

[a] The color of the radical fades in a few minutes at 165 °K.

[b] The color of the radical is still weakly present after 10 minutes at 190 °K.

Arylsulfur radicals are also formed in the photolysis of thiophenols [13c], which is not surprising in view of the large chain-transfer constants [*] [17, 18] and the numerous free-radical addition reactions [22] of the mercaptans [51]. The ESR spectrum of the prussian-blue *p*-xenylsulfur radical produced by photolysis of *p*-phenylthiophenol (*p*-xenyl mercaptan) is very similar to that of the phenylsulfur radical (Fig. 1). On photolysis of dixenyl disulfide, on the other hand, the spectrum of the xenylsulfur radical shows a second free radical signal with a high g value. It is believed that in this case homolysis of the S–C bond has also occurred, as well as cleavage of the S–S bond, giving rise to the polysulfur diradical ($\cdot S-S_n-S\cdot$) or the *p*-xenyldisulfur radical ($C_6H_5\ C_6H_4-S-S\cdot$). This view is supported by the position of the anisotropic ESR signal at higher g values (which correspond to the g value of 2.030 for the aminopolysulfane radical $R_2N-S_n-S\cdot$ [49]), by the approximately equal dissociation energies of the S–S and C–S bonds [51], and by the appearance of hydrogen sulfide [*] on reduction of the recombination product with $LiAlH_4$ [13c].

radical after mathematical elimination of a foreign radical signal, and carried out an MO calculation of the electron distribution in the phenylsulfur radical. Our own ESR measurements, repeated several times, on the phenylsulfur radical prepared by our method from diphenyl disulfide *or* thiophenol, have only given traces of a free-radical signal at the high g value of 2.1246, the maximum strength of this signal being 3% of that of the main signal. The high g value of 2.1246 published by the American authors is not, therefore, attributable to the phenylsulfur radical, but to a foreign radical which is formed in high concentrations together with the phenylsulfur radical under the drastic conditions used by *Michaelsen*. The agreement between the result of the MO calculation described by *Zandstra* and *Michaelsen* and their experimental results is probably fortuitous.

[*] The chain-transfer constant of the mercaptan or disulfide is defined as $K = v_K/v_M$, where $v_K$ = rate of reaction of the macroradical with the chain-transfer agent (disulfide or mercaptan); $v_M$ = rate of addition of the macroradical to the monomeric olefin. The greater the chain-transfer constant of a mercaptan or disulfide, the more readily will its S–H or S–S bond be cleaved homolytically by a carbon radical. For the determination of chain-transfer constants, see the standard works on polymerization kinetics.

[51] The dissociation energy of the S–H bond was at least in the aliphatic series – found to be rather greater than that of the S–S bond: $CH_3S-H = 88.8$ kcal/mole; $CH_3S-SCH_3 = 73.2$ kcl/a mole; $CH_3-SCH_3 = 73.2$ kcal/mole [*J. L. Franklin* and *H. E. Lumpkin*, J. Amer. chem. Soc. *74*, 1023 (1952)].

## IV. Free-Radical Displacement Reactions on the Sulfur of Organic Disulfides

The regulating action of disulfides on the vinyl polymerization has been already mentioned in the introduction (Section I.3). The chain-transfer constants have been measured for many disulfides [17, 18]. A simple displacement reaction on the disulfide sulfur is the reaction of triarylmethyl radicals with disulfides to form thioethers [52].

To examine the effect of substituents on the homolysis of the S–S bond, reaction (s) of the cyanoisopropyl

$$(CH_3)_2\dot{C}-CN + RS-SR \rightarrow (CH_3)_2C(CN)-SR + RS\cdot \quad (s)$$

radical with various disulfides was studied under standardized conditions [53] (see Table 3). With aromatic disulfides, free-radical displacement on the sulfur of the S–S bond is facilitated by the presence of electron donors in the *p*-position. This agrees with the fact that

Table 3. Homolytic cleavage of disulfides by cyanoisopropyl radicals or by macroradicals during styrene polymerization.

| Disulfide | Cleavage [%] by cyanoisopropyl radicals [53] [a] | K (°C) [b] of the styrene polymerization [17, 18] |
|---|---|---|
| $(C_6H_5-S-)_2$ | 11.8 | 0.14(99) |
| | | 0.06(50) |
| $(CH_3O-C_6H_4-S-)_2$ | 16.8 | 0.33(99) [c] |
| $((CH_3)_2N-C_6H_4-S-)_2$ | 31 | |
| $(ROOC-C_6H_4-S-)_2$ | 13.3 | 0.11(50) |
| $(C_6H_5-CH_2-S-)_2$ | 5.8 | 0.01(99) |
| $(n\text{-}C_4H_9-S-)_2$ | 1.2 | 0.005(99) [d] |
|  | 5.5 | |
|  lipoic acid | 12 | |

[a] The disulfides were allowed to react under standardized conditions with a tenfold excess of azo-isobutyronitrile in dioxan until the azo-compound was completely decomposed. The degree of conversion was then determined from the concentration of the unreacted disulfide.

[b] For the definition and determination of the chain-transfer constant K, see footnote [*] in opposite column.

[c] Transfer constant of di-(*p*-ethoxyphenyl) disulfide.

[d] Transfer constant of diethyl disulfide.

[*] Hydrogen sulfide can arise only from the sulfur or the polysulfides which result on heating the *p*-xenyldisulfur radical.

[52] *H. Lecher*, Ber. dtsch. chem. Ges. *48*, 524 (1915); *A. Schönberg, A. Stephenson, H. Kaltschmitt, E. Petersen*, and *H. Schulten*, ibid. *66*, 237 (1933).

[53] *U. Schmidt* and *A. Müller*, Liebigs Ann. Chem. *672*, 90 (1964).

the chain-transfer constant of dianisyl disulfide is greater than that of diphenyl disulfide. Among the aliphatic disulfides, only those with strained five- and six-membered rings react with the inert cyanoisopropyl radical [54]; the greater strain of the five-membered ring manifests itself clearly in the higher rate of reaction on free-radical attack. It should be mentioned that dibenzyl disulfide undergoes free-radical cleavage much more easily than the purely aliphatic disulfides; the chain-transfer constant is also greater than for aliphatic disulfides.

[54] *W. A. Pryor* and *P. K. Platt* [J. Amer. chem. Soc. *85*, 1496 (1963)] have recently investigated the reaction between phenyl radicals and aliphatic disulfides. As the steric hindrance of the disulfide group increases, the free-radical displacement on the sulfur is suppressed in favor of a dehydrogenation by the phenyl radical. The effect of steric hindrance of aliphatic disulfides in a free-radical displacement reaction on the sulfur also manifests itself in the smaller chain-transfer constants of branched disulfides.

# Chromatographic Separations on Porous Gels [*]

BY DR. H. DETERMANN

INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT FRANKFURT/MAIN (GERMANY)

*Over the past few years, fractionation of mixtures of substances on the basis of differences in their molecular weights has become an important method in chemistry and biochemistry. A survey is given of the theory and practice of separations applying porous gels, and the multifarious uses of such gels are indicated.*

## 1. Introduction

Modern methods of separation, *e.g.* partition chromatography, countercurrent distribution, adsorption or ion-exchange chromatography, and electrophoresis, generally make use of differences in solubility or molecular charge. It is only comparatively recently that advantage has been taken of differences in molecular sizes [1, 1a], although zeolites [2], which have been known for some time, are in fact molecular sieves consisting of three-dimensional networks of $SiO_4$ and $AlO_4$ tetrahedra enclosing cavities (about 50 % of the volume) connected by pores. Zeolites are now produced synthetically and are used, for example, for drying gases or for separating olefins from gas mixtures; even at extreme temperatures they have specific affinities for polar substances.

The first generally applicable method for separating large from small molecules, namely dialysis through porous membranes, was derived directly from macroscopic filtration. In the meantime, dialysis techniques have been refined by the development of membranes with graduated, well-defined pore sizes. "Ultrafilters" or "membrane filters" [2a] consist of foams of cellulose derivatives or regenerates, and are used predominantly in biochemistry for the concentration and desalting of protein solutions, or in electrodialysis. In these preparations, in contrast to the zeolites, pores and cavities are identical and account for about 80 % of the volume of the filter.

The pore sizes of agar membranes have recently been determined by diffusion of proteins and viruses of various particle weights [3]. *Craig* used pretreated cellulose membranes to obtain information about the shapes of peptide and protein molecules in solution from their rates of diffusion [4]. *Synge* reported attempts to separate cytochrome c, insulin, gramicidin S, and valine by multistage electrodialysis [5]; in the course of their migration in an electric field, the ions were made to pass through membranes of increasing density, being more or less retained by these according to size. This technique may be compared with the multistage dialysis processes due to *Signer* [6] and *Craig* [7], in which the dialysate of the first unit becomes the liquid to be dialysed in the second stage, and so on. The output from the separation is poor, as regards both quality and quantity, in relation to the effort involved.

Much better separations can be achieved by the simple chromatographic process of gel filtration. This in-

volves the swelling of grains of polymeric material with solvents, the pores [7a] being filled with solvent. If the average diameter of these pores bears the correct relationship to the molecular size of the mixture to be separated, then, on loading the gel, molecules diffuse into the gel grains to a greater or lesser extent, or not at all, according to their size. For the largest particles only the solvent outside the gel is available; they are therefore the first to leave the gel packing (*e.g.* a perpendicular column) on elution, while smaller molecules penetrate for various distances into the internal phase. The substances therefore appear in the eluate of the chromatographic column in the order of decreasing molecular weights. Thus, gel filtration can be regarded as multiple dialysis, in which the gel grains act simultaneously as dialysis membranes and as receivers for the dialysate. Owing to the numerous separations repeated over the length of the column, the efficiency of gel filtration bears the same relationship to that of the dialysis process as partition chromatography does to extraction in a separating funnel (cf. [8]).

## 2. Gel Formers

Porous materials have been used in chromatography for some time, in the form of synthetic ion-exchange resins, and gel filtration effects have indeed been observed occasionally. Thus it soon became known that in ion-exchangers not only the degree of swelling, but also the capacity for large counter-ions, depends on the degree of cross-linking [9, 10]. Ions of macromolecules are eluted more rapidly than low molecular-weight ions of equal charge [11–13]. Thus, as early as 1952, *Partridge* separated amino acids, peptides, and proteins on a sulfonated polystyrene resin [14]. Even for uncharged polyalcohols, there is a qualitative relationship between the elution volume [14a] and the molecular weight on ion-exchange resins [15, 16]. Following these more casual observations, systematic attempts were soon made to find porous gels for molecular-weight chromatography, with the following requirements in mind.

The gel material must be insoluble but capable of swelling in the desired solvent; the diameters of the resulting pores must be comparable with the molecular dimensions (including the solvation sheath) of the substances to be separated.

These properties are exhibited by particles of macromolecules which have been rendered insoluble and given a porous structure by cross-linking. For optimum separation, it must be possible to vary the pore sizes accurately. Particles of highly cross-linked gels are no longer penetrable even by relatively small molecules. The gel bed [16a] should have no adsorptive properties, so that the substances to be separated can move freely according to their relative sizes. The rate of flow is governed by the size and shape of the gel particles in the column. Spherical particles are preferable to irregularly shaped particles, since even at high rates of flow the former provide a fine grain and hence promote rapid establishment of equilibrium.

In some natural materials, which exhibit gel-filtration phenomena, the macromolecules are only hydrogen-bonded. Suspensions of agar gel [17, 18] and agarose [19], can be used for fractionating macromolecules according to molecular weight. Agarose, which contains no polar groups, appears to be the most appropriate large-pored material, particularly for very high molecular and particle weights [19a]. *Hjertén* [20] has described a process for the preparation of regular spherical particles.

In gels made of natural products the degree of cross-linking is predetermined. The pore size can be adapted for particular separations by varying the quantity of swelling agent. Stiff gels correspond to high degrees of cross-linking, while the pores of less stiff gels (lower dry weight) are accessible even to large molecules [20a]. This is also recognized with homogeneous starch gels in the electrophoretic separation of proteins by *Smithies'* method [21]. Table 1 shows how much the migration of macromolecules in the electric field is affected by the three-dimensional network structure of the support [22].

Table 1. Molecular weights and relative rates of migration of proteins in a starch gel in an electric field.

| Protein | Molecular weight | Relative rate of migration | |
|---|---|---|---|
| | | on paper | in starch gel |
| β-Lipoprotein | 1300000 | 1.0 | 0.14 |
| Transferrin | 90000 | 1.0 | 0.88 |
| Hemoglobin | 60000 | 1.0 | 1.0 |

Starch grains have also been used for the chromatographic separation of amino acids and peptides [23], and of oligo- and polysaccharides [24].

In principle, it is possible to obtain cross-linked macromolecules from any polymerizable monomer by copolymerization with a bifunctional monomer. These completely synthetic materials include not only gels such as polyacrylamide [25–27] which swell in water,

[7a] The dry material is not porous, but the pores which appear on swelling are preformed by the cross-linking of the polymers.

but also those, *e.g.* cross-linked polystyrene, which swell in organic solvents [28,28a]. Poly(methyl methacrylate) cross-linked with ethylene bismethylacrylate forms a purely aliphatic network, which can also be prepared in the form of beads [29]. In the completely synthetic gels, the pore sizes are adjusted by variation of the ratio of monomer to cross-linking agent, or by variation of the quantity and nature [30] of the solvent present during polymerization.

A third group consists of partially synthetic gels, in which natural macromolecules are given a three-dimensional structure with the aid of cross-linking agents, *e.g.* latex cross-linked by vulcanization with sulfur. Small pieces of rubber (milled surgical gloves) swell in organic solvents and act as molecular sieves [31]. In 1954, *Deuel* and *Neukom* reported the first instance of a modified plant polysaccharide which, when swollen with water, was capable of desalting a protein solution [32].

*Porath* and *Flodin* etherified water-soluble dextran molecules with epichlorohydrin and obtained a gel which swelled only in water, and which is now known by the trade name of "Sephadex" [32a]. The size of the pores in the gel decreases as the number of hydroxy groups in the dextran replaced by ether bridges is increased. Extensive investigations on the pore structures of such dextran gels and a theoretical basis of gel filtration provided by *Porath*, *Flodin*, *Gelotte*, and *Bennich* [33–39], together with the fact that Sephadex is commercially available in several well-defined degrees of cross-linking (recently also in the bead form), have contributed to the rapid development of gel filtration into a widely used laboratory technique. Dextran gels are used in more than 95 % of all chromatographic work on gels. The present review will therefore focus attention on this material.

## 3. Theory of Gel Filtration

We have regarded gel filtration as multiple dialysis, but it can equally well be referred to as partition chromatography: the gel acts as support for the stationary solvent phase and confers on the latter the property of being only partly accessible to molecules above a certain size. Thus, a partition coefficient $K_d$, which is a function of molecular size, can be defined for the partition of every substance between the two resultant phases ("internal" and "external" solvent). This $K_d$ value is a true quotient of two concentrations only if either small molecules can diffuse unhindered (both concentrations equal; $K_d = 1$) or if large molecules are completely unable to penetrate into the solvent within the gel particles (internal concentration = 0; $K_d = 0$). However, the pore size inside the gel grains is by no means uniform, so that for intermediate molecular sizes, the $K_d$ value is a measure of the portion of the stationary phase which is available to a particular type of molecule.

$K_d$ can be calculated from the elution volume $V_e$. For molecules which are large in comparison to the pore size ($K_d = 0$), the elution volume corresponds to the solvent outside the gel particles ($V_o$), whereas for small molecules ($K_d = 1$) it also includes the volume inside the gel particle ($V_i$). Since only part of the internal solvent is accessible to molecules of intermediate size ($0 < K_d < 1$), the elution volume for these molecules is [40]

$$V_e = V_o + K_d \cdot V_i. \quad (1)$$

This gives

$$K_d = \frac{V_e - V_o}{V_i} \quad (2)$$

The external volume $V_o$ and the internal volume $V_i$ are the characteristic volumes of the gel packing. $V_o$ is obtained from the elution volume of a substance whose molecular weight is high relative to the pore size, and $V_i$ from the solvent-absorbing capacity of the dry gel. $V_i$ naturally depends on the degree of cross-linking. To determine the degree of swelling quantitatively, a weighed quantity of dry gel is swollen in excess solvent, which is then separated by centrifuging through a sintered glass plate. The solvent absorption per gram is known as the swelling power $S_r$ (solvent regain) [g of solvent/g of dry gel]. Water is the swelling agent for dextran gels, for which this generally valid theory was developed (cf. [39]); the water regain $W_r$ of these gels is normally printed on the package or container. The internal volume is then given by the simple expression

$$V_i = a \cdot W_r, \quad (3)$$

where a is the dry weight in grams of the column packing. If a is unknown, the internal volume $V_i$ can be calculated from the total volume $V_t$ and the mean specific gravity $d = (W_r + 1)a/(V_t - V_o)$ of the gel bed:

$$V_i = \frac{W_r \cdot d}{W_r + 1} (V_t - V_o) \quad (4)$$

If two substances with different molecular weights have $K_d'$ and $K_d''$ on a certain gel, then their elution volumes, according to Equation (1), are given by:

$$V_e' = V_o + K_d' V_i$$

[28] *M. F. Vaughan*, Nature (London) *188*, 55 (1960).

[28a] However, polystyrene has a strong tendency to adsorb aromatic substances, and so is not ideal for gel filtration.

and

$$V_e'' = V_o + K_d'' V_i.$$

The separation volume $V_s$ is a measure of the separating efficiency of a column:

$$V_s = V_e' - V_e'' = (K_d' - K_d'') V_i \quad (5)$$

These volumes are shown in Figure 1, the elution diagram for three substances with $K_d$ values of 0.0, 0.5, and 1.0.

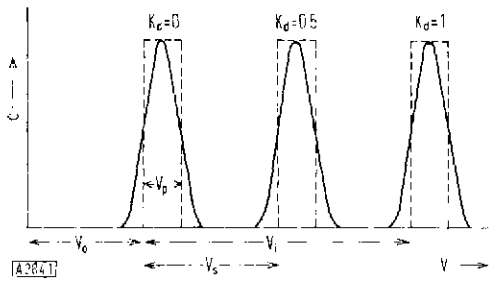

Fig. 1. Schematic elution diagram for three materials with $K_d$ values of 0.0, 0.5, and 1.0.
(- - -): theoretical shape of the bands;
(— —): experimental Gaussian distribution curves;
$V_o$ and $V_i$ = volumes of solvent outside and inside the gel;
$V_p$ = sample volume; $V_s$ = separation volume.

Every gel bed can be characterized by various parameters. Thus it is advantageous to know the size of molecules which are just unable to penetrate the gel grains, *i.e.* the "exclusion limit", and the volume relationships. Table 2 gives some data for the various types of Sephadex. The exclusion limits were determined with dextran fractions. It appears that they are considerably higher for proteins and considerably lower for nucleic acids.

Table 2. Properties of commercial Sephadex dextran gels (swelling in water; volume data based on 1 g of dry gel) [a].

| Type | Exclusion limit (molecular weight) | $W_r$ | d | $V_t$ | $V_o$ | $V_i$ |
|---|---|---|---|---|---|---|
| G-25 | 5000 | 2.5 ± 0.2 | 1.13 | 5 | 2 | 2.5 |
| G-50 | 10000 | 5.0 ± 0.3 | 1.07 | 10 | 4 | 5 |
| G-75 | 50000 | 7.5 ± 0.5 | 1.05 | 13 | 5 | 7 |
| G-100 | 100000 | 10 ± 1.0 | 1.04 | 17 | 6 | 10 |
| G-200 | 200000 | 20 ± 2.0 | 1.02 | 30 | 9 | 20 |

[a] Details of the experimental technique are to be found in the manufacturer's literature and in [39,41].

Polyacrylamide and agarose gels are prepared directly as swollen gels and are characterized by the chromatographic behavior of standard substances. Figure 2 shows the relationship between the "$R_F$ values" ($V_o/V_e$) of various substances and the absolute concentration of the gel former (which is a measure of the average pore size) for agarose gels [12]. It is possible on the basis of such a diagram, as well as from Table 2, to select for a given separation the gel with the optimum pore-size distribution.

It can be seen from Equation (5) and Figure 1 that, for small $\Delta K_d$, the internal volume $V_i$ must be large and the sample volume (volume of solvent in which the mixture is introduced into the column) must be as small as possible to achieve satisfactory separation.

[41] *H. Determann* and *B. Gelotte* in *H. M. Rauen:* Biochemisches Taschenbuch. 2nd Edit., Springer, Berlin 1964, Vol. 2.

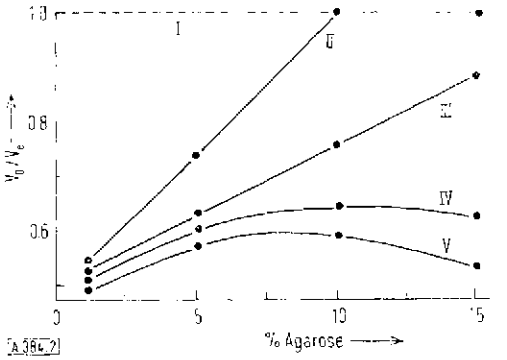

Fig. 2. Dependence of the "$R_F$ value" $V_o/V_e$ on the concentration of agarose (based on dry weight) in gel [19]. I: indian ink; II: R-phycoerythrin; III: haemoglobin; IV: cytochrome c; V: potassium dichromate.

Thus, the rules of column chromatography are valid here too: the separation is improved by long columns and sharp starting zones.

Applications of the molecular-sieve effect will be described in Section 6. If, in the separation of low and high molecular-weight substances, the difference $K_d' - K_d''$ in Equation (5) reaches its upper limit (unity), the separation volume is theoretically equal to the internal volume. The sample volume could then be made as large as $V_i$, if there was no widening of the bands as a result of diffusion. Perfectly satisfactory results are still obtained if the sample volume is 20–30 % of the total volume $V_t$ of the column. Such separations are referred to here as *gel filtration*.

Gel filtration can be carried out with relatively short columns, thus circumventing extreme dilution of the separated substances. In contrast to all other chromatographic methods, the concentration of the substances to be separated does not affect gel filtration, except at high viscosities (< 5 cp), where diffusion is limited, this leading to unsharp separations [39].

## 4. Sorption Phenomena

Behavior which differs from the gel-filtration theory is sometimes observed on highly cross-linked dextran gel packings, particularly with substances of low molecular weight. The secondary effects responsible for such deviations can be divided into two groups:

a) Certain substances are retarded on the column, owing to their structures, and largely independently of the eluent; $K_d$ is greater than expected on theoretical grounds. For example, borate and hydroxide ions are retained by complex formation; the same applies to many aromatic and heterocyclic compounds. Since this adsorption effect is completely reversible, it permits fractionation, for example, of phenols [42,43], nucleic acid constituents [44,44a], peptides containing tryptophan [45], amino acids [36,37,46], or extracts from roasted coffee [47].

[47] *H. Streuli*, Chimia *16*, 371 (1962).

b) Ion exchange may be observed on elution with pure water, owing to the very low carboxyl content of the dextran gels. Bases are adsorbed, and acids appear in the eluate earlier than expected, if they are introduced in very small quantities. This phenomenon may be eliminated by small additions of electrolyte to the eluent or even to the solution of the sample. These salt effects can also be used for the separation of proteins [48–50], peptides [51], or phosphoric acid derivatives [52] of roughly equal molecular weights.

Particular care must be taken in working with radioactively labelled anions such as iodide [53] or phosphate [54]. If the total concentration of ions is not high, a very small portion of these anions, which is detectable only radiochemically, may be prevented from diffusing freely by the carboxyl groups and may remain in the external volume $V_o$.

## 5. Gel Filtration

Highly cross-linked gels (with relatively small pores) are necessary for achieving quantitative separation of large molecules from low molecular-weight substances. The dextran gels Sephadex G-25 and G-50 (cf. Table 2) are mainly used for this purpose. Gel filtration is most frequently used for desalting colloid (often protein) solutions. These solutions are not appreciably diluted if the volume relationships discussed above are taken into account. Figure 3 shows the elution curves of two experiments with the same column; here the sample

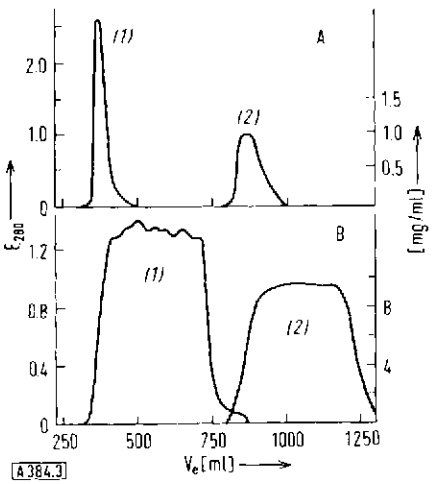

Fig. 3. Separation of haemoglobin (1) and sodium chloride (2) on a 1070 ml column containing Sephadex G-25. A: with 100 mg of haemoglobin and 100 mg of NaCl in 10 ml of water; B: with 400 mg of haemoglobin and 4 g of NaCl in 400 ml of water [39].

Left ordinate: extinction of haemoglobin at 280 mμ;
Right ordinate: mg of NaCl per ml of solution.

volumes differ by a factor of 40. Even under the extreme conditions of experiment B, the protein (zone 1) is practically completely desalted, although its solution is diluted by only 25 %. In experiment A the dilution is tenfold [39] (cf. [55]).

If another salt solution is used as eluent instead of water, the ions present in the sample solution are exchanged [39]. This may be important for desalting proteins which can be kept in solution only by electrolytes. If the second electrolyte is completely volatile, the protein can be obtained salt-free by freeze-drying after elution.

Figure 3 can be used to illustrate many of the separations to be discussed here, *e.g.* the determination of strontium in milk [56], and the desalting of virus suspensions (even under sterile conditions) [57]. The separation from macromolecules of low molecular-weight components which are not salts can be termed group separation. Thus, for example, viruses can be separated from dyestuffs, amino acids, and sugars [58], nucleic acids from nucleotides [44, 59–61] and phenol [62], and low molecular-weight antigens from antibodies [63]. The method is particularly interesting in medicine, *e.g.* for rapid determinations of polysaccharides in the presence of sugars [64, 65], of oestrogens in the urine of pregnant women [66], and of free iodide in the presence of protein-bound iodine [67–70a]. Gel filtration is the best method for separating modified protein from excess low molecular-weight reagents, *e.g.* in staining with fluorescent dyes [71–79] or in the reversible reduction of disulfide bridges [80, 80a].

*Complex formation* between molecules of various molecular weights gives rise to special separating effects during gel filtration. For example, vasopressin and oxytocin form complexes with proteins contained in tissue extracts. These complexes can be separated from low molecular-weight components on a column of Sephadex G-25. The complex dissociates on acidification, and a further separation gives the hormone, many times concentrated, in the slowly migrating zone [81].

Vitamin $B_{12}$ can be similarly concentrated from sea-water, polysaccharide being added for complex formation [82]; it can also be isolated as a protein complex from human gastric juice [83]. The compounds formed by various pharmaceuticals [84–86c], metals [87–89], or lipids [90] with proteins have been studied on gel columns. The "radiobiuret" complex containing radioactive copper can be used with the gel filtration method for continuous microdetermination of proteins in column eluates [91]. Immunochemical investigations have also been carried out on gel columns [63, 92–95].

Particularly promising is a method for the determination of the affinity of enzymes for coenzymes, substrates, or inhibitors, as first described for the interaction of ribonuclease and 2-cytidylic acid [96]. The gel bed is equilibrated with a buffer solution containing the substrate, and the protein is then introduced into the column and eluted with the same solvent: the protein-substrate band is followed by a zone of low substrate concentration (Fig. 4). With lactic dehydrogenase, this technique can be used to determine the number of active sites on the protein with the aid of DPNH [97]. In another example, the peptide substrate of carboxypeptidase is so firmly bound to the enzyme in the absence of Zn ions that it becomes an inhibitor and

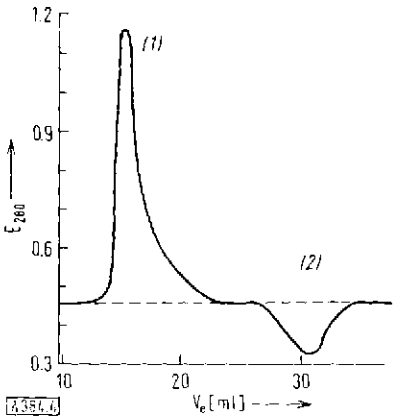

Fig. 4. Elution diagram for 3 mg of ribonuclease chromatographed in 0.1 M acetate buffer (pH 5.3) containing $9 \times 10^{-5}$ M cytidylic acid on Sephadex G-25. The enzyme-inhibitor complex passes out at (1) and is followed by a zone (2) which lacks the inhibitor [96].
Ordinate: extinction at 280 mμ.

migrates with the protein [98]. The complex from cytochrome c and cytochrome oxidase can also be isolated by gel filtration [99].

Gel filtration has proved extremely useful for the fractionation of mixtures of natural products and for purification of isolated substances. The otherwise arduous task of separating amino acids from peptide mixtures can be effected easily and quantitatively [37, 100], as can the separation of mixtures of peptides and glycopeptides [111–113] obtained by enzymatic [101–108] and chemical [109, 110] hydrolysis. Partial hydrolysates of nucleic acids [114–117] can also be fractionated, and hormones concentrated [118–122]. It is very

convenient, particularly for incorporation experiments with radioactive amino acids, that insulin can now be isolated with ease from very small quantities of crude pancreatic extract [123, 124].

The enzymatic activities of snake venoms can be separated [125–127], and proteases [128–132a] and many other proteins, with and without enzymatic activities [25, 133–140], can be purified on gels which are only slightly cross-linked. Plasma proteins can be divided into three fractions [141 to 142b]; Figure 5 shows the effect of cross-linking on the efficiency of separation [143]. Fragments of γ-globulins have been separated on porous gels [144, 145]. A synthetic mixture of deoxyribonucleic acid and ribonucleic acid has been separated on agarose gel [61].

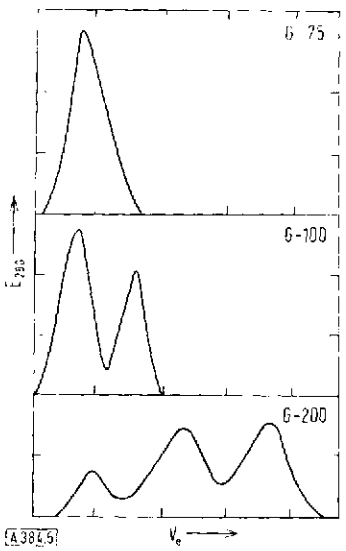

Fig. 5. Separation of about 15 ml of bovine plasma on Sephadex dextran gels of various swelling capacities under comparable conditions in 0.1 M *tris* buffer (pH 8.0; 1 M NaCl). The column volumes $V_t$ were so chosen that the external volumes $V_o$ were equal (cf. Table 2). In the experiment with Sephadex G-200 ($V_t$ = 1600 ml), the macroglobulins were found in the first band, the globulins in the second, and the albumins in the third [143].

Ordinate: extinction at 280 mμ.

## 6. Gel Chromatography

Fractionation of polymers can be achieved by the use of long columns, small sample volumes, small grain size, and slow elution, as was first shown for dextran fractions [35, 146, 147] and oligosaccharides [148]. Figure 6 shows the sharpness of the separation of oligosaccharides from glucose up to its hexamer. With chromoprotein mixtures, the progress of the separation can be seen directly from the zones on the column; the separating efficiencies of dextran gel Sephadex G-75 [149], polyacrylamide gel [26], agar gel [17], and agarose gel [19] were demonstrated in this way.

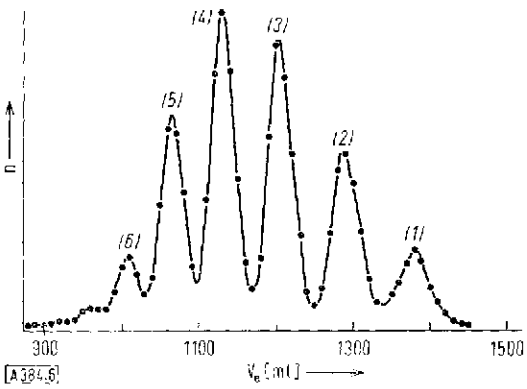

Fig. 6. Elution diagram of glucose oligomers, obtained by acetolysis of a polysaccharide followed by alkaline hydrolysis, from a Sephadex G-25 column [148]. (1) Glucose, (2) cellobiose, *etc.* up to (6) cellohexaose.

Ordinate: refractive index on a linear scale.

If a mixture is not completely separated, the sample must be passed through a longer gel bed, *e.g.* by connecting two columns in series [150]. Difficult separations can be achieved on a relatively short column if the eluate is recycled through the column in fractions, this procedure being repeated until the purification is complete. The separation can be conducted almost completely automatically if the eluate is immediately returned to the start by means of a pump; the progress of the separation can be observed with the aid of a flow photometer

and unwanted mixed fractions removed through a multichannel valve [151]. Figure 7 shows a diagram of such an arrangement.

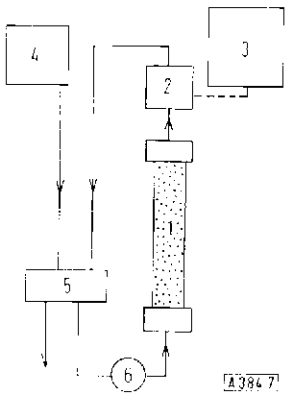

Fig. 7. Diagram of a recycling gel-chromatography apparatus.
1: Chromatographic column; 2: flow photometer; 3: recorder; 4: solvent reservoir; 5: valve; 6: recycling pump. In order to avoid compression of the gel bed, the flow passes from the bottom upwards [151].

The efficiency of gel chromatography is particularly well illustrated by the fractionation of protein associates: oligomeric serum albumins [152] are separated, as well as the enzymatically active, aggregated forms of ribonuclease, which are formed on freeze-drying of a solution of the protein in 50 % acetic acid [153].

If the elution volume is carefully recorded, gel chromatography can also be used for the estimation of molecular weights by comparison of the $K_d$ values of the unknown molecules with those of known substances. In this connection, *Porath* [154] proposed a concept which has been found to be very useful. It is based on a model involving spherical molecules of radius r and conical pores in the gel. Since the $K_d$ value of a molecule is proportional to its volume, *i.e.* to $r^3$, and its molecular weight is proportional to $r^2$ [154a], the cube root of its $K_d$ value should bear a linear relationship to the square root of its molecular weight. This is in fact the case for both polysaccharides [154] and proteins [155]. Figure 8 shows the calibration curve for proteins on Sephadex G-200. This enables the molecular weight of an unknown protein to be easily estimated from its $K_d$ value [155].

*Andrews* had previously plotted the elution volumes of various proteins from agar gel against the logarithm of their molecular weights in a single diagram and had similarly found a linear relationship over a certain range [156–156b]; he recently found the same kind of relationship for the various types of Sephadex gels [157]. The pore diameters of granulated agar gels with different degrees of swelling (cf. p. 610) have been determined experimentally from the chromatographic behavior of substances with known molecular or particle diameters [158]. Molecular-weight determinations are also possible in homogeneous gels. The substance under investigation is allowed to diffuse into a gel, and the velocity of the migrating front is compared with that of markers. The analysis can be carried out either immunologically (by precipitation [159]) or by working up individual layers [160]. Conclusions can also be drawn regarding the molecular weight of proteins from their electrophoretic behavior on gels of different densities [161].

## 7. Special Applications of Dextran Gels

Commercial Sephadex dextran gel has been found suitable for applications which do not correspond to gel filtration in general. For example, the huge water absorption of dry "G-25 coarse" causes considerable concentration when it is stirred into aqueous solutions of macromolecular materials and then centrifuged out [162, 163]; no change occurs in the ionic strength or pH. Sephadex acts as an inert hydrophilic support in electrophoresis in horizontal layers [164] and in vertical columns [142, 165–166a], as well as in partition chromatography of peptides [5, 167–168b], dinitrophenyl-

amino acids [169], and soluble ribonucleic acids [170]. In comparison with cellulose used in paper chromatography, dextran gel has the advantages of greater stability and purity, as well as of higher capacity and flow rate.

The differences in solubility of proteins in saline and salt-free solutions can be used for their separation on dextran gel columns. Serum proteins, which are insoluble in the absence of salt, leave the gel bed only when sodium chloride is admixed to the eluent; other proteins appear earlier, according to size [171]. This technique can be further refined by repeated precipitation and dissolution cycles, using a salt gradient in the dextran gel [172]. Fine Sephadex G-25 powder adheres to glass plates without a bonding agent. Very small quantities of proteins [173] or protein structural units [174] can be separated by thin-layer chromatography on plates coated with Sephadex.

## 8. Gel Chromatography on Lipophilic Gels

Following the success of gel chromatography on materials which swell in water, attempts have recently been made to find suitable lipophilic gels. Here, even more than in water, particular attention must be paid to adsorption. The polystyrenes with various degrees of cross-linking used as the basis of synthetic ion-exchange resins are not very suitable, since the order of elution is often governed more by the structures of substances than by their molecular weights [28, 175].

On the other hand, separations achieved on small pieces of rubber [31] appear to be based on the molecular-sieve effect. The $K_d$ values of polyisobutene (mol. wt. 18000), pentaerythritol tetrastearate (mol. wt. 1200), squalane (mol. wt. 423), and azulene (mol. wt. 128) are related in a linear manner to the logarithm of their molecular weights. The behavior of oligomeric polystyrenes on purely aliphatic poly(methyl methacrylate) gel corresponds perfectly to the laws known for gels which swell in water. Thus, a linear relationship is again found between the cube root of the $K_d$ value and the square root of the molecular weight [29]. Similar gels should be suitable for determining the molecular-weight distribution of polymers, if it becomes possible to synthetize rigid networks with sufficiently large pores [30].

It also appeared worthwhile to convert Sephadex dextran gels into derivatives which would swell in organic solvents [176]. Sephadex G-50, medium, was suspended in benzene and acetylated with excess acetic anhydride; after careful washing, the content of acetyl groups was found by alkaline hydrolysis to be 30 % by weight, *i.e.* about 50 % of the hydroxy groups of the dextran had been esterified. The material swells, *e.g.* in methylene chloride, to about twice its original volume and acts as a molecular sieve. Figure 9 shows the result of an experiment with polystyrene fractions [177] on acetylated

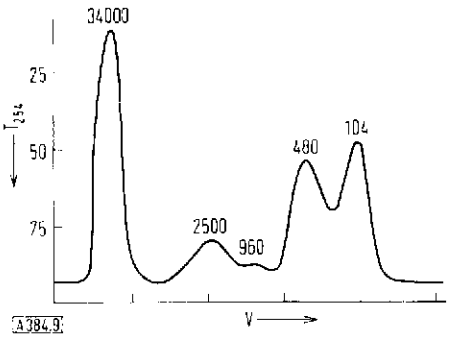

Fig. 9. Elution of five polystyrene fractions (concentration of each 2–5 mg/ml) in methylene chloride from a gel bed of acetylated Sephadex (column: 1.5 cm diameter, 120 cm length). The figures are the osmotically determined molecular weights.
Ordinate: transmission [%] at 254 mμ.

Sephadex [178]. It is found that, despite its lower swelling in solvents, its exclusion limit was higher than that of the poly(methyl methacrylate) gels, possibly owing to the fact that the pore size increases from the inside towards the outside.

## 9. Conclusions

The gel structure is not absolutely necessary for chromatographic separations by molecular weight. *Pedersen* observed that larger proteins dissolved in aqueous buffer pass through a glass tube filled with glass beads (diameter 20–35 μ) more rapidly than smaller proteins [152]. A similar phenomenon was described by *Vaughan*, who fractionated a polystyrene mixture in benzene on a silicate (Santocel A), with a result comparable to that obtained by conventional fractional precipitation methods [179]. Powdered plastic had no separating action, and cellulose powder was only slightly active. In the flow of blood through capillary blood vessels, the corpuscles, which only migrate in the middle, proceed at an appreciably higher speed than the plasma proteins; this effect may be compared to the fractionation of proteins on glass powder described above [152]. Thus, separations should be possible on any "rough" surface, provided the irregularities are of the correct order of magnitude. Small molecules migrate very close to the surface and so must travel greater distances than large molecules, which follow a straight path, unhindered by irregularities, in the proximity of the surface.

[178] *H. Determann*, unpublished work.
[179] *M. F. Vaughan*, Nature (London) *195*, 801 (1962).

*Pedersen* therefore proposed that the term "gel filtration" should be replaced by the term "exclusion chromatography" for the high molecular-weight range. Other authors disliked the name "filtration" for this chromatographic process and suggested the terms "restricted diffusion chromatography" [158] or "gel permeation chromatography" [30]. However, *Tiselius* supports the hitherto usual term "gel filtration" [180], and points out the fundamental difference between this and other chromatographic separations, namely, that the concentration in the stationary phase can, at the most, be only as great as that in the mobile phase.

Some of the difficulties in nomenclature can be avoided by agreeing to the division attempted in this summary (from practical considerations, among others) into "*gel filtration*" and "*gel chromatography*". Whatever name is given to the process, its use guarantees clean and easy separation of substances with different molecular sizes, as shown by the profusion of the applications quoted.

# Electron Affinity of Organic Molecules

BY PROF. DR. G. BRIEGLEB

INSTITUT FUR PHYSIKALISCHE CHEMIE DER UNIVERSITÄT WÜRZBURG (GERMANY)

*Dedicated to Dr. W. Foerst on the occasion of his 65th birthday*

*The formation of organic radical ions by direct electron exchange between a donor molecule D and an acceptor molecule A is becoming increasingly important, particularly with regard to reaction mechanisms involving intermediate radical ions. All redox processes also involve electron exchange. Finally, the knowledge of electron affinities and ionization energies of organic molecules is necessary for a quantitative theoretical interpretation of intermolecular resonance and of the semiconductor properties of crystalline organic compounds and molecular compounds.*

The electron-donating properties of organic molecules can be estimated from their ionization energies which for some organic molecules are directly measurable. However, direct experimental determination of the electron affinities of organic molecules, which govern their electron-accepting properties, was not possible until only a few years ago. This paper deals with the methods and means of determining the electron affinities of organic molecules; the discussion will be restricted to neutral molecules and will exclude consideration of radicals as electron donors and acceptors. The electron-donor and electron-acceptor properties of aromatic hydrocarbons will be treated separately in Chapter II. All the electron donors discussed this article are listed in Table 1.

The electron affinity EA of an electron-acceptor molecule A is the energy $E_j$ of the lowest unoccupied orbital of A in the ground state and is equal to the difference in energy ($E_{A^-} - E_{A + e_0^-}$) between the anion $A^-$ and the uncharged molecule $A + e_0^-$.

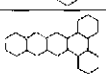
$$(1) \qquad E_j = -EA = E_{A^-} - E_{A + e_0^-}$$

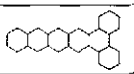
The ionization energy I of an electron-donor molecule D is equal to the energy $E_i$ of the highest occupied orbital of D in the ground state or to the difference in energy ($E_D - E_{D^+ + e_0^-}$) between the cation $D^+ + e_0^-$ and the uncharged molecule D.

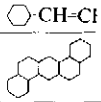
$$(2) \qquad E_i = -I = E_D - E_{D^+ + e_0^-}$$

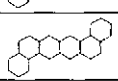
The difference in energy between the lowest vibrational level of the ground state of the neutral molecule and the corresponding level of the ion is termed the adiabatic ionization energy, or the adiabatic electron affinity, respectively. The energy difference between the energy level of the ground state and that part of the potential curve of the ionized state to which – applying the Franck-Condon principle – transition is most likely to occur, is denoted as vertical ionization energy and vertical electron affinity, respectively.

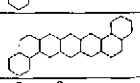
## I. Organic Electron Acceptors (excluding Aromatic Hydrocarbons)

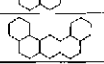


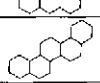


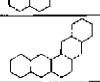


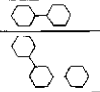


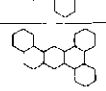


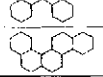


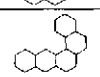


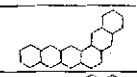


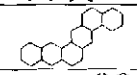


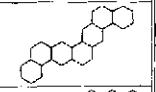


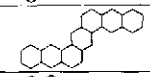


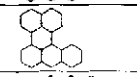


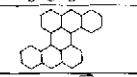


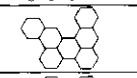


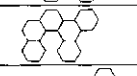


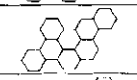


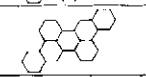


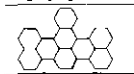


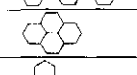


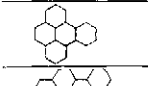


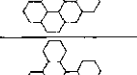


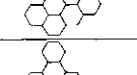


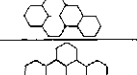


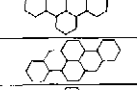


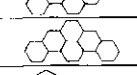


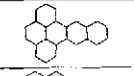


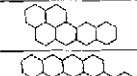


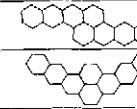


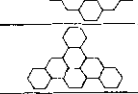


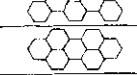


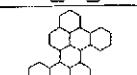


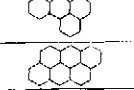


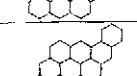


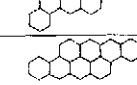


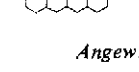


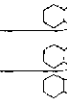


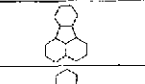












### 1. Electron Affinities Derived from the Electron Absorption Coefficient

*Lovelock* [1] determined the electron absorption coefficient $\chi$

$$(3) \qquad [e^-] = [e^-]_0 \exp(-\chi [A])$$

for the capture of thermal electrons $e^-$ by a few organic molecules A. This represents the only possibility for experimental determination of the relative order of electron affinities. Under experimental conditions for which $[e^-] \gg [A]$, the absolute electron absorption coefficient $\chi$ becomes identical with the equilibrium constant $K_A$ [2]:

$$(4) \qquad K_A = \frac{g_{A^-}}{g_A \cdot g_{e^-}} e^{EA/RT} = \frac{[A^-]}{[A]\,[e^-]}$$

The electron affinity EA can be calculated from Equation (4) by setting $g_{A^-}/g_A = 2$, and hence $g_{A^-}/g_A \cdot g_{e^-} = 1$. *Lovelock* reported several electron absorption coefficients $\chi' = K'_A$ referred to chlorobenzene as standard (Table 6, Column 2). *Wentworth* and *Becker* [3] determined the absolute equilibrium constant for electron capture by anthracene. Using this value and Equation (4), they obtained a value of 0.42 eV for the electron affinity of anthracene. For a given acceptor A, and for $K'_{anthracene} = 12$ [2a], we have:

$$(5) \qquad RT \ln K_A = EA_A = RT \ln K'_A + 0.42 - RT \ln 12$$

The electron affinities of a few organic acceptors, calculated for $\chi' = K'_A$ using Equation (5) are listed in Table 5, Column 3.

### 2. Electron Affinities derived from the Electron-Transfer Energy and from the Ionization Energy of the Electron Donor

On the basis of *Mulliken*'s theory [4] of intermolecular interaction between electron-acceptor and electron-donor molecules, it is possible to derive an expression for the energy $\tilde{\nu}_{CT}$ of electron transfer from D to A in terms of the ionization energy I of the electron donor and the electron affinity EA of the acceptor [5,6]:

$$(6) \qquad \tilde{\nu}_{CT} = I - (EA - E) + \frac{C_2}{I-(EA-E)}$$

[2] $[e^-]$: Stationary electron concentration at equilibrium; $[e^-]_0$: electron concentration before approach of acceptor A to electron gas; g: number of realizable quantum states ("quantum weight"). For $e^-$, $g = 2$ ($s = \pm 1/2$); see, for example, *T. L. Hill:* Introduction to Statistical Thermodynamics, Addison-Wesley Publ. Co., Reading, Mass. (U.S.A.) 1960. Equation (3) can be written, to a good approximation, as follows: $[e^-] = [e^-]_0 - [A^-] = [e]_0(1 - \chi[A])$. Then, for the case where $[e^-] \gg [A]$ or $[A^-] \ll [e^-]_0$ we obtain:

$$(3a) \quad \chi = \frac{[A^-]}{[e^-]_0\,[A]} \approx \frac{[A^-]}{[e^-]\,[A]}$$

[2a] If $K_{ClBz}$ is the electron-capture equilibrium constant for chlorobenzene, then, for an acceptor A, we have:

$K_A/K_{ClBz} = K'_A$ and $K_{anthracene}/K_{ClBz} = 12$

and hence: (4') $K_A = (K'_A/12) \cdot K_{anthracene}$.

The change in free energy for electron capture by A is by definition $-EA = -RT \ln K_A$, and, hence, using Equation (4'), we obtain Equation (5).

Chem. *59*, 184 (1955); *63*, 6 (1959); Angew. Chem. *72*, 401 (1960); *R. Foster*, Nature (London) *181*, 337 (1958).

[6] For further details, see *G. Briegleb:* Electronen-Donator-Acceptor Komplexe. Springer, Berlin-Göttingen-Heidelberg, 1961.

E is predominantly the energy of the Coulomb attraction between $D^+$ and $A^-$ after the transfer of one electron from D to A. E also comprises the polarization energy [6, 7] and an energy contribution $\Delta H$ from the intermolecular bond D···A in the ground state. $C_2$ can be calculated theoretically [6].

Theoretically, Equation (6) is based on the adiabatic ionization energy. However, it is not yet certain whether the various methods for determining the ionization energy of organic molecules (*e.g.*, the electron impact and photoionization methods) yield the adiabatic or the vertical ionization energy.

It has been established that E and $C_2$ can be assumed to be nearly constant, for electron-donor/electron-acceptor complexes (EDA complexes) of the same bond type [10], so that for complexes involving one and the same acceptor, Equation (6) reduces to Equation (7).

$$(7) \qquad \tilde{\nu}_{CT} = I - C_1 + \frac{C_2}{I - C_1}$$

$C_1$ can be determined experimentally [11] by plotting $\tilde{\nu}_{CT}$ against I for the EDA complexes of a given acceptor with various donors, when Equation (7) is normalized to a standard, *e.g.* naphthalene.

The electron affinities listed in Column 4 of Table 6, were calculated from $C_1$ according to Equations (6) and (7) using the value $E \approx E_{coul} \approx -4.3$ eV for the $\pi,\pi$-complexes. It was assumed here that the average intermolecular distance for the $\pi,\pi$-complexes is nearly constant. This assumption is supported by the fact that the validity of Equations (6) and (7) has been demonstrated for a large number of EDA complexes [11]. The charge on $D^+$ and $A^-$ is shifted towards the center of the complex molecule. Because of the approximations used, electron affinities derived from $C_1$ (Table 6, Column 4) have an uncertainty of about $\pm 0.2$ eV.

In Table 2, the electron affinities calculated by *Person* [9] and by *Jortner* and *Sokolov* [12] for the halogens

Table 2. Electron affinities [eV] for halogens and iodine chloride.

| | $I_2$ | | $Br_2$ | | $Cl_2$ | | ICl | |
|---|---|---|---|---|---|---|---|---|

| EA from Eq. (25) [**] [12, 16] | 1.56 | | 1.48 | | 1.3 | | 1.43 | |

[*] Calculated theoretically from the potential curves for $Hal_2$ and $Hal^-_2$ by applying the Morse function and making use of the interatomic equilibrium distance, dissociation energy, and fundamental vibrational frequency.

[**] Relative to the iodine atom with EA = 3.23 eV [15].

[7] The valence bond energy $E_{Val}$ contributes to a slight extent to the polarization energy $E_{pol}$ and vice versa. In general, $E_{pol}$ should be equal to about 0.1 $E_{Coul.}$. Only for iodine-amine complexes does the contribution of $E_{val}$ apparently become larger [8, 8a], as a result of the relatively small intermolecular distance (about 2.3 Å). According to *Person* [9], for iodine-amine complexes $E_{val} \approx 0.25\ E_{Coul.}$. In the case of n, σ-complexes, for example, those between iodine and amines, the constants $C_1$ and $C_2$ in Equation (6) are markedly different compared to those for $\pi,\pi$- or $\pi,\sigma$-complexes. *H. Yada, J. Tanaka*, and *S. Nagakura*, Bull. chem. Soc. Japan *33*, 1660 (1960) proved this for iodine-amine complexes. See also [8a].

[*] For polycyclic aromatic hydrocarbons.

[**] Average values for substituted benzenes. To be precise, methoxybenzenes (a = 0.74; b = 3.64), methylbenzenes (a = 0.68); b = 3.01), and halogenobenzenes (a = 0.60; b = 2.34) [18a] would have to be distinguished.

and iodine chloride are given for comparison with those of organic acceptors. The order of these affinities seems reasonable.

X-ray studies [13] of the complexes of iodine and the other halogens with π-donors, particularly benzene, have indicated that a configuration in which the axis of the halogen molecule is vertical to the benzene plane is more probable than the alternative configuration with parallel axes. According to Equations (6) and (7) $E_\perp$ and $E_\parallel$ differ by about 1 eV [14].

At sufficiently large ionization energies (I > 7.5 eV), the third term in Equation (6) can be neglected:

$$\tilde{\nu}_{CT} = I - EA + E \qquad (8)$$

Hence, for EDA complexes between one and the same acceptor and various donors, the following approximation is often used [17].

$$\tilde{\nu}_{CT} = aI + b \qquad (9)$$

As comparison with Equation (6) shows, the term b in Equation (9) contains the electron affinity of the acceptor and the Coulomb energy E; thus, when E is nearly constant, b can be taken as a measure of the electron affinity and is therefore often referred to as the apparent electron affinity. For EDA complexes of the same bond type [10] the term a can be assumed to be constant, *i.e.*, largely independent of the acceptor. This, however, is not always true, particularly for interactions with weaker donors [18] (cf. Table 3, where the values of a and b obtained from Equation (9) are listed for a few acceptors). The values of a and b for complexes of the very strong electron-acceptors tetracyanoethylene and bromanil with polycyclic aromatic hydrocarbons differ from those obtained for their complexes with substituted benzenes [18a, 19].

Judging from the strengths of their EDA complexes with aromatic hydrocarbons, the following order of electron affinities can be derived from the b values listed in Table 3:

bromanil > tetracyanoethylene > chloranil = 1,3,5-trinitrobenzene > 2,6-dichloro-*p*-benzoquinone > chloro-*p*-benzoquinone > *p*-benzoquinone > 2,4,6-trinitrotoluene > *m*-dinitrobenzene.

This order is *not* in agreement with the relative order of electron affinities resulting from Equations (5), (7), (14), (23), and (25); see Table 6. Obviously, the constant b in Equation (9) is less suitable to determine a relative sequence of electron affinities.

From Equations (8) and (2) we obtain

$$\tilde{\nu}_{CT} = -E_i - EA + E \qquad (10)$$

As we shall see in the following, there are numerous possibilities for expressing I or $-E_i$ by means of other quantities.

### 3. Electron-Transfer Energy as a Function of the Ionization Energy of the Donor

For polycyclic aromatic hydrocarbons as donors, it follows from *Hückel*'s simple AMO theory that:

$$E_i = -I = \alpha_0 + f_H \cdot \beta \qquad (11)$$

In Equation (11), $\alpha_0$ is the Coulomb integral, β the resonance integral for two neighboring atoms (k, l), and $f_H$ is the Hückel coefficient which expresses the contribution of β to the total energy $E_i$. The electron overlap integral is assumed to be zero, and the electron repulsion is neglected.

The decrease in electron repulsion on transition from D to $D^+$ may be taken into account (by a decrease in the Coulomb attraction) in $\alpha_0$ [20]. In a simplification recently proposed by

[13] *O. Hassel*, Molecular Physics *1*, 241 (1958); *O. Hassel* and *K. O. Stromme*, Acta chem. scand. *12*, 1146 (1958).

[14] The value EA = 0.8 eV for $I_2$ quoted by *Briegleb* and *Czekalla* [5] refers to the parallel model, which was originally adopted because of symmetry considerations [4] arising from the quantum-mechanical group theory.

[15] *O. H. Pritchard*, Chem. Reviews *52*, 529 (1953).

[16] It is improbable that the values of E for EDA complexes of atomic iodine, molecular halogens, and ICl are identical. However, the order of the electron affinities calculated by *Jortner* and *Sokolov* [12] agrees – within the limits of error – with the electron affinities calculated by *Person* [9] for the vertical model.

[18c] See [6]; pp. 79 et seq.

[19] *H. Kuroda, M. Kubayashi, M. Kinoshita*, and *S. Takenioto*, J. chem. Physics *36*, 457 (1962).

[20] *G. W. Wheland* and *D. E. Mann*, J. chem. Physics *17*, 264 (1949) assume that the increase in α, expressed in units of β, is proportional to the positive charge (1−q)β on the carbon atom (q is the relative negative charge on the carbon).

*Ehrenson* [22], $\alpha$ can be expressed in units of $\beta$ as follows ($\alpha$,$\alpha_0$, and $\beta$ are negative; $|\alpha| < |\alpha_0|$):

$$\alpha = \alpha_0 \cdot (1 - 1/n)\omega\beta \quad (12)$$

where $\omega$ is an empirical proportionality factor and n is the number of conjugated $\pi$-electrons in the aromatic hydrocarbon.

Substituting $\alpha$ for $\alpha_0$ in Equation (11) and using Equation (12), we obtain:

$$-E_i = I = -\alpha_0 - (f_H - \frac{n-1}{n}\omega)\beta = -\alpha_0 - \varkappa\beta \quad (13)$$

When $\alpha$ = 9.878 eV, $\beta$ = −2.11 eV, and $\omega$ = 1.4 [21], Equation (13) gives satisfactory values for the ionization energy of aromatic hydrocarbons [22].

Substituting Equation (13) into Equation (10), one obtains:

$$\tilde{\nu}_{CT} = (-EA - \alpha_0 + E) - \varkappa\beta = k - \varkappa\beta \quad (14)$$

$$k = -EA - \alpha_0 + E \quad (14a)$$

This expression is based on the observation that the values of EA and E for EDA complexes of analogous donors (*e.g.* polycyclic aromatic hydrocarbons) with one and the same acceptor are nearly constant.

According to Equation (14), $\tilde{\nu}_{CT}$ should be linearly proportional to $\varkappa$. Figure 1 shows for the example of the EDA complexes of tetracyanoethylene with aromatic hydrocarbons that this requirement is satisfactorily fulfilled, considering the variability of E and $\tilde{\nu}_{CT}$ and the uncertainty in I as obtained from Equation (13). (The values of $\varkappa$ and $f_H$ in Figure 1 are listed in Columns 5 and 6 of Table 4.)

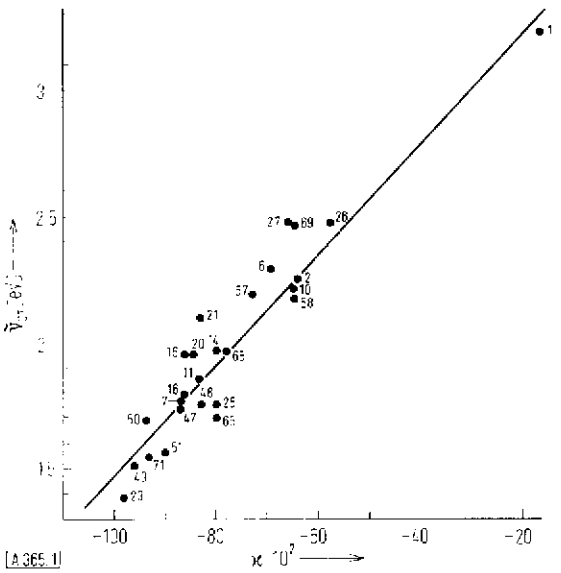

Fig. 1. Linear dependence of the electron transfer energy $\tilde{\nu}_{CT}$ on the value of $\varkappa$ obtained from Equation (14) for tetracyanoethylene-hydrocarbon complexes (the numbers refer to the hydrocarbons listed in Table 1).

The charge-transfer band maxima $\tilde{\nu}_{CT}$ for EDA complexes between the acceptors given in Table 4 and the donors listed in Column 5a of Table 6 and the corresponding $\varkappa$ values are related by the linear function represented by Equation (14). The values of $\beta$ and k calculated from this linear $\tilde{\nu}_{CT}$ *vs.* $\varkappa$ relationship, and the electron affinities derived from the k values obtained from Equation (14a) by setting E = −4.3 eV and $\alpha_0$ = −9.88 eV are listed in Table 4 for the electron acceptors tetracyanoethylene, chloranil, 2,4,7-trinitro-9-fluorenone, 1,3,5-trinitrobenzene, and iodine [23].

Table 4. Electron affinities of a few typical organic electron acceptors and of iodine, calculated from the values of k obtained according to Equations (14) and (14a) [*].

| | Tetracyanoethylene | Chloranil | 2,4,7-Trinitro-9-fluorenone | 1,3,5-Trinitrobenzene | Iodine [*] | |
|---|---|---|---|---|---|---|
| −β [eV] | 2.2 | 2.3 | 2.6 | $2.3_5$ | 1.9 | |
| k [eV] | $3.6_7$ | 4.1 | 4.6 | $4.8_6$ | $4.5_5$ | |
| EA [eV] | 1.9 | 1.5 | 1.0 | 0.7 | 1.0 (∥) | $1.9_5$ (⊥) |

[*] For $I_2$, E = −4.3 eV or E = −3.5 eV, depending on whether the parallel or vertical model is considered.

Within the limits of error (± 0.2 eV), the electron affinity values calculated using Equation (14) are in good agreement with those calculated from $C_1$ in Equation (7); compare Columns 4 and 5 of Table 6. The values of $\beta$ listed in Table 4 refer to the aromatic hydrocarbons summarized in Column 5a of Table 6 and correspond to the values quoted by *Streitwieser* [21] and *Hoijtink* [31].

## 4. Ionization Energy and Intermolecular Electron-Transfer Energy as a Function of the Electron Excitation Energy $\tilde{\nu}_0$ of Aromatic Hydrocarbons as Donors

Setting for a given molecule, in general:

$$E_i = \alpha + f\cdot\beta \quad \text{and} \quad (15a)$$

$$E_j = \alpha + f'\cdot\beta, \quad (15b)$$

we obtain for the energy difference between the highest occupied and the lowest unoccupied orbital:

$$E_j - E_i = \tilde{\nu}_0 = (f' - f)\beta \quad (16)$$

[21] *A. Streitwieser* and *P. M. Nair*, Tetrahedron *5*, 149 (1959); *A. Streitwieser*, J. Amer. chem. Soc. *82*, 4123 (1960). – *Hoijtink*'s calculations [31], based on the one-electron half-wave reduction potential of aromatic hydrocarbons (p. 626 and p. 629), in combination with *Hückel*'s equation (Equation (15b)] and *Wheland*'s f'-values [20], gave an average value of $\beta$ = −2.26 eV. See also *P. Balk*, *S. De Bruijn*, and *G. J. Hoijtink*, Recueil Trav. chim. Pays-Bas *76*, 860 (1957).

[22] *S. E. Ehrenson*, J. physic. Chem. *66*, 706 (1961).

[23] Instead of Equation (10), *Dewar* and *Lepley* [24] use

$$\tilde{\nu}_{CT} = I - EA = E_j - E_i \quad (10')$$

In other words, the energy term E is omitted. Moreover, *Dewar* and *Lepley* use *Hückel*'s simple equation [Equation (11)] for I and obtain, in place of Equation (14), a linear relationship between $\tilde{\nu}_{CT}$ and $f_H$:

$$\tilde{\nu}_{CT} = k' - f_H\beta \quad (14')$$

$$k' = -EA - \alpha_0 \quad (14a')$$

However, the simple, uncorrected Hückel equation [Equation (11)] gives less satisfactory values for the ionization energy than Equation (13) [21]. In addition, the values of k' calculated by *Dewar* and *Lepley* from Equation (14') differ by a factor of E from those obtained using Equation (14). As a result, the EA values derived from k' are 3.5–4.5 eV too high.

[24] *M. J. S. Dewar* and *A. R. Lepley*, J. Amer. chem. Soc. *83*, 4560 (1961); *M. J. S. Dewar* and *H. Rodgers*, ibid. *84*, 395 (1962); *A. R. Lepley*, ibid. *84*, 3577 (1962).

From Equations (15a), (15b), and (16), we obtain:

$$(17) \qquad E_j = \alpha + \frac{f}{f'-f} \cdot \tilde{\nu}_0$$

The data listed in Column 6 of Table 5, show that $f/(f'-f)$ is in rough approximation constant for several aromatic hydrocarbons for which f and f′ have been calculated theoretically [26]. Hence, from Equation (12), the ionization energy will be, in general:

$$(18) \qquad I = C + \gamma\tilde{\nu}_0.$$

[*] The numbers refer to the hydrocarbons listed in Table 1.

Equation (18) can be fitted to experimental data only with limited accuracy, because ionization energies are known to within an accuracy of 0.1–0.2 eV for only a few aromatic hydrocarbons. Moreover, often the first excitation energy of aromatic hydrocarbons cannot be determined with great accuracy. This energy is determined a) by taking the maximum of the longest wavelength absorption band as $\tilde{\nu}_0$, and b) by basing the calculation on the 0,0-frequency $\tilde{\nu}_{00}$, provided the latter can be identified [25].

*Matsen* [26] selected for $\tilde{\nu}_0$ the frequency of the longest wavelength absorption maximum (Table 8, Column 6), as recommended by *Clar* [27], and obtained

$$(19) \qquad I = 4.39 + 0.857\ \tilde{\nu}_0\ [eV] \text{ (Fig. 2, II)}$$

*Becker* and *Wentworth* [28] based their calculation on the O,O-frequency and obtained:

$$(20) \qquad I = 5.156 + 0.775\ \tilde{\nu}_0\ [eV] \text{ (Fig. 2, III)}$$

Considering the ionization energies (which have been determined with some certainty for only relatively few aromatic hydrocarbons), cf. Table 8, Column 4, and using the $\tilde{\nu}_0$ frequencies (Table 8, Column 6), we obtain:

$$(21) \qquad I = 5.11 + 0.701\ \tilde{\nu}_0\ [eV] \text{ (Fig. 2, I)}$$

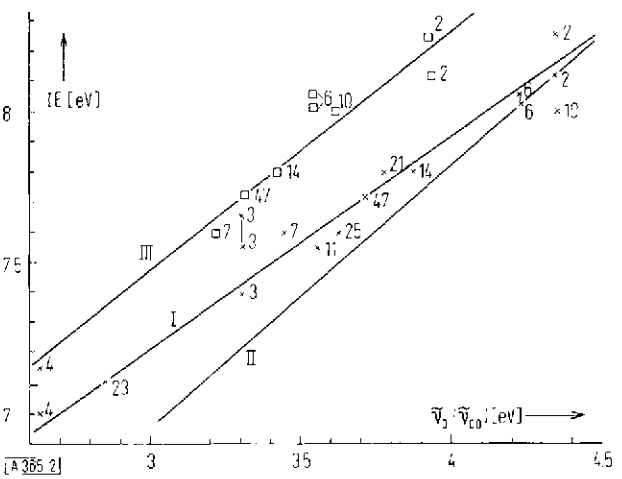

Fig. 2. Experimentally determined ionization energies $I_{exp}$ (Table 8, Column 4) of some aromatic hydrocarbons as a function of their first excitation energy $\tilde{\nu}_0$ (Table 8, Column 6); the numbers refer to the hydrocarbons listed in Table 1. Differing ionization energy values were obtained for Nos. 2, 3, 4, and 6 by various authors using different methods. I: Equation (21); II: Equation (19); III: Equation (20).

The ionization energies calculated from Equation (21) are listed in Column 5 of Table 8.

Substitution of Equation (18) into Equation (10) gives (since $I = -E_j$):

$$(22) \qquad \tilde{\nu}_{CT} = \gamma\tilde{\nu}_0 + C - EA + E$$

Considering EDA complexes of the same bond type [10] between an acceptor and analogous donors (*e.g.*, angularly condensed, unsubstituted aromatics), so that $E = -4.3$ eV [29] may be considered as nearly constant, we obtain:

$$(23) \qquad \tilde{\nu}_{CT} = \gamma\tilde{\nu}_0 + C'$$

where $C' = C - EA + E$

[25] The 0,0-frequency is the excitation energy required to raise an electron from its zero vibrational energy level in the ground state to the zero vibrational level in the excited state.

[26] See, among others, *F. A. Matsen*, J. chem. Physics *24*, 602 (1956); *G. W. Wheland*, J. Amer. chem. Soc. *63*, 2025 (1941).

[27] *E. Clar:* Aromatische Kohlenwasserstoffe, Springer, Berlin 1941.

[28] *R. S. Becker* and *W. E. Wentworth*, J. Amer. chem. Soc. *85*, 4263 (1963).

Substitution of Equations (18) and (21) into (23) reduces the latter to:

$$(23') \quad \tilde{\nu}_{CT} = 0.701\ \tilde{\nu}_0 + 0.81 - EA\ [eV] \qquad [29]$$

The calculation of electron affinities from Equation (23′) is limited by the inaccuracy in the values of I obtained from Equation (18) or (21). The uncertainties in the values of $I_{exp}$ and $\tilde{\nu}_0$ or $\tilde{\nu}_{00}$ are strongly reflected in those of the electron affinities (variations of 0.2 to 0.3 eV). The electron affinities of acceptors in EDA complexes with aromatic hydrocarbons of known excitation frequency $\tilde{\nu}_0$ can be calculated using Equation (23′) provided the values of $\tilde{\nu}_{CT}$ for the EDA complexes are known. The electron affinities of a given acceptor in EDA complexes with various donors (Table 6, Column 6a) were calculated using Equation (23′) and the average values are listed in Column 6 of Table 6.

Figure 3 shows a plot of the electron-transfer energies $\tilde{\nu}_{CT}$ *vs.* the first excitation energies $\tilde{\nu}_0$ of a series of aromatic hydrocarbons for EDA complexes of 1,3,5-trinitrobenzene, chloranil, and tetracyanoethylene. The values given in parentheses in Equations (24a)–(24c) correspond to the experimental straight lines shown in Figure 3.

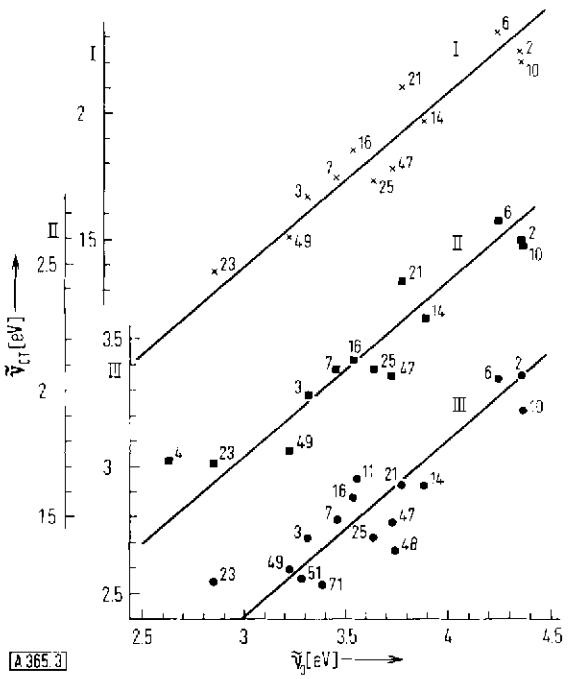

Fig. 3. Relationship between the electron transfer energy $\tilde{\nu}_{CT}$ and the first donor excitation energy $\tilde{\nu}_0$ for a few EDA complexes of the acceptors tetracyanoethylene (I), chloranil (II), and trinitrobenzene (III). The numbers refer to the hydrocarbons (donors) listed in Table 1.

(24a) Tetracyanoethylene:
(EA = 1.8 eV) $\tilde{\nu}_{CT} = 0.701\ \tilde{\nu}_0 - 0.99\ (0.72)$ [eV]

(24b) Chloranil:
(EA = 1.37 eV) $\tilde{\nu}_{CT} = 0.701\ \tilde{\nu}_0 - 0.56\ (0.37)$ [eV]

(24c) 1,3,5-Trinitrobenzene:
(EA = 0.7 eV) $\tilde{\nu}_{CT} = 0.701\ \tilde{\nu}_0 - 0.10\ (0.3)$ [eV]

[29] For halogens and XY-type interhalogen compounds, we must set E = −3.5 eV, in accordance with the vertical model (p. 619). Equation (23′) then becomes

$\tilde{\nu}_{CT} = 0.701\ \tilde{\nu}_0 + 1.61 - EA$

The deviations of the values given in parentheses from those expected from Equation (23′) fall within a range of inaccuracy of about 0.2 eV.

The averaged electron affinities calculated by different methods, *viz.* according to Equations (5), (7), (14), (23′), and (25), are collected together in Table 6, Column 8. For EDA complexes of a given acceptor (EA = const.) with analogous donors (E = const.), it follows from Equation (22) that:

$$(23'') \quad \tilde{\nu}_{CT} - \tilde{\nu}_0 = (\gamma - 1)\ \tilde{\nu}_0 + C''$$

$$(23''a) \quad C'' = C\ EA + E = 0.81\ EA$$

and from (21) that:

$$(23''') \quad \tilde{\nu}_0 - \tilde{\nu}_{CT} = 0.299\ \tilde{\nu}_0 - 0.81 + EA\ [eV]$$

Thus, although we have complexes of one and the same acceptor, *i.e.* EA = constant, $(\tilde{\nu}_0 - \tilde{\nu}_{CT})$ is not constant, as is to be anticipated if *Hückel*'s simple relationships [Equations (15a) and (15b); f = f′] were valid; instead, $(\tilde{\nu}_0 - \tilde{\nu}_{CT})$ decreases as the wavelength of the first excitation energy of the donor increases. The empirical approximate constancy of $\tilde{\nu}_0 - \tilde{\nu}_{CT}$ [6, p. 74] is valid only for aromatic hydrocarbons of nearly equal $\tilde{\nu}_0$ within the limit of accuracy (about ± 0.2 eV) of Equation (23‴).

### 5. Electron Affinities Relative to Chloranil

If we assume that for EDA complexes of the same bond type [10] and configuration [6, 13], *e.g.* π,π-complexes E may be considered to be nearly constant – an assumption that is approximately correct – then from Equation (8) we obtain the following expression for two acceptors, relative to one and the same donor:

$$(25) \quad (\tilde{\nu}_{CT})_i - (\tilde{\nu}_{CT})_k = EA_k - EA_i$$

Hence, after normalization to a given standard acceptor, Equation (25) can be used to calculate the electron affinities of other acceptors of the same type [30]. In Column 7 of Table 6, a list is given of electron affinities relative to chloranil (EA = 1.37 eV) calculated using Equation (25).

The agreement between electron affinities calculated from Equation (25) and those obtained from Equations (5), (7), (14), and (23′) in Columns 3, 4, 5, and 6 of Table 6, respectively, is satisfactory. The accuracy of the absolute electron affinity values is certainly not better than about 0.2 eV. Considering this error, their relative order should be correct.

[30] *M. Batley* and *L. E. Lyons*, Nature (London) *196*, 573 (1962) use iodine as acceptor standard. With iodine (EA = 1.8 eV) and Equation (25), they calculate the values of EA for π-acceptors (quinones, trinitrobenzene, tetracyanoethylene, *etc*). However, since it is known that EDA complexes of iodine (which is a σ-acceptor) have an entirely different configuration than the corresponding complexes of π-acceptors (trinitrobenzene, chloranil, *etc.*) [6], it is certain that the values of E [Equation (8)] for the iodine complexes are different from those for the π-acceptors (cf. the values of E given on p. 621 for the parallel and vertical model of iodine complexes with aromatic hydrocarbons). The values of E for EDA complexes of iodine with aromatic hydrocarbons are about 0.8–1.0 eV less than the values for π-acceptors. Correspondingly, the electron affinities (relative to iodine) of π-acceptors calculated by *Batley* and *Lyons* should be too high by the same amount.

Table 6. Energy data for organic electron acceptors [**].

### 6. Electron Affinities from Polarographic Half-Wave Reduction Potentials

The first step of reversible polarographic reduction of an electron acceptor or of reversible oxidation of an electron donor proceeds as follows:

(26a) $A_{solv} + e^- \rightleftharpoons A^-_{solv}$ : $E^{Red}_{1/2}$

(26b) $D_{solv} \rightleftharpoons D^+_{solv} + e^-$ : $E^{Ox}_{1/2}$

*Maccoll* [31] was the first to show that, for angularly condensed aromatic hydrocarbons, there is a relationship between the polarographic one-electron half-wave reduction potential, $E^{Red}_{1/2}$, and the energy of the highest unoccupied orbital, $E_i$.

The reduction potential, measured against a saturated calomel electrode, is given by the expression:

(27) $-E^{Red}_{1/2} = EA - \Delta F_{solv} - 5.07 = EA' - 5.07$ [eV] [32, 33]

*Peover* [34] measured $E^{Red}_{1/2}$ for a number of typical acceptors in acetonitrile and dimethylformamide as solvent. The half-wave potentials are largely independent of the solvent. Using EA' and $\overline{EA}$ (Table 6, Column 6) in Equation (27), it is possible to calculate the difference in solvation energy of the anion and of the neutral acceptor molecule $\Delta F_{solv}$ (Table 6, Column 10). Since $^{A^-}F_{solv} \gg {}^{A}F_{solv}$, the major part of $\Delta F_{solv}$ is represented by the solvation energy of the anion. $\Delta F_{solv} \approx {}^{A^-}F_{solv}$ is nearly constant [35]. For $^{A^-}F_{solv}$ = 3.66 eV, obtained as an average value from the values of $\Delta F_{solv}$ (Table 6, Column 10), we obtain:

(28) $EA = -E^{Red}_{1/2} + 1.41$

Figure 4 shows a plot of $\overline{EA}$ against $E^{Red}_{1/2}$ [34]; the agreement with Equation (28) is satisfactory. The straight line in Figure 4 corresponds to Equation (28').

(28') $EA = -1.04\ E^{Red}_{1/2} + 1.39$ [eV]

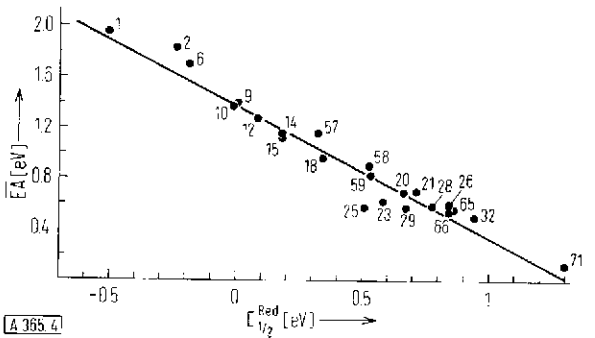

Fig. 4. Linear relationship between the electron affinity $\overline{EA}$ and the half-wave reduction potential $E^{Red}_{1/2}$ according to Equation (28'); for the numerical values and numbering of the acceptors, see Table 6.

The average value of $\Delta F_{solv}$ (= 3.66 eV) for the acceptors in Table 6 is of the correct magnitude, as indicated by comparison with the solvation energies the anions of aromatic hydrocarbons (Table 8, Columns 8 and 9). The values of $\Delta F_{solv}$ for the acceptors (Table 6) are relatively constant; this is probably due to the fact that the negative charge of the $A^-$ ion is located in certain parts of the molecule (*e.g.* $-C{=}O$, $-C{=}N$, $-NO_2$ groups), whereas in the anions of polycyclic hydrocarbons, the negative charge is dispersed over larger portions of the molecule. Therefore, in these cases $^{A^-}F_{solv}$ is not constant.

Since Equation (28) is fulfilled satisfactorily, Equation (28') can be used to estimate the electron affinities of acceptors for which only $E^{Red}_{1/2}$ has been measured. Electron affinities calculated in this manner from Equation (28') are listed for a few acceptors in Column 11 of Table 6.

According to Equations (27) and (8), there must be some relationship between $\tilde{\nu}_{CT}$ and $E^{Red}_{1/2}$ [35] when $\tilde{\nu}_{CT}$ is based on EDA complexes of different acceptors with one and the same donor:

(29) $E^{Red}_{1/2} = \tilde{\nu}_{CT} - (I + E - \Delta F_{solv} - 5.07)$

If the ionization energies of pyrene, hexamethylbenzene, and tetramethyl-*p*-phenylenediamine are taken as 7.8, 8.0, and 6.7 eV, respectively, and E = −4.3 eV is used for the Coulomb energy of the EDA complexes of the acceptors listed in Table 6 (for complexes with tetramethyl-*p*-phenylenediamine E = −3.9 eV), the following linear relationships result for the different acceptors, when $\Delta F_{solv}$ in Equation (29) is assumed to be −3.66 eV:

(30) Pyrene: $E^{Red}_{1/2} = \tilde{\nu}_{CT} - 2.09$ (2.13) [eV]

Hexamethylbenzene: $E^{Red}_{1/2} = \tilde{\nu}_{CT} - 2.29$ (2.40) [eV]

Tetramethyl-*p*-phenylenediamine: $E^{Red}_{1/2} = \tilde{\nu}_{CT} - 1.35$ ($1.36_5$) [eV]

---

Batley* and *L. E. Lyons*, Nature (London) *196*, 573 (1962); *M. E. Peover*, J. chem. Soc. (London) *1962*, 4540.

[32] *E. A. Matsen*, J. chem. Physics *24*, 602 (1956); *R. M. Hedges* and *F. A. Matsen*, ibid. *28*, 950 (1958); *G. J. Hoijtink* and *J. van Schooten*, Recueil Trav. chim. Pays-Bas *71*, 1089 (1952); *A. Laintinen* and *S. Warzonek*, J. Amer. chem. Soc. *64*, 1765 (1942).

[33] The electrochemical process:

$A_{solv} + Cl^-_{solv} + Hg_{liq} \rightarrow A^-_{solv} + (HgCl)_{solv}$ : $(E^{Red}_{1/2})$

can be separated into the following steps

$A_{gas} + e^- \rightarrow A^-_{gas}$ : $(-EA)$

$A_{solv} : A^-_{gas} \rightarrow A_{gas} + A^-_{solv}$ : $(\Delta F_{solv} = {}^{A}F_{solv} - {}^{A^-}F_{solv})$

$Hg_{liq} + Cl^-_{solv} \rightarrow (HgCl)_{solv} + e^-$ (in Hg)

: $(\Delta F_{Hg_2Cl_2} = \varepsilon_{Hg_2Cl_2} = 0.53$ eV)

$e^-$ (in Hg) $\rightarrow Hg_{liq} + e^-$ : (4.54 eV)

According to Equation (26a), negative values of $E^{Red}_{1/2}$ should be used for strong acceptors, and positive values for weak acceptors (the sign is sometimes given in the opposite sense). $\Delta F_{solv}$ is negative, EA is positive by convention. It is assumed that electron addition at a dropping mercury electrode according to Equation (26a) is sufficiently fast and reversible so that overvoltage phenomena and secondary reactions can be neglected. Moreover, no proton addition should take place (solvents devoid of proton activity, such as acetonitrile, dimethylformamide, or dioxane, must be used).

[34] *M. E. Peover*, Nature (London) *191*, 702 (1961); Trans. Faraday Soc. *58*, 656, 2370 (1962).

[35] *M. E. Peover*, Trans. Faraday Soc. *58*, 1656 (1962).

The numerical values refer to straight lines plotted in Figure 5 which best fit the experimental $E_{1/2}^{Red}$ and $\tilde{\nu}_{CT}$ values. Because of the uncertainty in E and the variability of $\Delta F_{solv}$, deviations are not of great importance.

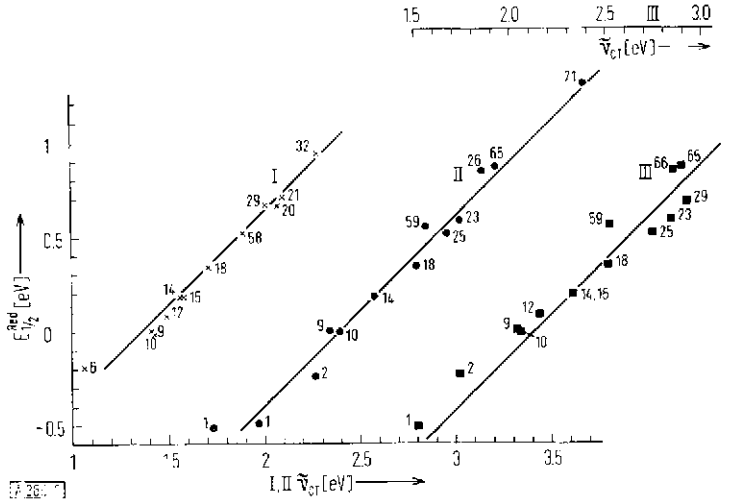

Fig. 5. Correlation between the half-wave reduction potential of the acceptor $E_{1/2}^{Red}$ [34,35] and the electron transfer energy $\tilde{\nu}_{CT}$ for donor acceptor complexes, according to Equations (29) and (30). Donors: tetramethyl-*p*-phenylenediamine (I), hexamethylbenzene (II), and pyrene (III). The numbers on the experimental points refer to acceptor numbers given in Table 6.

## 7. Electron Affinities from Polarographic Half-Wave Oxidation Potentials

According to Equation (26b), polarographic oxidation of aromatic unsubstituted and substituted hydrocarbons may be described in terms of a relationship corresponding to Equation (28) in which the first polarographic half-wave oxidation potential is a function of the ionization energy of the hydrocarbon. *Pysh* and *Yang* [36] found empirically:

(31) $I = 1.473\ E_{1/2}^{Ox} + 5.82$

From Equations (31) and (8), using E = −4.3 eV, we obtain:

(32) $EA = -\tilde{\nu}_{CT} + 1.473\ E_{1/2}^{Ox} + 1.52$

The values of $E_{1/2}^{Ox}$ [36] and $\tilde{\nu}_{CT}$ for EDA complexes between the donors listed in Column 12a and the acceptors listed in Column 1 of Table 6 have been determined experimentally. Thus, for the donors in Column 12a, the electron affinities can be calculated and averaged using Equation (32) [see Column 12]. However, the electron affinities obtained from Equation (32) are somewhat low compared to those obtained and averaged using Equations (23′) and (25) [see Table 6, Column 8].

## 8. Correlation between Electron Affinity and Electron-Transfer Energy

It follows from Equation (8) that, for complexes of one and the same donor with various acceptors, an approximately linear relationship must exist between the electron-transfer energy $\tilde{\nu}_{CT}$ and the electron affinity EA of the acceptor. Applying the ionization energies and values of E given above for pyrene, hexamethylbenzene, and tetramethyl-*p*-phenylenediamine, Equation (8) gives the following linear relationships:

(33) Pyrene: $\tilde{\nu}_{CT} = -EA + 3.51\ (3.42)$ [eV]

Hexamethylbenzene: $\tilde{\nu}_{CT} = -EA + 3.7\ (3.75)$ [eV]

Tetramethyl-*p*-phenylenediamine:
$\tilde{\nu}_{CT} = -EA + 2.8\ (2.78)$ [eV]

The straigbt lines in Figure 6 refer to the numerical values given in parentheses. In view of the relatively large inaccuracy in the EA values, the agreement between Equations (33) and (8) is satisfactory.

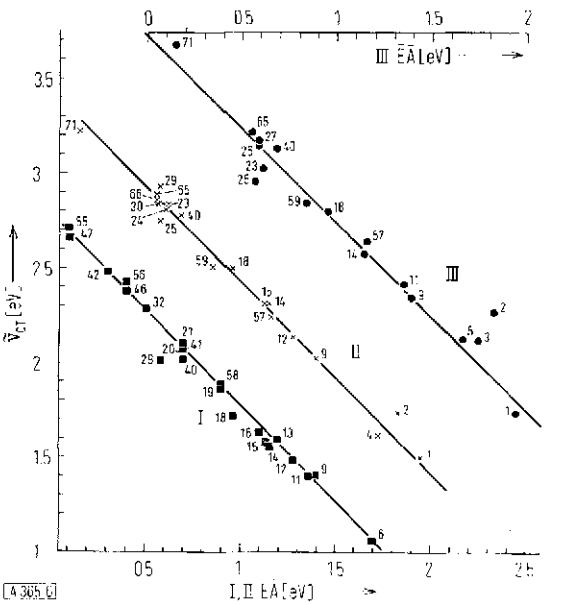

Fig. 6. Electron-transfer energy $\tilde{\nu}_{CT}$ of EDA complexes as a function of the electron affinities $\overline{EA}$ of various acceptors, according to Equation (33). Donors: tetramethyl-*p*-phenylenediamine (I), pyrene (II), and hexamethylbenzene (III). For the $\overline{EA}$ values and acceptor numbering, see Table 6.

## 9. Electron Affinity and Chemical Constitution

The relatively great inaccuracy in the electron-affinity values precludes discussion of the more refined effects induced by the structure of the compounds involved.

The strongest acceptors are 2,3-dichloro-5,6-dicyano-*p*-benzoquinone, tetracyanoethylene, 2,6-dinitrobenzoquinone, tetracyano-*p*-benzoquinone, 2,3-dicyanobenzoquinone, and bis(dicyanomethylene)quinones. The electron affinities of unsubstituted quinones lie in the following order: 9,10-anthraquinone < 1,4-naphthoquinone ≈ 9,10-phenanthrenequinone ≈ 1,2-naphthoquinone ≈ *p*-benzoquinone < *o*-benzoquinone < 1,8-diphenoquinone.

Alkyl substituents tend to reduce the electron affinity, the effect becoming more pronounced as their number increases. Electrophilic (halogeno, CN, $NO_2$) groups

[36] *E. S. Pysh* and *N. C. Yang*, J. Amer. chem. Soc. *85*, 2124 (1963).

tend to augment the electron affinity of a compound, this effect increasing with the number of such substituents. CN and $NO_2$ tend to increase the electron affinity to a larger extent than do halogens. Cl, Br, and I do not differ appreciably in this respect. The nitroaromatics are relatively good acceptors: 2,4,7-trinitrofluorenone > 1,3,5-trinitrobenzene ≈ 1,4-dinitrobenzene > nitrobenzene > 1,3-dinitrobenzene > 1,2-dinitrobenzene. With the exception of 1,2-dinitrobenzene, the electron affinity increases with increasing number of nitro groups. Unexpectedly, the electron affinity of 1,3-dinitrobenzene is less than that of nitrobenzene. (Since the electron affinity of these two nitro compounds has been determined only once, and by two different methods, this difference may be due to the difference in the methods used.) The fact that the electron affinity of 1,2-dinitrobenzene (in contrast to that of 1,3- and 1,4-dinitrobenzene) is practically zero is consistent with steric inhibition of the mesomeric stabilization of the 1,2-dinitrobenzene anion, *i.e.*, both nitro groups cannot become coplanar with the benzene ring. Substitution by methyl generally decreases the electron affinity: 1,3,5-trinitrobenzene > 1,3,5-trinitrotoluene > 1,3,5-trinitro-*m*-xylene; also, 1,3-dinitrobenzene > 2,4-dinitrotoluene. The polycyanobenzenes are definitely poorer acceptors than the corresponding nitrobenzenes. The electron affinity of polycyanobenzenes increases with increasing number of cyano groups. Simply substituted halogenobenzenes are relatively good acceptors. An increase in the number of halogen substituents on the benzene ring does not seem to exert as strong an influence as does substitution by $NO_2$. This is exemplified by hexachlorobenzene.

Molecules with two adjacent electrophilic carbonyl groups, *e.g.* diacetyl, ethyl pyruvate, and dimethyl oxaloacetate, are relatively good electron acceptors (comparable to trinitrobenzene). The electron affinity of these compounds and that of the electrophilic -CO-C-C-CO- group, *e.g.*, in diethyl maleate and diethyl fumarate, are nearly equal.

Compounds with β-dicarbonyl groups have lower electron affinities (acetylacetone, ethyl acetoacetate).

Phthalic anhydride is practically devoid of electron-acceptor properties. It acquires such properties by electrophilic substitution (tetrachlorophthalic anhydride).

The relatively high electron affinity of $CCl_4$ is noteworthy. This is consistent with the fact that, in the presence of $CCl_4$, donors such as hexamethylbenzene show a characteristic absorption band indicative of electron-donor/electron-acceptor interaction [36a]. Carbon tetrachloride and chloroform are σ-acceptors which, despite their high electron affinity, have an EDA interaction energy that seems to be lower than that of π-acceptors with comparable electron affinities [36a].

## II. Aromatic Hydrocarbons as Electron Acceptors

### 1. Quantum-Mechanical Calculation of Electron Affinity

According to *Pople* and *Brickstock* [37], the energy of the highest occupied and that of the lowest unoccupied orbital of an aromatic hydrocarbon are:

$$E_i = -I = \alpha' + F \qquad (34a)$$

$$E_j = -EA = \alpha' - F \qquad (34b)$$

F [38] can be calculated by the semiempirical ASMOSC [42] method. The electron affinities calculated by *Pople* and *Brickstock* [37] and by *Hedges* and *Matsen* [39] from Equation (34b) are listed in Columns 3 and 4 of Table 7. $\alpha'$ was normalized by *Hedges* and *Matsen* to the ionization energy of naphthalene (8.12 eV) to $\alpha' = -3.87$ eV.

These calculations [37, 39] were carried out by *Hoyland* and *Goodman* [40] with even fewer assumptions; they also took into account the changes in electron density following removal or capture of an electron, as well as the effect of the σ-electron energy. The electron affinities calculated by these workers [40] are listed in Column 5 of Table 6.

The ω-approximation in the simplified treatment proposed by *Ehrenson* [22] gives an expression for the electron affinity corresponding to Equation (13):

$$-E_j = EA = -\alpha_0 - (f_{II} - \frac{n+1}{n}\omega)\beta = -\alpha_0 - x\beta \qquad (34')$$

As already mentioned, the ω-approximation [Equation (13)] gives satisfactory values for the ionization energies of aromatic hydrocarbons when $\alpha = -9.878$ eV, $\beta = -2.11$ eV, and $\omega = 1.4$. On the other hand, the electron affinities obtained from Equation (34) with $\omega = 1.4$ are much too high. To obtain good agreement with the electron affinities calculated from Equation (34') by *Hedges* and *Matsen* [39], *Poples* [37], and *Hoyland* and *Goodman* [40], as well as with the experimental values of *Wentworth* and *Becker* [3], the very high value of

[37] *J. A. Pople*, Trans. Faraday Soc. *49*, 375 (1953); *A. Brickstock* and *J. A. Pople*, ibid. *50*, 901 (1954); *J. A. Pople*, J. physic. Chem. *61*, 6 (1957); *C. J. Koothaan*, Rev. mod. Physics *23*, 61 (1951).

[38] $F = 2\sum_{\mu<\nu} \chi_{N\mu}\cdot\chi_{N\nu}(\beta_{\mu\nu} - \gamma_{\mu\nu}\cdot\sum_{i=1}^{N}\chi_{i\mu}\cdot\chi_{i\nu})$

$\gamma_{\mu\nu}$ = Coulomb interaction between one electron at atom μ and one electron at atom ν. $\beta_{\mu\nu}$ = resonance integral for two adjacent atoms μ and ν. N = number of occupied orbitals in the aromatic hydrocarbon. $\chi_{i\mu}$ and $\chi_{i\nu}$ = Hückel coefficients of the μ-th and ν-th atomic orbitals in the i-th molecular orbital. The x-values can be calculated with good approximation using the simple MO theory.

[39] *R. M. Hedges* and *F. A. Matsen*, J. chem. Physics *28*, 950 (1958). See also: *A. Streitwieser* and *P. M. Nair*, Tetrahedron *5*, 149 (1959); *A. Streitwieser*, J. Amer. chem. Soc. *82*, 4123 (1960); *W. F. Wolf*, Abstracts J. Amer. chem. Soc. Meeting, New York 1960.

[40] *J. R. Hoyland* and *L. Goodman*, J. chem. Physics *36*, 12, 21 (1962).

$\omega = 3.77$ must be used in Equation (34') [43,44]; similarly, a value of $\omega = 3.73$ must be used for phenanthrene, benzo[*c*]phenanthrene, and triphenylene [44]. No theoretical explanation is available for the fact that the calculations of I using Equation (13) and of EA using Equation (34') require different values of $\omega$.

In Column 6 of Table 7, a list is given of the electron affinities calculated by *Ehrenson* [22] according to the $\omega$-method, using a $\omega = 3.5$. Column 2 contains the electron affinities obtained for a few aromatic hydrocarbons by *Wentworth* and *Becker* [3] using the electron absorption coefficients determined experimentally by *Lovelock* [1].

## 2. Semiempirical Methods for Determining Electron Affinities

### a) *Electron Affinity and the Longest-Wavelength Absorption Band of the Donor*

It follows from (34) that

$$(35) \qquad (EA + I)/2 = \alpha'$$

On the basis of the electron affinities determined experimentally for a few aromatic hydrocarbons (Table 7, Column 2) and the experimental values for the first ionization energies $I_{exp}$ (Table 8, Column 4), one obtains in agreement with *Becker* and *Wentworth* [28] an average value of 8.14 eV for the sum (I + EA). From Equations (21) and (35), we obtain for $\alpha' = 4.07$:

$$(36) \qquad EA = 3.03 - 0.701\ \tilde{\nu}_0$$

The electron affinities calculated from $\tilde{\nu}_0$ (Table 8, Column 6) using Equation (36) are given in Column 2 of Table 8.

The differences between the electron affinities calculated by the ASMOSC method (Table 6, Columns 3, 4, 5, and 6), those obtained from $\tilde{\nu}_0$ (Table 8, Column 2) using Equation (36), and the few experimental EA values (Table 7, Column 2) may be considerable. The $\overline{EA}$ values obtained by averaging all EA values are given in Column 3 of Table 8.

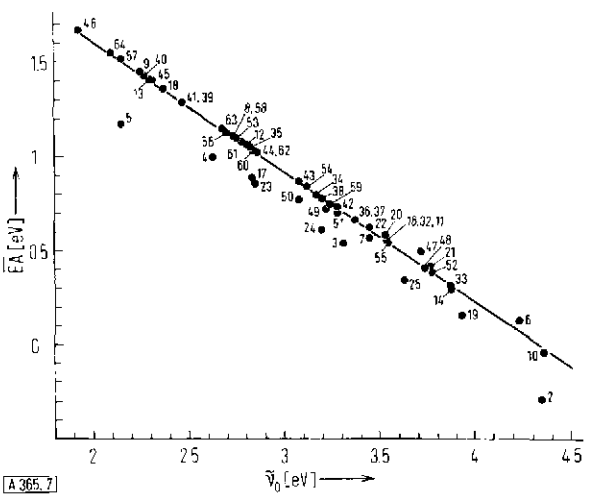

Fig. 7. Averaged electron affinities of aromatic hydrocarbons (calculated by different methods) as a function of the first excitation energy $\tilde{\nu}_0$. The straight line corresponds to Equation (37); for numerical data and key numbers to hydrocarbons, see Tables 8 and 7, respectively.

Their absolute accuracy is never better than ± 0.2 eV. Figure 7 shows a plot of these electron affinities against $\tilde{\nu}_0$ for aromatic hydrocarbons. The linear relationship

$$(37) \qquad \overline{EA} = 2.991 - 0.700\ \tilde{\nu}_0$$

obtained in this manner is in good agreement with Equation (36), which was derived directly from experimental data, and with the expression of *Becker* and *Wentworth* [28]:

$$(38) \qquad EA = 2.92 - 0.762\ \tilde{\nu}_{00}$$

It is noteworthy that the linear functions (21) and (36), which agree best with the experimental values for ionization energies and electron affinities, have the same gradient.

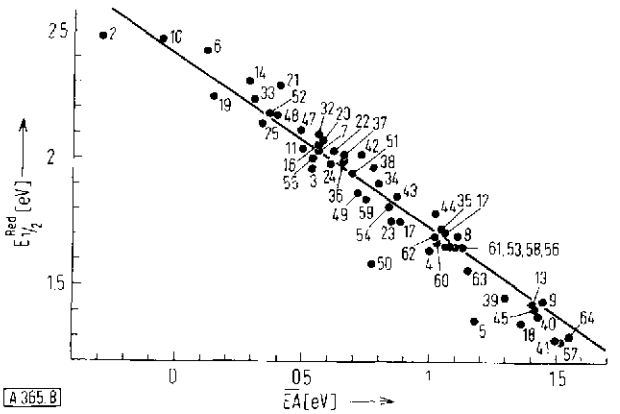

Fig. 8. Half-wave reduction potentials $E^{Red}_{1/2}$ [47] of aromatic hydrocarbons as a function of averaged electron affinities $\overline{EA}$ calculated by different methods. The solid straight line corresponds to Equation (39). For numerical data and key numbers to hydrocarbons, see Tables 8 and 1, respectively.

b) *Electron Affinity, Half-Wave Reduction Potential and Solvation Energy*

Figure 8 shows a plot of $E^{Red}_{1/2}$ (Table 8, Column 7 [45]) obtained from Equation (27) *vs.* $\overline{EA}$ (Table 8, Column 3). The $E^{Red}_{1/2}$ and EA values fit Equation (39):

(39) $$E^{Red}_{1/2} = 2.416 - 0.692\ \overline{EA}$$

It follows from Equations (39) and (27) that there is a functional relationship between $\Delta F_{solv}$ and EA. If we set

(40) $$\Delta F_{solv} = -\eta_{solv} + \delta \cdot EA$$

then from Equations (27) and (40) we obtain:

(41) $$-E^{Red}_{1/2} = EA\,(1-\delta) + \eta_{solv} - 5.07\ [eV]$$

and, by comparison with Equation (39):

$$\delta = 0.308 \text{ and } \eta_{solv} = 2.654$$

Hence:

(42) $$\Delta F_{solv} = 0.308\ EA - 2.654$$

Equation (42) can be checked by using Equation (27) to calculate $\Delta F_{solv}$ ($R^{Red}_{1/2}$ from Column 7, $\overline{EA}$ from Column 3 of Table 8).

(43) $$\Delta F_{solv} = EA - 5.07 + E^{Red}_{1/2} = EA - EA'$$

The values of $\Delta F_{solv}$ calculated using Equation (43) are listed in Column 8 of Table 8, and give rise to the following linear relationship:

(44) $$\Delta F_{solv} = 0.2714\ \overline{EA} - 2.624\ [eV]$$

which is in good agreement with Equation (42). The $\Delta F_{solv}$ values derived from Equation (44) are given in Table 8, Column 9.

The decrease in solvation energy with increasing electron affinity of aromatic hydrocarbons is possibly associated with the distribution of the negative charge over the entire molecule. The solvation energy decreases, and the increase in electron repulsion energy on transition from the neutral molecule to the anion also becomes less (*i.e.*, the electron affinity of the aromatics increases) as the range of dispersion of the negative charge over the aromatic anion increases. Also the interaction energy with the solvent molecules decreases with increasing radius of the aromatic anion.

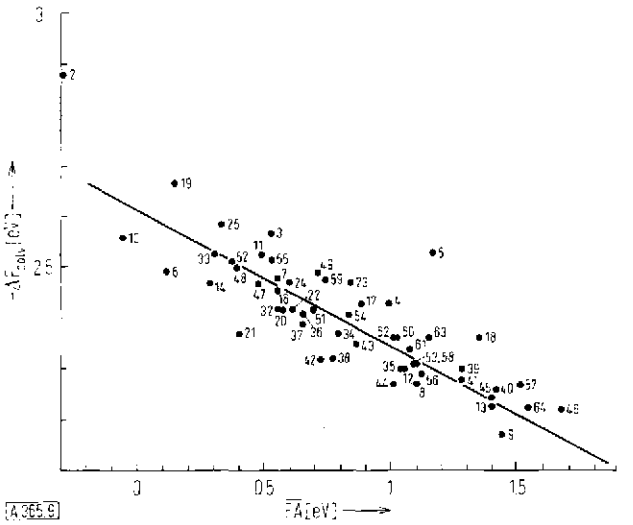

Fig. 9. Solvation energy $\Delta F_{solv}$ of aromatic hydrocarbons as a function of the electron affinity $\overline{EA}$ according to Equation (44); for numerical data and the key numbers of the aromatic hydrocarbons, see Tables 8 and 1, respectively.

Extrapolation of Equations (21) and (37) to $\tilde{\nu}_0 \rightarrow 0$ is of questionable validity because these equations have been shown to be valid only within the rather narrow range from $\tilde{\nu}_0 \approx 2.5$ to 4 eV. Extrapolation to $\tilde{\nu}_0 \rightarrow 0$ would assume I and EA to be linear functions of $\tilde{\nu}_0$ [Equations (21) and (37)] even for very low values of $\tilde{\nu}_0$; this, however, has never been proved. Though the difference (I EA) = (1.4 $\tilde{\nu}_0$ + 2.12 [eV]) [Equations (21) and (37)] decreases with decrease in the excitation energy of aromatic hydrocarbons, Equations (21) and (37) give different values, *viz.* $I_{\tilde{\nu}_0=0} = 5.11$ eV and $EA_{\tilde{\nu}_0=0} = 2.99$ eV. However, according to Hückel's theory, $\tilde{\nu}_0$ should tend to zero and I should tend to EA for infinitely large, conjugated aromatic ring systems, *e.g.* in graphite. The work function of graphite is 4.39 eV [46].

For hydrocarbons, we should expect $I_{\tilde{\nu}_0 \rightarrow 0} \neq EA$ since the electron repulsion energy of the hydrocarbon anion is greater than that of the hydrocarbon cation. Accordingly, $I_{\tilde{\nu}_0 \rightarrow 0} > EA_{\tilde{\nu}_0 \rightarrow 0}$. Finally, it should be borne in mind that Equations (21) and (37) refer to two-dimensional aromatic ring systems in the gaseous state.

### 3. Electron Affinity and Chemical Constitution [*]

a) The electron affinity increases with the number of rings fused together in a line, whereas the ionization energy decreases correspondingly (see Table 1, Nos. 1–5, 6–9, 10–13, and 14–18).

[45] *I. Bergman*, Trans. Faraday Soc. *50*, 829 (1954); *G. J. Hoijtink*, Recueil Trav. chim. Pays-Bas *73*, 355 (1954); *74*, 1525 (1955), where references to previous publications are given. The $E^{Red}_{1/2}$-values of *Bergman* must be increased by 0.5 eV in order to obtain the $E^{Red}_{1/2}$-values measured in 75% dioxane against a saturated $Hg_2Cl_2$-electrode. The $E^{Red}_{1/2}$-values measured in 75% and 96% dioxane show practically no differences.

[46] *A. Braun* and *G. Busch*, Helv. physica Acta *20*, 33 (1947).

[*] The fact that aromatic hydrocarbons are electron donors as well as electron acceptors enables them to undergo intermolecular EDA-interaction. *Wentworth* and *Chen* proved this using the spectral shift of the absorption spectra of a few polycyclic hydrocarbons on addition of hexamethylbenzene in heptane solution: J. physic. Chem. *67*, 2201 (1963).

[*] For key to hydrocarbon numbers, see Table 1.

and from 9 to 12), at the 7,8-positions (from No. 6 to 19, from 7 to 20, and from 11 to 31) has essentially no effect on the electron affinity and ionization energy. Accordingly, the EA and I values for tribenz[*a*,*c*,*g*]anthracene (No. 31) and dibenzo[*a*,*g*]chrysene (No. 32) compared to dibenz[*a*,*g*]anthracene (No. 20) and benzo[a]chrysene (No. 30), respectively, are practically identical.

c) Beginning with pyrene (Table 1, No. 47), an additional benzene or naphthalene ring fused on at the 1,2- and/or 6,7-positions (*i.e.* the [*a*] or [*f*] sides) has no particular effect on the electron affinity and ionization energy. This is indicated by comparison of No. 47 with Nos. 48, 52, and 55. The electron affinity of pyrene increases, and its ionization energy decreases, as a result of fusion of benzene or naphthalene rings onto sides other than the [*a*], *e.g.* at the 3,4-, 8,9-, and 9,10-positions ([*c*], [*h*], and [*i*] sides). This can be seen by comparing the electron affinity of pyrene with those of Nos. 49, 53, 54, 56, 57, and 58. Fusion onto the [*c*, *h*] sides has a greater effect on the electron affinity than [*c*, *i*] fusion (Table 1; increase in EA in going from Nos. 53 and 57 to Nos. 54 and 58, respectively).

d) Fusion of one or two benzene rings onto the [*a*] or [*a*, *g*] sides (Table 1, Nos. 39 and 40, respectively) of perylene (Table 1, No. 23) increases the electron affinity and decreases the ionization energy to the same degree as does double fusion onto the [*b*, *h*] or [*a*, *j*] sides (No. 44 or No. 41). On passing from perylene (No. 23) to benzo[*l*]perylene (No. 24) and to coronene (No. 25), the electron energy decreases and the ionization increases correspondingly.

e) The following compounds have the highest electron affinities, and, correspondingly, the lowest ionization energies: benzo[*g*]terylene (No. 46): EA = 1.4 eV; I = 6.46 eV; dibenz[*b*, *h*]anthanthrene (No. 64): EA = 1.55; I = 6.58 eV; dibenzo[*a*, *g*]perylene (No. 40): EA = 1.4; I = 6.7 eV; benzo[*a*]pentacene (No. 9): EA = 1.45; I = 6.69 eV; dibenzo-[*a*, *c*]pentacene (No. 13): EA = 1.4, I = 6.72 eV, and dibenzo-[*a*, *d*]pentacene (No. 18); EA = 1.4 eV, I = 6.77 eV.

## An Unusual Cyclization of a Steroid N-Chloroamine [1]

By Dr. G. Adam and Dr. habil. K. Schreiber

Institut für Kulturpflanzenforschung Gatersleben der Deutschen Akademie derWissenschaften zu Berlin (Germany)

In an attempt to prepare the cyclic azomethine *(3)* from *(22R, 25S)-N*-chloro-22,26-imino-5α-cholestan-3β-ol *(1)* [2] by heating it for 75 min with 5 % methanolic KOH in order to eliminate hydrogen chloride, we obtained instead the *Solanum* steroid alkaloid demissidine *(2)*, m.p. 218–220 °C, $[\alpha]_D^{18} = +26.9°$ (c = 0.423 in $CHCl_3$), in 57 % yield. Careful chromatographic separation of the reaction product on $Al_2O_3$ yielded, in addition to *(2)* and 24 % dechlorinated starting material, 3.5 % of the desired $\Delta^{22(N)}$-unsaturated compound *(3)*, m.p. 190–193 °C, $[\alpha]_D^{19} = -40.6°$ (c = 0.413 in $CHCl_3$),

which has an infrared band at 1661 $cm^{-1}$. In contrast, when the *(22S, 25R)*-stereoisomer of *(1)* was dehydrochlorinated under identical conditions, it yielded the expected *(25R)*-azomethine in 60 % yield, but no solanidan [3].

In order to account for the formation of *(2)* from *(1)*, direct elimination of HCl involving participation of the non-activated C–H bond at C-16 must be assumed. This anomalous octahydropyrrocoline ring closure is likely to be due to a particularly favorable steric arrangement of the centers involved in this reaction, and to the stability of the *(22R,25S)*-solanidan skeleton once formed.

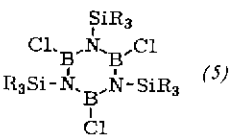
## Bis(trimethylsilyl)aminohalogenoboranes [1]

By Dr. P. Geymayer, Prof. Dr. E. G. Rochow, and Prof. Dr. U. Wannagat

Department of Chemistry, Harvard University, Cambridge, Mass. (U.S.A.) and

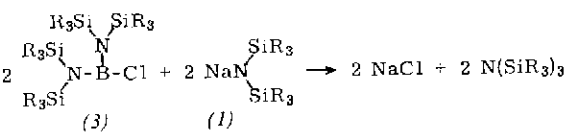
Institut für anorganische Chemie der Technischen Hochschule Graz (Austria)



Disilazanes are cleaved at the Si–N bond by boron halides [2, 3], and are transaminated by aminoboranes [4]; both reactions lead to compounds containing the >B–NH–Si< grouping.

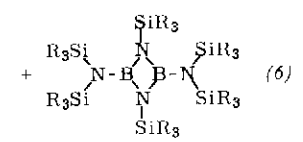
We have now succeeded in preparing compounds with a >B–N(Si<)$_2$ grouping.

$$X_3BO(C_2H_5)_2 + n\ NaN(SiR_3)_2 \rightarrow \underset{(1)}{} X_{3-n}B[N(SiR_3)_2]_n + n\ NaX + O(C_2H_5)_2$$



R = $CH_3$; *(2)*, X = F, n = 2; *(3)*, X = Cl, n = 2; *(4)*, X = Cl, n = 1

A solution in ether of sodium bis(trimethylsilyl)amide *(1)* [5] is added dropwise to a solution in ether of boron trihalide etherate; subsequent fractional vacuum distillation yields bis-[bis(trimethylsilyl)amino]fluoroborane *(2)*, m.p. 1 °C, b.p. 76 °C/0.2 mm, as a stable viscous liquid, which is only slowly decomposed by $CH_3OH$/HCl and which does not react further with *(1)*, even under vigorous conditions. Products obtained similarly are bis[bis(trimethylsilyl)amino]chloroborane *(3)*, m.p. 36 °C, b.p. 105 °C/11 mm, crystals that are very sensitive to hydrolysis, and bis(trimethylsilyl)aminodichloroborane *(4)*, m.p. 5–6 °C, b.p. 82 °C/11 mm, a colorless liquid which is also very sensitive to hydrolysis. The fluoro compound analogous to *(4)* could not yet be obtained. The structures proposed are supported by elementary analyses and infrared and proton magnetic resonance spectra: δ (relative to TMS) = 0.18 ppm for *(2)* with a doublet structure at high resolution, δ = 0.27 ppm for *(3)*, and δ = 0.30 ppm for *(4)*. Compound *(4)* is thermally unstable and undergoes intermolecular condensation in boiling xylene with elimination of $R_3SiCl$ to give 1,3,5-tristrimethylsilyl-2,4,6-trichloroborazole *(5)*, m.p. 140 °C, which sublimes at 95 °C/2 mm;



*(5)*

*(5)* has δ = 0.35 ppm and characteristic infrared peaks at 1325 and 950 $cm^{-1}$.

*(3)* *(1)*

*(6)*

Compound *(3)* does react with *(1)* under more vigorous conditions (refluxing xylene, 20 h), but instead of the expected tris[bis(trimethylsilyl)amino]boron, tris(trimethylsilyl)amine and hexakistrimethylsilyl-1,3-diaminocyclo-2,4-diboradiazetane *(6)*, m.p. 212 °C, are obtained. Compound *(6)* is a white sublimable (110 °C/0.1 mm) solid; its NMR spectrum has peaks at δ = 0.20 and 0.16 ppm in an integral ratio of 2:1 [6].

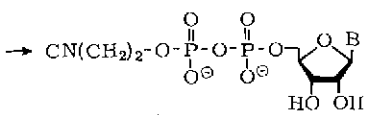
## A Simple Method for Preparing Nucleoside Diphosphates [1]



By Dr. K. H. Scheit and Dr. W. Kampe

Chemische Abteilung der Medizinischen Forschungsanstalt der Max-Planck-Gesellschaft, Göttingen (Germany)

All the known syntheses of nucleoside diphosphates start from activated nucleoside monophosphates, *e.g.* nucleoside-5'-phosphoroimidazoles [2] or nucleoside-5'-phosphoromorpholidates [3]. The method we have discovered avoids activation of the nucleoside 5'-phosphate, a process which usually involves complications. The readily accessible 2-cyanoethyl-α-pyridyl phosphate *(1)* [4] reacts in pyridine at room temperature with monotriethylammonium salts of nucleoside 5'-phosphates *(2)* to yield unsymmetrical pyrophosphoric diesters *(3)*.

*(1)* *(2)*

*(3)*

B = uracil, cytosine, adenine

Mild alkaline hydrolysis of *(3)* at 0 °C yielded nucleoside diphosphates. The course of the reactions was followed by paper chromatography. The yields were usually 60 % based on the nucleoside 5'-phosphate used as starting material.

## Reactions with Single Crystals of Niobium Oxides [*]

By Dr. R. Gruehn, Dr. F. Schulte, and Prof. Dr. H. Schäfer

Anorganisch-Chemisches Institut der Universität Münster (Germany)

Chemical transport [1] gives rise to various modifications of $Nb_2O_5$ [2, 3], as well as phases including Nb(IV) and Ti(IV) [4–6], as single crystals which are often several millimeters in size. We have found that some of the substances undergo transformations and redox reactions without loss of their single-crystal character (see Table).

Reactions with single crystals [3] (heated in air; experiments 21 and 23: *reduction with* $H_2/H_2O$).

| | Starting material (single crystal) | Annealing °C | Annealing h | Result (opt. and X-ray data) |
|---|---|---|---|---|
| 1 | B–$Nb_2O_5$ (blue; $Nb_2O_{2.496}$) | 860 | 80 | single cryst. B–$Nb_2O_5$ (blue [7]) |
| 2 | Product from 1 | 900 | 18 | single cryst. B–$Nb_2O_5$ (blue); colorless, polycryst. H–$NbO_{2.50}$ at the edges |
| 3 | B–$Nb_2O_5$ (blue) | 950–1000 | 4 | polycryst. H–$NbO_{2.50}$ (colorless) |
| 4 | P–$Nb_2O_5$ (blue) | 800 | 80 | single cryst. P–$NbO_{2.50}$(colorless) |
| 5 | Product from 4 | 800 | 80 | single cryst. P–$Nb_2O_5$ |
| 6 | P–$Nb_2O_5$ (colorless) | 850 | 16 | single cryst. P–$Nb_2O_5$ + polycryst. H–$Nb_2O_5$ |
| 7 | Product from 6 | 830–1000 | 80 | polycryst. H–$Nb_2O_5$ |
| 8 | N–$Nb_2O_5$ | 910 | 30 | single cryst. N–$Nb_2O_5$ |
| 9 | N–$Nb_2O_5$ | 1000 | 20 | single cryst. N–$Nb_2O_5$ + polycryst. H–$Nb_2O_5$ |
| 10 | Product from 9 | 1050–1150 | 20 | further transformn. N → H–$Nb_2O_5$ |
| 11 | M–$NbO_{2.48}$ (blue) | 830 | 12 | single cryst. M–$NbO_{2.50}$ (colorless) |
| 12 | Product from 11 | 830 | 12 | single cryst. M–$Nb_2O_5$ |
| 13 | Product from 12 | 1150 | 12 | single cryst. H–$Nb_2O_5$ |
| 14 | $NbO_{2.467}$ (II) | 650 | 4 | single cryst. $NbO_{2.50}$, X-ray pattern as for $NbO_{2.467}$ (II) |
| 15 | Product from 14 | 1150 | 150 | single cryst. $NbO_{2.50}$, X-ray pattern almost as for H–$Nb_2O_5$ |
| 16 | $NbO_{2.417}$ (I) | 650 | 50 | single cryst. $NbO_{2.50}$; diffuse X-ray pattern |
| 17 | Product from 16 | 1100 | 50 | single cryst. H–$Nb_2O_5$ |
| 18 | $NbO_{2.417}$ (II) | 650 | 4 | crystal disintegrated into similarly orientated single crystals; diffuse X-ray pattern |
| 19 | Product from 18 | 1100 | 12 | polycryst. H–$Nb_2O_5$ |
| 20 | H–$NbO_{2.49}$ (blue) | 1100 | 12 | single cryst. H–$NbO_{2.50}$ (colorless) |
| 21 | H–$NbO_{2.50}$ | 1100 | 50 | single cryst. $NbO_{2.44}$ (blue), distinctive X-ray pattern; like $NbO_{2.467}$ (II) |
| 22 | Product from 21 | 1100 | 12 | single cryst. H $NbO_{2.50}$ |
| 23 | $Nb_3O_7Cl$ (colorless) | 360–380 | 30 | single cryst. $Nb_3O_7Cl$ (blue) [8] |
| 24 | $Nb_3O_7Cl$ (deep blue) | 580 | 30 | single cryst. $Nb_3O_7Cl$ (pale blue) |
| 25 | Product from 24 | 580 | 75 | single cryst. $Nb_3O_7Cl$ (pale blue) and polycryst. B–$Nb_2O_5$ |
| 26 | $Nb_3O_7Cl$ (deep blue) | 700 | 75 | polycryst. B–$Nb_2O_5$ + P–$Nb_2O_5$ |

It was especially noteworthy that monoclinic $NbO_{2.417}$(I) could be converted into H–$Nb_2O_5$, which is also monoclinic, but that rhombic $NbO_{2.417}$(II) could not.

The transformation of P-$Nb_2O_5$ and B-$Nb_2O_5$ results in polycrystalline H-$Nb_2O_5$ without appearance of the M-form; well-ordered H-$Nb_2O_5$ is obtained from P-$Nb_2O_5$ at temperatures as low as 850 °C.

H-$Nb_2O_5$ can be reduced with $H_2/H_2O$ as a single crystal to $NbO_{2.44}$ [7] with clear alteration of the Guinier diagram. On reducing more strongly or for longer times, $NbO_2$ is formed, the phase $NbO_{2.417}$ being omitted.

The behavior of single crystals enables transformation relationships to be recognized which can yield information concerning structural relationships between allied substances.

## The Course of Dehalogenation of Ethylaluminum Sesquichlorides with Sodium

By Ing. Dr. J. Dvořák and prom. Chem. V. Fic

Forschungsinstitut für Makromolekulare Chemie, Brno (Czechoslovakia)

The production of triethylaluminum by dehalogenation of ethylaluminum sesquichlorides with sodium [1]

$$C_2H_5AlCl_2 + (C_2H_5)_2AlCl + 3\ Na \rightarrow (C_2H_5)_3Al + Al + 3\ NaCl \quad (a)$$

proceeds by a reaction more complicated than shown in Equation (a).

On adding a suspension of sodium in n-decane to a solution of ethylaluminum sesquichloride in n-decane at 120 °C with vigorous stirring under nitrogen, only ethylaluminum dichloride reacts at first. Diethylaluminum chloride, very finely dispersed sodium chloride, and metallic aluminum result.

$$2\ C_2H_5AlCl_2 + 3\ Na \rightarrow (C_2H_5)_2AlCl + 3\ NaCl + Al \quad (b)$$

Sodium chloride reacts with ethylaluminum dichloride to form a complex $Na[Al(C_2H_5)Cl_3]$, which precipitates.

$$C_2H_5AlCl_2 + NaCl \rightarrow Na[Al(C_2H_5)Cl_3] \quad (c)$$

Further additions of sodium react with this complex to give diethylaluminum chloride, sodium chloride, and aluminum.

$$2\ Na[Al(C_2H_5)Cl_3] + 3\ Na \rightarrow (C_2H_5)_2AlCl + 5\ NaCl + Al \quad (d)$$

Reactions (b)–(d) are strongly exothermic and proceed very rapidly. The dehalogenation of diethylaluminum chloride proceeds more slowly.

$$3\ (C_2H_5)_2AlCl + 3\ Na \rightarrow 2(C_2H_5)_3Al + 3\ NaCl + Al \quad (e)$$

A relative excess of sodium may be present towards the end of this reaction, since Reaction (e) takes place at the surface of the sodium, and the mixture is rather viscous owing to the separated sodium chloride and aluminum. The diffusion of diethylaluminum chloride towards the sodium surface may then be slower than the reaction of the triethylaluminum formed at the sodium surface with the sodium.

$$4\ (C_2H_5)_3Al + 3\ Na \rightarrow 3\ Na[Al(C_2H_5)_4] + Al \quad (f)$$

$Na[Al(C_2H_5)_4]$ reacts with a molecule of diethylaluminum chloride to form sodium chloride and triethylaluminum.

$$(C_2H_5)_2AlCl + Na[Al(C_2H_5)_4] \rightarrow 2\ (C_2H_5)_3Al + NaCl \quad (g)$$

The dehalogenation proceeds differently if the sesquichloride is added to a suspension of sodium in a high-boiling aliphatic hydrocarbon (n-decane; 120 °C; nitrogen atmosphere; vigorous stirring). Since the sodium is now present in excess, with each addition of sesquichloride, Reactions (b)–(f) occur successively. The product of this sequence of reactions is a mixture of the complex $Na[Al(C_2H_5)_4]$ with precipitated aluminum and sodium chloride. When more sesquichloride is added, it is dehalogenated by the $Na[Al(C_2H_5)_4]$. The $C_2H_5AlCl_2$ reacts first,

$$2\ C_2H_5AlCl_2 + Na[Al(C_2H_5)_4] \rightarrow 3(C_2H_5)_2AlCl + NaCl \quad (h)$$

and then the diethylaluminum chloride reacts according to Equation (g).

## Addition of Methyl Acetoxyacetate onto Olefins by a Free-Radical Mechanism [1]

By Dr. Yu. N. Ogibin and Dr. G. Y. Nikishin

N. D. Zelinskii Institute of Organic Chemistry, Academy of Sciences of the U.S.S.R., Moscow (U.S.S.R.)

We have succeeded in synthesizing α,β-unsaturated alkenoic esters by pyrolysis of 2-acetoxyalkanoic esters *(3)* [2], which were prepared from methyl acetoxyacetate *(1)* and α-olefins *(2)* in the presence of di-t-butyl peroxide. The molar proportions *(1)*:*(2)*:peroxide were 10:1:0.25. The table summarizes the yields and properties of the products.

| R | Yield [%] | B.p. [°C/mm] | Yield [%] [a] | B.p. [°C/mm] |
|---|---|---|---|---|
| $H_3C-(CH_2)_4-$ | 68 | 115/3 | 86 | 67–68/3 [b] |
| $H_3C-(CH_2)_5-$ | 53 | 120–121/4 | | |
| $H_3C-(CH_2)_9-$ | 66 | 182–183,5/5 | 80 | 117–118/1,5 |
| $H_3C-(CH_2)_{10}-$ | 63 | 174/4 | | |
| $H_3CO_2C-(CH_2)_8-$ | 47 | 189–190/4 | 85 | 144–145/2 |
| $HOH_2C-(CH_2)_8-$ | 40 | 165–167/2 | | |
| $H_3C-CO_2CH(CH_3)-$ | 55 | 135/3 | [c] | |
| $H_3C-CO_2CH_2-$ | 30 | 111–113/2 | | |

[a] Yields based on the ester *(3)*.
[b] 80 % *trans*- and 20 % *cis*-isomer.
[c] Pyrolysis yields a mixture of methyl hexadienoate and acetoxyhexenoate.

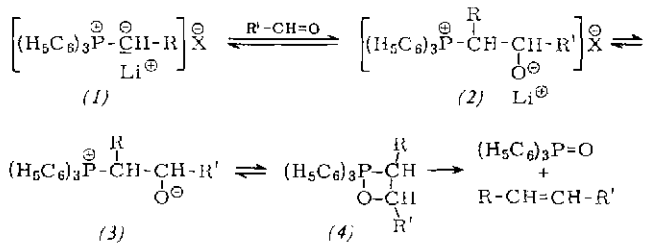
## Intermediates of the Wittig Reaction with Non-Stabilized Phosphorylides

By Dr. M. Schlosser and cand. chem. K. F. Christmann

Organisch-Chemisches Institut der Universität Heidelberg (Germany)

When freshly prepared from organolithium compounds, phosphorylides *(1)* which are not stabilized by mesomerism [R = H, alkyl, OR] immediately add onto carbonyl compounds; however, the adduct does not usually react further in the cold to form the olefin. The reaction of *(1)*, R = H, with benzaldehyde in ether does not yield any styrene at 0 °C, and on heating at 70 °C for several days, only a 30 % yield is obtained.

$(H_5C_6)_3\overset{\oplus}{P}-\overset{\ominus}{\underline{C}}H-R$ *(1)*



It was now found that addition of at least 1.1 equivalent of potassium t-butoxide (as its 1:1 complex with t-butanol) accelerates the Wittig reaction considerably. After 0.5 15 hours at 22 °C, the olefins were obtained in high yields (see Table).

| Phosphonium salt | Carbonyl component | Olefin | Yield [%] |
|---|---|---|---|
| $[(H_5C_6)_3P-CH_3]Br$ | Cyclohexanone | Methylenecyclohexane | 91 [b,c] |
| $[(H_5C_6)_3P-CH_3]Br$ | Benzaldehyde | Styrene | 68 [a] |
| $[(H_5C_6)_3P-CH_2CH_3]Br$ | Benzaldehyde | α-Methylstyrene | 75 [a], 100 [b] |
| $[(H_5C_6)_3P-CH(CH_3)_2]Br$ | Benzaldehyde | α,α-Dimethylstyrene | 63 [a] |
| $[(H_5C_6)_3P-(CH_2)_3CH_3]Br$ | Butyraldehyde | 4-Octene | 85 [b,c] |
| $[(H_5C_6)_3P-(CH_2)_4CH_3]Br$ | Benzaldehyde | 1-Phenyl-1-hexene | 61 [a] |
| $[(H_3C)_4P]I$ | Benzophenone | 1,1-Diphenylethylene | 60 [a] |

[a] Preparative yield; [b] Gas-chromatographic yield; [c] Could not be separated by distillation from accompanying benzene (derived from phenyl-lithium which was applied for the ylide formation).

The rate of reaction was strongly influenced by the efficiency of mixing. In the reaction leading to α-methylstyrene, yields of 67–99 % were found by gas chromatography after 20 minutes at 0 °C. In the absence of potassium t-butoxide or in the presence of less than stoichiometric proportions, *e.g.* 0.1 equivalent, only 0–5 % olefin was formed under the same conditions. Solvent-free, sublimed potassium t-butoxide was less effective than its 1:1 complex with t-butanol.

We assume that the adduct formed from the phosphorylide *(1)* and the carbonyl component does not occur as the "free" betaine *(3)*, but as a betaine-lithium ion pair *(2)* and that only the free betaine *(3)* can cyclize to the four-membered ring *(4)*. Potassium t-butoxide apparently exchanges $Li^{\oplus}$ for $K^{\oplus}$ in *(2)* and thus increases the dissociation *(2)* → *(3)*.

If the reaction *(2)* → *(3)* is really the rate-determining step in many Wittig olefinations, then it becomes plausible why polar solvents, such as tetrahydrofuran [1] or water [2], accelerate the reactions. The following observations also indicate the intermediate formation of *(2)*: the lithium compounds of β-hydroxyalkylphosphine oxides are more stable than the corresponding potassium derivatives [3]; and an adduct *(2)* or *(3)* [R = R′ = $C_6H_5$] was isolated which contained firmly bound LiBr [4].

## The Effect of X-Rays on the Protein Synthesis in vitro

By Prof. Dr. A. Wacker and P. Chandra

Institut für Therapeutische Biochemie der Universität Frankfurt/Main (Germany)

Pyrimidines are distinctly more sensitive to X-rays than purines [1]. Thus, about 450 kr destroy 50 % cytosine, thymine, and uracil and 20 % guanine in aqueous solution, but only 8 % adenine [2]. The same sensitivity of uracil and adenine occurs in polynucleotides: 160 kr destroy 32 % of the uracil in polyuridylic acid (poly-U) and 3 % of the adenine in polyadenylic acid (poly-A). We found that this differing sensitivity toward X-rays also occurs with protein synthesis in cell-free systems [3].

As shown in the Table, the incorporation of phenylalanine (m-RNA = poly-U) falls off in dependence on the radiation dose, 50 % inhibition being obtained with about 45 kr. On the other hand, the synthesis of polylysine (m-RNA = poly-A) is inhibited by only slightly over 30 % by a dose of even 160 kr. The corresponding transfer-RNAs (t-RNAs) show radiation sensitivity opposite to that of the m-RNAs: lysine-transferring t-RNA is nearly twice as sensitive as phenylalanyl-t-RNA. This may be an indication that the anticodons AAA for phenylalanine and UUU for lysine are in fact present in the t-RNA and are necessary for cooperation with the m-RNA in protein synthesis.

Destruction of the ribose-phosphate chain in nucleic acids must also be considered [1]. As the chain length of poly-U and poly-A influences protein synthesis [4], shortening of the m-RNA would have an inhibitory effect on protein synthesis. However, it can be assumed that the ribose-phosphate chains of different nucleic acids are destroyed to about equal amounts, so that the differing sensitivity towards radiation of the incorporation of phenylalanine and lysine can be due only to the differing destruction of the bases uracil and adenine in the codons. In addition to the specific radiochemical changes of purines and pyrimidines observed

| X-ray dose [kr] | % Inhibition of synthesis of polyphenylalanine on irradiation of | | polylysine on irradiation of | |
|---|---|---|---|---|
| | m-RNS | t-RNS | m-RNS | t-RNS |
| 0 | 0 | 0 | 0 | 0 |
| 20 | 32 | 9 | 13 | 15 |
| 40 | 45 | 11 | 23 | 19 |
| 80 | 71 | 14 | 31 | 23 |
| 160 | 87 | 17 | 33 | 31 |

Cell-free extract from *Escherichia coli* B [6]. Method: [3] (without UTP and CTP). t-RNA was isolated according to [7] and was an enriched mixture of different t-RNAs. Irradiation of t-RNA after uptake of phenylalanine or lysine. X-Ray tube RT 100 [Messrs. C. H. F. Müller, Hamburg (Germany)] 100 kV, 8 mA, dose rate 30 kr/min, unfiltered. Poly-U and poly-A (Messrs. Miles & Co., Elkhart, Indiana, U.S.A.) were irradiated in aqueous solution (1 mg/ml).

after irradiation with ultraviolet light [5], this phenomenon offers a further possibility for sequence analysis of the triplets necessary for protein synthesis.

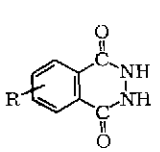
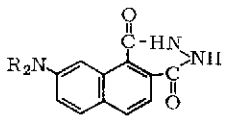
## 7-Dialkylaminonaphthalene-1,2-dicarboxylic Hydrazides – New Strongly Chemiluminescent Compounds



By Prof. Dr. K.-D. Gundermann and Dr. W. Horstmann [1]



Organisch-Chemisches Institut der Bergakademie Clausthal, Technische Hochschule Clausthal (Germany)

The chemiluminescence of 3-aminophthalic hydrazide (luminol) *(1)* has hitherto been surpassed only by that of 4-diethylaminophthalic hydrazide *(2)* [2] and the 3-amino-5,6-di- and -4,5,6-trimethoxyphthalic hydrazides [3]. These compounds exhibit 1.30, 1.13, and 1.30 times the chemiluminescence of *(1)*, respectively.

On hemin-catalysed oxidation with $H_2O_2$ in aqueous alkali, the newly prepared 7-dialkylaminonaphthalene-1,2-dicarboxylic hydrazides *(3)* and *(4)*, which can be regarded as vinylogues of 3-dialkylaminophthalic hydrazides, show intense, green chemiluminescence [*] ($\lambda_{max}$ = 500 mμ) with about twice the maximum intensity and quantity of light afforded by *(1)* under optimum conditions.

Compounds *(3)* and *(4)* were made from 7-methoxynaphthalene-1,2-dicarboxylic anhydride [4] via 7-hydroxy- and 7-aminonaphthalene-1,2-dicarboxylic acid.

*(1)*, R = 3-$NH_2$
*(2)*, R = 4-$N(C_2H_5)_2$
*(3)*, R = $CH_3$
*(4)*, R = $C_2H_5$

Whereas alkali concentrations greater than 0.03 N lead to a sharp decline in the intensity and quantity of light given by *(1)* [1,5], the light yield of *(2)*, *(3)*, and *(4)* reaches a maximum at an alkalinity of ca. 0.1 N, and remains practically constant up to 1.0 N. The fluorescence spectra of *(3)* and *(4)* during the chemiluminescence reaction clearly show that, as with *(1)* [3], it is the excited 7-substituted naphthalene-1,2-dicarboxylate anions, formed from *(3)* and *(4)* in the luminous reaction, which cause the chemiluminescence.

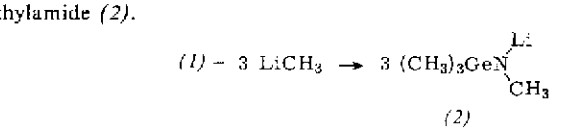
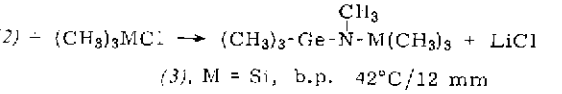
## Synthesis and Cleavage of a Six-Membered Germanium-Nitrogen Ring

By Prof. Dr. Max Schmidt and Dr. I. Ruidisch



Institut für Anorganische Chemie der Universität Marburg/Lahn (Germany)

Reaction of methylamine with dimethyldichlorogermane in ether gives a 80 % yield of the trimeric dimethylgermanylmethylamine *(1)* as a colorless, viscous liquid, b.p. 80 °C/2 mm, which is readily soluble in organic solvents but is very sensitive to moisture.



*(1)*

Compound *(1)* can be split quantitatively with methyl-lithium in ether to give a solution of lithium trimethylgermanylmethylamide *(2)*.

*(2)*

Compound *(2)* is highly reactive and with trimethylchlorosilane, -germane, -stannane, and -plumbane affords very good yields of the mixed ammonia derivatives trimethylsilyl- *(3)*, trimethylgermanyl- *(4)*, trimethylstannyl- *(5)*, and trimethylplumbyl-trimethylgermanylmethylamine *(6)*, plus LiCl. Compound *(2)* does not react with t-butyl chloride.

*(3)*, M = Si, b.p. 42 °C/12 mm
*(4)*, M = Ge, b.p. 172 °C/735 mm
*(5)*, M = Sn, b.p. 28 °C/2 mm
*(6)*, M = Pb, b.p. 49 °C/2 mm

All the new compounds are colorless liquids, readily soluble in organic solvents, and are rapidly hydrolysed to methylamine and the corresponding metaloxane. Proof for their structures is given by their NMR and infrared spectra and by elementary analyses.

## 1,2,4-Trithia-3,5-diborolanes

By Prof. Dr. Max Schmidt and Dipl.-Chem. W. Siebert

Institut für Anorganische Chemie der Universität Marburg/Lahn (Germany)

Attempts to synthesize a six-membered ring containing four sulfur and two boron atoms from boron halides and hydrogen disulfide surprisingly resulted in about 60 % yields of five-membered cyclic compounds containing three sulfur and two boron atoms (1,2,4-trithia-3,5-diborolanes).

(X = Cl, Br)

*(1)*, R = Br
*(2)*, R = $C_6H_5$

It was shown by PMR-spectroscopy during the reaction that $H_2S$ (which could be formed from $H_2S_2$) does not participate in the cyclization [1].

Compounds *(1)* and *(2)* are very sensitive to protonic and many oxygen-containing solvents as well as to oxygen; they have, however, surprising thermal stability. Thus, *(1)* is a colorless liquid, b.p. 50–52 °C/1.5 mm, m.p. 17 °C, that can be maintained at 190 °C for 6 h without decomposition. Compound *(2)*, colorless plates, m.p. 110–112 °C, is also very stable at this temperature. In agreement with spectroscopic data [3] this increased stability, relative to $B_3S_3Br_3$ [2], can be explained by a sort of resonance stabilisation. The infrared and $^{11}$BMR-spectra of *(1)* and *(2)*, and corresponding experiments with silicon and aluminum halides, will be reported elsewhere.

## Synthesis of the First Theophylline 9(N)-Glycoside

By Dipl.-Chem. E. Bühler and Prof. Dr. W. Pfleiderer

Institut für Organische Chemie der Technischen Hochschule Stuttgart (Germany)

Because of the shielding of N-9 in theophylline *(7)* by the 3-methyl group, alkylation and glycosidation [1–3] invariably result in substitution at N-7. In order to achieve a synthesis of a theophylline 9(N)-glycoside, we therefore treated 1,3-dimethyl-4-chloro-5-nitrouracil *(1)* [*] with 1-amino-2,3,4,6-tetra-*o*-acetyl-β-D-glucopyranose *(2)* in chloroform at room temperature to produce 1,3-dimethyl-5-nitro-4-(2,3,4,6-tetra-*o*-acetyl-β-D-glucopyranosylamino)uracil *(3)*, m.p. 164 to 166 °C, $[\alpha]_{578}^{28} = -299°$ (in $CHCl_3$), in 46 % yield.

$R^1$ = 2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyl.

Conversion of *(3)* into the corresponding 5-amino derivative *(4)* was accomplished by catalytic reduction with Raney nickel and hydrogen. The amine *(4)* is labile and could not be obtained pure; it was therefore immediately cyclized with $CS_2$ in pyridine to give a 10 % yield of 1,3-dimethyl-9-(2,3,4,6-tetra-*o*-acetyl-β-D-glucopyranosyl)-8-thiouric acid *(5)*, m.p. 163–166 °C, $[\alpha]_{578}^{29} = +32.8°$ in $CHCl_3$. The small yield from this cyclization and our inability to convert *(4)* directly, into *(6)* with ethyl orthoformate/acetic anhydride or dimethylformamide diethylacetal demonstrate that the close proximity of the 3-methyl group and the sugar residue oppose imidazole formation for steric reasons. Desulfuration of *(5)* with Raney nickel, and subsequent deacetylation with methanolic ammonia finally gave 9-β-D-glucopyranosyltheophylline *(6)*, m.p. 218–220 °C, $[\alpha]_{578}^{25} = -42°$ (in $H_2O$), $\lambda_{max}$ = 238 and 266 mμ, log ε = 3.97 and 3.96, in 32 % yield. Compound *(6)* is the first theophylline 9(N)-glycoside of established structure. The alleged 1,3-dimethylxanthosine mentioned in the literature [4] is a mixture of at least 5 substances; after hydrolysis of the mixture with acid no theophylline could be detected, in contrast to the claims of the author. After boiling with 1 *N* HCl for only 15 min, *(6)* gave theophylline *(7)* and glucose, which were identified by paper chromatography and mixed melting points.

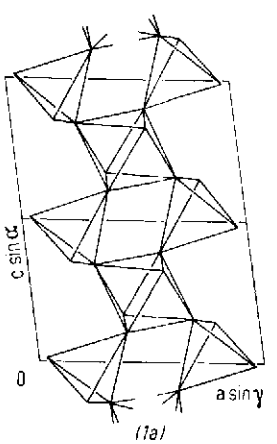
## The Structure of $As_2O_5 \cdot 5/3\ H_2O$

By Prof. Dr. E. Thilo, Dr. K.-H. Jost, and Dipl.-Chem. H. Worzala

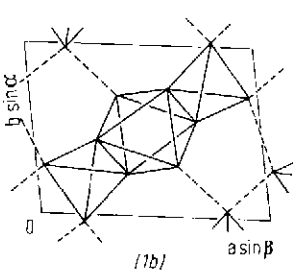
Institut für Anorganische Chemie der Deutschen Akademie der Wissenschaften zu Berlin, Berlin-Adlershof (Germany)



The 5/3-hydrate of arsenic(V) oxide, $As_2O_5 \cdot 5/3\ H_2O$ [1, 2], has been examined using X-rays (single crystals of the hygroscopic substance sealed in thin-walled tubes). The dimensions of the unit cell were found to be:

$a = 7.31$ Å, $\alpha = 100°$
$b = 5.73$ Å, $\beta = 98°$
$c = 4.66$ Å, $\gamma = 100°$

$\text{Density}_{pykn.} = 3.39$ g/cm³



These data correspond to a cell containing 1.5 formula units (exp.: 1.45). The space group is probably $P\bar{1}$, but P1 cannot be ruled out completely. Weissenberg photographs of the zero and first layers were taken along [100], [010], and [001]; the coordinates of the arsenic atoms were ascertained from Patterson projections, and the approximate coordinates of the oxygen atoms from normal and generalized projections of the electron-density distribution. Refinement of the coordinates using difference electron-densities led for all three directions of projection to a reliability factor R = 0.13 (taking unobservable reflections into account). Accurate intensity measurements (integrated photographs) for the (hk0) reflections led to R = 0.10.

From these results it follows that $As_2O_5 \cdot 5/3\ H_2O$ is a highly polymeric compound and consists of arsenic-oxygen tetrahedra and octahedra linked to form ribbons running parallel *(1a)*. The unit cell contains two $AsO_4$ tetrahedra and one $AsO_6$ octahedron. Each $AsO_4$ tetrahedron is linked to two $AsO_6$ octahedra, and the $AsO_6$ octahedron with four tetrahedra; the ribbons are joined by hydrogen bonds [broken lines in *(1b)*].

*(1a)*

Projection in the direction of b-axis

*(1b)*

Projection in the direction of the c-axis

The mean As–O distance is 1.70 Å in the $AsO_4$ tetrahedron and 1.82 Å in the $AsO_6$ octahedron; the mean As–O As bond angle at the bridging oxygen atom is 127°, and the angle between the octahedral plane and octahedral diagonal is 87°. The length of each hydrogen bond (5 per unit cell) is between 2.53 and 2.78 Å. $As_2O_5 \cdot 5/3\ H_2O$ is therefore not a triarsenic acid $H_5As_3O_{10}$.

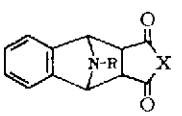
## The Preparation of N-Alkylisoindoles from N-Alkylisoindoline N-Oxides

By Dr. R. Kreher and Dipl.-Ing. J. Seubert



Institut für Organische Chemie
der Technischen Hochschule Darmstadt (Germany)

*Dedicated to Prof. C. Schöpf on the occasion of his 65th birthday*

When treated with acetic anhydride/triethylamine at 0 °C, *N*-alkylisoindoline *N*-oxides *(1)*, which are obtained in good yields from *N*-alkylisoindolines and 30 % $H_2O_2$ [1], are converted into *N*-alkylisoindoles *(2)*, which can be isolated in yields of up to 75 % by distillation or crystallization. With dienophiles such as maleic anhydride [2] or *N*-phenylmaleimide, *(2)* forms the adducts *(4)* and *(5)*, respectively.

*(1)* *(2)*

*(4)*, X = >O
*(5)*, X = >N-C6H5

R = $CH_3$-$CH_2$-,
b.p. 78–82 °C/0,01 mm
R = $CH_3$-$(CH_2)_3$-,
b.p. 99–102 °C/0,01 mm
R = $C_6H_5$-$CH_2$-,
m.p. 119–120 °C

The formation of the *N*-alkylisoindoles *(2)*, which are readily accessible from *(1)* by this method, is analogous to the preparation of *N*-alkylpyrroles from *N*-alkyl-$\Delta^3$-pyrroline *N*-oxides [3]. When the decomposition of *(1)* is carried out in the melt at 120 °C instead of in acetic anhydride/triethylamine at 0 °C, an inseparable mixture of *N*-alkylisoindole and *N*-alkylisoindoline is obtained [1].

## N-Sulfonylcarbodiimides

By Dr. H. Ulrich and Dr. A. A. R. Sayigh

The Upjohn Company, Carwin Research Laboratories,
North Haven, Conn. (U.S.A.)

Recently, *Aumüller* [1] formulated *N*-sulfonylcarbodiimides as intermediates in the reaction of chloramine-T and cyclohexylisonitrile. Since the sulfonylcarbodiimides could not be isolated nor sufficiently characterized, *Aumüller* assumed that they are very reactive compounds which polymerize instantaneously.

We have found that *N*-sulfonylcarbodiimides can be obtained in good yield from sulfonylthioureas and either phosphorus pentachloride or preferably phosgene (see Table).

$$RSO_2NH\text{–}CS\text{–}NHR' \xrightarrow{COCl_2} RSO_2N{=}C{=}NR'$$

The structures of the sulfonylcarbodiimides were elucidated by elementary analysis and infrared spectroscopy. All the compounds showed a characteristic N=C=N– absorption at 4.58–4.6 μ, *i.e.* in the region for cumulative double-bonds. The polar sulfonyl group causes a shift of this absorption band; carbodiimides normally absorb at 4.7 μ. Small amounts of the corresponding sulfonyl isothiocyanates were obtained as by-products. In the latter compounds, the polar sulfonyl group causes a shift in the opposite direction in the infrared spectrum. Sulfonyl isothiocyanates absorb at 5.25 μ, simple isothiocyanates at 4.9 μ.

Surprisingly, sulfonylcarbodiimides are quite stable. Whereas aliphatic carbodiimides containing primary alkyl groups, e.g. *N,N'*-di-n-butylcarbodiimide, polymerize within a few days, aliphatic sulfonylcarbodiimides are stable. The basicity of both nitrogen atoms is presumably considerably lowered, so that sulfonylcarbodiimides are less reactive than carbodiimides in many reactions. For instance, carbodiimides react with phosgene at room temperature [2], but sulfonylcarbodiimides do not react with phosgene at all.

## Trisdithiobenzilmetal Complexes

By Priv.-Doz. Dr. G. N. Schrauzer, Dipl.-Chem. H. W. Finck, and Dr. V. Mayweg

Institut für Anorganische Chemie
der Universität München (Germany)

We recently formulated the dithiobenzil complexes of chromium, molybdenum, tungsten, vanadium, rhenium, ruthenium, and osmium [1,2] as planar structures by analogy to the bisdithiononickel complexes; however, we have now prepared and examined larger quantities of the trisdithiobenzilmetal complexes and have thus come to the conclusion that they are in fact 6-coordinate compounds of structure *(1)*, resembling the known $CF_3$-substituted molybdenum complexes [3].

*(1)*

Our original formulation was supported mainly by the consistently low results of the C,H-analyses, and the re-

markable similarity of the infrared and ultraviolet spectra of these complexes with those of bisdithiobenzilnickel.

## Condensation of Active Methylene Compounds with Isothioamide Groups

By Dr. K. Hartke [*]

Instituto Central de Química, Universidad Concepción (Chile)

Enol ethers with activating groups (−CN, $-CO_2R$, $>C=O$) in the β-position react with amines to form amino olefins *(3)*. The latter are also readily obtained by condensation of compounds containing active methylene groups *(1)* with compounds *(2)* containing the group $-N=C\langle SR$ (isothioamides, isothioureas, or iminothiocarboxylic esters). The condensation takes place without a catalyst by mixing the components in a solvent, *e.g.* alcohol or ether. With compounds containing particularly reactive methylene groups, *e.g.* malonitrile or dimeric malonitrile, the reaction is frequently exothermic. In other cases the reaction mixture is allowed to stand for several hours to days at room temperature or is heated for some time on a water bath. Some compounds obtained in this way are given in the Table (structures determined by elementary analyses and infrared spectra; independent synthesis of *(3e)* [1]).

## An Explosion during the Oxidation of Tetralin with Hydrogen Peroxide in Acetone

By Dr. H. Seidl

Institut für Organische Chemie
der Universität München (Germany)

During the preparation of α-tetralone, tetralin was oxidized with 30 % $H_2O_2$ according to the method of *Treibs* et al. [1]. On subsequent evaporation of the reaction mixture *in vacuo*, as the last of the solvent distilled over, the distillation residue exploded with great violence, causing injuries and damage. Since the starch-iodide test for free $H_2O_2$ had been negative, we suspect the formation of acetone peroxides as the cause of the explosion. Other routes to α-tetralone are available[2].

## Radiochemical Hydroxylation of Phenolic Compounds

By Dr. F. Merger and Dipl.-Chem. D. Grässlin

Organisches-Chemisches Institut
der Universität Heidelberg (Germany)

We have found that gallic acid and other phenolic carboxylic acids are hydroxylated at room temperature in water by the action of $^{60}Co$ γ-rays. The hydroxylation, which can be carried out on a preparative scale, occurs with remarkable selectivity *ortho* to existing hydroxyl groups and proceeds more rapidly in the presence of oxygen than when oxygen is excluded. *m*-Dihydroxybenzoic acids are particularly easily hydroxylated between the two hydroxyl groups.

Irradiation of a 1 % aqueous solution of gallic acid saturated with oxygen (dosage rate of the $^{60}Co$ γ-ray source: $4.06\times10^5$ r/h; irradiation time: 300 h) gave 2,3,4,5-tetrahydroxybenzoic acid in 52.8 % yield with a G-value [*] of 0.22; separation of the residual gallic acid was achieved by fractional crystallization and preparative chromatography. The G-values for some other phenolic carboxylic acids are considerably higher.

Nitrophenols are hydroxylated much faster than phenolic carboxylic acids. *p*-Nitrophenol affords 4-nitrocatechol, and 4- or 5-nitropyrogallol give the hitherto unknown 1,2,3,4-tetrahydroxynitrobenzene (G = 1.41).

Received, July 20th, 1964 [Z 789/619 IE]

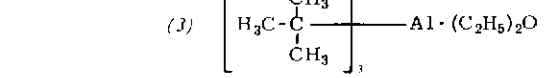
[*] The G-value indicates the number of molecules formed per 100 eV.

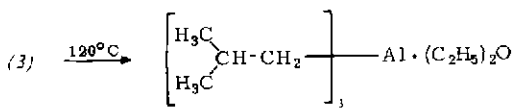
## t-Butylaluminum Compounds

By Dr. H. Lehmkuhl



Max-Planck-Institut für Kohlenforschung,
Mülheim/Ruhr (Germany)

The addition of al-H onto olefins occurs predominantly according to Markownikoff's rule [1,2]; the reaction of al-H with isobutene thus gives triisobutylaluminum *(1)*, but no tri-t-butylaluminum *(2)*.

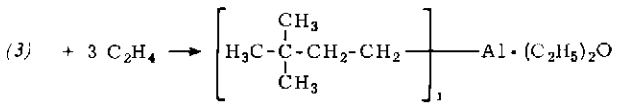


*(1)* *(2)*

It was expected [2] that *(2)* would be unstable and would rearrange to *(1) via* al-H and isobutene. Isomerization to the primary trialkylaluminum occurs with triisopropylaluminum [3]. We found, however, that *(3)*, the etherate of *(2)*, which is produced in 75 % yield by the reaction in ether of t-butylmagnesium chloride with $AlCl_3$ in a molar ratio of 3:1, is actually quite stable.

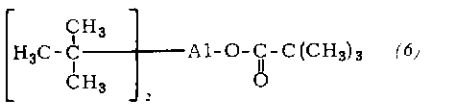
*(3)*

Compound *(3)* melts at an unusually high temperature (120–124 °C) and can be sublimed at 50 °C/$10^{-3}$ mm. On hydrolysis with $D_2O$, it gives the calculated amount of D-C(CH$_3$)$_3$, and on prolonged heating (30 h) at 120 °C it isomerizes only partly (30 %) to *(4)*.



*(4)*

This isomerization is complete after heating for 24 h at 170 °C, 1 mole of isobutene and 1 mole of ethane being evolved simultaneously per mole of *(3)*. The dibutylaluminum hydride produced by the elimination of isobutene at this high temperature clearly reacts with the ether:



$$Bu_2AlH + (C_2H_5)_2O \rightarrow Bu_2AlOC_2H_5 + C_2H_6$$

In tri-t-butylaluminum etherate *(3)*, the bonds between the Al and the tertiary carbon atoms are considerably activated (like those in t-butyl-lithium [4]). Reaction of *(3)* with ethylene (ca. 60 atm) at 100–110 °C for 24 h gives a quantitative yield of *(5)*.

*(5)*

Under these conditions, trialkylaluminum etherates with bonds between the Al and primary carbon atoms react to only a very minor extent; triethylaluminum etherate, for example, gives only ca. 14 % tributylaluminum etherate. Propene does not add onto *(3)* and, as with other trialkylaluminum etherates [5], only one Al–C bond in *(3)* reacts with $CO_2$ at 100 °C; this reaction affords the crystalline compound *(6)*, which does not melt until 240 °C.

*(6)*

Replacement of one of the t-butyl groups in *(3)* by an alkoxy group gives ether-free di-t-butylaluminum alkoxides which no longer show abnormal reactivity towards ethylene.

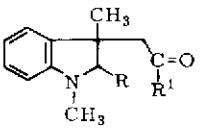
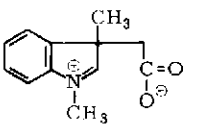
## A New Synthesis of the Eserine Skeleton



By Dr. P. Rosenmund and A. Sotiriou

Organisch-Chemisches Institut
der Universität Frankfurt/Main (Germany)



We have found that the lactone *(1)* obtained *via* 1,3-dimethyl-3-ethoxycarbonylmethylindolenine from the *N*-methylphenylhydrazone of ethyl β-formylbutyrate by hydrolysis with alcoholic KOH and acidification (overall yield for the 3 stages: 21 %) reacts quantitatively with primary amines at 50 °C in methanol as solvent to yield the corresponding lactams. Thus, methylamine yields the lactam *(2)*, which is quantitatively reduced by $LiAlH_4$ to the eserine skeleton *(3)* [eserine = *(4)*]. With equimolar amounts of dimethylamine, in addition to unchanged *(1)*, the amide *(5)* and its derivative

*(1)*, R = H, $R^1$ = O, $R^2$ = O
*(2)*, R = H, $R^1$ = N-CH$_3$, $R^2$ = O
*(3)*, R = H, $R^1$ = N-CH$_3$, $R^2$ = H$_2$
*(4)*, R = O-CO-NHCH$_3$, $R^1$ = N-CH$_3$, $R^2$ = H$_2$

*(5)*, R = OH, $R^1$ = N(CH$_3$)$_2$
*(6)*, R = N(CH$_3$)$_2$, $R^1$ = N(CH$_3$)$_2$

*(7)*

*(6)*, which is formed by interaction of *(5)* with dimethylamine, are obtained. Free carboxylic acid is not produced. It is therefore concluded that the conversion of the lactone into the lactam is initiated by a normal hydrolysis and does not involve the zwitterion *(7)*.

## Photochemical Synthesis of Endiol Ethers from Thiocarboxylic O-Esters

By Prof. Dr. Ulrich Schmidt and Dr. K. H. Kabitzke

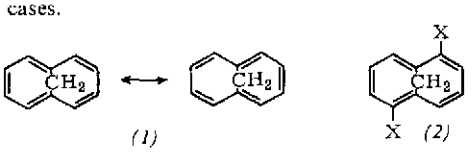
Chemisches Laboratorium
der Universität Freiburg/Breisgau (Germany)

While searching for a reaction medium which would liberate monomolecular sulfur under mild conditions, we discovered a new photochemical process for the formation of C–C bonds. If *O*-ethyl thioacetate is irradiated with light of 254 mμ wavelength at 40 °C in the absence of solvent, 2,3-diethoxy-2-butene (b.p. 83–84 °C/80 mm, $n_D^{20}$ = 1.4161, *cis*: *trans* ≈ 2:3) is formed at 25 % conversion in 65 % yield. This compound reacts with dinitrophenylhydrazine in strongly acidic solution to give the bisdinitrophenylhydrazone of diacetyl. 3,4-Diethoxy-3-hexene (b.p. 64 66 °C/12 mm, $n_D^{20}$ = 1.4263) is formed in 60 % yield at 20 % conversion on irradiation of *O*-ethyl thiopropionate.

*(1)*

We are attempting to determine whether the dialkoxy olefins are formed by dimerization of the thiocarboxylic esters to 1,2- or 1,3-dithiacyclobutanes followed by stepwise elimination of sulfur *via* ethylene sulfides, *e.g. (1)*, or whether an ethoxycarbene is formed first and reacts with the thiocarboxylic ester to give the ethylene sulfide. A small amount of the ethylene sulfide *(1)*, m.p. 50–52 °C, $\lambda_{max}$ – 254 mμ, was isolated from an irradiation experiment.

C=S compounds with a π–π* transition at ca. 250 mμ appear to lose sulfur readily on irradiation; isocyanides are formed from isothiocyanates.



Received, May 19th, 1964; supplemented, June 22nd, 1964
Publication deferred until now at the authors' request [Z 775/605 IE]

## Substitution of 1,6-Methanocyclodecapentaene

By Prof. Dr. E. Vogel and Dr. W. A. Böll

Institut für Organische Chemie
der Universität Köln (Germany)

On the basis of its NMR spectrum, we proposed that 1,6-methanocyclodecapentaene has the structure *(1)* with a delocalized system of 10 π-electrons [1]. Further investigations have shown that also the chemistry of this hydrocarbon is in accord with the concept of aromaticity. Although *(1)* formally contains five double bonds, it shows no tendency to polymerize and does not react with maleic anhydride in boiling benzene. When treated with electrophilic agents, it gives rise to mono- and disubstituted 1,6-methanocyclodecapentaenes *(2)* [2]; an addition-elimination mechanism seems to be involved at least in some cases.

*(1)* *(2)*

monosubstituted: X = Br, Cl, $COCH_3$, COOH, $NO_2$
disubstituted: X = Br, $NO_2$

Bromination of *(1)* with 1 mole of *N*-bromosuccinimide yields 90 % of a yellow monobromo derivative, b.p. 87 to 88 °C/0.05 mm; NMR: complex multiplet at 2.1–3.4 τ and an AB system at 10.5 τ (proton ratio 7:2); ultraviolet spectrum: maxima at 244 (ε = 17700), 266 (49500), 313 (6700), 395 (260), 405 (285), and 415 mμ (225) [3]. Reaction of *(1)* with 2 moles of *N*-bromosuccinimide leads to 40 % of a yellow dibromo compound, m.p. 87 °C; NMR: ABC system at 2.1–3.2 τ and a singlet at 10.3 τ (proton ratio 6:2); ultraviolet spectrum: maxima at 234 (ε = 13500), 277 (61000), 327 (8200), and 419 mμ (530). The monobromo derivative can be converted easily into the Grignard compound, which on carboxylation affords 82 % of an orange-brown carboxylic acid, m.p. 172–173 °C. Acetylation of *(1)* with acetic anhydride and $SnCl_4$ produces 82 % of an orange monoacetyl derivative, b.p. 92–94 °C/0.06 mm, which can also be converted into the carboxylic acid mentioned above by reaction with NaOBr. Nitration of *(1)* with $Cu(NO_3)_2$ in acetic anhydride leads to 53 % of a yellow mononitro product, b.p. 109–110 °C/0.04 mm, which is probably a mixture of the 2- and 3-nitro compounds, plus 4 % of a yellow-orange dinitro derivative, m.p. 113 °C.

Although the spectra of the new compounds indicate clearly that they are all substitution products of *(1)*, the position of the substituents as being at C-2 and C-7 *(2)* is supported only by the NMR spectra [4] of the dibromo and dinitro derivatives. However, X-ray structural analysis [5] of the dibromo compound has recently confirmed that the bromine atoms are in fact at C-2 and C-7.

In addition to maxima at 256 (ε = 68000), 259 (63000), and 298 mμ (6200) [1], the ultraviolet spectrum of *(1)* exhibits a long-wavelength band with 8 maxima between 350 and 400 mμ (ε = 95–185), which gives the hydrocarbon a yellow cast [6]. Low-temperature NMR spectra (down to −145 °C) give no indication of a fluctuating structure; the appearance of the spectrum remains unchanged [7]. Further evidence against the valence-bond isomeric cyclopropane structure previously considered for the hydrocarbon is the $^{13}C$–H coupling constant of the methylene hydrogen atoms (142 cps) [7]. This value is compatible with a C–$CH_2$–C bond angle of about 90 °, which is suggested by models of the molecule [8].

[1] *E. Vogel* and *H. D. Roth*, Angew. Chem. *76*, 145 (1964); Angew. Chem. internat. Edit. *3*, 228 (1964).

[2] The chemical properties of *(1)* are strikingly similar to those of *trans*-15,16-dimethyldihydropyrene [*V. Boekelheide* and *J. B. Phillips*, Proc. nat. Acad. Sci. *51*, 550 (1964)], which has a system of 14 π-electrons.

[3] The reaction of *(1)* with bromine at −10 °C also leads to the monobromo derivative, but at −75 °C a tetrabromide (addition product), m.p. 145–146 °C, is formed which gives spectra that indicate a cyclopropane structure.

[4] We wish to thank Dr. *H. Günther* and Prof. *A. A. Bothner-By* for interpretation of the NMR spectra.

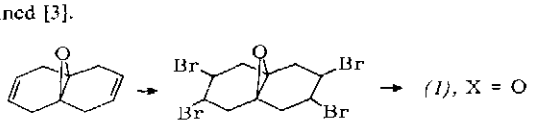
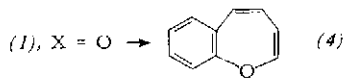
## Cyclodecapentaenes with a 1,6-Heteroatomic Bridge [*]

By Prof. Dr. E. Vogel, Dipl.-Chem. M. Biskup, Dipl.-Chem. W. Pretzer, and Dr. W. A. Böll



Institut für Organische Chemie
der Universität Köln (Germany)

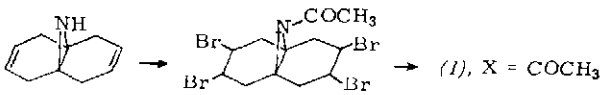
The synthesis and properties of 1,6-methanocyclodecapentaene *(1)*, X = $CH_2$, [1] gave rise to the expectation that dehydrobromination of the tetrabromides *(3)* and *(6)* with suitable bases would lead to stable cyclodecapentaenes *(1)* bridged by an oxygen or a nitrogen atom, respectively. The analogous sulfur-bridged compound would most probably lose sulfur readily to form naphthalene.



*(1)*, X = $CH_2$, O, $NCOCH_3$, (S)

The tetrabromide *(3)*, m.p. 152–154 °C, is obtained from *(2)* [2] and is probably a mixture of isomers; on dehydrobromination with potassium t-butoxide in ether at −10 °C it affords 60 % of a pale yellow, stable compound $C_{10}H_8O$, m.p. 52–53 °C. Its NMR spectrum consists only of an $A_2B_2$ system centred at 2.56 τ. The ultraviolet spectrum has maxima at 257 (ε = 74500) and 302 mμ (7100) and about sixteen maxima between 345 and 435 mμ (ε between 50 and 300). These spectra correspond to those of 1,6-methanocyclodecapentaene. This proves that the 1,6-oxygen-bridged cyclodecapentaene *(1)*, X = O, has been obtained [3].

*(2)* *(3)*



The chemical properties of *(1)*, X = O, are also in accord with the proposed structure. Treatment of the compound with acids leads to α-naphthol and other products; during chromatography on silica gel it isomerizes to 1-benzoxepin *(4)* [3], a yellow liquid, b.p. 101–102 °C/14 mm, $n_D^{20}$ = 1.6015 (yield up to 77 %). The structure of the rearrangement

*(1)*, X = O → *(4)*

product *(4)* is secured by its spectra and its catalytic hydrogenation to yield the known tetrahydro-1-benzoxepin, m.p. 30 °C [4].

The aziridine *(5)*, b.p. 76–77 °C/0.6 mm, required for the synthesis of the acetylimino-bridged compound *(1)*, X = $NCOCH_3$, was prepared from the nitrosochloride [2] of 1,4,5,8-tetrahydronaphthalene using the method of *Closs* [5]. Bromination of the *N*-acetyl derivative of *(5)*, m.p. 73–74 °C, gave the tetrabromide *(6)* as an oil, which reacted with potassium t-butoxide in tetrahydrofuran at −15 °C to form *(1)*, X = $NCOCH_3$, as pale yellow crystals, m.p. 160–161 °C,

*(5)* *(6)* → *(1)*, X = $COCH_3$

in 25–30 % yield [6]. The main evidence for structure *(1)*, X = $NCOCH_3$, is again given by the NMR spectrum of the compound; it exhibits an $A_2B_2$ system (8 protons) centred at 2.35 τ and a $CH_3$ singlet at 8.97 τ. Further support for structure *(1)*, X = $NCOCH_3$, is obtained from the ultraviolet spectrum, which has maxima at 252 (ε = 57000), 299 (5500), 387 (300), 398 (500), and 408 mμ (570) and agrees well with the ultraviolet spectra of *(1)*, X = $CH_2$, and *(1)*, X = O [7].

## Attempted Synthesis of Cyclodecapentaenes by Valence-Bond Isomerization of 9,10-Dihydronaphthalenes

By Prof. Dr. E. Vogel, Dipl.-Chem. W. Meckel, and Dr. W. Grimme

Institut für Organische Chemie
der Universität Köln (Germany)

Valence-bond isomerization of 9,10-dihydronaphthalenes represents an attractive approach to the synthesis of the hitherto unknown simple cyclodecapentaenes [1]. With the *cis*-9,10-dihydronaphthalene recently described by *van Tamelen* [2], observation of thermal isomerization to (or of establishment of an equilibrium with) cyclodecapentaene is rendered difficult by the fact that the tetraene undergoes dehydrogenation to give naphthalene even at relatively low temperatures. However, with dimethyl *cis*-9,10-dihydronaphthalene-9,10-dicarboxylate *(3)*, dehydrogenation or 1,5-hydrogen shift as reactions competing with the isomerization to a cyclodecapentaene derivative are excluded [3].

*(1)* *(2)* *(3)*

*(4)* + *(5)*

+ *(6)*

Dimethyl *cis*-$\Delta^{2,6}$-hexalin-9,10-dicarboxylate [4] is a suitable starting material for the synthesis of *(3)*, but attempts to convert it into *(3)* remained without success. In contrast, the corresponding anhydride *(1)* reacted smoothly with 2 moles of *N*-bromosuccinimide to give a dibromo derivative from which 25–30 % of the tetraene *(2)*, m.p. 74–75 °C, were obtained by dehydrobromination with quinoline. The structure of *(2)* was confirmed by its catalytic hydrogenation to *cis*-decalin-9,10-dicarboxylic anhydride and by its NMR spectrum, which shows only an $A_2B_2$ system centred at 4.17 τ. The maximum at 243 mμ (ε = 7900) in the ultraviolet spectrum of *(2)* corresponds to that of other known *cis*-9,10-dihydronaphthalene derivatives [2, 3]. Esterification of *(2)* with methanol led to a thermolabile dimethyl ester, m.p. 103–104 °C, whose spectra [NMR: $A_2B_2$ system centred at 4.30 τ plus singlet at 6.38 τ, proton ratio 8:6; ultraviolet absorption maximum at 258 mμ (ε = 7100)] and catalytic hydrogenation to dimethyl *cis*-decalin-9,10-dicarboxylate indicated that it was the desired compound *(3)*.

When heated at 90 °C for 2 h, *(3)* rearranges to a mixture of esters which probably consists mainly of isomeric 9,10-dihydronaphthalenedicarboxylic esters. Subsequent heating of this mixture at 150 °C, with or without Pd, produces dimethyl 1,5-, 2,6-, and 1,2-naphthalenedicarboxylates *(4)*–*(6)* and other unidentified products. While the formation of *(4)* and *(5)* is indicative of the transient occurrence of an unstable cyclodecapentaene derivative [5], the isolation of *(6)* demonstrates that there are modes of rearrangement of *(3)* other than that originally visualized.

# Meeting of West German Chemistry Lecturers

**April 27th–30th, 1964 in Freiburg/Breisgau (Germany)**

From the Agenda:

## Reactions of Metal-Substituted Hydrides with Halogenosilanes

*E. Amberger, H. D. Boeters,* and *Maria-Regina Kula,* Munich (Germany)

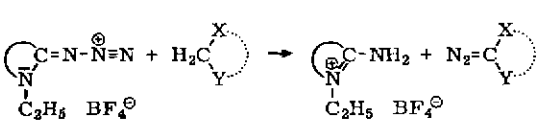
The reaction of silyl bromide with potassium dihydrogen phosphide, arsenide, or antimonide in dimethyl ether at the melting point of the ether ( 138 °C) yields the expected monosilyl derivatives of phosphine, arsine, or stibine according to Equation (1).

$$H_3SiBr + KEH_2 \rightarrow H_3SiEH_2 + KBr \qquad (1)$$

E = P, As, or Sb

Trisilylphosphine and phosphine or trisilylarsine and arsine are formed at higher temperatures [Equation (2)].

$$H_3SiEH_2 + 2\ H_3SiBr + 2\ KEH_2 \rightarrow E(SiH_3)_3 + 2\ KBr + EH_3 \qquad (2)$$



Silylstibine $H_3SiSbH_2$, on the other hand, does not form trisilylstibine according to Equation (2), but disproportionates to form silane, a polymeric antimony hydride, and hydrogen.

The first step in the formation of the trisilyl derivative is not a kind of α-elimination from the silyl bromide followed by electrophilic addition of the $SiH_2$ onto phosphorus dihydride anions, but rather a nucleophilic substitution of $PH_2$ or $AsH_2$ on the silicon. This is followed by an acid-base reaction of the resulting monosubstituted product with potassium dihydrogen phosphide or arsenide, leading to the formation of the trisilyl derivatives. Similar acid-base reactions are observed in syntheses of higher silanes by the reaction of silylpotassium with silicon halides. Trisilylstibine has been prepared by treating silyl bromide with finely divided tripotassium antimonide. The isologous carbon derivative trisilylmethane $HC(SiH_3)_3$ has been prepared by hydrogenation of $HC(SiCl_3)_3$.

## Introduction of Diazo Groups into Reactive Methylene Compounds by Azidinium Salts

*H. Balli,* Marburg/Lahn and *V. Müller,* Karlsruhe (Germany)

Diazo compounds of the type *(3)* can be prepared simply from azidinium salts *(1)* [1] and compounds with reactive methylene groups *(2)*.

*(1)* *(2)* *(3)*

Hitherto, the range of application of this synthesis was investigated predominantly by testing the reaction of 2-azido-3-ethylbenzothiazolium fluoroborate with C–H acidic compounds *(2)*, in which the activating groups X and Y are >CO, >C=C<, –CN, and >C=N–, generally as ring members. Multiple reaction occurs with components *(2)* containing several reaction centers.

The following diazo compounds and quinone diazides have been prepared (yield in % in parentheses): 5-diazobarbituric acid (84), 4-diazo-3-phenylisoxazol-5-one (77), 4-diazo-1-phenyl-3-methylpyrazol-5-one (96), 2-diazoindane-1,3-dione (84), 2-diazodimedone (77), ω-diazo-ω-cyanoacetophenone (88), 1-diazo-2-naphthol (21), 2,4-bisdiazoresorcinol (31), and trisdiazophloroglucinol (95).

The mechanism of the transfer reaction was discussed.

## Preparation of Helium from Lithium Deuteride by Thermonuclear Fusion

*F. Baumgärtner,* Munich (Germany)

Nuclear fusion of deuterium and tritium yields helium and a neutron with a kinetic energy of 14 MeV:

$$(1) \quad T + D \rightarrow He + n_{14\,MeV}.$$

Tritium is produced in the nuclear reaction

$$(2) \quad {}^6Li + n_{therm} \rightarrow T + He.$$

In this reaction, the triton receives an initial energy of 2.74 MeV. This is considerably higher than the energy of 0.2 MeV normally used in particle accelerators for the D–T reaction of Equation (1). Consequently, the high-energy tritons from reaction (2) appeared suitable for use in the fusion reaction (1). The sum effect of this coupled reaction is that lithium-6 and deuterium are converted into helium:

$$(1) + (2) \quad {}^6Li + D \rightarrow 2\ He + 22.4\ MeV.$$

A tube made of $^6LiD$ with walls 1 mm thick was placed in a thermal neutron field. The walls were sufficiently thick to ensure quantitative conversion of the incident neutrons according to Equation (2). Titanium or chromium probes were placed inside the tubes to detect the fast neutrons.

These elements give positively identifiable positron radiation, resulting from an (n,2n) reaction with fast neutrons with kinetic energies of 13.2 and 13.3 MeV. The thermal neutron flux present is simultaneously measured on the outside of the tube with a cobalt wire using the nuclear reaction $^{59}Co(n,\gamma)^{60}Co$.

This conversion of $^6LiD$ to helium is economically unsuitable for the production of energy, since the power density for a flux of $10^{13}$ neutrons/cm²/sec is only about 35 mW/cm³, and furthermore, the reaction is not self maintaining. However, it is advantageous to be able to convert thermal neutrons into fast neutrons (14 MeV) in this way [2], obtaining a partly higher, but above all more durable flux of fast neutrons than with simple accelerators.

## Catalytic Dehydration with Elemental Boron

*H. J. Becher, L. Marosi,* and *H. Widmann,* Stuttgart (Germany)

The catalytic properties of elemental boron (99 %, prepared by reduction of $BBr_3$ with $H_2$ at 750 °C; shown by electron microscopic and X-ray investigations to be the very finely

[1] *H. Balli* and *F. Kersting,* Liebigs Ann. Chem. *647,* 1 (1961).

[2] *F. Baumgärtner,* Radiochim. Acta *1,* 222 (1963).

crystalline α-modification; particle diameter 0.075 μ) were investigated in various decomposition reactions. Formic acid vapor is dehydrated between 200 and 300 °C. The dehydration of acetic acid vapor to acetic anhydride only becomes measurable above 350 °C, and proceeds in about 25 % yield at 500–550 °C. Alcohols are also almost exclusively dehydrated at 250–350 °C. On the other hand, α-boron has no effect on the reaction of ethylene or isopropylene with benzene at normal pressure and at temperatures of up to 550 °C.

The catalytic activity of boron in dehydrations corresponds roughly to that of γ-$Al_2O_3$, but the concurrent dehydrogenation evidently plays a less important part in the case of boron. Moreover, considerably less α-boron than $Al_2O_3$ is required for the reactions. The catalysis probably takes place on BO- or BOH-groups on the surface of the catalyst. The boron-boron arrangement must also be important, however, since finely powdered boron with a higher amorphous fraction and greater oxygen content shows weaker activity at moderate temperatures.

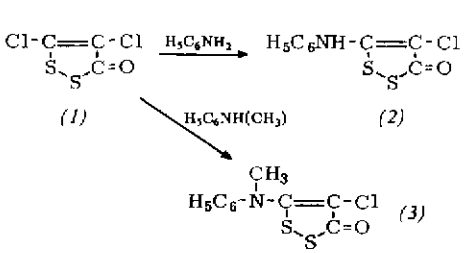
## Amino-Acid Sequences in Phosvitin

*H.-D. Belitz*, Berlin (Germany)

Phosvitin, the principal phosphoprotein of hen's egg yolk, with a phosphorus content of about 10 %, was cleaved with trypsin. The enzymatic hydrolysate was separated into peptides on Dowex 1X2 anion exchanger. The amino-acid sequence of a peptide containing 63 amino acid residues:

$asp_3,ser_{42},glu,gly,val,leu,his_5,lys_5,arg_4,(PO_3H_2)_{42}$

was investigated. The large peptide was broken down into smaller fragments by partial hydrolysis with HCl and by enzymatic dephosphorylation followed by cleavage with trypsin. Amino-acid and end-group analyses of the fragments gave the following partial structural formula:

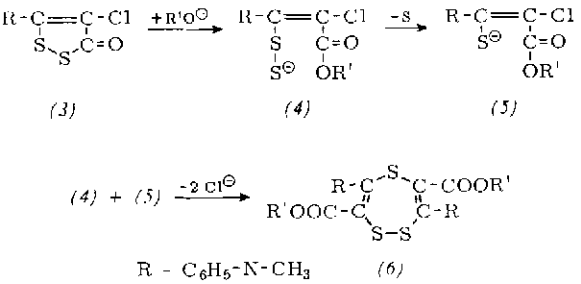


asp — $Pser_6$ — arg—asp—(Pser$_6$,lys)—(Pser$_6$,lys)— arg—(Pser$_6$,his)—
$Pser_6$ his—lys—asp—gly—val—(Pser$_3$, glu)—lys—(leu, Pser$_3$)—
his—his —arg—$Pser_6$— arg—his—lys

This indicates that phosvitin contains successions of 3–6 phosphoserine residues, separated by other, predominantly basic amino acids. The peptide investigated corresponds to about one-third of the total phosvitin molecule, which has a molecular weight of about $3\times10^4$, and contains about 170 amino-acid residues.

## Alkaline Cleavage of the 1,2-Dithiacyclopenten-3-one Ring

*F. Boberg*, Hannover (Germany)

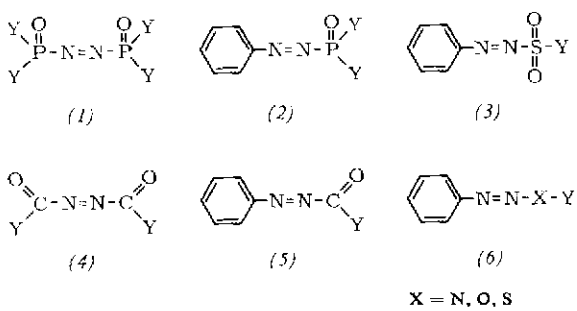


4,5-Dichloro-1,2-dithiacyclopenten-3-one *(1)* [3] reacts with aniline to form the 5-anilino compound *(2)*, which has an acidic NH group. Methylation of the *N*-sodium or *N*-potassium derivative of *(2)* leads to *(3)*, which can also be prepared directly from *(1)* and *N*-methylaniline.

*(1)* *(2)* *(3)*

[3] *F. Boberg* and *A. Marei*, Angew. Chem. *74*, 495 (1962).

The action of alcoholic alkali on *(3)* yields the 1,2,5-trithiacycloheptadiene derivative *(6)*. This shows that nucleophilic



*(3)* *(4)* *(5)* *(6)*

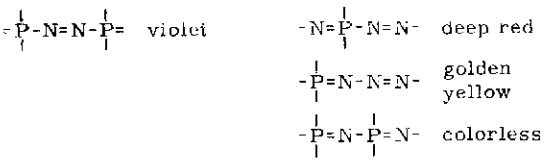
reagents open the 1,2-dithiacyclopentenone ring at the CO–S bond. 1,2,5-Trithiacycloheptadienes with other residues R and R′ can also be prepared by this method.

## Relationships between the Color and Constitution of Azo Compounds

*H. Bock*, *E. Baltin*, *J. Kroner*, and *G. Rudolph*, Munich (Germany)

The π-electron system of azobis(phosphonic acid) derivatives *(1)* [4] is not very extensive. Their fascinating violet color led to the preparation and spectroscopic characterization of more than 60 azo compounds of types *(1)*–*(6)*.

*(1)* *(2)* *(3)* *(4)* *(5)* *(6)*



X = N, O, S

In the course of these investigations, regularities were observed, particularly for the color-determining $n\rightarrow\pi^*$ transitions, which justified the assumption of substituent-specific absorption increments. Thus, the wavelengths and intensities of the $n\rightarrow\pi^*$ maxima of unsymmetrically substituted azo compounds A–N=N–B lie, in all the compounds of types *(1)*–*(6)* studied, between those of A–N=N–A and B–N=N–B [5]. However, the mechanism of the substituent effect is not yet known, since within an LCAO/MO description, besides inductive raising of the n term and conjugative lowering of the π*-level, the $n\rightarrow\pi^*$ excitation could also be displaced toward longer wavelengths by effects of suitable d-orbitals, which are difficult to evaluate. In this connection, the following properties were discussed: the related $\pi\rightarrow\pi^*$ transitions, which, however, do not follow any analogous rules, the minute solvatochromic effects, and the different band shapes of compounds belonging to classes *(1)* to *(6)*. In the phosphorus-azo compounds *(1)* and *(2)*, inhibition of conjugation by phosphorus atoms with a coordination number of four can be verified by a linear relationship between the PO valence vibration frequency and the electronegativity of the substituents, on the basis of the similar absorption of P–O, P–S, and P–NR azo systems and the color of subsequently synthesized phosphorus-nitrogen chains [6].

[4] *H. Bock* and *G. Rudolph*, Chem. Ber. *94*, 1457 (1961).

[5] *H. Bock*, *E. Baltin*, and *G. Rudolph*, Angew. Chem. *75*, 789 (1963); Angew. Chem. internat. Edit. *2*, 484 (1963).

[6] *H. Bock* and *W. Wiegräbe*, Angew. Chem. *75*, 789 (1963); Angew. Chem. internat. Edit. *2*, 484 (1963).

These substituent effects were described here in detail for the first time but appear to be of a more general nature: according to our investigations, similar influences determine the $n \rightarrow \pi^*$ transitions of other chromophores.

## The Chemistry of $TiO_2$ Surfaces

*H.-P. Boehm* and *M. Herrmann*, Heidelberg (Germany)

Fresh cleavage surfaces of a $TiO_2$ crystal contain $Ti^{4+}$ and $O^{2-}$ ions. On access of water, the vacant coordination sites on the $Ti^{4+}$ ions are occupied by $H_2O$ molecules, each of which gives up a proton to the surface $O^{2-}$ ions. This proton transfer leads to a more uniform charge distribution. The two resulting hydroxide ions are attached in different ways and differ in chemical reactivity, as was shown by investigations on finely divided anatase.

On treatment of $TiO_2$ with alkali fluoride solutions, the hydroxide ions are exchanged for fluoride ions. The liberated hydroxide ions can be titrated, their quantity being dependent upon the specific surface area. After reaction of $TiO_2$ with thionyl chloride, the chloride content was equivalent to the amount of hydroxide ions. On shaking $TiO_2$ powder with basic solutions of aluminum chloride, one aluminum ion was adsorbed per hydroxide ion. An equivalent degree of conversion was also achieved in a few other reactions, *e.g.* neutralization with alkali. On the other hand, in other reactions, *e.g.* with unbuffered NaF solution, ammonia, or diazomethane, only half of the hydroxide ions was found to react.

$TiO_2$ surfaces are strongly polar and always adsorb some $CO_2$ on contact with air. The adsorbed carbon dioxide was detected by infrared spectroscopy and by chemical analysis. $NO_2$ is also very strongly adsorbed; nitrate ions could be detected on the surface. Furthermore, the surface of finely divided $TiO_2$ always contains organic contaminants, which must be eliminated prior to any investigation, in order to prevent reduction of the surface $Ti^{4+}$ ions. If this reduction is allowed to occur, the $TiO_2$ surface acquires strongly acidic properties, as was shown by the change in color of adsorbed dimethylaminoazobenzene.

## Formation and Properties of Alkali Disilylamides

*H. Bürger* and *H. Seyffert*, Graz (Austria)

Colorless, crystalline alkali disilylamides $MN(SiR_3')_2$ [M = Li, Na, K (m.p. 165 °C), Rb (m.p. 178 °C), or Cs (m.p. 195 °C)] are formed by metallation of $HN(SiR_3')_2$ with MX [X = alkyl, aryl, H, or $NH_2$]. Using $H^{15}N$-$[Si(CH_3)_3]_2$ it was shown that the reaction

$$HN(SiR_3')_2 + NaNH_2 \rightarrow NaN(SiR_3')_2 + NH_3 \quad [R' = CH_3]$$

is a true metallation, in contrast to the silylation of urea according to the equation

$$HN(SiR_3')_2 + H_2N{-}CO{-}NH_2 \rightarrow R_3'Si{-}NH{-}CO{-}NH{-}SiR_3' + NH_3$$

$LiN(SiR_3')_2$ and $NaN(SiR_3')_2$ can be distilled without decomposition. The compounds $MN(SiR_3)_2$ are readily soluble in aromatic hydrocarbons, but only sparingly soluble in aliphatic hydrocarbons. Their solubility increases with increasing electropositivity of M. The compounds $MN(SiR_3)_2$ react with practically all polar solvents and add on $NH_3$, pyridine, ether, tetrahydrofuran, and $HN(SiR_3')_2$, which all act as Lewis bases. In benzene, the compounds $MN(SiR_3)_2$ exist as dimers *(1)*; neither these solutions nor the fused compounds conduct electricity. On the other hand, $KN(SiR_3')_2$ forms a solution of high conductivity in liquid $NH_3$ in which metathetical reactions can occur, *e.g.* with $Ag(NH_3)_2Cl$ to form explosive $AgN(SiR_3')_2$. Spectroscopic studies have shown that the contribution of salt-like structures *(2)* increases with decreasing electronegativity of the cation.

$$[(R_3Si)_2{-}NM]_2 \longleftrightarrow 2\,[R_3\overset{\ominus}{Si}{=}\overset{\oplus}{N}{=}\overset{\ominus}{Si}R_3] + 2\,M^+$$
*(1)* *(2)*

$NaN(SiR_3')_2$ in tetrahydrofuran or ether is the most suitable reagent for the preparation of other metal disilylamides. Thus, transition metal halides gave silylamides of the elements Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Cd, and Hg, which are all extremely sensitive to hydrolysis.

## A New Synthesis of Oxide Iodides

*K. Dehnicke*, Stuttgart (Germany)

Gaseous ozone reacts exothermally at room temperature with metal iodides dissolved in inert solvents (cyclohexane, carbon tetrachloride). For example:

$$TiI_4 + O_3 \rightarrow TiOI_2 + O_2 + I_2$$

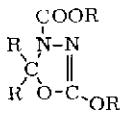
This reaction gives good yields of the hitherto unknown oxide iodides $TiOI_2$ and $SnOI_2$ as very hygroscopic brown solids which are amorphous to X-rays. $TiOI_2$ splits off elemental iodine at 105 °C to form TiOI. Magnetic measurements indicate that TiOI is antiferromagnetic. $SnOI_2$ disproportionates above 110 °C to $SnO_2$ and $SnI_4$.

Infrared spectra indicate that $TiOI_2$ exists as polymeric $[TiO]^{2+}_{\infty}\,2\,I^-$, with Ti O–Ti–O chains, while $SnOI_2$ has a structure with isolated complex ions (island structure). $TiOI_2$ reacts with pyridine to form an adduct of composition $TiOI_2{\cdot}3\,Py$, which may be formulated as $[TiO(Py)_3]^{2+}\,2\,I^-$. Owing to its island structure (coordination number 3), $SnOI_2$ adds on only one mole of pyridine.

## 1,4(N,O)-Cycloadditions of Azodicarboxylic Esters

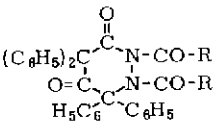
*E. Fahr*, *K. H. Keil*, *F. Scheckenbach*, and *A. Jung*, Würzburg (Germany)

The formation of oxadiazolines *(1)* in the reaction of diazo compounds with azodicarboxylic esters suggests that the latter can undergo not only the known 1,2(*N*,*N*)-additions but also 1,4(*N*,*O*)-cycloadditions. This assumption was found to be confirmed in the reaction of diphenylketene with azodicarboxylic esters, which yields both a 2:1 and a 1:1 adduct.



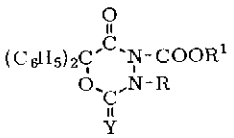
Structure *(2a)* has been discussed for the 2:1 adduct by *Ingold* and *Weaver* [6a] and by *Horner* and *Spietschka* [6b]. We were able to show, as follows, that the 2:1 adduct has the structure of the hitherto unknown bicyclic azetidinone System *(3a)* formed by 1,4(*N*,*O*)-cycloaddition of the azodicarboxylic ester: *(3a)* reacts with alcohols ($R^2OH$) to give *(4a)*, and with dilute acids to give *(4b)*. Compound *(4a)* reacts with dilute acids to give *(4b)*, and with alkalis to give *(4c)*, which is in turn converted by dilute acids into *(4d)*. The reaction of *(4d)* with diphenylacetyl chloride leads to *(4b)*, and with alkalis to benzilic acid; *(4b)* reacts with alkalis to yield *(5)*. On heating, *(3a)* irreversibly loses diphenylketene to yield the 1:1 adduct which, according to its infrared spectrum, should not be assigned the structure *(6)*, but presumably the diazetidinone structure *(7)*. The 1:1 adduct reacts with acids to give *(4d)*.

---

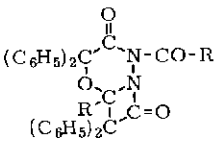


[6a] *C. K. Ingold* and *S. D. Weaver*, J. chem. Soc. (London) *127*, 378 (1925).

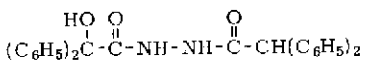
[6b] *L. Horner* and *E. Spietschka*, Chem. Ber. *89*, 2765 (1956).



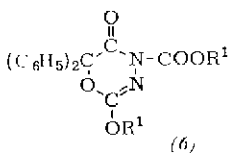
In analogy with *(3a)*, the structure of the 2:1 adduct of diphenylketene and azodibenzoyl (m. p. 161 °C) is not *(2b)* [6b], but *(3b)*. Degradation of *(3b)* yields *(5)*, among other products.



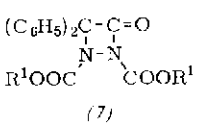
*(1)*



*(2a)* : R = $OR^1$
*(2b)* : R = $C_6H_5$



*(4a)* : R = $CO\text{-}CH(C_6H_5)_2$; Y = $OR^1$ + $OR^2$
*(4b)* : R = $CO\text{-}CH(C_6H_5)_2$; Y = O
*(4c)* : R = H; Y = $OR^1$ + $OR^2$
*(4d)* : R = H; Y = O



*(3a)* : R = $OR^1$
*(3b)* : R = $C_6H_5$

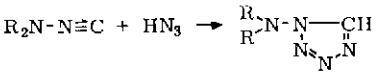
## The Relative Reactivities of Positional and Geometric Isomers of High Molecular-Weight n-Olefins

*B. Fell, F. Asinger, G. Steffan*, and *G. Hadik*, Aachen (Germany)

The following olefin reactions were studied for the nine positionally and geometrically isomeric n-undecenes, some prepared for the first time free from other isomers, as a function of the position and configuration of the double bond in the olefin molecule: addition of bromine, ionic addition of hydrogen bromide, epoxidation (Prileshayeff reaction), hydrogenation with hydrazine, and the addition of mercury(II) acetate in methanol (methoxymercuration). The rates of the first four reactions alternate in both the *cis-* and *trans-* series of n-undecenes, *i.e.* the 3- and 5-isomers in each case have higher rate constants than the 2- and 4-isomers. In the methoxymercuration reaction, on the other hand, the rate constant decreases continuously as the double bond approaches the center of the molecule; this behavior emphasizes the unique nature of this olefin reaction. Some of the reactions named were also carried out with positional and geometric isomers of n-octene. The rate constants of the isomers with internal double bonds again alternate. Thus, *cis-* and *trans*-n-3-octene react more rapidly than the respective 2- or 4-isomers.

## Amino Isocyanides

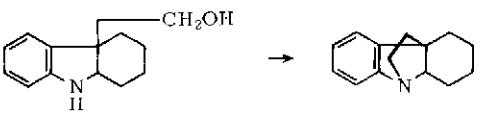


*B. Föhlisch, H. Bredereck*, and *K. Walz*, Stuttgart (Germany)

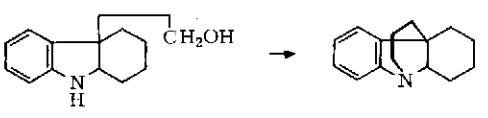
Dialkylamino isocyanides *(1)* are obtained in yields of 60–80% by the action of phosgene on *N,N*-dialkyl-*N'*-formylhydrazine in boiling methylene chloride in the presence of tertiary amines [7]. The dialkylamino isocyanides decompose at room temperature, and more rapidly on heating to form glyoxylonitrile-*N',N'*-dialkylhydrazones *(2)* and Schiff bases *(3)*.

*(1)* *(2)* *(3)*

The rate of decomposition can be followed spectroscopically and depends on the substituents R and on the solvent. Dialkylamino isocyanides react with $HN_3$ to form the hitherto unknown 1-dialkylaminotetrazoles *(4)*.



*(4)*

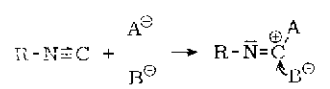


## Restricted Resonance in New Indolines with Fixed Nitrogen Torsion Angles

*H. Fritz* and *O. Fischer*, Frankfurt/Main (Germany)

The two tetracyclic indoline systems *(3)* and *(4)*, in which resonance is suppressed, have been synthesized respectively from *(1)* and from the new compound *(2)*, which was prepared by us by reduction of the corresponding acid with $LiAlH_4$.

*(1)* *(3)*

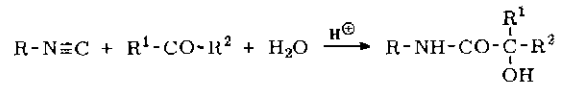


*(2)* *(4)*

These two twisted indolines enabled us to answer the question which is of theoretical interest and of importance in connection with the chromophores of alkaloids, namely what is the torsional angle at which the n-π conjugation is so greatly reduced that an aniline-type ultraviolet spectrum changes over to a benzene-type spectrum? This angle is about 65 °C, since *(4)*, in which φ = 60 °, still has an indoline spectrum, whereas *(3)*, with φ = 70 °, has a benzene-type spectrum. It is possible to test the quantitative validity of the $\cos^2\varphi$ function [*] by experimental determination of the energy contents [**] of compounds of types *(3)* and *(4)* with fixed torsional angles.

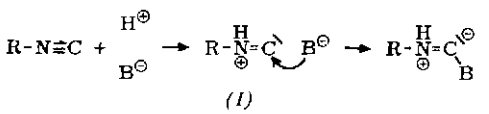
## A Contribution to the Chemistry of Isocyanides

*Ilse Hagedorn, U. Eholzer*, and *H. D. Winkelmann*, Freiburg/Brsg. (Germany)



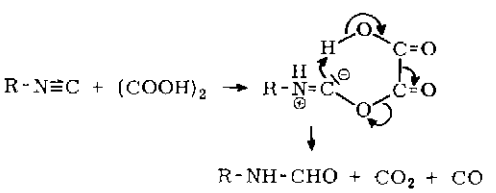
The isocyanide group reacts rapidly with protons and, in the Passerini reaction, which is catalysed by carboxylic acids, also with carbonium ions. Consequently, it is concluded that the isocyanide carbon has an exceptionally high nucleophilicity.

[7] *H. Bredereck, B. Föhlisch*, and *K. Walz*, Angew. Chem. *74*, 388 (1962); Angew. Chem. internat. Edit. *1*, 334 (1962).



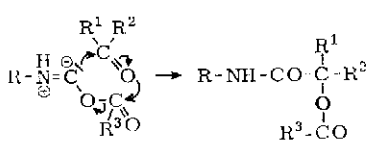
[*] The $\cos^2\varphi$ function describes the dependence of resonance energy upon the torsion angle φ in a conjugated system: $M_\varphi = M_0 \cdot \cos^2\varphi$ ($M_0$ = maximum resonance energy when the system is undistorted; $M_\varphi$ = resonance energy on distortion by an angle φ).
[**] *e.g.* through thermochemical data.

However, we found in a modified Passerini reaction that isocyanides, which are considered to be extremely sensitive to acids, react with carbonyl compounds even in the presence of molar quantities of aqueous mineral acids to form α-hydroxy amides. This reaction proceeds rapidly and in high yield, even at 0 °C.



This discovery was confirmed by several examples and rules out the possibility that the isocyanide carbon has nucleophilic activity, since the protons from the mineral acid should be the preferred coreactant and should suppress the formation of C–C linkages.

The first step in any isocyanide reactions in the presence of acid is therefore assumed to be *N*-protonation, leading via an ammonium carbene *(1)* to a carbanion.



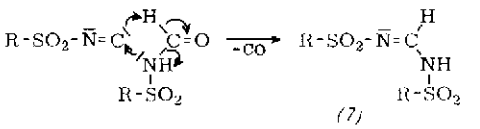
*(1)*

All the reactions of isonitriles which proceed so rapidly in the presence of acid, *e.g.* the quantitative determination of the isocyanide group with oxalic acid, may be formulated in this way.

Assuming initial *N*-protonation, the classical Passerini reaction can then be represented as follows:

Reactions of isocyanides in neutral media generally occur only on heating and are regarded as electrophilic reactions of the carbene form *(2)*, in which the electron sextet on the

carbon atom is augmented to form an octet in the initial step. Similar behavior was observed, for example, with the β-keto isocyanide *(3)*, which is converted practically quantitatively under mild conditions into *(4)*.



*(3)* *(4)*

This carbene character is recessive in the ground state of the isocyanide group but should be enhanced by electron-attracting groups. To test this hypothesis, an attempt was made to dehydrate *N*-formylarylsulfonamides *(5)* with $POCl_3$ in pyridine in order to obtain sulfoisocyanides *(6)*.

*(5)* *(6)*

It proved impossible to isolated *(6)* under these conditions, but in agreement with our hypothesis, *(6)* reacts spontaneously with starting material, even at 0 °C, liberating CO to give up to 90 % of *N,N'*-bisarylsulfonylformamidines *(7)*.

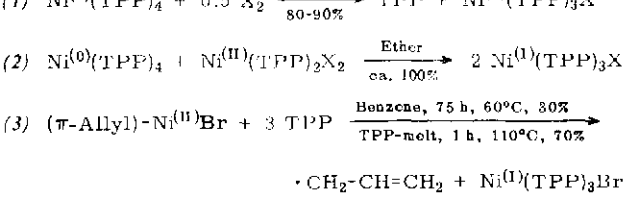
*(7)*

## Bonding of Dyes to Deoxyribonucleic Acid

*G. Hartmann* and *M. Liersch*, Würzburg (Germany)

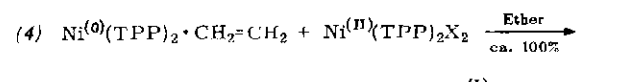
The biological action of deoxyribonucleic acid (DNA) is blocked by dyes such as proflavin and actinomycin. These substances are bound by the DNA in a manner which is not yet precisely known. An intact helical structure is reported to be a prerequisite for this bonding [8,9].

We have found that DNA denaturated by heating binds proflavin and actinomycin at least as well as native DNA; the complex was isolated by gel filtration on Sephadex. By working at 4 °C and carrying out control experiments, we made certain that the denaturated DNA was not reconverted to the helical structure during the gel filtration.



Furthermore, the maximum bonding capacity of the DNA in the presence of excess dye is not affected by denaturation. The dye complexes formed with denaturated DNA and those with DNA differ only in the somewhat higher extinction coefficients of the former, but not in the position of the absorption band.

Thus, the helical structure of DNA cannot be an essential condition for complex formation with proflavin and actinomycin.



## Changes in the Coordination Numbers of Ni(0) and Ni(I) Compounds

*P. Heimbach*, Mülheim/Ruhr (Germany)

Crystalline tristriphenylphosphinylnickel(I) halides, which have not hitherto been described, can be prepared by oxidation *(1)*, disproportionation *(2)*, or reduction *(3)*

A second group of bistriphenylphosphinylnickel(I) halides (pale yellow compounds) is formed according to the equation

The ESR spectra of all the Ni(I) compounds exhibit the signal characteristic for an unpaired electron on the metal atom. Thus, the complexes are true Ni(I) compounds and do not exhibit Ni–Ni interaction. This is confirmed by the magnetic moment $\mu_B$ = 2.2 Bohr magnetons [10] obtained

[8] *L. S. Lerman*, J. molecular Biol. *3*, 18 (1961).

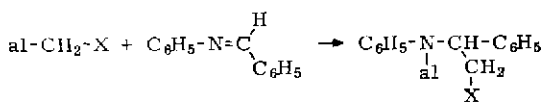
[9] *E. Reich*, Science (Washington) *143*, 684 (1964).

[10] I wish to thank Prof. *W. Klemm* for the measurement of the magnetic moment.

for $Ni^{(I)}[TPP]_3Cl$. This corresponds to one unpaired electron plus an additional orbital moment, which is to be expected for tetrahedral coordination of the ligands.

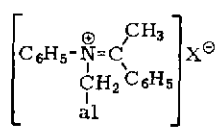
The molecular weights of the Ni(I) compounds, as well as of a few Ni(0) compounds which have not yet been described, were determined by cryoscopy and are shown in the Table.

| Complex | Mol. Wt. | | Solvent |
|---|---|---|---|
| | calc. | found | |
| $Ni^{(I)}(TPP)_3I$ [*] | 972.5 | 500–520 | Benzene |
| $Ni^{(I)}(TPP)_3Br$ [*] | 925.5 | 510–520 | Benzene |
| $Ni^{(I)}(TPP)_3Cl$ [*] | 881 | 510–520 | Benzene |
| $Ni^{(I)}(TPP)_2Br$ | 663.2 | 670 | Benzene |
| $Ni^{(0)}(TPP)_4$ [*] | 1108 | 510–540 | Benzene |
| $Ni^{(0)}(TPP)_4$ [*] | 1108 | 520 | Cyclohexane |
| $Ni^{(0)}(TPP)_3$ | 846 | 790 | Benzene |
| $Ni^{(0)}[P(OC_6H_5)_3]_4$ | 1300 | 1290 | Benzene |
| $Ni^{(0)}[P(OC_6H_5)_3]_2(TPP)_2$ | 1204 | 1050 | Benzene |



[*] Compound dissociates in solution into TPP and the corresponding complex of lower coordination number.

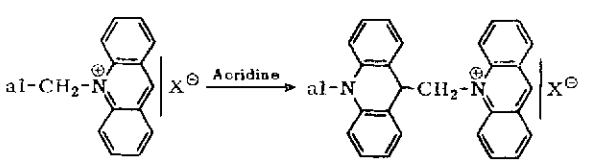
On reaction with excess triphenylphosphite, $Ni^{(I)}(TPP)_3Cl$ disproportionates into violet $Ni^{(II)}[P(OC_6H_5)_3]_2Cl_2$ and white $Ni(0)[P(OC_6H_5)_3]_4$.



## Reactions of the Halogenomethylaluminum Compounds with Azomethines and N-Heterocycles

*H. Hoberg*, Mülheim/Ruhr (Germany)

Halogenomethylaluminum dialkyls can be prepared from dialkylaluminum halides and diazomethane and add on in the absence of electron donors to C–C multiple bonds through the al–C bond of the $X–CH_2–al$ group (al = 1/3 Al, X = halogen). Subsequent spontaneous 1,3-elimination of al–X leads to the formation of cyclopropane compounds [10a]. We have found that the al–C bond of the $X–CH_2–al$ group also adds onto the C=N bond of azomethines, even at low temperatures.

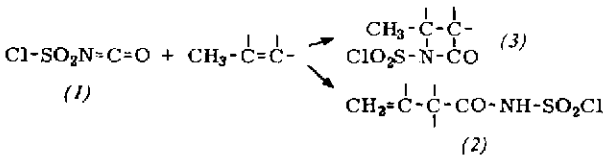


Elimination of HX from the hydrolysed product (H instead of al) with alkali hydroxide yields *N,C*-diphenylethylenimine. Intermolecular elimination of HX (without addition of base) gives 1,2,4,5-tetraphenylpiperazine. The X–C bond of the halogenomethylaluminum dialkyls is activated by the metal in the α-position and also reacts with other Schiff bases (*e.g.* acetophenone anil), the nitrogen being quaternized *(1)*.

*(1)*

N-Heterocycles, *e.g.* acridine, initially give only secondary products of the quaternization step; only thereafter does a further acridine molecule add onto the al–C bond *(2)*.

*(2)*



[10a] *H. Hoberg*, Liebigs Ann. Chem. *656*, 1, 15 (1962).

The reaction products show that it is the $al–CH_2–X$ group, and not a carbene formed by 1,1-elimination, that reacts with the C=N bond.

## Reactions of N-Carbonylsulfamyl Chloride with Dienes

*H. Hoffmann* and *H. D. Diehr*, Mainz (Germany)

According to *Graf* [11], N-carbonylsulfamyl chloride *(1)* reacts with olefins to form *N*-chlorosulfonylcarboxamides *(2)* or *N*-chlorosulfonyl-β-lactams *(3)*.

*(1)* *(3)* *(2)*

The following rules were discovered for the reaction of 1,3-dienes with *(1)*:

1. Dienes generally react with *(1)* much more readily than do comparable olefins.

2. *N*-Chlorosulfonyl-β-lactams *(3)* are predominantly formed at lower temperatures, and *N*-chlorosulfonylcarboxamides *(2)* at higher temperatures. *N*-Chlorosulfonyl-δ-lactams could not be detected.

3. The direction of addition is determined by the substituents, *e.g.* butadiene gives an *N*-chlorosulfonyl-β-lactam with a terminal amino group *(4)*, whereas 1-methylbutadiene gives an *N*-chlorosulfonyl-β-lactam with a terminal carbonyl group *(5)*.

*(4)* *(5)*

4. Compound *(1)* undergoes *cis*-addition with cyclic dienes. However, the initial products can be rearranged by subsequent reactions.

## Nucleophilic Substitutions on Silylamines

*J. Hundeck*, Munich (Germany)

Amino groups $NR_2'$ bonded to silicon may be substituted by acyl groups X by reaction with acids HX [12], *e.g.* according to Equation (1):

$$R_3Si–NR_2' + 2\,HX \rightarrow R_3SiX + NHR_2' \cdot HX \qquad (1)$$
$$(R = \text{Alkyl};\ R' = H, \text{Alkyl};\ X = \text{Acyl}).$$

Silylamines react analogously with alkyl halides R″X, particularly alkyl iodides, according to Equation (2):

$$R_3Si–NR_2' + 2\,R''X \rightarrow R_3SiX + NR_2'R'' \cdot R''X \qquad (2)$$

The silylammonium derivatives $[R_3Si(NR_2'R'')]X$ expected as the initial products of the reactions according to Equations (1) and (2) could not be isolated. They are, however, formed from tertiary amines $NR_3$ and iodosilanes, *e.g.* $(H_3C)_3SiI$ [13]:

$$(H_3C)_3SiI + NR_3 \rightarrow [(H_3C)_3Si–NR_3]I. \qquad (3)$$

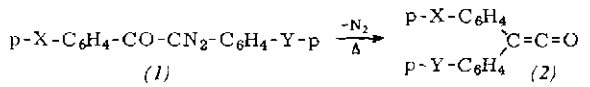
Adducts of this type react as expected with protonic substances HX such as hydrogen sulfide (X = SH), or with alkyl halides RX, according to Equation (4):

$$[R_3Si–NR_3]I + HX \rightarrow R_3SiX + [HNR_3]I \qquad (4)$$

An adduct of *N,N*-diethyltrimethylsilylamine and $BF_3$ reacts in a similar manner:

$$(H_3C)_3Si–N(C_2H_5)_2 \cdot BF_3 + RX \rightarrow (H_3C)_3SiX + N(C_2H_5)_2R \cdot BF_3. \qquad (5)$$

[11] *R. Graf*, Liebigs Ann. Chem. *661*, 111 (1963).



[12] *J. Hundeck*, Ph. D. Thesis, Universität München, 1961.

[13] *L. Kreuzbichler*, Diploma Thesis, Universität München, 1959, p. 25.

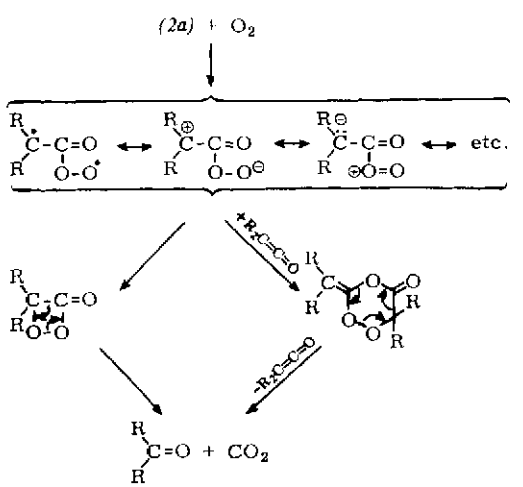
## New Diarylketenes and Their Autoxidation

*E. F. Jenny, H. Droescher,* and *A. Melzer,*
Freiburg/Brsg. (Germany)

Three new ketenes, di-*p*-anisyl- *(2a)*, di-*p*-nitrophenyl- *(2b)*, and *p*-anisyl-*p*-nitrophenylketene *(2c)* were prepared from diazoketones in solution.

*(1)* *(2)*

*(a)*: X = Y = $OCH_3$; *(b)* X = Y = $NO_2$; *(c)* X = $OCH_3$; Y = $NO_2$



So far only *(2b)* has been isolated in crystalline form. Compound *(2a)* reacts much more readily with oxygen, and *(2b)* with nucleophilic reagents, than unsubstituted diphenylketene.

The kinetics of the thermal Wolff rearrangement of the diazoketones *(1a)*–*(1d)* [the latter with X=Y=H] in ethylene chloride were determined. The reaction is always of the first order and shows the following activation parameters.

| | $k_1$ (relative values) | $\Delta H^{\neq}$ [kcal/mole] | $\Delta S^{\neq}$ [cal/deg/mole] |
|---|---|---|---|
| *(1d)* | ca. 50 | 23.8 | −2.0 |
| *(1a)* | ca. 2000 | 20.3 | −6.7 |
| *(1b)* | ca. 2 | 28.0 | 4.6 |
| *(1c)* | ca. 1 | 28.5 | 4.5 |

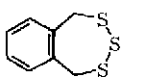
These values form an isokinetic straight line. Since the thermal stabilities of *(1b)* and *(1c)* are approximately equal, we believe that even the "mixed" diazoketone, with substituents suitable for a synchronous rearrangement (X = $OCH_3$ favors migration; Y = $NO_2$ makes the formation of carbene difficult), is converted into the ketene via an intermediate ketocarbene. The correctness of this assumption should be confirmed by the results of further kinetic investigations.

Dianisylketene, which is produced *in situ* in benzene, reacts with oxygen to give 4,4'-dimethoxybenzophenone and $CO_2$ in a molar ratio of 1:1, the yield increasing rapidly at the expense of the copolymer as the dilution increases. Oxidation of *(2a)* with labelled oxygen gives labelled 4,4'-dimethoxybenzophenone and labelled carbon dioxide. This result indicates that the autoxidation of *(2a)* probably proceeds, at least at high dilutions, not via a copolymer, but via a four- and/or six-membered cyclic peroxide according to Scheme 1.

Scheme 1. Oxidation of di-*p*-anisylketene *(2a)* [R = *p*-$CH_3O$-$C_6H_4$-].

The mechanism of this reaction will be deduced from the distribution of $^{18}O$ in the oxidation products and from the effect of the various *p*-substituents on the rate of oxidation.

## Proton Resonance Investigations on the Conformational Mobility of Cyclic Di- and Trisulfides



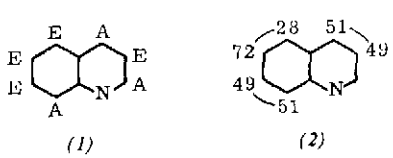
*S. Kabuss, H. Friebolin,* and *A. Lüttringhaus,*
Freiburg/Brsg. (Germany)

The rate and enthalpy of activation $\Delta G^{\neq}$ of the conformational rearrangements of cyclic disulfides (which exist in enantiomeric forms, owing to the non-planar conformation around the S–S group) and cyclic trisulfides of various ring sizes were determined from the temperature-dependence of their proton resonance frequencies. The maximum $\Delta G^{\neq}$ value for cyclic disulfides is 15 kcal/mole, and conformational inversion occurs more than ten times per second at room temperature. The free enthalpies of activation of the trisulfides are mostly significantly higher than those of the corresponding 1,2- and 1,3-dithia compounds (see Table 1).

Table 1. Frequencies k of conformational inversion and free enthalpies of activation $\Delta G^{\neq}$ of cyclic di- and trisulfides at their coalescence temperature $T_A$.

| | $T_A$ [°C] | k [$sec^{-1}$] | $\Delta G^{\neq}$ [kcal/mole] |
|---|---|---|---|
| 1.3-Dithiane | −80 | 100 | 9.4 |
| 1.2-Dithiane [14] | −46 | 46 | 11.6 |
| 1,2,3-Trithiane | −8 | 78 | 13.2 |
| 5,5-Dimethyl-1,3-dithiane | −65 | 73 | 10.3 |
| 5,5-Dimethyl-1,2,3-trithiane | +20 | 91 | 14.6 |
| 2*H*, 4*H*, 7*H*-1,3-Dithiepin | −100 | 67 | 8.5 |
| 4*H*, 7*H*-1,2,3-Trithiepin | −90 | 120 | 8.9 |
| 2*H*, 4*H*, 7*H*-1,3-Benzo-[*e*]dithiepin | −55 | 64 | 10.9 |
| 3*H*, 6*H*, 7*H*-1,2-Benzo-[*d*]dithiepin | −3 | 58 | 14.3 |
| 4*H*, 7*H*-1,2,3-Benzo[*e*]trithiepin | +110 | 93 | 19.3 |

The "stiffening" of the ring system by the third sulfur atom is particularly pronounced in the case of 4*H*,7*H*-1,2,3-benzo[*e*]trithiepine *(1)*, $\Delta G^{\neq}$ being 19.3 kcal/mole. Separation of the conformational isomers is therefore almost possible.



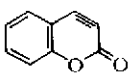
*(1)*

## Investigations on Heterocyclic Arynes

*Th. Kauffmann, J. Hansen, K. Udluft,* and *R. Wirthwein,*
Darmstadt (Germany)

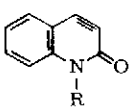
In the reaction in ether at 35 °C of lithium piperidide/piperidine with quinolines which are monohalogenated on the isocyclic ring, halogen in the 5-, 6-, and 7-positions is substituted by an elimination mechanism (E; cf. [15]) involving 5,6- and 7,8-dehydroquinoline, while halogen in the 8-position is unexpectedly substituted entirely by an addition-elimination mechanism (A). Thus, for reactions of monohalogenoquinolines (Hal = Cl or Br) with lithium piperidide/piperidine, the "mechanism chart" *(1)* can be drawn up. The ratio of products obtained in the addition of piperidine onto 5,6-, 7,8-, and 3,4-dehydroquinoline [15] is shown by *(2)*

*(1)* *(2)*



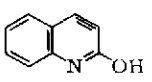
[14] *G. Claeson, G. M. Androes,* and *M. Calvin,* J. Amer. chem. Soc. *82*, 4428 (1960); ibid. *83*, 4357 (1961).

[15] *Th. Kauffmann, F.-P. Boettcher,* and *J. Hansen,* Liebigs Ann. Chem. *659*, 102 (1962).

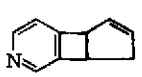


When piperidine is heated with 4-chloropyrimidine, 4-bromocoumarin, 4-bromo-*N*-methylcarbostyryl, and 4-bromocarbostyryl, it yields only the 4-piperidino compounds, but on heating at 180 °C with 5-bromopyrimidine, it gives a mixture of 4- and 5-piperidinopyrimidines; the analogous reactions (40–180 °C) with the 3-halogeno compounds (Hal = Br or Cl) of coumarin, *N*-methylcarbostyryl, and carbostyryl give mixtures of the 3- and 4-piperidino compounds. Formation of the mixture is most simply explained by assuming the intermediates *(3)*, *(4)*, *(5)*, and *(6)* or *(7)* [16]. Formation of the intermediate *(4)* in the reaction with 3-bromocoumarin is supported by the fact that, although this compound is stable to methanol and aniline under the experimental conditions, it gives 4-methoxy- or 4-anilinocoumarin as well as 3- and 4-piperidinocoumarin (ratio ca. 1:2) when subjected simultaneously to piperidine + methanol or piperidine + aniline.

*(3)*

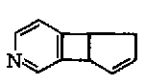


*(4)*



*(5)*, R = $CH_3$

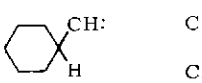
*(6)*, R = H



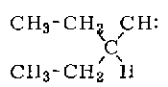
*(7)*

3,4-Dehydropyridine produced from pyridine-3-diazonium-4-carboxylate, was treated with cyclopentadiene. The adduct (53 % yield) forms cinchomeronic acid on oxidative degradation; in contrast to the dehydrobenzene-cyclopentadiene and 2,4-dehydropyridine-furan adducts, it does not add on phenylazide, and must be assigned the constitution *(8)* or *(9)*.

*(8)*

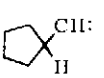


*(9)*



## Steric Effects in Carbene Reactions

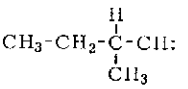
*W. Kirmse* and *G. Wächterhäuser*, Marburg/Lahn (Germany)



We have investigated the effect of steric factors on intramolecular insertion reactions of alkylcarbenes. The relative yields of olefins and cyclopropane derivatives in the series *(1)*–*(3)* point to a transition state for the insertion reaction in which the carbene carbon and the C–H bond lie approximately in a common plane.

*(1)*

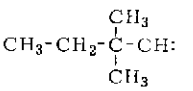
*(2)*



*(3)*

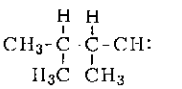
Olefin:Cyclopropane =

| 11.5 | 2.8 | 0.38 |
|---|---|---|



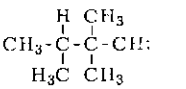
Thus the preferential formation of *trans*-1,2-dialkylcyclopropanes from alkylcarbenes, *e.g. (2)*, can be attributed to the "eclipsing effect" of the *cis*-transition state.

Similarly, the "natural" preference for secondary and tertiary hydrogens in the insertion reaction is reversed by the stepwise introduction of methyl groups [*(4)*–*(7)*].



*(4)*

sec:prim (*trans*) 1.80
(*cis*) 0.75



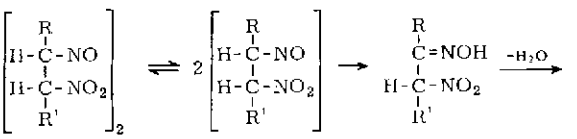
*(5)*

sec:prim 0.78

*(6)*

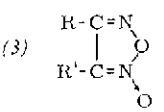
tert:prim 0.96

*(7)*



tert:prim 0.39

Equal steric "increments" [*(4) trans→(4) cis*; *(4) trans→(5)*; *(6) → (7)*] cause equal changes in the ratio of the products. With the aid of these results the "freedom" of the carbene intermediate can be more precisely defined than before.

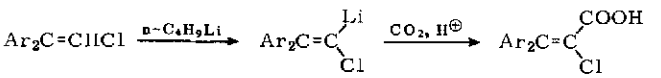


## Syntheses of α,ω-Diamines via Pseudonitrosites, Nitroximes, and Furoxans

*D. Klamann* and *W. Koser*, Hamburg (Germany)

Vicinal nitro and nitroso groups can be introduced into aliphatic or alicyclic hydrocarbons with particular ease by passing a freshly prepared mixture of nitrogen monoxide and air or oxygen into solutions of mono- or polyolefins. It was hitherto not generally possible to convert the resulting pseudonitrosites *(1)* into reactive compounds with both nitrogen functions intact. This requires monomerization of the dimeric nitroso groups, a process which can be achieved by heating in aprotic dipolar solvents; prolonged heating at lower or shorter heating at higher temperatures or treatment with superheated steam leads to rearrangement of *(1)* to the nitroximes *(2)*. The nitroximes do not undergo Beckmann rearrangements, but readily yield furoxans *(3)* on treatment with dehydrating agents; the latter can be reduced directly or in two stages to furazans. The furoxans can also be prepared directly from the pseudonitrosites *(1)*.

*(1)* *(2)*



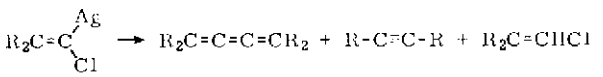
*(3)*

Catalytic hydrogenation of the furoxan molecule gives two primary amines $R-CH_2NH_2$ and $R'-CH_2NH_2$. Furoxans with alicyclic skeletons give α,ω-diamines, which can now be produced industrially by this method.

## Preparation and Reactions of Metallated Chloroethylenes

*G. Köbrich*, *H. Trapp*, *K. Flory*, *H. Fröhlich*, and *W. Drischel*, Heidelberg (Germany)

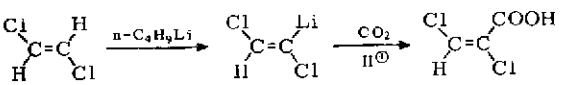
1,1-Diaryl-2-chloroethylenes *(1)* react at low temperatures with n-butyl-lithium to give the lithium compounds *(2)*, which were characterized as carboxylic acids *(3)*.



*(1)* *(2)* *(3)*

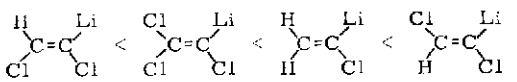
[16] *Th. Kauffmann* and *A. Risberg*, Tetrahedron Letters *1963* 1459.

The rate of metallation of *(1)* and the stability of the organolithium compounds *(2)* are affected by substituents on the aromatic nucleus, being decreased by electron-repelling groups. The compounds *(2)* rearrange on warming up to diarylacetylenes, with elimination of lithium chloride. Our experimental results show that this Fritsch-Buttenberg-Wiechell rearrangement proceeds from the (potential) carbanion and that the aromatic nucleus migrates with its bonding electron pair to the neighboring carbon atom.



Compound *(2)*, Ar = $C_6H_5$, reacts with silver chloride to give *(4)*, which is more stable than *(2)*, but decomposes on warming up to form tetraphenylbutatriene, tolane, and diphenylchloroethylene.

*(4)*



R = $C_6H_5$

1,2-Dichloroacrylic acid *(5)* is formed in 99 % yield by the reaction at −110 °C of *trans*-dichloroethylene with n-butyl-lithium and subsequent carboxylation; similarly, vinyl chloride gives 100 % α-chloroacrylic acid, and trichloroethylene gives 81 % trichloroacrylic acid. The stabilities of

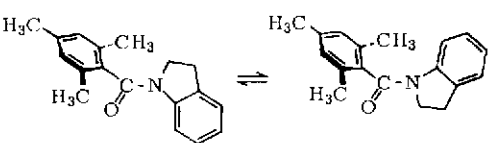
*(5)*

the intermediate lithium compounds are represented by the series

The two less stable compounds probably decompose by *trans*-β-elimination, the others by α-elimination [17].

## Trifluorophosphinyl Complexes of Transition Metals

*Th. Kruck*, Munich (Germany) [18]



Hexakistrifluorophosphinylmetal(0) complexes $M(PF_3)_6$, which are closely analogous to the hexacarbonyls of the chromium group, have been prepared from dibenzenechromium(0) and dibenzenemolybdenum(0) with $PF_3$ at pressures of 300–500 atm. High pressure reaction of $PF_3$ with the tricarbonyls $M(CO)_3L_3$ (M = Cr, $L_3$ = 3 $NH_3$; M = Mo, $L_3$ = mesitylene) yields crystalline, extremely volatile tristrifluorophosphinylmetal(0) tricarbonyls $M(PF_3)_3(CO)_3$, with *cis*-arrangement of the three $PF_3$ ligands in an octahedral complex. Trifluorophosphine is a ligand with weak donor but pronounced acceptor properties (comparison of the C–O valence frequencies of molybdenum tricarbonyls) and is thus similar to carbon monoxide. It therefore seems very suitable for the stabilization of extremely low oxidation states of transition metals.

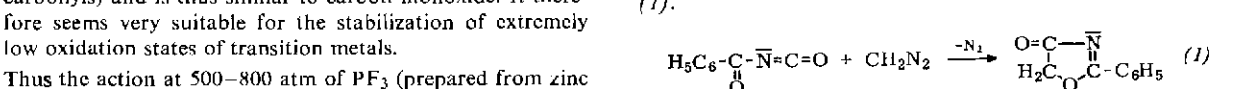
Thus the action at 500–800 atm of $PF_3$ (prepared from zinc fluoride and phosphorus trichloride, and purified only by recondensation) on dicobalt octacarbonyl gives the almost colorless, diamagnetic hydride $HCo(PF_3)_3CO$, b.p. 80.5 °C/715 mm, in ca. 90 % yield. The compound is formed very readily, and its thermal stability is considerably higher than that of cobalt carbonyl hydride; it is also stable toward oxidizing agents (atmospheric oxygen, $MnO_2$). It reacts with potassium amalgam with liberation of hydrogen to give the ether-soluble salt $K[Co(PF_3)_3CO]$, which is stable in dry air. Tristrifluorophosphinylcarbonylcobaltate(I) can be precipitated with bulky cations, and is the first known complex with anionically bound trifluorophosphine [19]. The potassium salt dissolves in water to give a neutral solution, volatile hydride being reformed on treatment with mineral acids. In the transition from $HCo(PF_3)_3CO$ to $[Co(PF_3)_3CO]^{\ominus}$, both the C–O and the P–F valence frequencies are displaced toward longer wavelengths.

## Rotational Isomers of Mesitylenecarboxamides

*A. Mannschreck*, Heidelberg (Germany)

Rotation about the C–N bond is restricted in amides, since the two planar conformations of the amide group are favored by resonance. If the substituents on the nitrogen atom are different, rotational isomers may occur. The proton magnetic resonance spectra of a series of *N*-substituted mesitylenecarboxamides prove the preferential occurrence of two conformations, *e.g. (1)* and *(2)*. The isomers could be unambiguously assigned on the basis of this steric arrangement of the groups; the ratio of *(1)*:*(2)* was found to be 66:34 in [$D_6$]acetone at 37 °C. The ratios of the isomers are governed predominantly by the steric requirements of the

*(1)* *(2)*



respective substituents on the nitrogen atom. The temperature-dependence of the spectra supports the explanation given above.

Since carboxamides in acids are protonated on the oxygen atom [20], two isomers exist in the equilibrium in strongly acidic solutions, too, *e.g.* the cations of *(1)* and *(2)* are present in trifluoroacetic acid in the ratio of 45:55. If a crystalline amide is dissolved in a strong acid, this equilibrium ratio is slowly established (*e.g.* $\tau_{1/2} \approx 5$ min in $CF_3COOH$ at 37 °C). Immediately after dissolution, the proton magnetic resonance spectrum shows that one of the isomers [*(1)* in the example chosen] greatly predominates. It can therefore be assumed that the crystal consists of one rotational isomer, which isomerizes partially after dissolution. The mechanism of this reaction has not yet been fully elucidated.

## Cycloadditions with Isocyanates as 1,4- and 1,2-Dipoles

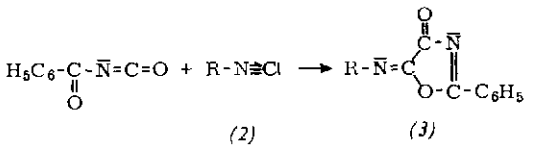
*R. Neidlein*, Marburg/Lahn (Germany)

Equimolar quantities of benzoyl isocyanate [21] and diazomethane interact at room temperature in anhydrous ether with elimination of nitrogen to form 2-phenyloxazolin-4-one *(1)*.

*(1)*

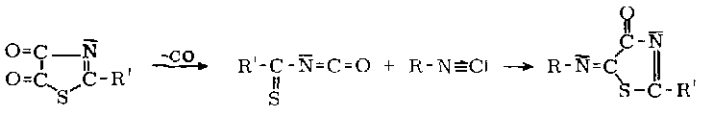
The most suitable compounds which could theoretically enter into dipolar cycloadditions similar to those of methylene groups were isocyanides. Isocyanides can be regarded as stabilized carbenes. Equimolar quantities of benzoyl iso-

[17] Cf. *G. Köbrich* and *H. Trapp*, Z. Naturforsch. *18b*, 1125 (1963); *G. Köbrich*, *H. Trapp*, and *I. Hornke*, Tetrahedron Letters *1964*, 1131; *G. Köbrich* and *K. Flory*, ibid. *1964*, 1137.



[18] In collaboration with *W. Lang*.

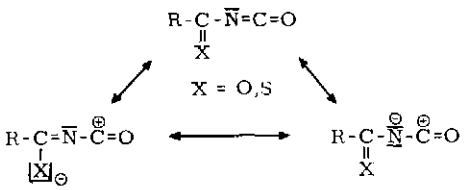
[19] To be published in detail in Chem. Ber.



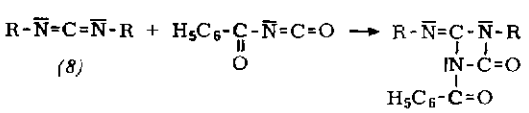
[20] *A. R. Katritzky* and *R. A. Y. Jones*, Chem. and Ind. *1961*, 722.

[21] *J. C. Sheehan* and *P. T. Izzo*, J. Amer. chem. Soc. *71*, 4059 (1949).

cyanate in absolute benzene react as 1,4-dipoles with isocyanides *(2)*, *e.g.* phenyl isocyanide, in anhydrous ether at room temperature by cycloaddition to form derivatives of 5-iminooxazolin-4-one *(3)*; the final products are only sparingly soluble and can be easily isolated. Reaction of equimolar quantities of thioacyl isocyanates *(4)* [22] as 1,4-dipolar compounds with isocyanides *(2)* similarly yields 5-iminothiazolin-4-one derivatives *(5)*. The thioacyl isocyanates are very reactive and are not isolated before being subjected to the latter reactions. They are supplied by 2-aryl- or 2-alkylthiazolin-4,5-diones [23], which expel CO on heating in boiling xylene; the nascent thioacyl isocyanate reacts with the isocyanide in the same solution (yields: 80–95 %).

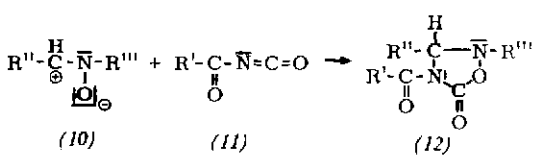


*(2)* *(3)*



*(4)* *(2)* *(5)*

The acyl and thioacyl isocyanates react as 1,4-dipoles *(6)* in the cases mentioned, but they can also function as 1,2-dipoles *(7)*. The following resonance structures can be formulated for the isocyanates.



*(6)* *(7)*

For example, reaction of carbodiimides *(8)* at room temperature in an anhydrous 1:1 ether/benzene mixture with equimolar quantities of benzoyl isocyanate gives iminouretone derivatives *(9)* [24] in 60–70 % yields after removal of the solvent.

*(8)* *(9)*

1,3-Dipoles such as *N*-methylbenzaldoxime *(10)* – a nitrone – react with equimolar amounts of acyl isocyanate *(11)* at room temperature in an anhydrous 1:1 ether/benzene mixture to form five-membered rings, *viz.* 1,2,4-oxadiazolidin-5-ones (yields: 80–90 %).

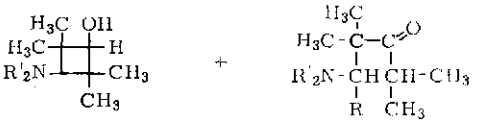
[23] *J. Goerdeler* and *H. Horstmann*, Chem. Ber. *93*, 671 (1960).

[24] Cf. *W. Neumann* and *P. Fischer*, Angew. Chem. *74*, 801 (1962); Angew. Chem. internat. Edit. *1*, 621 (1962).

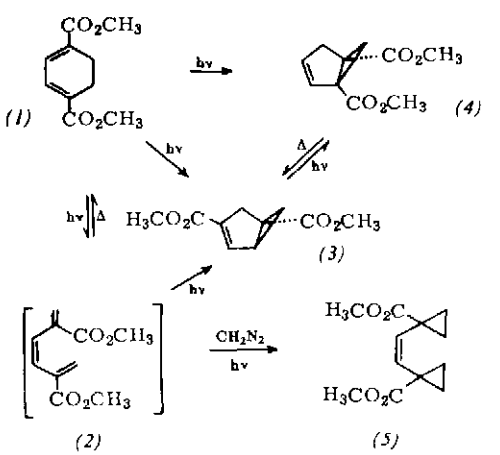


## Ring-Opening of β-Dialkylaminocyclobutanones

*G. Opitz* and *M. Kleemann*, Tübingen (Germany)

When heated, enolizable β-aminocyclobutanones rearranged with ring-opening to form β-aminovinyl ketones. Non-enolizable β-aminocyclobutanones *(1)* can form three products with Grignard reagents: 1. normal addition gives tertiary β-aminocyclobutanols *(2)*; 2. reduction gives secondary β-aminocyclobutanols *(3)*; and 3. ring-opening gives saturated β-amino ketones *(4)*. The β-amino ketones *(4)* can be converted into saturated ketones either by heating, with elimination of a vinylamine, or by warming with sodium hydroxide solution, with elimination of an aldehyde and a secondary amine.

*(1)* *(2)*



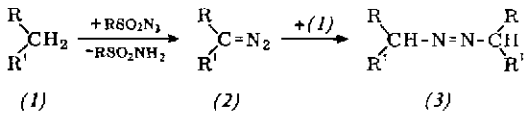
*(3)* *(4)*

The ring-opening is interpreted as a fragmentation reaction. The tendency for the ring to open is governed not by the basicity, but by the electromeric effect of the amino group (pyrrolidino > hexamethyleneimino > piperidino > morpholino). Whether the Grignard reaction proceeds normally or abnormally depends, in a manner which cannot yet be explained, on the solvent and on the organometallic residue.

## Photochemical Valence Isomerization of 1,3-Cyclohexadiene Derivatives

*H. Prinzbach* and *H. Hagemann*, Freiburg/Brsg. (Germany)

Unsensitized irradiation of dimethyl 1,3-cyclohexadiene-1,4-dicarboxylate *(1)* ($\lambda_{max}$ = 307 mμ) in ether (uviol glass filter; Hg high-pressure lamp Q 81) yields the bicyclic diester *(4)* in 20–25 % yield in $1.5\times10^{-2}$ M solution or in at least 60 % yield in $3\times10^{-3}$ M solution. The sterically hindered open-chain 1,3,5-hexatriene-2,5-dicarboxylate *(2)* and the [3,1,0]-bicyclic ester *(3)* can be shown to be very probable intermediates in this photochemical isomerization. The *cis*-triene *(2)* ($\lambda_{max}$ = 240–245 mμ, $\varepsilon \approx 6500$) – which cannot be isolated, since the thermal reverse reaction to form *(1)* is very rapid ($\tau^1/_2 \approx 10$ min at 20 °C) – is trapped with diazomethane in 70 % yield as *(5)*. Compound *(2)* can be photochemically



*(1)* *(4)* *(3)* *(2)* *(5)*

converted in the presence of iodine into the thermally more stable *trans*-1,3,5-hexatriene ($\lambda_{max}$ = 285 mμ, ε ≈ 13000). Irradiation of *(1)* through a pyrex filter leads to *(3)* ($\lambda_{max}$ = 237 mμ; ε = 6440) as the main product of the isomerization. The photochemical vinylcyclopropane isomerization of the thermodynamically more stable isomer *(3)* to *(4)* can be reversed thermally ($E_a$ = −26.3 kcal/mole).

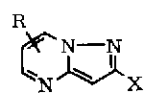
## Synthesis of Aliphatic Azo and Diazo Compounds from Active Methylene Compounds and Sulfonyl Azides

*M. Regitz*, Saarbrücken (Germany)

Compounds with activated methylene groups *(1)* react with sulfonyl azides in the presence of bases to form diazo compounds *(2)* and sulfonamides [25].

*(1)* *(2)* *(3)*

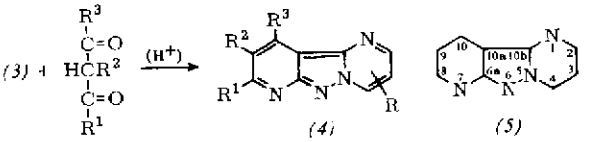
(R and R′ are activating residues, *e.g.* >C = C<, >C=O, > $SO_2$, and aryl).



Depending on the proton mobility of the CH-acid component *(1)*, even aqueous ammonia, organic amines, or alkaline solutions are suitable as bases; more weakly acidic compounds are converted into their carbanions by alkali metal alkoxides or lithium alkyls. If the rate of coupling of the diazo compound *(2)* with the methylene component *(1)* which is still present is greater than the rate of formation of *(2)*, symmetrical azo compounds *(3)* are obtained. These can generally also be prepared from the CH-acids *(1)* with half an equivalent of sulfonyl azide and are occasionally (*e.g.* with dihydrothionaphthen-3-one 1,1-dioxide) susceptible to thermal azo decoupling. Methylene compounds *(1)* containing ester groups generally undergo nucleophilic substitution of the alkoxyl residue by the sulfonamide formed in the reaction. The sulfonamide also converts diazo compounds *(2)* with R = aryl and R′ = CO-aryl or CO-alkyl into carboxy sulfonamides with elimination of $N_2$, partly by a reaction similar to the Wolff rearrangement.

The usefulness of this reaction is shown by the preparation of the diazo derivatives of cyclohexadienes, β-diketones, β-keto sulfones, monoketones, and carboxylic esters, as well as the corresponding azo compounds.

## Synthesis of the 1,5,8a,9-Tetraazafluorene System [26]

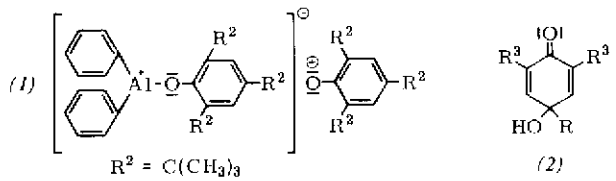


*W. Ried* and *K. P. Peuchert*, Frankfurt/Main (Germany)

2-Bromopyrazolo[1,5-*a*]pyrimidines *(2)* are prepared from 2-hydroxypyrazolo[1,5-*a*]pyrimidines *(1)* [27] and phosphorus oxybromide. The former react with ammonia to form 2-aminopyrazolo[1,5-*a*]pyrimidines.

*(1)*: X = OH
*(2)*: X = Br
*(3)*: X = $NH_2$

Proton-catalysed condensation of *(3)* with 1,3-dicarbonyl compounds gives a new, quasi-aromatic heterocyclic system, *viz.* 1,5,8a,9-tetraazafluorene *(4)*, numerous derivatives of which have been prepared.



*(3)* *(4)* *(5)*

According to IUPAC rules, the new system should be referred to as pyrido[3′,2′:4,3]pyrazolo[1,5-*a*]pyrimidine and should be numbered as in *(5)*. The compounds exhibit fluorescence in solution, according to the nature and number of substituents present.

## Monovalent Reactions on Organometallic Compounds

*A. Rieker*, Tübingen (Germany)

The reaction of aroxyl radicals with organometallic compounds (RLi, RMgX, $R_2Mg$, $R_3Al$) causes liberation of carbon radicals R· via intermediate free-radical complexes; these carbon radicals dimerize or dehydrogenate the solvent or organometallic compound to form mainly hydrocarbons R–R and R–H in varying quantities (20–100 % overall). In the triphenylaluminum/2,4,6-tri-t-butylphenoxyl system, EPR measurements gave direct evidence of a free-radical complex, for which the constitution *(1)* has been proposed on the basis of isotope experiments. In this complex, the free electron on the aluminum has a finite spin density; a "mesomeric aluminum radical" is present.

*(1)* $R^2 = C(CH_3)_3$ *(2)*

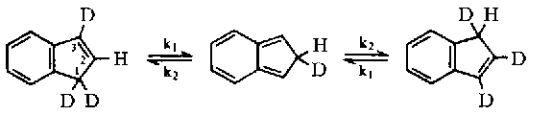
Many sterically hindered quinones also behave as monovalent electron acceptors towards organomagnesium compounds. Combination of the components in equimolar ratios gives highly colored paramagnetic complexes, the structures of which are not yet known; they are not identical with the corresponding free semiquinones and decompose immediately in the presence of excess organomagnesium halide RMgX. The final products isolable are quinols *(2)* (25–80 %), hydroquinones, and, again, the hydrocarbons R–R and R–H (together up to 40 %).

## 1,5-Hydrogen Shifts in Cyclopentadiene and Indene

*W. Roth*, Köln (Germany)

We have examined the thermal hydrogen shift in cyclopentadiene using 5*H*-perdeuterocyclopentadiene. At temperatures around 50 °C, the NMR spectrum indicates reorientation of the hydrogen by successive 1,5-hydrogen shifts, the intramolecular nature of which was ascertained by mass-spectroscopic analysis of the starting material and rearranged product. The rate of rearrangement was followed between 45 and 65 °C, both in the gas phase and in solution. The reaction is of first order, is affected only to a negligible extent by the surface area of the reaction vessel and the polarity of the solvent, and can be described by the Arrhenius equation

$$k = 1.3 \times 10^{12} \cdot \exp(-24.3 \pm 0.5)\ \text{kcal/RT}\ [\text{sec}^{-1}].$$



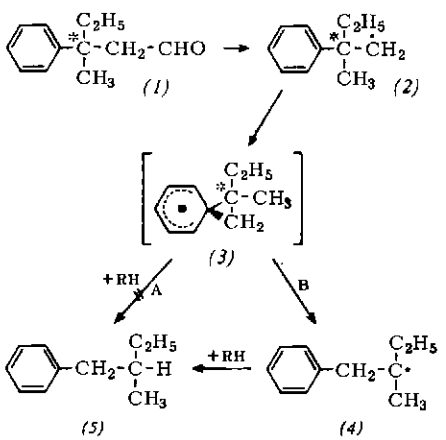
An analogous 1,5-hydrogen shift has been observed in indene leading to isoindene, which in turn undergoes another 1,5-

[25] *W. v. E. Doering* and *C. H. De Puy* [J. Amer. chem. Soc. *75*, 5955 (1953)] were the first to prepare diazocyclopentadiene in this manner.

[26] Part of the Ph. D. Thesis of *K.-P. Peuchert*, Universität Frankfurt/Main, 1964.

[27] *W. Ried* and *E.-U. Köcher*, Liebigs Ann. Chem. *647*, 116 (1961); *W. Ried* and *K.-P. Peuchert*, ibid. *660*, 104 (1962).

hydrogen shift at 220 °C with rapid reformation of indene. However, the occurrence of isoindene *(2)* can be detected during the isomerization of 1,1,3-trideuteroindene *(1)* by



*(1)* *(2)*

introducing deuterium at C-2 of the indene. This reaction is also intramolecular and of the first order, and is not catalysed by the walls of the vessel.

## The Stereochemical Criterion for Phenyl Migration by a Free-Radical Mechanism

*C. Rüchardt* and *H. Trautwein*, Munich (Germany)

The stereochemistry of the decarbonylation of optically active 3-methyl-3-phenylvaleraldehyde *(1)* was studied in an attempt to find out whether, in aryl migrations proceeding via a free-radical mechanism, an intermediate *(3)* can react directly with the hydrogen donor [RH = *(1)*] (Route A), or whether the reaction proceeds through the isomeric radical *(4)*.

Detection of Route A would also be a direct proof that *(3)* is a true intermediate and not a transition state. The complete racemization of *(5)* shows that only Route B is significant, since optical activity should be retained by Route A, as with corresponding ionic intermediates.

The tendency of the phenyl group to migrate is greater in *(1)* than in the related neophylaldehyde, probably owing to steric effects. A photochemical Arndt-Eistert chain extension with migration of an optically active tertiary carbon atom, was carried out during the synthesis of *(1)*; complete retention of optical activity was found for this reaction.

## Olefination of $N_2O$ and other Attempts to Synthesize Diazomethane

*W. Rundel*, Tübingen (Germany)

By analogy to the reaction of *C*-nitroso compounds with Wittig reagents to form Schiff bases, that of $N_2O$ and methylenetriphenylphosphorane *(1)* should lead to the most straightforward synthesis of diazomethane.

$$(C_6H_5)_3P=CH_2 + N_2O \rightarrow (C_6H_5)_3P=O + H_2C=N_2$$

In practice, however, diazomethane or isodiazomethane is obtained only on hydrolysis of the precipitate formed from $N_2O$ and *(1)*. On the other hand, diazomethane is taken up by *(1)* in a 1:1 ratio, to form a precipitate *(2)*, which again yields (iso-)diazomethane on hydrolysis. The reaction should therefore be formulated as follows.

$$2\,(C_6H_5)_3P=CH_2 + N_2O \rightarrow (C_6H_5)_3P=O + [HCN_2^{\ominus} + (C_6H_5)_3\overset{\oplus}{P}CH_3] \quad (2)$$

$$(2) + H_2O \rightarrow [(C_6H_5)_3\overset{\oplus}{P}CH_3]\,OH^{\ominus} + H_2CN_2 \text{ (yield: 25 \%)}$$

The small yields are due to the indirect route through the diazomethyl anion and to side reactions, *e.g.* reduction of $N_2O$ to $N_2$, and addition of a further methylene group to the diazomethane molecule to form triphenylphosphine and hydrazine derivatives [28]. Higher diazoalkanes which do not form $RCN_2^{\ominus}$ anions cannot be obtained by this method. Chloramine and formaldoxime give 70–75 % yields of diazomethane [29], but no cyclic products.

$$\text{Diazirine} \leftarrow\!\!\!\!\!\!\diagdown\!\!\!\!\!\!\diagup \quad H_2C=NOH + NH_2Cl \xrightarrow{CH_3ONa} CH_2N_2$$

Diazomethane was also obtained – albeit in maximum yields of only 10 % – by introducing methylenetoluenesulfonylhydrazine *(3)* into hot potassium hydroxide solution in a current of nitrogen.

$$H_2C-N-NHSO_2C_7H_7 \xrightarrow{KOH} CH_2N_2 + RSO_2^{\ominus}$$
*(3)*

From formaldehyde and *p*-toluenesulfonylhydrazine hydrochloride compound *(3)* (or its dimer?) is obtainable as a colorless microcrystalline product but only in aqueous solution. It resinifies rapidly with decomposition on contact with organic solvents. Attempts to use *(3)* in carbene reactions were unsuccessful; only hydrogenation of C=C bonds, presumably by side reactions, was observed [30].

## Radiation-Induced Formation of Sulfuric Acid in the System $SO_2/O_2/H_2O$

*R. Schrader* and *S. Schönherr*, Freiberg/Sachsen (Germany)

Sulfuric acid can be obtained in appreciable quantities by the action of ionizing radiation on sulfur dioxide (gaseous, liquid or dissolved in water) and oxygen. For the reaction in aqueous solution, a mixture of sulfur dioxide and oxygen of constant composition is led in continuously. The solution is irradiated with 180 kV X-rays with a dose rate of $3\times10^{16}$ eV/ml/min. Sulfuric acid and traces of dithionic acid are formed. The rate of reaction of 0.2–0.9 M sulfurous acid remains approximately constant at $\approx$ 15 mmole/l/h in the irradiated solution between 20 and 80 °C. In the thermal reaction, the rate of reaction of the sulfurous acid increases with increasing concentration and temperature. For 0.2 M sulfurous acid at 20 °C, $G(H_2SO_4) \approx 560$ [31]. This figure decreases to $\approx$ 0.7 in the absence of oxygen. Thus the reaction cannot proceed only via the products of radiolysis of water.

Additions of 0.01 M $Cu^{2+}$, 0.01 M $Fe^{2+}$, and 0.01 M or 0.001 M $Fe^{3+}$ eliminate the irradiation effect. When the irradiation is interrupted, the rate of the irradiation reaction falls below that of the thermal reaction. Sulfur dioxide and oxygen are taken up during the reaction in roughly stoichiometric proportions.

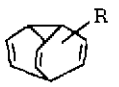
The experimental results suggest a chain reaction, which can probably be represented by the overall reaction (a).

$$H + O_2 + 2\,SO_2 + 2\,H_2O \rightarrow 2\,H_2SO_4 + H \qquad (a)$$

[28] According to *G. Wittig* and *M. Schlosser* [Tetrahedron *18*, 1023 (1962)], this is the main reaction for the pair benzylidenetriphenylphosphorane/phenyldiazomethane (formation of dibenzylideneazine).

[29] *W. Rundel*, Angew. Chem. *74*, 469 (1962); Angew. Chem. internat. Edit. *1*, 403 (1962).

[30] Hydrogenation of olefins by *p*-toluenesulfonylhydrazine: Cf., for example, *R. S. Dewey*, J. Amer. chem. Soc. *83*, 3729 (1961).



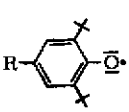
[31] $G(H_2SO_4)$ = number of sulfuric acid molecules formed per 100 eV of radiation energy absorbed.

## Molecules with Rapid Reversible Valence Isomerism. Synthesis and Properties of Bromobullvalene and Alkyl Bullvalyl Ethers

*G. Schröder, R. Merenyi,* and *J. F. M. Oth,*
Karlsruhe (Germany) and Brussels (Belgium)

Bromobullvalene [32] and potassium alkoxides interact in dimethyl sulfoxide at 20 °C to give excellent yields of the alkyl bullvalyl ethers.

It is remarkable that the rate of the valence isomerism of t-butyl bullvalyl ether *(1)* is greater than that of methyl bullvalyl ether *(2)*. Owing to steric hindrance, the π-orbitals of the double bond in *(1)* cannot lie parallel to the orbitals of the lone pair of electrons on the ether oxygen. Thus, the valence isomerism in *(1)* is only slightly, or not at all, hindered by conjugation. In *(2)*, conjugation of the vinyl ether system is not prevented by steric factors.



| R | M.p. [°C] | τ-Value of the bullvalene protons | Measuring temperature [°C] | Line width [cps] | Rel. rates at 0 °C |
|---|---|---|---|---|---|
| $OCH_3$ *(2)* | 23–26 | 5.97 | 91 | 30 | 12 |
| $OC_2H_5$ | 70–88 | 6.00 | 92 | 22 | 16 |
| $OCH(CH_3)_2$ | 28–32 | 6.02 | 93 | 15 | 20 |
| $OC(CH_3)_3$ *(1)* | 16–19 | 5.97 | 91 | 9 | 39 |
| Br | 41–43 | 5.78 | 90 | 6 | 53 |
| H (Bullvalene) | 96 | 5.78 | 92 | 1.68 | 100 |

## A Simple EPR Method for Measuring the g-Factors of Free Radicals, Applied to Substituted Aroxyls

*H. B. Stegmann* and *K. Scheffler*, Tübingen (Germany)

g-Factors of free radicals can be determined with great accuracy (± $5\times10^{-6}$ to ± $30\times10^{-6}$) depending on the line width of the signal studied with simple equipment adaptations. The method consists essentially in recording the EPR spectrum of a calibrated standard, diphenyl-*S*-(4-oxyl-3,5-di-t-butylphenyl) thiophosphorate, simultaneously with the EPR spectrum of the radical to be studied. The hyperfine structure for the standard radical is so designed that no overlapping of the two signals occurs in the central part of the spectrum. Since both radicals are situated at the same place in the $H_0$ field of a conventional EPR spectrograph during the measurement, the desired g-factor can be obtained simply by measuring the distance between the centers of the two signals.

The effects of substituents in aroxyls of type *(1)* were investigated. It was found that the g-factors were practically

*(1)*

constant (2.00451, 2.00461, and 2.00536) within each of the series

R = $CH_3$, $C_2H_5$, $CH(CH_3)_2$, $C(CH_3)_3$;

R = $OCH_3$, $OC_2H_5$, $OCH(CH_3)_2$, $OC(CH_3)_3$; and

R = $SCH_3$, $SC_2H_5$, $SCH(CH_3)_2$, $SC(CH_3)_3$; $S(CH_2)_3CH_3$, $SCH_2CH_2C_6H_5$.

For R = $SeC(CH_3)_3$, the g-factor was found to be 2.00846. Thus, whereas alkyl groups have no controlling effect on the g-factors, the latter can clearly be seen to depend on the atom linking the aroxyl group to the substituent. Thus, participation of spin-free atoms in the free-radical state can also be detected from g-factors.

[32] *G. Schröder, R. Merenyi,* and *J. F. M. Oth,* Tetrahedron Letters *1964*, 773.

## Preliminary Studies on Peptide Syntheses from Isocyanides [33,34]

*I. Ugi, K. Offermann,* and *H. Herlinger,*
Leverkusen (Germany)

L-(−)-α-Methylbenzylamine *(1)*, 2-methylpropanal *(2)*, benzoic acid *(4)*, and t-butyl isocyanide *(8)* combine almost quantitatively to form the L-valine derivative *(12t)* [33], m.p. 116–116.5 °C, $[\alpha]_{578} = +36°$, c = 5 in methanol, and the D-valine derivative *(12e)*, m.p. = 136–136.5 °C, $[\alpha]_{578} -200°$. The ratio *(12t)*:*(12e)* = Q depends on the reaction conditions and can be accurately determined [± 1 % *(12t)*] from the rotation of purified *(12t)* + *(12e)* (without separation of the diastereoisomers) and from the rotation of the valine obtained from *(12t)* and *(12e)* by acidic dealkylating hydrolysis [33].

If methanolic solutions of equivalent quantities of *(1)* + *(2)* + *(4)* or *(7)* + *(4)* of concentration $c_0$ are treated at 0 °C with *(8)*, the steric course of the reaction, within the limits of analytical error, follows Equation (a) with $Q_E = 3.72$, $Q_A = 0.15$, and f = 2.20 (cf. Equations (b) to (d) and Table).

| $c_0$ [mole/kg] | 0.010 | 0.050 | 0.105 | 0.256 | 0.522 | 1.075 | 1.59 | 2.41 |
|---|---|---|---|---|---|---|---|---|
| $Q_{found}$ | 3.52 | 3.28 | 2.97 | 2.36 | 1.78 | 1.23 | 0.96 | 0.72 |
| $Q_{calculated}$ from Eq. (a) | 3.65 | 3.34 | 3.05 | 2.43 | 1.81 | 1.21 | 1.00 | 0.71 |

This reaction course can be represented by the simplified model

$$A \leftarrow B \leftrightharpoons C \rightleftharpoons D \rightarrow E$$

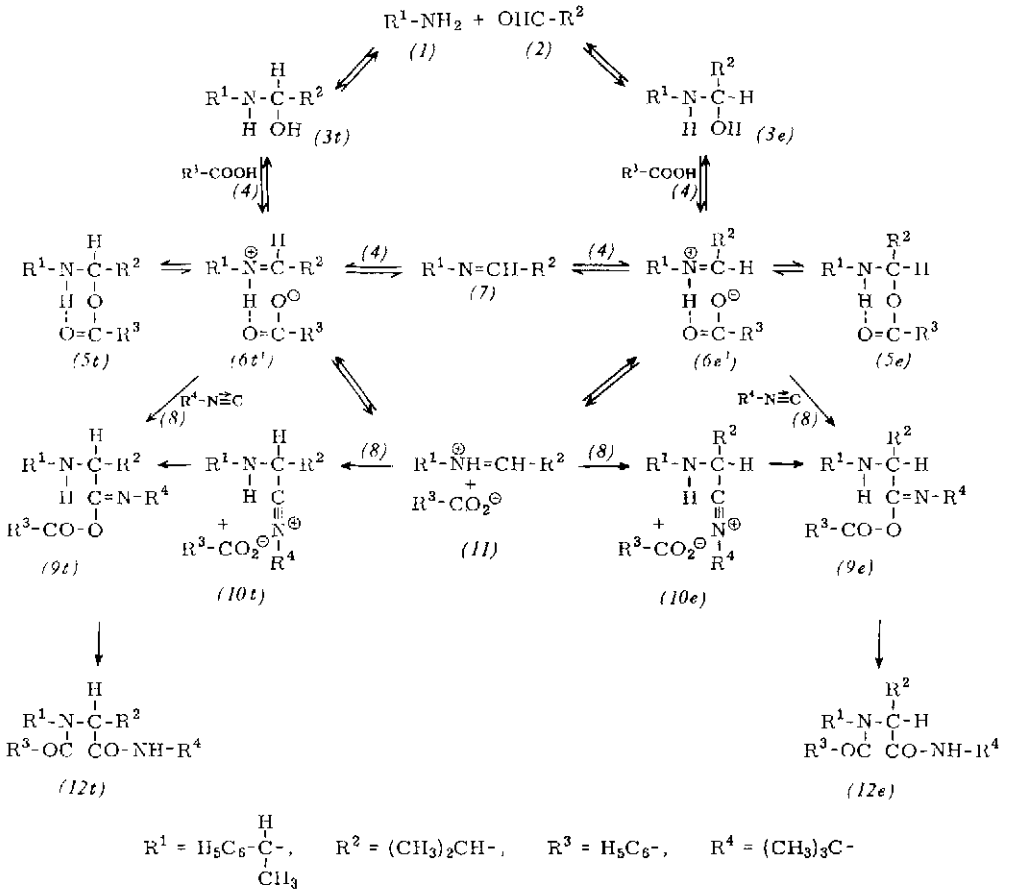
in which *(5t)*, *(5e)*, *(6t')*, and *(6e')* are grouped together as reaction system B, *(4)* + *(1)* + *(2)* or *(4)* + *(3t)* + *(3e)* or *(4)* + *(7)* as C, and *(11)* as D. Product A, which is formed by insertion of *(8)* into the *threo-* and *erythro*-oriented ion pairs *(6t')* and *(6e')* [the reactive forms of *(5t)* and *(5e)*, which might be protomeric with H-bond adducts of *(4)* + *(7)*] that are unseparated by solvent molecules, corresponds to *(12t)* + *(12e)* in the ratio $Q_A$, while E stands for a mixture of *(12t)* + *(12e)* in the ratio $Q_E$, derived [via the intermediates *(10t)* and *(10e)*] from the solvated, unoriented ion pair *(11)*. Provided that the reactions B ⇋ C ⇌ D and *(6t')* ⇌ *(6e')* proceed more rapidly than B → A and D → E, and with the additional proviso that $c_B \ll c_0$, Equation (a) can be deduced with the aid of this model representation:

$$\frac{Q - Q_E}{Q - Q_A} = -f \cdot c_0 \quad \text{(a)},$$

$$\text{where } Q_A = \frac{k_{6t' \rightarrow 9t} \cdot K_{6e' \rightleftharpoons 6t'}}{k_{6e' \rightarrow 9e}} \quad \text{(b)},$$

$$Q_E = \frac{k_{11 \rightarrow 10t}}{k_{11 \rightarrow 10e}} \quad \text{(c) and}$$

$$f = \frac{(1+Q_E)\,(k_{6t' \rightarrow 9t} \cdot K_{6e' \rightleftharpoons 6t'} + k_{6e' \rightarrow 9e})\,K_{4+7 \rightleftharpoons 6t'+6e'}}{2\,(1+Q_A)\,(1+K_{6e' \rightleftharpoons 6t'})\,(k_{11 \rightarrow 9t} + k_{11 \rightarrow 9e})\,(1+\sqrt{K_{4+7 \rightleftharpoons 11}})\,\sqrt{K_{4+7 \rightleftharpoons 11}}} \quad \text{(d)},$$



k being the reaction rate constant and K the equilibrium constant of the reaction specified by the subscripts.

The difference in the conformational strains of the two diastereoisomeric transition states is

$$F^{\rightleftharpoons}_{11 \rightarrow 10e} - F^{+}_{11 \rightarrow 10t} = 0.71 \text{ kcal/mole}$$

[33] Cf. *I. Ugi* and *K. Offermann*, Angew. Chem. *75*, 917 (1963); Angew. Chem. internat. Edit. *2*, 624 (1963); *K. Offermann*, Ph. D. Thesis, Universität München, 1964.

[34] *I. Ugi*, Angew. Chem. *74*, 9 (1962); Angew. Chem. internat. Edit. *1*, 8 (1962); *K. Sjöberg*, Svensk kem. Tidskr. *75*, 493 (1963).

$R^1 = H_5C_6-\underset{CH_3}{\overset{H}{\underset{|}{\overset{|}{C}}}}-$, $R^2 = (CH_3)_2CH-$, $R^3 = H_5C_6-$, $R^4 = (CH_3)_3C-$

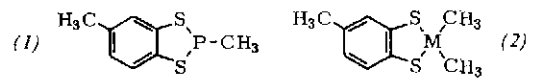
*t* = threo forms; *e* = erythro forms.

for the exclusively *kinetically controlled* branch of the reaction [cf. (c)], and for the equilibrium-dependent branch [cf. (b)], according to the Curtin-Hammett principle,

$$F^{+}_{6t' \rightarrow 9t} - F^{+}_{6e' \rightarrow 9e} = 1.02 \text{ kcal/mole}$$

## Promethium and Some of Its Compounds

*F. Weigel*, Munich (Germany)

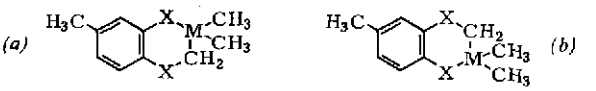


Promethium (element 61) was isolated from a crude concentrate from Oak Ridge National Laboratory. In addition to 50 curies of promethium 147, the concentrate also contained larger quantities of europium, samarium, neodymium, and americium. A promethium-americium fraction was first isolated using ion-exchange chromatography on Dowex 50 at 87 °C by elution with 0.5 M ammonium α-hydroxyisobutyrate at pH 3.5. The americium and promethium were then separated on a Dowex 1 anion-exchange column by elution with 8 M ammonium thiocyanate. The resulting pure promethium was freed from residual thiocyanate by repeated reprecipitation as the hydroxide. The last hydroxide precipitate was dissolved in $HNO_3$ to obtain a promethium(III) nitrate solution, which was used as the starting material for the production of the metal and the preparation of a few compounds. Several samples of about 300 μg of Pm metal each were obtained by reduction of $PmF_3$ with Li at about $10^{-6}$ mm in a tantalum double crucible system. Pm is a silvery-white metal, which is more stable in air than neodymium, but is similar in appearance to the latter. Its melting point was found by the "welded joint rupture" method to be 1090 ± 8 °C. The following promethium compounds were prepared: $Pm(OH)_3$ purplish pink, $PmCl_3 \cdot xH_2O$ lemon yellow, $Pm_2O_3$ purplish pink, $PmF_3$ purplish pink, $PmPO_4$ pink, $PmAsO_4$ pink, $Pm(IO_3)_3$ yellow pink, and $Pm_2(C_2O_4)_3 \cdot 10\ H_2O$ purplish pink.

Promethium(III) phosphate crystallizes in the monoclinic system with a = 6.71 Å; b = 6.905 Å; c = 6.36 Å; β = 103° 56′. The oxalate $Pu_2(C_2O_4)_3 \cdot 1\ OH_2O$ has a = 11.43 Å; b = 9.57 Å; c = 9.97 Å; β = 118° 55′. These values for the lattice constants are preliminary.

## Some Bicyclic Heterocycles

*M. Wieber* and *M. Schmidt*, Marburg/Lahn (Germany)

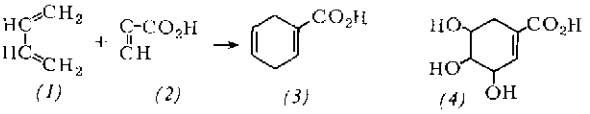


The organometalloid halides $CH_3PCl_2$, $(CH_3)_2SiCl_2$, $(CH_3)_2GeCl_2$ and $(CH_3)_2SnCl_2$ react in inert solvents with 3,4-dimercaptotoluene in the presence of stoichiometric quantities of triethylamine as hydrochloric acid acceptor to afford very good yields of the bicyclic heterocycles *(1)* and *(2)*.

M = Si, Ge, Sn

Organometalloid monohalides which are halogenated on the organic group, *e.g.* chloromethyldimethylchlorosilane or -germane, also react with 3,4-dimercapto toluene and its oxygen analogue with ring formation.

The $^1H$-NMR spectra showed that *(3a)* and *(3b)*, *(4a)* and *(4b)*, or *(5a)* and *(5b)* are formed.



*(3)*: X = S, M = Si; *(4)*: X = S, M = Ge; *(5)*: X = O, M = Si

Form *(b)* is the predominant product [*(a)*:*(b)* :1.3].

The course of the hydrolysis of the 5- and 6-membered rings is fundamentally different. In the first case, 3,4-dimercaptotoluene is reformed, together with polymeric organometalloid oxide, whereas organosiloxanes or -germoxanes are formed in the second case. [VB 815/154 1E]

German version: Angew. Chem. 76, 573 (1964)
Translated by Express Translation Service, London

**A new synthesis of shikimic acid** *(4)* is described by *R. Grewe* and *J. Hinrichs*. Butadiene *(1)* and propiolic acid *(2)* react to form cyclohexadienecarboxylic acid *(3)*, m.p. 120 °C, in 85 % yield. The methyl ester, b.p. 98–99 °C/22 mm, is treated with hydrogen peroxide in formic acid to give the *trans*-dihydroxy ester, m.p. 97 °C, in 85 % yield; this is converted into methyl 4,5-diacetoxy-1-cyclohexene-1-carboxylate, m.p. – 61 °C, in 80 % yield by acetic anhydride in pyridine.

*(1)* *(2)* *(3)* *(4)*

This diacetate is brominated with *N*-bromosuccinimide in $CCl_4$, and the resulting 3-bromo compound is converted into methyl shikimate by treatment with silver acetate followed by hydrolysis with methanolic potassium hydroxide. The pure ester (m.p. 172 °C, yield 20 %) is separated on a cellulose column from isomeric compounds and from unbrominated methyl dihydroxycyclohexenecarboxylate (m.p. 97 °C, recovery 21 %). Free (–)-shikimic acid, m.p. 190–191 °C, is obtained by hydrolysis. The individual fractions are purified via the cyclohexylidene compound of the methyl esters; besides pure (–)-shikimic acid, (±)-shikimic acid, (±)-epishikimic acid, epiisoshikimic acid, and (±)-isoshikimic acid were also isolated. The cyclohexylidene compounds are obtained in almost quantitative yield in dimethylformamide/benzene in the presence of an acid ion-exchanger, the water formed being removed continuously by means of a separator. / Chem. Ber. *97*, 443 (1964) / –W. [Rd 938/275 IE]

**The relationship between the molar extinction coefficient ε of DNA and its guanine and cytosine content** was investigated by *S. L. Bunch* and *B. V. Siegel*. It was shown for 9 samples of DNA that $\varepsilon_{260\ m\mu}$ is a linear function of the content of guanine plus cytosine. Regression equations were calculated in order to estimate the individual contributions. Since the extrapolated values of ε for polyguanylic acid and polycytidylic acid corresponded to the values for guanylic acid and cytidylic acid, it was concluded that there is only weak hydrogen bonding between guanine and cytosine in the double helix. / Experientia *20*, 14 (1964) / –Re. [Rd 908/261 IE]

A **volumetric determination of silicon** is proposed by *H. Bartels* and *H. Erlenmeyer:* it is based on the formation of a 1:3 complex between silicon and catechol. The silicon compound, which should be present at a concentration of about $10^{-2}$ M, is mixed with a threefold excess of catechol or a catechol derivative and stirred or shaken with a known excess of NaOH, until complex formation is complete (15 min to a few hours, according to the nature of the silicon compound). For each mole of Si present, 2 moles of NaOH are neutralized by the $H^{\oplus}$ ions liberated during complex formation. The excess $OH^{\ominus}$ is back-titrated. / Helv. chim. Acta *47*, 13 (1964) / – Hz. [Rd 939/276 IE]

**The molecular weight of interferon** was determined by *C. Jungwirth* and *G. Bodo* by gel filtration. Interferon is a protein that is formed after the infection of cells by viruses. Fowl embryo tissue infected with influenza virus yielded interferon preparations which after purification were chromatographed on Sephadex G-100 columns. Comparisons with the behavior of test proteins gave a molecular weight of 32000 to 35000 for interferon. / Biochem. Z *339*, 382 (1964) / –Sch. [Rd 999/287 IE]

**Apamin, a polypeptide from bee venom** which causes excitation of the central nervous system, was isolated from lyophilized bee venom by *E. Habermann* and *K.-G. Reiz* using chromatography on Sephadex and carboxymethylcellulose. Apamin forms about 2–3 % of the dry weight of the venom and is a strongly basic polypeptide composed of 16 amino-acid residues; in rats, besides strongly increasing capillary permeability, it affects only the central nervous system, *e.g.* it increases spontaneous motor activity. This polypeptide appears to be the first naturally occurring peptide to show such effects. Apamin poisoning can perhaps be used as a model for the study of pathological excitation of the central nervous system. / Naturwissenschaften *54*, 61 (1964) / –Sch. [Rd 904/260 IE]

**The reduction of DPN during carbonic-acid assimilation** was observed by *L. Kiesow* in homogenates of *Nitrobacter winogradskii*. Assimilation of $CO_2$ by the chemoautotrophic *Nitrobacter* can only take place in the presence of nitrite, which provides the necessary energy for the assimilation by its oxidation from $NO_2^-$ to $NO_3^-$. The $CO_2$ fixation and $NO_2^-$ oxidation take place in equivalent amounts, as was shown by ionopherograms using $NaH^{14}CO_3$. The oxidation of $NO_2^-$ is linked to a reduction of DPN. By means of this reaction, the energy provided by oxidation of nitrite is chemically "bound" and converted so that it is available for $CO_2$ assimilation. The DPN reduction/$NO_2^-$ oxidation exhibits an optimum at pH 8.2–8.3. / Biochem. Z. *338*, 400 (1963) / –De. [Rd 905/259 IE]

**Peat has been used as a cation-exchanger in the purification of radioactive sewage** by *E. Schmid, P. Stipanits*, and *F. Hecht*. In comparison with cheap inorganic exchangers such as permutits, glauconites, and montmorillonites, which can be used only once, peat has roughly the same exchange capacity (about 37 % of the dry weight consists of humic acids) and offers important advantages: the volume containing the radioactivity after absorption can be greatly reduced by combustion (maximum ash content 8 %). Sorption tests carried out either in a standard column (diameter: 1 cm; length: 12 cm; flow: 1 ml/min) or in a batch process (shaking with peat suspensions) showed that the exchange capacities in the batch process are always lower. The peat was boiled with water, dried at 110 °C, ground, sifted, and washed free of cations with 5 N HCl. Free excess acid was then removed with distilled water. In the column, penetration capacities D of 0.05–0.10 and saturation capacities S of 0.3–0.6 mequiv/g of peat were found for $^{137}Cs$, $^{89}Sr$, $^{60}Co$, and $^{140}Ba$ at pH 3–5. A solution of 1 μC activity, free from carrier and extraneous electrolytes, could be quantitatively purified in the standard column. Owing to its varied acidic groups, the exchange capacity of peat depends on the pH: at pH 1, S ≈ 0.1, at pH 5, S ≈ 0.5, and above pH 6–7, S rises to about 2 mequiv/g, as a result of incipient precipitation of hydroxide. / Österr. Chem.-Ztg. *65*, 9 (1964) / – Jg. [Rd 935/272 IE]

**The degradation of DNA by cysteamine or L-cysteine** in the presence of metal complexing agents or catalase was studied by *K. Berneis* and *M. Kofler*. Cysteamine is a better radiation shield than L-cysteine and does not change the DNA structure. In contrast, in aqueous solution under aerobic conditions, L-cysteine causes a degradation of DNA which is greatly increased by ethylenediaminetetraacetic acid or catalase. It was concluded from model experiments that these agents promote autoxidation of cysteine. This is the converse of the situation in the degradation of DNA by $H_2O_2$, for the latter is strongly inhibited by ethylenediaminetetraacetic acid or catalase. / Experientia *20*, 16 (1964) / –Re. [Rd 909/262 IE]

**A new cell for the electrochemical determination of oxygen** has been developed by *E. Proksch* and *H. Bildstein*. It works on a principle resembling polarography: stationary diffusion of oxygen produces a diffusion boundary current at a noble metal cathode (an Ag gauze cylinder packed with Ag wool), which is proportional to the oxygen concentration. The cathode potential is not varied, but is present by an unpolarizable anode (Cd/Ni), in such a way as to remain within the range of the diffusion boundary current. The Ag cathode is placed in a horizontal glass tube, half-filled with 15 % KOH; the Cd/Ni anode is placed in a vertical limb (a Pt accessory electrode is used to regenerate the anode). The gas to be examined is saturated with water vapor and is passed over the KOH solution; the gas must be absorbed to the point of equilibrium or at a constant rate. The cell is connected in series with an electrolytic cell for calibration with known quantities of oxygen. The readings are strictly linear from 0.1 to 600 ppm of oxygen; using a calibration curve, up to 1000 ppm of oxygen can be determined. For contents of less than 100 ppm, the cell can be used for months without regeneration. The maximum sensitivity at 20 °C is 3–4 μA/ppm $O_2$, at a flow rate of 30–100 ml of gas/min. At 50 °C, the sensitivity is increased by a factor of about 4. In comparison with similar earlier cells, the sensitivity, the rate of response, and the linearity range (formerly a maximum of 150 ppm) have been considerably improved. The cell is easy and inexpensive to make, and can be used for automatic supervision of gas scrubbers and gas circulations, *e.g.* in nuclear reactors. Owing to its low cost, this method of determining oxygen is superior to gas chromatography and mass spectrometry. / Österr. Chem.-Ztg. *65*, 41 (1964) / –Jg.

[Rd 936/273 IE]

**The substrate of alcohol dehydrogenase is free acetaldehyde.** *B. Müller-Hill* and *K. Wallenfels* reached this conclusion by measuring the enzymatic reduction of aqueous acetaldehyde solutions at 0 °C. About 25 % of the aldehyde was immediately consumed, but it was impossible to follow the progress of this reaction by normal means. For the reduction of the remaining 75 % a monomolecular reaction was rate-determining. If a solution of acetaldehyde in anhydrous tetramethylurea was stirred into the reaction mixture, 80 % of the aldehyde reacted at once and the remainder with measurable velocity. Since, according to *Bell* and *Clunie* [1], 26.5 % of the acetaldehyde in aqueous solution exists in the free form at 0 °C, it can be concluded that only the free aldehyde and not the hydrate is the substrate of the enzyme. This result is important for the interpretation of the kinetics of the enzymatic reaction. / Biochem. Z. *339*, 349 (1964) / –Sch. [Rd 2/292 IE]

# BOOK REVIEWS

**Ullmanns Encyklopädie der technischen Chemie** (Ullmanns Encyclopaedia of Chemical Technology). Third completely revised edition, compiled by *W. Foerst*, edited by *Hertha Buchholz-Meisenheimer*. Verlag Urban & Schwarzenberg, München-Berlin. Vol. 11: Kunststoffe bis Lithium. 1960, XII, 798 pp., 308 illustrs.; Vol. 12: Lösungsmittel bis Nitrochlorobenzole und Toluole. 1960, XII, 800 pp., 226 illustrs.; Vol. 13: Nitro- und Nitrosofarbstoffe bis Picrinsäure. 1962, XV, 823 pp., 158 illustrs. Price per volume in linen binding DM 128.– (about $32.–). Subject Index for Vols. 3–13 (200 pp., paper back).

The present three volumes contain articles (in German) listed under key-word headings as follows: Vol. 11: Plastics to Lithium; Vol. 12: Solvents to Nitrobenzenes and -toluenes; Vol. 13: Nitro- and Nitroso Dyestuffs to Picric Acid.

It is noticeable that the experience gained in editing the original volumes of this handbook has been put to use in the later volumes. The aim to present truly encyclopaedic information, to give a general survey as well as to set forth methods and recipes in detail, and to provide straightforward directions for individual cases, is accomplished better than ever. This is successfully achieved by the enlistment of numerous specialists – over 200 authors have cooperated in the 3 volumes – and by intense editorial work to ensure a terse arrangement, to provide cross-references, and to eliminate duplication and overlapping. Let us look more closely at some individual chapters.

Vol. 11 contains 18 articles including: Plastics, 119 pp.; Paints and Surface Coatings, 138 pp.; Food stuffs, 128 pp.; Light Production and Measurement, 64 pp. The highlights of the article on plastics comprise the questions of their properties (27 pp.) and processing (27 pp.). A good introduction (14 pp.) provides the general context. In other sections, coloring, surface treatment, testing, and analysis are dealt with; a discourse on economic aspects and plastics literature concludes the article. Not all of the processes known for manufacturing plastics are discussed in this article – references to a large number of special topics are given here instead. Space is thus left for some more detailed information. The section on 'Properties' occupies only 5 pp. of text but 8 pp. of diagrams and 14 pp. of tables, thus giving an extremely concise survey of all the more important plastics, subdivided into groups according to their major properties. (Modified natural products, amorphous-crystalline and amorphous thermoplasts, cross-linked, non-cross-linked polymers, and so on.) In the chapter on surface treatment, a description is given, for example, of how velvet- and suede-like leather foils are produced by electrostatic flocculation of plastics and textile fibres. Recipes and 25 suitable pigments for coloring poly(vinyl chloride) are specified. The chapter on testing contains numerical data on 30 characteristic properties, a boon to the practician. Details on commercial information are rather scant. The chapter on the historical background gives historical data in great detail, but the development trends in individual classes of plastics (an account of the commercial and technical problems) would also have been worth mentioning here. – In addition to its comprehensive detailed information, this article fulfills its ultimate aim by references to numerous manufacturing processes, production technology, and equipment methodology as well as by correlation of this information with the theoretical-scientific aspects of the work. It thus fulfills as task which can no longer be accomplished by a monograph.

The section on food stuffs technology is fully up-to-date. Seventeen authors have contributed to the article on foodstuffs (126 pp.): 100 pp. are devoted to the preservation of food, 8 pp. to coloring, 4 pp. to analysis, and 10 pp. to packaging. These chapters are again predisposed to make it easy to find details. Thus, in the section on "Preservation by Chemical Means", the sub-headings "Official Regulations and Guide to Applications" or "Use of Chemical Preservatives for Confectionary and Bakery Products" are encountered. The methods of manufacturing cans are described, and a table gives informtaion on the tin and iron content in preserved foods in mg/kg as a function of the storage life for fruit, vegetables, fish, and meat – for a total of 25 goods. In conclusion, preservation by refrigeration is dealt with – from the beginning of the 19th century, when ice from Norway was sent to the tropics, to modern refrigeration technique and its technical and economical advantages. In the chapter on colors, 85 dyestuffs are given together with the statutory requirements for their admission in 51 countries. In the section on packaging technique, a table is given of 22 important packaging characteristic properties for each of 19 coated and non-coated films including their behavior towards moisture, gas

permeability, chemical resistance, and stability towards heat and ageing. The article is divided into 85 sub-chapters. It quotes numerous references to, for example, fruit juices, cereals, baking, milk, vitamins, microbiology, and freeze drying and thus simultaneously forms the guide to all the information on the hwole field of foodstuffs in *Ullmann*. Whoever finds himself in a developing country with the task of setting up a foodstuffs industry will be unable to find any better information in the literature with regard to completeness, conciseness, and arrangement.

Volume 12 contains 60 articles including among the larger ones: Milk and Milk Products, 50 pp.; Solvents and Solutions, 48 pp.; Magnesium, 31 pp.; and Microbiology, 27 pp. – The modern technology of dairying is fully treated; it is only the commercial information, consisting of a table from the FAO Production Year Book for 1958, that is too brief. – The article on microbiology both affords an account of the technology of microbiological processes (10 pp.) and provides an enhancement and scientific extension of foodstuffs chemistry. A number of drawings in the general introduction would have made the subject more comprehensible. The readability of articles of this type from borderline subjects could have been improved further if the author had added a small list of seldomly used expressions and their meanings. Not everyone knows what endspores and sexual spores are or is familiar with expressions such as heterotrophic, xerophilic, involution forms, and so on. Even better known expressions, *e.g.* adaptation, have sometimes changeable meanings in the literature. – The article on solvents and solutions (48 pp.) characterizes in its special section (32 pp.) 127 solvents arranged according to subject matter and supplemented by an alphabetical index. The excellent general section (16 pp.) starts with the theory of intermolecular forces, discusses the most important solvent properties, requirements for use in various fields such as extraction processes and chemical reactions, and finally deals with solvent transport, analysis, purification, and recovery. The space allotted to the present review does not leave roo for appraisal of other good smallom articles in Vol. 12. The articles on sodium carbonate and sodium hydroxide (19 pp.) and sodium chloride (20 pp.) are particularly good.

Volume 13 contains 26 articles of which the section on pharmatherapeutics (165 pp.) is especially noteworthy. After antibiotics, antihistamines, chemotherapeutics (antiseptics), homeopathic medicines, drugs, enzymes, hormones, and medicinal preparations had already heen dealt with in previous volumes, the wide field of medicaments has undergone comprehensive revision in this article. The main theme is the classical field of chemical medicaments which have chiefly symptomatic action; these are arranged according to the points of attack on the body. The presentation is comprehensive and takes into account modern development up to 1963. Thirty-three specialists from 9 companies in the chemical-pharmaceutical industry, including the Swiss firms Hoffmann-La Roche, Ciba, and Sandoz, have cooperated on this article. The individual sections contain general introductions on physiological and chemical aspects. A large number of substances are characterized under chemical properties, method of preparation, and commercial products. Since the article is of great interest in providing general information to chemists who are not experts on drugs, a short glossary with explanations of certain terms would also he worthwile here. Likewise, the brief hut pregnant article on parasitic infections falls into the medicinal field (8 pp.). In the discourse on the Pärchenegel (Schistosomiasis) one misses the name Bilharzia; the more familiar name of the disease Bilharziosis should also be mentioned.

Especially noteworthy in Volume 13 is the article on photography (92 pp.) under the direction of *H. Ulrich* and *E. Klein* from Agfa Leverkusen, in which further 13 specialists have cooperated. In its concise account covering the entire field of photography from elementary photographic processes via raw materials and production problems to application technique, the article is highly instructive. Here again fundamental to detailed relationships are set forth; *e.g.* timing arrangements and examples of recipes are given for the 13 processing stages in the development of cine color film. In this article, too, the commercial information is again limited to a scant table on the production and export and import in the German Federal Republic. For the technically interested reader, however, commercial statistics are important characteristic values from which he can measure the relative importance of various fields of work and production methods and record them in his mind. The paragraph on commercial aspects is generally too brief. This surely deserves a good treatment similar to that, for example, of the chapters on the toxicology of pigments so excellently prepared by *H. Oettel*. Along with Vol. 13, a new subject index for Volumes 3–13 has been published (Vols. 1 and 2 are not alphabetically arranged). It is to be replaced at a later date by a complete subject index of the alphabetically arranged part. In consideration of the vast amounts of subject matter arranged non-alphabetically within the large individual articles, increased importance must be attached to this strictly alphabetically arranged index. Once again, the editors have profited from the experience gained in compiling the earlier subject indices. The new subject index contains 24000 keywords which are fairly evenly distributed over the whole field, so that the location of required information no longer presents any difficulties.

In summary it can be said that in this encyclopaedia a new kind of differentiated hut editorially coordinated collaboration of specialists has been realized. The result is a very versatile work of reference which provides authoritative material and which despite its versatility and abundance of detail still remains handy for the user. It is hoped that the work will make rapid progress towards completion.

*H. Sachsse* [NB 213/95 IE]

# Structure and Acidity of Organic Compounds [1]

BY PRIV.-DOZ. DR. W. SIMON

LABORATORIUM FÜR ORGANISCHE CHEMIE
DER EIDGENÖSSISCHEN TECHNISCHEN HOCHSCHULE, ZÜRICH (SWITZERLAND)

*Elucidation of the structures of organic acids and bases with the aid of their acidity constants is greatly hindered by their low solubilities in water and by the small quantities of material normally available. Apparent acidity constants K* can be determined potentiometrically on small samples (about 0.5 mg) for many classes of compounds of medium acidity. The apparent acidity constants $K^*_{MCS}$ determined in the solvent system methyl cellosolve/water can be correlated, in a similar manner to thermodynamic quantities, with structural parameters (e.g. Hammett's σ and Taft's σ* values). $K^*_{MCS}$ values can yield information on the axial or equatorial position of carboxyl groups in cyclohexanecarboxylic acids.*

## I. Introduction

Some excellent reviews have been written on the relationships between structure and acidity of a wide range of compounds [2–5].

In this connection acids and bases are defined according to *Brønsted* [6] and *Lowry* [7] as proton donors and proton acceptors, respectively, so that acid-base equilibria in an amphiprotic [8] solvent LH of high dielectric constant may be formulated as follows:

$$AH + LH \rightleftarrows A^{\ominus} + LH_2^{\oplus} \qquad (1)$$

In Equation (1), AH is the acid to be investigated and $A^{\ominus}$ the base formed from AH by the removal of a proton. No assumptions will be made regarding the nature of AH and $A^{\ominus}$; it should merely be noted that $A^{\ominus}$ contains one hydrogen atom less, and carries one unit charge more, than AH. The pairs $AH/A^{\ominus}$ and $LH_2^{\oplus}/LH$ are referred to as conjugate acid-base pairs. For the equilibrium constant

$$K' = \frac{a_{A^{\ominus}} \cdot a_{LH_2^{\oplus}}}{a_{AH} \cdot a_{LH}} = \frac{c_{A^{\ominus}} \cdot f_{A^{\ominus}} \cdot c_{LH_2^{\oplus}} \cdot f_{LH_2^{\oplus}}}{c_{AH} \cdot f_{AH} \cdot c_{LH} \cdot f_{LH}} \qquad (2)$$

(a = activity; c = concentration; f = activity coefficient)

obtained by applying the law of mass action to Equilibrium (1), the following relationship is valid:

$$\Delta F = -2.303\ RT \log K' = 2.303\ RT\ pK' \qquad (3)$$

According to Equation (3), the pK′ value of the acid AH is directly proportional to the change in free energy ΔF of the acid-base reaction of Equation (1):

$$\Delta F = \Delta H - T\Delta S \qquad (4)$$

For a change in ΔF of 1.0 kcal/mole at 25 °C, Equation (3) gives a change in pK′ of 0.73 units. In principle, both ΔF (or pK′) and ΔH can be correlated with the structure of the compound studied. However, opinions are divided as to which of the two quantities is the more suitable one [3, 9–14].

Quantitative investigations on acid-base equilibria are generally carried out on systems in which relatively small quantities of AH are allowed to react with a large quantity of solvent LH. The activity $a_{LH}$ of LH at constant temperature and pressure may therefore be regarded as constant, and the dissociation constant is obtained from Equation (2):

$$K = K' \cdot a_{LH} = \frac{a_{A^\ominus} \cdot a_{LH_2^\oplus}}{a_{AH}} = \frac{c_{A^\ominus} \cdot f_{A^\ominus} \cdot a_{LH_2^\oplus}}{c_{AH} \cdot f_{AH}} \quad (5)$$

Instead of the pK value (pK = −log K) of an acid-base pair, the so-called basicity constant ($pK_B$) is sometimes used. In contrast to the pK value, this constant applies to an equilibrium of the type:

$$B + LH \rightleftarrows BH^\ominus + L^\ominus \quad (6)$$

To avoid confusion, this terminology will be avoided here as far as possible. Consequently, in the remainder of this article the basicity of the base B will be defined by the acidity of the conjugate acid $BH^\oplus$. Thus, for the acid $BH^\oplus$ there is an acid-base equilibrium similar to Equation (1):

$$BH^\oplus + LH \rightleftarrows B + LH_2^\oplus \quad (7)$$

## II. Determination of Acidity Constants

Routine determinations of dissociation constants are generally carried out by potentiometric or spectrophotometric methods [15]. In the potentiometric method the activity of the hydrogen ions is measured potentiometrically (*e.g.* with a glass electrode/calomel electrode combination [16]) for a given ratio $c_{A^\ominus}/c_{AH}$. Assuming that $f_{A^\ominus}/f_{AH} = 1$, the constant K can then be calculated from Equation (5). Errors due to neglect of the activity coefficients are about 0.05 pK units [17] for 1:1 electrolytes in aqueous systems with sample concentrations of 0.01 M. The ratio $c_{A^\ominus}/c_{AH}$ can be adjusted by mixing a given amount of the acid with varying amounts of its salt. At the half-neutralization point in the potentiometric titration [18–22] $c_{A^\ominus} \approx c_{AH}$ and $c_{A^\ominus}/c_{AH} \approx 1$, so that at this point the pH value of the solution ($pH = -\log a_{LH_2^\oplus}$) is equal to the pK of AH [cf. Equation (5)].

In spectrophotometric determinations of pK values [15,23–26], the sample is generally dissolved in a system of constant hydrogen ion activity (buffer solution), and the ratio $c_{A^\ominus}/c_{AH}$ is obtained by spectrophotometry. If the pH of the solution is known, K can be calculated from Equation (5), ignoring activity coefficients. Constants which have been obtained applying this approximation are often called apparent dissociation constants.

In the systematic determination of dissociation constants for qualitative analysis of organic natural products, two main restrictions must be considered:

a) It should be possible to carry out the measurements on small quantities of sample (0.3–1.5 mg).

b) Owing to the low solubility of most organic compounds in water, the determinations must be carried out in non-aqueous solvents.

Under these conditions, determinations of thermodynamic dissociation constants K must be abandoned in favor of those of apparent acidity or dissociation constants K*. Potentiometric microtitration [20,22,27] is the most suitable method for rapid routine determinations.

Solvents used so far include: alcohol and alcohol/water [28 to 32], ethylene glycol mixed with other organic solvents [33–35], acetonitrile [36–38], dimethylformamide [39–41], cyclohexanone [42], dioxane/water [43–45], benzene [46], nitrobenzene [36,48], acetone [47,49], pyridine [50,51], glacial acetic

acid [52, 53], and methyl cellosolve [27, 54]. In these solvents the results of potentiometric determinations of acidity constants are reproducible only if all operations of the determination procedure are highly standardized [55, 56].

A standard method has been developed in our laboratory for the determination of apparent dissociation constants in the system methyl cellosolve/water (80:20% by weight), using samples of 0.1 mg and more [*]. The compound to be investigated is titrated according to a predetermined program using a glass-electrode/calomel-electrode combination which has been conditioned in water and calibrated with aqueous buffer solutions. The apparent pH of the solution [**] at half-neutralization of the functional group to be determined is assumed to be equal to $pK^*_{MCS}$, *i.e.* equal to the negative decadic logarithm of the apparent acidity constant $K^*_{MCS}$(MCS: methyl cellosolve, ethylene glycol monomethyl ether $CH_3OCH_2CH_2OH$).

Details of the standard method can be obtained from earlier publications [20, 55–60]. The standard deviations found for a single determination were 0.07 [58] and 0.04 $pK^*_{MCS}$ units [58] for semi-automatic [20] and fully automatic [56] titrations, respectively. With the semi-automatic titration equipment, 1 ml of a $3\times10^{-3}$ to $4\times10^{-3}$ M solution is normally titrated at a constant speed, and the neutralization curve is plotted simultaneously [20, 61]. The $pK^*_{MCS}$ values of well over a thousand organic acids and bases have been published so far [63–65].

[*] Methyl cellosolve is a good solvent for many compounds. Admixture of 20% by weight of water increases the stability of the potential of the glass electrode, without greatly reducing its universal solvent power.

[**] Measured in accordance with the definition of pH values on the so-called practical pH scale [16, 57]. According to this scale, the pH values of aqueous solutions are determined on the basis of pH standards. By analogy, the apparent pH of the sample ($pH^*_{MCS}$) is defined with reference to a standard buffer solution as follows:

$$pH^*_{MCS} = pH_s - \frac{(E-E_s)}{0.05916}$$

where

$pH_s$ = 4.005 (pH of 0.05 M potassium hydrogen phthalate at 25 °C);

E = electromotive force [abs. volts] obtained at 25 °C with the electrode system in the solution being investigated;

$E_s$ = electromotive force [abs. volts] obtained at 25 °C with the electrode system in 0.05 M potassium hydrogen phthalate in water.

$E_s$ and E are given the sign of the conductor system of the glass electrode.

The denominator 0.05916 corresponds to the theoretical electrode function; it is adjusted to match the electrode function determined in aqueous systems.

Figure 1 shows the glass-electrode/calomel-electrode measuring cell with an interchangeable electrode membrane (cup-type electrode) [20, 60, 62], which serves as titration vessel, and a piston burette with a digital readout; the titrant is displaced from the burette by means of a tantalum piston (normal rate of titration: 1.4 µl/min). A control unit starts and stops the titration and controls the flow of nitrogen for agitation of the solution. The signal of the pH meter [Type 7666, Leeds & Northrup Co., Philadelphia, Pa. (U.S.A.)] is registered by a strip chart recorder [Speedomax Type G, Leeds & Northrup Co.].

## III. Interpretation of Apparent Acidity Constants

At constant temperature and pressure the apparent acidity constants K* determined by the method outlined above are functions of the structure of the compound under investigation, as well as of the solvent, concentration, and determination procedure. These constants K* no longer have the well-defined thermodynamic significance of an equilibrium constant in the sense of Equations (2)–(5). Standardization (solvent, concentration, determination procedure, temperature, and pressure are kept constant) leads however to $pK^*_{MCS}$ values which depend only on the structures of the compounds under investigation. Since conclusions are to be drawn from these apparent acidity constants $K^*_{MCS}$ regarding the structure of organic compounds, the question arises as to how far it is justifiable to interpret these $pK^*_{MCS}$ values in a manner analogous

to thermodynamic pK values. It has been shown that such an analogous interpretation is justified [66, 67].

As an example, Figure 2 shows the $pK^*_{MCS}$ values for *m*- and *p*-substituted benzoic acids, phenols, and salicylic acids plotted as a function of the corresponding Hammett σ values [66] (which are independent of the

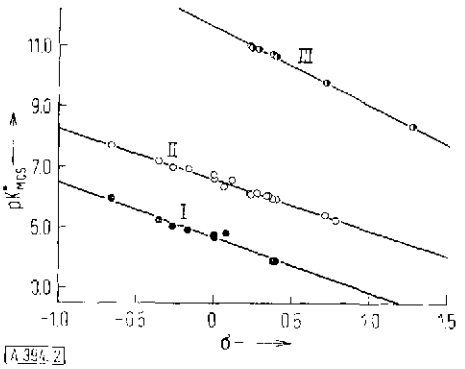

Fig. 2. $pK^*_{MCS}$ values for benzoic acids, phenols, and salicylic acids as a function of the corresponding Hammett σ values.
Curve I: Salicylic acids: 4-$NH_2$; 4-OH; 4-$OCH_3$; 4-$CH_3$; 5-OH; 3-OH; 4-$C_6H_5$—CONH; 5-Cl; 5-Br.
Curve II: Benzoic acids: *p*-$NH_2$; *p*-OH; *p*-$OCH_3$; *m*-$NH_2$; *m*-OH; H; *p*-F; *m*-$OCH_3$; *p*-Cl; *p*-Br; *p*-I; *m*-F; *m*-I; *m*-Cl; *m*-Br; *m*-$NO_2$; *p*-$NO_2$.
Curve III: Phenols: *p*-Cl; *p*-Br; *p*-I; *m*-Cl; *m*-Br; *m*-$NO_2$; *p*-$NO_2$.
(The order of the acids corresponds to the order of the plotted points, from left to right).

nature of the reaction, but depend on the type of substituent) in order to test the validity of Hammett's ρσ rule [9]

$$pK^*_{MCS} = pK^*_{MCS}(0) - \rho\sigma \qquad (8)$$

In Equation (8), the $pK^*_{MCS}(0)$ value corresponds to the $pK^*_{MCS}$ value of the unsubstituted compound. It can be seen from Figure 2 that the apparent acidity constants of the *m*- and *p*-substituted phenols, benzoic acids, and salicylic acids are affected in the same way by the substituents on the aromatic nucleus as the equilibrium and rate constants of other reactions of side-chain derivatives of benzene. The accuracy of the linear regression of the $pK^*_{MCS}$-values on σ is not significantly different from that of the corresponding K values [66].

## IV. Influence of Solvent on the Acidity Constant

The influence of the solvent used on the acidity constant is essentially due, on the one hand, to its dielectric constant DC [68], and on the other hand, to its protolytic character [69]. A basic solvent accepts a proton easier than an acidic one, so that acidity constants are higher (lower pK value) in basic solvents, *e.g.* pyridine, than in acidic solvents, *e.g.* glacial acetic acid [cf. Equation (1)]. With suitable solvents it is therefore possible to bring compounds of extremely high or low acidities into an easily measurable acid-base equilibrium with the solvent. For example, phenols can be studied in pyridine [70], and aromatic amines in glacial acetic acid [71].

In the interpretation of the effect of the dielectric constant, two fundamental types of acid-base equilibria must be distinguished:

$$AH + LH \underset{\text{(DC small)}}{\overset{\text{(DC large)}}{\rightleftharpoons}} LH_2^{\oplus} + A^{\ominus} \qquad (9)$$

$$AH^{\oplus} + LH \rightleftharpoons LH_2^{\oplus} + A \qquad (10)$$

According to the Born relationship[72], the energy required to form an ion is inversely proportional to the dielectric constant of the solvent and to the ionic radius. When a neutral acid AH dissociates, two ions are formed. This process requires more energy in organic media, as their dielectric constants are normally low compared with that of water (*e.g.* for methyl cellosolve:water (80:20 by weight) at 25 °C, DC = 32.0 [67]), so that in changing from water to organic solvents, the extent of dissociation should be expected to decrease (increase in the pK* values). For positively charged conjugate acids, the effect of the dielectric constant should be very small, since for each ion formed, another simultaneously disappears. However, some individuality should result from the different ionic radii, so that a simple correlation between the pK values determined in different media (cf. [32, 68, 73]) is not to be expected. As a result of the superposition of the effect of the dielectric constant and that of the protolytic character of the solvent, the pK* values of acids of the type shown in Equation (9) generally increase on changing from water to organic solvents, such as alcohols, glycols, and glycol ethers, while those of the type shown in Equation (10) decrease [30, 74] as a result of the increased basicity of the solvent [3].

In Figure 3, the $pK^*_{MCS}$ values of about 200 functional groups are compared with the pK values determined in water ($pK_{H_2O}$) [75]. Two regression lines can be recognized, one of which (II) can be assigned to equilibria of the type shown in Equation (9), the other (I) to that of Equation (10). As expected, the $pK^*_{MCS}$ values for the first type are higher, and those for the second type lower, than the corresponding $pK_{H_2O}$ values.

If a single regression line [76] is calculated for all the compounds considered in Figure 3, the standard deviation of the $pK^*_{MCS}$ values from this line is found to be 3.15 $pK^*_{MCS}$ units (95 % confidence limit). Calculation of the $pK^*_{MCS}$ values from $pK_{H_2O}$ — and vice versa — is thus in general completely useless. The $pK^*_{MCS}$ values can be predicted with much greater accuracy if we restrict ourselves to a single class of compounds (cf. Figure 3). Thus, for acids with an equilibrium of the type of Equation (9), the standard deviation of the $pK^*_{MCS}$ values from the regression line is 1.15 $pK^*_{MCS}$ units (95 % confidence limit). The standard deviation for acids of the equilibrium type of Equation (10) is of the same order

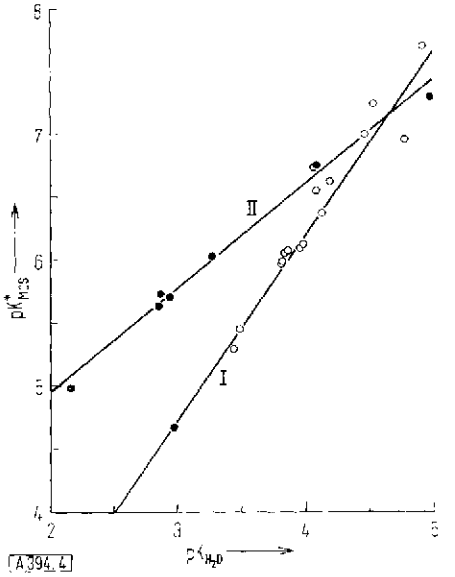
of magnitude. If we consider only classes in which the compounds are structurally closely related, *e.g.* *m*- and *p*-substituted benzoic acids (cf. Figure 4), *m*- and *p*-substituted phenols, benzenesulfanilides, anilines, *etc.*, the $pK^*_{MCS}$ values can be predicted with much greater accuracy on the basis of the $pK_{H_2O}$ values. The $pK^*_{MCS}$ values for *m*- and *p*-substituted phenols, for example, can be predicted from the $pK_{H_2O}$ values with an accuracy of 0.18–0.22 units (95% confidence limit).



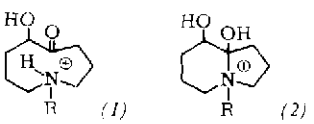


Fig. 4. Correlation of $pK^*_{MCS}$ values with $pK_{H_2O}$ values for benzoic acids [75].
Curve I: *m*- and *p*-substituted benzoic acids; *p*-$NO_2$; *m*-$NO_2$; *m*-Br; *m*-Cl; *m*-I; *m*-F; *p*-Br; *p*-Cl; *m*-OH; *m*-$OCH_3$; *p*-F; benzoic acid; *p*-$OCH_3$; *p*-OH; *m*-$NH_2$; *p*-$NH_2$.
Curve II: *o*-substituted benzoic acids; *o*-$NO_2$; *o*-Br; *o*-I; *o*-Cl; *o*-OH; *o*-F; *o*-$OCH_3$; *o*-$NH_2$.
Salicylic acid forms an exception owing to the pronounced hydrogen bonding between its *o*-hydroxyl group and its carboxylate group; it was therefore not considered in the calculation of the regression lines. The order of the acids corresponds to the order of the plotted points, from left to right.

The change in the acidity constant with the composition of the solvent can be used for the determination of the nature of the acid functions. Thus, for example, it has been shown [77] that in dimethylformamide/$H_2O$ (2:1) protonated 1-alkyl-1-azacyclononan-5-ol-6-one with

R = $CH_3$ or $C_2H_5$ exists as a bicyclic structure *(2)* and that it is the tertiary hydroxyl group which dissociates. The isopropyl and t-butyl compounds [R = $CH(CH_3)_2$ or $C(CH_3)_3$], on the other hand, are present in the monocyclic form *(1)*, and dissociation takes place at the nitrogen function [77].

## V. Acidity of Cyclohexanecarboxylic Acids

Valuable conclusions regarding the structure of cyclohexanecarboxylic acids can be drawn from their $pK^*_{MCS}$ values [78–80], since equatorial and axial carboxyl

[*] The values in this column are the differences in the pK values of *cis*- and *trans*-4-t-butylcyclohexane-1-carboxylic acids, and were determined potentiometrically. The values in the other columns were obtained from thermodynamic data in combination with the dissociation constants of unsubstituted or alkyl-substituted acids.

groups differ appreciably in acidity [81–84]. As can be seen from Table 1, the difference in the free energies of cyclohexanecarboxylic acids with axial and those with equatorial carboxyl groups is about 1.6 kcal/mole; the difference for the corresponding anions is about 2.2 kcal/mole [81,82,84]. The fact that the acidity of the axial isomer is 0.5 $pK^*_{MCS}$ units lower than that of the equatorial isomer can be attributed to hindrance of solvation of its anion by about 0.6 kcal/mole relative to the anion of the equatorial isomer [81,82,85] (cf. also [86]). This additional hindrance of solvation is essentially due to interactions with axial substituents in the γ-positions with respect to the axial carboxyl group (1,3-interactions) [cf. Formula *(3)*].

*(3)*

On the assumption that the effects of these axial substituents are additive, the $pK^*_{MCS}$ increment for one axial hydrogen atom in γ position to an axial carboxyl group is 0.25 units, relative to the acid without such an interaction. Within the range of validity of this assumption, it should be possible to estimate the $pK^*_{MCS}$ values by counting the 1,3-interactions [78–80]. The prediction of the $pK^*_{MCS}$ values of cyclohexanecarboxylic acids can be extended by taking into account the effects of substituents in the α-position relative to the carboxyl group.

Some indication of the effect of substituents R on the acidity of carboxylic acids of the type R–COOH is given

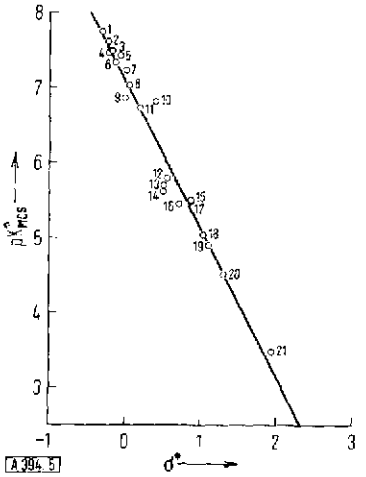

Fig. 5. $pK^*_{MCS}$ values of acids R–COOH as a function of the polar substituent constants σ*.
1: Pivalic acid; 2: Diethylacetic acid; 3: Cyclohexanecarboxylic acid; 4: α-Methylbutyric acid; 5: Cyclohexylacetic acid; 6: Isovaleric acid; 7: γ-Phenylbutyric acid; 8: β-Phenylpropionic acid; 9: Acetic acid; 10: Diphenylacetic acid; 11: Phenylacetic acid; 12: Glycolic acid; 13: Methoxyacetic acid; 14: Formic acid; 15: Iodoacetic acid; 16: Mandelic acid; 17: Phenoxyacetic acid; 18: Chloroacetic acid; 19: Fluoroacetic acid; 20: Cyanoacetic acid; 21: Dichloroacetic acid. in Figure 5, in which $pK^*_{MCS}$ values are plotted as a function of Taft's polar substituent constants σ* [10] [cf. Equation (8)]. If a hydrogen atom on the carbon atom α to the carboxyl group is replaced by a methyl group, or if ring fusion takes place in the α-position, σ* changes by −0.10 to −0.12 units [10], corresponding to a mean increment in $pK^*_{MCS}$ of 0.22 units [cf. Figure 5].

Since the $pK^*_{MCS}$ value of cyclohexanecarboxylic acid is 7.44 [87], the $pK^*_{MCS}$ values of alicyclic monocarboxylic acids can be estimated, under certain assumptions, using the following rule [78–80]:

$$pK^*_{MCS} = 7.44 + 0.25\,a + 0.22\,b \qquad (11)$$

where a: number of 1,3-interactions; and
b=1 for an α-$CH_3$ or for ring-closure in the α-position;
b=0 for α-H.

Since the equilibrium contribution of the epimeric cyclohexanecarboxylic acid with an axial carboxyl group is only about 5 %, it may be neglected within the limits of accuracy of the $pK^*_{MCS}$ determinations (standard deviation s = 0.04 or 0.07 $pK^*_{MCS}$ units [88]). The rule given in Equation (11) for the evaluation of $pK^*_{MCS}$ values has so far been found to be valid for 60 compounds, some of which were very complex, *e.g.* vinhaticoic acid *(4)* [*]. No exceptions are yet

known. The standard deviation of the calculated values from the measured ones is 0.11 $pK^*_{MCS}$ units; the largest deviation observed was 0.24 $pK^*_{MCS}$ units.

For example, the rule expressed by Equation (11) was used for the determination of the structures of two isomeric decalincarboxylic acids *(5a)* and *(5b)* [m.p. 51 and 142–143 °C, respectively] prepared by *Brown* [89]. The problem was that of assigning the *cis* and *trans* ring

$pK^*_{MCS}$ calc. 8.66, found 8.86 — $pK^*_{MCS}$ calc. 8.16, found 8.30

fusion. Titration of 0.7 mg of each compound yielded the answer within an hour. On the basis of a comparison of the measured $pK^*_{MCS}$ values with the calculated ones, the compound which melts at 51 °C must be assigned the *trans*-ring fusion.[k] Definite assignment would hardly have been possible by other methods, and would certainly have required considerably more effort [89] (cf. also [90–97]).

## VI. The $pK^*_{MCS}$ Range

The maximum usable $pK^*_{MCS}$ range is determined by titration of a strong acid and titration of a strong base (hydrochloric acid and tetramethylammonium hydroxide) [*]. According to *Auerbach* and *Smolczyk* [98], two inflections are recognizable in the titration curves of dicarboxylic acids when the difference in pK of the two carboxyl groups is at least 1.2. Accordingly, an inflection should be discernible in the titration curve of an acid or base, when the $pK^*_{MCS}$ values are 1.2 units or more within the $pK^*_{MCS}$ range. The limiting values shown in Table 2 agree well with the observed values.

Table 2. $pK^*_{MCS}$ range for acid-base titrations in methyl cellosolve/$H_2O$ (80:20 by weight) [75].

| | |
|---|---|
| Maximum $pK^*_{MCS}$ range | 12.3–2.5 |
| Extreme $pK^*_{MCS}$ values at which inflections in the titration curve are still recognizable | 11.1–3.7 |

The $pK^*_{MCS}$ ranges for various classes of compounds are shown in Figure 6 [75]. The limiting $pK^*_{MCS}$ values for each class of compounds were in part determined experimentally; in some cases the range was calculated

1 and 2: Aliphatic dicarboxylic acids $HOOC-(CH_2)_n-COOH$, $pK_1$ and $pK_2$; 3 and 4: Phthalic acids $HOOC-C_6H_4-COOH$, $pK_1$ and $pK_2$; 5: Saturated aliphatic monocarboxylic acids $H-(CH_2)_n$ COOH; 6: Aliphatic monocarboxylic acids with a substituent in the α-position and a conjugation barrier between the substituent and carboxyl group; 7: Cyclohexanecarboxylic acids without an additional heteroatom; 8: Benzenesulfanilides $C_6H_5-SO_2-NH-C_6H_4X$ (X in the *m*- or *p*-position); 9: Benzenesulfanilides $X-C_6H_4-SO_2-NH-C_6H_6$ (X in the *m*- or *p*-position); 10: *m*- and *p*-substituted phenols; 11: *m*- and *p*-substituted benzoic acids; 12: 3-, 4-, or 5-monosubstituted salicylic acids; 13: Primary aliphatic amines n-alkyl-$NH_2$; 14: Secondary aliphatic amines $(n\text{-alkyl})_2NH$; 15: Tertiary aliphatic amines $(n\text{-alkyl})_3N$.

using the Hammett equation [9], *e.g.* for *m*- and *p*-substituted benzoic acids, phenols, disubstituted benzoic acids, and benzenesulfanilides, or the Ingold-Taft equation [10], *e.g.* for α-monosubstituted alkanoic acids.

## VII. Acidity Measurements in Acetic Acid

It can be seen from Figure 6 and Table 2 that differentiation between the acidities of very strong and very weak acids and bases is not possible in the solvent system methyl cellosolve/water (80:20 by weight). This

[*] The $pK^*_{MCS}$ range is governed by the levelling effect of the solvent. The alkali error of the glass electrode should be negligible under the experimental conditions.

[98] *F. R. Auerbach* and *E. Smolczyk*, Z. physik. Chem. *110*, 65 (1924).

requires the use of solvents with other levelling properties [8], *i.e.* other proton-donor and proton-acceptor properties. However, potentiometric pK* determinations according to the standard procedure described are possible only if electrode systems can be found which are suitable to measure the activity or concentration of the protonated solvent [$LH^{\oplus}_2$ in Equation (1)] in these solvents. It has been shown that certain glass electrodes satisfy this requirement for the solvents acetic acid, acetic acid/0.5 % water [99–102], and methyl isobutyl ketone [102]. Thus, in acetic acid with a water content of 0–0.5 % by weight, the glass electrode responds quantitatively over a wide acidity range to the concentration of protonated acetic acid (symholized by $[AcOH_2^{\oplus}]$), so that the quantity:

$$-\log [AcOH_2^{\oplus}] = pH_{AcOH} \qquad (12)$$

can be determined in the same manner as the pH of aqueous systems.

Acid-base equilibria in solvents of low dielectric constants are not easy to interprete, owing to the presence of ion-pairs and other associates. For example, in a solvent such as acetic acid (DC – 6.2 at 25 °C [107]), an acid AH forms an ion-pair:

$$AH + AcOH \rightleftharpoons AcOH_2^{\oplus}A^{\ominus} \qquad (13)$$

with the ionization constant

$$K_i^{AH} = \frac{[AcOH_2^{\oplus}A^{\ominus}]}{[AH]}$$

The ion-pair dissociates according to

$$AcOH_2^{\oplus}A^{\ominus} \rightleftharpoons AcOH_2^{\oplus} + A^{\ominus} \qquad (14)$$

with the dissociation constant [53,103–106]:

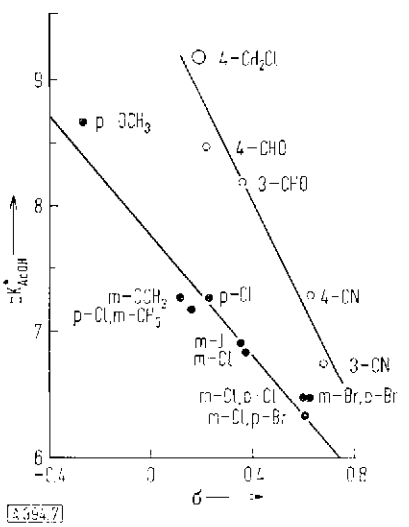
$$K_d^{AH} = \frac{[AcOH_2^{\oplus}]\,[A^{\ominus}]}{[AcOH_2^{\oplus}A^{\ominus}]}$$

In order to avoid misunderstanding in the characterization of acid-base equilibria in non-aqueous media, the expressions "ionization constant" and "dissociation constant" have been avoided in favor of the non-commital term "acidity constant" [cf. Equation (5)].

By analogy to the standard method for the determination of $pK^*_{MCS}$, it is possible to determine $pK^*_{AcOH}$ values which correspond essentially to the $pH_{AcOH}$ value of the half-neutralized sample [99,101]. If the pressure, temperature, sample and water concentrations, parameters of the apparatus, and determination procedure, are kept constant or are standardized, $pK^*_{AcOH}$ values are obtained which under certain conditions are essentially a function of the "overall dissociation constant" $K_{AH}$ of the acid AH (or base) under investigation [99,101]:

$$K_{AH} = \frac{[AcOH_2^{\oplus}]\,[A^{\ominus}]}{[AH] + [AcOH_2^{\oplus}A^{\ominus}]} = \frac{K_i^{AH} \cdot K_d^{AH}}{1 + K_i^{AH}} \qquad (15)$$

The strength of an acid AH in solvents of low dielectric constant is expected to be determined by the ionization constant $K_i^{AH}$ [105] assigned to the equilibrium of Equation (13). The constant $K_{AH}$ is in turn related to this ionization constant $K_i^{AH}$ and to the dissociation constant $K_d^{AH}$ of the equilibrium (14) by Equation (15). Since $K_d^{AH}$ is of the same order of magnitude for various acids (about $10^{-7}$) [104], $pK^*_{AcOH}$ values are mainly determined by the values of $K_i^{AH}$, and can therefore be correlated with the structure of organic compounds, analogously to other equilibrium constants, as shown, for example, in Figure 7. Similar considerations naturally also apply to bases B.



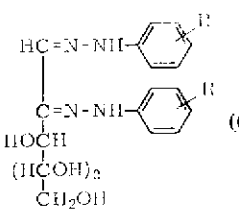


Fig. 7. $pK^*_{AcOH}$ values of pyridines (o) and glucose phenylosazones *(6)* (●) as a function of the Hammett substituent constant σ.

The lines were obtained by calculating linear regressions, assuming equal standard deviations for the individual experimental values [76]. From Helv. chim. Acta *45*, 962 (1962).

(6)

It is thus now possible, using new standard procedures, to carry out routine measurements of acid-base equilibria on small amounts of compounds having very high or low acidity [99,101].

# Surface Oxides of Carbon

BY DOZ. DR. H.-P. BOEHM, DR. E. DIEHL, DIPL.-CHEM. W. HECK, AND DIPL.-CHEM. R. SAPPOK

ANORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT HEIDELBERG (GERMANY)

*On oxidation of graphitic carbon, acidic surface oxides (or hydroxides in the presence of water) are formed at the boundaries of the carbon layers. It was found that the reaction of oxygen with microcrystalline carbon at 400–450 °C yields four groups of different acidities. One strongly acidic group and one weakly acidic carboxyl group have been detected, as well as a phenolic hydroxyl group; a carbonyl group is probably also present. With dissolved oxidizing agents, one equivalent of another strongly acidic carboxyl group is formed in addition at room temperature. The possible constitutions of the acidic surface oxides are discussed. Chemically detectable surface oxides are also formed on the surface of diamond. In the presence of oxygen at 800–900 °C under reduced pressure, diamond is transformed into black carbon. Surface oxides play a part in this transformation.*

## I. Introduction

The crystalline forms of elemental carbon are diamond and graphite. All the carbon aroms within the three-dimensional diamond lattice or the graphite layer structure are joined by covalent bonds. The free valences at the surface can be saturated by oxygen, for example, surface compounds being formed.

Surface oxides affect the properties of carbon surfaces, *e.g.* their wettability, the adsorptive power of active charcoal, or the dispersibility of ink blacks. The carbon blacks used as reinforcing fillers in rubber also invariably contain surface oxides [*]. Moreover, surface oxides of carbon play an important part as oxygen-transfering agents in atmospheric oxygen electrodes. The acidity and redox behavior of surface oxides can be used for the removal of salt from sea-water [1].

The surface oxides of microcrystalline black carbon have often been described. Active charcoal reacts with oxygen at temperatures as low as 300 °C, and part of the oxygen consumed remains bound to the surface, being liberated as CO and $CO_2$ only on subsequent heating [2, 3]. Surface oxides of carbon give a basic or acidic reaction, according to the conditions under which they are prepared [4].

If black elemental carbon is freed from all surface compounds by heating *in vacuo* followed by cooling in the absence of oxygen, its surface becomes covered with basic surface oxides on access of oxygen [5]. The constitution of these oxides is not yet known in detail.

Acidic surface oxides are formed on oxidation with oxygen at high temperatures or with dissolved oxidizing agents, *e.g.* NaOCl; these have been studied in much greater detail [6, 7]. The present article is a contribution to the knowledge of acidic surface oxides.

## II. Starting Material

Microcrystalline carbon is more suitable than graphite for investigations of the surface oxides of graphitic carbon, since its specific surface area is much larger. Hence it can bind correspondingly larger quantities of oxygen.

Black microcrystalline carbon, formerly referred to as "amorphous" carbon, is well known, *e.g.* in the form of active charcoal, carbon black, and carbon electrodes, and consists of extremely small crystallites built up, like graphite, of layers of six-membered carbon rings. These layers are stacked together in piles, but do not possess the mutual three-dimensional orientation observed in the graphite lattice. The distance between layers is larger than in graphite (3.44–3.65 Å and 3.354 Å, respectively). *Hofmann* et al. [8, 9] found that typical active charcoal contains layers with a diameter of ca. 30 Å; the average height of the stacks is 10–13 Å.

In our work we used mainly carbons prepared from sugar charcoal [10], since this can be obtained in very

[*] The surface oxides do not appear to be directly responsible for the reinforcing effect, since other finely divided substances, *e.g.* Aerosil® (silica which is morphologically very similar to the carbon blacks) have a similar action. However, many of the properties of carbon blacks are affected by surface oxides; for example, channel blacks in aqueous suspension give an acidic reaction, furnace blacks and thermal blacks give a basic reaction. How surface oxides affect the vulcanization and properties of the rubber has not yet been entirely explained.

pure form. To make the pores as large as possible, thus ensuring easy accessibility to the surface, the sugar charcoals were "activated" by oxidation with $CO_2$ at 950 °C. In this way, individual crystallites are burned out of the structure. The specific surface area reaches a maximum when the loss by burning is about 50 %; it is only slightly affected by further oxidation [8, 11]. The products were partly coked, *i.e.* heated at 1100 °C in pure nitrogen. This treatment eliminates the greater part of the oxygen and hydrogen which they contain. The specific surface areas of activated and coked sugar charcoals were found by *Brunauer, Emmett*, and *Teller* [12] by nitrogen adsorption to be 900–1100 $m^2/g$. Technical active charcoal and a few typical carbon blacks were also investigated.

The products were coated with surface oxides either by exposing them to air during the cooling stage following activation or by oxidation in oxygen for 5–20 hours at 400–450 °C [13]. Cooling of the activated sugar charcoal in pure $CO_2$ gave only basic surface oxides.

In the "wet oxidation" method, the products were subjected to prolonged stirring with solutions of NaOCl, $KMnO_4$, or $(NH_4)_2S_2O_8$, followed by thorough washing. The $MnO_2$ which was formed in the oxidation with $KMnO_4$ was dissolved out by boiling with hydrochloric acid.

Crude sugar charcoal heated to a maximum of 450 °C was often also studied for comparison, although it is not pure carbon. However, its X-ray diffraction diagram still shows the characteristic reflexes of microcrystalline carbon.

## III. Chemical Reactions

### 1. Neutralization of the Acidic Groups

Direct potentiometric titration of the acidic surface oxides is difficult, since the end value of the potential is often attained only after long periods. We therefore determined the acidity by neutralization with bases of various basicities. The most suitable of these were $NaHCO_3$, $Na_2CO_3$, NaOH, and $NaOC_2H_5$. In 0.05 to 0.1 N solution, each of these bases gave characteristic maximum consumptions for neutralization. With higher concentrations of base, only sodium ethoxide gave a slight increase in consumption. Thus, in each case, only those acidic groups which were much more strongly dissociated than the conjugate acids of the bases were completely neutralized.

The pK values of the conjugate acids are: 6.37 and 10.25 for the first and second dissociations of carbonic acid, 15.74 for water, and 20.58 for ethanol.

Surprisingly, the quantities of bases neutralized generally bear simple, whole-number relationships to one another (cf. Table 1). In principle, all types of carbon

[**] By difference.

show the same behavior, but the simple numerical relationships are found only with completely oxidized products. Twice as many acidic groups are neutralized by $Na_2CO_3$ as by $NaHCO_3$. The differences between the quantities of NaOH and $Na_2CO_3$ used, and between the quantities of $NaOC_2H_5$ and NaOH used, are approximately equal to the quantity of $NaHCO_3$ used. If the amounts required for neutralization of various samples did not quite agree, the groups neutralized with $NaHCO_3$ and those neutralized with NaOH alone, as well as the groups neutralized with $Na_2CO_3$ and those neutralized with $NaOC_2H_5$, usually occurred none the less in equivalent quantities.

Activated or coked products which had not been oxidized neutralized practically no sodium hydroxide. Carbon blacks required more ethoxide than was expected. Carbon black contains appreciable quantities of disordered, tetrahedrally bonded carbon [14], which readily forms alcoholic or aldehydic groups which react with sodium ethoxide.

The agreement between these whole-number ratios of the quantities of base required for neutralization do not appear to be fortuitous, but rather indicates the presence of equivalent quantities of (at least) four different types of acidic groups of definite acidities. Thus, all four functions are probably constituents of a larger grouping. We shall refer to the groups as I to IV in order of increasing acidity, *e.g.* group II is neutralized only by $Na_2CO_3$ (or stronger bases), but not by $NaHCO_3$.

The simple numerical ratios observed in the neutralization experiments were also found in many other reactions. Thus, for example, the various carbon preparations were treated with a solution of KI and $KIO_3$. This solution reacts with $H^+$ ions with liberation of equivalent quantities of iodine; the pH of the solution remains at 7.5. The quantity of iodine

liberated by the acidic surface oxides was always equivalent to the quantity of $NaHCO_3$ required for neutralization.

The ratios of the neutralization values after "wet" oxidation at low temperatures were somewhat different (Table 2). Here two groups which could be neutralized with $NaHCO_3$ were formed for every one group which could be neutralized with $Na_2CO_3$, NaOH, or $NaOC_2H_5$.

Table 2. Neutralization of the acidic surface oxides on wet-oxidized products.

| Product | Consumption [meq./100 g] | | | |
|---|---|---|---|---|
| | $NaHCO_3$ | $Na_2CO_3$ | NaOH | $NaOC_2H_5$ |
| SC 12, act. coked, ox. $KMnO_4$ | 61 | 89 | 125 | [illegible] |
| Eponite, coked, ox. $KMnO_4$ | 79 | 116 | 160 | 220 |
| Eponite, coked, ox. NaOCl | 107 | 163 | 214 | 262 |
| Eponite, coked, ox. $(NH_4)_2S_2O_8$ | 145 | 203 | 269 | 339 |
| CK 3, coked, ox. $(NH)_2S_2O_8$ | 21 | 30 | 36 | 57 |

Thus, the quantities of base required for neutralization are in ratios of 2:3:4:5. On subsequent heating, one of the two more strongly acidic groups is destroyed with liberation of the equivalent quantity of $CO_2$; this process starts at about 200 °C. The titrant ratios are then again found to be 1:2:3:4. The other groups are successively broken down at somewhat higher temperatures.

Again, the simple whole-number ratios were observed only after repeated, complete oxidation. The oxidation was complete as soon as small quantities of a brown colloid separated from the solid phase in alkaline media. Group IV and one of the two groups I are formed first in the oxidation, and group III and the second of the more strongly acidic groups I last (with simultaneous increase in the quantities of the other groups).

## 2. Methylation of the Acidic Groups

### a) *With Diazomethane*

The reaction with diazomethane has often been used for assaying acidic surface oxides [6, 15, 16]. Some of the resulting methoxyl groups can be readily hydrolysed with hot dilute hydrochloric acid.

The methylation was carried out using diazomethane, dissolved in some cases in dry ether and in others in ether saturated with water. As may be seen from comparison of Tables 1 and 3, the individual neutralization values are not accidentally governed by the strengths of the bases chosen. All the acidic groups which could be neutralized with NaOH, *i.e.* groups I–III, were methylated in dry ether. On the other hand, the methoxy values found after methylation in aqueous ether corresponded to the quantity of ethoxide required for neutralization. As expected, the methoxy values obtained with crude sugar charcoals in aqueous ether corresponded to the sum of the NaOH and $NaHCO_3$ consumptions.

The methoxyl groups which remained after hydrolysis with hot dilute hydrochloric acid corresponded, with only one exception, to group III, *i.e.* to the group which is neutralized by NaOH but not with $Na_2CO_3$. This behavior implies the presence of phenols. All the hydrolysable methoxy groups in the products which had been methylated in dry ether must have been esters of carboxylic acids or groups of similar acidity. The extra methoxy groups formed when moist ether is used in place of dry ether were not stable to hot dilute hydrochloric acid, and are not, therefore, methyl ethers of an alcohol.

Diazomethane generally forms readily hydrolysable methyl esters with carboxylic acids, but non-hydrolysable phenolic ethers with phenols. Diazomethane reacts with alcohols only in the presence of catalysts such as $BF_3$, $ZnCl_2$ [17], or $H_2O$ [18]: lactones of the fluorescein type are rearranged to their quinonoid form with methylation of the carboxyl groups [19].

After hydrolysis, the neutralization behavior towards $NaHCO_3$ and $Na_2CO_3$ remained unchanged, but the NaOH consumption fell to the $Na_2CO_3$ value (Table 3). This behavior was the same, regardless of whether the methylation had been carried out in dry or aqueous ether.

Table 3. Methylation of acidic surface oxides with diazomethane.

| Product | Methoxy groups [meq./100 g] [*] | | | Consumption of base [meq./100 g] after hydrolysis | | |
|---|---|---|---|---|---|---|
| | Total | non-hydrolysable | hydrolysable | $NaHCO_3$ | $Na_2CO_3$ | NaOH |
| SC 3, coked, ox. | 124 | 43 | 81 | 40 | 84 | 81 |
| SC 1, act. ox. | 72 (92) | 30 (30) | 42 (62) | 21 | 41 | 42 |
| Sc 1, act. coked ox. | (140) | (41) | (99) | 36 | [illegible] | 69 |
| SC 1, crude | 82 (109) | 32 (30) | 50 (79) | 27 | 49 | 54 |
| Eponite, ox. | (107) | (61) | (146) | — | — | — |
| CK 3, ox. | 89 | 33 | 56 | 32 | 57 | 55 |

[*] The values in brackets are for solutions in ether saturated with water, the others for solutions in pure ether.

Dimethyl sulfate gave the same results as dry diazomethane solutions when dilute sodium hydroxide was added slowly, so that the solution always remained slightly alkaline. If the methylation was carried out in the usual fashion in strongly alkaline medium, the methoxy content corresponded to the group III content.

### b) *With Methanol*

A few products were esterified with methanol plus hydrogen chloride. The quantities of methyl esters formed were equivalent to the group I or group II contents (Table 4).

[15] *M. L. Studebaker, K. W. D. Huffmann, A. C. Wolfe,* and *L. G. Nabors,* Ind. Engng. Chem. *48*, 162 (1956).

Table 4. Esterification of acidic surface oxides with methanol and hydrogen chloride.

| Product | Content [meq./100 g] | | |
|---|---|---|---|
| | Group I [b] | Group II [c] | Methoxyl |
| SC 3, coked, ox. | 42 | 40 | 44 |
| SC 1, act. ox. | 21 | 22 | 23 |
| SC 1, act. coked, ox. | 47 | 53 | 57 |
| CK 3, ox. | 31 | 29 | 35 |
| Eponite, coked, ox. NaOCl | 107 | 56 | 60 [d] |
| Eponite, coked, ox. $KMO_4$ [a] | 14 | 15 | 16 [d] |

[a] Incompletely oxidized.

[b] The group-I content was obtained by neutralization with $NaHCO_3$.

[c] The group-II content was determined from the difference between the $Na_2CO_3$ and $NaHCO_3$ consumptions.

[d] These products had been esterified by passing a mixture of methanol vapor and nitrogen over the material at 120 °C.

Which of the two groups had been esterified was determined by the neutralization behavior of an esterified product (SC 3, coked, ox.): the $NaHCO_3$ and $Na_2CO_3$ consumptions were equal (44 and 40 meq./100 g, respectively); thus, group II had been esterified. At the same time, the sodium ethoxide consumption fell to 82 meq./100 g. The esterification of group II apparently also led to inhibition of the reactivity of group IV towards ethoxide, so that only groups II and III remained neutralizable.

## 3. Detection of Phenolic Hydroxyl Groups

The quantitative agreement between the amount of non-hydrolysable methoxy groups and the difference between the NaOH and $Na_2CO_3$ titers indicates the presence of phenols. This assumption was confirmed by reaction with two typical phenol reagents, 2,4-dinitrofluorobenzene and *p*-nitrobenzoyl chloride.

Dinitrofluorobenzene does not react with carboxylic acids, and reacts only extremely slowly or not at all with alcohols.

Table 5. Detection of phenolic hydroxy groups in acidic surface oxides.

| Product | Content [meq./100 g] | | Conversion [meq./100g] with | |
|---|---|---|---|---|
| | Group III [a] | non-hydrolysable $OCH_3$ groups | 2,4-dinitrofluorobenzene [b] | *p*-nitrobenzoyl chloride |
| SC 3, coked, ox. | 42 | 43 | 42 | – |
| SC 1, act. ox. | 29 | 30 | 30 | – |
| SC 4, act. coked, ox. | 39 | – | 37 | 40 |
| SC 1, crude | 31 | 32 | 28 | – |
| CK 3, ox. | 32 | 33 | 13 | 29 |

[a] The group-III content was found from the difference between the NaOH and $Na_2CO_3$ titers.

[b] Reaction according to [21], followed by nitrogen determination.

Very weakly acidic phenolic hydroxy groups, such as that in salicylic acid (pK 13.4), also give no reaction, but can be methylated with dimethyl sulfate [20].

The close agreement of the phenolic hydroxy contents determined by four characteristic phenol reactions can be seen from Table 5.

## 4. Detection of Carboxyl Groups

The facts that the more strongly acidic groups can be neutralized by $NaHCO_3$ and that they form hydrolysable methoxy groups suggest that these are carboxyl groups. This assumption was confirmed by other reactions.

### a) *Reaction with Thionyl Chloride*

In the reaction with thionyl chloride, part of the chlorine is bound to the carbon in a readily hydrolysable form, whereas the remainder is stable even to hot sodium hydroxide solution [13]. The readily hydrolysable chloride must be present as the chloride of a carboxylic acid. Hydrolysis occurs only very slowly with pure water, and more rapidly with alkali, especially on warming. This behavior corresponds to that of aromatic acyl chlorides.

Table 6. Reaction of acidic surface oxides with thionyl chloride.

| Product | Content [meq./100 g] | | Change in consumption of base [meq./100 g] | | | |
|---|---|---|---|---|---|---|
| | Group II | Hydrolysable Chloride | $NaHCO_3$ | $Na_2CO_3$ | NaOH | $NaOC_2H_5$ |
| SC 1, coked, ox. | 15 | 16 | – | + 20 | + 18 | 0 |
| SC 3, act. ox. | 46 | 48 | + 47 | + 45 | + 41 | – 34 |
| SC 1, act. coked, ox. | 28 | 36 | – | – | + 33 | – |
| SC 3, act. ox. red. $LiAlH_4$ | 35 | 35 | + 35 | + 35 | + 35 | – 31 |
| SC 2, crude (degassed at 100 °C) | 61 | 61 | + 70 | + 61 | + 62 | – |
| SC 2, crude (degassed at 330 °C) | 9 | 11 | – | – | – | – |
| Eponite, coked, ox. $(NH_4)_2S_2O_8$ | 30 | 31 | + 30 | + 32 | + 30 | + 8 |

The chloride titrated was equivalent to the quantity expected for group II (Table 6).

This is clearly shown by the products "SO 3, act. ox.", "SC 3, act. ox., red. $LiAlH_4$", and a partially thermally decomposed sugar charcoal "SC 2"; most other preparations contained equal quantities of group I and II acids.

The products which had been treated with thionyl chloride were titrated with the four bases. Owing to neutralization of the hydrogen chloride formed, the titer corresponded to the sum of the original neutralization figure and the hydrolysable acyl chloride. However, the products described as "activated" required less ethoxide than originally (Table 6). The decrease corresponded to half of the $NaHCO_3$ consumption of the products.

The low $NaOC_2H_5$ consumption can be explained by an assumption which was later confirmed experimentally. The more strongly acidic carboxyl groups occur in pairs on directly adjacent sites and react with thionyl chloride to form a carboxylic anhydride. Acyl chlorides and anhydrides each consume only 1 mole of sodium ethoxide:

$$-CO-Cl + NaOC_2H_5 \rightarrow -CO-OC_2H_5 + NaCl,$$

$$-CO-O-CO- + NaOC_2H_5 \rightarrow -CO-OC_2H_5 + -COONa.$$

Thus, acyl chlorides consume the same quantity of ethoxide as the free carboxylic acids, whereas anhydrides consume only half as much. The anhydrides bind two moles of NaOH.

[20] *F. Sachs* and *V. Herold*, Ber. dtsch. chem. Ges. *40*, 2714 (1907).

[21] *H. Zahn* and *A. Würz*, Z. analyt. Chem. *134*, 183 (1951).

Nothing is yet known regarding the bonding of the hydrolysis-resistant chlorine which is present in a quantity corresponding to twice the $NaHCO_3$ titer.

b) *Reaction with Ammonia*

The pK values of two adjacent carboxyl groups generally differ by 2–3 units. Consequently, the ammonium salt of the more weakly acidic carboxyl groups has a strong tendency towards hydrolysis, and decomposes readily on heating. The behavior of the carbon preparations towards ammonia can give information as to the position of their more strongly acidic groups.

"Coked" and "crude" sugar charcoals which had been treated with 0.05 N ammonia and degassed at 20 °C contain a quantity of ammonia equivalent to the $NaHCO_3$ consumption. The same results were obtained when the products were allowed to react with gaseous or concentrated aqueous ammonia and degassed at 100 °C.

In the products which had formed anhydrides on treatment with thionyl chloride, half of the group-I ammonium salts were decomposed. Thus, the more strongly acidic carboxyl groups (I) in the activated sugar charcoals occur in pairs occupying adjacent sites, so that anhydrides or imides can be formed. When products which had been treated with concentrated aqueous or with gaseous ammonia were degassed at only 20 °C, more $NH_3$ was retained, but the quantity again corresponded to the $NaHCO_3$ or $Na_2CO_3$ consumption.

The ammonia contents of the products in these experiments were determined by expelling the $NH_3$ with hot 2 N NaOH. Since amides or imides both decompose under these conditions, the true ammonium salts were again determined with the weak base $Mg(OH)_2$. The consumption of 0.05 N HCl (taking into account the basic surface oxides already present) and the quantity of $NH_4^+$ ions formed were also measured. The quantity of ammonium ions almost always agreed with the $NH_3$ content determined by expulsion with NaOH. Thus the carboxyl groups I had not formed amides or imides even at 100 °C.

c) *Friedel-Crafts Reactions*

Several products, *e.g.* "Eponite coked, ox. $(NH_4)_2S_2O_8$", were converted into acyl chlorides by treatment with thionyl chloride (cf. Table 6), and were then treated with a solution of dimethylaniline and $AlCl_3$ in nitrobenzene. The nitrogen content of the reaction product corresponded to the chloride content, *i.e.* half of the bicarbonate consumption, and was therefore equivalent to group I or group II. The $NaHCO_3$ consumption decreased by half, and the neutralization values for the four bases were in the ratios of 1:2:3:4. Thus, in this wet-oxidized product, one of the two groups I (neutralizable with $NaHCO_3$) had formed a carbonyl chloride on reaction with thionyl chloride, as shown by the smooth progress of its subsequent Friedel-Crafts reaction. The other group I was thermally stable at 200 °C.

Group I also reacted in "coked" sugar charcoals which had been oxidized with oxygen; neutralization after the Friedel-Crafts reaction gave ratios of the acidic groups of 0:1:2:3. With an "activated" sugar charcoal which had been oxidized with oxygen, both the anhydride formed by reaction with $SOCl_2$ and the acyl chloride of group II reacted under the same conditions.

d) *Schmidt Degradation*

The carboxyl groups were detected directly by *Schroeter*'s variant [22] of the Schmidt degradation. After treatment with thionyl chloride, the product "Eponite coked, ox. $(NH_4)_2S_2O_8$" was treated with sodium azide in ethanol; the product contained a quantity of nitrogen corresponding to the replacement of one carboxyl group by a urethane group. The neutralization values decreased by half of the $NaHCO_3$ neutralization value.

5. Detection of Carbonyl Groups

The acidic groups detected so far account for only part of the oxygen content of the surface oxides. In the literature, the surface oxides are often formulated as carbonyl groups bonded to the periphery of the carbon layers. The consumption of ethoxide in the neutralization experiments may be due to carbonyl groups which react in the presence of a sufficient excess of alkali to form the salt of a hemiacetal. Secondary reactions, such as aldol condensations or Cannizzaro reactions, which take place readily under these conditions, cannot occur with carbonyl groups fixed at the peripheries of carbon layers. This assumption is plausible, since many aldehydes with adjacent negative substituents (hydroxy groups) contain appreciable quantities of acetal in aqueous solution [23]. In the presence of sodium ethoxide, the intermediate (hemiacetal) is fixed as the salt.

The consumptions of characteristic carbonyl reagents such as hydrazine, semicarbazide, or hydrogen cyanide were in the region of the quantity of $NaHCO_3$ or $Na_2CO_3$ required for neutralization. However, the consumptions of the various reagents were unequal.

After reaction with HCN, followed by hydrolysis, the $NaHCO_3$ consumption of a sample of activated and oxidized sugar charcoal increased to twice the initial value; thus an equivalent quantity of new carboxyl groups had been formed.

Almost all the carbonyl reagents used are also strong reducing agents, and furthermore, they can form salt-like compounds. Unambiguous interpretation of the results is therefore difficult.

6. Acetylation

Several products were treated with acetyl chloride. The acetyl contents of the purified products always corresponded to the quantity of NaOH required for neutralization. Pairs of adjacent carboxyl groups react with acetyl chloride to give cyclic anhydrides. Other carboxylic acids, phenols, and even alcohols bind acetyl groups. Thus, the subsequent reaction with sodium ethoxide is not a simple neutralization of an acidic hydroxyl group, since otherwise the acetyl content (of the "coked" products at least) should correspond to the $NaOC_2H_5$ consumption.

One product (SC 1, act. ox.) was boiled under reflux with acetic anhydride and a little sodium acetate. After the usual

[22] *G. Schroeter*, Ber. dtsch. chem. Ges. *42*, 3356 (1909).

[23] *N. C. Melchior*, J. Amer. chem. Soc. *71*, 3651 (1949).

purification, 182 meq. of NaOH/100 g of charcoal were required for neutralization. (The acetyl groups were not determined directly). If, as in the reaction with acetyl chloride, all the groups which could be neutralized with NaOH (70 meq./100 g) had been acetylated, the NaOH consumption should have doubled in alkaline hydrolysis. However, an additional 42 meq. of acetyl groups per 100 g of charcoal had apparently been bound (the formation of new acidic groups during acetylation is unlikely). These additional acetyl groups presumably did not react with hydroxyl groups, since acetyl chloride introduced 70 meq. of acetyl groups/100 g.

It is possible that a geminal diacetate $-CH(OAc)_2$ had been formed from an aldehyde [24]. We presume that the group IV (20 meq./100 g in the strating material) is an aldehyde or a ketone (see below).

### 7. Reductions

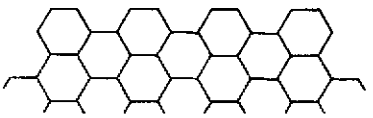
The acidic surface oxides behaved differently toward reducing agents (Table 7). On *Clemmensen* reduction with amalgamated zinc and hydrochloric acid, all four

Table 7. Change in the quantity of acidic groups after reduction of the acidic surface oxides.

| Product | Reduced with | Change in groups [b] | | | |
|---|---|---|---|---|---|
| | | I | II | III | IV |
| SC 3, coked, ox. [a] | – | (20) | (21) | (1) | (20) |
| | Zn/HCl (at 20 °C) | +18 | −19 | −1 | −19 |
| SC 3, act. ox. | – | (60) | (46) | (61) | (47) |
| | Zn/HCl (at 20 °C) | 0 | 0 | −16 | −13 |
| | Zn/HCl (at 100 °C) | −11 | −15 | −10 | −18 |
| | $LiALH_4$ | 0 | −11 | 0 | −14 |
| | $NaBH_4$ | 0 | −21 | −3 | −11 |

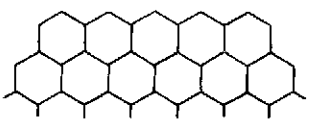
[a] This product was obtained by rapid quenching of oxidized sugar charcoal. Practically no groups III were formed during this treatment.

[b] The values in brackets give the content [meq./100 g] in the starting material; the figures without brackets are the changes after reduction.



groups are usually, and group IV is always, attacked. The contents of groups II and III frequently decrease in the same proportion; the two groups are probably closely related.

In two products ("SC 3, coked, ox." reduced by the method of *Clemmensen*, and "SC 1, act. ox." reduced with $LiAlH_4$), the decrease in group II content was accompanied by an equivalent increase in group I. Thus, group II had become more strongly acidic as a result of the reduction. Group II is probably, like group I, a carboxyl group. However, in other cases, *e.g.* in "SC 3, act. ox.", group II was reduced with $LiAlH_4$ or $NaBH_4$ without formation of a more strongly acidic carboxyl group. This suggests that group II is normally present as a lactone. This result agrees with a structure similar to that of fluorescein [16], but other structures are possible also (see below).

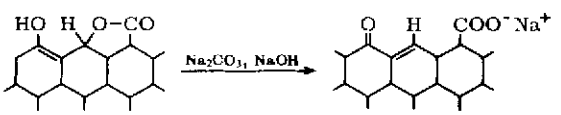


## IV. Possible Structures of Carbon Surface Oxides

The data available from the literature and from our own investigations are insufficient to afford complete and unambiguous information about the constitution of the acidic surface oxides. However, the most important results are reviewed briefly below. In comparing the work of different authors, it should be noted that the products used were rarely even similar.

Oxidation of single crystals of graphite with absolutely dry oxygen leads to an "arm chair" (11$\bar{2}$1) boundary *(1)* of the carbon layers, while a "zig-zag" (10$\bar{1}$1) boundary *(2)* is formed in the presence of water [25].

*(1)*



*(2)*

Our starting materials always contained hydrogen, and consequently, oxidation probably gave form *(2)*. It is not known which boundary is formed on oxidation with $CO_2$, *i.e.* on activation. We observed differences in the behavior of the surface oxides on coked and on activated sugar charcoals. It seems possible that the original boundary is largely retained on coating with surface oxides.

The acidic surface oxides are bound at the edges of the carbon layers. Carbon black graphitized at 2700 °C neutralizes no sodium hydroxide after oxidation at 450 °C with oxygen [26]. The surface of graphitized carbon black consists only of the basal planes of graphite [27] and contains only very few edge carbon atoms which can form acidic (*e.g.* phenolic) groups.

We detected four acidic groups of various strengths, which were generally present in equivalent quantities: a more strongly acidic carboxyl group (I), a more weakly acidic carboxyl group (II), a phenolic hydroxyl group (III), and a fourth group (IV) which is probably a carbonyl group. Groups II and IV appear to be closely related. One explanation for this would be that the more weakly acidic carboxyl group II is present as a hydroxy lactone which resembles phenolphthalein or fluorescein. A plausible arrangement of lactone and hydroxy groups is shown in formula *(3a)*. This would afford a satisfactory explanation of the lower acidity of the carboxyl group II, since phenolphthalein is known to form its colored salt, analogous to the form *(3b)*, with sodium carbonate, but not with sodium bicarbonate. This as-

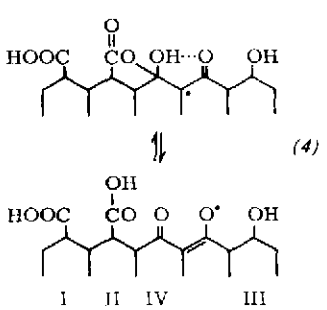
*(3a)* *(3b)*

[24] *E. Knoevenagel*, Liebigs Ann. Chem. *402*, 127 (1914).

[25] *G. R. Hennig*, Proceedings 5th Conference on Carbon (Pennsilvania State University, 1961). Pergamon Press, London 1962, Vol. I, p. 143; Z. Elektrochem., Ber. Bunsenges. physik. Chem. *66*, 629 (1962).

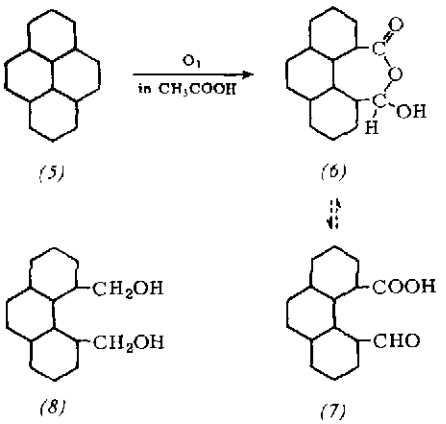
[26] *H. P. Boehm, E. Diehl*, and *W. Heck*, Rev. gén. Caoutchouc *41*, 461 (1964).

[27] *H. P. Boehm*, Z. anorg. allg. Chem. *297*, 315 (1958).



sumption is confirmed by an absorption band in the infrared spectrum of the strongly oxidized color black "Carbolac®", which was attributed to the carbonyl group of a γ-lactone [16].

The H–C bond in *(3a)* or *(3b)* could be the result of decarboxylation. Carbon oxidized at room temperature loses a carboxyl group on heating; on oxidation of the carbon at 400 °C, this carboxyl group is lost immediately after its formation.



Sugar charcoal activated with $CO_2$ always contains pairs of carboxyl groups I which are so close together that they can form an anhydride (cf. the reaction with $SOCl_2$). A structural model of the surface oxides, which also takes these observations into account, is discussed in detail elsewhere [26].

Quinonoid groups have also been detected on the surfaces of carbon blacks [28]. During polarographic reduction, a wave occurred at a voltage corresponding to the reduction of quinones. The polarographic reduction wave disappeared after the carbon black had been treated with $LiAlH_4$. Hydroquinones have been detected in the same manner by polarographic oxidation. The carbon black could no longer be oxidized after methylation with diazomethane. The infrared spectrum of the color black "Carbolac" contains an absorption band at 1580 $cm^{-1}$ due to a hydrogen-bonded carbonyl group [28]. This absorption was displaced on methylation to ca. 1690 $cm^{-1}$, corresponding to a normal carbonyl group. Free radicals can be detected in oxidized carbon blacks [29,30]. The radicals are probably closely connected with the quinonoid groups [30].

Another explanation for the coupled occurrence of the carboxyl group II and the carbonyl group IV, which is also compatible with experimental findings, would be the presence of a lactone of a formylcarboxylic acid or of a ketocarboxylic acid.The model of a zig-zag edge containing all the groups detected, as well as such a lactol, is shown in *(4)*. (A further carboxyl group is formed on oxidation in acidic solutions.) The lactol is very similar to the fluorescein-like lactone.

The presence of such a lactol is supported by the following data: Oxidation of pyrene *(5)* with ozone in glacial acetic acid [31] or with $H_2O_2$ and $OsO_4$ [32] gives 4-formylphenanthrene-5-carboxylic acid *(7)* which normally exists as the lactol *(6)* [33,34]. Compound *(6)* or *(7)* reacts with diazomethane to form a hydrolysable methylcarboxylate [34]; on the other hand, alcohol plus mineral acid gives the pseudoester of the lactol form

[33,34]. Both compounds are reduced to the diol *(8)* by $LiAlH_4$ [35]. On reduction of *(7)* with amalgamated zinc and hydrochloric acid, both the aldehyde group and the carboxyl group are attacked, with formation of 1,8-dihydropyrene [33].

Ketocarboxylic acids whose functional groups are at the peri positions of a condensed ring system behave in a similar manner to formylcarboxylic acids [34].

The behavior of the acidic surface oxides on reduction can be explained on the assumption that a lactol is present. On reduction with amalgamated zinc, the carboxyl groups II and IV are attacked to an equal extent. The reaction with sodium ethoxide, when the latter is added in large excess, may be regarded as the formation of the salt of a hemiacetal of the aldehyde group. Secondary reactions, such as aldol condensation or the Cannizzaro reaction, cannot occur.

It is very difficult to decide whether it is preferable to formulate the surface oxides as a lactone *(3a)* or as a lactol *(4)*. The principles of organic chemistry derived from work on relatively small molecules cannot be applied directly to very large oxidized ring systems.

It is also conceivable that in each case only two acidic groups, *e.g.* I and III or II and IV are adjacent. The equal frequency of occurrence of all four groups could then be due to the fact that the two combinations are bonded to carbon edges with different structures occurring with equal probability.

The functional groups detected explain, at the most, 50 % of the analytically determined oxygen content. This has been confirmed by other authors [15,36]. When graphite was extremely finely ground and then oxidized, it evolved elemental oxygen as well as carbon dioxide on degassing *in vacuo* between 100 and 250 °C [36]. The bonding of this oxygen has not yet been explained. It is perhaps chemisorbed on sites of high π-electron density associated with defects in the layer planes.

## V. Surface Oxides on Diamond

The diamond which is found in the "blue ground" of volcanic pipes of South Africa is hydrophobic, as is any freshly comminuted diamond. This permits its easy separation from the hydrophilic matrix rock, *e.g.* by flotation or, as formerly, with tarred or greased beds, to which the diamonds adhere, while the rock is washed away by water. On the other hand, diamonds which occur in sediments are hydrophilic. *K. A. Hofmann* observed that finely powdered diamond forms stable suspensions in dilute ammonia after treatment with calcium hypochlorite solution [37]. It was obvious to assume that this was due to the presence of surface oxides.

Investigation of the surface oxides on diamond seemed particularly attractive, since diamond can be regarded as the parent substance of aliphatic compounds, whereas aromatic compounds are derived from graphite. The surface oxides of diamond should therefore be expected to be different: *e.g.* phenolic hydroxyl groups cannot be formed.

Only relatively small specific surface-areas were available for the investigations on diamond, and correspondingly small quantities of surface oxides were therefore formed. Owing to the high price and limited availability of sufficiently finely-powdered diamond, the sample weights used could not be increased as desired. We managed to obtain diamond powder with a specific surface area of about 17 $m^2/g$, which is just high enough for investigations of surface oxides using modified analytical methods.

Diamond purified with aqua regia and hydrofluoric acid was oxidized with oxygen at 400 °C, or with solutions of sodium hypochlorite or ammonium persulfate at about 20 °C. The products were thoroughly washed, if necessary, and dried by degassing *in vacuo* at 100 °C.

The oxidation with oxygen was studied with the aid of a thermomicrobalance. Surface oxides start to form at about 260 °C. Perceptible liberation of oxides of carbon gradually begins at 350 °C and becomes very pronounced at 380 °C.

Potentiometric titrations of the acidic groups gave a curve which rose relatively slowly and showed no distinct inflexions. No simple ratios of the quantities of base consumed were observed on neutralization by shaking with bases of various basicities (Table 8). The results

Table 8. Neutralization of oxidized diamond powder.

| Product | Consumption [meq./100 g] | | | |
|---|---|---|---|---|
| | $NaHCO_3$ | $Na_2CO_3$ | NaOH | $NaOC_2H_5$ |
| Diamond, ox. $O_2$ | 3.3 | 4.9 | 5.2 | 6.9 |
| Diamond, ox. NaOCl | 0 | 1.2 | 1.4 | 2.8 |
| Diamond, ox. $(NH_4)_2S_2O_8$ | 1.2 | 2.7 | 3.4 | 4.8 |

of some other reactions are listed in Table 9. As can be seen from the agreement between the results of direct titration (to pH 7), neutralization with $NaHCO_3$, and reaction with thionyl chloride, the diamond contained about 2.5 meq. of more strongly acidic carboxyl groups per 100 g of sample. These were probably bound to the corners and edges of the diamond crystals.

[37] *K. A. Hofmann:* Anorganische Chemie. 1st Edit., Vieweg, Braunschweig 1918, p 287.

Table 9. Chemical reactions of the surface oxides of diamond.

| Pretreatment | Reaction | Conversion [meq./100 g] |
|---|---|---|
| ox. $O_2$ | titration to pH 7 | 2 [a] |
| ox. $O_2$ | $NaHCO_3$ | 2.5 |
| ox. $O_2$ | $SOCl_2$ | 2.5 |
| ox. NaOCl | diazomethane | 7.4 [a] |
| ox. NaOCl | acetyl chloride | 3.7 [a] |
| ox. $O_2$, degassed at 100 °C | potassium | 20 |
| ox. $O_2$, degassed at 500 °C | potassium | 11 |
| degassed *in vacuo* at 800 °C | $Cl_2$ (at 100 °C) | 20 |
| | $Cl_2$ (at 500 °C) | 17 |
| degassed at 800 °C, then Hr at 800 °C | potassium | 4.1 |

[a] These results were obtained with starting materials other than those used for the other values.

We assumed that the octahedral faces of the diamond crystals are saturated with tertiary hydroxyl groups. The active hydrogen content can be determined by salt formation with metallic potassium. This determination was carried out by distilling potassium *in vacuo* onto oxidized diamond; the excess potassium was then distilled off at 300 °C. On degassing between 25 and 400 °C, about 20 meq. of potassium per 100 g of diamond always remained fixed; this could be determined acidimetrically after hydrolysis (cf. Table 9). The number of active groups decreased above 400 °C; this agrees with the result of thermogravimetric analysis. At 800 °C, almost all the surface oxides were decomposed, and the consumptions of $NaHCO_3$ and NaOH required for neutralization fell respectively to zero and 0.5 meq./100 g.

We believed that free radicals were formed during the thermal decomposition of the surface coating. The quantity of these should be determinable by direct reaction of diamond degassed at 800 °C with elemental chlorine, without prior contact with air. The quantity of chlorine bound agreed very well with the result of the reaction with potassium, if this reaction and the subsequent degassing were carried out between 100 and 400 °C (conversion about 20 meq./100 g). The bound chlorine was resistant to hydrolysis, even with hot sodium hydroxide. The diamond powder was treated with hydrogen in a similar manner at 800 °C; it was then able to bind only very much less potassium (cf. Table 9). The products which had been degassed at high temperatures were hydrophobic, in contrast to the hydrophilic oxidized diamond. The heat of wetting [*] of an oxidized diamond preparation with water was 0.7 cal/g; the value for the same product after degassing at 800 °C was 0.5 cal/g, and 0.35 cal/g after treatment with hydrogen at 800 °C.

These reactions prove the existence of surface oxides on diamond. Some surface oxides are formed even on storage in air. This can cause appreciable interference in the technical separation of diamonds by flotation [38]. The coefficient of friction of diamond that has been heated *in vacuo* decreases significantly on admission of air [39].

[*] We wish to thank Dipl.-Chem. *W. Häbich* for conducting the measurements.

[39] *F. P. Bowden* and *A. E. Hanwell*, Nature (London) *201*, 1279 (1964).

The same phenomenon is known to occur with graphite [40] [**]. The surface oxides formed at room temperature in air are not acidic.

## VI. Transformation of Diamond into Black Carbon

During the thermal decomposition of surface oxides we made an interesting observation: at oxygen pressures of about $10^{-2}$ to $10^{-1}$ mm, diamond becomes dark in color. This blackening, which had been described earlier [41], is due to the transformation of diamond on the surface into the black, microcrystalline form of carbon, which is thermodynamically favored. The transformation is catalysed by traces of oxygen. The dark coating on the diamond was rapidly oxidized to oxides of carbon at 400 °C and an oxygen pressure of 1 atm.

In large diamond crystals, the (111) and (110) faces become covered with velvet-black carbon at an oxygen pressure of 0.4 mm between 650 and 850 °C; above 850 °C, the (100) surfaces become covered too [41]. Diamond remains unchanged *in vacuo* even at 1350 °C. In the presence of a little oxygen, the transformation proceeds more rapidly than the oxidation of the black carbon produced; the latter oxidizes more rapidly only at higher oxygen pressures.

Surface oxides must play a part in this catalysis by oxygen. In the stationary state of the black layer, the rate of transformation is governed by the diffusion of oxygen through the layer. Thus, oxygen is continuously being consumed; surface oxides are presumably formed, and these decompose to oxides of carbon and black carbon. We observed no transformation with pure CO at 900 °C, and only a slight darkening with pure $CO_2$. A Boudouard equilibrium such as

$$C_{diamond} + CO_2 \rightarrow 2\,CO \rightleftharpoons CO_2 + C_{black}$$

can therefore be ruled out.

We have proved that the darkening was actually due to the catalytic activity of the black microcrystalline carbon in the synthesis of hydrogen bromide.

The equilibrium

$$H_2 + Br_2 \rightleftharpoons 2\,HBr$$

lies almost completely to the right at 150 °C, but no HBr is formed in the homogeneous gas phase in the absence of catalyst. The reaction is catalysed by graphite and black microcrystalline carbon [42]. The catalytic efficiency is a measure of the specific surface area [43].

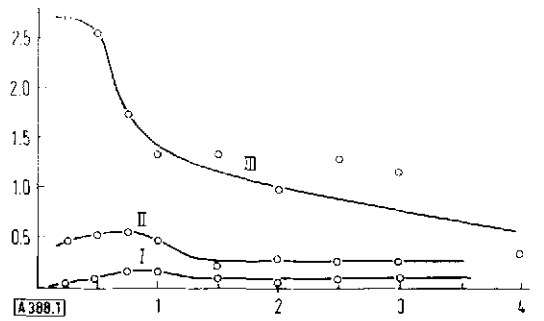

Fig. 1. Change of catalytic efficiency with time in the synthesis of HBr (T = 150.0 °C; $H_2$ pressure Q 1 atm; $Br_2$ pressure = 67 mm).

I: Diamond coated with surface oxides.

II: The same product as in I, after degassing *in vacuo* at 800 °C.

III: The same product as in II, after darkening at low $O_2$ pressure at 800 °C.

Ordinate: Catalytic efficiency [mmole of HBr per hour per g of carbon]; Abscissa: Time [h].

Figure 1 shows the catalytic efficiency of the same sample of diamond after various pretreatments. The diamond was used in three forms: after oxidation with NaOCl, after subsequent degassing *in vacuo* ($< 10^{-5}$ mm) at 800 °C, and finally after covering with the black coating by heating at 800 °C in oxygen at ca. $10^{-1}$ mm. With the third sample, the catalytic efficiency fell off gradually in a peculiar manner during the measurements, and became almost zero. The diamond powder was again light in color at the end of this experiment, *i.e.* the dark coating had volatilized off under the conditions of the HBr catalysis. It must be concluded from this that the coating of black carbon was extremely finely-divided and reactive. This is supported by an earlier observation [44] that diamond which had been heated in an evacuated Crookes' tube by a glow discharge and had become coated with carbon became lighter in color after storing for some years in air.

*We wish to thank the Deutsche Forschungsgemeinschaft and Union Carbide European Research Associates, Brussels, for their support in these investigations. Messrs. Diamanten-Winter, Hamburg, supplied us with finely powdered diamond at a special rate. We are deeply indebted to Prof. U. Hofmann for his help and valuable encouragement.*

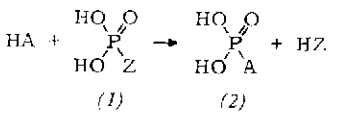
# The Design of Phosphorylating Agents



BY V. M. CLARK, D. W. HUTCHINSON, A. J. KIRBY, AND S.G. WARREN

UNIVERSITY CHEMICAL LABORATORY, CAMBRIDGE (ENGLAND)

*Phosphorylating agents are compounds capable of transferring the group $(HO)_2P(O)-$ in free or esterified form. Numerous phosphorylating agents can be classified into P–XYZ systems, in which the element or group Z must be capable of accommodating the electrons of the P–X bond. Systematic classification of P–XYZ compounds and numerous examples of phosphorylation in chemistry and biochemistry are given.*

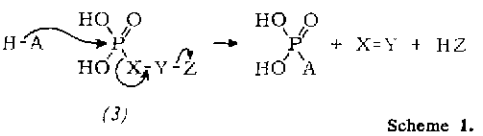
## I. Phosphorylation

Phosphorylation of alcohols to give phosphoric esters (phosphates) [*(2)*, A = RO], of amines to give phosphoramidates [*(2)*, A = R–NH], and of phosphates to give pyrophosphates [*(2)*, A = $(RO)_2P(O)$] requires the addition of a phosphoryl group $(HO)_2P(O)-$ to a nucleophilic center.

*(1)* *(2)*

This can be achieved, for example, when Z, the group bonded to the phosphorus atom in the phosphorylating agent *(1)*, is readily displaced as $Z^{\ominus}$; hence reagents of the acid-anhydride type might be expected to be good phosphorylating agents. However, phosphoric acid is tribasic, and the free hydroxyl groups in *(1)* can compete with external nucleophiles to give polymeric by-products. In practice, anhydride-type reagents are useful only if they bear two protecting groups, as in $(PhO)_2P(O)Cl$ [1].

Many naturally occurring phosphorus compounds are mono- or di-esters of ortho-, pyro-, or polyphosphoric acids (*e.g.* sugar phosphates, nucleotides): a few are *N*-substituted phosphoramidates (*e.g.* the phosphagens). During their synthesis, protecting groups may have to be removed and, although methods have been developed to accomplish this, the aim of much recent work has been to devise reagents which can transfer an unsubstituted phosphoryl group directly [1].



Two approaches have been used with some success. In one, the phosphorylating agent is generated *in situ* from an appropriate phosphate anion or phosphoric acid (*e.g.* in the carbodiimide and trichloroacetonitrile methods); in the other, a less reactive reagent, such as a phosphoramidate, is used. In both methods, the potential leaving group is probably first protonated, so that a neutral molecule is displaced. Fundamentally, whether the leaving group be $Z^{\ominus}$ or HZ, it must accommodate the electron pair that originally formed the P–Z bond. Consideration of how this can best be done is important not only for an understanding of the process of phosphorylation in general but also for the improvement of the design of reagents for particular purposes.

[1] *D. M. Brown* in *R. A. Raphael, E. C. Taylor,* and *H. Wynberg:* Advances in Organic Chemistry: Methods and Results. Interscience, New York 1963. Vol. 3, p. 75.

## II. The P-XYZ System

### A. Definition

Any molecule of general formula *(3)*, where X, Y, and Z are atoms of any element, but commonly H, C, N, O, S, or Hal, is a potential phosphorylating agent if the electrons of the P–X bond can be formally accommodated on Z. During phosphorylation, the bond-order between X and Y increases, and that between Y and Z decreases,

*(3)*

Scheme 1.

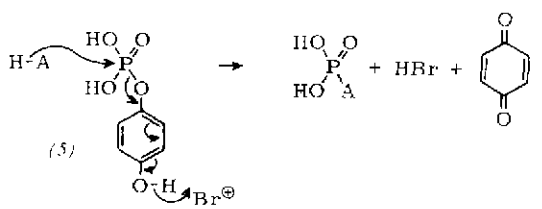
each by one unit (Scheme 1). Since Z acts as the primary electron-acceptor, it must be strongly electronegative or must become so via attack by an electrophile or an oxidizing agent.

### B. Advantages

Examination of the properties of the generalized P-XYZ system suggests that it may have important advantages over simple P–Z type reagents. Two extra centers are involved in the transition state of the phosphorylative step, and it is therefore possible to alter the activation energy of the process by varying X and Y for a given Z, without necessarily varying the overall free-energy change for the reaction. Both in principle and in practice, stable unprotected phosphorylating agents with powerful leaving groups can be designed. For example, in contrast to phosphorochloridic acid $(HO)_2P(O)Cl$, which is highly reactive and is hydrolysed in water, 2-chloro decyl phosphonate $(HO)_2P(O)\text{-}CH_2\text{-}CHCl\text{-}C_8H_{17}$ can be kept in aqueous acidic solution [2]: in alkali,

[2] *J. A. Maynard* and *J. M. Swan*, Austral. J. Chem. *16*, 596 (1963).

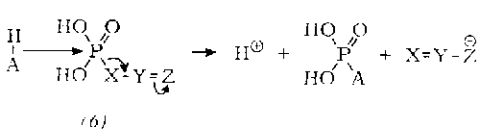
rapid decomposition, with accompanying phosphorylation, ensues [*].



### C. The P-X Bond

The prerequisites for a P–XYZ system *(3)* to be a phosphorylating agent are that the P–X bond should be weak and that Z should be as strongly "electron-attracting" as possible. Bonds involving phosphorus and highly electronegative elements are particularly strong since the lone pair of electrons possessed by all such elements can be donated into the vacant 3d orbitals of the phosphorus atom, thereby augmenting the binding energy by virtue of a pπ–dπ contribution. In the system P–XYZ, pπ–dπ overlap is eliminated if X has no lone pair of electrons (*e.g.* when X = $sp^3$-hybridized carbon); alternatively, where such electrons are present, pπ–dπ bonding can be reduced by introducing pure pπ bonding with an $sp^2$-hybridized Y atom, as in system *(4)*.

*(4)*

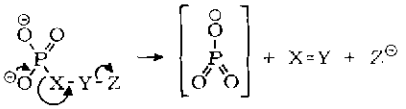


There is, of course, no reason why the Y–Z bond should not be part of an extended π-bonded system. Thus, in oxidative phosphorylation involving hydroquinone phosphates *(5)* [3], it is part of an aromatic ring:

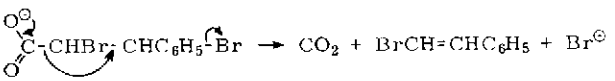
*(5)*

### D. Entropy Effects

When a compound of the P–XYZ type *(6)* acts as a phosphorylating agent, a stable mesomeric anion may be displaced.



*(6)*



Alternatively, if Y and Z are singly bonded, fragmentation must occur, and the number of molecules present must increase during the phosphorylative step (cf. Scheme 1). The entropy change, and probably the entropy of activation, should be positive for this type of reaction.

### E. Metaphosphate Intermediates

Unprotected phosphorylating agents may react either by the bimolecular mechanism just considered, or by an initial unimolecular dissociation into monomeric metaphosphate, this being a (presumably) highly reactive and therefore non-selective phosphorylating agent [4].

This process corresponds to decarboxylation, *e.g.* of bromocinnamic acid *(7)*, in organic chemistry.

*(7)*

The advantages of the P–XYZ system hold equally well for this mechanism, and the entropy factor should be even more favorable. *Di Sabato* and *Jencks* [5] have shown that the (possibly unimolecular) hydrolysis of acetyl phosphate at pH 5 has a low positive $\Delta S^{+}$. For reactions according to Scheme 1, it should be higher still. Moreover, the reactivity of such phosphorylating agents should be strongly temperature-dependent, providing them with an additional valuable feature.

## III. Classification of P-XYZ Systems

### A. No pπ-dπ Contribution to the P-X Bond

a: P–C–C–Hal
b: P–C–C–C
c: P–C–C=O

### B. Attenuation of the pπ-dπ Contribution by Pure pπ Bonding

1. Attenuation in the ground state

a: P–N–C=O
b: P–N–N=N
c: P–N–N=O
d: P–O–C=O
e: P–O–N=O

2. Attenuation by electrophilic attack on Z

a: P–N–C=N
b: P–O–C=C
c: P–O–C=N
d: P–O–C=O
e: P–O–N=C

3. Attenuation by oxidative attack on Z

a: P–N–N–H
b: P–O–O–H

[*] The energy of activation for the P–C–C–Hal transphosphorylation process is sufficiently greater than that of P–Hal cleavage for phosphate polymerization to be negligible. On the other hand, the overall free-energy change in both reactions is approximately the same (bond energies: P–C = 62, C–C = 62; C–Cl = 77, P–Cl = 77 kcal/mole).

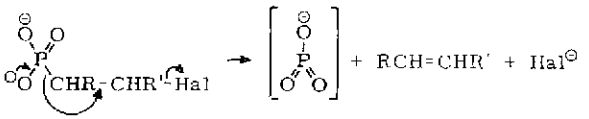
[3] *V. M. Clark, D. W. Hutchinson, G. W. Kirby,* and *A. R. Todd,* J. chem. Soc. (London) *1961*, 715.

[4] *J. D. Chanley* and *E. Feageson,* J. Amer. chem. Soc. *85*, 1181 (1963).

[5] *G. Di Sabato* and *W. P. Jencks,* J. Amer. chem. Soc. *83*, 4393 (1961).

4. Attenuation by loss of $Z^{\ominus}$

a: P C–C–Hal

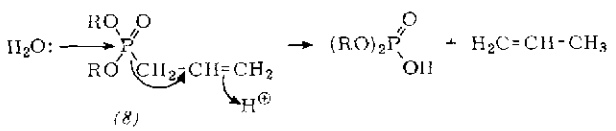


b: P–N–C Hal

c: P–S C Hal

## IV. Examples of P-XYZ Systems

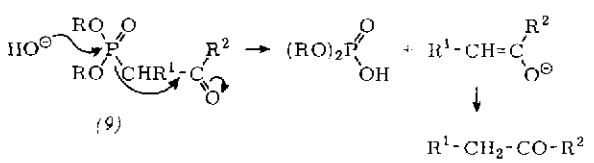
### Aa: P—C– C—Hal (X = Y = C, Z = Hal); β-Halogenoalkylphosphonates



Saturated β-halogenoalkylphosphonates are stable in acidic solution, but in alkali undergo rapid decomposition to an olefin and phosphate with expulsion of a halide ion [2,6 9].

The alkali-catalysed decomposition may be either an intramolecular process (as indicated) or an intermolecular process involving external nucleophilic attack at the phosphorus atom. Compounds of this type have found use as phosphorylating agents in the presence of base [2].

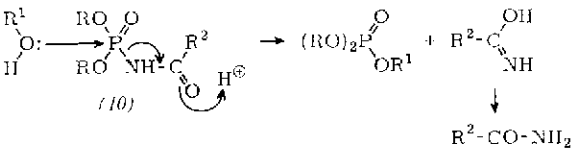
### Ab: P—C—C=C (X = Y = Z = C): Allylphosphonates



Electron withdrawal from Z can be effected by protonation: thus, allylphosphonates *(8)* undergo hydrolysis in aqueous acid to give an olefin and a phosphate [10].

*(8)*

### Ac: P—C—C=O (X = Y = C, Z = O) β-Ketoalkylphosphonates

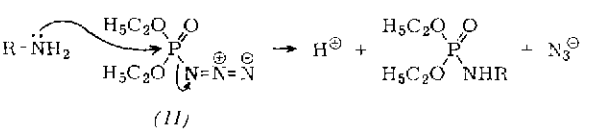


β-Ketoalkylphosphonates *(9)* undergo alkaline hydrolysis to phosphate and the carbonyl compound [11,12].

*(9)*

### B 1a: P–N–C=O (X = N, Y = C, Z = O): *N*-Acylphosphoramidates

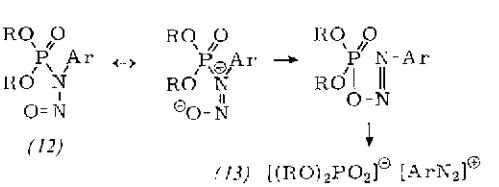
*N*-Acylphosphoramidates *(10)*, in contrast to phosphoramidic esters, phosphorylate alcohols in neutral solution [13]. Their enhanced reactivity is due to the decrease in $p\pi-d\pi$ bonding between the nitrogen and phosphorus atoms in consequence of conjugation involving the carbonyl group and a p-orbital on the nitrogen atom.



*(10)*

*N*-Acylphosphoramidates undergo hydrolysis in aqueous acid but here it is difficult to distinguish between a mechanism of the P–XYZ type and one following the accepted mode of hydrolysis of phosphoramidates, *i.e.* one involving protonation on the nitrogen [14]. The acidic hydrolysis of *N*-phosphorourethanes shows analogous features [15].

### B 1b: P—N—N=N (X = Y = Z = N): Phosphoroazidates



Azide ions have a catalytic effect similar to that of nitrite ions [35] on the alkaline hydrolysis of *N,N,N',N'*-tetraalkylphosphordiamidyl chlorides [16]. Phosphoroazidates *(11)* have in fact been isolated and have been used to phosphorylate amines [17].

*(11)*

### B 1c: P—N—N=O (X = Y = N, Z = O): *N*-Nitrosophosphoramidates

Nitrosation of *N*-arylphosphoramidates by nitrosyl hydrogen sulfate or nitrosyl chloride leads to the aryldiazonium salt *(13)* of the corresponding phosphoric acid [18]. The reaction probably proceeds by a rapid intramolecular rearrangement of the *N*-nitroso-*N*-arylphosphoramidate *(12)*.

*(12)* *(13)* $[(RO)_2PO_2]^{\ominus}\,[ArN_2]^{\oplus}$

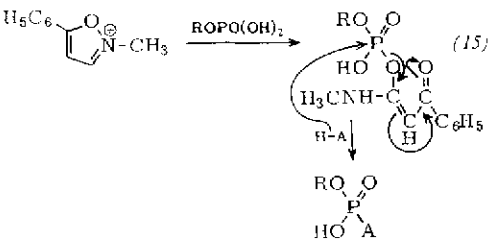
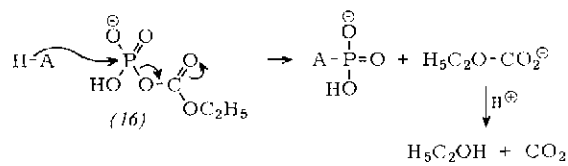
## B 1d: P—O—C—O (X = Z = O, Y = C) [*]: Acyl Phosphates



Acyl phosphates *(14)* can function as acylating or phosphorylating agents; in the latter reaction they are P XYZ systems.

*(14)*



Nucleophilic attack usually occurs at the carbonyl carbon atom, with elimination of phosphate. However, evidence has been obtained which indicates that attack at the phosphorus can occur, especially during basic hydrolysis [20–22].

Nucleoside-$P^1$,$P^2$-diesters of pyrophosphoric acid have been synthesized by the action of acetyl chloride or acetic anhydride on mononucleotides [23]. The phosphorylating agent in this reaction must be an acetyl phosphate derivative. Moreover, treatment of phosphoric monoesters with isoxazolium salts [24] gives vinylogous acyl phosphates *(15)* which are also phosphorylating agents [25, 26].

*(15)*

In the alkaline hydrolysis of carbamyl phosphate [27–30], P–O bond fission occurs: again a P XYZ system is indicated. Moreover, hydrogenolytic debenzylation of dibenzyl ethoxycarbonyl phosphate *(16)* leads to extensive decomposition with evolution of carbon dioxide [31].

*(16)*

[*] Calculations of the electron density on the O in P–O–C–O [19] show that it is more electron deficient than the O in P–O–$CH_3$.

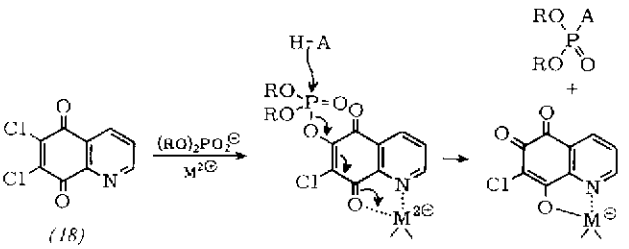
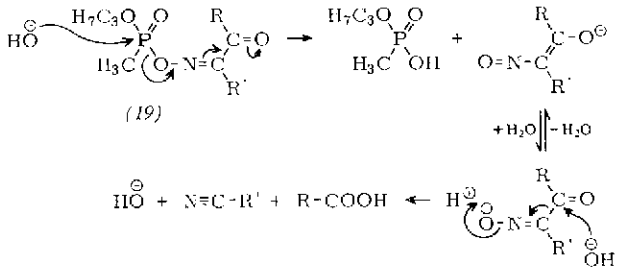
[31] *A. Lapidot* and *M. Halmann*, J. org. Chemistry *28*, 1394 (1963).



Diketene reacts with phosphoric monoesters to produce phosphorylating agents [32], nucleophilic attack occurring on

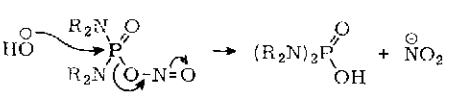
*(17)*



the intermediate *(17)* generated *in situ*, giving carbon dioxide, acetone, and the phosphorylated nucleophile.

6,7-Dichloroquinoline-5,8-quinone *(18)* can convert certain transition-metal salts of phosphoric diesters into phosphorylating agents [33]. The nitrogen and the quinone oxygen atoms chelate with the metal ion, thereby activating the quinonoid ring towards nucleophilic attack. The 6-chlorine atom can then be displaced by a phosphate mono-anion to give a vinylogous acyl phosphate.

*(18)*



α-Hydroximino ketones react rapidly with Sarin (isopropyl methylphosphonofluoridate) in neutral or slightly alkaline solution [34], the initial reaction product *(19)* being an azavinylogue of an acyl phosphate which breaks down into isopropyl methylphosphonate, a carboxylic acid, and a nitrile.

*(19)*

## B 1e: P—O—N—O (X = Z = O, Y = N): Phosphoronitrites and Phosphoronitrates

The reaction of *N,N,N',N'*-tetraalkylphosphorodiamidyl chlorides with hydroxide ions is catalysed to a marked extent by nitrite ions [35], possibly via the mixed anhydride of the tetraalkylphosphorodiamidic acid and nitrous acid *(20)*.

*(20)*

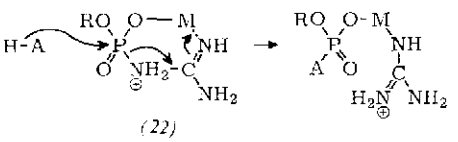
[34] *A. L. Green* and *B. Saville*, J. chem. Soc. (London) *1956*, 3887.

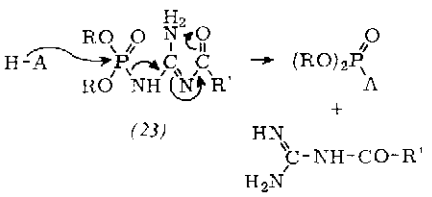
[35] *E. W. Crunden* and *R. F. Hudson*, J. chem. Soc. (London) *1962*, 3591.

Mixed anhydrides of this type have not yet been isolated, but their vinylogues are known to be phosphorylating agents. Thus, picryl chloride has been used to form nucleoside 2',3'-cyclophosphates from a mixture of the nucleoside 2'- and 3'-phosphates [36,37], and phosphoric esters have been isolated from the reaction of an alcohol with phosphate ion in the presence of picryl chloride [37]. The reactive intermediate must be a picryl phosphate *(21)*, *i.e.* a vinylogue of the phosphoronitrates.



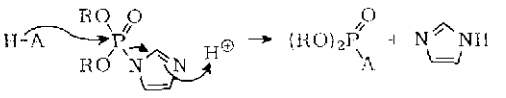
*(21)*

### B 2a: P—N—C=N (X = Z = N, Y = C): *N*-Phosphoroguanidates



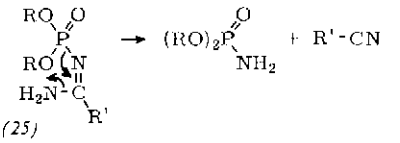
In contrast to phosphoramidates [38], phosphoroguanidates are difficult to hydrolyse, even with acid. They are not phosphorylating agents in the usual sense.

The guanidine moiety can exist in two different tautomeric forms, in one of which the carbon-nitrogen double bond is in conjugation via d-orbitals with the phosphorus atom. This gives rise to strong pπ–dπ interaction between the phosphorus and nitrogen atoms. If this interaction is weakened by withdrawal of electrons, *e.g.* by formation of a metal-ion complex, the phosphoroguanidate becomes a phosphorylating agent *(22)* [39].



*(22)*

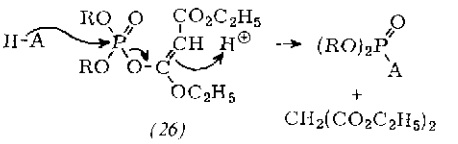
Acylation of the guanidine residue has a similar effect; *N*-acylphosphoroguanidates *(23)* function as phosphorylating agents under weakly basic conditions [40].



*(23)*

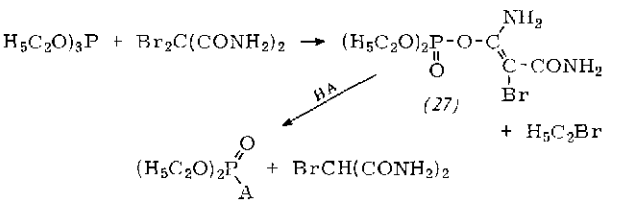
In contrast, *N*-phosphoroimidazoles *(24)* [41–45] are phosphorylating agents in the presence of acid.

*(24)*



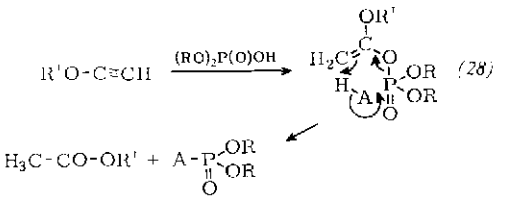
A further example of a P–N–C=N system is to be found in the *N*-phosphoroamidinates *(25)* [46] which rearrange probably through a four-centre transition state.

*(25)*



### B 2b: P—O—C=C (X = O, Y = Z = C): Enol Phosphates

Under conditions leading to electron withdrawal from the carbon-carbon double bond, *e.g.* by protonation or oxidation, enol phosphates are phosphorylating agents [47]. Thus, for example *(26)* can react with a carboxylic or phosphoric acid to produce an anhydride [48–50].



*(26)*

Moreover, catalytic amounts of mineral acid in ethanol cleave any dialkyl enol phosphate ester selectively to give the corresponding dialkyl ethyl phosphate and the appropriate carbonyl compound [47]. On the other hand, in aqueous acid or alkali, hydrolysis leads to a dialkyl phosphate [51]. Vinyl phosphates *(27)* are produced in the reactions of trialkyl phosphites with dibromomalonamide [52].

*(27)*

Such mixtures have been used to carry out phosphorylations. In addition, alkoxyacetylenes can activate phosphoric acids by forming 1-alkoxyvinyl phosphates [53,54].

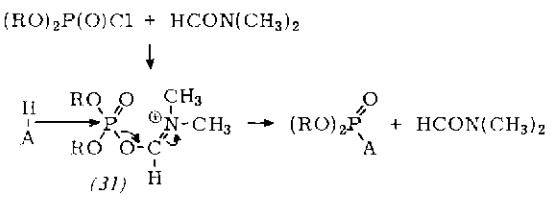
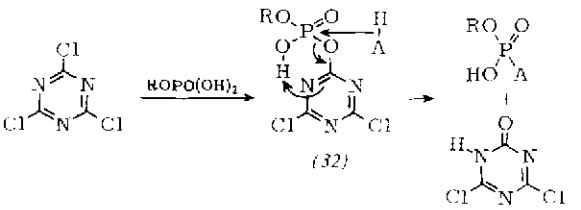
### B 2c: P—O—C=N (X = O, Y = C, Z = N): Imidoyl Phosphates

Imidoyl phosphates *(29)* [55] are formed *in situ* during the reaction of phosphate esters with carbodiimides [56,57], cyanamides [58], nitriles [59], keteneimines [60], and isocyanates [29,30]: no intermediate has ever been isolated, although the corresponding acid chlorides are well known [61,62]. In the presence of proton donors, imidoyl phosphates are powerful phosphorylating agents and have been used extensively in the synthesis of both phosphoric and pyrophosphoric diesters [63].



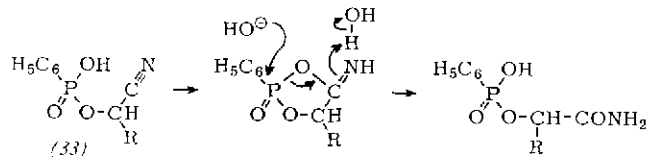
*(29)*

Beckmann rearrangement of an oxime in the presence of a phosphoric acid also leads to an imidoyl phosphate *(30)* [64].



*(30)*

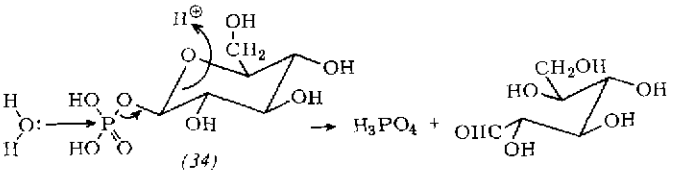
Catalysis of the reaction between an alcohol and a phosphorochloridic diester by *N,N*-dimethylformamide has been observed: again an imidoyl phosphate *(31)* is believed to be the key intermediate [65].



*(31)*

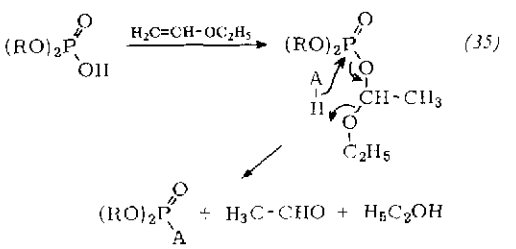
In the presence of cyanuryl chloride, phosphoric monoesters are good phosphorylating agents [66]; an imidoyl phosphate *(32)* is the probable intermediate.

*(32)*



Phosphonic esters of α-hydroxy nitriles *(33)* are hydrolysed in alkali to the corresponding amides [67]. The cyclic imidoyl phosphate which is presumably formed as an intermediate can be attacked at phosphorus by hydroxide ions.

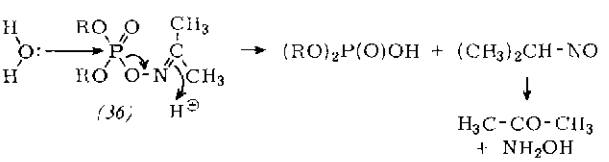
*(33)*



### B 2d: P—O—C—O (X = Z = O, Y = C): 1-Alkoxyalkyl Phosphates

The hydrolysis of glucose 1-phosphate *(34)* is catalysed by acids and proceeds with ring opening [68,69]; the alkaline hydrolysis of acetoxymethyl phosphate could well proceed by an analogous route [70].

*(34)*



Phosphoric diesters react with ethyl vinyl ether to give 1-ethoxyethyl phosphates *(35)*. In the presence of appropriate nucleophiles, these are phosphorylating agents [32].

*(35)*

### B 2e: P—O—N=C (X = O, Y = N, Z = C): *O*-Phosphoryloximes

Acidic hydrolysis of *O*-phosphoryloximes *(36)* can lead to a ketone, but the nature of the phosphorylated intermediate has not yet been determined [71].

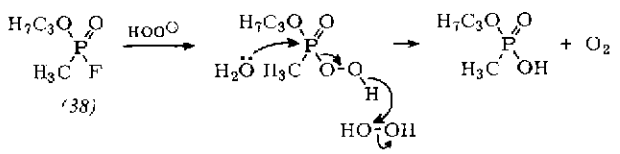
[71] *J. F. Allen,* J. Amer. chem. Soc. *79*, 3071 (1957).

The acceleration of hydrolysis of phosphorohalidates by hydroxamic acids [35] or by oximes [72] may be due to the formation of analogous structures.

### B 3a: P—N—N—H (X = Y = N, Z = H): Phosphorohydrazidates

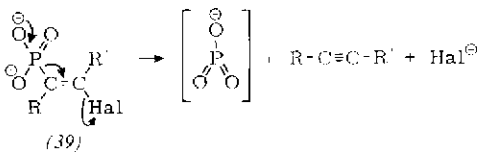
Phosphorohydrazidates *(37)* can act as phosphorylating agents either in the presence of acid, where their behavior may parallel that of phosphoramidates [38,73], or under oxidizing conditions, where they can react as shown in Scheme 2 [73,74].



Scheme 2.

The actual course of this oxidative acylation reaction has yet to be determined.

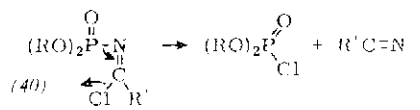
### B 3b: P—O—O—H (X = Y = O, Z = H): Peroxyphosphates and Hydroquinone Phosphates



The reaction between Sarin (isopropyl methylphosphonofluoridate) *(38)* and hydrogen peroxide proceeds by attack of the perhydroxide ion on phosphorus. The peroxyphosphate formed can be oxidized to give oxygen and isopropyl methylphosphonate [75].

Hydroquinone phosphates are, in a formal sense, vinylogous peroxyphosphates (cf. Section IIC); both transfer phosphate under oxidizing conditions [3,76,77].

### B 4a: P—C=C—Hal (X = Y = C; Z = Halogen): β-Halogenovinylphosphonates

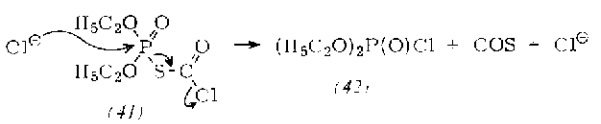


Vinylogues of phosphorochloridic acid *(39)* are much more stable than the parent acids, *e.g.*, β-halogenovinylphosphonates are stable in acidic solution. However, in alkaline solution, such phosphonates are hydrolysed to acetylenes with concurrent expulsion of halide ion [8,9].

As with saturated β-halogenoalkylphosphonates, the alkaline hydrolysis can proceed either intra- or intermolecularly. The fragmentation which occurs in both cases favors this type of reaction by the consequent gain in entropy.

### B 4b: P—N=C—Hal (X = N, Y = C, Z = Hal): *N*-Phosphoroimidoyl Halides

When heated *in vacuo*, *N*-phosphoroimidoyl chlorides *(40)* undergo rearrangement to give a phosphorochloridate and a nitrile [78].



Scheme 3

Such rearrangements might be intramolecular, as shown in Scheme 3, or might be due to attack of external chloride on the phosphorus atom. Again, fragmentation occurs with concurrent gain in entropy.

### B 4c: P—S—C—Hal (X = S, Y = C, Z = Hal): *S*-Halocarhonyl Thiophosphates

Salts of *O,O'*-diethyl phosphorothioic acid react with phosgene to give diethyl phosphorochloridate *(42)* [79]. Diethyl *S*-chlorocarbonyl phosphorothioate *(41)* is presumably formed first and is subsequently attacked by chloride ion to give *(42)* and carbon oxysulfide.

## V. Biological Phosphorylations

Phosphorylating agents capable of converting ADP into ATP *in vivo* are of the types B1 (pπ–dπ interaction attenuated in the ground state by competitive pπ–pπ overlap), B2, or B3 (pπ–dπ interaction removed by electrophilic or oxidative attack on Z). Acetyl phosphate *(43)* [80,81], acetyl-AMP *(44)* [82,83], carbamyl phosphate *(45)* [84,85], and 1,3-diphosphoglyceric acid

[85] *M. E. Jones*, Science (Washington) *140*, 1373 (1963).

*(46)* [86] are of the B1 (X = Z = O, Y = C) type, while the phosphorylating reactions of phosphoenolpyruvate *(47)* [87–90] fall into the B2 (X = O, Y = Z = C) category.

Phosphagens, *e.g.* phosphorocreatine *(48)*, can be considered as B2 reagents (X = Z = N, Y = C), but recent chemical evidence [40] suggests that the active entity could be the cyclic *anhydro*-form [*e.g.* phosphocreatinine *(49)*] with a B1 type of XYZ activation (vinylogous X = N, Y = C, Z = O).

[90] *T. T. Tchen* and *B. Vennesland*, J. biol. Chemistry *213*, 533 (1955).

Less well understood are the various reactions by which ATP is synthesized during oxidative [91,92] and photosynthetic [93,94] phosphorylation. In the cytochrome chain [95], ATP is generated from ADP at three sites, two of which probably involve, respectively, a flavoprotein [96] and a quinone [97]. The oxidation of hydroquinone phosphates with the production of ATP has already been mentioned; this reaction is regarded as a model for the *in vivo* process [98,99].

These chemical speculations are supported in some instances by experimental evidence, but they still require biochemical confirmation. However, they do provide a critical, as well as an analytical basis for further discussion. Thus, it is clear that phosphohistidine

*(50)*

*(50)* is a phosphorylating agent of the B2a type and cannot be implicated in oxidative reactions of the B3 type. Although *(50)* may play a role in oxidative phosphorylation [100], unlike the nicotinamide nucleotides [101,102], it cannot interconvert a redox and an acylating system.

In this way, the P–XYZ classification of phosphorylating agents has both a predictive and a critical aspect.

# Metallo-Complexes

BY PRIV.-DOZ. DR. G. BERGERHOFF [1]

ANORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT BONN (GERMANY)

*Ternary and quasiternary compounds consist of either one cationic and two anionic, or one anionic and two cationic components. The size of the ions and the bonding forces between them determine the structure of the compounds. A compound is regarded as a complex when its lattice contains structural groups in which the interaction between the constituent atoms is substantially greater than or different from that between these structural groups and the other components of the compound. Metallo-complexes are built up of one cationic and two anionic components; in contrast to the complexes with cationic central atoms which have been thoroughly investigated, they contain an anionic central atom surrounded by cationic ligands. A list is given of many compounds which can be formulated as metallo-complexes after discussion of methods for their preparation and their chemical properties; the reason that only few metals can function as ligands of an anionic central atom is deduced from the pertinent crystal structures.*

## A. Introduction

In modern chemistry, a salt is defined as a substance whose components are arranged in an ionic lattice [2]. If we consider a salt $K_mA_p$ in which the lattice sites are occupied by cations K and anions A, the type of lattice assumed is determined by the sizes of the ions involved, the bonding forces between them, and the principle of electrical neutrality. In ternary compounds

$K(1)_mK(2)_nA_p$ or $K_mA(1)_pA(2)_q$,

either the K or the A sites are occupied by two different elements. The magnitudes of the bonding forces K(1)-A and K(2)-A or K-A(1) and K-A(2) are normally different, and hence play a significant part in determining the crystal structure. Typical mixed crystals are formed when the bonding forces are approximately equal in magnitude, and typical complex salts result when the bonding forces are vastly different.

Although complex salts of the form $K(1)_m[K(2)_nA_p]$ have been investigated in great detail ever since the studies of *Werner*, little attention has been given to ternary compounds of the type $[K_mA(1)_p]A(2)_q$.

The names of such complexes can be formed in various ways according to the I.U.P.A.C. Rules for Nomenclature of Inorganic Chemistry [3]:

1. The addition of protons to mono-atomic anions yields cations of the type $[XH_4]^+$, which are named by adding -onium to the Latin name of the anionic element (Rule 3.14). If the protons are displaced by other cations (a possibility not considered in the I.U.P.A.C. Rules), the names remain unchanged (Rule 7.321) and terms such as trisilversulfonium nitrate for $[SAg_3]$ $[NO_3]$ are obtained.

2. If substitutive nomenclature is to be avoided in inorganic chemistry, the name of the complex $[SAg_3]^+$ can be formed by listing the partners. In this case neither the cationic ligand silver (Rule 7.321) nor the central atom sulfur (Rule 7.24) are given a distinguishing termination. The name of $[SAg_3]$ $[NO_3]$ would then be trisilversulfur nitrate.

3. Rule 7.321, which requires that the name of a cationic ligand be used without change, does not list any pertinent example. This is to be regretted, since otherwise it would have become clear that it seems advisable to denote the position of a positive ligand within a complex also by using the ending -o.

$[SAg_3]$ $[NO_3]$ may thus be referred to as trisilversulfonium nitrate, trisilversulfur nitrate, triargentosulfonium nitrate, or triargentosulfur nitrate. In this article, the last system of nomenclature will be used, in accordance with *Lieser* [4]. Complexes with an anionic central atom and cationic ligands may be conveniently designated general as metallo-complexes.

## B. A Systematic Classification of Multicomponent Compounds

### 1. Ternary Compounds

In order to arrive at an unambiguous definition of metallo-complexes, let us arrange the structures of the ternary compounds $K(1)_mK(2)_nA_p$ and $K_mA(1)_pA(2)_q$ into a series, with the difference in bond strengths of K(1)-A and K(2)-A or of K-A(1) and K-A(2) as parameter. Four groups are formed.

*Group 1 – Solid Solutions and Double Salts with Binary-Salt Type Structures*

If the sizes and polarizability of the elements K(1) and K(2) at the K-sites or A(1) and A(2) at the A-sites are very similar, then K(1) and K(2) or A(1) and A(2) are mutually interchangeable. They are randomly distributed, and the relative proportions of the elements need not even be stoichiometric, so that mixed crystals can occur as well as double salts (Table 1).

[1] Excerpts from the Habilitation Thesis of *G. Bergerhoff*, Universität Bonn, 1962 (D 5).

[2] See, for example, *G. Schwarzenbach:* Allgemeine und anorganische Chemie. S. Hirzel, Stuttgart 1948, p. 76.

[3] I. U. P. A. C. Nomenclature of Inorganic Chemistry 1957. Butterworths, London 1959.

[4] *K. H. Lieser*, Z. anorg. allg. Chem. *295*, 106 (1958).

*Group 2 – Double Salts with Structures Derived from Binary-Salt Structures by Ordered Distribution of the Two Types of Cations or Anions*

A greater difference in bond strengths forces the elements to assume an ordered distribution, resulting in a new type of structure. However, the essential structural relationships of the binary salts are retained, and consequently the coordination numbers of K(1) and K(2) or A(1) and A(2) are practically equal (Table 1).

**Table 1.** Examples of the classification of ternary compounds [a].

| Group | a: $K(1)_mK(2)_nA_p$ | | Ref. | b: $K_mA(1)_pA(2)_q$ | | Ref. |
|---|---|---|---|---|---|---|
| | Compound | Structure [b] | | Compound | Structure [b] | |
| 1 | (K,Na)Cl | NaCl type, mixed crystals | | Ag(Br,I) | NaCl type, mixed crystals | |
| | $KLaF_4$ | Fluorite type, double salt | [5] | HoOF | Fluorite type, double salt | [6] |
| 2 | $CuFeS_2$ | Related to zinc blende | [7] | $Cu_4(OH)_6Br_2$ | Related to burcite | [8] |
| 3 | $RbMgF_3$ | Perovskite type CN of K(1):12 CN of K(2):6 | [9] | β-$Ag_3SI$ | Antiperovskite CN of A(1):6 CN of A(2):12 | [10] |
| | $MgAl_2O_4$ | Spinel type CN of K(1):4 CN of K(2):6 | [9] | PbFCl | Layer lattice CN of A(1):4 CN of A(2):5 | [11] |
| 4 | $K_2[SO_4]$ | Island complex | | $[(ClHg)_3O]Cl$ | Two-shell complex | [17] |
| | $K_2[Cr_2O_7]$ | Polynuclear complex | | | | |
| | $K_2[CuCl_3]$ | Chain complex | [18] | $[Hg(NH_2)]Br$ | Chain complex | [17] |
| | $K_2[NiF_4]$ | Layer complex | [19] | | | |
| | $Ba[ZnO_2]$ | Framework | [20] | $[Hg_2N]Br$ | Framework | [17] |

[a] Although $Cu_4(OH)_6Br_2$ and $Hg(NH_2)Br$ are quaternary compounds, they are included here since the proton practically disappears in the electron cloud of its bonding partner.
[b] CN = Coordination number.

*Group 3 – Lattice Compounds in which the Two Types of Cations or Anions have Different Properties*

If the difference in bond strengths is even greater, then K(1) and K(2) or A(1) and A(2) assume different coordination numbers, although the nature of the bonds between the cations and the anion or between the anions and the cation remains similar. The resulting structures can no longer be traced back to the binary-salt type (Table 1).

*Group 4 – Complex Compounds*

The series is terminated by compounds which were defined by *Werner* [12] in 1913 as follows: "If compounds of higher order are characterized by stability in aqueous solution, in that they do not dissociate into their components, they are called complex compounds". This definition is unsatisfactory nowadays, for we know that on principle complexes dissociate into their components in solution, although there are great differences among the complex formation constants and the rates of dissociation. Moreover, dissociation of complexes is regarded as a chemical reaction, the course of which depends on the nature of the reaction partners. A true complex compound may even be present when its components can be detected in solution. It seems useful to abandon this "dynamic" definition, and as with the concept of a "salt", to give a "static" definition based on the structure of the solid state:

*Complex compounds are compounds whose lattices contain structural groups in which the interaction between the constituent atoms is substantially greater than or different from that between these structural groups and the other components of the compound.*

Of course, the interaction between the atoms of a crystal lattice cannot be determined readily by experiment; however, assignments can be made in most cases from considerations based on bonding theory. For example, it may be plausible, from the electron configuration of the atoms or from comparison of the interatomic distances, to assume that the bonding for a given compound is homopolar. Sometimes it can be determined from the size and charge of the ions, and from their polarizability and polarizing action, whether the compound in question is a complex.

Structural groups consisting of discrete units made up of a central atom surrounded by ligands are usually known as "island complexes". If these ligands in turn act as central atoms and become surrounded by a second outer ligand sphere, which is also to be regarded as part of the structural group, the compounds are referred to as two-shell or supercomplexes [13, 14].

[14] *H. Remy:* Lehrbuch der anorganischen Chemie. Akademische Verlagsgesellschaft Geest u. Portig, Leipzig 1959, Vol. II, p. 364.

However, the ligands of a complex can also link up several central atoms to form polynuclear complexes, and these logically include complexes which extend in one or more directions to infinity (polymeric complexes) [15]. It appears to be convenient to refer to the atom with the greater coordination number as the central atom; it is then possible to differentiate between complexes with cationic and anionic central atoms. Some examples are shown in Table 1.

### 2. Quasiternary Compounds

The above division into four groups provides a basis for a systematic classification of inorganic complex structures; which largely reflects the relationships between the various lattice types. Groups 1 and 2 have been characterized already by the fact that their structures can be traced back to those of binary compounds. If lattice sites are occupied by complexes (in the sense of discrete structural groups), ternary compounds, such as $K_2[SO_4]$, can be regarded as quasibinary compounds, and quaternary or higher-order compounds, such as $[K(H_2O)_6]\,[Al(H_2O)_6]\,[SO_4]_2$, as quasiternary.

The series can now be extended to include quasiternary compounds. Some examples are shown in Table 2.

Table 2. Examples of the application of the systematic classification to quasiternary compounds.

| Group | a: $K(1)_mK(2)_nA_p$ | | | b: $K_mA(1)_pA(2)_q$ | | |
|---|---|---|---|---|---|---|
| | Compound | Structure | Ref. | Compound | Structure | Ref. |
| 1 | (Ba,Sr) $[SO_4]$ | Barite type | [21] | $Mg_2(OH)_3Cl$ | Related to brucite | [22] |
| 2 | $CaMg[CO_3]_2$ | Related to calcite | [23] | $Cu_4(OH)_6[NO_3]_2$ | Related to brucite | [24] |
| 3 | $Mg_3Al_2Si_3O_{12}$ | Garnet type | [25] | $Pb_5[PO_4]_3Cl$ | Apatite type | [26] |
| 4 | $K_4[Ni(NO_2)_6]$ | | [27] | $[Hg_3O_2][SO_4]$ | | [17] |

## C. Metallo-Complexes

### 1. General Discussion and Examples

The examples of Group 4b in Tables 1 and 2 will be referred to as metallo-complexes. *Werner* [28], in the systematic application of his coordination theory, distinguished between "the great majority of coordination compounds, in which the centers of complex formation are elementary atoms which are more electropositive than the elementary atoms which accept the linkages of the added molecular components", and a "small group of compounds in which the opposite is the case". By way of example, *Werner* [28] quoted the compound $[IAg_3][NO_3]_2$, in which *Hellwig* [29] had observed migration of a complex ion $[IAg_3]^{2+}$ during electrolysis. This salt and similar silver salts are still the classical examples of this type of complex, although the number of compounds which can be formulated as metallo-complexes has steadily grown. Evidently the lack of a good example of a typical island complex was the reason for alternative formulations. Thus, *Hayek* [30] regarded whole "salt molecules" as ligands, *e.g.* in $[Hg(HgI_2)_2][ClO_4]_2$, because he required cationic central atoms as in conventional complexes. *Yatsimirskii* [31] listed numerous compounds which can be described as complexes with anionic central atoms, but did not prove his assumptions. It is only recently that modern physical methods have been applied to silver compounds and that mercury compounds in particular have been investigated by X-ray methods. As prerequisites for the formation of metallo-complexes, *Lieser* [32] named high polarizability of the negative central atom, and *Yatsimirskii* its low electron affinity. Obviously not all metals are capable of forming complexes of this type; according to *Yatsimirskii*, a high ionization potential is necessary. Frequently, the difficulties encountered in preparing compounds of this type indicate that their free enthalpy of formation is not very great, so that even small effects can reverse its sign. The extra-complex ion A(2) is also of importance, since it can change the lattice energy, and can even act as a complexing ligand for a cationic central atom.

Table 3 shows some compounds which can be formulated as metallo-complexes. Their structures are known only in a few cases. The Table, which is not meant to be complete, shows how many structures might be ordered using the concept of "metallo-complexes". However, only an elucidation of these structures will finally prove the value of this list.

| Pseudohalogen-Komplexes | $[(CN)Ag_3]^{2+}$ | $NO_3^-$ | Framework | [29, 75] |
| | $[(SCN)Ag_3]^{2+}$ | $NO_3^-$ | Framework | [29, 75] |
| | $[(SeCN)Ag_3]^{2+}$ | $NO_3^-$, $ClO_4^-$ | | [76] |

[*] This group includes a few "basic salts"; most of these form structure of Groups 1, 2, and 3.

## 2. Preparation of Metallo-Complexes

Metallo-complexes can be conveniently prepared by three methods:

$$p\,KA(1) + q\,KA(2) \rightarrow [A(1)_pK_{p+q}]A(2)_q \quad (a)$$

$$(p + m)\,KA(1) + q\,A(2)X \rightarrow [A(1)_pK_{p+m}]A(2)_q + A(1)_mX_q \quad (b)$$

$$(q + m)\,KA(2) + p\,A(1)X \rightarrow [A(1)_pK_{q+m}]A(2)_q + A(2)_mX_p \quad (c)$$

Metallo-complexes are formed according to Equation (a) either in melts [71], *e.g.* $[IAg_3]\,[NO_3]_2$, or on annealing by reaction in the solid state, *e.g.* $[S_2Hg_3]Cl_2$. This stage may be preceded by another reaction, such as a redox reaction in the preparation of $[SAg_4]\,[SO_4]$ from silver nitrate and sulfur. The salts KA(1) are often only sparingly soluble in water, but dissolve to an appreciable extent in a sufficient excess of KA(2) solution. Thus, the salts AgI, AgCNS, $Ag_2Te$, *etc.* are soluble in concentrated aqueous solutions of silver nitrate, complexes being precipitated on careful dilution. Mercury(II) iodide is soluble in hot aqueous mercury(II) perchlorate, and $I_4Hg_3]\,[ClO_4]_2$ crystallizes out on cooling [46].

Addition of A(2) according to Equation (b) leads to the formation of $\{[OBe_4]\,[CH_3COO]_6\}$ from beryllium hydroxide and acetic anhydride since excess hydroxide ions are taken up by the acetic anhydride to form acetic acid.

Very many metallo-complexes are formed according to Equation (c). Thus, at the beginning of the precipitation with hydrogen sulfide of many heavy metals, such as thallium, lead, or mercury, brightly colored "sulfobasic" salts appear, *e.g.* $[STl_3]Cl$. "Basic salts", which may also be metallo-complexes, are generally formed when the pH is increased, *i.e.* on addition of $OH^-$ or $O^{2-}$ ions. The formation of complexes with a central nitrogen atom is so far known only for mercury, with ammonia as the source of A(1); in this reaction the driving force is probably the insolubility of the "salts of Millon's base". Phosphine can give phosphorus complexes with silver or mercury compounds.

However, these methods of preparation usually yield the compounds at best only in microcrystalline form. Larger crystals can be obtained if A(1) is slowly formed by chemical reaction. Of the series methyl iodide, isopropyl iodide, and 2,4-dinitroiodobenzene, only the middle member forms large crystals of triargentoiodine nitrate with concentrated silver nitrate solution:

$$(CH_3)_2CHI + H_2O + 3\,AgNO_3 \rightarrow [IAg_3]\,[NO_3]_2 + HNO_3 + (CH_3)_2CHOH.$$

Carbon disulfide can be used as the source of sulfur for the preparation of large crystals of triargentosulfur nitrate:

$$CS_2 + 2\,H_2O + 6\,AgNO_3 \rightarrow 2\,[SAg_3]\,[NO_3] + 4\,HNO_3 + CO_2.$$

The crystal size can be further increased if the compounds are formed in silica gel, for in this colloidal capillary system, the crystal seed is held fast and can grow by influx of material from all sides by diffusion. For example, crystals of $[SAg_3]\,[NO_3]$ up to 1 mm long have been obtained as well-defined rhombohedra.

The capillary structure of silica gel containing silver nitrate can be very elegantly demonstrated by covering the gel with a layer of reducing agent; this procedure results in growth of silver whiskers up to 1 cm long in which, according to rotating crystal photographs, the filament direction is always [110].

## 3. Structure of Metallo-Complexes

The structures of only a few metallo-complexes are known at present. All of them represent well-known complex types.

Thus, trischloromercury(I)-oxygen chloride $[O(HgCl)_3]Cl$ is a two-shell complex or supercomplex (Fig. 1).

In the first sphere, the central oxygen atom occupies the apex of a trigonal pyramid [77], the base of which is formed by three mercury atoms at distances of 2.06 Å (sum of the covalent radii – 2.10 Å apart); these in turn are linked to chlorine at a distance of 2.29 Å (Hg–Cl distance in $HgCl_2$ = 2.34 Å), forming a second sphere of covalently bonded ligands around the central oxygen atom. In contrast, the chloride ions at a distance of 2.99 and 3.09 Å from the mercury atoms should be regarded as

lying outside the complex. Another example is "basic beryllium acetate" $\{[OBe_4][CH_3COO]_6\}$. In this complex, the central oxygen atom is tetrahedrally surrounded by four beryllium atoms; the carboxyl groups link the beryllium atoms in pairs, in the manner of chelates, thus forming an inner complex salt. The beryllium atoms, like the oxygen atom, therefore have a coordination number of four, so that the compound might also be regarded as a tetranuclear complex of beryllium; however, oxygen certainly is the central atom.

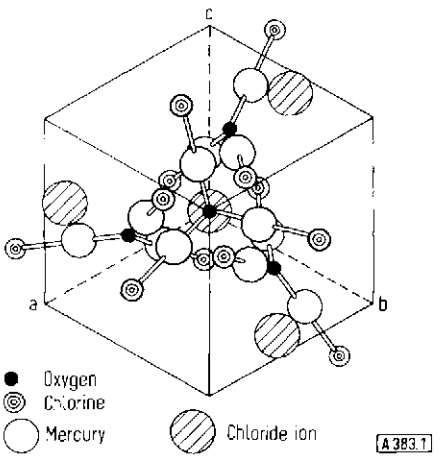

Fig. 1. Projection of the [O(HgCl)] [Cl] structure in the direction of one of its threefold axes (anions omitted) [77].

"Basic mercury chlorate" or hydridomercury(I)-oxygen chlorate [OHHg] $[ClO_3]$ forms a chain complex (Fig. 2), in which the oxygen and the mercury atoms alternate.

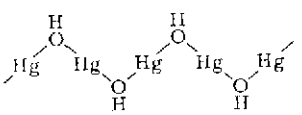

Fig. 2. Chain structure of the [HOHg] $(ClO_3]$ complex (anions) omitted.

However, the oxygen atom has a coordination number of three, owing to the additional bond to the hydrogen, while that of the mercury atom is only two, since the chlorate ions lie at the ionic bond distance. "Mercuryamido bromide" $[(NH_2)Hg]Br$ has a similar structure. The lattice is traversed by chains of alternating mercury and nitrogen atoms. The coordination number of the nitrogen atom is four, so that it must be regarded as the central atom.

The class of layer complexes is represented by the mercury(I)-oxygen compound $[O_2Hg_3][SO_4]$, and also by "mercuryimido bromide" $[(NH)_2Hg_3]$ $[HgBr_3]Br$. According to preliminary structural determinations, mercury atoms and oxygen or nitrogen atoms form networks, the meshes of which receive the oppositely charged ions (Fig. 3).

The oxygen or nitrogen atom has a coordination number of three and is the central atom of the complex. The sulfate groups in trimercury(I)-dioxygen sulfate are bonded ionically (Hg–O distance in the complex = 2.03 Å; Hg–$OSO_3$ distance = 2.47 Å).

Examples of framework complexes are dimercury(I)-nitrogen salts such as $[NHg_2]Br$, dimercury(I)-phosphorus chloromercurate(II) $[PHg_2]$ $[HgCl_3]$, and tri-

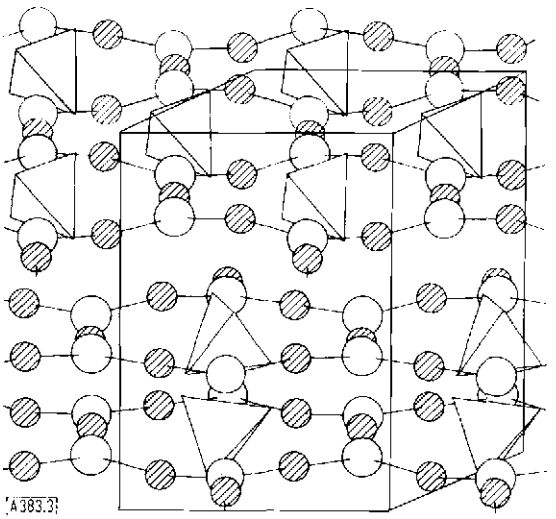

Fig. 3. Section of three layers of $(O_2Hg_3)$ $(SO_4)$. After [45]. The upper layer has been continued backwards. Hatched circles = mercury; open circles = oxygen; terahedra = sulfate.

argentosulfur nitrate $[SAg_3][NO_3]$. The mercury(I)-complexes have a tridymite structure in which the tetrahedrally coordinated silicon atom is replaced by nitrogen or phosphorus, and in which mercury takes the place of the 2-coordinate oxygen atom. The oppositely charged ions are situated in the spaces between the tetrahedra. Similarly, $[SAg_3][NO_3]$, which is cubic, contains approximately trigonal prismatic $SAg_6$ structural groups [78], linked through common corners to form a three-dimensional framework (Fig. 4). The cavities are sufficiently large to accommodate the nitrate groups which are ionically bonded.

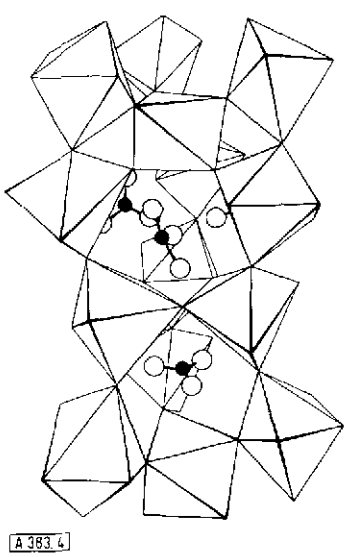

Fig. 4. Three-dimensional structure of the SAg $NO_3$ complex showing the $SAg_6$ polyhedra and the nitrate ions (● = N; o = O).

[78] The structure published earlier [59] has meanwhile been more accurately calculated by the method of least squares, using an IBM 704 computer. The program made it possible to presuppose the planar arrangement of the nitrate groups and the N–O distance of 1.218 Å [79], and used the difference $F_{obs}-F_{calc}$ for the weighting, with $w = 1/(F_{obs}-F_{calc})^2 + 0.5$ [80]. A reliability factor of $R = 14\%$ (only with $F \neq 0$) was obtained. The following parameters were finally obtained:

Ag: 12b; $x = 0{,}308 \pm 2$ $y = 0.9942 \pm 3$ $z = 0.3582 \pm 2$ $B = 2.82 \pm 5$

S: 4a; $x = 0.1367 \pm 8$ $B = 2.3 \pm 1$

N: 4a; $x = 0.414 \pm 1$

O: 12b; $x = 0.532$ $y = 0.318$ $z = 0.391$ } $B = 1.2 \pm 2$

## 4. Requirements for the Formation of Metallo-Complexes

Examination of all the metallo-complex structures described shows that island and polynuclear complexes are not encountered. Both types have a common factor, namely that their structural units must contain terminal metal atoms; a hypothetical island complex $[SAg_3]^-$ and a dinuclear complex $[Ag_2SAg_2SAg_2]^{2+}$ would contain metal atoms with a coordination number of 1. The tendency towards formation of structures of this type is obviously small.

It is known that the orbitals of cationic central atoms undergo hybridization when ligands are added, so that the resulting coordination polyhedron is more or less symmetrical. Anionic ligands, on the other hand, can be bonded by a singly occupied atomic-p-orbital, *i.e.* one-sidedly. In the sulfate ion, for example, if double-bond contributions are neglected, the electron structure may be pictured as follows: sulfur, with the ground state $s^2p^4$, gives up two electrons, and the remaining $s^1p^3$-electrons occupy four new tetrahedrally arranged equivalent orbitals. These hybridized orbitals overlap with the singly occupied atomic p-orbitals of four oxygen ions in the configuration $s^2p^5$, which are formed by the uptake of four electrons – two from the sulfur, and two through formation of the counter-ions.

The structure of metallo-complexes becomes understandable if it is assumed that the more electropositive atom of a complex, whether it be the central atom or a ligand, always appears to have a stronger tendency towards hybridization than the more electronegative atom. In general, the negative atom (central atom) is already hybridized. The tendency of the positive ligands to form hybrids will therefore be even greater. However, since hybridization allows the existence of at least two bonds in two directions, the ligand cannot be terminal in the structural group, *i.e.* it can never be monodentate. Instead, it will either attach itself to a second central atom, giving rise to polynuclear complexes, or will become saturated by other anionic ligands to form a two-shell complex. Conversely, the formation of two-shell complexes is not to be expected with cationic central atoms, since a cationic element cannot terminate a structural group. Thus, *Werner*'s [16] example $[Co(NH_3)_5NCSAg]\ [NO_3]_3$ probably has some other structure. The only exception to this rule is the hydrogen atom. Owing to its small size, it is largely embedded in the electron cloud of its bonding partner, so that hydroxo-complexes are not regarded as two-shell complexes, nor hydroxides as complexes.

It follows also from the structure of the metallo-complexes that not every element can participate in complexes of this type. As may be seen from Table 3, all elements which occur as anions are suitable, but of the cationic elements, only those which have low specific coordination numbers can take part. The reason is that the coordination number of the ligands must, by definition, be lower than that of the central atom, and that for steric reasons, ligands belong to more than two coordination polyhedra only in special cases.

These requirements are satisfied for example by elements of the B groups of the periodic table. In the case of ions with a $d^{10}$-electron configuration this behavior can be attributed to the development of a ds-hybrid, for which the excitation energy is relatively small, particularly for the $Cu^+$, $Ag^+$, $Au^+$, and $Hg^{2+}$ ions [81]. The crystal field theory shows that an octahedral environment is then so strongly distorted that two strong linear bonds remain.

A second group of elements with apparently lower coordination numbers forms ions which possess s-electrons in addition to ten d-electrons. A hybrid of s- and p-orbitals is now partially occupied by the electrons of the atom, and this leads to development of extremely unsymmetrical and low coordination states. Numerous examples of this are provided by the structures of compounds of $Tl^+$, $Sn^{2+}$, $Pb^{2+}$, $Bi^{3+}$, and $Sb^{3+}$.

## 5. Properties of Metallo-Complexes

*Lieser* determined the stability constants of argento-halogen complexes [82] in aqueous solution; these increase with the size of the central atom. However, it is not known to what extent the tendency of metal ligands towards coordination in solution is satisfied by the associated water molecules. The roles of the central atom and the ligand can be interchanged in competitive reactions, so that complexes with cationic central atoms are formed. Thus, for example, all argento-complexes decompose upon contact with molecules containing nitrogen, *e.g.* ammonia or acetonitrile, the corresponding silver complex being formed immediately.

The metallo-complexes are predominantly polynuclear complexes. The most notable of their reactions are those in which the complex ion remains stable and the compounds assume ion-exchanger characteristics. Thus, *Lieser* was able to exchange nitrate ions in $[IAg_3]\ [NO_3]_2$ for hydroxide or chloride ions. *Weiss* et al. displaced alkali ions from $K[NHg(SO_3)]$ with tetraalkylammonium ions. Similarly, $[S_2Hg_3]Cl_2$ reacts with dilute nitric acid to yield $[S_2Hg_3]\ [NO_3]_2$ [40], and almost any desired group can be built into the framework of the $[CHg_3O]^+$ ion.

These chemical properties show clearly how reasonable it is to single out structural groups from lattices, even when the former occur as "infinitely" extended components of a complex compound.

*I should like to thank Prof. O. Schmitz-Du Mont and the Deutsche Forschungsgemeinschaft for their generous support of this work.*

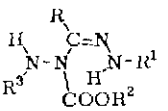
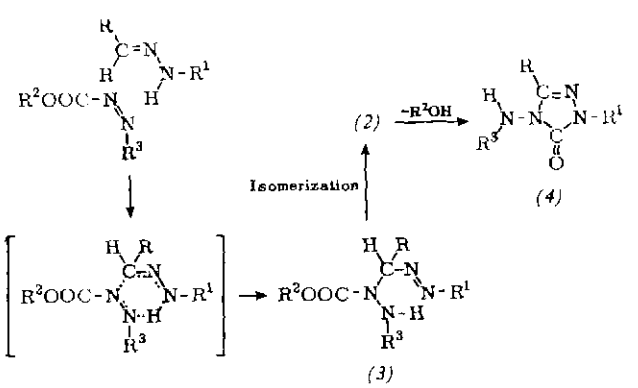
## The Structure of the "Tetrazanes" Produced from Alkoxycarbonylazo Compounds and Aldehyde Phenylhydrazones



By Priv.-Doz. Dr. E. Fahr and Dipl.-Chem. H.-D. Rupp [1]

Chemisches Institut der Universität Würzburg (Germany)

The reaction of azodiformates ROOC-N=N-COOR or ethyl phenylazoformate with aldehyde phenylhydrazones gives 1:1 adducts for which 1-alkylidene-2-phenyltetrazane structures *(1)* [2] and hydrazidine structures *(2)* [3] have been proposed. We have shown by ultraviolet, infrared, and $^1$H-NMR spectroscopy and by synthesis of the previously unknown hydrazidines *(2)*, $R^3$ = $COOR^2$ or $C_6H_5$, that the adducts actually possess 1-azo-1-hydrazinoalkane structures *(3)*, $R^3$ = $COOR^2$ or $C_6H_5$.



*(1)*

*(2)*

The adducts give a band at ca. 400 mμ which can be assigned to the n-π* transition of the azo group of *(3)* but to no part of the tetrazane or hydrazidine structures *(1)* or *(2)* (Table). The molecular extinction of this band for each adduct corresponds to those of other azo compounds and, with increasing dielectric constant of the solvent, the band is shifted to shorter wavelengths as expected for an n-π* transition. In agreement with structure *(3)*, the infrared spectra show only one N–H band. The $^1$H–NMR spectra of compounds *(3a)* and *(3g)* show signals at τ = 3.17 and 3.19 ppm, respectively, corresponding to the α-benzyl proton of *(3)*. Hydrogenation of *(3a)* with diimine, which can attack the N=N bond of *(3)* but not the C=N bond of *(2)* or the N–N bond of *(1)* [4], gives benzaldehyde phenylhydrazone and *N,N'*-bisethoxycarbonylhydrazine; this confirms structure *(3)*.

The 1-azo-1-hydrazinoalkanes *(3)*, $R^3$ = $COOR^2$ or $C_6H_5$, can be isomerized to the corresponding hydrazidines *(2)*, $R^3$ = $COOR^2$ or $C_6H_5$, by dissolution in a small amount of pyridine at room temperature. After a few minutes, the base is evaporated *in vacuo*, and the residual oil is induced to crystallize by scratching under ligroin. The hydrazidines *(2)* are unstable and, when heated in solution or treated with acid or alkali, they lose alcohol to give dihydrotriazole derivatives *(4)* [3]. The structures of the hydrazidines *(2)* were proved by their elementary analyses, molecular weights, and infrared spectra, which show the two N–H bands required by *(2)* (Table).

| | R | $R^1$ | $R^2$ | $R^3$ | *(3)* $\lambda_{max}$ [mμ] | *(3)* ε [a] | *(2)* Fp [°C] | *(2)* N–H Bands [μ] [d] |

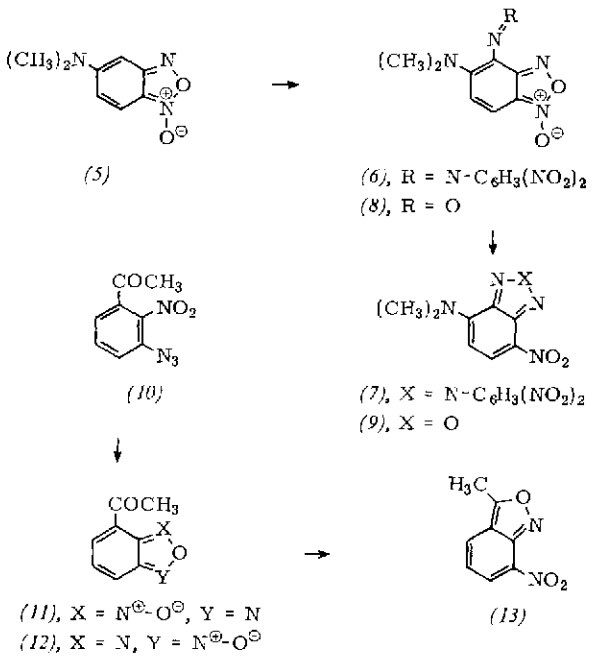
## A General Rearrangement of Heterocycles, and Novel Syntheses of the Benzotriazole, Benzofurazan, and Anthranil Systems [1]

By Dr. A. J. Boulton, P. B. Ghosh, and Prof. Dr. A. R. Katritzky [2]

School of Chemical Sciences, University of East Anglia, Norwich (England)

The ease of isomerization [*(1)* → *(2)*] of 4-nitrobenzofuroxans [3] led us to postulate the reaction *(3)* → *(4)* as a new general rearrangement of heterocyclic compounds; A and D



*(1)* *(2)* *(3)* *(4)*

may represent N, $N^{\oplus}$–$O^{\ominus}$, or CR, and B and E may represent O, NR, or CHR. The number of possible combinations is large. Here we wish to report three examples, which simultaneously constitute novel syntheses of the benzotriazole, benzofurazan, and anthranil systems.

5-Dimethylaminobenzofuroxan *(5)*, m.p. 123–124 °C, was prepared from 3,4-dinitro-*N,N*-dimethylaniline by replace-

ment of the 3-nitro group by an amino group, followed by diazotization of the latter, treatment of the diazonium salt with $NaN_3$, and thermal decomposition of the 3-azido-4-nitro-*N*,*N*-dimethylaniline, m.p. 82–83 °C (decomp.), produced. The dimethylamino compound *(5)* reacted with

*(5)*

*(6)*, R = N-C$_6$H$_3$(NO$_2$)$_2$
*(8)*, R = O

*(7)*, X = N-C$_6$H$_3$(NO$_2$)$_2$
*(9)*, X = O

*(10)*

*(11)*, X = $N^{\oplus}$-$O^{\ominus}$, Y = N
*(12)*, X = N, Y = $N^{\oplus}$-$O^{\ominus}$

*(13)*

either 2,4-dinitrobenzenediazonium sulfate or nitrous acid in $H_2SO_4/H_2O/C_2H_5OH$ (1:3:20 v/v) at 15–20 °C, but in each case the initial reaction products *(6)* and *(8)* rearranged spontaneously to yield the benzotriazole *(7)*, m.p. 287 °C (decomp.), or the benzofurazan *(9)*, m.p. 215–216 °C, respectively, as shown by infrared and NMR spectroscopy and by chemical evidence.

Heating of the azide *(10)*, m.p. 140–141 °C (decomp.), which was prepared from the corresponding amino derivative, did not give rise to the benzofuroxan [*(11)* ⇌ *(12)*] but instead to a 60 % yield of the anthranil *(13)*, m.p. 165–166 °C, as shown by the infrared spectrum.

## Interaction of Disubstituted Cyanamides with Phosgene and Oxalyl Chloride

By Dr. K. Bredereck and Dipl.-Chem. R. Richter

Institut für Textilchemie und Institut für Organische Chemie der Technischen Hochschule, Stuttgart (Germany)

It is known that acyl chlorides, *e.g.* benzoyl chloride, add on readily to molecular compounds of nitriles and electrophilic metal chlorides to form *N*-acylnitrilium salts [1]. We have found that phosgene reacts particularly readily without catalysis by metal chlorides with disubstituted cyanamides, *i.e.* with nitriles whose cyano group is joined to electron-donating groups. Surprisingly, however, the phosgene does not add onto the cyano group; instead, the reaction proceeds with elimination of carbon dioxide, yielding very reactive compounds which, judging from their properties, elementary analysis, and reactions, are assumed to have the structure *(1)*. The same products are formed when oxalyl chloride is used instead of phosgene.

*(1a)*, R = R$^1$ = CH$_3$
*(1b)*, R + R$^1$ = -(CH$_2$)$_5$-
*(1c)*, R + R$^1$ = -(CH$_2$)$_2$-O-(CH$_2$)$_2$-

The products *(1)* react with amines to yield triazine derivatives. Thus, (5-dimethylamino-1,3,5-trichloro-2,4-diazapenta-2,4-dien-1-ylidene)dimethylammonium chloride *(1a)*, m.p. 125 °C, is converted by ammonia in chloroform under mild conditions into 2,4-dimethylamino-6-chloro-1,3,5-triazine [2]. The action of aqueous ammonia on *(1a)* yields 2-amino-4,6-dimethylamino-1,3,5-triazine [3].

In order to prepare *(1)*, equimolar proportions of the components are kept in an indifferent solvent at room temperature for 20 h. In ether or benzene, the products *(1)* separate out as crystals or oils. In chloroform or methylene chloride, the products remain in solution and are obtained by concentration. The yields exceed 90 %.

Other acyl chlorides also yield definite reaction products; the study of their reactions is in progress.

## Solvent Effects on the Position of the First Overtone of the O–H Valence Vibration

By Dr. G. Habermehl

Institut für Organische Chemie der Technischen Hochschule Darmstadt (Germany)

We reported recently on the use of the first overtone of the O–H valence band to distinguish between primary, secondary, and tertiary alcohols [1]. The values measured in $CCl_4$ were 7090–7115 cm$^{-1}$ for primary alcohols, 7067 to 7078 cm$^{-1}$ for secondary alcohols, and 7042–7053 cm$^{-1}$ for tertiary alcohols.

It can be seen from the Table that these three groups are just as sharply separated in the non-polar solvent n-hexane. Also, in all the other solvents so far examined the frequency of the first overtone for primary alcohols is always greater than that for secondary, and this in turn is greater than that for tertiary alcohols, although the frequency regions sometimes overlap. Apart from n-hexane and $CCl_4$ triethylamine, acetone, and acetonitrile are suitable solvents for the differentiation of primary, secondary, and tertiary alcohols.

The dielectric constant of the solvent has no influence on the position of the first overtone of the O–H band. In polar solvents and those with π-electron systems, the band lies at lower frequencies than in n-hexane and $CCl_4$. This shift is due to the formation of hydrogen bonds. The amount of shift is a measure of the length of the hydrogen bond [2].

| Solvent | DK | Band position for primary, secondary, tertiary alcohols [a] |
|---|---|---|
| n-Hexane | 1.88 | 7109—7135<br>7089 7096<br>7046—7073 |

## The Preparation of 3-Hexen-2-one from 1-Methoxybut-1-en-3-one

By Prof. Dr. W. K. R. Franke and Dr. W. Ring

Wissenschaftliches Laboratorium der Chemische Werke Hüls, Marl, Kreis Recklinghausen (Germany)

The interaction of acetoacetaldehyde dimethylacetal *(1)* and ethylmagnesium bromide and subsequent alkaline hydrolysis affords 1,1-dimethoxy-3-methylpentan-3-ol *(2)*, b.p. 93 °C/20 mm, $n_D^{20} = 1.4270$. On successive treatment of *(1)* with triethylaluminum in benzene and alkali one obtains, in addition to *(2)*, ethylene and 1,1-dimethoxybutan-3-ol *(3)* (b.p. 84 °C/20 mm, $n_D^{20} = 1.4196$). Compounds *(2)* and *(3)* are formed in the approximate ratio 1:3, irrespective of the reaction temperature. Yields decrease with increasing temperature, because of the formation of products of higher molecular weight: 0–10 °C: 13 % *(2)*, 43.6 % *(3)*; 15–20 °C: 8.9 % *(2)*, 34.4 % *(3)*, 35 °C: 10.3 % *(2)*, 29.3 % *(3)* [1].

Triisobutylaluminum reacts with *(1)* producing isobutene and *(3)* [56 % yield at 35–40 °C]. A product corresponding to *(2)* was not identified, its formation being probably prevented by steric factors.

The interaction of 1-methoxybut-1-en-3-one *(4)* with triethylaluminum at 0–5 °C produces 21.4 % *trans*-3-hexen-2-one (b.p. 55.5 °C/28 mm, $n_D^{20} = 1.4391$). Thus, methoxybutenone behaves only partially as a vinylogous carboxylic ester: the methoxy group is replaced by alkyl, but the carbonyl group remains largely intact. The reaction mixture contains only about 4 % of unsaturated alcohols free of methoxy groups. There are also formed compounds of higher molecular weight that have so far not been identified (distillation: residue: 52 %).

In all cases, only one of the three alkyl groups of the organoaluminum compound reacted with *(1)* or *(4)*, in agreement with previous observations by *K. Ziegler* [2].

Received, July 20th, 1964 [Z 807/635 IE]
German version: Angew. Chem. 76, 817 (1964)

[1] Because of the solubility in water of the dimethoxy alcohols, we were unable to isolate compounds *(2)* and *(3)* completely by ether-extraction of the strongly basified reaction mixture.

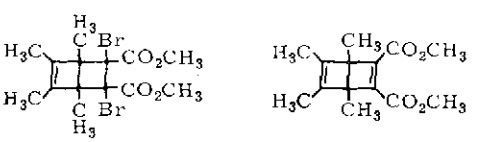
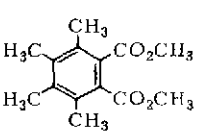
## A Crystalline Derivative of "Dewar Benzene"



By Prof. Dr. R. Criegee and Dipl.-Chem. F. Zanker

Institut für Organische Chemie der Technischen Hochschule Karlsruhe (Germany)



A solution in ether of 3,4-diiodotetramethylcyclobutene *(1)* [1] and dibromomaleic anhydride *(2)* was stirred with mercury for 48 h, under nitrogen and afforded 67 % of the tricyclic anhydride *(3)*, which was converted into the dimethyl ester *(4)*, m.p. 104 °C. Elimination of bromine from *(4)* was achieved with the copper-zinc couple in boiling ether. The halogen-free dimethyl "Dewar tetramethylphthalate" *(5)*, m.p. 32–33 °C, was obtained in 92 % yield; decagram quantities are easy to prepare. The NMR spectrum [*] of *(5)* in *o*-dichlorobenzene contains three sharp singlets of equal areas with τ-values of 9.06 (bridgehead methyl groups), 8.72 (methyl groups at the double bond), and 6.64 (ester methyl groups). On heating at 130 °C, *(5)* is rapidly and quantitatively converted into dimethyl tetramethylphthalate *(6)* [3], m.p. 127 °C (NMR spectrum in *o*-dichlorobenzene:

*(1)* *(2)* *(3)*

*(4)* *(5)*

*(6)*

3 singlets of equal areas at τ-values of 8.26, 8.08, and 6.06) According to NMR measurements, the half-life of *(5)* in the valence-bond isomerization *(5)* → *(6)* in *o*-dichlorobenzene at 90.1 °C is 4.7 h. Compound *(5)* is thus considerably more stable than the unsubstituted "Dewar benzene" of *van Ta-*

*melen* and *Pappas* [4], which is stated to have a half-life of 48 h at 20 °C. The monoester of *(5)* was also prepared in pure form (m.p. 111–112 °C).

Received, July 20th, 1964 [Z 788/623 IE]

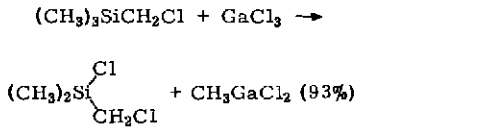
## A Simple Route to Organogallium Compounds

By Priv.-Doz. Dr. H. Schmidbaur and
Dipl.-Chem. W. Findeiss

Institut für Anorganische Chemie
der Universität Marburg/Lahn (Germany)

Tetramethylsilane reacts, even at temperatures only slightly above room temperature, with anhydrous gallium trichloride to form trimethylchlorosilane and methylgallium dichloride:

$$(CH_3)_4Si + GaCl_3 \rightarrow \left[(CH_3)_3Si(CH_3)GaCl_2(Cl)\right] \rightarrow$$



$$(CH_3)_3SiCl + CH_3GaCl_2$$

Simplicity and high yields (>90 %) make this reaction the best method for the preparation of organogallium dihalides. Similarly, triethylchlorosilane and ethylgallium dichloride are obtained from tetraethylsilane and $GaCl_3$.

*$CH_3GaCl_2$*
M.p. 75–76 °C [2, 3].
Sublimation temperature: 70 °C/1 mm.
Molecular weight: 314 (calc. for dimer: 311.34).
NMR: $\delta = -48.0$ c.p.s. [4].
IR [5]: 2881 cm$^{-1}$(m), 2870 cm$^{-1}$ (sh) [νCH];
1263 cm$^{-1}$(m), 1210 cm$^{-1}$ (w) [$\delta_s CH_3$];
837 cm$^{-1}$ (sh), 813 cm$^{-1}$ (sh), 751 cm$^{-1}$ (vst) [ρCH$_3$].

*$C_2H_5GaCl_2$*
M.p. 44 °C, b.p. 64 °C/1 mm.
Molecular weight: 346 (calc. for dimer: 339.39).
NMR: $A_3B_2$-multiplet with $\delta_{CH_3} = -79.0$ c.p.s., $\delta_{CH_2} = -82.3$ c.p.s., and $J_{HCCH}$ ca. 8.0 c.p.s. [4].
IR [5]: 2959 cm$^{-1}$(vst), 2915 cm$^{-1}$(sh), 2874 cm$^{-1}$(st) [νCH];
1462 cm$^{-1}$(st), 1418 cm$^{-1}$(m), 1383 cm$^{-1}$(m) [δCH$_3$, CH$_2$];
1205 cm$^{-1}$(m), 1012 cm$^{-1}$(vst), 966 cm$^{-1}$(m), 952 cm$^{-1}$(m) [νC–C, ρCH$_3$];
752 cm$^{-1}$(w), 669 cm$^{-1}$ (vst) [ρCH$_2$].

When electron-donating substituents are present on the carbon, the unsubstituted alkyl groups are preferentially transferred:

$$(CH_3)_3SiCH_2Cl + GaCl_3 \rightarrow$$

$$(CH_3)_2Si(Cl)(CH_2Cl) + CH_3GaCl_2 \ (93\%)$$

Similarly, gallium trichloride is completely converted to methylgallium dichloride (yield: 91 %) by tetramethylgermane under even milder conditions (<20 °C):

$$(CH_3)_4Ge + GaCl_3 \rightarrow (CH_3)_3GeCl + CH_3GaCl_2$$

Tetramethyltin undergoes a distinctly exothermic reaction with $GaCl_3$ at 0 °C; in this reaction, $(CH_3)_3SnCl$ and $CH_3GaCl_2$ are produced in the form of a coordination compound *(1)*:

$$(CH_3)_4Sn + GaCl_3 \rightarrow (CH_3)_3SnCl\text{-}CH_3GaCl_2 \quad (1)$$

This compound can also be synthesized from trimethylchlorostannane and methylgallium dichloride [1]. When *(1)* is distilled, the two components go over together, and the overall composition is displaced only slightly in favor of $CH_3GaCl_2$.

Indium trichloride does not react with tetramethylsilane even at 220 °C. Above 200 °C, tetramethylgermane yields a little $(CH_3)_3GeCl$. $CH_3InCl_2$ is no longer stable at these temperatures.

## Cleavage of Siloxanes with Gallium Trichloride

By Priv.-Doz. Dr. H. Schmidbaur and
Dipl.-Chem. W. Findeiss

Institut für Anorganische Chemie
der Universität Marburg/Lahn (Germany)

Hexamethyldisiloxane is cleaved by boron and aluminum trihalides at the Si–O–Si bridge only. The products are trimethylhalogenosilane and trimethylsiloxyboron halide or trimethylsiloxyaluminum halide [1, 2]. On cleavage with gallium trichloride, alkylation of the gallium also occurs:

$$x\ (CH_3)_3SiOSi(CH_3)_3 + x\ GaCl_3 \rightarrow x\ (CH_3)_3SiCl + x\ CH_3GaCl_2 + [(CH_3)_2SiO]_x.$$

The yields of $CH_3GaCl_2$ are about 85 %.

Dimethylpolysiloxanes are also cleaved by $GaCl_3$ with simultaneous transalkylation

$$[(CH_3)_2SiO]_x + GaCl_3 \rightarrow CH_3GaCl_2 + [CH_3SiClO]_x,$$

in contrast to the reactions with $BCl_3$ and $AlCl_3$ [3, 4]. The yields of alkylgallium halide are again higher than 85 %, so that both reactions provide simple methods for the monoalkylation of gallium trihalides [5].

No di- or trialkylation of the gallium has so far been observed. $InCl_3$ does not react with siloxanes, even at temperatures far in excess of 200 °C.

## Double Silanolates of the Alkali Metals

By Priv.-Doz. Dr. H. Schmidbaur and Susanne Waldmann

Institut für Anorganische Chemie
der Universität Marburg/Lahn (Germany)

The alkali metal trimethylsilanolates $MOSi(CH_3)_3$, with M = Li, Na, K, Rb, or Cs, form a class of compounds with unusual properties and difficult structural relationships [1, 2]. We have now found that silanolates react with one another to form complex compounds having the composition $M^1\{M^2[OSi(CH_3)_3]_3\}$.

| | | M.p. [°C] | NMR [c.p.s.] [3] | | |
|---|---|---|---|---|---|
| | | | $\delta$ | $J(^1H-^{13}C)$ | $J(^1H-C-^{29}Si)$ |
| *(1)* | $Na\{Li[OSi(CH_3)_3]_2\}$ | 232–235 | − 2.75 | 116 | 6.45 |
| *(2)* | $K\{Li[OSi(CH_3)_3]_2\}$ | 258–260 | +3.20 | 115.5 | 6.35 |
| *(3)* | $K\{Na[OSi(CH_3)_3]_2\}$ | 235–237 | +3.00 | 114.5 | 6.40 |

Potassium trimethylsilanolate is only sparingly soluble in organic solvents [1, 2], but dissolves practically instantaneously in solutions of the lithium and sodium silanolates. Careful evaporation of the clear solutions leads to crystallization of the double silanolates *(2)* and *(3)*. Compound *(1)* crystallizes in the pure form from a solution of equimolar quantities of lithium and sodium trimethylsilanolates in carbon tetrachloride.

The structural identity of the two siloxy residues is shown by the fact that the NMR spectra of *(1)*, *(2)*, and *(3)* in $CCl_4$ show only one sharp signal accompanied by weak $^1H-^{13}C-$ and $^1H-C-^{29}Si$ satellites [2, 4].

All the important bands in the infrared spectra of the double silanolates differ markedly from those of the alkali metal silanolates. The spectroscopic results indicate that the siloxy oxygen atoms in the double silanolates are alternately coordinated to the different alkali metal atoms. Since the influence of the lighter alkali metal predominates, the compounds are formulated as $M^1\{M^2[OSi(CH_3)_3]_2\}$.

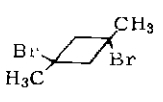
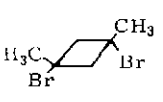
## Electrophilically Induced Cyclodimerization of Methylacetylene by Hydrogen Bromide [1]



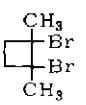
By Dr. K. Griesbaum

Central Basic Research Laboratory, Esso Research and Engineering Company, Linden, New Jersey (U.S.A.)



Contrary to a previous report [2] the reaction of hydrogen bromide with methylacetylene affords not only the classical diadduct 2,2-dibromopropane *(2)*, but at least four additional components in the indicated ratios [3].

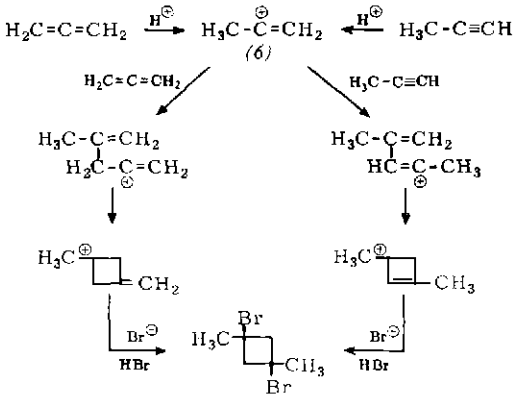
$H_3C-CBr=CH_2$ *(1)*, 24%



$H_3C-CBr_2-CH_3$ *(2)*, 34%

*(3)*, 32%

*(4)*, 9%



*(5)*, < 1%

Vacuum distillation of the crude adduct mixture afforded the conventional adducts *(1)* and *(2)*. The two cyclodimerization products *(3)* and *(4)* were isolated as a crystalline mixture from the distillation residue. Separation of this mixture by preparative gas chromatography yielded the pure compounds *(3)* and *(4)*.

Compound *(3)* was identified by comparison of its physical and spectral properties with those of an authentic sample [1].

The structure proof of *(4)*, m.p. 75–76 °C, is based on the following data: elemental analysis pointed to the empirical formula $(C_3H_5Br)_n$. The mass spectrum showed the characteristic 1:2:1 pattern (m/e = 240, 242, 244 respectively) of a dibromo compound [4] for the parent peak, thus establishing the formula $C_6H_{10}Br_2$. Neither the infrared nor the NMR spectrum of *(4)* contained any evidence for a double bond. The NMR spectrum exhibited a singlet signal at $\tau = 8.12$ with a relative intensity of 3 and a four-line pattern centered at $\tau = 6.81$ [5] with a relative intensity of 2.

Compound *(5)* could not be isolated pure. Combined gas-liquid chromatography and time-of-flight mass spectroscopy [6] showed, however, that the compound is a dibromide exhibiting the same molecular ion and fragment ions as *(3)* and *(4)*. It is assumed, therefore, that *(5)* may represent one of the isomeric 1,2-dibromo-1,2-dimethylcyclobutanes.

The results reported here demonstrate that the electrophilic addition of hydrogen bromide to methylacetylene cannot be exhaustively described by the classical theory of addition reactions. It seems that the particular nature of the vinylcarbonium ion intermediate *(6)* [7] may be the key in understanding the cyclodimerization reactions of both methylacetylene and allene [1].

[2] *M. S. Kharasch, J. G. McNab*, and *M. C. McNab*, J. Amer. chem. Soc. *57*, 2463 (1935).

[3] Percent by weight based on capillary gas chromatography. In some cases, substantial amounts of the isomeric 1-bromopropenes were also formed, apparently by concurring radical addition reactions. This complication could, however, be effectively suppressed by the addition of inhibitors to the reaction mixture.

[4] *J. H. Beynon:* Mass Spectrometry and Its Application to Organic Chemistry. Elsevier, Amsterdam 1960, p. 299.

[5] The midpoint of this quartet has the same position as the methylene singlet signal of the *trans*-compound *(3)*. This is an argument against the alternate possible structure of a 1,2-dibromo-1,2-dimethylcyclobutane for *(4)*. Since the methylene groups in such a 1,2-dibromo compound would be vicinal to only one bromine atom each, one would expect their signals at higher fields.

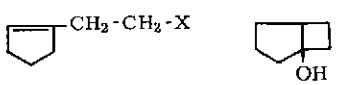
[7] *P. E. Peterson* and *J. E. Duddey* [J. Amer. chem. Soc. *85*, 2865 (1963)] pointed out recently that the nature and the chemistry of vinylcarbonium ions is rather ill-defined.

## The Preparation of Condensed Cyclobutane Derivatives and spiro-Cyclopropane Compounds by Homoallylic Rearrangement

By Doz. Dr. M. Hanack and Dipl.-Chem. H.-J. Schneider

Chemisches Institut der Universität Tübingen (Germany)

The easily accessible cyclohexenylethyl derivatives *(1)*, X = $NH_2$, OH, open up a simple route for the synthesis of the previously unknown spiro[2.5]octan-4-ol *(3)*, and of the bicyclo[4.2.0]octan-1-ol *(2)* [1] which could so far only be obtained with difficulty.



*(1)* *(2)* *(3)*

The primary homoallyl cation, formed from *(1)*, X = $NH_2$, by deamination, or from *(1)*, X = *p*-$O_3S$–$C_6H_4$–$CH_3$, by hydrolysis, rearranges to the more stable secondary cyclopropylmethyl and tertiary cyclobutyl cations [2].

When cyclohexenylethylamine *(1)* X = $NH_2$, [3] (prepared in 77 % yield by reduction of cyclohexenylacetonitrile with $LiAlH_4$) was treated with aqueous $HClO_4$ and $NaNO_2$ at pH 4 for 5hr. under nitrogen, a mixture of alcohols, containing 81 % of *(2)*, 12 % of *(1)*, X = OH, 3 % of *(3)*, and 4 % of an unidentified compound, was formed. Pure bicyclo[4.2.0]octan-1-ol *(2)* could be obtained in 30 % yield by fractional distillation. The melting points of the alcohol and its phenylurethane agree with those previously reported [1]. Its infrared and NMR spectra are in agreement with the structure given. Compound *(2)* is formed predominantly by rearrangement of the unstable spiro-alcohol *(3)*. If the deamination is carried out at 20 °C under potentiometric control at pH 6, *(3)* and *(2)* are formed in the ratio 70:30, together with other products. The spiro-alcohol *(3)* can be rearranged to *(2)* and *(1)*, X = OH, with toluenesulfonic acid at pH 5.

The pure spiro-alcohol *(3)* was prepared as follows: cyclohexenylethanol *(1)*, X = OH, [4] (obtained in 88 % yield by reduction of cyclohexenylacetic acid with $LiAlH_4$) was converted to the tosyl derivative which was then solvolysed at 85 °C for 10 days in acetone/water (20:80) with addition of $CaCO_3$. The reaction product contained 65 % of the alcohol *(3)*, 33 % of the alcohol *(2)* and 2 % of the alcohol *(1)*, X = OH. Pure *(3)* (b.p. 88–89 °C/20 mm, m.p. of the *p*-nitrobenzoate: 84.5–85.5 °C, 50 % yield) was obtained by distillation through a spinning-band column; its infrared and NMR spectra are in agreement with the structure given (singlet at $\tau$ = 7.92; multiplets at $\tau$ = 6.9, ca. 8.5, 7.6, and 9.9; ratio of peak areas 1:1:8:2:2).

Cyclopentenylethylamine *(4)*, X = $NH_2$, (prepared in 40 % yield by reduction of cyclopentenylacetonitrile with $LiAlH_4$ [5]) gave, on deamination in weak perchloric acid solution (pH 4, 4 hr., 50 °C), a mixture of alcohols which contained 65 % bicyclo[3.2.0]heptan-1-ol *(5)* and 6 % cyclopentenylethanol *(4)*, X = OH; three further components (29 %) were not identified.

*(4)* *(5)*

Compound *(5)* (m.p. 47–48 °C; m.p. of *p*-nitrobenzoate 117.5–118 °C) could be separated by preparative gas chromatography. Its infrared and NMR spectra are in agreement with the structure given (singlet at $\tau$ = 6.09; multiplets at $\tau$ = 7.7 and ca. 8.4; ratio of peak areas 1:1:10). As expected for a tertiary alcohol, *(5)* gives a chromate ester with $CrO_3$ in $CCl_4$.

Cyclopentenylethanol *(4)*, X = OH [6], (prepared in 84 % yield by reduction of ethyl cyclopentenylacetate with $LiAlH_4$) was converted to the β-naphthalenesulfonyl derivative *(4)*, X = $O_3S$–$C_{10}H_7$, which was hydrolysed in acetone/water as described above to give a mixture of alcohols containing 21 % of *(5)*, 68 % of *(4)*, X = OH, and 11 % of the same by-products as were produced on deamination.

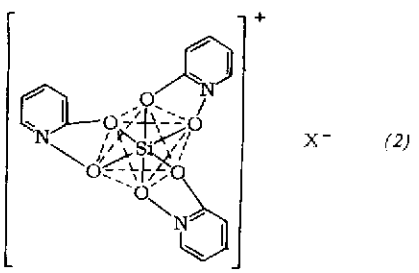
## Water-Stable, Cationic Complexes of Silicic Acid with 1-Hydroxypyridine N-Oxide



By Prof. Dr. Armin Weiss and Dr. D. R. Harvey

Institut für Anorganische Chemie
der Universität Heidelberg (Germany)

1-Hydroxypyridine *N*-oxide *(1)* [1] forms a cationic silicon complex *(2)* [2], which was characterized as its chloride, chloroferrate(III) and hexachlorostannate(IV).

*(1)*

*(2)*

| X | color | soluble in |
|---|---|---|
| Cl | white | $H_2O$, $C_2H_5OH$, $C_2H_2Cl_4$ |
| $[FeCl_4]$ | pale yellowish | $H_2O$, $C_2H_2Cl_4$ |
| $1/2\ [SnCl_6]$ | white | |

The chloroferrate(III) darkens above 220 °C without melting. In the case of the chlorostannate(IV) a change begins at 204–206 °C. The chloride appears macroscopically unchanged even at 300 °C, but X-ray studies show it to be amorphous.

Orthosilicic acid (<110 mg $SiO_2$/l) also can be smoothly converted into the cationic complex *(2)* at pH 6. Experiments with colloidal silicic acid showed that the complex forms faster than polysilicic acids are depolymerized.

When compared with the corresponding complexes formed by 1,3-diketones [2a], the addition compounds of silicon halides and pyridine *N*-oxide [3], or the silicon ester complex of 1-hydroxypyridine, the stability of the complex *(2)* in water appears striking. The chloride is recovered unchanged on evaporation of an aqueous solution. This stability prob-

ably depends on the fact that the positive charge in *(2)* can be distributed over several atoms. Comparison of the infrared spectra with those of anionic silicon-*o*-diphenol suggests an octahedral structure for the cation.

The complex *(2)* appears of interest in connection with the observation by *Schlipköter* [4], that polyvinylpyridine *N*-oxide in animal experiments inhibits significantly the formation of silicotic tissue after the application of the quartz. Model experiments have revealed no direct interaction between polyvinylpyridine *N*-oxide and silicon dioxide or the silicic acid dissolved from it. Therefore, a direct effect on the macrophages has recently been discussed [5].

However, if one assumes that pyridine *N*-oxide can be oxidized by the organism, then 1-hydroxypyridine *N*-oxide merits attention. Animal experiments with derivatives of 1-hydroxypyridine *N*-oxide and quartz are therefore desirable.

## Silicon Diiodide $[SiI_2]_x$

By Prof. Dr. M. Schmeisser and Dipl.-Chem. K. Friederich

Institut für Anorganische Chemie und Elektrochemie der Technischen Hochschule Aachen (Germany)

Following the preparation of $[SiBr_2]_x$ [1], $[SiCl_2]_x$ [2], and $[SiF_2]_x$ [3], the hitherto unknown $[SiI_2]_x$ [4,5] has now been synthesized by three routes:

1. When $SiI_4$ is passed over silicon in a high vacuum at 800 to 900 °C, a solid, brittle, amorphous, yellow-red substance of the composition $[SiI_2]_x$ is formed in about 1 % yield (based on $SiI_4$).

2. The pyrolysis of $SiI_4$ under the same conditions yields the same product, which is soluble in benzene and very sensitive to hydrolysis; it turns brown in dry air, with separation of iodine, and on heating with oxygen it burns to give $SiO_2$ and iodine vapor.

3. When $SiI_4$ vapor is subjected to a glow discharge in a high vacuum, a 60 to 70 % yield (based on $SiI_4$) of a solid, amorphous, yellow-red silicon subiodide of the composition $[SiI_{2.2}]_x$, which is insoluble in all common solvents, is obtained in quantities of 60 to 90 g per experiment.

$$x\ SiI_4 \rightarrow [SiI_{2.2}]_x + 0.9\ x\ I_2.$$

Pyrolysis of this substance at 220 to 230 °C in a high vacuum leads to the formation of a deep red $[SiI_2]_x$, together with $SiI_4$ and $Si_2I_6$.

The chemical properties of the compounds $[SiI_2]_x$ obtained in this manner are identical, with the exception of their solubilities in benzene.

Pyrolysis of $[SiI_2]_x$ at 350 °C in a high vacuum yields $SiI_4$, $Si_2I_6$, and an orange-red, brittle solid of the composition $[SiI]_x$. The compound $[SiI_2]_x$ reacts with chlorine or bromine at temperatures between −30 and +25 °C to form benzene-soluble, mixed silicon subhalides such as $[SiClI]_x$ and $[SiBrI]_x$. At higher temperatures, the Si–Si chains are cleaved by chlorine or bromine, with simultaneous complete displacement of the iodine. The products are compounds of the type $Si_nX_{2n+2}$ (n = 2–6 in the case of Cl, and 2–5 in the case of Br; X = Cl or Br). On reaction with iodine at 90 to 120 °C in a sealed tube, $[SiI_2]_x$ is completely converted to $SiI_4$ and $Si_2I_6$.

The compound $Si_2I_6$, which had formerly been difficult to prepare [5], is now available in any desired quantities by pyrolysis of $[SiI_{2.2}]_x$ or $[SiI_2]_x$ or by reaction of these compounds with iodine, and can be easily separated from $SiI_4$ by sublimation in a high vacuum.

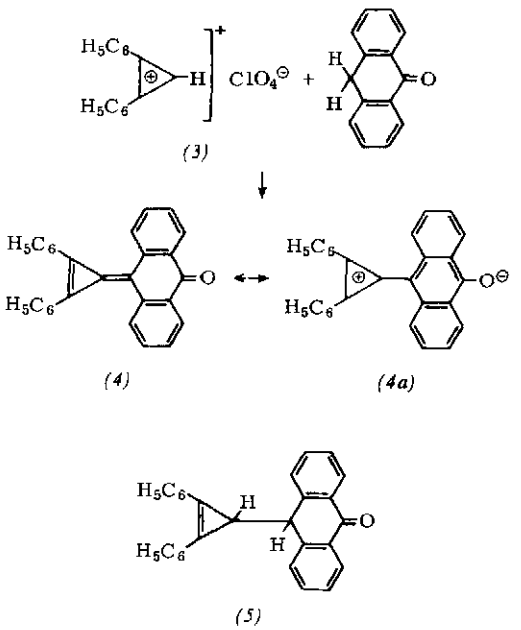
## The Synthesis of a Methylenecyclopropene Derivative

By Dr. B. Föhlisch and Dipl.-Chem. P. Bürgle

Institut für Organische Chemie und Organisch-Chemische Technologie der Technischen Hochschule Stuttgart (Germany)

Activated aromatic compounds may be *C*-alkylated by cyclopropenylium salts. Substituted tetraarylcyclopropenes *(2)* are produced when triphenylcyclopropenylium bromide *(1)* is heated in glacial acetic acid/pyridine (10:1) with dimethylaniline, anisole, di-*O*-methylresorcinol, 2-methoxynaphthalene, or anthrone.

*(1)* *(2)*



*(2a)*: Ar = *p*-dimethylaminophenyl, m.p. 189–190 °C
*(2b)*: Ar = *p*-methoxyphenyl, m.p. 124–126 °C
*(2c)*: Ar = 2,4-dimethoxyphenyl, m.p. 193 °C
*(2d)*: Ar = 2-methoxynaphthyl, m.p. 123–125 °C
*(2e)*: Ar = anthron-10-yl, m.p. 198–199.5 °C

The infrared spectra of *(2)* show the characteristic band at ca. 1800 $cm^{-1}$ assigned to the $\nu_{C=C}$-vibration of the cyclopropene ring.

Diphenylcyclopropenylium perchlorate *(3)* reacts with anthrone to give 10-(diphenylcyclopropenylidene)anthrone *(4)*, a thermally very stable derivative of methylenecyclopropene [1].

We believe that 10-(diphenylcyclopropenyl)anthrone *(5)*, formed initially from anthrone and *(3)*, is dehydrogenated with a further molecule of *(3)* to *(4)* *via* the cyclopropenylium ion. In agreement with this, the yield of *(4)* is considerably greater when 2 moles of *(3)* per mole of anthrone are used. Compound *(4)* is also obtained from bis(diphenylcyclopropenyl)ether and anthrone under the same conditions. It

gives yellow needles, m.p. 322–324 °C (from n-butanol), $\lambda_{max}$ (in chloroform): 242 mμ (log ε = 4.59), 275 (4.47), 315 (shoulder), 368 (shoulder); broad band with indistinct structure at 405 mμ (log ε = 4.10). It dissolves in conc. $H_2SO_4$ to give a carmine-red solution, $\lambda_{max}$ (in $H_2SO_4$): 251 mμ (log ε = 4.68), 287 (4.26), 379 (4.11), 432 (4.04),

(3) (4) (4a) (5)

540 (4.15). The zwitterionic structure *(4a)* contributes to the ground-state of *(4)* as the $\nu_{C=O}$-vibration occurs at 1639 $cm^{-1}$ (in chloroform), *i.e.* at a much lower wavelength than that of derivatives of 10-methyleneanthrone [2].

## Silicon Difluoride $[SiF_2]_x$

By Prof. Dr. M. Schmeisser and Dr. K.-P. Ehlers

Institut für Anorganische Chemie und Elektrochemie der Technischen Hochschule Aachen (Germany)

Following the syntheses of $[SiBr_2]_x$ [1] and $[SiCl_2]_x$ [2], we turned our attention to $[SiF_2]_x$ which, by analogy to the disproportionation of the hexahalogenodisilanes to $SiX_2$ and $Si_nX_{2n+2}$ [3–5], should be obtainable as follows:

$$x\ Si_2F_6 \rightarrow [SiF_2]_x + x\ SiF_4$$

Preliminary experiments [6] have shown the feasibility of this reaction, but the analyses of the products were not unambiguous.

Gas chromatography showed that the $Si_2F_6$ prepared according to [7] by fluorination of $Si_2Cl_6$ with $ZnF_2$ was always contaminated with $SiCl_3F$ and $SiCl_4$, which could scarcely be separated from each other by distillation. Purification of $Si_2F_6$ was possible by preparative gas chromatography (identification by analysis and infrared spectroscopy). Fluorination of $Si_2Br_6$, instead of $Si_2Cl_6$, with $ZnF_2$ gave mixtures which could be separated by distillation.

Pyrolysis of pure $Si_2F_6$ at 700 °C in a high vacuum yielded $SiF_4$ together with $SiF_2$, which condenses out as a yellow solid in liquid air. Above −80 °C $SiF_2$ polymerizes to yield colorless $[SiF_2]_x$. Both products are extremely sensitive to moisture and oxygen.

The same products resulted from the reaction of $SiF_4$ with silicon at 1200 °C in a sealed silica tube, as has already been described in a patent application [8]. However, silicon difluoride obtained in this way contained oxygen (probably derived from the silica of the tube [Si:F:$H_A$:O = 1:1.75:1.75:032] whereas $[SiF_2]_x$ prepared from $Si_2F_6$ had Si:F:$H_A$ = 1:2.03:1.90 ($H_A$ = hydrogen evolved by alkali, in atoms of H/atom of Si).

## Tris(trifluorophosphine)nitrosylcobalt and Bis(trifluorophosphine)dinitrosyliron [1]

By Dr. Th. Kruck and Dipl.-Chem. W. Lang

Anorganisch-Chemisches Laboratorium der Technischen Hochschule München (Germany)

A trifluorophosphine nitrosyl complex was first prepared by the reaction of nitrosylcobalt chloride with trifluorophosphine at 350 atm and 50 °C:

$$[Co(NO)_2Cl]_2 + 6\ PF_3 + 2\ Cu \rightarrow 2\ Co(NO)(PF_3)_3 + 2\ NO + 2\ CuCl$$

The compound, which is an analogue of nitrosylcarbonylcobalt, is a red-brown, light-sensitive, extremely volatile liquid, m.p. −92 °C, b.p. 81 °C/732 mm. It is fairly stable to moisture and oxidizing agents. Its intensely yellow vapors are almost odorless. Its decomposition point (163 °C) lies by more than 100 °C above that of $Co(NO)(CO)_3$. The infrared spectrum [2] of the diamagnetic compound contains ν(P–F) vibrations at 931, 900, 890, and 864 $cm^{-1}$ and an intense N–O valence vibration at 1844 $cm^{-1}$, which is by 22 $cm^{-1}$ below that of the isosteric nitrosylcarbonylcobalt.

With trifluorophosphine at 350 atm and 50 °C, dimeric nitrosyliron bromide yields volatile $Fe(NO)_2(PF_3)_2$, which – similar to the analogous nitrosylcarbonyliron – is a red-brown, diamagnetic liquid, decomposing at 118 °C. Its infrared spectrum contains two sharp ν(N–O) bands at 1838 and 1788 $cm^{-1}$ as well as three ν(P–F) bands at 907, 887, and 864 $cm^{-1}$.

We have indications that the manganese compound $Mn(NO)_3PF_3$ also exists, as would be expected from the nitrosyl displacement principle.

## Rhenium-Cobalt Enneacarbonyl

By Dr. Th. Kruck and Dipl.-Chem. M. Höfler

Anorganisch-Chemisches Laboratorium
der Technischen Hochschule München (Germany)

Binuclear mixed metal carbonyls $[L_n(CO)_{5-n}MM'(CO)_m]$, n=0, and their substitution products with *o*-phenanthroline ($L_2 = C_{12}H_8N_2$) [1] can be prepared by thermal decomposition of carbonyl salts such as $[M(CO)_{6-n}L_n]^+[M'(CO)_m]^-$ (M = Mn(I), Re(I); M' = Co(−I), Mn(−I); m = 4 or 5). The reaction is initiated by an intramolecular redox process. With the loss of one molecule of CO per molecule of carbonyl salt the two carbonyl radicals are linked by a metal-metal bond.

In addition to the compounds $MnCo(CO)_9$ [2] and $MnRe(CO)_{10}$ [3], which were already known and were also prepared by us [4] from the carbonyl salt $[Mn(CO)_6][Co(CO)_4]$ or by the reaction of $[Mn(CO)_6]Cl{\cdot}HCl$ with $Na[Re(CO)_5]$ and of $[Re(CO)_6]Cl{\cdot}HCl$ with $Na[Mn(CO)_5]$, respectively, rhenium-cobalt enneacarbonyl was now obtained:

$$[Re(CO)_6][Co(CO)_4] \xrightarrow{60\,^\circ C} (CO)_5ReCo(CO)_4 + CO$$

The diamagnetic compound sublimes at 40–50 °C/$10^{-3}$ mm yielding orange-brown, matted needles, m.p. 66 °C, decomposition point 148 °C. The infrared spectrum of the solution in $CCl_4$ contains three intense, sharp bands at 2064, 2035, and 1990 $cm^{-1}$, *i.e.* in the range for terminal CO groups; no bands characteristic for bridging CO groups were observed.

Dry heating of $[Re(CO)_4(C_{12}H_8N_2)][Co(CO)_4]$ produces the deep-red *o*-phenanthrolinetricarbonylrhenium-tetracarbonylcobalt. According to the reaction

$$[Re(CO)_4(C_{12}H_8N_2)][Co(CO)_4] \xrightarrow{90\,^\circ C} (C_{12}H_8N_2)(CO)_3ReCo(CO)_4 + CO$$

and to the infrared spectrum [$\nu_{C-O}$ = 2048(st), 2039(st-m), 2010(vst), 1931(vst), and 1892(vst) $cm^{-1}$] the bidentate ligand is associated with the rhenium, and a pure rhenium-cobalt bond exists. This structure is supported by a photoreaction in tetrahydrofuran which yields the yellow compound $[Re(CO)_3(C_{12}H_8N_2)]_2$.

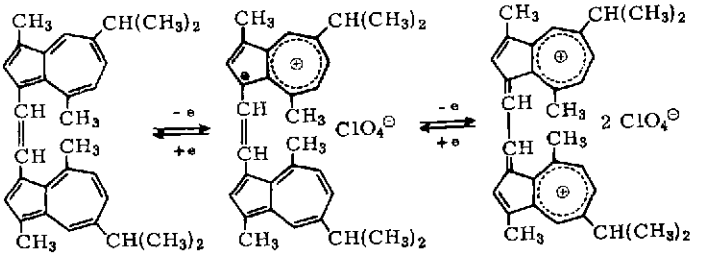
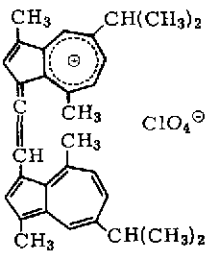
## A Stable Radical-Cation of a Hydrocarbon [1]



By Prof. Dr. S. Hünig, Dipl.-Chem. D. Scheutzow, and Dr. H. J. Friedrich

Chemisches Institut der Universität Würzburg (Germany)

Guaiazulene [1a], glyoxal, and perchloric acid in acetonitrile readily yield the diperchlorate *(1)* [2]; this is converted in hot methanol into a blue monoperchlorate from which perchloric acid in acetonitrile reforms the diperchlorate *(1)*. *Kirby* and *Reid* [2] considered an acid-base reaction and ascribed an allene structure *(4)* to the monoperchlorate.



We have found, however, that methanol acts as a reducing agent. The blue monoperchlorate has structure *(2)* and appears to be the first stable radical-ion of a hydrocarbon.

A $2.5\times10^{-2}$ M solution of *(2)* in ethylene chloride/methylene chloride (1:9) shows, immediately on dissolution, a paramagnetic molecular susceptibility $\chi^{mol}_{para} = 1232\times10^{-6}$ and a paramagnetic moment $\mu$ = 1.70 B. M. [3]. This corresponds

*(3)* *(2)*, blue *(1)*, red

to a radical content of at least 95 %; in the concentrated solution this decreases rapidly and disappears within one day. In $10^{-5}$ M solution in methylene chloride, *(2)* is considerably more stable and shows characteristic absorption bands at 718 mμ (log ε = 4.85) and 995 mμ (log ε = 4.26).

*(4)*

Reduction of *(2)* by $NaBH_4$ gave a hydrocarbon – so far not completely pure – which might be formulated as *(3)*.

The action of one equivalent of *(3)* on *(1)* ($10^{-5}$ mole/l) in methylene chloride yields $1.6\times10^{-5}$ mole/l of *(2)*; coproportionation must therefore have occurred. The regeneration of *(1)* from *(2)* by perchloric acid in acetonitrile must therefore be regarded as a disproportionation, during which *(3)* is removed from the equilibrium by protonation.

## The Preparation of Difluorodiazine and the Existence of Chlorofluorodiazine

By Dr. H. W. Roesky, Prof. Dr. O. Glemser, and cand. chem. D. Bormann

Anorganisch-Chemisches Institut
der Universität Göttingen (Germany)

The methods known for the preparation of difluorodiazine [1–5] are either not very productive or very dangerous.

We have found a simple, safe method for continuous preparation of large quantities of $N_2F_2$ (1–2 ml of *trans*-$N_2F_2$ per h). Technical sodium azide (98–99 % pure) is allowed to react at room temperature with elemental fluorine in a revolving-cylinder reactor made of nickel. The $N_3F$ formed as an intermediate is not isolated but is immediately decomposed by heating at 70–75 °C in a nickel spiral, so that the reaction proceeds without explosion via the biradical $\cdot\dot{N}F$ to $N_2F_2$:

$$2\,N_3F \rightarrow 2\,N_2 + 2\cdot\dot{N}F$$
$$2\cdot\dot{N}F \rightarrow N_2F_2$$

During the thermal decomposition of $N_3F$, excess fluorine must not be present, otherwise the $N_2F_2$ is fluorinated to $NF_3$. This is prevented by having a large excess of sodium azide in the reactor. Admixture of water vapor or preferably of hydrogen fluoride to the fluorine stream increases the yield of $N_2F_2$. The product is contaminated with $N_2O$ [6] and displays the characteristic infrared absorption band of *trans*-$N_2F_2$ at 995 $cm^{-1}$; after vacuum distillation the molecular weight was found to be 66.5 (calculated for $N_2F_2$: 66). When the nickel spiral is heated to about 85 °C, *cis*-$N_2F_2$ [7] occurs together with *trans*-$N_2F_2$ [8].

Sodium azide slightly dampened with water reacts with chlorine in the revo ·r g-cylinder reactor at room temperature to give chloroa de which is completely decomposed in the nickel spiral by heating at 110 °C. When fluorine is mixed with the chlorine stream ($Cl_2$: $F_2$ – 1:1) and the nickel spiral is heated to 120 °C, a gaseous product results which condenses in a trap cooled with liquid air to give a solid whose color is yellower than that of chloroazide. Purification was not possible since violent explosions occurred on condensation and distillation *in vacuo* of this material. The infrared spectrum of the gaseous product showed the bands of *cis*- and *trans*-$N_2F_2$ and $N_2O$, plus bands at 1540, 1060, and 670 $cm^{-1}$ which were attributed to $\nu_{N-F}$, $\nu_{N=N}$, and $\nu_{N-Cl}$ frequencies.

The existence of the new compound chlorofluorodiazine F–N=N–Cl is therefore probable.

[6] If HF is mixed with the fluorine stream, the $N_2O$ content of the product is low.

[7] *R. L. Kuczkowski* and *E. B. Wilson*, J. chem. Physics *39*, 1030 (1963).

[8] *cis*-$N_2F_2$ also results on heating *trans*-$N_2F_2$. At 285 °C, for example, there is an equilibrium between 13 % *trans*- and 87 % *cis*-$N_2F_2$. At 300 °C $N_2F_2$ decomposes into $N_2$ and $F_2$ [3].

## The Synthesis of New Organoarsenic and Organophosphorus Amines

By Dr. O. J. Scherer and Prof. Dr. Max Schmidt

Institut für Anorganische Chemie
der Universität Marburg/Lahn (Germany)

Dimethylchloroarsine *(1)* reacts with methylamine or *N,N'*-dimethylethylenediamine *(3)* in ether to form bis(dimethylarsino)methylamine *(2)* [b.p. 70–72 °C/14 mm, m.p. –34 °C],

$$2\,(CH_3)_2AsCl + 3\,CH_3NH_2 \quad (1)$$

$$\rightarrow (CH_3)_2As\text{-}\underset{\displaystyle CH_3}{N}\text{-}As(CH_3)_2 + 2\,CH_3NH_2\cdot HCl \quad (2)$$

$$2\,(1) + 2\,(3) \rightarrow (4) + (5)$$

(4): $(CH_3)_2As\text{-}\underset{\displaystyle CH_3}{N}\text{-}CH_2\text{-}CH_2\text{-}\underset{\displaystyle CH_3}{N}\text{-}As(CH_3)_2$

(5): $(H_3C\text{-}HN\text{-}CH_2\text{-})_2\cdot 2\,HCl$

and *N,N'*-bis(dimethylarsino)dimethylethylenediamine *(4)* [b.p. 94–96 °C/1 mm], respectively, with very good yields (80–90 %).

The As–N bond in *(2)* is very easily broken using methyllithium [1,2]:

$$(2) + LiCH_3 \rightarrow (CH_3)_2As\text{-}\underset{\displaystyle CH_3}{N}\text{-}Li + As(CH_3)_3 \quad (6)$$

The lithium (dimethylarsino)methylamide *(6)* formed is very reactive and is a useful starting material for further reactions; for example, with trimethylchlorosilane it produces dimethylarsino(trimethylsilyl)methylamine *(7)* [b.p. 66–68 °C/14 mm, m.p. –50 °C.].

$$(6) + (CH_3)_3SiCl \rightarrow (CH_3)_2As\text{-}\underset{\displaystyle CH_3}{N}\text{-}Si(CH_3)_3 + LiCl \quad (7)$$

Using *(3)* and phosphorus or arsenic trichlorides, one does not obtain the halogen analogues of *(4)*, but rather 2-chloro-1,3-dimethyl-1,3,2-diazophospholidine *(8)* [b.p. 98–100 °C/14 mm, m.p. 1–3 °C] and 2-chloro-1,3-dimethyl-1,3,2-diazoarsenolidine *(9)* [b.p. 103–105 °C/14 mm, m.p. 19–21 °C] The yields are about 50 %.

$$2\,(3) + MCl_3 \rightarrow (5) + Cl\text{-}M\langle \text{1,3-dimethyl-1,3,2-diazaheterolidine} \rangle \quad (8),\ M = P;\ (9),\ M = As$$

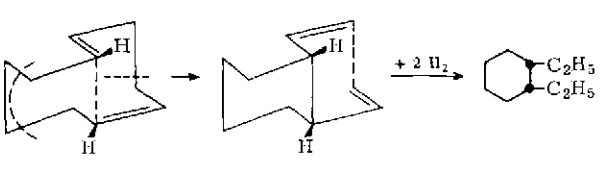
## Valence-Bond Isomerization of cis,trans-Cyclodeca-1,5-dienes

By Dr. P. Heimbach

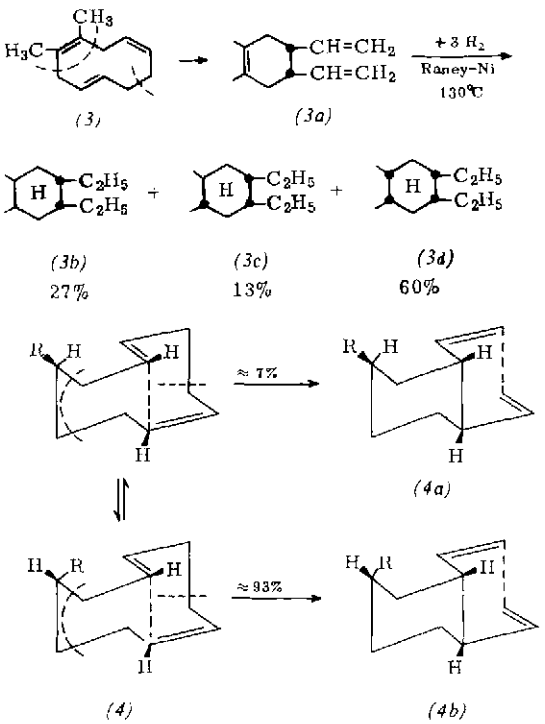


Max-Planck-Institut für Kohlenforschung,
Mülheim/Ruhr (Germany)

*Cis,trans*-cyclodeca-1,5-diene *(1)* can be prepared in high yield from butadiene and ethylene, using new nickel-based π-complex catalysts [1]. The thermal rearrangement of *(1)* [1] (see Table 1) is stereospecific (>99.7 %), and yields *cis*-1,2-divinylcyclohexane *(2)*. The oxidative degradation of *(2)* leads exclusively to *cis*-hexahydrophthalic acid (m.p. 190 to 191 °C) in 55 % yield.

Table 1. Rearrangement of *cis,trans*-cyclodeca-1,5-diene *(1)*

| 60 °C [a] | | 80 °C [a] | | 120 °C [a] | | 150 °C [a] | |
|---|---|---|---|---|---|---|---|
| Time [h] | Yield [%] | Time [h] | Yield [%] | Time [h] | Yield [%] | Time [h] | Yield [%] |
| 170 | 3.3 | 3 | 7.3 | 1 | 12 | 0.25 | 38 |
| | | 20 | 15.8 | 6.9 | 56 | 1.25 | 88 |
| | | 170 | 63.3 | 47 | 99 | 5.25 | 99 |



[a] Reaction temperature ± 2 °C.

(1) (2) (2a)

Acetylene, 2-butyne, and styrene also combine, like ethylene, with butadiene on catalysts such as those used for the synthesis of cycloocta-1,5-diene [1] to give mono- or disub-

stituted *cis,trans*-cyclodeca-1,5-dienes (or *cis,cis,trans*-cyclodeca-1,4,7-trienes) [3]. These ten-membered cyclic compounds, like *(1)*, show no tendency to thermal polymerization such as that exhibited by *cis,trans*-cycloocta-1,5-diene [2] or *cis,trans*-cyclonona-1,5-diene [4]; instead, like *(1)*, they are converted by heat, *via* a four-center arrangement [5] to mono- or di-substituted *cis*-1,2-divinylcyclohexanes (or *cis*-1,2-divinylcyclohexenes), *e.g.* *(3)* gives *(3a)*, while *(4)* gives *(4a)* and *(4b)*. Unsubstituted *(3)* is converted to unsubstituted *(3a)* which gives *(2a)* on hydrogenation.

The *cis*-form *(4b)* predominates, probably because it is thermodynamically more stable than the *trans*-form *(4a)*. *Trans*-1,2-divinylcyclohexanes (or *trans*-1,2-divinylcyclohexenes) are also formed to a small extent. These may arise from a six-center arrangement of *cis,trans*-cyclodeca-1,5-dienes, or from a four-center arrangement of the *trans,trans*-dienes [3], which are present in small quantities. Some of the physical properties of the compounds are shown in Table 2.

Table 2. Physical properties of the compounds *(1)*, *(2)*, *(2a)*, *(3a)*–*(3d)*, and *(4b)*.

| Compound | B.p. [°C/mm Hg] | $n_D^{20}$ |
|---|---|---|
| *(1)* | 38/2 | 1.4958 |
| *(2)* | 63/20 | 1.4704 |
| *(2a)* | 92.5/50 | 1.4479 |
| *(3a)* | 92/20 | 1.4869 |
| *(3b,c,d)* [a] | | 1.4520 |
| *(4b)* | 168/20 | 1.5368 |

[a] A definite assignment of the isomers is not yet possible but all evidence so far points to the assignment given.

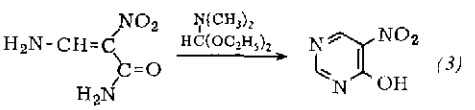
## Synthesis of 4-Hydroxy-5-nitropyrimidines

By Dr. G. Simchen



Institut für Organische Chemie und Organisch-Chemische Technologie
der Technischen Hochschule Stuttgart (Germany)

5-Nitropyrimidines in which only the 4-position is substituted by a first-order substituent have until now not been obtainable by direct synthesis. We have succeeded in preparing 2-phenyl-4-hydroxy-5-nitropyrimidine *(2)*, starting from

nitromethane, by reacting the intermediate *N*-benzoyl-α-nitro-β-dimethylaminoacrylamide *(1)* with ammonia in dimethylformamide. The final yield of *(2)* (m.p. 278 °C) was 42 %, based on the nitromethane.

4-Hydroxy-5-nitropyrimidine *(3)* (m.p. 192 °C) was obtained in 20 % yield from α-nitro-β-aminoacrylamide by reaction with dimethylformamide diethyl acetal in ethanol at 50 °C.

The hydroxynitropyrimidines *(2)* and *(3)* can be used for the synthesis of condensed heterocyclic systems.

## Preparation of Volatile Mixed Hydrides of Phosphorus, Arsenic, Nitrogen, and Germanium, and of Triphosphine and Triarsine

By Prof. Dr. P. Royen, Dipl.-Chem. C. Rocktäschel, and Dr. W. Mosch

Institut für anorganische Chemie
der Universität Frankfurt/Main (Germany)

Acidic hydrolysis of phosphides, arsenides, nitrides, and germanides of magnesium and calcium yields phosphines, arsines, ammonia, and germane. Mixed hydrides are formed on hydrolysis of the corresponding solid solutions [1] (magnesium phosphide/magnesium arsenide, magnesium phosphide/magnesium nitride, or magnesium arsenide/magnesium nitride). Since the reaction has a radical mechanism, the formation of mixed hydrides of phosphorus, arsenic, nitrogen, and germanium also occurs in good yields even when compressed or tempered mixtures of the finely crystalline salts are hydrolysed.

The phosphides, arsenides, and germanides of calcium and magnesium were obtained from magnesium powder [99.85 % purity from Messrs. Schuchardt, München (Germany)] or

calcium turnings (99.5 % purity, from same source) and red phosphorus or resublimed arsenic or germanium (99.999 % purity, from Messrs. Schuchardt) in stoichiometric proportions by heating at 1100 °C for 24 h in evacuated quartz ampoules. Magnesium nitride and calcium nitride were produced by passing gaseous ammonia over magnesium or calcium turnings at 850 °C.

The starting materials were mixed in 1:1 molar ratios and compressed under a pressure of 10000 kg/cm² or sintered in evacuated quartz tubes at 1000 °C for 48 h.

The gases resulting from the hydrolysis were identified by mass spectroscopy [2]. In order to preclude decomposition of readily labile hydrides before their introduction into the spectrometer, the crystalline mixed phases were decomposed with 2 N HCl with cooling (0 °C) in an evacuated apparatus directly within the instrument. Apart from the known hydrides of phosphorus, arsenic, nitrogen, and germanium, the following products were obtained:

$P_3H_5$, $As_3H_5$, and $PH_2AsH_2$ from $Mg_3P_2/Mg_3As_2$;
$P_3H_5$, $PH_2NH_2$, $PH(NH_2)_2$, $P(NH_2)_3$, and $P_2H_3NH_2$ from $Mg_3P_2/Mg_3N_2$;
$As_3H_5$, $AsH_2NH_2$, $AsH(NH_2)_2$, and $As(NH_2)_3$ from $Mg_3As_2/Mg_3N_2$;
$P_3H_5$ and $GeH_3PH_2$ [3] from $CaGe/Ca_3P_2$,
$As_3H_5$ and $GeH_3AsH_2$ [3] from $CaGe/Ca_3As_2$;
$GeH_3NH_2$ and $GeH_2(NH_2)_2$ from $CaGe/Ca_3N_2$.

## Reaction of Amide Acetals with Isocyanates. The Synthesis of Parabanic Acid O,N-Acetals

By Prof. Dr. H. Bredereck, Dr. G. Simchen and cand. chem. E. Göknel

Institut für Organische Chemie and Organisch-Chemische Technologie
der Technischen Hochschule Stuttgart (Germany)

In the course of our investigations on the reaction of acetals of carboxamides with cumulative double-bond systems, we reacted dimethylformamide diethyl acetal *(1)* with isocyanates by heating a mixture of the components (molar ratio 1:1) at 100–130 °C for several hours. *O,N*-Acetals of 1,3-disubstituted parabanic acids [*(2a)*, m.p. 120 °C; *(2b)*, m.p. 93 °C] were obtained in 80 to 85 % yield, with elimination of ethanol (as urethane).

*(1)* + 3 R–N=C=O → *(2)* + $RNHCOOC_2H_5$

*(2a)*: R = $C_6H_5$; *(2b)*: R = $C_6H_{11}$

## Imidodiphosphinatometal Chelates, Neutral Complexes with Carbon-Free Chelate Rings

By Dr. A. Schmidpeter, Dipl.-Chem. R. Böhm, and cand. chem. H. Groeger

Institut für Anorganische Chemie
der Universität München (Germany)

Only a few metal chelates are known in which the ring contains no carbon. In the course of our work on heterocycles containing P and N [1], we have prepared several compounds of a new type *(1)*. Here the donor functions X are bridged by $-(C_6H_5)_2P-N-P(C_6H_5)_2-$ groups.

| | X | M | Color | M.p. [°C] |
|---|---|---|---|---|
| *(1a)* | NH | Cu | blue | 178–180 (decomp.) |
| *(1b)* | O | Zn | colorless | 228–229.5 |
| *(1c)* | S | Ni | brown | 265–266 (decomp.) |
| *(1d)* | S | Cd | colorless | 309–311 (decomp.) |

A green precipitate separates from a methanolic solution of tetraphenylimidodiphosphinic diimide hydrochloride $N[(C_6H_5)_2PNH_2]_2Cl$ [2] and $CuCl_2 \cdot 2\,H_2O$ on treatment with sodium methoxide. Careful hydrolysis of this precipitate yields *(1a)*. Compound *(1b)* is formed from tetraphenylimidodiphosphinic acid $N[(C_6H_5)_2PO]_2H$ [3] and zinc dust in boiling benzonitrile. Compounds *(1c)* and *(1d)* are precipitated from a methanolic solution of $NiCl_2 \cdot 6\,H_2O$ or $CdCl_2 \cdot H_2O$ by potassium tetraphenyldithioimidodiphosphinate $KN[(C_6H_5)_2PS]_2$ [4].

The compounds are insoluble in water, and can be crystallized from polar organic solvents and benzene. According to osmometric and cryoscopic molecular-weight determinations, *(1a)* and *(1b)* are not associated. Further ligands, *e.g.* pyridine, can add onto *(1c)*.

## Europium as an Alkaline Earth Metal

By Prof. Dr. W. Klemm, Dipl.-Chem. H. Kock, and W. Mühlpfordt

Anorganisch-Chemisches Institut
der Universität Münster (Germany)

According to their atomic volumes, europium and ytterbium do not fit into the series of the rare earth metals but resemble the alkaline-earth metals; their magnetic behavior also indicates that they contain the species $M^{2+}$, but not $M^{3+}$ [1]. The atomic volume of Eu lies between those of Ca and Sr, but closer to Ca; however, Eu does not crystallize in the face-centered cubic system like Ca and Sr, but in the body-centered cubic system like Ba.

*Behavior of europium towards calcium* [1a]: Extensive mixed crystal formation occurs in the system Ca/Eu. The lattices are face-centered from 0 to about 55 atom-% of Eu, and body-centered from about 60 to 100 atom-% of Eu. The miscibility gap for samples obtained by rapid cooling of the melt is only a few atoms percent. The variation of the lattice constants of the mixed crystals with a high Eu content roughly corresponds to that of Vegard's straight line for body-centered cubic Ca (stable only at high temperatures), the volume of which does not differ appreciably from that of face-centered cubic Ca. The face-centered mixed crystals with a high calcium content behave, as regards their lattice constants, as if the volume of Eu with a (hypothetical) face-centered crystal structure were a few percent more than the body-centered variety.

*Behavior towards magnesium* [1b]: Mg and Ca form an $Mg_2Ca$ phase, while in the system Mg/Sr, besides $Mg_2Sr$, the phase $Mg_{17}Sr_2$ and one or two phases in the range $Mg_5Sr$ $Mg_4Sr$ also occur [2]. The existence of MgSr is the subject of controversy [3]. We were able to detect the following phases by X-ray methods in the system Mg/Eu: $Mg_{17}Eu_2$ [4], one or two phases between $Mg_5Eu$ and $Mg_4Eu$, $Mg_2Eu$ [4], and MgEu (stable only below 500 °C). In this behavior, therefore, Eu resembles Sr, and not Ca. The lattice constants of $Mg_2Eu$ [$MgZn_2$-type (C 14), $D^4_{6h}$–$P6_3/mmc$; $a = 6.37_9$; $c = 10.30_8$ Å] lie between those of $Mg_2Ca$ [$a = 6.23$; $c = 10.12$ Å] and $Mg_2Sr$ [$a = 6.439$; $c = 10.494$ Å], and rather closer to the latter. The values for $Mg_{17}Eu_2$ [$Ni_{17}Th_2$-type, $D^4_{6h}$–$P6_3/mmc$; $a = 10.49$; $c = 10.33$ Å] and $Mg_{17}Sr_2$ [$a = 10.533$; $c = 10.341$ Å] are particularly similar. However, the lattice constant of MgEu [CsI-type (B 2), $O^1_h$–$Pm3m$; $a = 4.10_2$ Å] is not strictly compatible with the value given by *Nowotny* [3] for MgSr [$a = 3.908$ Å]. Whereas $Mg_{17}Eu_2$ is practically volume-additive, the formation of $Mg_2Eu$ and MgEu is accompanied by a pronounced contraction; the electronegativities of Sr and Eu must therefore be somewhat different [5]. Thus europium behaves towards magnesium as a typical alkaline earth metal, closely related to strontium. The extent to which the alloys mentioned contain the species $Eu^{2+}$ is being investigated [6].

The variation of the lattice constants in the case of the $MBe_{13}$ phases ($NaZn_{13}$-type, $O^6_h$–$Fm3c$; $EuBe_{13}$: $a = 10.300$ Å [7]; $CaBe_{13}$: $a = 10.312$ Å [8]; $SrBe_{13}$: $a = 10.470$ Å [9]) indicates that Eu occurs in the trivalent state. This will also be checked by magnetic measurements.

## Preparation of Thioamides from Alkenylamines and Sulfur at Room Temperature

By Prof. Dr. Roland Mayer and J. Wehl

Institut für Organische Chemie
der Technischen Universität Dresden (Germany)

Elemental sulfur reacts with alkenylamines in some polar solvents (preferably dimethylformamide) at room temperature and atmospheric pressure to give thioamides. The yields from vinylamines of type *(1)* are about 75 %; those from propenylamines of type *(2)* lie between 20 and 60 %. Ketialkenylamines and amines derived from aldehydes react differently under these conditions.

*(1)* *(3)*

*(2)*

This useful variant of the Willgerodt-Kindler reaction can start directly from ketones, which are treated in the conventional manner with a secondary amine and sulfur, a catalyst, *e.g. p*-toluenesulfonic acid, then being added to accelerate the formation of the alkenylamine. Examples:

a) *N*-(α-styryl)morpholine (18.5 g), sulfur (3.5 g), and dimethylformamide (20 ml) are mixed together. The solution rapidly turns dark brown and loses its turbidity. After standing overnight at 15–20 °C, it is poured into 100 ml of a 1:1 methanol/water mixture and cooled to at least 0 °C. A crude product [1] separates out and is crystallized from 50 % methanol, giving *(3)*, $R' = C_6H_5$, $R_2 = -(CH_2)_2O-(CH_2)_2-$, m.p. 79–79.5 °C, in 75 % yield (16.3 g).

b) A mixture of acetophenone (12.0 g), *p*-toluenesulfonic acid (0.5 g), morpholine (18 g), and sulfur (3.2 g), is refluxed for 3 h at 130 °C and then poured into 50 ml of methanol and cooled to 0 °C. Work-up as above yielded 20.7 g (94 %) of the same product *(3)*. A control experiment without catalyst afforded a yield of only 49 %.

Received, September 14th, 1964 [Z 825/645 IE]
German version: Angew. Chem. 76, 861 (1964)

[1] A separate report will be given on a yellow impurity $C_{16}H_{12}S_2$ formed in this reaction.

## Products of the Thermolysis of Sulfenic Acid Derivatives

By Prof. Dr. Roland Mayer and H.-J. Frey

Institut für Organische Chemie
der Technischen Universität Dresden (Germany)

Sulfenic acid derivatives *(1)* are sensitive to heat and can therefore be distilled, if at all, only in a good vacuum [1]. We have found that these compounds decompose between 60 and 110 °C as indicated in the following equation. While

*(1)* *(2)*

| | | |
|---|---|---|
| *(a)* | $R = C_6H_5$; | $X = Cl$ |
| *(b)* | $R = p\text{-}CH_3\text{-}C_6H_4$; | $X = Cl$ |
| *(c)* | $R = p\text{-}CH_3O\text{-}C_6H_4$; | $X = Cl$ |
| *(d)* | R = Alkyl; | $X = Cl$ |
| *(e)* | $R = C_6H_5$; | $X = SCN$ |
| *(f)* | $R = C_6H_5$; | $X = SC_6H_5$ |

*(2)* can be isolated on a preparative scale, the sulfur generally occurs in subsequent products.

After 30 min at 100 °C, benzenesulfenyl chloride *(1a)* affords chlorobenzene *(2a)* in 60 % yield, together with diphenyl disulfide and $S_2Cl_2$. The *p*-methyl and *p*-methoxy groups on the benzene ring of *(1b)* and *(1c)*, respectively, accelerate the decomposition which is complete after only 10 min at 90 °C; nitro groups inhibit cleavage.

Aliphatic sulfenyl chlorides *(1d)*, especially those which branch at the α-carbon atom, also decompose at about 100 °C into alkyl chlorides, although here the yields are lower than in the aromatic series.

The requisite thermolysis temperature depends on the stability of the sulfenyl derivative in question. Thus, benzenesulfenyl thiocyanate *(1e)* forms phenyl isothiocyanate *(2e)* in 70 % yield at only 70 °C; since *(2e)* is stabilized by resonance, it only starts to decompose to benzonitrile at 190 °C.

Thermolytic cleavage of monosulfides into disulfides is already known [2] but proceeds at higher temperatures; it deserves a similar interpretation. For example, diphenyl disulfide *(1f)* gives an almost quantitative yield of diphenyl sulfide *(2f)* and sulfur within about an hour at 200 °C.

# CONFERENCE REPORTS

## Chemical Storage and Processing of Information in Biological Systems

The Gesellschaft für Physikalische Biologie and the Neuroscience Research Foundation organized a conference on May 5th and 6th in Berlepsch Castle near Göttingen (Germany). The subject of the conference was "Chemical Means of Storage and Readout of Information in Biological Systems". Some 90 participants, about one-third from abroad, discussed the four topics "Molecular Interactions", "Antigen-Antibody Reactions", "RNA Replication" and "Possible Relations to Psychic Memory". The very lively discussions were interrupted by an evening of chamber music, with works by Baroque composers, improvised by the participants themselves.

### Molecular Interactions

*M. Eigen*, Göttingen (Germany), opened the conference with an introduction to the problem of molecular interactions. Although our knowledge of the interactions occurring among simple inorganic ions is relatively good, the interactions of large organic ions and molecules are as yet largely unexplored. However, it is these very interactions that are important in biological systems.

Ionic interactions are normally non-specific, *i.e.* a free ion can be situated with almost equal probability at a point x or $x + \Delta x$. Although hydrogen bridges are spatially fixed, they are structurally non-specific, and hydrophobic interactions, as such, are also without appreciable specificity. In biological systems, however, interplay of these three types of interactions leads to considerable specificity, owing to the spatial fixation of the mutally interacting partners. Examples of this are seen in the tertiary structure of proteins, in antigen-antibody reactions, and in enzymatic processes.

Hydrophobic interactions, *e. g.* between uncharged side-chains of a protein or between the various heterocyclic bases of nucleic acids, are of importance to the molecular structure primarily in polar solvents, and hence particularly in aqueous solution. They cause the disappearance of the structure of the solvent between hydrophobic surfaces. The resulting gain in free energy, together with other effects, particularly $\pi-\pi$ interactions, leads to stabilization.

In many biologically important molecular structures, the interactions described are cooperative, *i.e.* one interaction facilitates the occurrence of another of the same type. Consequently, after a critical value has been reached, a relatively small change in the external conditions can lead to a radical change in structure. Thus, the pH or temperature range within which a nucleic-acid double helix changes into two coiled strands is much narrower than would be expected if the known interactions were simply additive in their effects. Systems with cooperative interactions can therefore respond to external influences by all-or-none reactions.

Owing to their short half-lives, all molecular interactions, whether ionic, hydrophilic, or hydrophobic in nature, are suitable only for transient assimilation of information. Permanent storage of information, *i.e.* for about the duration of a human life, probably requires reactions with an activation energy of at least 25 kcal/mole, *i.e.* reactions which lead to the formation of covalent bonds.

Incidentally, this lecture was based on a manuscript which had been sent in advance to the conference participants [*] and in which an attempt was made to redefine a number of concepts borrowed from psychology, but nevertheless applicable to molecular processes. These concepts range from simple "interaction" on the basis of a force law, through „distinction" and "recognition" to "memory", and include functions such as "storage", "transfer", and "readout" of information, and go on to "adaptation" and "learning". We are quite familiar with molecular processes of distinction and of storage, transfer, and recognition of information in enzymology and molecular genetics. Learning and memory functions, on the other hand, pass beyond a simple adaptation and are known only on the cellular level.

In the discussion, which was led by *L. Onsager*, New Haven, Conn. (U.S.A.), *J. Kendrew*, Cambridge (England), reported on the structure of myoglobin. Only 70 % of the molecule has a helical structure. Between the regions which are arranged in this manner, there are seven relatively short sections which are non-helical. The longest of these sections consists of eight amino acids. The amino-acid sequence (the myoglobin molecule contains a total of 153 amino-acid units) gives no answer, in the light of present-day knowledge, to the question why a helical region begins and why it ends. The four proline units in the molecule, which are sterically incompatible with an α-helix, evidently play a part, and so do the six serine and five threonine residues, whose side-chains interfere with the hydrogen-bonded structure of the α-helix. The end of a helical region is almost certainly also influenced by hydrogen bridges between the free carboxyl groups of aspartic acid units and amide NH groups in the main chain, since such interactions are possible only where a helical region ends.

[*] To be published.

Myoglobin has to a large extent the same tertiary structure as the α- and β-chains of hemoglobin. The homologies in the amino-acid sequences, *i.e.* in the primary structure of the three protein chains, are astonishingly slight in comparison with the similarities in tertiary structure: only 23 out of the 153 amino acids present, *i.e.* only about 15 %, are homologous. However, if we compare the amino acids whose side-chains are located in the interior of the spherical molecules, the number of homologies increases to about 33 %. It appears, therefore, that hydrophobic interactions are of major importance for the tertiary structure of myoglobin and hemoglobin, and hence also, indirectly, for the function of these proteins. This would agree with the fact that abnormal hemoglobins which are formed by mutations are almost always modified in the amino acids whose side-chains point outwards, as long as the mutations are not lethal.

*O. Sinanoglu*, New Haven, Conn. (U.S.A.), pointed out that deoxyribonucleic acid (DNA) can form a double helix in water, but is denaturated in other similar solvents (formamide or alcohols). In the search for a parallelism between this phenomenon and other physical properties of the solvent, a relationship was found to exist with the interfacial energy: the higher the interfacial energy, the smaller the denaturing influence of the solvent on the DNA structure.

*D. Crothers*, Göttingen (Germany), found that the relaxation period for the helix-coil transition in the DNA of T2 phages depends on the square of the molecular weight. This dependence disappears almost completely above a molecular weight of about $2\times10^7$. To explain this result, it was assumed that there are at least six single-strand bridges per T2–DNA molecule of molecular weight $>2\times10^7$, *i.e.* that the strands of the DNA double helix are broken at several points, and that the molecule is held together at these points only by the strand which is not broken. These measurements also permitted the calculation of a coefficient of friction for the unwinding of the double helix into two separate strands by rotary diffusion. This coefficient is about $10^3$ times greater than would be expected in water, probably owing to the greater microscopic viscosity of an ordered water structure in the immediate vicinity of the DNA molecule. The fact that the viscosity of the aqueous solution can be increased one hundredfold by addition of glycerol, without appreciably changing the coefficient of friction, lends support to this hypothesis.

*J. Lehninger*, Baltimore, Md. (U.S.A.), reported on higher forms of organization at the molecular level. Every enzyme has a catalytically active site at which transformation of the substrate into the product takes place. However, there are evidently also other centers which are independent of the catalytically active site and which interact with substances referred to as allosteric effectors. These alter the tertiary structure (and hence the activity) of the enzyme. This gives rise to a new possibility for the control and regulation of the activity of enzyme chains. The product of the enzyme last in a chain may be an allosteric effector which modifies a preceding enzyme of the chain in such a way that its activity is decreased. In contrast to enzyme inhibition by feedback, where the inhibitor must be similar to the substrate of the inhibited enzyme (since it interacts with the catalytically active site), the effector in allosteric inhibition does not need to resemble any substrate whatsoever of the enzyme chain (since its point of interaction is different from that of the substrates).

The enzymes of an enzyme chain probably always form complexes during the catalysis of successive steps, even when they are found to be soluble on isolation. The complex formation is probably due to the presence in the enzymes of bonding sites which may have the character of allosteric centers and which appear to be specific for one another. The enzyme complexes which have been most thoroughly studied to date, and which can be isolated as such, are the fatty-acid synthetase and the α-keto-acid dehydrogenase systems. In both systems, the substrate is bonded covalently to the enzyme complex while it passes through the reaction chain.

Membrane-bound enzyme systems exhibit another feature, namely directionality. For example, when an ATP-ase reaction ($ATP + H_2O \rightarrow ADP + PO_4^{3-}$) occurs in a membrane, it can give rise to a pH gradient across the membrane when the ions of water participating in the reaction come from different sides of the membrane. The same is true of the respiratory chain ($XH_2 + 1/2O_2 \rightarrow X + H_2O$), if the ions of the water formed are given up on different sides of the membrane.

Membranes themselves are forms of higher organization at the molecular level. They consist, among other things, of double layers of phospholipids separated by layers of protein. Membranes constitute about 60 % of the total cell material and reach large surface areas (for example, the total surface of the plasma membrane of a liver cell is about 8000 $\mu^2$ and the mitochondrial membranes of the same type of cell have a total surface area of 29000 ($\mu^2$). Bearing in mind that the phospholipids of a membrane, like proteins, have many side-chains of different types, it becomes clear that the membranes of a cell offer enormous possibilities for coding, *i.e.* for the storage of information. It would thus be feasible, for example, that proteins could be bonded to a membrane only according to the underlying phospholipid pattern.

## Antigen-Antibody Reactions

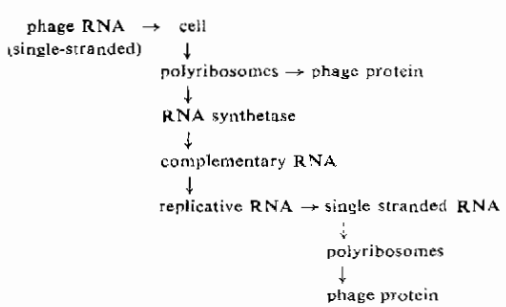
*G. Edelman*, New York (U.S.A.), gave an excellent introduction to the present-day knowledge of the structure of antibodies. Antigen-antibody reactions were discussed in this symposium because they are examples of "memory" at the cellular level.

If an antigen is injected into a mammal, antibodies can be detected in the serum from about the fifth day onwards and sediment out in the ultracentrifuge with a sedimentation constant of 19 S. Their production reaches a maximum after a further four days, and then decreases rapidly, provided the antigen dose does not exceed a threshold value. On injection of a quantity of antigen above this threshold value, the conditions are initially the same: 19S antibodies can be detected after about five days. Their production then declines, and 7S antibodies appear, whose quantity reaches a maximum which is not exceeded as long as no further antibody is injected.

The dimensions of a 7S antibody are about $240\times57\times19$ Å$^3$ (determined from small-angle X-ray scattering). 7S Antibodies consist of four proteins which are similar in pairs and which are referred to as the L and H components. The molecular weight of the L component is 20000–24000, that of the H component 55000–60000. Two H components are linked together by disulfide bridges, and one L component is bonded to each H component. H and L components can be separated and recombined, and it is possible in this way to obtain H/L hybrids from different antibodies of the same type of animal, and recently even of different types of animals. It has not yet been settled whether the information required for the formation of each specific antibody is already present in the cell and the antigen simply triggers off the corresponding reaction chain, or whether the cell "learns" the formation of the antibody from the antigen.

In the discussion, *O. Westphal*, Freiburg/Brsg. (Germany), reported on attempts to immunize cattle with pure *Pneumococcus* polysaccharides as antigens. There is an optimum dose, *viz.* 200–400γ of polysaccharide per injection. If more antigen is given, the quantity of antibody no longer increases, but decreases again on further increase of the antigen dose. The production of antibodies against various antigens is additive, but some cows form no antibodies at all against these antigens; this suggests that competent cells (competent for the recognition of antigens and production of antibodies) must be present. The larger the antigen, the better is the production of the antibody. It is increased by the use of cross-linked polysaccharide antigens.

It is an interesting fact that γ-globulin components which form precipitates with erythrocytes are found in the hemolymph of the horseshoe crab. This appears to indicate the presence of a primitive antigen-antibody system. So far antigen-antibody reactions have been detected only in higher animals.



*A. Rubin*, Brookline, Mass. (U.S.A.), reported on the formation of antibodies after surgical transplantations. If 6-mercaptopurine is given to a patient on the same day as or on the day after a kidney graft, the transplanted organ is not rejected by the body. Thus, 6-mercaptopurine interferes with the formation of antibodies against the foreign kidney, probably at the stage of macrophage-RNA.

In experiments which have not yet been completed it is being checked whether the organs of an immunized animal which synthetize antibodies contain RNA types characteristic of the antibodies. To this end, rabbits were injected with human albumin and ferritin. At maximum antibody production the animals were slaughtered and the ribosomes in their spleens centrifuged in a density gradient.

## Ribonucleic Acid Replication

The introductory lecture was delivered by *R. Smellie*, Glasgow (Scotland). RNA-polymerase synthesizes ribonucleic acid from the four ribonucleoside triphosphates in the presence of DNA and $Mn^{2+}$. Native and single-stranded DNA (DNA from ΦX-174 phages or DNA preparations denatured by heating) may serve as matrices. The nucleotide sequence of the synthetic RNA is complementary to the base sequence of the DNA; this indicates pairing of complementary bases during the RNA synthesis. The complementary nature of the matrix and the product is shown by analysis of immediately adjoining bases (nearest-neighbor analysis), by the formation of DNA/RNA hybrids, and by the base ratios in the matrix and in the product. Both strands of native DNA are used *in vitro* as matrices for the formation of RNA, since single-stranded ΦX-174 DNA gives an RNA with a complementary base composition, whereas double-stranded ΦX-174 DNA gives a product with the identical base composition. On the other hand, only one of the two strands of native DNA is evidently copied *in vivo*. This is indicated by the following experiment: the two strands of a native phage DNA could be separated by centrifuging in a density gradient. Each of these strands gave RNA *in vitro*, whereas m-RNA synthetized by bacteria which had been infected with the phages forms a hybrid with only one of the two DNA strands.

The replication of virus RNA was the subject of the lecture by *S. Ochoa*, New York (U.S.A.). If *Escherichia coli* is infected with MS2 phages, which contain single-stranded RNA, the cells form an RNA synthetase, which can be isolated. The enzyme contains ribonucleic acid in a form which is partly stable towards ribonuclease. This is evidently double-stranded RNA. On annealing with other types of RNA, this RNA, which is referred to as the replicative form, gives a hybrid only with MS2-RNA. It must therefore be assumed that the cells infected with the MS2 phages first synthesize a complementary RNA strand which forms a double helix with the original bacteriophage RNA. This replicative form then serves as a matrix for the synthesis of new phage RNA. Destruction of the replicative RNA bound to the enzyme leads to irreversible inhibition of the enzyme. The formation of new bacteriophages in infected cells probably follows the scheme:

However, it is not yet known whether the RNA synthetase which has been isolated forms also the complementary RNA, or whether another enzyme is responsible for this reaction.

## Possible Relations to Psychic Memory

*H. Hydén*, Göteborg (Sweden), gave an introductory report on experiments with rats which had to learn a new mode of behavior and whose brains were then analysed for their RNA content in the appropriate sections (analysis of the cell nuclei of individual neurons; sensitivity of detection: μμg). "Right-handed" rats learned to take their food from a tube with the right fore-foot. The tube was then moved so that the food could only be reached with the left fore-foot. The part of the somatosensory cortex which determines whether the animal is right- or left-handed was then analysed. A distinct increase was observed in the RNA content in the cell layers of the right half of the brain. The corresponding cells of the left half of the brain were used as controls. The RNA isolated from the cells of the right (learning) half of the brain also exhibited a higher ratio of purine to pyrimidine bases.

In a second experiment, the animals had to crawl up a thin steel wire 1 m long and inclined at an angle of 45° in order to reach their food. With a daily learning period of 45 min, the rats took only 4–5 days to master the new mode of behavior. The large nerve cells and the neuroglia of the lateral vestibular nucleus were analysed, using neurons and neuroglia from other parts of the brain of the same animal and from other animals as controls. An increase in the RNA content of the nerve cells and in the adenine:uracil ratio of the nuclear RNA in the nerve cells and that of the neuroglia RNA was again found.

The interpretation of these results may be that repressed sections of the chromosomal DNA in the brain cells become active during learning and produce a corresponding RNA which in turn leads to the synthesis of specific proteins. The presence of these proteins or the rate of their production might then affect the transmission of nervous impulses. The neuroglia may also participate in this process, possibly by controlling the induction of the RNA synthesis in the neuron.

Finally, *F. O. Schmitt*, Cambridge, Mass. (U.S.A.), showed some possibilities for the storage of information in the central nervous system. The system consisting of neurons, nerve fibers, and synapses in the brain can be regarded as a three-dimensional network, resembling the tracks of a marshalling yard. The fate of an impulse then essentially depends on the part of the network through which it is transmitted. This may be decided by the neurons. One way in which they could carry out this decision is by sending specific proteins through their nerve fibers to the synapses; the proteins would then permit the transmission only of certain impulses. It is certain that protein is being constantly synthetized in the neurons and migrates through the nerve fibers to the synapses. However, it is not yet known whether this protein is used only for the metabolism of the nerve cells, or as a structural material for the production of specific routes of communication, or even as a molecular information store. ## Cycloadditions of Alkenylamines and 1,1-Bisdialkylaminoethylenes

*G. Opitz*, Tübingen (Germany)

Cycloaddition of alkenylamines onto ketenes, isocyanates, or sulfenes affords β-dialkylaminocyclobutanones *(1)*, β-dialkylamino-β-lactams *(2)*, and β-dialkylaminotrimethylene sulfones *(3)*, respectively. Whereas the enolizable β-aminocyclobutanones rearrange on heating to alkyl β-aminovinyl ketones, compounds *(1)*, which are not capable of enolization, are thermally stable; so are β-aminotrimethylene sulfones *(3)*. At higher temperatures, β-amino-β-lactams *(2)*, which are also formed from amidines and ketenes, are in equilibrium with the corresponding alkyleneamines and isocyanates.

Interaction of non-enolizable β-aminocyclobutanones *(1)* with Grignard reagents may result in four different reactions: a) normal addition to form a tertiary β-aminocyclobutanol, b) reduction to form a secondary β-aminocyclobutanol, c) ring-opening to form a β-amino ketone, and d) reductive ring-opening to form a different β-amino ketone. The derivatives of pyrrolidine and hexamethyleneimine possess a more pronounced tendency towards ring-opening than those of piperidine and morpholine.

*(1)* *(2)* *(3)* *(4)* *(5)* *(6)*

On acetylation, followed by a diene synthesis with ketene and amine elimination, 1,1-bisdialkylaminoethylenes and ketene give rise to 4-dialkylamino-6-methylcoumalins *(4)* which react with phenylmagnesium bromide to yield 1,3,5-triphenylbenzene and which are degraded by sodium hydroxide to acetone, acetic acid, and dialkylamines. In the reaction of 1,1-bisdialkylaminoethylenes with aliphatic sulfonyl chlorides in the presence of triethylamine, acylation to give *(5)* competes with the cyclization to 3-dialkylaminothietene 1,1-dioxides *(6)*.

The synthesis of three-membered cyclic sulfones from diazoalkanes and aliphatic sulfonyl chlorides in the presence of triethylamine provides further support for the assumption of intermediate formation of sulfenes.

## The Reaction of White Phosphorus with Free Radicals from γ-Radiolysed Organic Liquids

*A. Henglein*, Berlin (Germany)

Irradiation of solutions of white phosphorus in $CCl_4$ with γ-rays produces trichloromethylphosphorus dichloride, phosphorus trichloride, red phosphorus, hexachloroethane, and a polymer $(CCl_2)_n$. At room temperature the main product is red phosphorus to which one trichloromethyl group (from radiolysis of the solvent) per 7 phosphorus atoms is chemically attached. Above 80 °C, the low molecular-weight phosphorus compounds are formed almost exclusively *via* a chain reaction. A mechanism is indicated whereby free radicals from the solvent add onto the $P_4$ molecules and the resultant $RP_4$ units either form red phosphorus or react with the solvent with abstraction of chlorine. Abstraction of a chlorine atom requires an activation energy of 8.2 kcal/mole and is therefore favored by high temperatures during the irradiation.

In cyclohexane, free cyclohexyl radicals (from radiolysis of the solvent) react with dissolved phosphorus to form red phosphorus containing one $C_6H_{11}$ group per 4 phosphorus atoms. About 30 % of the phosphorus added appears in the form of soluble organophosphorus compounds containing several phosphorus atoms per molecule. The radical attack in cyclohexane leads neither to the scission of all the P-P bonds of the $P_4$ molecules nor to a chain reaction. If $CCl_4$ is added, however, at higher temperatures, three simultaneous chain reactions appear, which lead to a) chloroform and cyclohexyl chloride, b) trichloromethylphosphorus dichloride, and c) cyclohexylphosphorus dichloride. The trichloromethyl radical is thus a common intermediate in the three chain reactions, which are linked with one another.

White phosphorus participates in the polymerization of styrene induced by γ-rays. The rate of polymerization is slightly increased, but the average molecular weight is greatly lowered. In addition, phosphorus is incorporated into the polymer (one atom/100 molecules of monomer). These results indicate that $P_4$ molecules intercept growing styrene chains, thereby initiating more than one new chain per interception, and that breakdown of the kinetic chain by mutual deactivation follows. It is concluded from the transfer constant found that white phosphorus is a relatively poor trap for free carbon radicals and does not react with them at each encounter.

Pulse radiolysis experiments with solutions of white phosphorus in cyclohexane and $CCl_4$ produced a short-lived intermediate which has an absorption maximum at 650 mμ and which disappears by reactions of first or second order, depending on the $P_4$ concentration, to give a stable entity which absorbs at 350 mμ. The short-lived species is probably either the $C_6H_{11}P_4$ or the $CCl_3P_4$ radical.

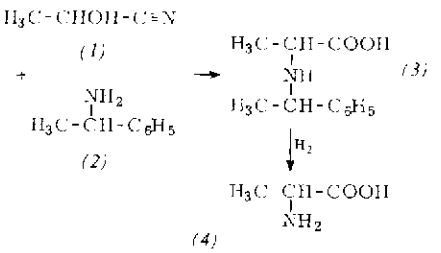
# SELECTED ABSTRACTS

**Isoenzymes of creatine kinase** were found by *A. Burger, R. Richterlich*, and *H. Aebi* in electrophoretic investigations of human, rabbit, and rat tissues. Three bands migrating at different speeds were detected. All three bands were found in smooth muscle, but in skeletal muscle only that migrating most slowly towards the cathode, and in the brain mainly the band moving very quickly towards the anode were observed. It is probable that – as in the case of lactic dehydrogenase – isoenzymes composed of different subunits [1] exist for this enzyme, which is responsible for ATP-production from creatine phosphate. There may be two different sub-units of creatine kinase which can combine to give three electrophoretically separable, enzymatically active dimers. In principle, the same observations were described by *Sjövall* and *Voigt* [2]. / Biochem. Z. *339*, 305 (1964) / –Sch. [Rd 998/289 IE]

[1] *T. Wieland* and *G. Pfleiderer*, Angew. Chem. *74*, 261 (1962); Angew. Chem. internat. Edit. *1*, 169 (1962).

[2] *K. Sjövall* and *A. Voigt*, Nature (London) *202*, 701 (1964).



**A new type of base-catalysed rearrangement of nitroso groups** is reported by *H. U. Daeniker*. In methanol *N*-substituted *N*-nitrosoaminoacetonitriles *(1)* undergo an intramolecular rearrangement to form α-isonitrosoaminoacetonitriles *(2)*. If the cyano group of *(1)* is replaced by other active groups, no such rearrangement takes place, Schiff bases being formed instead. Reaction of *(2)* with phosgene in pyridine leads to 4-substituted 3-cyano-1,2,4-oxadiazolin-5-one derivatives *(3)*,

*(1)* *(2)* *(3)*

an unusual group of compounds accessible with difficulty. Examples for *(2)*: R = $C_6H_5$, m.p. 141–144 °C (decomp.); R = *p*-$ClC_6H_4$, m.p. 151–153 °C (decomp.); R = *p*-$CH_3O$-$C_6H_4$, m.p. 157–158 °C (decomp.); R = $CH_3$, m.p. 155 to 157 °C (decomp.); R = n-$C_4H_9$, m.p. 77–78 °C. / Helv. chim. Acta *47*, 33 (1964) / –Ma. [Rd 4/288 IE]

**A novel stereospecific synthesis of optically active α-amino acids** was described by *K. Harada* and *S. W. Fox*. Racemic lactonitrile *(1)*, for example, was allowed to stand at 25 °C for 48 h with D-( )-α-methylbenzylamine *(2)* in methanol. The crude product *(3)* was subjected to catalytic hydrogenolysis in alcohol and after working up and purification gave optically nearly pure L-(+)-alanine *(4)* in 17% yield. The

reaction mechanism is not known. Similar reactions may have been responsible for the formation of optically active compounds on the primitive earth under abiotic conditions. / Naturwissenschaften *51*, 106 (1964) / –Sch. [Rd 1000/286 IE]

**The problem of information transfer in chemistry** was studied by *H. Erlenmeyer* and *H. Bartels* taking thin-layer chromatography as an example. Silica gel precipitated in the presence of *N,N*-dimethyl- or *N,N*-diethylaniline and washed free from amines adsorbed dimethyl- or diethylaniline more strongly than untreated gel. Measurement of the adsorption isotherms showed that methyl orange and ethyl orange were also somewhat more strongly adsorbed by the gel after pretreatment with dimethyl- or diethylaniline. Evidently the dialkylamino group of the dialkylaniline molecule is able to influence the silica gel in such a way that more complicated molecules containing this grouping are more strongly adsorbed. / Helv. chim. Acta *47*, 46 (1964) / –Kr. [Rd 3/290 IE]

**The assimilation of carbon from carbonates,** formerly known only with algae, has now been observed in higher land plants by *J. Materna* and *R. Kohout*. Spruce and fir shoots and leaves of deciduous trees were immersed in solutions of $NaH^{14}CO_3$ and $Na_2{}^{14}CO_3$ for a few seconds to several hours. After extraction with methanol and water, an examination for the presence of labelled glycides and other organic compounds was carried out by paper chromatography. In all experiments (particularly those with spruce, fir, and oak), glucose, fructose, and sucrose labelled with $^{14}C$ were found after incubation periods of only a few seconds, together with other labelled compounds, including insoluble components of the shoots and leaves. / Naturwissenschaften *51*, 116 (1964) / De. [Rd 949/269 IE]

**The rate-determining step of the reaction catalysed by alcohol dehydrogenase from yeast** was established by *B. Müller-Hill* and *K. Wallenfels*. For many substrates, the conversion of the enzyme-substrate complex into the enzyme-product complex is rate-determining. Sometimes, however, the rate of diffusion of the substrate or coenzyme away from the enzyme is also decisive for the overall reaction velocity. Such diffusion-controlled processes are characterized by low activation energies. The very low activation energy which was found for the acetaldehyde-NADH-reaction above 20 °C leads to the conclusion that, at this temperature, removal of the NAD by diffusion becomes rate-determining. / Biochem. Z. *339*, 338 (1964) / –Sch. [Rd 1/291 IE]

# BOOK REVIEWS

**Magnetische Kernresonanz und chemische Struktur** (Nuclear Magnetic Resonance and Chemical Structure), by *H. Strehlow*. Fortschritte der physikalischen Chemie, Vol. 7. Dr. Dietrich Steinkopff Verlag, Darmstadt 1962. 1st edit. 179 pp., 94 illustr., 22 tables. Price DM 36.– (about $ 9.00).

The non-physical chemist who would like to apply nuclear magnetic resonance to chemical problems and to read the pertinent literature critically will be content at first with a minimum knowledge of physical theory but will want to become more thoroughly acquainted with the possibilities of structural determination. Experience shows that at this stage he faces two major difficulties: complex spin splittings and fast reactions such as chemical exchange or intramolecular motions. The study of such phenomena by perusal of original literature and detailed monographs is very laborious. The book by *H. Strehlow* thus fills a gap by dealing with the physical aspects of NMR primarily more qualitatively and without mathematical derivations; rigorous treatments are often added in a special chapter.

The book is not intended to be a working basis for structural elucidations, like *Bellamy*'s monograph for infrared spectroscopy. Nevertheless one would have liked the chapter on the determination of the structures of organic and inorganic compounds (22 pp.) to be somewhat more detailed. Quotation of the chemical shift in Hz [eps] relative to tetramethylsilane is disturbing here since, when dealing with that parameter earlier on in the book, the author has used δ-values based on benzene. In the chapter on spin-spin interaction there is unfortunately no mention of the frequently occurring ABX spectrum which may be analysed in an elementary manner; on the other hand tables for a number of more complex systems are listed. The brief discussion of fast reactions with many examples deserves special mention. Other chapters of importance to the chemist deal with the experimental technique as well as the use of nuclear magnetic resonance for solutions of electrolytes and solids.

The book is excellently written and can be highly recommended to every chemist who is interested in the principles of the method. It is to be regretted, however, that the high price of the paper-backed edition is rather a setback to wide circulation.

*A. Mannschreck* [NB 189/87 IE]

**Gmelins Handbuch der anorganischen Chemie** (Gmelin's Handbook of Inorganic Chemistry), 8th completely revised edition. Published by the Gmelin-Institut für anorganische Chemie und Grenzgebiete in der Max-Planck-Gesellschaft zur Förderung der Wissenschaften. Initiated by *R. J. Meyer*, continued by *E. H. Erich Pietsch*. Verlag Chemie, GmbH., Weinheim/Bergstr.

**System No. 3: Oxygen.** Vol. 5 (Systems. Ordinary Water up to Chemical Behavior, excluding Electrochemical Behavior). 1963, IV, XVIII, 548 pp., 104 figs. cloth DM 410.– (about $ 105.–). Revised by *Krista von Baczko, Anna Bohne-Neuber, Erna Brennecke, P. Koch, H. K. Kugler*, and *Gertrud Pietsch-Wilcke*.

The previously published Vols. 1 (1943 Historical), 2 (1951 Occurrence, Technology), 3 (1958 Elemental Oxygen), and 4 (1960 Air, Active Oxygen, and Ozone) consisted of 1184 pp. with 208 figs. (total price DM 722.– or about $ 185.–) dealing with the element oxygen $O_2$ (including atomic oxygen O and ozone $O_3$), and so correspond to the usual Part A of the "Gmelin" arrangement. The present Volume 5 begins what would normally be Part B (Compounds of Oxygen). According to the Gmelin "last-place" principle, this Part B is confined to compounds with hydrogen, *i.e.* water and hydro-

gen peroxide. Vol. 5 is specially devoted to "ordinary" (natural) water, with the exception of its electrochemical behavior; this will be dealt with in Vol. 6, which is still in preparation. Further volumes will deal with the other 18 forms of "light" and "heavy" water (combinations of the hydrogen isotopes $^1H$, $^2H$, and $^3H$ with the oxygen isotopes $^{16}O$, $^{17}O$, $^{18}O$) and those of "light" and "heavy" hydrogen peroxide.

In particular, Vol. 5 deals with the systems $O_2$/inert gases, $O_2/H_2$, and $O_2/H_2O$ (7 pp.), up to the preparation of ordinary water in the pure form (16 pp.) and its properties (525 pp.), the last being divided, rather arbitrarily, into 10 chapters of varying importance: thermodynamics (6 pp.), the $H_2O$ system (34 pp.), special forms (1 p.), evaporation and condensation (33 pp.), physical properties (323 pp.), chemical behavior (37 pp.), behavior as a solvent (62 pp.), behavior towards radiation (15 pp.), behavior towards sound (6 pp.), and material transport by steam (8 pp.).

The brief data on the systems of oxygen with inert gases, with hydrogen, and with water are particularly interesting with regard to the stability and existence of possible compounds (*e.g.* oxygen hydrate).

Since technical processing and purification of water has already been described in Vol. 2, and since the synthesis of water from its elements has no preparative importance, the chapter on the preparation of pure water is confined to the production and purity testing of distilled water for laboratory use. Purity requirements vary according to whether conductivity water is desired for conductometric studies, perfectly neutral water for volumetric studies, metal-free water for biological studies, sterile water for medical studies, or dust-free water for optical work.

The thermodynamic discussions deal with the enthalpy, the free energy, the entropy of reaction, and the equilibrium constant of the decomposition and formation of water, according to the equation $H_2O \rightleftarrows H_2 + {}^1/_2O_2$, and with dissociations according to the equations $H_2O \rightleftarrows {}^1/_2H_2 + OH$, $H_2O \rightleftarrows H + OH$, and $H_2O \rightleftarrows H_2 + O$.

The chapter on the $H_2O$ system starts with a description of the phase diagram of water, due consideration being given to the range of stability and existence of the 6 stable and the 2 unstable modifications of ice known at present and to the variant and invariant equilibria between the different system phases. A detailed discussion is given of the existence of the individual phases outside their normal ranges, particularly the supercooling of liquid water and the transcendency of the stability limits of the various types of ice; superheating of liquid water and supercooling of steam are postponed to the later chapter on evaporation or condensation.

The section on special forms of water deals exclusively with the colloidal distribution of water and ice. Data on the preparation of single crystals are given in the later chapter on physical properties (crystallography); the production of vitreous ice is dealt with in the preceding chapter on the $H_2O$ system (modifications of ice), and the formation of films of water is discussed under physical properties (sorption).

The chapter on the evaporation and condensation of water is particularly interesting, especially since detailed investigations into the kinetics and retardation of these processes have been carried out. Condensation processes in the atmosphere (formation of mist, clouds, rain, hoar frost, snow, hail) and the artificial production of rain are also discussed.

The greater part ($\approx 60\,\%$) of this volume is taken up by the chapter on physical properties. This begins with brief details (9 pp.) of the $H_2O$ molecule (disposition of the electrons, configuration, moment of inertia, dipole moment, polarizability, force constants, molecular vibrations, dissociation energy, association) and then passes onto its crystallographic properties (26 pp.), including the crystal structure of the various modifications of ice, the preparation of single crystals, the growth of ice crystals on various matrices, the rate of crystallization, the regelation of ice, and the lattice energy. Prominent among the mechanical-thermal properties (218 pp.) are the anomalies of water due to structural factors (such as its density maximum at 4 °C, its decrease in compressibility with increasing temperature up to 50 °C, its decrease in internal friction with increasing pressure below 32 °C, its expansion on freezing, and its relatively too high boiling point). Of particular interest are the p–v–T relationships given in the steam tables, together with the equations of state which satisfy them, considerations on the melting and the boiling point of water as fixed points of the international temperature scale, and details on the adsorption of water on a wide range of surfaces. A brief (8 pp.) discussion is given of the acoustic properties (velocity of sound in water, absorption of sound by water, cavitation by the action of sound and ultrasonics). This is followed by the optical (38 pp.) and the magnetic and electrical properties (24 pp.). The dielectric constant is discussed in particular detail with regard to the use of water as reference basis in magnetic susceptibility measurements.

The chapter on the chemical behavior begins with general considerations on the macrostructure of water and the resulting inferences relative to its anomalous mechanical-thermal properties; it then deals with the electrolytic dissociation of water, which in turn leads on to the amphoteric nature of water. Remarks on the behavior of water toward elements and compounds are restricted to discussions of the chemical changes occurring in its coreactant; the solvent power of water without chemical change of the solutes is discussed in the following chapter.

The chapter dealing with water as a solvent is subdivided into sections on solubilities, hydration, physical properties of aqueous solutions, ionic mobility, diffusion rates and reactions in aqueous solution (neutralization, precipitation, complex formation, and redox reactions).

The volume closes with two chapters on the behavior of water on irradiation (decomposition of water by ionizing radiation, photochemical decomposition) and on acoustic irradiation (action of sound and ultrasonic waves), and a chapter on material transport by steam, in which the transport of readily volatilized substances (steam distillation) as well as that of substances which are difficult to volatilize (formation of pneumatolytic deposits, salting up of high-pressure steam turbines) are discussed in detail.

**System No. 9: Sulfur.** Part B, Vol. 3 (Conclusion of "Compounds"). 1963, IV, XLII, 745 pp., 245 figs. and 9 foldout tables, cloth, DM 612.– (about $155.–). Revised by *M. Atterer, Anna Bohne-Neuber, Inge Flachsbart, P. Koch, A. Kotowski, W. Lippert, E. Müller, W. Schröder,* and *L. Thaler.*

Vol. B 3 completes System No. 9 "Sulfur" (which now comprises a total of 2637 pp. and 586 figs. at a total price of DM 1777.– or about $450.–). It follows Vol. B1 (1953 Compounds of Sulfur with Hydrogen and Oxygen) and B2 (1960 Oxacids of Sulfur), and opens with a continuation of the report on aqueous solutions of $SO_2$ (400 pp.), which was started but not completed in Vol. B2. This is followed by a discussion of compounds of sulfur with nitrogen (167 pp.) and with halogens (178 pp.), dealing with all the sulfur compounds to be treated in the sulfur volume in accordance with the Gmelin "last-place" principle. All other compounds are discussed under higher system numbers.

The comprehensive report on the system $SO_2/H_2O$, which occupies more than half of Vol. B3, is divided into two chapters: the solubility of $SO_2$ in water and aqueous solutions (163 pp.), and the oxidation of aqueous solutions of $SO_2$ and sulfites (237 pp.).

The remarks on the solubility of $SO_2$ begin with data on the rates of its absorption in and desorption from water. This is followed by expert discussions on the p–t–x space diagram (pressure p, temperature t, concentration x), on the problems and methods associated with the determination of solubility (purity of starting material, preparation of solutions, equilibration, determination of total pressure, calculation of the partial pressure of $SO_2$, determination of the $SO_2$ concen-

tration), and finally on the numerous investigations concerning the solubility of $SO_2$ in water reported in the literature, mainly arising from technical problems (*e.g.* purification of waste gas). To illustrate the results in the form of comparative graphical summaries, the literature values (recalculated where necessary to bring them into alignment) are presented in tables and diagrams as two-dimensional sections of the p–t–x space diagram (dependence of one variable on a second when the third is kept constant), *i.e.* in the form of x–p isotherms (t constant), x–t isobars (p constant), and p–t isopleths (x constant). The results are also collected in a lucid graphical layout into eight large foldout tables, which are arranged from different points of view, which testify to the admirable consciousness of the abstractor, and which will undoubtedly be gratefully received by industry. The chapter closes with discussions on the validity of Henry's law applied to the solution of $SO_2$ in water, since this validity is upset at low temperatures and low $SO_2$ concentrations by the simultaneous formation of $H_2SO_3$. The experimental data are again illustrated by tables and graphs, including a foldout table. A similar treatment is then given for the solubility of $SO_2$ in aqueous solutions of acids (sulfuric acid, acetic acid, thiocyanic acid), salts (halides, thiocyanates, sulfates, nitrates, hydrosulfites), and technical absorbents, touching problems which are important for the removal of $SO_2$ from waste gases. The relationships between solubility and the constitution of the solutions is also discussed in this connection. The chapter on the oxidation of aqueous $SO_2$ and sulfite solutions begins with oxidation by oxygen (also in the presence of catalysts and inhibitors). This part is divided into sections on the homogeneous oxidation of aqueous $SO_2$ and sulfite solutions, the heterogeneous oxidation, and the theory of the oxidation reaction. All related questions are of vast importance, both scientifically and technically, and are therefore justifiably discussed in detail. Thus, the oxidation of sulfite, which is particularly sensitive toward many catalysts and inhibitors at pH 8–10, *i.e.* in the region of exclusive existence of $SO_3^{2-}$, has been widely studied as a model reaction for better understanding of the negative catalysis. The action of sulfite as an inductor in induced oxidation reactions has contributed greatly to the explanation of induced oxidations and, as one of the first reactions to be recognized as a chain process in solution, it has been of great importance to the theory of these reactions. The technical importance can be appreciated on consideration of the catalytic production of $H_2SO_4$ or $(NH_4)_2SO_4$ from the $SO_2$ of flue gases or the removal of corrosive oxygen from boiler feed-water by means of sulfite. All these results obtained with these various aims in mind are dealt with in this chapter from a uniform point of view. The same applies to the subsequent discussion of the oxidation of aqueous $SO_2$ and sulfite solutions by ozone (with and without additives).

The chemistry of the compounds of sulfur with nitrogen has been considerably extended in recent years, so that for the sake of developing a complete picture, it was necessary to include, even if imcompletely, many results from post-1949 literature, contrary to the usual fixed deadline for literature (the end of 1949). This chapter deals first with the nitrides of sulfur [such as $(S_2N)_2$, $(S_2N)_x$, SN, $(SN)_2$, $(SN)_4$, $(SN)_x$], placing emphasis on the preparation, constitution, and properties of tetrasulfur tetranitride $(SN)_4$, which has been studied particularly thoroughly in the past few years. This is followed by the amides and imides of sulfur such as $S_7NH$, $S_6(NH)_2$, and $S_4(NH)_4$. Of the S–N–O compounds, which belong to very different classes according to their constitution, particular mention should be made of dinitrosyl disulfate $(NO)_2S_2O_7$, and of the S–N–O–H compounds, of sulfamic acid $HSO_3NH_2$, sulfurylamide $SO_2(NH_2)_2$, nitrosyl hydrogen sulfate $(NO)HSO_4$, the "blue acid" $(N_2O_2)HSO_4$, and the system $N_2O_5/SO_3/H_2O$ [1].

The chapter on the compounds of sulfur with halogens is almost entirely (about 94 %) devoted to the fluorine (51 pp.) and chlorine (116 pp.) compounds, whilst the bromine, iodine, and astatine compounds are confined to 11 pp. Owing to the various valence states of sulfur and the small atomic radius and high electronegativity of fluorine, there is a relatively large number of binary S–F compounds ($S_2F_2$, $SF_2$, $SF_4$, $S_2F_{10}$, $SF_6$), which have all been studied in detail and are therefore discussed at length. Among the S–F–O compounds, thionyl fluoride $SOF_2$, sulfuryl fluoride $SO_2F_2$, and fluorosulfuric acid $HSO_3F$ are treated in particular detail. The S–N–F, S–N–F–O, and S–N–F–O–H compounds are rather too briefly discussed, since the 16 compounds listed in the volume [2], *viz.* SNF, NSF, $S_3N_3F_3$, $S_4N_4F_4$, $NSF_3$, $SN_2F_2$, $S_3N_2F_2$, $SF_5NF_2$, $HNSOF_2$, $(NSOF)_n$, $OS(F)NH_2$, $H_2NSO_2F$, $F_2NOSO_2F$, $FSO_2NO$, $NOSO_3F$, and $NO_2SO_3F$, all became known after 1949, and the references quoted on the subject are very incomplete, owing to observance of the literature deadline (the end of 1949). Of the chlorine compounds of sulfur, particular mention should be made of the details on the systems $S/S_2Cl_2$ and $S_2Cl_2/Cl_2$, the binary chlorides $S_2Cl_2$, $SCl_2$, and $SCl_4$, and the S–O–Cl and S–O–Cl–H compounds $SOCl_2$, $SO_2Cl_2$, $S_2O_5Cl_2$, and $HSO_3Cl$.

The fact that Vol. B 3 of sulfur completes another System No. moves the reviewer to cast a brief backward glance over the achievements of the Gmelin editorial staff to date. It is now exactly 40 years since the publication of the first volume (Zinc, 1924) of the present 8th edition of "Gmelin." Since then, 52 of the projected 71 System Numbers have been completed. However, 8 of these volumes are now more than 30 years old, another 22 more than 20 years old, and 6 more than 10 years old; only 5 volumes are of recent date, and supplements to the remaining 11 have recently been published. Six System Numbers (O, Si, Al, Cr, Fe, Cu) are drawing to a close, two others (Hg, Rare Earths) have been started [3] and two (C,P) are in preparation, but the 9 others (Sn, Pb, V, Nb, Tl, U, Mn, Ag, Transuranium Elements) have not yet been started. As this list shows, the Gmelin editorial staff still has extensive important work to do, and it can only be hoped that, even if the outstanding System Numbers cannot be completed by the 50th anniversary of the 8th edition of "Gmelin", it might be possible, by increasing the staff, at least to make a start on them. However, there will then be scarcely a single chemist who has witnessed both the beginning and final completion of the 8th edition, either as a contributor or as a beneficiary.

# Fundamental Aspects of Diffusion Processes

BY PROF. DR. W. JOST

INSTITUT FÜR PHYSIKALISCHE CHEMIE DER UNIVERSITÄT GÖTTINGEN (GERMANY)

*A simple description of diffusion processes and a derivation of the general laws of diffusion are given. The distribution with time of particles according to a random-walk process is considered and compared with results derived from a differential equation. Diffusion coefficients for and examples of diffusion processes in various media (e.g. gases, solutions, solids, and high polymers) are given. "Uphill" diffusion, i.e. diffusion against the concentration gradient, is also discussed. In addition, diffusion in anisotropic systems, in systems consisting of more than one phase, and in multicomponent systems is treated.*

## I. Introduction

Diffusion is a process which, normally [*], leads to homogenization of a mixture. This process is easily understood in a qualitative way, if we treat it as a "random-walk" phenomenon in the molecular picture. A given molecule has, on the average, a definite kinetic energy equal to 3/2 kT (kT/2 per degree of freedom), where T is the absolute temperature, and k is Boltzmann's constant. The corresponding average velocity v is usually of the order of a few hundred meters per second for simple molecules, with such extremes as 1800 m/sec for the hydrogen molecule at room temperature and about 150 m/sec for the rather heavy molecule $UF_6$. A protein molecule of relative mole mass 1000000 would still have an average thermal velocity of 3 m/sec.

A molecule usually will not travel in one second the distance given by its speed multiplied by one second (except in extraterrestrial space), but only a much shorter distance, owing to the fact that its free path is limited by collisions. An oxygen molecule in air has a free path of roughly $10^{-5}$ cm, *i.e.* 1000 Å, which at a pressure of $10^{-5}$ atm (corresponding to a height of 100 km in the terrestrial atmosphere) would increase to 1 cm (cf. Figure 1, which applies for a pressure of 10 atm).

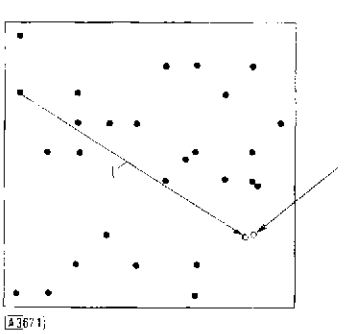

Fig. 1. Free path (ca. 90 Å) of oxygen molecules at 10 atm and room temperature (idealized molecule diameter ca. 3.0 Å; average intermolecular distance ca. 20 Å).

[*] The restriction refers to the following facts: we may have an originally homogeneous non-isothermal system of two components, and diffusion processes lead to a partial separation of the components. Instead of an equalization we may even have a very efficient separation of isotopes as applied in *Clusius'* separation tube, a multistage thermal diffusion column.

There are numerous examples of diffusion in solid phases where the presence of an unequally distributed third component may induce separation of the two main compenents without phase splitting. Similar phenomena may occur even in almost ideal gas mixtures [1–3]. Analogous phenomena are observed in liquids. In systems consisting of more than one phase, "uphill" diffusion, *i.e.* diffusion from lower to higher concentrations, may almost always be achieved if the solute is initially present in the solvent of lower dissolving power (*e.g.* iodine in water, with carbon tetrachloride as second solvent).

These cases, when properly formulated, do not lead to contradictions. The simple diffusion laws hold for binary mixtures at constant temperature and pressure and not too far from ideal behavior, *i.e.* especially in dilute solutions. A phase is defined by *Gibbs* as a homogeneous region of matter. Here we shall treat a region with continuously changing concentration as one phase, which in thermodynamics is objectionable.

## II. Diffusion and State of Aggregation

It is a basic problem of diffusion theory to find the average distance which such a particle travels in unit time when delayed and forced to make detours by the many collisions suffered in one second (*e.g.* ca. $3\times10^9$ collisions per second at atmospheric pressure).

The phenomena are largely analogous, irrespective of the state of aggregation, but the free paths available differ widely. In a liquid, the free path is usually below the dimensions of the molecule, while for oxygen in the atmosphere, it is almost 1000 times the molecular dimensions and 30 times the average distance between the molecules at atmospheric pressure.

In liquids and solids (to which high polymers are closely related), there is a fundamental difference compared with gases. A gas molecule almost always moves freely, except during the very short time intervals during collisions. For particles in liquids and solids, the opposite is true: they never move freely, except during short intervals of favorable geometric and energetic constellations. In a solid, each particle is restricted to a definite lattice site about which it is oscillating. Its center of gravity usually does not undergo any average displacement. However, owing to a process to be discussed later, it may happen that a neighboring lattice site is empty. If in addition to this favorable geometric constellation the particle has enough energy to overcome any energetic barriers, then it can move over just one lattice distance into a new equilibrium position (cf. Fig. 2). Instead of the presence of an empty site next to a mobile

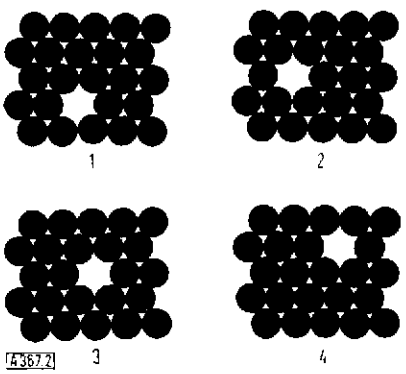

Fig. 2. Close-packed plane crystal lattice with a vacancy migrating by successive displacements of neighboring particles ($1 \rightarrow 2 \rightarrow 3 \rightarrow 4$)

particle, the following process, which also creates vacancies, may be considered (this is, however, not the only possible process): A lattice particle may accumulate sufficient energy by fluctuations to leave its lattice site and move into an interstitial site (cf. Fig. 3) [*]. Thus a vacancy and a mobile interstitial site are created (*I. Frenkel*, 1926). At equilibrium, there is always a definite fraction of lattice defects present in solids; they are responsible for any diffusion (and, if the particles are charged, for the ionic conduction) occurring in the solids. Unoccupied lattice sites from

[*] According to usual concepts, the interstices may be "too small" to accommodate the particle. This means that sufficient energy must be supplied to make the transition possible.

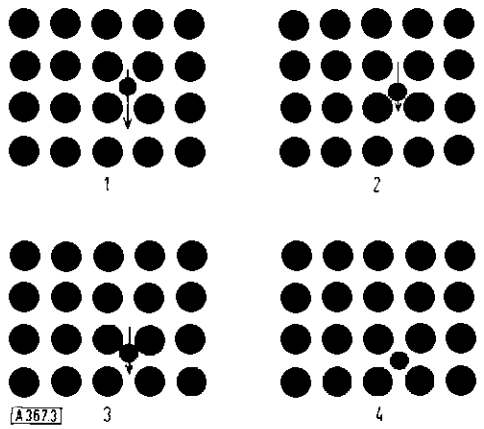

Fig. 3. Interstital particle migrating across a potential barrier ($1 \rightarrow 2 \rightarrow 3 \rightarrow 4$); energy maximum between steps 2 and 3 (maximum in the direction of movement; saddle point when increase to the sides is taken into consideration).

suitable sources, *e.g.* surfaces or dislocations, can also diffuse into the interior of a crystal, or in other words, particles diffuse out of the lattice into unoccupied sites on surfaces or dislocations. The thermodynamic theory of lattice defects was developed by *W. Schottky* and *C. Wagner* in 1929; first quantitative calculations on the energies involved have been carried out by *Jost* since 1933, cf. [2]. The fraction of particles capable of surmounting an energy barrier of E cal/mole is given to a certain approximation by $\exp[-E/RT]$, *i.e.* by a Boltzmann factor. We may express this situation, somewhat arbitrarily, as follows: in a solid, a particle can move over a free path d (equal to its lattice distance) with an average speed $\bar{v}\cdot\exp[-E/RT]$, *i.e.* a very small average speed. During most of its oscillations (*e.g.* roughly $10^{13}$ per sec), the particle does not move away from its site at all, but in the fraction of oscillations given by the Boltzmann exponential, it moves with speed $\bar{v}$. In other words, the particle moves once over the distance d in an average time $\tau$ of roughly $d/(\bar{v}\cdot\exp[-E/RT])$.

The picture for a liquid is similar, though less precise. In liquids, the particle is not fixed to a definite lattice site, because a liquid has a much less rigid structure than a crystal. However, if we look at the surroundings of a given particle (Fig. 4.1), there is still something like a "short-distance" order resembling somewhat the

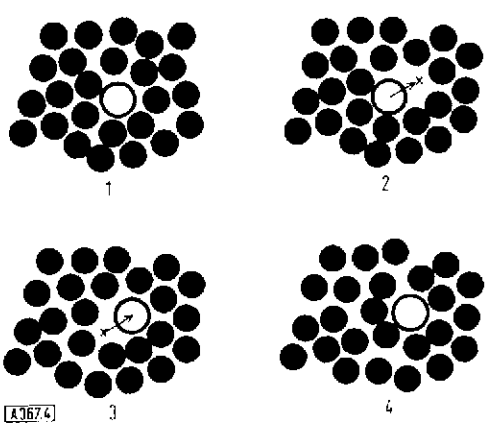

Fig. 4. Migration ($1 \rightarrow 2 \rightarrow 3 \rightarrow 4$) of a particle dissolved in a liquid by displacement of neighboring particles.

arrangement in a crystal, but the nearest neighbors are slightly farther away from the central atom, and are less ordered. This has been described as the "cage" model of a liquid. The central atom moves in a "cage" of neighboring atoms, without changing its average position over a certain period of time (Fig. 4.2). Then, very similar to a true crystal, a constellation of the cage may arise (Fig. 4.3) which provides a new equilibrium position for the central atom. This position, unlike that in the crystal, may be less than a lattice distance away from the original position, and the energy barrier obstructing the movement will accordingly be considerably smaller than that in the crystal (*e.g.* in Fig. 6 but not in Fig. 5).

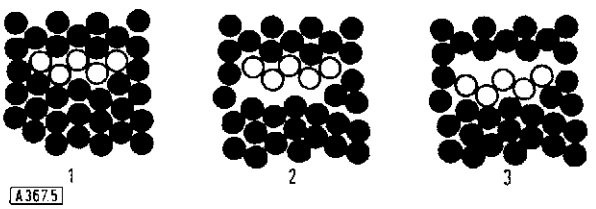

Fig. 5. Migration (1 → 2 → 3) of a rigid molecule in a liquid. This is an unfavorable and hence improbable mechanism.

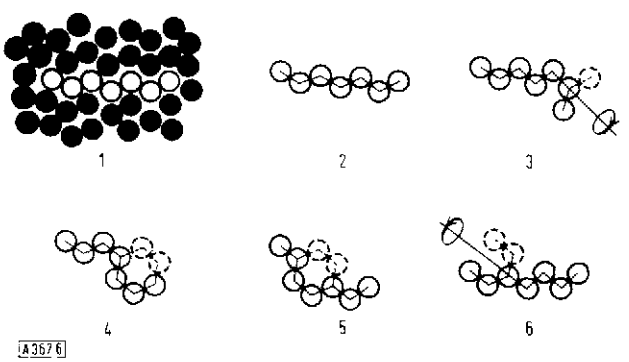

Fig. 6. Diffusion (migration) of a large, non-rigid molecule requiring less free space (compared to the rigid molecule in Figure 5).

The resulting expression for $\tau$ or $\bar{v}$ will be very similar in form, but will give a much higher average mobility than in a crystal [*].

## III. Models for the Diffusion of Single Mobile Particles

In the following, using a simplified picture, we shall trace the path of a single particle, irrespective of the underlying model. We shall introduce some simplifications compared to the process occurring in nature, but these will not affect essentially the results to be derived.

### 1. With a Discontinuous Source

In Figures 7 and 8, the motion of a single particle is represented beginning with the time t = 0. The abscissa gives the displacement of the particle, +1, +2l, *etc.* to

[*] There are exceptional cases where the mobility in a crystal is as high as in solution, *e.g.* that of protons in palladium or of the cations in α-CuI, α-CuBr, and α-AgI. The ionic conductance of α-AgI and of α-CuBr near the melting point is even higher than that of the melt.

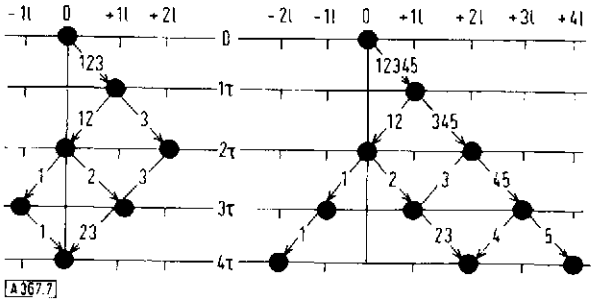

Fig. 7. Model of random walk: examples for the motion of 3 particles (1, 2, 3) moving discontinuously from t = 0 to t = 4 τ [left], and of 5 particles (1, 2, 3, 4, 5) [right].

the right of x = 0, its position at t = 0, and −1, −2l, *etc.* to the left of x = 0. The ordinate is time with the values τ, 2τ, *etc.* Since any displacement by x = ± l during time τ is of equal probability, the particle after time t − τ, may

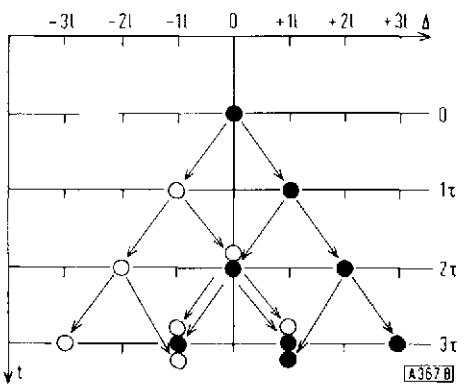

Fig. 8. Distribution of particles moving at random (cf. Figure 7).

be at ± 1, after t = 2τ at 0, ± 2l, *etc.* For t = τ, the positions ± l can be reached in one way each, and for t = 2τ there is one possibility for positions ± 2l, but two possibilities for x = 0, *etc.*

In the second column of Table 1, the number of possibilities n is listed for t = 0τ, 1τ, *etc.* in accordance with Figure 8; the next column gives the possible displacements Δ; Column 4 gives the sum of the squared displacements $\Sigma\Delta^2$; every displacement has been counted separately, *i.e.* for t = 3τ once the displacements ± 3l, three times the displacements ± l, thus altogether 2×4 = 8 displacements. Column 5 contains the sum of all the squared displacements divided by the number n of displacements.

Table 1. Mean square displacement $\overline{\Delta^2}$ for random walk as a function of the diffusion time.

| t | n | Δ | $\Sigma\Delta^2$ | $\frac{1}{n}\Sigma\Delta^2 = t \cdot l^2/\tau = \overline{\Delta^2}$ |
|---|---|---|---|---|
| 0 τ | 1 | 0 | 0 | 0 |
| 1 τ | 2×1 | ± 1 l | 2 l² | l² |
| 2 τ | 2×2 | 0 ; ± 2 l | 8 l² | 2 l² |
| 3 τ | 2×4 | ± l, ± 3 l | 24 l² | 3 l² |

Thus, from this simple model we obtain empirically the relation for the "mean square" displacement

$$\overline{\Delta^2} = \frac{1}{n}\Sigma\Delta^2 = t\,\frac{l^2}{\tau},$$

*i.e.* $\overline{\Delta^2}$ is proportional to the time.

If we set

$$\frac{l^2}{2\tau} = D,$$

and call this magnitude – of dimension [length]$^2$·[time]$^{-1}$ – a diffusion coefficient, then we arrive at the relationship

$$\overline{\Delta^2} = 2Dt,$$

an expression which was first derived from another starting point by *Einstein* in 1905.

In diffusion experiments, we do not observe the mean displacement of a single particle (as we actually can do with Brownian movement), but instead the concentration distribution at a time t, starting from a given initial distribution at t = 0. The mean behavior in the above example should approach the concentration distribution given by a differential equation when t and x are sufficiently large. This differential equation is for the "one-dimensional" case, *i.e.* diffusion in the ±x direction only, in a vessel of constant cross-section in a plane perpendicular to x, for the sake of simplicity assumed to have an area of 1 cm$^2$:

$$(1) \qquad \partial c/\partial t = D\,\partial^2 c/\partial x^2 .$$

Equation (1) is a linear partial differential equation, which for the initial conditions corresponding to the above example (amount s of substance at x = 0 at the time t = 0) and for an infinite system (*i.e.* no boundary conditions for x) is solved by

$$(2) \qquad c = \frac{s}{2\sqrt{\pi\, Dt}} \cdot \exp[-x^2/4Dt]$$

In Figures 9–11, the concentration distribution given by Equation (2) is compared with that derived from the former model for 256 particles (= s) at x = 0 for t = 0. In Figure 9, a diffusion curve is shown that has been calculated according to Equations (1) and (2), assuming that in an infinite cylinder of 1 cm$^2$ cross-sectional area the total amount of substance s (here set equal to 256)

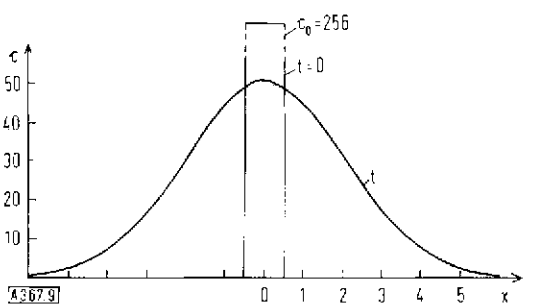

Fig. 9. Concentration distribution of 256 particles according to Equation (2) for:
a) D = 2 × 10$^5$ cm$^2$/sec; t = 10$^{-5}$ sec;
b) D = 0.7 cm$^2$/sec; t = 3 sec ($H_2$—$O_2$);
c) D = 0.6 × 10$^{-5}$ cm$^2$/sec; t = 3 × 10$^5$ sec;
d) D = 5 × 10$^{-8}$ cm$^2$/sec; t = 4 × 10$^7$ sec.

had been present at x = 0 at time t = 0. The curve denoted by t would result for thermal neutrons in graphite after $10^{-5}$ sec, for interdiffusing hydrogen and oxygen after 3 sec, for a low molar-mass compound dissolved in water, or for Cu ions diffusing in solid α-AgI above 147 °C (approximately 400 °C below its melting point) after about 3.5 days, and for protein molecules diffusing in water after a time of the order of one year.

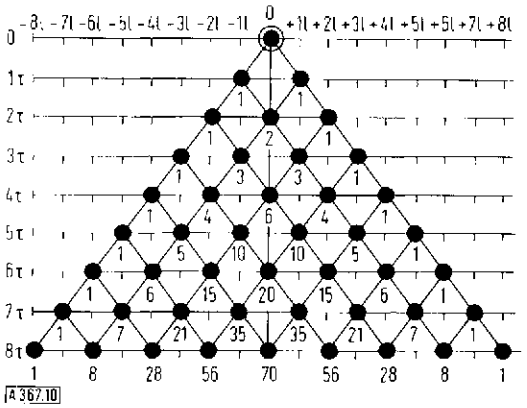

Fig. 10. Most probable distribution for 256 particles starting from x = 0 at time t = 0, up to t = 8 τ (last line).

In Figure 10 we show the distribution of particles under the original assumption of random walk, if at t = 0 we had 256 particles at x = 0 and they were moving by random-walk processes over distances ± l for t = τ. Thus for t = τ, with equal probabilities for ±l, we would have 128 particles both for x = l and x = −l. For t = 2τ, there would be 128 particles at x = 0 and 64 particles at both x = 2l an x = −2l, *etc.* Finally, at t = 8τ, we should have the distribution indicated in Figure 10: *viz.* 70 particles at x = 0, 56 particles eacn at x = ±2l, 28 particles each at x = ±4l, 8 particles each at x = ±6l, and 1 particle each at x = ±8l.

This distribution, of course, is a spezilization again, for we assume that the 256 particles move according to the maximum probability. Actually, other (especially asymmetric) distributions will occur in addition to the most probable distribution, but the average of many experiments will approach the distribution of Fig. 10. In Fig. 11 discontinuos distributions are shown for t = 0, τ, 2τ, etc. A comparison with the corresponding continuous distributions is possible only, if we compare corresponding areas under the curve, as is done in Fig. 11. It is seen that, except for t = 0 and x = 0, there is no exact agreement between the two sets of diagrams. The agreement, however, is as close as one might reasonably expect, and for t = 8τ is already rather good.

### 2. With Several Discontinuous Sources

From the preceding we have some idea of the depth of penetration Δ of diffusing particles whose mean square ($\overline{\Delta^2}$) equals 2Dt. Normally we do not have a discontinuous source at x = 0 but a certain concentration distribution over a finite distance in x. How this affects the result will again be easily seen. Figure 12 shows an "initial distribution" corresponding to four "instantaneous sources" of strengths 2s at x = ±h/4 and x = ±3h/4. We consider this a certain approximation

towards a homogeneous distribution of concentration $c_0$ between $x = -h$ and $x = +h$; naturally a better approximation is obtained by assuming twice the number of

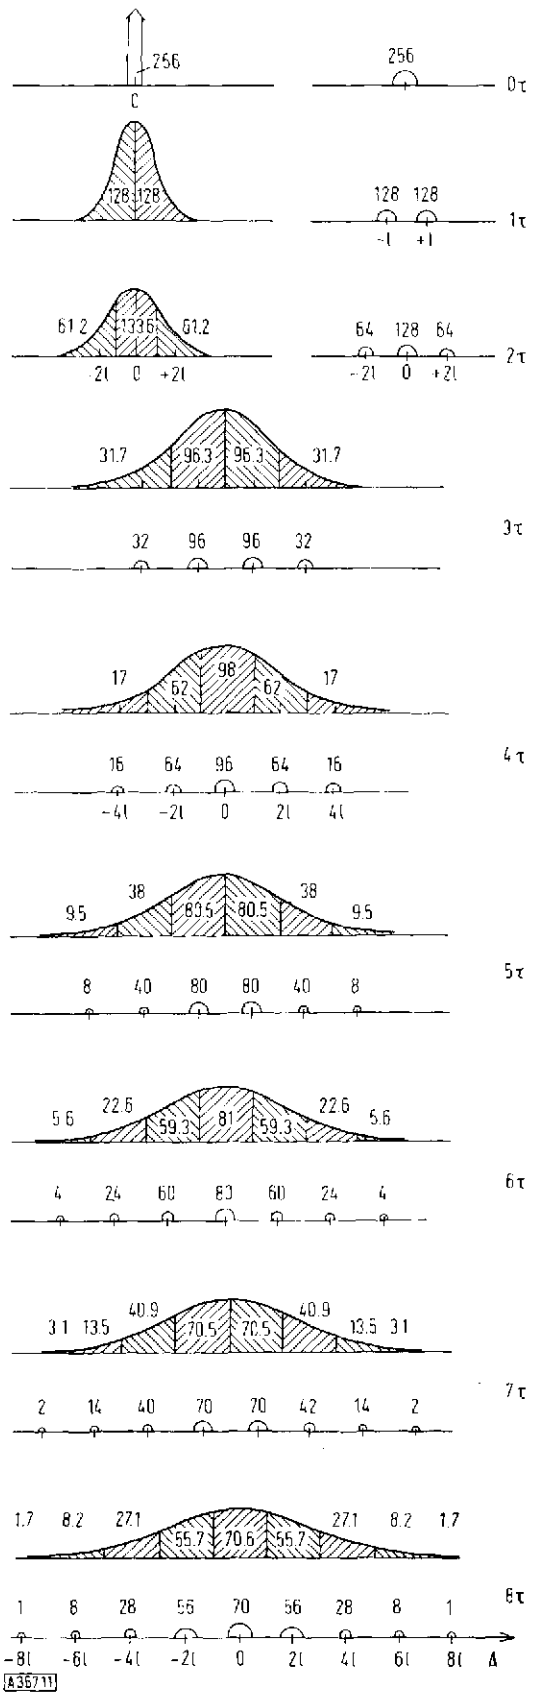

Fig. 11. Distribution of 256 particles, starting from $x = 0$ at time $t = 0$ and after times $\tau$, $2\tau$, ..... $8\tau$ according to the molecular model (cf. Fig. 10) [right or below], and according to Equation (2) [left or above].

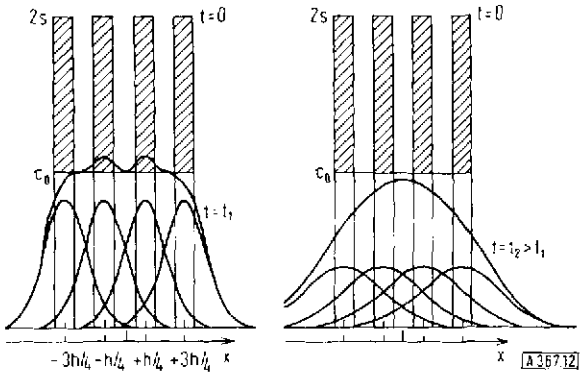

Fig. 12. Approximation of a continuous distribution by superposition of discontinuous distributions from four sources at $-3h/4$, $-h/4$, $+h/4$, $+3h/4$ at time $t = 0$ (above) and for two other times $t_2 > t_1 > 0$ (below).

sources of half the above strength and at half the above spacing, *etc.*

We claim that the concentration (particle) distribution resulting from superposition of these sources is obtained simply by superposition of the distributions arising from the individual sources. In the particle picture, this follows immediately, because the particles are considered to move independently of each other. In the picture of the continuous concentration distribution it is a consequence of the linearity of the underlying diffusion equation [Equation (1)]. In the upper part of Figure 12, the concentration (particle) distribution for $t = 0$ is indicated, and underneath the individual concentration distributions resulting from diffusion from the original sources for a time $t = t_1 > 0$ and for a later time $t_2 > t_1$ are shown together with the superposition obtained.

Analytically, the following expression would be obtained for the limiting continuous distribution with $c = c_0$ for $-h < x < +h$ and $c = 0$ for $|x| > h$ at $t = 0$:

$$(3)\quad c = c_0\left[\operatorname{erf}\frac{(h+x)}{2\sqrt{Dt}} + \operatorname{erf}\frac{(h-x)}{2\sqrt{Dt}}\right],$$

where erf is the Gauss error integral or error function [*]

$$(4)\quad \operatorname{erf}(\xi) = \frac{2}{\sqrt{\pi}}\int_0^{\xi} e^{-\eta^2}\,d\eta\,.$$

Examples for Equation (4) are contained in Figure 13.

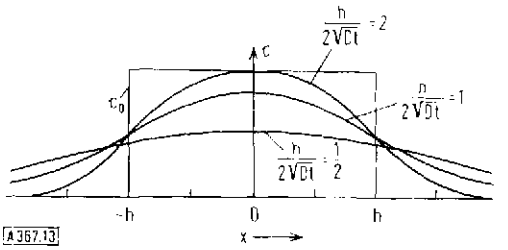

Fig. 13. Concentration distributions according to Equation (3); rectangular distribution at $t = 0$ (increasing argument $h/2\sqrt{Dt}$ corresponds to decreasing time).

[*] Values for this function are to be found in tables, so that it is very easy to apply, cf. [2].

## IV. Special Types of Diffusion

### 1. Diffusion Resulting in Directed Flow

So far we have considered only examples involving complete symmetry with respect to $x = 0$, *i.e.* no mean displacement of the center of gravity of the particles or of the diffusing substance. Normally, however, we have a preferential direction of diffusion.

The question is then how can this directed flow result if forward and backward movements of a particle are equally probable? It should be noted that the distributions obtained either by random walk or from the diffusion equation were symmetrical with respect to $x = 0$, *i.e.* all distributions found are even functions of x and there is no resulting mean displacement of a particle. If we cut our system in two at $x = 0$, leaving half the particles to the left and half to the right, then nothing would be changed. Consequently, the distributions for $x > 0$ are maintained, if half the original concentration is given at $t = 0$ and an impermeable boundary is introduced at $x = 0$. An illustration of the influence of the wall on the random-walk model is given in Figure 14. Here one possible path for a particle is shown (full circles) lying totally to the right of $x = 0$. Instead of the last two steps, we might just as well have a path to the left (open circles).

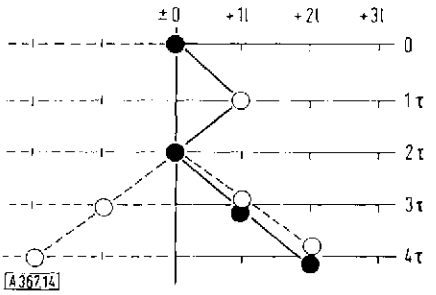

Fig. 14. Random motion of a particle near $x = 0$, with and without a separating wall. (At $x = \pm l$ and $t = \tau$ there should be a full circle).

Owing to the wall at $x = 0$, we must assume that this path is "reflected" at $x = 0$, giving the path to the right (open circles). However we had concluded that the introduction of the wall does not change anything. This is to be understood as follows: In the original model, without the wall, there was another path, the mirror image of the full circles. Up to $t = 2\tau$ this path is situated to the left of $x = 0$, and then corresponds to the open circles at $x > 0$. Cutting the distribution at $x = 0$ actually does not change anything, because the new reflected path is identical with another path which was initially present but whose first half has been cut away.

The same conclusion can be reached using the differential equation (1). This equation is a consequence of Equation (5), the equation for the diffusion flux in the $-x$ direction

$$(5) \quad J = -D\partial c/\partial x ,$$

This is to be understood in the following way: The diffusion flux J, *i.e.* the amount of substance crossing unit area perpendicular to the x direction in unit time in the $+x$ direction, is proportional to the negative of the concentration gradient $\partial c/\partial x$; the factor of proportionality is the diffusion coefficient D identical with the value defined earlier. The concentration is given as the amount of substance per unit volume. The unit chosen for the amount of substance is irrelevant but must of course be the same in J and in c. The fact that diffusion normally leads to an equalization is expressed by the fact that J is set proportional to $-\partial c/\partial x$; this implies a diffusion flux from high to low concentrations.

Having qualitatively understood the meaning of Equation (5), we can see how the "boundary condition" at $x = 0$ for an impermeable wall is to be formulated. An impermeable wall means vanishing diffusion flux, and for non-vanishing D this vanishes only for $\partial c/\partial x = 0$ at $x = 0$. This, however, is automatically obtained by cutting the previous distributions at $x = 0$ where, on account of symmetry, the tangent is horizontal.

In the random-walk picture, unidirectional flow can be understood as follows. If we start with a distribution such as that shown in Figure 13, *i.e.* $c = c_0 = \text{constant}$ for $-h < x < +h$, which we assume cut at $x = 0$, then for $t = 0$ and $x < h$, the particles present will move with equal probability in the $+x$ or $-x$ directions. Some therefore cross the plane at $x = h$, thus giving rise to a flux in the $+x$ direction. Since at time $t = 0$ there are no particles present at $x > h$, no flux in the opposite direction can arise. For $t > 0$, there are particles present at $x > h$, but their concentration is smaller than that for $x < h$. Thus, there will be a preferential flow in the $+x$ direction. With increasing time, the concentration differences, $\partial c/\partial x$ and the diffusion flux J will diminish. Of course it must not be forgotten that at the boundary $x = 0$ all particles moving to the left are reflected; consequently, near $x = 0$, only a flux to the right is possible. Thus random walk leads to a complete qualitative understanding of diffusion phenomena.

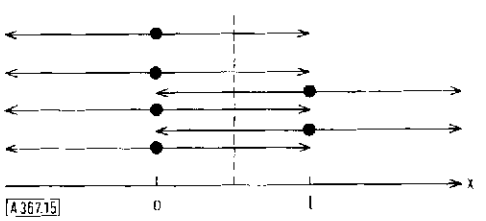

Fig. 15. Diffusion flux in the molecular model with more particles crossing the plane at $x = 1/2$ towards the right than towards the left.

Now we must consider the question of the "stationary flux". In order to obtain the "flux" of particles, we consider Figure 15. The particles at $x = 0$ have equal probability for moving by $\pm 1$ in time $\tau$. If their number ("concentration") is $n_0$, then we expect a flux $J_+$ in the $+x$ direction (number of moving particles times velocity):

$$(6) \quad J_+ = n_0 \, l/2\tau$$

$l/\tau$ being their average velocity in the $+x$ direction. Correspondingly, of $n_1$ particles at $x = 1$, there will move to the left (the minus sign indicating the direction):

$$(7) \quad J_- = -n_1 \, l/2\tau .$$

Both together give a resulting flux J in the +x direction, across a reference plane of unit area at x = 1/2:

$$(8) \quad J = J_+ + J_- = -(n_1 - n_0)1/2\tau = -\frac{(n_1 - n_0)}{1} \frac{l^2}{2\tau}.$$

If we denote the difference in the concentration of particles over the distance $\Delta x = 1$ by $\Delta c = n_1 - n_0$, we obtain

$$(9) \quad J = -(\Delta c/\Delta x) D,$$

using the definition of D from p. 716. In the limiting case we obtain

$$(10) \quad J = -\lim_{\Delta x \to 0} \frac{\Delta c}{\Delta x} D = -D\, \partial c/\partial x,$$

as equation for the diffusion flux (usually called Fick's First Law). We calculate the diffusion flux for a simple hypothetical example.

We assume a membrane 0.01 mm thick with the properties of water. We wish to find the amount of oxygen diffusing through this wall if at one side (I) a partial pressure of 0.2 atm is maintained, and 0.1 atm at the other (II). In the stationary state, we may replace $\partial c/\partial x$ by $\Delta c/\Delta x$, where $\Delta x$ is the thickness of the membrane and $\Delta c$ is the difference in concentration $c_2 - c_1$ for equilibrium conditions at the interfaces. If the solubility coefficient be $\alpha$, we have

$c_1 = \alpha p_I$, $c_2 = \alpha p_{II}$

and therefore

$J = -D\, \partial c/\partial x = -\alpha D\, (p_2 - p_1)/\Delta x.$

If $\alpha = 0.03$ cm³/atm/cm³ at S.T.P. and $D = 2 \times 10^{-5}$ cm²/sec,

we obtain

$J = -0.03 \times 2 \times 10^{-5}\, (0.1 - 0.2) \times 10^3 = 0.06 \times 10^{-3}$ cm/sec,

*i.e.* oxygen, referred to its partial pressure in air, would flow with a linear speed $v = 0.3\ 10^{-3}$ cm/sec through the membrane. Assuming a surface area comparable with that of the human lung (ca. $10^6$ cm²), this would correspond to an air volume of 300 cm³ passing per second; this is sufficient to account for all observed phenomena.

Of course, for the absorption coefficient any other definition could be taken instead of the one chosen above: cm³ of gas absorbed per cm³ of liquid, at atmospheric pressure. In problems of permeation one normally finds, as in the above example, a permeability coefficient equal to the product $\alpha \cdot D$.

## 2. Experimental Examples

In order to give some quantitative information about diffusion flux and concentration equalization, numerical values for diffusion coefficients under widely varied conditions are summarized in Tables 2a–2d. The diffusion coefficients for gases at room temperature and atmospheric pressure lie between 0.1 and 1 cm²/sec, those for solutions and liquids of moderate molar mass between $10^{-5}$ and $10^{-6}$ cm²/sec. Under favorable conditions, solids have diffusion coefficients of the same order of magnitude as liquid solutions (*e.g.* the cations in the $\alpha$-phases of AgI, CuI, CuBr, $Ag_2S$, $Cu_2S$, $Ag_2Se$, *etc.*). The diffusion coefficient of silver ions in solid silver bromide at room temperature is not below $10^{-16}$ cm²/sec, a rather small value. The quantities of interest for purposes of orientation are:

a) The time for an average mean displacement (roughly equal to the square root of the mean square displacement), which is comparable with the time necessary for marked equalization of concentration differences over the same distance.

b) The magnitude of the diffusion flux in a quasi-stationary or stationary state, *e.g.* the rate of transport through an artificial membrane or a cell wall.

Let us start with an extreme example, namely that of solid silver bromide. Its lattice distance is roughly $4 \times 10^{-8}$ cm. The time necessary for the corresponding square displacement is roughly

$$\tau < (4 \times 10^{-8})^2/2 \times 10^{-16} = 8 \text{ sec},$$

*i.e.* a silver ion in solid silver bromide changes its site every few seconds. For many this may be a rather unexpected result.

The time necessary for a penetration of one lattice distance in a solid is roughly the same as for the equalization of concentration differences in a gas over a distance of 1 cm. A penetration of 0.1 mm within gases is obtained in less than a millisecond.

The diffusion coefficient of sucrose in water at room temperature is roughly $5 \times 10^{-6}$ cm²/sec. In Table 3, some values for the diffusion of sucrose in water are given. Thus it takes about a day to penetrate a 1 cm layer, while an equalization of concentrations over 1 $\mu$ takes only a millisecond.

The diffusion coefficients of oxygen, nitrogen, and carbon dioxide in water do not differ widely, and are

Table 2a. Diffusion coefficients [$\times 10^5$ cm²/sec] in water at 18 °C.

| NaCl | KCl | Methanol | Glycerol | Phenol | Urea | Glucose | $H_2$ | $O_2$ | $N_2$ | $CO_2$ |
|---|---|---|---|---|---|---|---|---|---|---|
| 1.35 | 1.7 | 1.1 | 0.8 | 0.8 | 1.1 | 0.6 | 3.6 | 2.0 | 1.6 | 1.5 |

Table 2b. Diffusion coefficients [cm²/sec] for interdiffusion of gases at S.T.P.

| $p$-$H_2$/$o$-$H_2$ | $H_2/O_2$ | $O_2/N_2$ | $O_2/CO_2$ |
|---|---|---|---|
| 1.29 | 0.70 | 0.18 | 0.14 |

Table 2c. Diffusion coefficients [$\times 10^5$ cm²/sec] of iodine in various solvents at 20 °C.

| n-Heptane | $CS_2$ | $CCl_4$ | $CH_3OH$ | $H_2O$ |
|---|---|---|---|---|
| 2.4 | 2.7 | 1.2 | 1.6 | 0.5 |

Table 2d. Diffusion coefficients [$\times 10^7$ cm²/sec] of some high polymers at 20 °C.

| Edestine/water | Tobacco mosaic virus/water | Soluble starch/water | Cellulose acetate/acetone |
|---|---|---|---|
| 3.2 | 0.5 | 11.5 | 5.4 |

Table 3. Diffusion times t for various depths of penetration (sucrose in water at room temperature).

| x [cm] | 1 | 0.1 | 0.01 | 0.001 | 0.0001 |
|---|---|---|---|---|---|
| t [sec] | $10^5$ | $10^3$ | 10 | $10^{-1}$ | $10^{-3}$ |

roughly four times those of sucrose. The rates of diffusion for small molecules in muscle and other tissues are comparable, though smaller than those in water. Thus, the above figures are adequate for estimates even in this case.

### 3. Three-Dimensional Case

Here it might only be mentioned that for the three-dimensional case Equation (10) should be replaced by Equation (11):

$$\text{(11)} \quad \mathfrak{J} = -D \operatorname{grad} c$$

which, specialized for Cartesian coordinates, gives for the three components of the flux vector

$$\text{(12)} \quad \begin{aligned} J_x &= -D\, \partial c/\partial x \\ J_y &= -D\, \partial c/\partial y \\ J_z &= -D\, \partial c/\partial z \end{aligned}$$

For non-isotropic systems, the diffusion coefficient would depend on direction, giving for the special case of the coordinate axes coinciding with the main axes of the diffusion tensor $\mathbf{D}$

$$\text{(13)} \quad \mathfrak{J} = -\mathbf{D} \operatorname{grad} c$$

$$\text{(14)} \quad \begin{aligned} J_x &= -D_x\, \partial c/\partial x \\ J_y &= -D_y\, \partial c/\partial y \\ J_z &= -D_z\, \partial c/\partial z \end{aligned}$$

with three main diffusion coefficients, two of which may be equal, *e.g.* in a crystal of hexagonal symmetry; in a crystal of cubic symmetry, all three coefficients are equal. Strongly direction-dependent diffusion coefficients are observed for the hexagonal crystals of zinc or bismuth. Only one diffusion coefficient occurs in each term of Equation (14) because of *Onsager*'s reciprocity relations, [2, 4, 5], but these cannot be discussed here.

### 4. Diffusion in Multicomponent Mixtures

Less simple is the case of unidimensional diffusion in a multicomponent mixture. For three components 1, 2, and 3, we write the "phenomenological relations":

$$\text{(15)} \quad \begin{aligned} J_1 &= -D_{11}\, \partial c_1/\partial x - D_{12}\, \partial c_2/\partial x \quad D_{13}\, \partial c_3/\partial x \\ J_2 &= -D_{21}\, \partial c_1/\partial x - D_{22}\, \partial c_2/\partial x - D_{23}\, \partial c_3/\partial x \\ J_3 &= -D_{31}\, \partial c_1/\partial x - D_{32}\, \partial c_2/\partial x - D_{33}\, \partial c_3/\partial x \end{aligned}$$

In Equations (15), in contrast to Equations (14), coupling coefficients $D_{ik}$ ($i \neq k$) appear as off-diagonal terms, although there are less than 9 independent coefficients. When we consider that the concentrations and consequently also the fluxes in a ternary system are not independent [*], and apply the Onsager reciprocity relations [**], we can show that of the nine coefficients in Equations (15), only three independent coefficients remain ($= 3\times 2/2$), or in general for an n-component system, there are $n(n-1)/2$ independent coefficients. Equations (15) do not yet contain the most general formulation possible.

We consider a special example, *viz.* the diffusion in a ternary gas mixture. *Hellund* [1] filled a diffusion tube fitted with a shutter in the middle, as follows. The lower half contained 570 mm Hg of both methane and carbon dioxide, while the upper half contained equal amounts of hydrogen and carbon dioxide. Both halves had a total pressure of 1140 mm Hg at 0 °C. The shutter was opened, and the partial pressure of $CO_2$ in the upper half rose by 68.2 mm. Thus, owing to the concentration gradients of $H_2$ and $CH_4$ and their interdiffusion, induced diffusion occurred with the $CO_2$ although originally it had no concentration gradient. This effect is sometimes called osmotic diffusion and is formally contained in Equations (15) as a result of the off-diagonal "coupling terms".

In the following, an attempt is made to understand this from a not purely formal point of view. When in the above example, the methane and hydrogen start to diffuse, each would move freely if it were not slowed down by the presence of the other component. Here the carbon dioxide causes resistance to the motion of the other two components, irrespective of the presence of a concentration gradient. Consequently, there is a frictional force between each pair of species, if only they are in relative motion.

According to the principle of action and reaction, the forces between two species i and k (referred to a volume element or to unit volume) will be of equal amount but of opposite sign, *i.e.*

$$\mathfrak{F}_{ik} = -\mathfrak{F}_{ki}.$$

These forces will naturally set the carbon dioxide in motion, even without a concentration gradient, except in the degenerate case where the frictional forces between $CO_2$ and $H_2$ are equal but of opposite sign to those between $CO_2$ and $CH_4$.

Thus we see that there may be considerable coupling forces in a ternary system, even for ideal gases. The preceding argument is essentially equivalent to the formal treatment by *Lamm* of diffusion in multicomponent systems [6]. We follow here a presentation given by *Ljunggren* [7].

If the total force acting on particle i ($i = 1, 2, 3$) is $\mathfrak{F}_i$, and if $N_i$ is the number of particles i per unit of volume, then

$$\text{(16)} \quad N_i \mathfrak{F}_i = -\sum_j{}' \Phi_{ij} (\bar{v}_i - \bar{v}_j), \quad i \neq j.$$

It is reasonable to set the frictional force between particles i and j proportional to the mean relative speed

[4] *I. Prigogine:* Etude de thermodynamique des Phenomenes irreversibles. Dunod, Paris-Liege 1947; Introduction to Thermodynamics of Irreversible Processes. Ch. Thomas, Springfield, Ill. 1955.

[5] *S. R. de Groot:* Thermodynamics of Irreversible Processes. North Holland Publishing Comp. Amsterdam 1951.

[*] Accordingly, in a binary system, there is only one coefficient of interdiffusion.

[**] Unfortunately, in the above formulation, these are not of the simple form $D_{ik} = D_{ki}$.

[6] *O. Lamm*, J. physic. Colloid Chem. *51*, 1063 (1947).

[7] *S. Ljunggren* in *J. W. Williams:* Ultracentrifugal Analysis in Theory and Experiment. Academic Press, New York 1963, pp. 29 et seq.

of the particles, $\Phi_{ij}$ being a factor of proportionality [*]. The choice of signs in Equation (16) is reasonable, because the friction will tend to decrease the relative speed. $\bar{v}_i$ and $\bar{v}_j$ are the mean speeds [**] of the interdiffusing particles (the frame of reference here, of course, is irrelevant). Naturally $\Phi_{ij}$ must be equal to $\Phi_{ji}$. If there are no external forces and the system is in thermal equilibrium [†], the system must be in mechanical equilibrium [††], *i.e.* $\sum_i N_i \mathfrak{F}_i = 0$. We now write Equations (16) explicitly for a three-component mixture:

$$
\begin{aligned}
N_1\mathfrak{F}_1 &= \quad * \quad - \Phi_{12}(\bar{v}_1-\bar{v}_2) - \Phi_{13}(\bar{v}_1-\bar{v}_3) \\
N_2\mathfrak{F}_2 &= \Phi_{21}(\bar{v}_2-\bar{v}_1) \quad * \quad - \Phi_{23}(\bar{v}_2-\bar{v}_3) \\
N_3\mathfrak{F}_3 &= -\Phi_{31}(\bar{v}_3-\bar{v}_1) - \Phi_{32}(\bar{v}_3-\bar{v}_2) \quad *
\end{aligned}
\qquad (16')
$$

with

$$\Phi_{12} = \Phi_{21}\ ;\ \Phi_{13} = \Phi_{31}\ ;\ \Phi_{23} = \Phi_{32}\ .$$

Obviously, the sum of the forces equals zero, *i.e.* $\sum_i N_i \mathfrak{F}_i = 0$. If we now assume that component 3 is the carbon dioxide in the above example and is originally at rest, *i.e.* $\bar{v}_3 \equiv 0$, Equations (16′) are reduced to

$$
\begin{aligned}
N_1\mathfrak{F}_1 &= \quad * \quad - \Phi_{12}(\bar{v}_1-\bar{v}_2) - \Phi_{13}\bar{v}_1 \\
N_2\mathfrak{F}_2 &= -\Phi_{12}(\bar{v}_2-\bar{v}_1) \quad * \quad - \Phi_{23}\bar{v}_2 \\
N_3\mathfrak{F}_3 &= +\Phi_{31}\bar{v}_1 + \Phi_{32}\bar{v}_2 \quad *
\end{aligned}
\qquad (16'')
$$

Thus

$$\mathfrak{F}_3 \neq 0\ ,$$

since for component 3 at rest

$$v_1 = -v_2$$

but except for singular conditions

$$\Phi_{31} \neq \Phi_{32}\ .$$

## 5. "Uphill" Diffusion

As mentioned above, there are other examples where the diffusion of one component is not simply proportional to a concentration gradient and in addition does not lead to concentration equalization. In order to understand this, we consider the lower part of Figure 16.

To the left we assume a shallow trough, to the right a deep one divided from the former by a porous wall. If we fill the left trough with water, this will slowly penetrate the wall and fill up the right trough to the level of the left one. If we compare the amount of water per unit area to the left and to the right, this amount has considerably increased, compared to that at the left, but in accordance with simple physical laws.

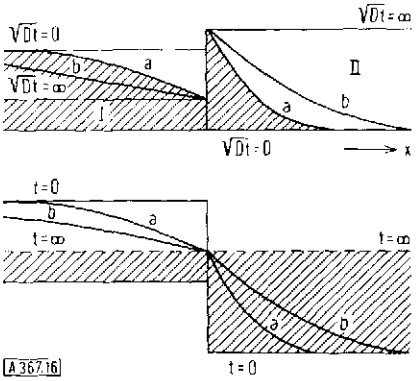

Fig. 16. Scheme for uphill diffusion. Above: concentration distribution for a partition coefficient ≠ 1 (cf. [2]). Below: model with two troughs of different depths.

Curve a: $t = t_1 > 0$

Curve b: $t = t_2 > t_1$.

For comparison: if a substance diffuses from one phase into another, *e.g.* iodine from water into carbon tetrachloride, then at equilibrium the "iodine level" in both phases is filled up not to equal concentrations, but to equal absolute activities (or equal chemical potentials) in both phases.

If a single phase is not homogeneous, it is not the drop in concentration that represents the driving force for diffusion, but the drop in chemical potential [*]. Diffusion in two-phase systems with distinct values of equilibrium concentrations (partition coefficient ≠ 1) and different diffusion coefficients were first treated by *Jost* in 1937 (cf. [2]). In a diffusing sample there may be concentration distributions for $t = 0$ and for $t = t_1 > 0$ as in Figures 17 and 18.

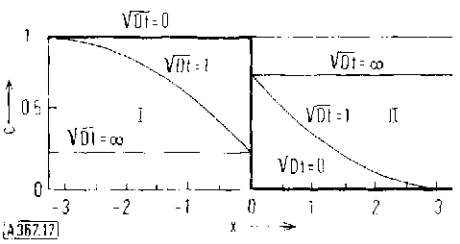

Fig. 17. Diffusion in an infinite system.
Original distribution of the concentration (bold line):

$c = 1$ for $x \leq 0$; $c = 0$ for $x > 0$.

There are two phases I ($x < 0$) and II ($x > 0$) for which $D_I = D_{II}$ and the partition coefficient $\varkappa = c_{II}/c_I = 3$.

[*] These considerations readily lead to a well known rational description of diffusion processes in non-ideal mixtures (cf. [2,4,5]). It is not reasonable simply to replace concentration by activity.

[*] $\Phi_{ij}$ plays the role of a friction coefficient between particles i and j. Of course $\Phi_{ii}$ ought to vanish; consequently the summation $\Sigma'$ is marked as being carried out over $i \neq j$.

[**] These speeds are usually extremely small compared to the mean root square velocity $\sqrt{\overline{v^2}}$, being of the order of 1 cm/sec if $\sqrt{\overline{v^2}} \geq 10^4$ cm/sec.

[†] This is always assumed, although diffusion actually causes small temperature differences owing to the so-called diffusion thermo-effect, the reverse effect of thermal diffusion.

[††] We might continue here by setting

$$\Phi_{ij} = R_{ij} N_i N_j$$

and showing that the new friction coefficients fit into the usual scheme of thermodynamics of irreversible proceses; cf. [7].

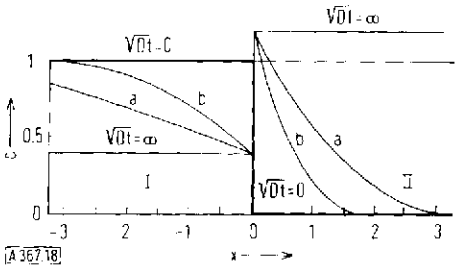

Fig. 18. Diffusion in an infinite system.
(cf. Fig. 17). $D_I = 4\ D_{II}$; $\varkappa = c_{II}/c_I = 3$.
Curve a: $\sqrt{D_I}$ t = 2; $\sqrt{D_{II}}$ t = 1.
Curve b: $\sqrt{D_I}$ t = 1; $\sqrt{D_{II}}$ t = 0.5.

*Darken* [8] obtained corresponding curves experimentally for the diffusion of carbon in alloyed steels, *e.g.* steels containing low and high amounts of Si or Mn. In a triangular diagram for the system Fe–Si–C (Fig. 19), the following course of the concentration with time may be observed: If the original samples A and B have different silicon contents but equal carbon contents, then, owing to the gradient in chemical potential of the carbon

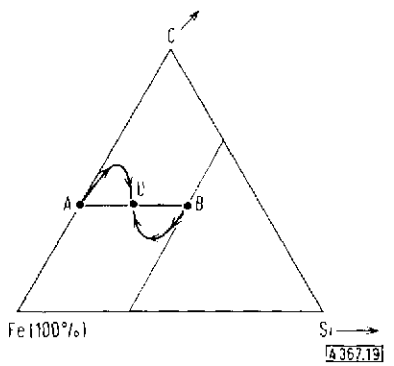

Fig. 19. Diffusion in the three-component system Fe—Si—C (steel); A and B indicate the original concentrations, U gives their final state. The curve marked with arrows indicates the change in concentration with time.

[8] *L. S. Darken*, Amer. Inst. Mining metallurg. Engr., techn. Publ., Metals Technology *15*, 2311 (1948).

caused by the different silicon contents, the carbon concentrations at A and B may shift in opposite directions, leading to differences in carbon content. Later, when the concentration of the slower diffusing silicon becomes equalized, the carbon concentration again becomes homogeneous. Locally a rise (fall) and then a fall (rise) in carbon concentration with time is observed, similar to that of the $CO_2$ concentration in the above example for gas diffusion. However, in the gas example, a gas-kinetic effect was responsible for the result, the gas mixture exhibiting almost ideal behavior, whereas in the iron-silicon-carbon system, deviations from ideal behavior are responsible for the observed phenomena.

Historically, the iron-carbon diffusion system is one of the oldest and most important ones. The Saga of Wieland der Schmied is supposed to provide information on the cementation of iron, *i.e.* carbonization of iron surfaces by diffusion, and surface hardening produced in this way. This technique must have been known in the early iron age. It is closely connected with the art of Damascening (Damascus steel, Damascus swords) by welding iron and steel. According to *Böhme* [9], the East Gothic king Theodorich described Damascened sword blades in a letter in the year 520 A. D. At about 1000 °C, diffusion coefficients of over $10^{-7}$ cm²/sec have been measured for carbon in iron. This would give a depth of penetration per day of $> 1$ mm, a depth which may appear unexpectedly high to those unfamiliar with diffusion phenomena in solids, and which is quite sufficient for hardening the surfaces of sword blades.

Incidently, the diffusion of carbon in iron (as well as that of nitrogen atoms and hydrogen atoms in many metals) does not involve a disorder in the basic metal. These particles are built-in on interstitial sites, and by surmounting a potential barrier can move from one interstitial site to a corresponding neighboring site.

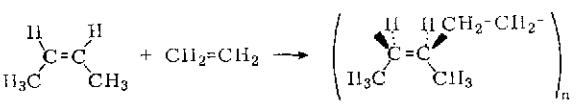
# Stereospecific Homopolymerization of Cyclopentene [*]

BY PROF. DR. G. NATTA, DOZ. DR. G. DALL'ASTA, AND PROF. DR. G. MAZZANTI

ISTITUTO DI CHIMICA INDUSTRIALE, POLITECNICO, AND ISTITUTO DI RICERCA BASE G. DONEGANI, SOC. MONTECATINI, MILAN (ITALY)

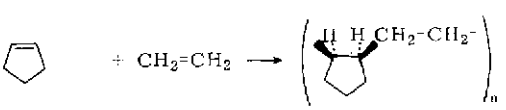
*The polymerization of cyclo-olefins, like that of olefins with an internal double bond, is sterically hindered. Within recent years it has become possible to prepare copolymers of these compounds with ethylene, with the aid of anionic coordination Ziegler catalysts. This copolymerization always results in cis-opening of the double bond. Despite the steric hindrance, cyclobutene and cyclopropene have also been homopolymerized, with opening of the double bond. – Rather surprisingly, the best catalysts for homopolymerization of cyclopentene are those which exhibit low activity in the polymerization of ethylene. Ring cleavage occurs with $MoCl_5/Al(C_2H_5)_3$ to give the cis-polypentenamer, whereas $WCl_6/Al(C_2H_5)_3$ gives the trans-polypentenamer. Both polypentenamers exhibit elastomeric properties. – Evidence from infrared spectra and oxidative degradation indicates that the monomer units in the trans-polypentenamer are linked head-to-tail. It is presumably the single bond adjacent to the double bond that is broken. Using X-ray methods at −50 °C, it was possible to determine the crystal structure of the crystalline trans-polypentenamer at about 400 % elongation.*

## I. Introduction



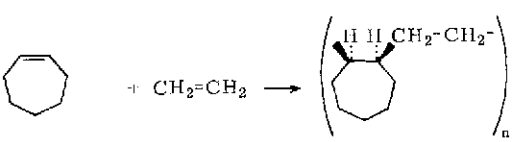
In theory, cyclo-olefins should be able to polymerize, either with opening of the double bond to form polycycloalkenes, or with ring cleavage to form unsaturated linear polymers.

Until a few years ago, all attempts to convert cyclo-olefins into high molecular-weight homopolymers were unsuccessful. To find the reason for failure, it is necessary to consider the two possible modes of reaction.



Cyclo-olefins are related to acyclic olefins which have an internal double bond. It is well known that such olefins (*e.g.* 2-butene) show very little or no tendency to polymerize. One of the reasons which have long been adduced to explain this behavior is steric hindrance due to the bulk of the substituents on both carbon atoms of the double bond. In recent years we have been able to show [1–5] that steric hindrance is indeed the main reason why these olefins do not tend to polymerize *via* opening of the double bond. We have succeeded, with the aid of suitable catalysts, in obtaining high molecular-weight products by copolymerization of both aliphatic and cyclic olefins with a comonomer such as ethylene, which has only slight steric hindrance on the carbon atoms of the double bond. Particularly suitable catalysts for this type of copolymerization are those which act by an anionic coordination mechanism, especially those prepared from vanadium salts and organoaluminum compounds.

However, even in these copolymers there is no direct linkage of monomer units derived from an olefin with an internal double bond; instead, each unit of this type alternates with one or more ethylene units. By using high molar ratios of olefins with an internal double bond to ethylene in the liquid reaction phase, we have succeeded in preparing so-called alternating copolymers, *i.e.* copolymers in which each monomer unit derived from an olefin with an internal double bond is followed by only one ethylene unit, and vice versa.



In the case of *cis*-2-butene [1,2], cyclopentene [3], and cycloheptene [4], we were able to prepare alternating copolymers in which the tertiary carbon atoms are stereoregular, with the result that these copolymers could be crystallized. The structures assigned to these alternating copolymers are shown in formulae *(1a)* · *(1c)*. In all

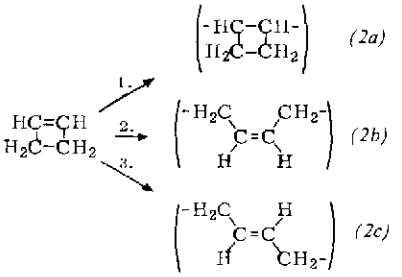
three crystalline alternating copolymers, the double bonds have opened exclusively in the *cis*-direction, resulting in an *erythro*-ditactic (and in this particular case *erythro*-diisotactic) structural regularity.

Until a few years ago, *cis*-opening of double bonds during polymerizations was regarded as unlikely. Classical organic chemistry has many examples of *trans*-additions to double bonds, and this mode of reaction is also regarded as preferable on thermodynamic grounds. Surprisingly, however, all polymerizations in which the direction of the addition to the double bond has been determined in recent years on the basis of a regular steric structure of the polymer have been found to be *cis*-additions. This was first demonstrated with poly(alkenyl alkyl ethers) [6] which are prepared by cationic coordination polymerization, and subsequently for the stereospecific cationic polymerization of both *cis*- and *trans*-β-chlorovinyl ethers [7]. Investigations of Japanese workers [8,9] on the infrared spectra of crystalline polymers of deuterated propylene prepared in our Institute [10] showed that the stereospecific polymerization of propylene to isotactic polymers also proceeds exclusively by *cis*-opening of the double bond; the same is true of the polymerization of ethylene with Ziegler catalysts [11].

The apparent reasons for the *cis*-opening of the cyclo-olefins and of *cis*-2-butene during their copolymerization with ethylene were recently discussed in detail [5].



Our investigations have indicated that steric hindrance, which, as mentioned above, makes direct linkage of monomer units derived from cyclo-olefins extremely difficult and usually impossible, is of decisive importance only in cycloalkenes higher than cyclobutene. Cyclo-olefins with smaller rings behave differently. Following the success of American workers [12] in demonstrating that a polymer obtained by spontaneous polymerization of cyclopropene is built up of interlinked, saturated three-membered rings, we succeeded in obtaining crystalline homopolymers by stereospecific anionic coordination polymerization of cyclobutene (which does not undergo spontaneous polymerization) using vanadium catalysts [13,14]. These homopolymers have the structure of saturated polycyclobutylenes *(2a)*; their formation has evidently been accompanied by opening of the double bond [*].

The main reasons for the direct linkage of cyclo-olefin units during polymerization of cyclopropene and cyclobutene are probably the following:

1. In contrast to larger ring systems, both cyclopropene and cyclobutene have planar conformations. Transition to the saturated polymer *(2a)* enables cyclobutene to assume non planar conformations, resulting in a much larger gain in energy than in the polymerization of larger rings.

2. Steric hindrance around the doubly-bonded carbon atoms is much less in the small rings, so that effective mutual approach of the monomer molecules is appreciably easier.

Moreover, with cyclobutene we first encountered another mode of polymerization of cyclo-olefins [13], namely polymerization with ring cleavage, so that the monomer units in the polymer still contain the double bond. This mode of polymerization occurs preferentially in anionic coordination polymerization with catalysts based on titanium. Depending on the type of catalyst used, the products are predominantly either *cis*- *(2b)* or *trans*-polybutadienes *(2c)*.

It should be pointed out in this connection that, in recent years, polymerizations accompanied by either opening of the double bond or ring cleavage have also been described for norbornene [16,17]. Its endocyclic methylene group makes this monomer a special one from both the steric and energetic points of view, and results in very high reactivity. We shall return to this case in Section IV.

Steric hindrance probably plays a much smaller part in polymerization of cyclobutene with ring cleavage than in polymerization involving opening of the double bond. For this reason, the former mode of polymerization ought to be favored. However, the opposite is in fact true. Pure polycyclobutenes can be obtained from cyclobutene, but it is impossible, even under the most favorable conditions, to convert cyclobutene into pure polybutadienes with the catalysts mentioned; this reaction is always accompanied by the formation of appreciable amounts of polycyclobutenes.

It might be supposed from the observations described above that cyclo-olefins higher than cyclobutene would show no significant tendency to form polymers by ring cleavage. Nevertheless, we decided to investigate the question whether higher cyclo-olefins, particularly cyclopentene, can homopolymerize by ring cleavage.

## II. Attempts to Homopolymerize Cyclopentene

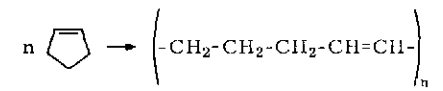
### 1. Catalysts with Anionic Coordination Reaction Mechanisms

We first carried out series of experiments in the presence of catalysts known to be suitable for the homopolymerization of ethylene and α-olefins to high molecular-weight linear polymers. To improve the expected low tendency of cyclopentene to polymerize, the experiments were carried out in the absence of solvent, and the catalyst was prepared directly in the cyclopentene itself. The results are shown in Table 1.

Table 1. Attempts to homopolymerize cyclopentene in the presence of catalysts (containing Ti, Zr, V, or Cr) with anionic coordination polymerization mechanisms (experimental conditions: 6 h at −30 °C, followed by 14 h at +20 °C; molar ratio of cyclopentene: transition metal = 30:1; all samples undiluted).

| Catalyst system | Yield of polymer [%] | X-ray investigation | Chemical structure of polymer |
|---|---|---|---|
| $TiCl_4 + Al(C_2H_5)_3$ | 1 | crystalline | *trans*-polypentenamer |
| $TiBr_4 + (Al(C_2H_5)_3$ | 2 | crystalline | *trans*-polypentenamer |
| $ZrCl_4 + Al(C_2H_5)_3$ | 1 | crystalline | *trans*-polypentenamer |
| $VCl_4 + Al(C_2H_5)_3$ | 1 | crystalline | alternating ethylene-cyclopentene copolymers |
| $VOCl_3 + Al(C_2H_5)_2Cl$ | 3 | crystalline | |
| V(triacac) [*] + $Al(C_2H_5)_2Cl$ | 1.5 | crystalline | |

[*] (triacac) = triacetylacetonate. No polymers were obtained with the catalyst systems $CrBr_3/Al(C_2H_5)_3$, $Cr(triacac)/Al(C_2H_5)_2Cl$, and $CrO_2Cl_2/Al(C_2H_5)_3$.



The following conclusions can be drawn from the experiments:

a) The behavior of cyclopentene depends largely on the transition element present in the catalyst.

b) Chromium-containing catalysts do not polymerize cyclopentene.

c) Vanadium-containing catalysts cannot homopolymerize cyclopentene. However, if ethylaluminum compounds are used in preparing the catalysts, the crystalline alternating cyclopentene/ethylene copolymers described above are formed. The tendency of the vanadium compounds to promote the formation of such products is evidently so strong that even the small quantities of ethylene eliminated from $Al(C_2H_5)_3$ during the reaction with the vanadium salts are sufficient for the formation of the copolymer.

d) Catalysts containing a Group IV metal, *e.g.* titanium or zirconium, can bring about homopolymerization of cyclopentene with ring cleavage to yield *(3)*.

As discussed in detail later, polymer *(3)* contains almost exclusively *trans*-double bonds. We shall term this polymer (which has not yet been described in the literature [*]) *trans*-polypentenamer, in accordance with the IUPAC nomenclature [15]. It is completely free from cyclopentene units resulting from opening of the double bond. The chemical and steric purity of the polymer *(3)* are the reasons for its crystallinity which can be observed to a small extent in the X-ray diagram of even the unstretched polymer.

e) However, polymerization of cyclopentene using the titanium or zirconium catalysts (Table 1) gives very low yields of *trans*-polypentenamer. This appeared to confirm our original supposition that the reactivity of cyclopentene would be very low compared with that of cyclobutene.

Despite the low conversion into polypentenamer with titanium or zirconium catalysts, it was observed with surprise that the reaction proceeded exclusively by ring cleavage. In view of the low ring strain in cyclopentene and the fact, mentioned above, that pure polybutadiene *(2b)*/*(2c)* is never obtained from cyclobutene under similar conditions, the polymer obtained from cyclopentene should also be expected to contain at best both possible forms of the monomer units. These observations led us to extend our investigations to other catalyst systems which, although they also act by an anionic coordination mechanism, are either inactive or nearly so in the homopolymerization of ethylene and α-olefins. The results are shown in Table 2.

The catalyst systems contained metals of Groups VI, VII, and VIII of the periodic table. These experiments have, surprisingly, shown the following:

a) Catalysts based on uranium, iron, manganese or cobalt are completely ineffective for polymerizing cyclopentene.

b) Catalysts based on molybdenum or tungsten promote homopolymerization of cyclopentene into polymers with the polypentenamer structure, in high yield. These

Table 2. Attempts to homopolymerize cyclopentene in the presence of catalysts with anionic coordination polymerization mechanisms. Experimental conditions: 4 h at −30 °C, followed by 14 h at 0 °C; molar ratio of cyclopentene: transition metal = 30:1; all samples undiluted. — No polymers were obtained with the catalyst systems $UF_4/Al(C_2H_5)_3$, $UO_2Cl_2/Al(C_2H_5)_2Cl$, $MnCl_2/Al(C_2H_5)_3$, $FeCl_3/Al(C_2H_5)_3$, $CoCl_2(Py)_2/Al(C_2H_5)_2Cl$, and $BaFeO_4/Al(C_2H_5)_2Cl$.

| Catalyst system | Yield of polymer [%] | Infrared analysis of polymer | | X-ray investigations | Chemical structure of polymer |
|---|---|---|---|---|---|
| | | Cyclopentylene units [%] | Pentenamer units [%] | | |
| $MoCl_5 + Al(C_2H_5)_3$ | 21 | 0 | 100 | amorph. | *cis*-polypentenamer |
| $WCl_6 + Al(C_2H_5)_3$ | 39 | 0 | 100 | cryst. | *trans*-polypentenamer |

[*] Polymers formed to a very low extent by ring cleavage of cyclopentene, are mentioned in the patent literature; however, the double bonds in the polymers obtained show no stereoregularity.

polymers contain no monomer units formed by opening of the double bond. It is of interest that, in the homopolymerization of cyclobutene, these catalyst systems neither exhibit high catalytic activity nor yield polymers with a pure polybutadiene structure.

c) The polypentenamer obtained with the catalyst system prepared from $WCl_6$ and $Al(C_2H_5)_3$ has the same steric structure as that obtained with the titanium or zirconium catalysts described above, *i.e.* it is essentially pure *trans*-polypentenamer. The polypentenamer obtained in the presence of the catalyst prepared from $MoCl_5$ and $Al(C_2H_5)_3$, on the other hand, has essentially a *cis*-polypentenamer structure. This polymer, too, has hitherto not been described in the literature. The next Section shows how the structures of the two polypentenamers were elucidated.

## 2. Chemical and Steric Structure of the Polypentenamers

The infrared spectra of the various polypentenamers enabled us to draw important conclusions regarding their chemical structures. It was first shown that the various polymers obtained in the presence of catalysts containing titanium, zirconium, or tungsten have practically identical infrared spectra (Fig. 1). These all show an intense absorption band at 10.35 $\mu$, characteristic of *trans*-double bonds; *cis* double bonds are present to an extent of only 2–3 %. Absorption bands due to other types of double bonds (*e.g.* vinyl, vinylidene, conjugated or other cumulative double bonds) are absent. Cyclic structures can be excluded owing to the absence of certain characteristic bands between 8 and 8.5 $\mu$, but mainly owing to the absence of the absorption band at 3.39 $\mu$, characteristic rather of cyclopentane structures. Quantitative determination of the double bonds gives almost exactly one double bond per pentenamer unit [*]. This interpretation of the infrared spectrum is sufficient to enable us to assign a *trans*-polypentenamer structure.

The infrared spectrum of the polymers obtained with the catalyst prepared from $MoCl_5$ and $Al(C_2H_5)_3$ is shown in Figure 2. The absorption bands at 7.12 and 13.8–13.9 $\mu$ can be ascribed to *cis*-double bonds. Only a small percentage of *trans* double bonds are present; other types of double bond are essentially absent. These spectra are also completely free from bands characteristic of cyclic structures. Quantitative determination again shows exactly one double bond per pentenamer unit [**]. Interpretation of the spectrum enables us to assign a *cis*-polypentenamer structure.

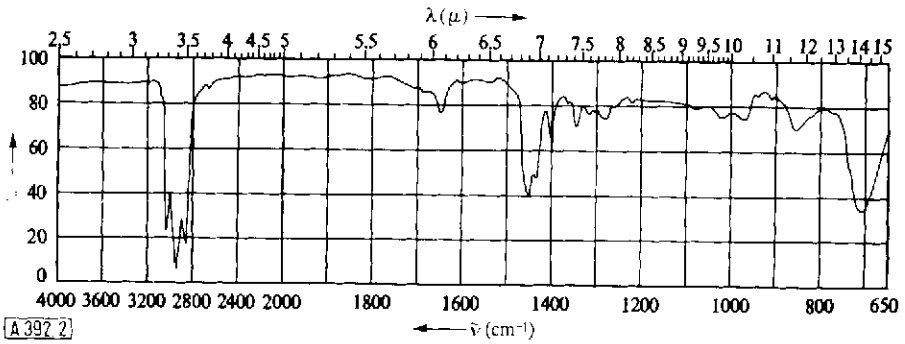


Fig. 2. Infrared spectrum of *cis*-polypentenamer (Perkin-Elmer 221 spectrophotometer; NaCl optics; film cast from benzene solution).

In order to define the chemical structure of the polymers precisely it is necessary to specify whether the monomer units are linked in a head to-tail or a head-to-head-tail-to-tail arrangement. The polymers expected in the two cases differ in the number of methylene groups between the pairs of double bonds. In head-to-tail polymers, each consecutive pair of double bonds must be separated by three methylene groups. In head-to-head-tail-to-tail polymers, on the other hand, two

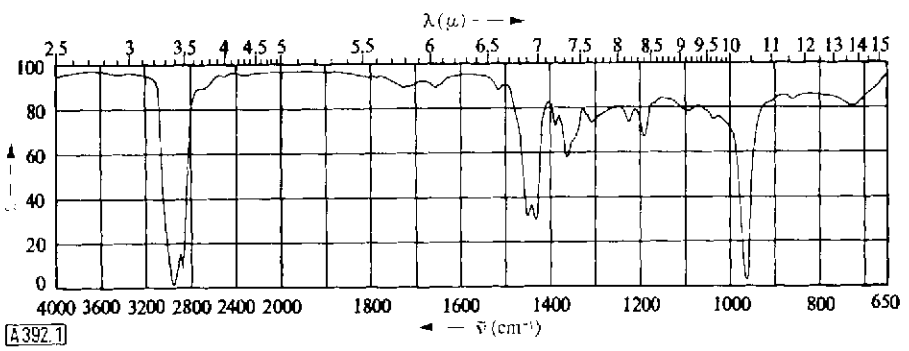

Fig. 1. Infrared spectrum of *trans*-polypentenamer (Perkin-Elmer 221 spectrophotometer; NaCl optics; film cast from benzene solution).

[*] The quantitative determination of the *trans*-double bonds was based on the following absorption coefficient: $K(10.35\ \mu) = 10 \times 10^4$ [mole·cm²/g] [18].

[**] Quantitative determination of the *cis*-double bonds was based on the following absorption coefficient: $K(7.12\ \mu) = 0.83 \times 10^4$ [mole·cm²/g] [18].

[18] *D. Morero, A. Santambrogio, L. Porri,* and *F. Ciampelli,* Chim. e Ind. *41*, 758 (1959).

structures are possible, according to the position in which the cyclopentene ring has been opened. If the single bond adjacent to the double bond is broken, the number of methylene groups between consecutive double bonds should be alternately six and none. If the ring opens at the single bond remote from the double bond, we should find alternately two and four methylene groups between two consecutive double bonds.

Since the infrared spectrum excludes the presence of conjugated double bonds, we rejected the possibility of an alternating series of six and no methylene groups, which would correspond to a polymer with pairs of conjugated double bonds. The remaining two cases, *viz.* head-to-tail and head-to-head-tail-to-tail linkages, are shown in formulae *(4)* and *(5)*, respectively.

$$-CH{=}CH-CH_2-CH_2-CH_2-CH{=}CH-CH_2-CH_2-CH_2-CH{=}CH-$$
*(4)*

$$-CH{=}CH-CH_2-CH_2-CH{=}CH-CH_2-CH_2-CH_2-CH_2-CH{=}CH-$$
*(5)*

In order to decide between these two possibilities, the *trans*-polypentenamer was ozonized in carbon tetrachloride and subjected to oxidative degradation with hydrogen peroxide. The sole degradation product from the first polypentenamer *(4)* should be glutaric acid, while the second polymer *(5)* should give equimolar amounts of succinic and adipic acids. The *trans*-polypentenamer yielded glutaric and succinic acids in a molar ratio of about 4:1, but no adipic acid [*].

In interpreting this result, it must be borne in mind that the oxidative degradation method used generally yields not only the expected acid, but also considerable quantities of the acid having one less carbon atom, as demonstrated by *Ziegler* et al. [19]. Degradation of the acid to the next lower homologue occurs during the treatment with hydrogen peroxide, probably by oxidation of an α-carbon atom followed by decarboxylation.

In view of this and of the fact that no adipic acid was found, it may be concluded that the polymer in question is head-to-tail *trans*-polypentenamer. Although our investigations on the *cis*-polypentenamer are not complete, we have good reason to believe that this polymer is also built up of units linked in a head-to-tail arrangement. The head-to-tail linkage was confirmed for the *trans*-polypentenamer by X-ray analysis. This polymer exhibits the behavior typical of many elastomers, particularly natural rubber: it is practically amorphous or only slightly crystalline in the unstretched state at room temperature, but on cooling or stretching it crystallizes to a considerable extent. A filament stretched to 400 % elongation and cooled to about −50 °C gives the spectrum of a highly oriented fiber with a large number of reflections (Fig. 3). According to this spectrum, the *trans*-polypentenamer has an orthorhombic unit cell with the following constants: a = 7.28 Å; b = 4.97 Å; c (fiber axis) = 11.9 Å.

[*] The acids were determined by thin-layer chromatography.

[19] *K. Ziegler, W. Hechelhammer, H. D. Wagner,* and *H. Wilms,* Liebigs Ann. Chem. *567*, 99 (1950).

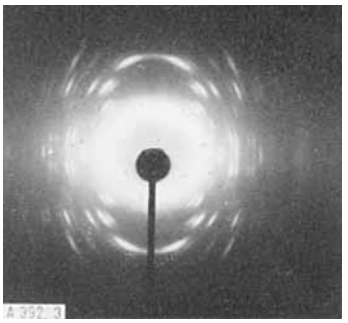

Fig. 3. X-ray fiber spectrum of the head-to-tail *trans*-polypentenamer (elongated by about 400 %; temperature ≈ −50 °C).

The model suggested by us for the macromolecule in the crystal lattice is shown in Figure 4. This model is characterized by a series of internal rotation angles of 120 ° and 240 ° about the single bonds adjacent to the double bond, and of 180 ° about all the other bonds.

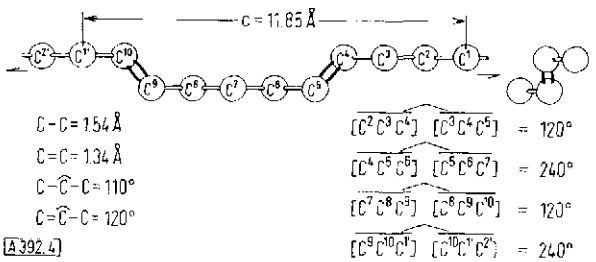

Fig. 4. Model of the crystalline *trans*-polypentenamer in side and front elevations (internal rotation angles which are not given separately are 180 °).

The recurring unit contains two monomer units; the symmetry element relating them is a twofold screw axis. The identity period of 11.85 Å calculated for this model agrees very closely with the experimental value.

Further interpretation of the fiber spectrum is possible on the basis of the unit cell described above; the most likely space group is either $C_{2v}^9$ or the centrosymmetric $D_{2h}^{16}$. The structural factors for these models agree closely with the experimental values.

## III. Properties of Polypentenamers with a Head-to-Tail Structure

The polypentenamers with regular *cis*- or *trans*-double bond structures described above are soluble in aromatic, alicyclic, and chlorinated hydrocarbons, but insoluble in alcohols, aliphatic ketones, and aliphatic ethers. The intrinsic viscosity [*] may lie between about 0.3 and 10, and was found to be between 2 and 8 for most polymers investigated.

The melting point of the *trans*-polypentenamer, +23 °C, was determined by dilatometry; that of the *cis*-polypentenamer, though probably much less than 0 °C, is still undetermined. In this connection, it should be recalled that the melting point of pure *trans*-polybutadiene is +145 °C, and that of pure *cis*-polybutadiene is +2 °C. Hence, as regards their melting points, it can be seen that an analogy exists between the polypentenamers

[*] The intrinsic viscosity is ten times the Staudinger viscosity z l/g).

and polybutadienes. Chemically, the former differ from the latter in possessing an additional methylene group per monomer unit. This additional methylene group produces considerable changes in the symmetry of the macromolecule and evidently causes *inter alia*, an appreciable depression of the melting point of the two polypentenamers. The very different melting points involve considerable differences in certain physical characteristics, especially the elastomeric properties.

It is well known that *cis*-polybutadiene possesses good elastomeric properties, whereas the *trans*-isomer is a thermoplastic material, mainly owing to its very high melting point, and exhibits no elastomeric properties at room temperature, even after vulcanization. The appreciable depression of the first-order transition temperature observed on passing from the polybutadienes to the polypentenamers brings both the *trans*- and the *cis*-polypentenamer into the elastomer field. In fact, *trans*-polypentenamer possesses excellent elastomeric properties.

Preliminary analysis indicates that these properties are due both to the large number of sequences of methylene groups, which confer high flexibility on the chains, and to the fact that the melting point is close to room temperature, like that of natural rubber.

The *trans*-polypentenamer can be readily vulcanized with all the systems commonly used for unsaturated elastomers. For example, we have vulcanized *trans*-polypentenamer using recipes based on either sulfur and accelerators or sulfur donors and accelerators.

The mechanical properties of these rubbers are excellent both with and without reinforcing fillers, *e.g.* carbon black. The stress-strain curve (Fig. 5) shows that the pure gum vulcanizate (curve I) gives the strong upward curvature characteristic of rubbers (*e.g.* natural rubber) which crystallize on stretching. Vulcanizates prepared in the presence of reinforcing fillers (curve II) show excellent mechanical and dynamic properties.

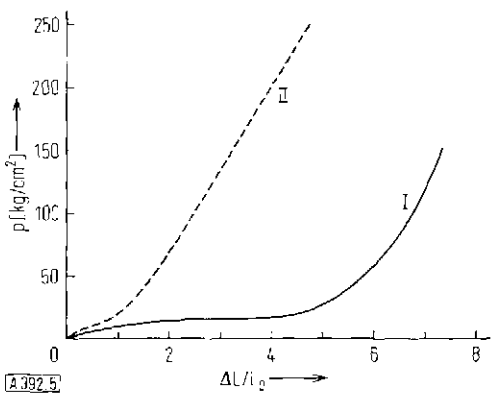

Fig. 5. Stress-strain diagram for unreinforced vulcanizates (curve I) and for rubber vulcanizates reinforced with HAF black (curve II).
Ordinate: Stress [kg/cm²].
Abscissa: Relative change in length.

The resilience [*] is shown in Figure 6 as a function of temperature. The temperature at which the rebound reaches a minimum is evidently very low. In this respect, the behavior of *trans*-polypentenamer resembles that of *cis*-1,4-polybutadiene, and differs from that of natural rubber.

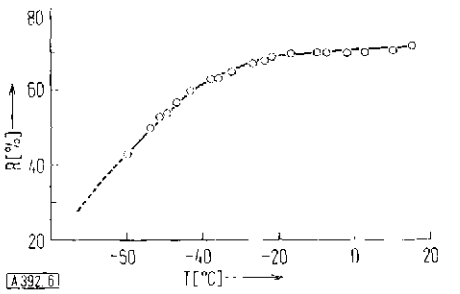

Fig. 6. Temperature-dependence of the rebound (R) of pure rubber vulcanizates.
(Micropendulum from Pirelli, S.p.A., Milan (Italy); height of fall = 0.125 mm).

## IV. Observations Concerning the Mechanism of Homopolymerization of Cyclopentene with Catalyst Systems Based on Molybdenum or Tungsten

The peculiar behavior of cyclopentene in the presence of catalysts prepared from molybdenum or tungsten salts and organoaluminum compounds induced us to investigate the mechanism of these catalysts in greater detail.

The polymerization mechanism is probably of the anionic coordination type. Evidence for this is provided by the observation that the individual components from which the catalyst is prepared and which normally exhibit a cationic or classical anionic mechanism, cause practically no polymerization of cyclopentene when used alone. The same is true of other Friedel-Crafts catalysts and a catalyst which acts by a free-radical mechanism (Table 3).

Table 3. Attempts to polymerize cyclopentene in the presence of various catalyst systems with different polymerization mechanisms.

| Catalyst | Solvent | Polymerization mechanism | Yield of polymer [*] |
|---|---|---|---|
| $TiCl_4$ | none | cationic | 0 |
| $CrO_2Cl_2$ | toluene | cationic | 0 |
| $CrO_2Cl_2$ | n-heptane | cationic | 0 |
| $WCl_6$ | none | cationic | slight; oil |
| $Al(C_2H_5)_2Cl$ | none | anionic | 0 |
| $Al(C_2H_5)_3$ | none | anionic | 0 |
| $CuCl_2 + Al(C_2H_5)_3$ | none | free-radical | 0 |

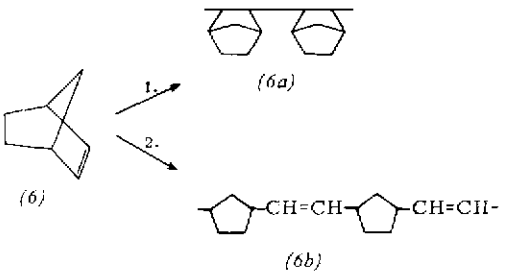
[*] After a reaction time of 24 h.

Another important point is to check whether any analogy exists between the mechanism of these polymerizations and that of the polymerization of aliphatic olefins (such as ethylene) in the presence of the same catalysts. For this reason, the experiments listed in Table 4 were carried out. It was found that the molybdenum and tungsten catalysts homopolymerize cyclopentene rapidly, but homopolymerize ethylene much more slowly. On the other hand, attempts to copolymerize cyclopentene with ethylene yielded no copolymers, but only homopolymers of cyclopentene, as if no ethylene had been present.

[*] The resilience is defined by the relative rebound height (cosine value) of a pendulum after impact on the sample (measure of the conversion of kinetic energy into heat on impact.)

Table 4. Attempts to homopolymerize cyclopentene or ethylene and to copolymerize cyclopentene with ethylene.

| Catalyst system | Monomers [a] | | Conversion [moles of monomer/ moles of catalyst] | Structure of polymer |
|---|---|---|---|---|
| | Cyclo-pentene | Ethylene | | |
| $MoCl_5 + Al(C_6H_{13})_3$ | – | + | 1 | polyethylene |
| $WCl_6 + Al(C_2H_5)_2Cl$ | – | + | 10 | polyethylene |
| $MoCl_5 + Al(C_6H_{13})_3$ | + | – | 20 | *cis*-polypent-enamer |
| $MoCl_5 + Al(C_6H_{13})_3$ | + | + | 20 | *cis*-polypent-enamer [b] |
| $WCl_6 + Al(C_2H_5)_2Cl$ | + | + | 30 | *trans*-polypent-enamer [b] |



[a] A minus sign indicates the absence, plus sign the presence of the monomer in question.

[b] The absence of ethylene units in the polypentenamer obtained from copolymerization of cyclopentene with ethylene was demonstrated using ethylene labelled with $^{14}C$.

The most likely explanation for this is that the coordination of cyclopentene to the catalytically active centers is greatly favored, *i.e.* the cyclopentene immediately occupies all active centers, so that the ethylene is unable to participate in the reaction.

As regards the position at which the cyclo-olefin ring opens during the polymerization, two possibilities arise in theory: cleavage of a single bond adjacent to the double bond, or cleavage of a single bond remote from the double bond. It is not easy to solve this problem by direct methods since, in a head-to-tail polymer, the structure of the macromolecule must be the same, irrespective of the position at which the ring opens. However, various considerations have led us to adopt the view that the cyclopentene ring opens at a single bond next to the double bond. The following two points support this view.

1. In the polymerization of norbornene *(6)*, in the presence of catalysts acting by an anionic coordination mechanism [16], the unsaturated five-membered ring is cleaved exclusively at the single bond adjacent to the double bond. The position of cleavage in this molecule is known with certainty from the structure of the polymer *(6b)*. However, this ring cleavage of norbornene is due to special circumstances, since the polymer which would be formed by cleavage of the unsaturated five-membered ring at a bond not adjacent to the double-bond would still contain a ring unsaturation (in the six-membered ring).

2. The double bond of cyclopentene is a *cis*-double bond. Ring cleavage at a single bond remote from the double bond would therefore be expected to yield exclusively, or at least predominantly, *cis*-polypentenamer, since this type of double bond is already present. Cleavage of a single bond next to the double bond, on the other hand, should have very little or no effect on the steric structure of the double bond in the polypentenamer, since the formation of *trans*-polypentenamer would require only isomerization of an electron pair. In this type of reaction the catalyst would probably determine the steric structure of the double bond in the growing chain. This consideration agrees with the experimental findings.

It is not easy at present to formulate a detailed reaction mechanism which explains all the observations reported above, including some others which will be reported later; however, it is hoped that this will be possible when more detailed information is available.

*The authors are grateful to Prof. I. W. Bassi for carrying out the X-ray structural investigations and to Dr. F. Ciampelli for carrying out the infrared measurements.*

# Photochemical Substitutions on Metal Carbonyls and Their Derivatives

BY PROF. DR. W. STROHMEIER

INSTITUT FÜR PHYSIKALISCHE CHEMIE DER UNIVERSITÄT WÜRZBURG (GERMANY)

*The photochemical reaction of n- and π-electron donors with metal carbonyls or their derivatives, which was discovered some years ago, provides a means of preparing a wide range of new metal-carbonyl derivatives which are obtainable only in poor yields or not at all by thermal reactions. – Preparative methods are described. The mechanism of this photochemically induced substitution was elucidated for selected examples, and an attempt has been made to gain an insight into the polarity of the metal-ligand bond. – This paper is intended as a survey of work published recently in this field.*

## I. Introduction

Two fundamental types of reaction have been observed for the action of electron donors D on metal carbonyls $M(CO)_x$ or their derivatives $Y_aM(CO)_x$ (M = metal; Y = ligand):

a) Substitution reactions, in which one molecule of carbon monoxide is eliminated from the metal carbonyl $Y_aM(CO)_x$ and replaced by the donor D:

$$Y_aM(CO)_x + D \rightarrow Y_aM(CO)_{x-1}D + CO.$$

b) Base reactions, in which the metal carbonyl disproportionates to form substituted ionogenic metal carbonylates [1], *e.g.*

$$3\ Mn_2(CO)_{10} + 12\ D \rightarrow 2\ [MnD_6][Mn(CO)_5]_2 + 10\ CO.$$

Whether a given metal carbonyl and a particular electron donor should be expected to give a substitution or a base reaction has already been discussed in detail in the literature [1]. Thus, the carbonyls of group VI metals undergo substitution with n-electron donors, while the carbonyls of group VII and VIII metals undergo a base reaction with donors incapable of back-donation (cf. p. 735); however, even the latter metal carbonyls are preferentially substituted as the tendency of the donor to participate in back-donation increases. The present work is concerned only with substitutions in which the photochemical reaction of π-electron donors [2a] and n-electron donors [2b] has been used as a new principle.

## II. The Difference between Thermal and Photochemical Substitutions

Thermal substitutions may proceed by an $S_N1$ mechanism, in which the intermediate electron acceptor $Y_aM(CO)_{x-1}$ is formed by thermal dissociation:

$$Y_aM(CO)_x \rightleftharpoons Y_aM(CO)_{x-1} + CO$$

This then adds onto the donor to fill up its electron deficiency. This $S_N1$ mechanism has been shown to occur in the formation of $Ni(CO)_2[P(C_6H_5)_3]_2$ from $Ni(CO)_4$ and $P(C_6H_5)_3$ [3]. It is also supported by the very rapid $^{14}CO$ exchange in $Ni(CO)_4$ [4]. On the other hand, the carbonyls of group VI metals, arene metal tricarbonyls, cyclopentadienylmanganese tricarbonyl, and $Mn_2(CO)_{10}$ undergo practically no exchange with $^{14}CO$ at room temperature [5], so that an $S_N1$ mechanism is ruled out for these carbonyls in thermal substitutions. They probably react by an $S_N2$ mechanism *via* a transition complex:

$$Y_aM(CO)_x + D \rightarrow [Y_aM(CO)_x \cdots D] \rightarrow Y_aM(CO)_{x-1}D + CO.$$

In contrast, the primary photochemical act in the preparation of metal-carbonyl derivatives by irradiation of dissolved metal carbonyls involves initial formation of an electron acceptor $\{Y_aM(CO)_{x-1}\}$ by removal of one molecule of CO from the excited molecule $\{Y_aM(CO)_x\}^*$. The existence of an electron acceptor $\{M(CO)_5\}$ has been proved both chemically [6] and spectroscopically [7]. The half-life of this unstable acceptor is of the order of a few minutes. The monosubstituted compound $Y_aM(CO)_{x-1}D$ is then formed simply by addition of an n- or π-electron donor into the electron deficiency of the photochemically generated acceptor. This reaction is basically a photochemically induced $S_N1$ process:

$$Y_aM(CO)_x + h\nu \rightarrow \{Y_aM(CO)_x\}^* \rightarrow \{Y_aM(CO)_{x-1}\} + CO$$
$$\xrightarrow{D} Y_aM(CO)_{x-1}D.$$

## III. Range of Application of Photochemical and Thermal Substitution Reactions

Experience has shown that thermal substitution of the carbonyls of group VI, VII, and VIII metals can generally be carried out between 50 and 150 °C, if a

[7] *I. W. Stolz, G. R. Dobson,* and *R. K. Sheline,* J. Amer. chem. Soc. *84*, 3589 (1962); *85*, 1013 (1963).

strong donor is used as co-reactant. However, there are certain metal carbonyl derivatives, *e.g.* cyclopentadienylmanganese tricarbonyl $C_5H_5Mn(CO)_3$, which do not undergo thermal reaction, *e.g.* with triphenylphosphine, even at 200 °C [8]. From the thermodynamic point of view, the reaction could be forced to occur by increasing the temperature. However, the maximum temperature which can be used for thermal substitutions is limited by the range of stability of the starting materials and final products, which experience has shown to become narrower for metal carbonyl derivatives, the weaker the donor properties of D.

However, in the photochemical reaction of metal carbonyl derivatives, the intermediate unstable acceptor $\{Y_aM(CO)_{x-1}\}$ is produced photochemically in the primary process, which can take place at or below room temperature. This makes it possible to isolate even relatively unstable substitution products, since the addition of a weak donor D to the acceptor always takes place at low temperatures. Thus, as is shown by the following Tables, a wide range of new compounds, which were not available by other methods, have become accessible by the photochemical route. Another advantage of photochemical procedures is that they permit specific preparation of mono- or disubstitution products, a feature which can be achieved only with difficulty, if at all, by thermal substitution reactions. Thus, $W(CO)_6$ undergoes direct thermal reaction with $CH_3CN$ to give the trisubstituted compound $W(CO)_3(CH_3CN)_3$ [9], but $W(CO)_5CH_3CN$ and $W(CO)_4(CH_3CN)_2$ have been prepared photochemically [10]. Moreover, the photochemical process is suitable for reactions with both n- and π-electron donors.

## IV. Procedures

### 1. Preparation of Metal Carbonyl Derivatives

The general method for the photochemical preparation of metal carbonyl derivatives involves ultraviolet irradiation of a solution of the metal carbonyl in the presence of the donor D, the CO liberated being removed from the solution by a stream of nitrogen. The course of the reaction can be followed by quantitative determination of the CO removed. An optical arrangement for quantitative measurements with monochromatic light has been described earlier [6]. For preparative work on a larger scale, the simpler arrangement shown in Figure 1 can be used.

The solution to be irradiated is placed in a vessel A, which is equipped with ground glass joints. A double-walled Pyrex-glass vessel B, containing a high-pressure mercury burner C (Type Q 81, Hanau) and cooled by running water, is inserted into A. If necessary, the burner can be cooled with compressed air *via* inlet P. The CO liberated is removed at $H_2$ by a current of nitrogen led in through the three-way tap $H_1$.

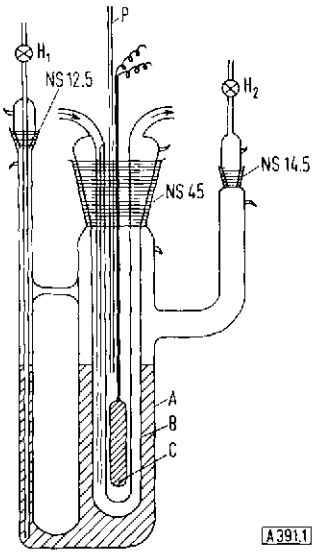

Fig. 1. Irradiation apparatus for preparative work. (Capacity about 50 ml.)

When the reaction is complete, the solution can be displaced from the irradiation vessel at tap $H_1$ by nitrogen or argon introduced through $H_2$, *i.e.* with exclusion of air. After removal of the solvent and the starting materials, the crude product is purified by recrystallization or sublimation *in vacuo*. The following is an example of a typical preparation. Precise procedures for each compound are to be found in the appropriate original publications (see Tables 2, 3, and 4).

Piperidinochromium pentacarbonyl: 270 mg (1.23 mmole) of $Cr(CO)_6$ and 1 ml of piperidine were dissolved in 25 ml of tetrahydrofuran and irradiated until 1.02 mmole of CO had been liberated; the solvent was then removed from the yellow solution at a bath temperature of 30 °C in a flash evaporator at 20 mm Hg. The yellow-brown oily residue was taken up in petroleum ether and freed from residual piperidine by shaking with 1 N HCl. The petroleum ether solution was dried and the solvent pumped off, the residue being immediately sublimed *in vacuo* at 60 °C bath temperature. The yield was 170 mg (60 %).

The operations must be carried out under nitrogen or argon, since most metal carbonyl derivatives are more or less sensitive to air in solution depending on the donor D. It has been shown experimentally that relatively slight decomposition is sufficient to make the isolation of a pure product difficult or impossible (poor crystallizability and great sensitivity of the contaminated crude product towards air).

### 2. Influence of the Solvent

The choice of a suitable solvent is of vital importance to the yield and isolation of pure samples of many photochemically prepared metal carbonyl derivatives. We have observed that the most suitable solvent varies from one metal carbonyl to another and with the nature of the donor. The best results were achieved with the solvents given in Table 1.

The following points have also been found to be important, under certain circumstances, to the yield and purity of the product.

a) The reaction product should be only sparingly soluble in the solvent, so that it is precipitated during irradiation. Analytically pure products were often obtained directly in this way, *e.g.* $C_5H_5Mn(CO)[(CH_3)_2SO]_2$ in diethyl ether [23]. A good rule of thumb is that monosub-

Table 1. Solvents for the photochemical preparation of metal carbonyl derivatives. (THF = tetrahydrofuran.)

| Metal carbonyl | Donor | | | | | |
|---|---|---|---|---|---|---|
| | nitrogen compound | $R_2S{=}O$ | phosphorus compound | nitrile | π-electron donors | $R_2S$ |
| $Cr(CO)_6$ | $CH_3OH$, THF | benzene | | benzene | | |
| $Mo(CO)_6$ | THF | | | benzene | | |
| $W(CO)_6$ | THF | benzene | | benzene | | |
| $ArM(CO)_3$ | benzene | benzene, $CH_3OH$ | benzene | benzene, $CH_3OH$ | THF | $CH_3OH$ |
| $C_5H_5Mn(CO)_3$ | THF, $CH_3OH/H_2O$ | benzene | benzene | $CH_3OH/H_2O$ | heptane | heptane |

stitution products are more readily soluble than disubstitution products, and these in turn are more readily soluble than trisubstitution products (for examples, see [11]).

b) If the photochemical reaction leads directly to the disubstitution product, it is advisable to carry out the elimination of CO – paradoxically – under a current of CO using a solvent in which the disubstituted compound is readily soluble. This derivative is then reconverted to the monosubstituted compound according to Equation 9.

c) With donors such as *p*-phenylene diamine which are photochemically unstable, the best method is donor exchange. The relatively weak donor tetrahydrofuran is used as solvent, and the tetrahydrofuran derivative, *e.g.* $Cr(CO)_5THF$, is first prepared photochemically. The photolabile donor D is then added to the solution, the solvent is removed, and $Cr(CO)_5D$ is obtained according to:

$$Cr(CO)_6 + THF \xrightarrow{h\nu} Cr(CO)_5THF \xrightarrow{D} Cr(CO)_5D + THF.$$

This method often yields very pure products.

## V. Reaction Mechanism and Quantum Yield

The reaction mechanism [6,12] and the quantum yield [12,13] have been elucidated in particular for photochemical reactions involving metal hexacarbonyls. As far as such investigations have been carried out on other metal carbonyls they agree with the results obtained on the hexacarbonyls. The quantum yield $\Phi$ of the photochemical primary reaction was found in all cases, independent of the central atom M and the donor D, to be 1.0 for time $t = 0$ at wavelengths $\lambda = 3660$ and 4360 Å. The quantum yield steadily decreases with increasing times of irradiation, since the reaction products themselves absorb light and undergo further chemical reactions. Several dark reactions also occur simultaneously at various rates. These secondary reactions depend on the central atom, on the nature of the metal carbonyl, and on the donor D. Intensive investigations indicated the following reaction scheme for metal hexacarbonyls:

Primary photochemical reaction:

$$M(CO)_6 + h\nu \rightarrow \{M(CO)_6\}^* \rightarrow \{M(CO)_5\} + CO \quad (1)$$

Secondary reactions:

$$\{M(CO)_5\} + D \rightarrow M(CO)_5D \quad (2)$$

$$\{M(CO)_5\} + (CO)_{solv} \rightarrow M(CO)_6 \quad (3)$$

$$M(CO)_5D + (CO)_{solv} \rightarrow M(CO)_6 + D \quad (4)$$

Reaction 3 (CO also acts as a donor) can be suppressed by removing the photochemically liberated CO and by using an excess of D.

Reaction 4 is unimportant at room temperature in the presence of excess donor, but it can be detected at higher temperatures and in the absence of the donor; it predominates at high CO pressures. In all systems in which the monosubstituted compound $M(CO)_5D$ is formed photochemically, the rate of Reaction 2 is greater than that of Reactions 3 and 4. The combined effect of Reactions 1–4 can best be seen, empirically and qualitatively, from the CO liberation curves [13a], since the quantity of CO liberated and removed at a given time is directly proportional to the photochemically formed products. At the same time, it is immediately seen how many equivalents of CO can be liberated photochemically.

The mechanism of the formation of photochemical substitution products of metal-carbonyl derivatives was elucidated for complexes $M(CO)_5D$. In the primary photochemical reaction, CO or the ligand D are split off from the excited molecule $\{M(CO)_5D\}^*$ according to either Equation 5 or 6. Since the photochemical reaction 6 does not contribute to the formation of the disubstitution product $M(CO)_4D_2$, the quantum yield $\Phi$ for the preparation of disubstitution products of metal carbonyl derivatives cannot be unity, even at time $t = 0$. It was found to be 0.05–0.3, depending on the system examined [13].

Primary photochemical reaction:

$$M(CO)_5D + h\nu \rightarrow \{M(CO)_5D\}^* \begin{cases} \nearrow \{M(CO)_4D\} + CO & (5) \\ \searrow \{M(CO)_5\} + D & (6) \end{cases}$$

Secondary reactions:

$$\{M(CO)_4D\} + D \rightarrow M(CO)_4D_2 \quad (7)$$

$$\{M(CO)_4D\} + (CO)_{solv} \rightarrow M(CO)_5D \quad (8)$$

$$M(CO)_4D_2 + (CO)_{solv} \rightarrow M(CO)_5D + D \quad (9)$$

$M(CO)_4D_2$ is formed in Reaction 7 and is consumed in Reaction 9. The contributions of Reactions 8 and 9 depend on the central atom and the solvent; that of Reaction 9 increases rapidly with temperature. Thus, if $M(CO)_4D_2$ is insoluble in the solvent, Reaction 9 is

[13a] *W. Strohmeier, D. v. Hobe, G. Schönauer,* and *H. Laporte,* Z. Naturforsch. *17b,* 502 (1962).

practically eliminated, and the reaction of $M(CO)_6$ leads directly to $M(CO)_4D_2$, *e.g.* $Mo(CO)_4D_2$ from $Mo(CO)_6$, even when, for example, only 1.6 moles of CO per mole of $M(CO)_6$ have been split off photochemically. If the final product $M(CO)_4D_2$ is soluble in the solvent, then at 80 % elimination of CO (*i.e.* 1.6 moles of CO per mole of hexacarbonyl), $Mo(CO)_6$ gives a mixture of $Mo(CO)_5D$ and $Mo(CO)_4D_2$, whereas $Cr(CO)_6$ gives only $Cr(CO)_5D$ [12]. Reactions 8 and 9 are more important in the case of $Cr(CO)_6$, in contrast to that of $Mo(CO)_6$, so that $Cr(CO)_4D_2$ can only be formed after all the $Cr(CO)_6$ has first been converted to $Cr(CO)_5D$.

The number of carbon monoxide ligands in a metal carbonyl or its derivatives which can be replaced photochemically by the donor D depends on both the type of metal carbonyl and donor concerned, and must be determined for each individual system, preferably by plotting the CO elimination curves [13a]. The differences in ability of the CO groups to undergo replacement is due to differences in the strengths of the M–CO and M–D bonds. These differences are chiefly responsible for the participation of Reactions 5 and 6 in the primary photochemical act.

## VI. Photochemical Preparation of Derivatives with n- and $\pi$-Electron Donors

The photochemical substitution products of metal carbonyls or their derivatives described so far in the literature are listed in Tables 2 and 3.

Table 2. Derivatives of metal carbonyls prepared photochemically with n-electron donors.

| Metal carbonyl | Donor |
|---|---|
| $Cr(CO)_6$ | aniline, pyridine [2]; n-propylamine, pyrrolidine, hexamethylene tetramine [53]; triethylamine, piperidine [*] [11]; α-picoline, 2,6-lutidine, 4-chloropyridine, quinoline, isoquinoline [16]; acetonitrile, benzonitrile [21]; dimethyl sulfoxide [28]. |
| $Mo(CO)_6$ | *p*-phenylene diamine [*], 4-aminopyridine [*] [29]; piperidine [*] [11]; pyridine [*] [14]; acetonitrile [*] [10]. |
| $W(CO)_6$ | aniline, pyridine [*] [15]; triethylamine, piperidine [*] [11]; acetonitrile [*] [10]; dimethyl sulfoxide [28] |
| $[(H_3CO_2C)_2C_6H_4]Cr(CO)_3$ | aniline, quinoline, acetonitrile, benzonitrile [20]; piperidine, pyridine, triphenylphosphine, dimethyl sulfoxide [17]; cyclohexyl isonitrile [54b] |
| $C_6H_6Cr(CO)_3$ | piperidine [**], quinoline, cyclohexyl isonitrile [54b]; pyridine, triphenylphosphine, dimethyl sulfoxide [17]; acetonitrile [**], benzonitrile [**] [20] |
| $[1,3,5\text{-}(CH_3)_3C_6H_3]Cr(CO)_3$ | piperidine [**], quinoline, benzonitrile [**], cyclohexyl isonitrile [54b]; pyridine, triphenylphosphine, dimethyl sulfoxide [17]. |
| $[(CH_3)_6C_6]Cr(CO)_3$ | piperidine [**], pyridine [**], quinoline, benzonitrile [**], triphenylphosphine, cyclohexyl isonitrile [**] [54b] |
| $Mn_2(CO)_{10}$ | triethylphosphine, triphenylphosphine, triphenyl phosphite [24] |
| $C_5H_5Mn(CO)_3$ | tetrahydrofuran [**] [55]; aniline, piperidine, triphenylstibine [51]; trimethylamine, dimethylamine, n-propylamine, n-hexylamine, pyrrolidine, 2,5-dimethylpyrrolidine, triethylamine[**], quinoline, ammonia[26]; piperazine, hexamethylene tetramine, triethylene diamine [22]; pyridine [18]; acetonitrile, benzonitrile [25]; triphenylphosphine [*] [8]; 1,2-bisdiphenylphosphinylethane [*], triphenylarsine [24]; sulfur dioxide, tetramethylene sulfoxide, diphenyl sulfoxide, ethylene glycol sulfite, hydrogen sulfide[**]diethyl sulfide, tetramethylene sulfide, diphenyl sulfide[27]; dimethyl sulfoxide [*] [23]; cyclohexyl isonitrile [54a]. |
| $[CH_3C_5H_4]Mn(CO)_3$ | piperidine [19]; pyridine [18]; triphenylphosphine, 1,2-bisdiphenylphosphinylethane [*], triphenylarsine [24]; sulfur dioxide, dimethyl sulfoxide, diphenyl sulfoxide [28]. |
| $[CH_3COC_5H_4]Mn(CO)_3$ | triphenylphosphine [28] |
| $Fe(CO)_5$ | triphenylphosphine [*], triphenylarsine [*], *o*-phenylene bisdimethylarsine [*] [24]. |

[*] Both mono- and disubstitution products were found.

[**] Experiments in which the photochemical formation of a compound was detected by infrared measurements, by elimination of CO, or indirectly by donor exchange but in which the compound could not be isolated in pure form.

Since the method is generally applicable and is limited only by the stability and hence the possibility of isolation of the reaction product, no attempt was probably made in many cases to obtain all other possible derivatives by analogous methods. Thus, for example, it was shown that substituted pyridines react photochemically with $Cr(CO)_6$, but the analogous reactions with $Mo(CO)_6$ and $W(CO)_6$ were not carried out.

In the particular case of $Mn_2(CO)_{10}$, photochemical reactions with strong donors such as $PR_3$ give diamagnetic substances $[Mn(CO)_4PR_3]_2$ [24], whereas thermal reactions yield paramagnetic compounds $Mn(CO)_4PR_3$ [54].

π-Electron donors such as olefins, oligo-olefins, and acetylenes react in the primary act in the same way as n-electron donors, *i.e.* the double or triple bond adds on at the coordination vacancy of the highly reactive fragment $\{Y_aM(CO)_{x-1}\}$. However, in addition to the photochemical substitution reaction, acetylene derivatives are often observed to undergo cyclization by addition of carbon monoxide. The structure and formula of the reaction products can be derived from the original publications (see Table 3).

## VII. Polynuclear Compounds with Bifunctional Donors

Bifunctional donors of general formula B–R B, where B is an atom from group V or VI of the periodic table or a residue containing double or triple bonds, can act as bridge ligands and form polynuclear substitution products according to the equation:

$$2\,Y_aM(CO)_X + B{-}R{-}B \rightarrow Y_aM(CO)_{X-1}B{-}R{-}B(CO)_{X-1}MY_a + 2\,CO$$

Such compounds can also be prepared advantageously by a photochemical method, as shown in Table 4. The structure of the reaction products obtained with bi- or multi-functional π-electron donors for any particular case can be found in the original literature; cyclizations were also observed, particularly with $Fe(CO)_5$.

Table 4. Polynuclear derivatives of metal carbonyls prepared photochemically with bifunctional donors B–R–B.

| Metal carbonyl | Donor |
|---|---|
| $Cr(CO)_6$ | triethylene diamine [53] |
| $C_5H_5Mn(CO)_3$ | piperazine, triethylene diamine [22]; 1,2-bisdiphenylphosphinylethane, *o*-phenylene bisdimethylarsine [24]; 1,3-cyclohexadiene [32]; 1,5-cyclooctadiene, norbornadiene [54a] |
| $[CH_3C_5H_4]Mn(CO)_3$ | 1,2-bisdiphenylphosphinylethane, *o*-phenylene bisdimethylarsine [24]. |
| $Fe(CO)_5$ | 1,2-bisdiphenylphosphinylethane [24]; cyclooctatetraene [45]; diphenylacetylene [42] |
| $C_5H_5Rh(CO)_2$ | cyclooctatetraene [52] |

[54b] *W. Strohmeier* and *H. Hellmann,* Chem. Ber. *97,* 1877 (1964).

## VIII. Photochemical Reactions with Donors Containing Oxygen

In contrast to the photochemical reaction of group V donors with metal carbonyl derivatives, there actions with donors containing oxygen do not proceed uniformly. Ethers such as tetrahydrofuran (THF) yield monosubstitution products $M(CO)_{x-1}THF$, which are stable for a time only in solution, whereas condensation occurs with ketones such as acetone and methyl ethyl ketone or with aldehydes [55]. It is particularly interesting in this connection that, in the presence of ketones or acetaldehyde, all the carbon monoxide ligands can be removed photochemically from $C_5H_5Mn(CO)_3$ or $Mn_2(CO)_{10}$, although it has not yet been possible to isolate a definite substitution product [55]. This behavior is similar to that of epoxides, *e.g.* propylene oxide [55]. However, ethers, ketones, epoxides, and acetaldehyde react much more slowly with $Mo(CO)_6$, and the reaction stops after about one mole of CO has been split off. The experimental evidence obtained to date indicates that $Mn_2(CO)_{10}$ and $C_5H_5Mn(CO)_3$ occupy a special position as regards photochemical reactions with donors containing oxygen, such as epoxides, ketones, and aldehydes. However, it has been proved that the primary photochemical act – again in analogy to Equation 1 – proceeds according to Equation 10 with a quantum yield of $\Phi = 1.0$ [55].

$$C_5H_5Mn(CO)_3 + h\nu \rightarrow \{C_5H_5Mn(CO)_3\}^* \rightarrow \{C_5H_5Mn(CO)_2\} + CO \quad (10)$$

In contrast to monofunctional ketones, bifunctional ketones such as hexafluoroacetylacetone or acetylacetone react photochemically with metal carbonyls with liberation of hydrogen and CO to form chelates, the metal atom being simultaneously oxidized [56]. The question whether thioethers and thioketones behave differently has not yet been investigated.

## IX. Stability of the Metal Carbonyl Derivatives

The donor-acceptor bond between the donor D and the central metal atom M which functions as electron acceptor in $Y_aM(CO)_{x-1}D$ is a $\sigma$-bond and is formed with nitrogen or oxygen compounds. Donors whose functional atom belongs to the second or a higher period of the periodic table have energetically favorable d-orbitals, so that charge is returned from the central atom to the original donor ("back-donation" or $d_\pi$-$d_\pi$ bonding). A similar situation prevails in the bonding between the metal and $\pi$-electron donors ($d_\pi$-$p_\pi$ bonding). The central atom is thus an electron acceptor with respect to the $\sigma$-bond, and a donor with respect to the superimposed $\pi$-bond. The reverse is true for the ligand D. The stability of the $\sigma$-bond in the metal-carbonyl derivatives depends on the donor strength of the ligand D and the acceptor strength of the unstable photochemical primary product $\{Y_aM(CO)_{x-1}\}$. Investigations to date on organic donors containing nitrogen have shown that the donor strength depends on the bond angle, and consequently on the hybridization of the nitrogen. The most stable derivatives were obtained from ligands with a C–N–C bond angle of 109°, *i.e.* with $sp^3$-hybridization [26]. The situation appears to be similar for donors containing oxygen, which are much weaker [57]. So far it has only been possible to isolate one derivative here, *viz.* that with tetrahydrofuran (C–O–C bond angle 111°, *i.e.* $sp^3$-hybridization of oxygen); none at all has been obtained with ketones ($sp^2$-hybridization of oxygen).

Preliminary investigations on the relative acceptor strengths of the central atoms M in complexes $Y_aM(CO)_2D$ gave the following results:

$$H_3CO_2C-C_6H_4-CO_2CH_3)Cr(CO)_2D \approx$$
$$Cr(CO)_3D > C_5H_5Mn(CO)_2D > C_6H_6Cr(CO)_2D > [(CH_3)_3C_6H_3]Cr(CO)_2D.$$

For a given metal carbonyl, the stability of the derivative $Y_aM(CO)_{x-1}D$ generally increases according to the donor, in the order:

$$\text{O-compound} < \text{nitrile} < \text{N-base} < \text{P-compound} < CO.$$

However, this series has not been investigated quantitatively. The carbonyl absorption frequency is generally regarded as a measure of the bond stability: a decrease in the wave number $\tilde{\nu}_{C=O}$ of the carbonyl bond of the substituted compounds $Y_aM(CO)_{x-1}D$ with respect to that of $Y_aM(CO)_x$ indicates an increase in the double-bond character of the M–C bond in M–C–O and weaker M–D bonding. However, the changes in $\tilde{\nu}_{C=O}$ reflect only large differences, such as the transition from donors containing nitrogen to those containing phosphorus.

## X. Polarity of the Metal-Ligand Bond

The donor-acceptor bond M–D in $Y_aM(CO)_{x-1}D$ naturally possesses some polarity; accurate information about this aspect can be obtained from dipole moment measurements and by calculation of the partial dipole moment $\mu$(D–M) [58]. Experimental investigations on many photochemically produced metal carbonyl derivatives led to the interesting result that the magnitude of the partial moment $\mu$(D–M) depends practically exclusively upon the central atom and the nature of the donor [59]. The values obtained are listed in Table 5.

In Table 5, $\mu$(Ar-M) is the partial dipole moment of the ring-metal bond in arene-metal tricarbonyl and cyclopentadienylmanganese tricarbonyl derivatives, $\mu$(OC-M) is the partial dipole moment of the metal-CO bond, and $\mu$(D-M) is the partial dipole moment of the metal-ligand bond. Positive values of the partial moment are directed towards the central atom, as is indicated by the order in the notation, *e.g.* $\mu$(Ar-M) [58].

[55] *W. Strohmeier, C. Barbeau*, and *D. v. Hobe*, Chem. Ber. *96*, 3254 (1963).

[56] *J. C. Goan, C. H. Huether*, and *H. E. Podall*, Inorg. Chem. *2*, 1078 (1963).

[57] *C. Barbeau*, Ph.D. Thesis, Universität Würzburg, 1963.

[58] *W. Liptay, W. Strohmeier*, and *H. Hellmann*, Ber. Bunsenges. physik. Chem. *64*, 91 (1964).

[59] *W. Strohmeier* and *H. Hellmann*, Ber. Bunsenges. physik. Chem. *64* (1964), in the press.

The values shown in Table 5 have been confirmed as regards their order and relative magnitudes; however, their absolute values are dependent upon the magnitude of the M–CO moment $\mu(OC-M) = 0.8$ Debyes. Since $\mu(OC-M)$ is invariably small, variations in $\mu(OC-M)$ cause only insignificant changes in the values given. The estimated margin of error in the partial moment $\Delta\mu$ was $\pm$ 0.3 Debyes.

Table 5. Partial dipole moments in metal carbonyl derivatives.

| Acceptor | μ(Ar–M) [*] [Debyes] | μ(OC–M) [*] [Debyes] | μ(OC–M) [**] [Debyes] | μ(D–M) for the donors | | | | |
|---|---|---|---|---|---|---|---|---|
| | | | | N-bases | RCN | $OSR_2$ | $P(C_6H_5)_3$ | RNC |
| $[H_3CO_2C)_2C_6H_4]Cr(CO)_2$ | 4.9 | 0.8 | 0.8 | 3.9 | 2.1 | | 3.1 | 2.0 |
| $C_6H_6Cr(CO)_2$ | 5.5 | 0.6 | 0.2 | 4.0 | 2.2 | | 2.8 | 1.7 |
| $[1,3,5-(CH_3)_3C_6H_3]Cr(CO)_2$ | 6.0 | 0.5 | 0.0 | 4.0 | 2.1 | | 2.6 | |
| $[(CH_3)_6C_6]Cr(CO)_2$ | 6.5 | 0.3 | 0.0 | 4.0 | | | 2.8 | |
| $C_5H_5Mn(CO)_2$ | 4.5 | 0.8 | 0.8 | 5.3 | 3.0 | | 4.4 | 3.0 |
| $Cr(CO)_5$ | | 0.8 | 0.8 | 5.3 | 4.0 | ca. 4 | 4.5 | 2.9 |
| $Mo(CO)_5$ | | 0.8 | 0.8 | 5.3 | | | | |
| $W(CO)_5$ | | 0.8 | 0.8 | 5.9 | | ca. 5 | 4.8 | |

[*] Measured in $XArCr(CO)_3$ or $M(CO)_6$.

[**] Measured in $XArCr(CO)_2D$ or $M(CO)_5D$.

The largest partial moments $\mu(D-M)$ were found for the nitrogen bases, as donors without back-donation. With ligands capable of back-donation, *e.g.* donors containing sulfur and phosphorus ($d_\pi$-$d_\pi$ bonding) and isonitriles ($d_\pi$-$p_\pi$ bonding), the partial dipole moments are smaller. However, no conclusion can be drawn from the relative decreases in $\mu(D-M)$ regarding increases in back-donation, since, for example, the partial dipole moments of the $\sigma$-bonds in derivatives containing nitriles as ligands are already smaller than those in nitrogenous derivatives. A detailed discussion of the variation of the partial dipole moments with the donor and substitution on the aromatic ring can be found in the original publications [59].

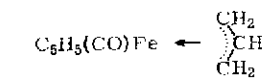
## XI. Photochemically Induced Exchange Reactions with $^{14}C$-Labelled Ligands

Most metal carbonyls and their derivatives do not undergo exchange of their CO ligands with $^{14}CO$ at room temperature and at higher temperatures [60,61], so that it was necessary to prepare the $^{14}CO$-labelled metal carbonyls by total synthesis.

On ultraviolet irradiation of metal carbonyls, CO is split off in the primary photochemical process, and is added on again in a dark reaction in the absence of a donor; this observation led to a simple photochemical method for the preparation of $^{14}CO$-labelled metal carbonyls and their derivatives: the inactive metal carbonyl is irradiated in an atmosphere of $^{14}CO$ [61,62], thus avoiding the complicated total synthesis with $^{14}CO$.

[60] *D. F. Keeley* and *R. E. Johnson*, J. inorg. nuclear Chem. *11*, 33 (1959).

[61] *W. Strohmeier* and *R. Müller*, Z. physik. Chem. N.F. *28*, 112 (1961).



[62] *W. Strohmeier* and *D. v. Hobe*, Z. Naturforsch. *18b*, 770 (1963).

Further investigations on these photochemically induced exchange reactions led to the interesting result that, on ultraviolet irradiation of arene-metal tricarbonyls in the presence of the corresponding [$^{14}C$]arenes, the latter were also exchanged [63]. It was therefore concluded that, in the photo-excited molecule $ArM(CO)_3$, not only is the M–CO bond broken, but also, to a certain extent, the Ar–M bond:

$$ArM(CO)_3 + Ar^* \xrightarrow{h\nu} Ar^*M(CO)_3 + Ar$$

## XII. Photochemical Rearrangements and Disproportionations

While the photochemical reactions of metal carbonyls and their derivatives described so far are generally applicable, mention will now be made of a few interesting photochemical reactions of metal carbonyl derivatives, for which there is no evidence as yet that they occur in other systems. Thus, for example, on ultraviolet irradiation and elimination of CO, the $\sigma$-allyl compound $C_5H_5Fe(CO)_2-CH_2CH=CH_2$ rearranges to form the $\pi$-allyl compound *(1)* [64]. An analogous

*(1)*

photochemical rearrangement was also achieved with $C_5H_5Mo(CO)_2-CH_2CH=CH_2$ [65]. A few photochemical rearrangements are also known for iron carbonyl acetylene derivatives. Thus, ultraviolet irradiation of $Fe_2(CO)_6[H_5C_6-C\equiv C-C_6H_5]_2$ yields tetraphenylcyclobutadienyliron tricarbonyl, and, in the presence of sulfur, tetraphenylthiophene. $Fe_2(CO)_7[H_6C_5-C\equiv C-C_6H_5]_2$ also undergoes photochemical rearrangement to give new compounds [66].

Disproportionations of metal carbonyls by the action of ultraviolet light have been described for the system $Fe(CO)_5 + (CH_3)_2SO$ [or $OAs(C_6H_5)_3$ or $OP(C_6H_5)_3$] [67]. These lead to carbonyltetraferrates and octacarbonyldiferrates.

[65] *M. L. H. Green*, J. chem. Soc. (London) *1963*, 889.

[66] *W. Hübel* and *E. H. Braye*, J. inorg. nuclear Chem. *10*, 250 (1959).

[67] *W. Hieber* and *A. Lipp*, Chem. Ber. *92*, 2085 (1959).

## XIII. Toxicity of Metal Carbonyl Derivatives

It is known that the vapors and dusts of metal carbonyls are highly toxic, but so far little systematic and quantitative work has been carried out. For some metal carbonyl derivatives – mostly prepared photochemically – the mouse test, in which the substances were injected intravenously, also showed occasionally high toxicities, with $LD_{50}$ values below 1 mg/kg [68]. A few examples are shown in Table 6.

Table 6. Toxicity of metal carbonyl derivatives in the mouse test.

| Substance | $LD_{50}$ [mg/kg] | Confidence limit [mg/kg] |
|---|---|---|
| Cycloheptatrienyl-$Cr(CO)_3$ | 0.708 | 0.501–1.00 |
| Cycloheptatrienyl-$Mo(CO)_3$ | >20 | – |
| Piperidino-$Cr(CO)_5$ | 0.708 | 0.562–0.891 |
| Piperidino-$W(CO)_5$ | 0.631 | 0.501–0.796 |
| $C_5H_5Mn(CO)_3$ | 3.16 | 0.316–31.6 |
| Piperidino-$Mn(CO)_2C_5H_5$ | 6.31 | 5.01–7.94 |
| $(C_6H_5)_3PMn(CO)_2C_5H_5$ | >20 | – |

The investigations so far have shown no connection between the toxicity and the ligands. All future preparative work on the production of metal carbonyl derivatives should therefore be carried out with care.

## XIV. Prospects

The photochemical reaction of metal carbonyls and metal carbonyl derivatives with n- and π-electron donors makes it possible to prepare a large number of hitherto unknown compounds. The principal advantage of the photochemical method is that it permits the synthesis of unstable derivatives. Moreover, since it is known that metal carbonyls are important catalysts which almost certainly involve their unstable derivatives as intermediates in the reaction mechanism, this phenomenon can now be investigated in greater detail if the photochemically prepared derivative is used directly as reaction partner instead of the metal carbonyl itself.

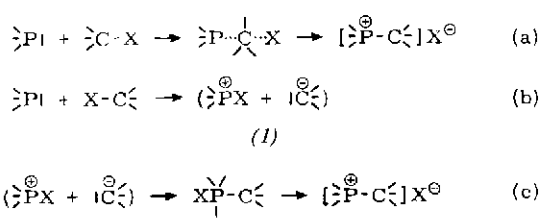
# Phosphonium Salt Formation of the Second Kind

BY PRIV.-DOZ. DR. H. HOFFMANN AND DIPL.-CHEM. H. J. DIEHR

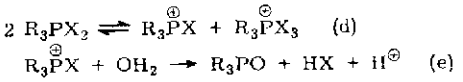
INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT MAINZ (GERMANY)

*Organic compounds containing a positively polarized halogen atom react with tertiary phosphines either with reductive elimination of the halogen or with formation of phosphonium salts and quasi-phosphonium salts, depending on the solvent. In this reaction, the phosphine first attacks the halogen.*



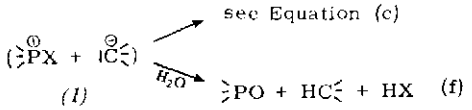
I. Introduction
II. *C*-Phosphonium salts
1. From α-bromo sulfones
2. From α-bromo nitriles
3. From phenylbromoacetylene
4. From polyhalogenomethanes
5. From α-halogenoalkylphosphonium salts and α-halogenoalkylphosphine oxides
III. Quasi-phosphonium salts
1. From bromoarylamines and bromophenols
2. From α-halogeno ketones and α-halogeno aldehydes
3. From amides and esters of α-halogenocarboxylic acids
4. From α,β-dihalogenoearbonyl compounds.

## I. Introduction

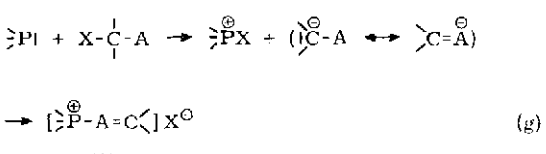


Owing to their strongly nucleophilic character, tertiary phosphines generally react with alkyl halides by an $S_N2$ mechanism. No comprehensive kinetic studies of the dependence of the rate of reaction on the constitution of the halogeno compound have yet been carried out for the formation of phosphonium salts by this process. However, the substituent effect may be assumed to be the same as that found for other $S_N2$ reactions: fundamentally, the reaction can be accelerated by both electron donors and electron acceptors. Since it involves both the formation and cleavage of bonds, the decisive factor is which of the two processes is further advanced in the transition state.

However, strong electron acceptors can cause a fundamental change in the reactivity of the halogeno compound by polarizing the carbon-halogen bond, thus giving the halogen atom a partial positive charge and simultaneously stabilizing the carbanion remaining after removal of a halogen cation. This favors nucleophilic attack on the halogen. The center of the $S_N2$ reaction is thus shifted from the carbon atom [Equation (a)] to the halogen [Equation (b)].



This means that, in the reaction of organic halides with tertiary phosphines, an ion pair with a halogenophosphonium cation and a carbanion is formed first [Equation (b)], instead of an alkylphosphonium cation and a halogen anion [Equation (a)]. As was first demonstrated by *Haszledine* [1], a phosphonium salt can be formed from the ion pair according to Equation (c) [2]. The initial product is an associate with a pentacovalent phosphorus atom, from which the halogen dissociates as an anion.



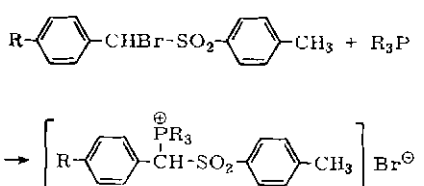
Such a *phosphonium salt formation of the second kind* can lead *via* reactive intermediates [Equations (b) and (c)] to the same product as direct $S_N2$ substitution of the halogen by primary attack of the phosphine on the carbon. The two reactions can be distinguished by the reactivity of the halogenophosphonium cation. It is known from studies of phosphine dihalides [Equation (d)] [3] that halogenophosphonium cations react extremely readily with solvolytic agents according to Equation (e).

Reactions involving initial attack on the halogen are therefore characterized by the fact that in solvolytic solvents phosphonium salt formation is partially or completely suppressed in favor of reductive dehalogenation of the organic halide [Equation (f)], the extent of suppression depending on the ratio of the rates of association and solvolysis.

Phosphonium salt formation of the second kind is therefore always to be expected when the carbanions formed by the primary dehalogenation are stabilized by resonance. However, as a result of the mesomerism of the anion, the linkage to the phosphorus in the association step can take place through heteroatoms A according to Equation (g).

[1] *R. N. Haszledine* and *B. O. West*, J. chem. Soc. (London) *1956*, 3631.

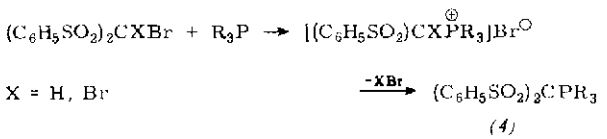
[2] Cf. *L. Horner* and *H. Oediger*, Chem. Ber. *91*, 437 (1958).



[3] See, for example, *L. Horner*, *H. Oediger*, and *H. Hoffmann*, Liebigs Ann. Chem. *626*, 26 (1959).

Thus, quasi-phosphonium salts *(2)* [4] can also be formed by a mechanism of the second kind. A few examples [5] of these reactions will be discussed below.

## II. C-Phosphonium Salts

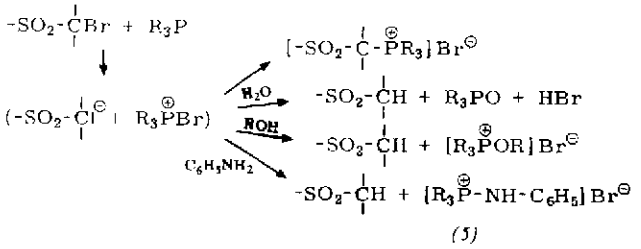


### 1. From α-Bromo Sulfones

Sulfone groups acidify adjacent C–H bonds owing to their strongly electron-attracting properties. For the same reason, the halogen in α-halogeno sulfones can be readily transferred as a cation, but undergoes anionic substitution only with difficulty [6]. The reactions of α-halogeno sulfones are therefore good examples of phosphonium salt formations of the second kind [7]. The reaction rates characteristically increase with increasing positive polarization of the halogen: in toluene, the sulfone *(3a)* forms a phosphonium salt only after prolonged boiling, but the nitro compound *(3b)* reacts practically instantaneously.

*(3a)*: R = H
*(3b)*: R = $NO_2$

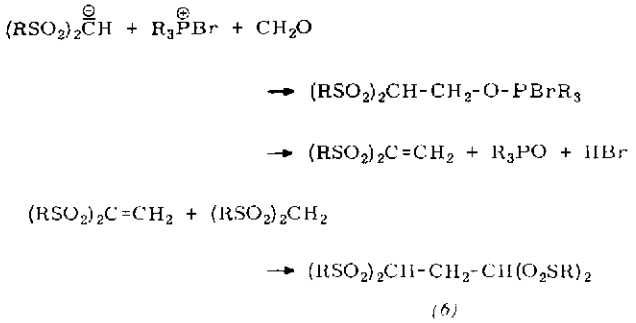
Bisphenylsulfonylbromomethane and bisphenylsulfonyldibromomethane also react very rapidly, but the phosphonium salts initially formed are unstable. They lose hydrogen bromide or bromine spontaneously to give a very stable ylide *(4)*.



Although the phosphonium salts and the ylides *(4)* are stable to hydrolysis, only dehalogenated sulfone, phosphine oxide, and hydrogen bromide are found after reaction of the components in the presence of water. In the presence of other reagents which can react with the bromophosphonium cation, the reaction proceeds in a similar manner. In alcohol an alkoxyphosphonium bromide which decomposes spontaneously to phosphine oxide and alkyl halide is formed together with dehalogenated sulfone. Reaction in aniline yields a phenylaminophosphonium salt *(5)* which can be isolated.

[4] The term "quasi-phosphonium salt" is applied to onium compounds of phosphorus in which organic residues are linked to the phosphorus through heteroatoms, *e.g.* $[R_3\overset{\oplus}{P}-OR']X^{\ominus}$ and $[R_2\overset{\oplus}{P}-NHR']X^{\ominus}$.

[5] Only reactions with *C*-halogeno compounds are mentioned.

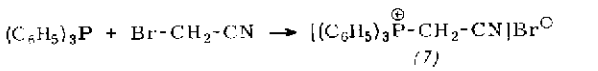


[6] *T. Thomson* and *T. S. Stevens*, J. chem. Soc. (London) *1932*, 69; *W. M. Ziegler* and *R. Connor*, J. Amer. chem. Soc. *62*, 2596 (1940).

[7] *H. Hoffmann* and *H. Förster*, Tetrahedron Letters *1963*, 1547.

(5)

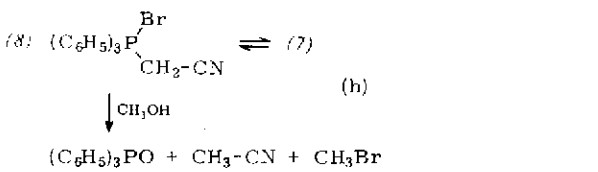
Formation of the tetrasulfone *(6)* in the reaction of bisphenylsulfonylbromomethane with triphenylphosphine in the presence of formaldehyde can be attributed to a trapping



(6)

reaction of a sulfone carbanion. The same compound *(6)* is formed from bisphenylsulfonylmethane and formaldehyde on addition of base [8].

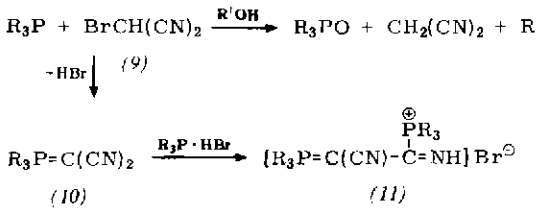
However, the possibility of carrying out the same condensations with the bisphenylsulfonylbromomethane/phosphine system as with the bisphenylsulfonylmethane/base system is very slight. As a rule, the carbanions react more rapidly with the bromophosphonium cation than with the added carbonyl compound.



## 2. From α-Bromo Nitriles

According to *Schiemenz* and *Engelhard* [9], bromoacetonitrile and triphenylphosphine react in benzene to form cyanomethyltriphenylphosphonium bromide *(7)*.

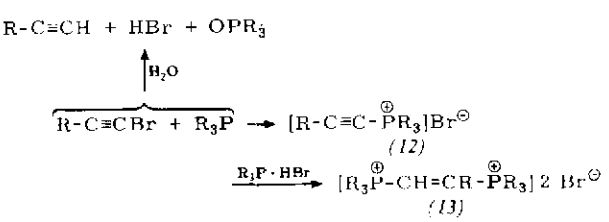
(7)



Although *(7)* does not react with alcohols, the yield in benzene containing methanol is much lower as dehalogenation predominates. *Schiemenz* showed that this reaction does not proceed by a free-radical mechanism, and assumed that a compound *(8)* containing pentacovalent phosphorus is formed directly, and is then either dissociated or solvolysed [Equation (h)].

(h)

Because of the equilibrium *(7)* ⇌ *(8)* this assumption is, however, incompatible with the stability of the phosphonium salt towards alcoholysis. Thus, here too the solvolysis must begin with the preceding carbanion-bromophosphonium ion pair [10].



It is noticeable that, in contrast to the behavior of bromo sulfones, phosphonium salt formation with bromoacetonitrile is not entirely suppressed in the presence of alcohol. Thus, here the rate of solvolysis must be comparable with the rate of association. However, the stability of the carbanion can be increased by introduction of a second cyano group, with a resultant decrease in the rate of association. Thus, bromomalonodinitrile reacts with phosphines in alcohol with complete dehalogenation [11]. In acetonitrile, the reaction of bromomalonodinitrile *(9)* is complicated by secondary reactions: addition of a phosphonium bromide onto the ylide *(10)* formed first results in a compound with the supposed constitution *(11)*.

## 3. From Phenylbromoacetylene

Theoretical considerations and *Arens'* studies [12] of the behavior of phenylbromoacetylene toward thiols indicate that the formation of phenylethynyltriphenylphosphonium bromide *(12)* described by *Viehe* and *Franchimont* [13] also involves initial attack on the halogen.

Like almost all other known phosphonium salts, *(12)* is not hydrolysed by water (either neutral or acidic). If phenylbromoacetylene is treated with triphenylphosphine in aqueous acetonitrile, only half of the acetylenic compound is converted into a phosphonium salt; the other half is dehalogenated to phenylacetylene. The dehalogenation gives rise to hydrogen bromide, which causes excess phosphine to add onto the ethynylphosphonium salt to form a bisphosphonium salt *(13)* [14].

Phosphonium salt formation is again only partly supressed in aqueous media. This may be explained by equality of the rates of solvolysis and C-phosphonium salt formation.

[8] *A. Kötz*, Ber. dtsch. chem. Ges. *33*, 1120 (1900).

[9] *G. P. Schiemenz* and *H. Engelhard*, Chem. Ber. *94*, 578 (1961).

[10] *A. J. Speziale* and *L. R. Smith*, J. Amer. chem. Soc. *84*, 1868 (1962).

[11] *H. Hoffmann* and *H. Beller*, unpublished work.

[12] *J. F. Arens*, Recueil Trav. chim. Pays-Bas *82*, 182 (1963).

[13] *H. G. Viehe* and *E. Franchimont*, Chem. Ber. *95*, 319 (1962).

[14] *H. Hoffmann* and *H. Förster*, Tetrahedron Letters *1964*, 983.

An alternative interpretation would envisage simultaneous phosphonium salt formation of both the first and second kinds. Since the reaction rates in dry and aqueous acetonitrile are practically equal, dehalogenation by the mechanism described for α-halogenophosphine oxides and α-bromocamphor (cf. Sections II.5 and III.2) can be ruled out.

### 4. From Polyhalogenomethanes

As mentioned above, *C*-phosphonium salt formation with initial attack of the phosphine on the halogen was first discussed by *Haszledine* [1] for the reaction of trifluoroiodomethane with trimethylphosphine. In addition to small quantities of trifluoromethane, this reaction yields mainly trifluoromethyldimethylphosphine, since the trifluoromethyltrimethylphosphonium iodide initially formed is demethylated by excess trimethylphosphine [see Equation (i)].

$$(CH_3)_3P + ICF_3 \rightarrow [(CH_3)_3\overset{\oplus}{P}\text{-}CF_3]I^{\ominus}$$

$$\xrightarrow{(CH_3)_3P} (CH_3)_2P\text{-}CF_3 + [(CH_3)_4\overset{\oplus}{P}]I^{\ominus} \quad \text{(i)}$$

The assumption of initial attack on the halogen agrees with various other reactions of trifluoroiodomethane: *e.g.* its reaction with hydroxide ions yields trifluoromethane and hypoiodite [15]. Tertiary amines also attack the iodine. However, since the electron octet on nitrogen cannot be expanded, no quaternary ammonium salt is formed; the trifluoromethyl anion reacts with the solvent to form trifluoromethane [1].

Despite the weaker positive polarization of their halogen atoms, carbon tetrabromide [16] and carbon tetrachloride [17, 18] are also initially attacked by triphenylphosphine at the halogen. In inert solvents, trihalogenomethylphosphonium salts are formed first, and these react with additional phosphine to form ylides *(15)*. In alcohol, the ion pair *(14)* initially formed is solvolysed with formation of trihalogenomethane, phosphine oxide, and alkyl halide [18].

$$R_3PO + HCX_3 + R'X$$

$$\uparrow R'OH$$

$$R_3P + CX_4 \rightarrow (R_3\overset{\oplus}{P}X + \overset{\ominus}{C}X_3) \rightarrow [R_3\overset{\oplus}{P}\text{-}CX_3]X^{\ominus}$$

*(14)*

$$\downarrow R_3P$$

$$R_3P{=}CX_2 + R_3PX_2$$

*(15)*

*Rabinowitz* [17] was able to rule out a free-radical mechanism for the reaction of tertiary phosphines with carbon tetrachloride. A carbene mechanism is also unlikely, since no cyclopropane derivative is formed in the presence of tetramethylethylene, although the latter is a better carbene scavenger than triphenylphosphine [17].

In contrast to the carbon tetrahalides, bromoform appears to react with triphenylphosphine by a free-radical chain reaction [19].

$$R_3P + {}^{\bullet}CHBr_2 \rightarrow R_3\overset{\bullet}{P}\text{-}CHBr_2 \xrightarrow{+Br_3CH}$$

$$[R_3\overset{\oplus}{P}\text{-}CHBr_2]Br^{\ominus} + {}^{\bullet}CHBr_2 \quad \text{(k)}$$

This reaction [Equation (k)] proceeds spontaneously at elevated temperatures and is initiated at room temperature by light or chain starters. On the other hand, in the presence of strong bases, ylides *(16)* are formed from bromoform, chloroform, or methylene chloride with tertiary phosphines *via* a carbene mechanism [20].

$$R_3P + IC\begin{matrix}X\\Y\end{matrix} \rightarrow R_3P{=}C\begin{matrix}X\\Y\end{matrix}$$

*(16)*

### 5. From α-Halogenoalkylphosphonium Salts and α-Halogenoalkylphosphine Oxides

The increase in the acidity of the hydrogen atom attached to the carbon atom adjacent to the phosphorus in phosphonium salts and phosphine oxides corresponds to a slight increase in the positive polarization of the halogen in α-halogenoalkylphosphonium salts and phosphine oxides. Consequently, the reaction of phenyllithium with the bromo- or iodomethyltriphenylphosphonium cation *(17)* results in removal of halogen cations as well as of protons. Methylenetriphenylphosphorane and the halogenomethylenetriphenylphosphorane are formed together (see Equation (l) [20, 21]):

$$[R_3\overset{\oplus}{P}\text{-}CH_2X]X^{\ominus} + RLi \begin{matrix}\nearrow R_3P{=}CH_2 + RX + LiX\\ \searrow R_3P{=}CHX + RH + LiX\end{matrix} \quad \text{(l)}$$

*(17)*

R = $C_6H_5$; X = Br, I

On the other hand, only protons are split off from the corresponding chloromethylphosphonium salt [22] since nucleophilic attack on chlorine is more difficult than on bromine, while chlorine increases more strongly the acidity of the C–H bond.

Chloromethylphosphonium cations *(17a)* react with tertiary phosphines only in acidic solution, where they undergo dehalogenation [23].

$$[R_3\overset{\oplus}{P}\text{-}CH_2Cl] + PR_3 + H^{\oplus} \rightarrow \left[R_3\overset{\oplus}{P}\text{-}\overset{H}{C}H_2 \cdots \overset{Cl}{P}R_3\right]$$

*(17a)*

$$\downarrow$$

$$[R_3\overset{\oplus}{P}\text{-}CH_3] + Cl\overset{\oplus}{P}R_3$$

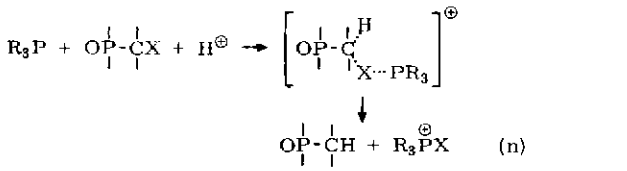
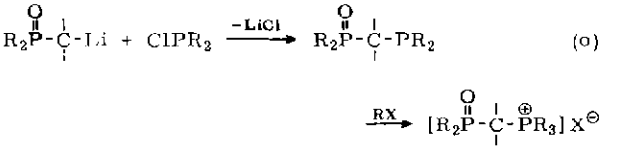
[23] *H. Hoffmann*, Habilitation Thesis, Universität Mainz, 1962.

This reaction evidently represents the limiting case: the positive polarization of the halogen is so slight that it can only be split off if a proton is available to neutralize the charge on the carbanion (push-pull reaction).

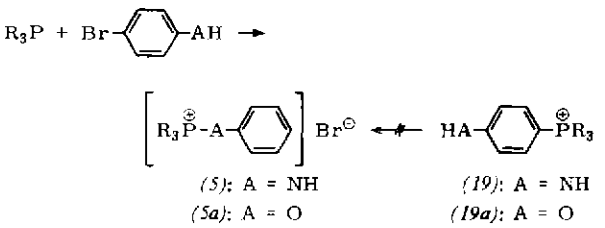


The bromomethyltriphenylphosphonium cation *(17b)* is sufficiently reactive to be dehalogenated by triphenylphosphine in alcohol [24] or to form a bisphosphonium salt in inert solvents [25].



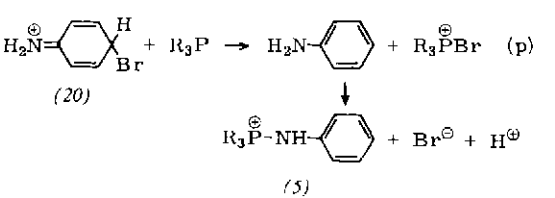
According to this formulation, the bisphosphonium salt *(18)* should be formed from the ylide and a bromophosphonium cation. However, such a reaction is evidently possible only with very reactive ylides. Thus, it can be concluded from findings of *Ramirez* [16] and *Rabinowitz* [17] that no bisphosphonium salts are formed from trichloromethyl- and tribromomethyltriphenylphosphonium salts, since Reaction (m) stops at the ylide.

Since the electron attraction of the phosphine oxide group is weaker than that of the phosphonium group, in the examples investigated so far, both α-chloroalkyl- and α-bromoalkylphosphine oxides are dehalogenated by phosphines only in acidic solution [see Equation (n)] [23].



Phosphoniophosphine oxides were not obtained in these reactions. However, they can be prepared by the route indicated in Equation (o) [23].

## III. Formation of Quasi-Phosphonium Salts



### 1. From Bromoarylamines and Bromophenols

It is solely *C*-phosphonium salts that are formed in the examples of phosphonium salt formation of the second kind referred to so far. The overall reaction corresponded to direct substitution of the halogen by the phosphine. However, as mentioned above, if the system formed by removal of the bromo cation is capable of resonance, quasi-phosphonium salts *(2)* can also be obtained. Examples of this are given by the reaction of *o*- and *p*-bromo- or iodoarylamines and -phenols [26, 27]. On reaction with tertiary phosphines in inert solvents or in the melt, these compounds form arylamino- or aryloxyphosphonium salts, *e.g. (5)* and *(5a)*.

Here the constitution of the products shows that no direct nucleophilic substitution of the halogen has occured. The unlikely hypothesis of initial formation and subsequent rearrangement of aminoaryl- or hydroxyarylphosphonium salts was easily disproved: compounds *(19)* and *(19a)*, which can be prepared by another route, do not undergo rearrangement.

From bromoarylamines and phosphines the corresponding dehalogenated amines are formed together with phosphine oxide and hydrogen bromide or alkyl halides in the presence of water or alcohol, even when conditions are applied under which the arylaminophosphonium salts are stable to solvolysis. A significant point in the explanation of the reaction mechanism is that the reaction of the halogenated arylamines is catalysed by the minute amounts of acid which are formed when these compounds are heated. This observation suggests that it is not the amine itself which reacts, but the cation *(20)* formed by addition of a proton at the *o*- or *p*-position. A halogen cation is removed from this by the phosphine at a rate which depends on its nucleophilicity. The resulting bromophosphonium cation then reacts either with the solvent or in a known manner with the amine (or phenol) according to Equation (p).

The formation of quasi-phosphonium salts from tertiary amines, *e.g. p*-bromodimethylaniline, is not possible, but the primary dehalogenation can occur [27a]. Thus, if *p*-bromodimethylaniline is treated with tertiary phosphines in the presence of aniline, the phenylaminophosphonium salt *(5)* is formed together with dimethylaniline.

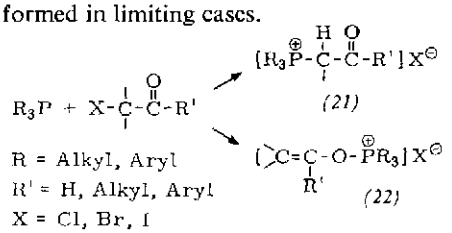
[27a] Iodoresorcinol dimethyl ether is also dehalogenated (*H. Hoffmann* and *E. Oppenheimer*, unpublished work):

$$R_3P + H^{\oplus} + C_6H_3I(OCH_3)_2 \rightarrow R_3\overset{\oplus}{P}I + C_6H_4(OCH_3)_2$$

## 2. From α-Halogeno Ketones and α-Halogeno Aldehydes

The reactions of α-halogenocarbonyl compounds with tertiary phosphines are particularly interesting. On the one hand, the conditions for phosphonium salt formation of the second kind are satisfied, since the halogen is positively polarized by the strongly electron-attracting carbonyl group, and the anion formed by removal of a halogen cation is capable of resonance. On the other hand, the α-halogen is in a type of allylic position and should therefore be readily susceptible to anionic substitution. The behavior of α-halogenocarbonyl compounds toward tertiary phosphines also appears to correspond to this "ambivalent" situation of the halogen: either β-keto- (aldehydo-) phosphonium salts *(21)* or enolphosphonium salts *(22)* are formed, depending on the structure of the halogenocarbonyl derivative (see Table 1) [28–30]; *mixtures* may also be formed in limiting cases.



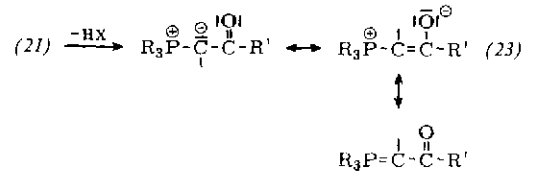


Table 1. Reactions of α-halogeno aldehydes and ketones with tertiary phosphines.

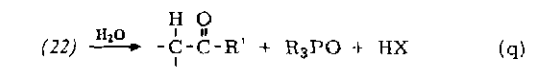

| α-Halogeno aldehyde or ketone | Phosphine | Reaction product [*] | Ref. |
|---|---|---|---|
| $ClCH_2$–CHO | $(C_6H_5)_3P$ | A (in water E) | [43] |

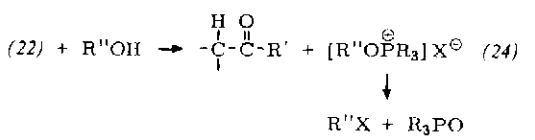
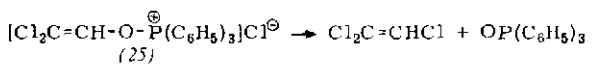
[*] K = ketophosphonium salt. A = aldehydophosphonium salt. E = enolphosphonium salt.

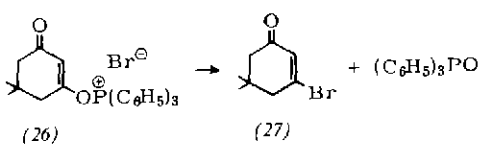
The two isomeric classes of phosphonium salts can be easily differentiated by their behavior on solvolysis. As *C*-phosphonium salts, the ketophosphonium salts *(21)*, which have been known for some time, are stable in neutral and acidic media. They react with bases, even in aqueous solution, to form ylides *(23)*, which are stabilized by the keto group.



On the other hand, like the constitutionally related aryloxyphosphonium salts, enolphosphonium salts *(22)* are extremely sensitive to solvolysis. They decompose with water to give the (singly) dehalogenated carbonyl compounds, phosphine oxide, and hydrogen halide, according to Equation (q).



(q)



When *(22)* is treated with alcohol, the alkenyloxy residue is exchanged for an alkoxy residue. An alkoxyphosphonium salt *(24)* is formed and immediately decomposes with formation of an alkyl halide.

The enolphosphonium salts *(22)* are sometimes very stable in the absence of solvolysing agents, *e.g.* the phosphonium salt *(25)* obtained from chloral and triphenylphosphine decomposes only on heating at 300 to 350 °C into trichloroethylene and triphenylphosphine oxide [30].

A similar cleavage of *(26)* to give *(27)* was described by *Borowitz* and *Grossmann* [29] and apparently proceeds even at low temperatures.

Enolphosphonium salts with hydrogen in the β-position can be decomposed thermally or by bases to acetylene derivatives [31,30].

[28] *S. Trippett*, J. chem. Soc. (London) *1962*, 2337.

[29] *I. J. Borowitz* and *L. I. Grossmann*, Tetrahedron Letters *1962*, 471.

[30] *H. Hoffmann* and *H. J. Diehr*, Tetrahedron Letters *1962*, 583.

[31] *S. T. D. Gough* and *S. Trippett*, J. chem. Soc. (London) *1962*, 2533.

As enol derivatives, the enolphosphonium salts add on bromine [30] to give adducts which also readily undergo solvolysis to yield a ketone with the same degree of halogenation as the original compound. This reaction allows partial exchange of chlorine for bromine, *e.g.* according to Equation (r):

$$R_3P + R'\text{-}CCl_2\text{-}CO\text{-}R' \rightarrow [R'\text{-}CCl{=}CR'\text{-}O\text{-}\overset{\oplus}{P}R_3]Cl^{\ominus} \quad (r)$$

$$\xrightarrow{Br_2} [R'\text{-}CClBr\text{-}CR'Br\text{-}O\text{-}\overset{\oplus}{P}R_3]Cl^{\ominus} \xrightarrow{H_2O}$$

$$R'\text{-}CClBr\text{-}CO\text{-}R' + R_3PO + HCl + HBr$$

$R' = C_6H_5$

It should be mentioned that, in the enolphosphonium salts, not only the alkenyloxy group but also the phosphine residue can be readily exchanged. Thus if an enolphosphonium salt prepared from triphenylphosphine is treated with a more nucleophilic phosphine, *e.g.* $C_6H_5P(C_2H_5)_2$, triphenylphosphine is liberated and the enolphosphonium salt of the more nucleophilic phosphine is formed [11]. With excessive phosphine, some enolphosphonium salts form vinylphosphonium salts [11], for example (R = $C_6H_5$):

$$R\text{-}CO\text{-}CH{=}CR\text{-}O\overset{\oplus}{P}R_3 + R_3P \rightarrow R\text{-}CO\text{-}CH{=}CR\text{-}\overset{\oplus}{P}R_3 + R_3PO$$

There are two similar reactions with tertiary phosphites corresponding to the reaction of the α-halogenocarbonyl compounds with phosphines to form keto- and enolphosphonium salts: the formation of β-ketophosphonates (a special case of the Michaelis-Arbuzow reaction) and the formation of enolphosphates according to *Perkow* [32]. The analogy between these two pairs of competing reactions is complete if it is assumed that the products are formed by elimination of alkyl halide from intermediate quasi-phosphonium salts.

$$\begin{array}{l} [\rangle C{=}CR'\text{-}O\text{-}PO(OR)_2] \\ \uparrow -RX \\ [\rangle C{=}CR'\text{-}O\text{-}\overset{\oplus}{P}(OR)_3]X^{\ominus} \quad (28a) \\ \rangle CX\text{-}CO\text{-}R' + (RO)_3P \\ [(RO)_3\overset{\oplus}{P}\text{-}\underset{|}{C}\text{-}CO\text{-}R']X^{\ominus} \quad (28b) \\ -RX \downarrow \\ (RO)_2OP\text{-}\underset{|}{C}\text{-}CO\text{-}R' \end{array}$$

It is therefore generally assumed that the formation of enolphosphonium salts and the first step of the Perkow reaction proceed by the same mechanism. However, despite numerous investigations, this mechanism is itself still in dispute. In principle, the initial attack on the phosphine or phosphite may be at one of the four following positions:

a) on the α-carbon,
b) on the carbonyl carbon,
c) on the carbonyl oxygen, or
d) on the halogen.

All of these possibilities have been discussed for the Perkow reaction.

Initial attack on the α-carbon would mean that the enolphosphonium salts must be formed by rearrangement of initially formed ketophosphonium salts [see Equation (s)].

$$R_3P + X\text{-}\underset{|}{C}\text{-}CO\text{-} \rightarrow R_3P\text{-}\overset{CO}{\underset{|}{C}}\text{-}X \quad (s)$$

$$\rightarrow [R_3\overset{\oplus}{P}\text{-}\underset{|}{C}\text{-}CO]X^{\ominus} \rightarrow [\rangle C{=}\underset{|}{C}\text{-}O\text{-}\overset{\oplus}{P}R_3]X^{\ominus}$$

R = Alkyl, Aryl, O-Alkyl

A mechanism of this type was suggested by *Cramer* [33] for the Perkow reaction (R – O-Alkyl), but could not be directly proved owing to the instability of the keto-quasi-phosphonium salt. This mechanism can be definitely ruled out for the formation of enolphosphonium salts. For example, α-benzoylbenzyl halides give ketophosphonium salts *(29)* as well as enolphosphonium salts *(30)* [30, 11]; the β-ketophosphonium salts *(29)* are stable and cannot be rearranged.

$$\begin{array}{l} [C_6H_5\text{-}CO\text{-}CH(C_6H_5)\text{-}\overset{\oplus}{P}R_3]Cl^{\ominus} \\ \quad (29) \\ C_6H_5\text{-}CO\text{-}CHCl\text{-}C_6H_5 \\ + \\ R_3P \\ [R_3\overset{\oplus}{P}\text{-}O\text{-}(C_6H_5)C{=}CH\text{-}C_6H_5]Cl^{\ominus} \\ \quad (30) \end{array}$$

Stronger arguments can be presented for primary attack on the carbonyl carbon. Thus, halogen-free aldehydes (and ketones) react with tertiary phosphines in the presence of electrophilic reagents to form phosphonium salts such as *(31)* and *(32)* by linkage through the carbonyl carbon [34,35].

$$\begin{array}{l} R_3P + R'CHO \\ \downarrow \\ R_3\overset{\oplus}{P}\text{-}\underset{|}{\overset{\ominus}{O}}\text{-}CHR' \quad (31) \\ \xrightarrow{HX} [R_3\overset{\oplus}{P}\text{-}\underset{|}{OH}\text{-}CHR']X^{\ominus} \quad (31) \\ \xrightarrow{R''COCl} [R_3\overset{\oplus}{P}\text{-}CHR'\text{-}O\text{-}CO\text{-}R'']X^{\ominus} \quad (32) \end{array}$$

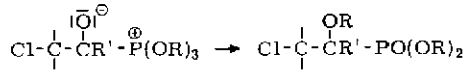
Halogeno ketones or aldehydes and phosphines or phosphites could therefore feasibly form adducts such as *(33)*, which then undergo a synchronous rearrangement to yield the enolphosphonium salt *(22)*.

$$Cl\text{-}\underset{|}{C}\text{-}\overset{O}{\overset{\|}{C}}\text{-}R' \xrightarrow{+PR'_3} Cl\text{-}\underset{|}{C}\text{-}\underset{|}{\overset{\ominus}{O}}\text{-}\overset{\oplus}{P}R_3 \quad (33)$$

$$\rightarrow (22)$$

$$\rightarrow [\rangle C\text{—}\overset{O}{\diagup\diagdown}CR'\text{-}\overset{\oplus}{P}R_3]Cl^{\ominus} \quad (34)$$

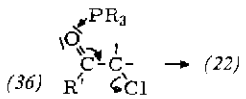
[32] *F. W. Lichtenthaler*, Chem. Reviews *61*, 607 (1961).



[33] *F. Cramer*, Angew. Chem. *72*, 236 (1960).

[34] See, for example, *H. Hoffmann*, Angew. Chem. *72*, 77 (1960).

[35] Mention should also be made of the formation of diphenylhydroxytrichloroethylphosphine from diphenylphosphine and chloral (*H. Diehr*, Diploma Thesis, Universität Mainz, 1962):

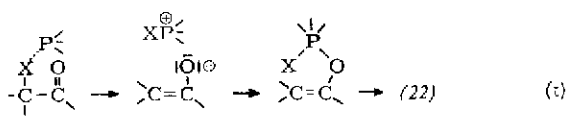


$$Cl_3C\text{—}CHO + HP(C_6H_5)_2 \rightarrow Cl_3C\text{—}CH(OH)\text{—}P(C_6H_5)_2$$

An objection to a mechanism of this type is that compounds with structure *(33)* should be converted at least in part into epoxides (cf. [32], or with phosphites, to α-alkoxy-β-chloroalkylphosphonates *(35)*.

*(35)*

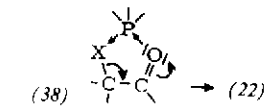
Other authors therefore reject the assumption of initial adduct formation and postulate direct attack on the carbonyl oxygen which, according to *(36)*, should lead to electron displacement with simultaneous elimination of the halogen anion.



*(36)* → *(22)*

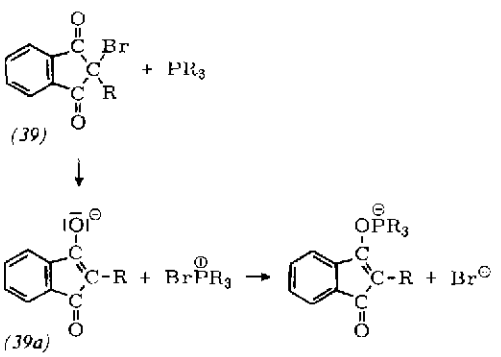
Models for such a process would be the well known $S_N2'$ reactions of allyl compounds. However, in order to apply the concepts developed for these reactions to α-halogenocarbonyl compounds, the nucleophilic reagent must be assumed to attack at a position of high electron density. The analogy therefore appears somewhat far-fetched. It can be argued further that $S_N2'$ reactions could occur not only with halides, but also – extremely readily – with the corresponding *p*-toluenesulfonates. "Perkow esters" or enolphosphonium salts should therefore also be formed from the tosylates of α-hydroxy ketones. However, the reaction of the *p*-toluenesulfonate of benzoin with triphenylphosphine yields the β-ketophosphonium salt *(37)* [11], while the main product from α-benzoylbenzyl chloride is the enolphosphonium salt.

*(37)*



The mechanism of the formation of the enolphosphonium salt is easy to explain if it is considered that, even in the α-halogenocarbonyl compounds, the halogen is under the influence of a strongly electron-attracting group. This undoubtedly facilitates attack by the phosphine on the halogen [29,30,38]. Removal of the halogen is then exactly analogous to the removal of a proton with bases [see Equation (t)].

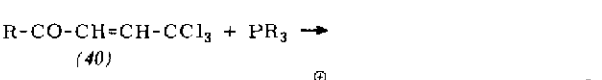
*(22)* (t)



The main advantage of a mechanism according to Equation (t) is that it permits an explanation of the fact that the ratio of the enolphosphonium salt to the ketophosphonium salt obtained depends on the constitution of the substrate: the quantity of enolphosphonium salt increases with increasing positive polarization of the halogen and increasing stability of the alkenyloxide ion. Thus, phenacyl chloride and triphenylphosphine give only the ketophosphonium salt, whereas α-benzoylbenzyl chloride gives a mixture of the keto- and enolphosphonium salts, and α-benzoylbenzylidene dichloride gives only the enolphosphonium salt (for further examples, see Table 1).

If the phosphine is assumed to attack initially on the halogen, the additional question arises whether the removal of the halogen and formation of the O–P bond occur in steps [as in Equation (t)], or synchronously.

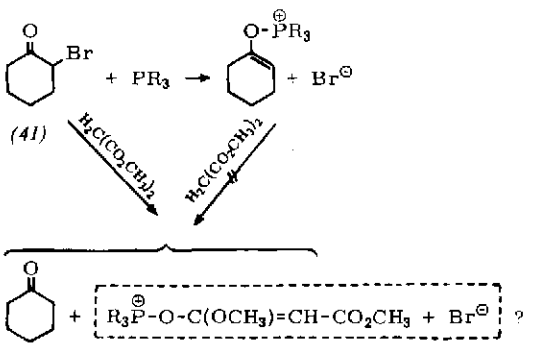
*(38)* → *(22)*



A synchronous mechanism *via* the transition state *(38)* would require close proximity of the carbonyl group to the halogen. It was found, however, that enolphosphonium salts could also be formed from cyclic ketones in which the carbon-halogen bond and the carbonyl group can no longer lie in the same plane. Examples of such ketones are 2-α-bromocholestanone [29] and bromophenylindanedione [11]. With bromophenylindanedione *(39)*, the stepwise mechanism is also supported by the brief appearance of a deep red color characteric of the alkenyloxide ion *(39a)*.

*(39)* *(39a)*

R = $C_6H_5$

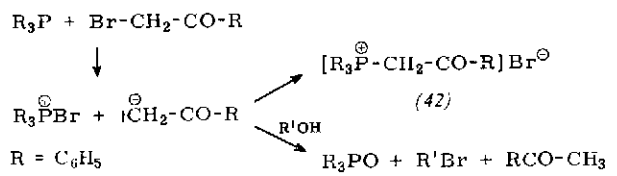


A synchronous mechanism is also very unlikely for vinylogous halogeno ketones such as *(40)*, which forms an enolphosphonium salt with triphenylphosphine [11].

*(40)*

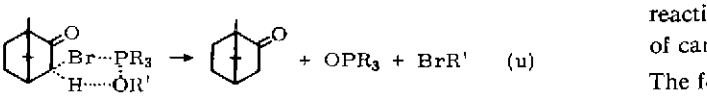
R = $C_6H_5$

A strong argument in favor of intermediate formation of an ion pair is the observation made by *Borowitz* and *Virkhaus* [36] that enolphosphonium salts are formed from 2-bromocyclohexanone *(41)* and triphenylphosphine when the reaction is carried out in the presence of



*(41)*

[36] *I. J. Borowitz* and *R. Virkhaus*, J. Amer. chem. Soc. *85*, 2184 (1963).

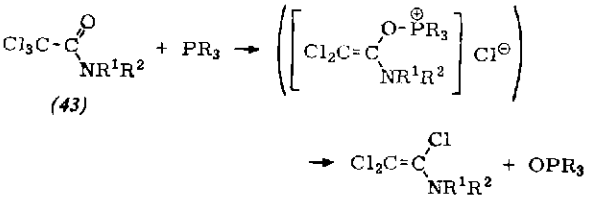


dimethyl malonate. The latter is sufficiently acidic to protonate the carbanion, but cannot decompose the enolphosphonium salt once it has been formed.

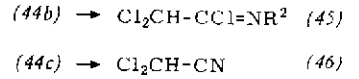
On the other hand, it can be argued that, like α-halogenoalkylphosphine oxides, α-halogeno ketones can be dehalogenated in the presence of acidic compounds by a "push-pull" mechanism. Independently of this, however, it is certainly justifiable to assume at least that a synchronous mechanism must not occur in every case. However, if an ion pair is formed from an alkenyloxide ion (or carbanion) and a halogenophosphonium cation [cf. *(1)* in Equation (b)], it is possible that the association will give rise not only to enolphosphonium salts, but also to ketophosphonium salts by a reaction of the second kind. This mechanism of formation might apply to ketophosphonium salts which are formed only in the absence of solvolytic agents.

For example, triphenylphosphine and phenacyl bromide give phenacyltriphenylphosphonium bromide *(42)* only in inert solvents; dehalogenation occurs in the presence of water or alcohol [36]:

However, the possibility of active participation in the reaction of the alcohol when the halogen is only weakly positively polarized must not be neglected. Thus, α-bromocamphor is smoothly dehalogenated by phenyldiethylphosphine in alcohol according to Equation (u), although no reaction occurs in acetonitrile under comparable conditions [11].



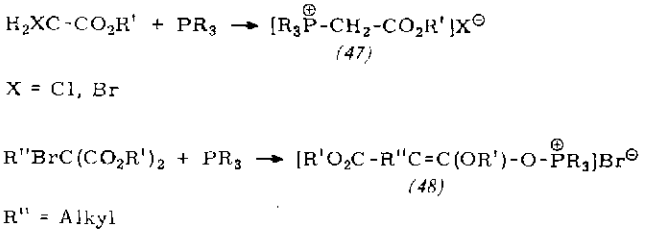
(u)



Formation of a ketophosphonium salt by an $S_N2$ mechanism of the first kind can always be expected when debalogenation by the alcohol is not appreciably favored. This is the situation, for example, in the reaction of α-benzoylbenzyl chloride with phenyldiethylphosphine: in ethanol, in benzene, and in a mixture of the two solvents, the ratio of the ketophosphonium salt to the enolphosphonium salt (or dehalogenation products) is fairly constant at 4:1.

### 3. Amides and Esters of α-Halogenocarboxylic Acids

The halogens in α-halogenated derivatives of carboxylic acids are subject to the same influences as those in α-halogeno ketones, but to a somewhat lesser extent. α-Chlorocarboxamides were investigated in detail in the comprehensive work of *Speziale* [37,38], who found that an initial step similar to that involved in the formation of enolphosphonium salts was followed by replacement of the phosphinoxy group by chlorine. Thus, *N,N*-disubstituted trichloroacetamides *(43a)* react with triphenylphosphine to yield tertiary trichlorovinylamines *(44a)*. *N*-Monosubstituted and unsubstituted acetamides give *N*-alkyl- or *N*-aryltrichlorovinylideneimines *(45)* and dichloroacetonitrile *(46)*, respectively, *via* similar reaction steps:



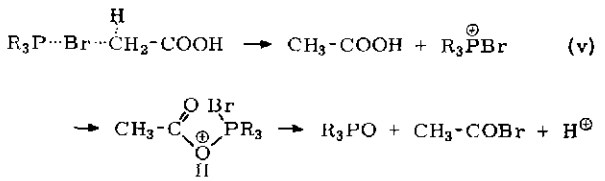
*(44a)*: $R^1 = R^2$ = Alkyl, Aryl
*(44b)*: $R^1$ = H; $R^2$ = Alkyl, Aryl
*(44c)*: $R^1 = R^2$ = H

The reactivity of α-halogenocarboxamides also depends strongly upon their structure. Aryl groups on the nitrogen or on the α-carbon increase the reactivity, since they promote formation of a carbanion, either by direct interaction of the aryl residue with carbanion electrons in the *C*-aryl derivative, or by reduction of the electron-donor character of the amino group in the *N*-aryl compound. Consequently, arylated dichloroacetamides still give good yields of dichlorovinylamines, whereas other dichloroacetamides react only sluggishly or with formation of *C*-phosphonium salts. It is interesting that even *N,N*-diethyldichlorofluoroacetamide is only weakly reactive. This can be explained by the lower stabilization of carbanions by fluorine [39].

The formation of enolphosphonium salts also increases rapidly with increasing positive polarization of the halogen in α-halogenocarboxylic esters; chloroacetates and bromoacetates yield *C*-phosphonium salts *(47)* [40], but bromomalonates give quasi-phosphonium salts *(48)* derived from the enolic form [9,30].

Only few experiments as yet have given information on the behavior of free α-halogenocarboxylic acids: chloroacetic acid reacts with triphenylphosphine to form a phosphonium salt [40], but bromoacetic acid *(49)* gives acetyl bromide and phosphine oxide [41].

[37] *A. J. Speziale* and *R. C. Freeman*, J. Amer. chem. Soc. *82*, 903 (1960).

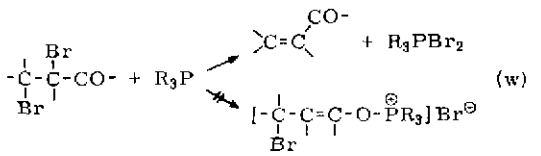


[38] *A. J. Speziale* and *L. R. Smith*, J. Amer. chem. Soc. *84*, 1868 (1962).

[39] *J. Hine, M. W. Burske, M. Hine*, and *P. B. Langford*, J. Amer. chem. Soc. *79*, 1406 (1957).

[40] *A. Michaelis*, Liebigs Ann. Chem. *293*, 193 (1896).

[41] *D. B. Denney* and *L. C. Smith*, J. org. Chemistry *27*, 3404 (1962); Chem. and Ind. *1961*, 290; *G. Aksnes*, Acta chem. scand. *15*, 438 (1961).



Proton-induced dehalogenation presumably takes place with *(49)* (as with α-halogenoalkylphosphine oxides), *e.g.* according to Equation (v).

(v)

4. From α,β-Dihalogenocarbonyl Compounds

The behavior of α,β-dihalogenocarbonyl compounds shows that removal of the α-halogen by phosphine does not necessarily lead to phosphonium-salt formation. Here, too, the phosphine first removes the α-halogen as a cation. However, just like the abstraction of the α-proton by bases, this process is accompanied by synchronous elimination of the β-halogen. Thus the reaction of triphenylphosphine with α,β-dibromophenethyl phenyl ketone does not yield an enolphosphonium salt, but phenyl styryl ketone and triphenylphosphine dibromide. Similarly, *meso*-dibromosuccinic acid is dehalogenated to fumaric acid by triphenylphosphine [see Equation (w)] [30].

(w)

If the mechanism given is correct, the elimination of the halogen should be a stereospecific *trans*-elimination [42], but since only *trans*-substituted ethylenes have been obtained so far from *erythro*-compounds, and there are no examples known of the formation of *cis*-compounds from *threo*-dibromides, this point has not yet been finally proved.

*We are indebted to the Deutsche Forschungsgemeinschaft and to the Fonds der Chemischen Industrie for support of the experimental work described here.*

# COMMUNICATIONS

## Formation of 1,2,3-Tri-t-butyltrifluorobenzene by Spontaneous Trimerization of t-Butylfluoroacetylene [1]

By Dr. H. G. Viehe, Dipl.-Ing. R. Merényi, Dr. J. F. M. Oth, and P. Valange [2]

Union Carbide European Research Associates, Brussels (Belgium)

t-Butylfluoroacetylene *(1)* has been prepared as the first example of an alkylated fluoroacetylene by dehydrohalogenation of the fluorohalogenoethylenes *(2a)* and *(2b)* with solid potassium hydroxide at about 120 °C and 35 mm pressure. When undiluted, *(1)* can be kept only at low temperatures; at room temperature it can be handled unchanged only as a gas or in dilute solution in ether for a short time. Even below 0 °C, liquid *(1)* spontaneously and exothermally forms various oligomers, mainly trimers. The major component of the crystalline portion of the mixture of oligomers was examined first; on the basis of physical measurements, particularly its characteristic nuclear magnetic resonance spectrum, it appears to have the structure *(3)*. The fluorine atom seems to be essential for the oligomerization, since t-butylchloroacetylene which is analogous to *(1)*, is thermally stable.

*(3)*, m.p. 112–114 °C
IR: C=C at 6.28 μ.
UV: $\lambda_{max}$ = 209; 228; 266; 319 mμ
$\varepsilon \cdot 10^{-3}$ = 14.7; 19.1; 4.1; 0.79

NMR-fluorine signals (internal standard $CCl_3F$): doublet at +127.7 ppm with a relative intensity of 2; triplet at +154.8 ppm with a relative intensity of 1 ($J_{FF(ortho)}$ = 19.5 cps).

NMR-t-butyl proton signals (internal standard tetramethylsilane): multiplet at −1.45 ppm with a relative intensity of 2; singlet at −1.39 ppm with a relative intensity of 1. The multiplet can be explained by long-range coupling [3] between protons of the flanking t-butyl groups and the neighboring fluorine atoms.

Assuming a coupling constant $J_{FF(meta)} = (J_{XX})$ of 4 cps, the proton multiplet would be part A of an $A_2X_2$ system with a coupling constant $J_{HF} = (J_{AX})$ of 1.3 cps. Because of the high multiplicity to be expected, this coupling appears in the doublet of the fluorine spectrum only as a line broadening; $F\text{-}F_{meta}$ coupling is not observed at all.

The spectral data exclude the 1,2,4- and 1,3,5-trifluoro isomers.

The formation of *(3)* represents the first trimerization of an acetylene derivative to yield a 1,2,3-trisubstituted benzene; this is especially surprising here because of the strain introduced by three neighboring t-butyl groups [4].

## Generation of Light by Fluorine Reactions in Flash Lamps

By Dr. L. M. Nijland, N.V. Philips' Gloeilampenfabrieken, Lichtgroep, Eindhoven (Holland)

and Dr. J. Schröder, Philips Zentrallaboratorium, Aachen (Germany)

Flash lamps should radiate the largest possible quantity of light during some milliseconds, the color temperature of the flash should correspond, as closely as possible, to daylight (*i.e.* the color temperature of a black body at 6000 to 6500 °K), and the lamps should be small, handy and safe. For this purpose, zirconium, in the form of fine wool, is burnt with oxygen in conventional combustion flash lamps.

A combustion flash lamp is essentially a thermal radiator. The heat of reaction heats the substance to be burnt, or already burnt, and causes it to emit radiation. Emission of visible radiation rapidly increases with rising temperature. The combustion reaction should therefore yield as much heat as possible per quantity of substances reacted. For many reactions (for examples see Table 1) this amount of heat at 25 °C and 1 atm is equal to the negative value for the enthalpy of formation, $\Delta H$, of the compound formed.

Table 1. Enthalpy of formation $\Delta H$ [kcal/mole] at 1 atm and 25 °C.

| Reaction | $\Delta H$ |
|---|---|
| $H_2 + 0.5\ O_2 \rightarrow H_2O$ | −58 |
| $H_2 + F_2 \rightarrow 2\ HF$ | −128 |
| $Be + 0.5\ O_2 \rightarrow BeO$ | −146 |
| $Be + F_2 \rightarrow BeF_2$ | −227 |
| $Zr + O_2 \rightarrow ZrO_2$ | −258 |
| $Zr + 2\ F_2 \rightarrow ZrF_4$ | −457 |
| $Si + O_2 \rightarrow SiO_2$ | −205 |
| $Si + 2\ F_2 \rightarrow SiF_4$ | −370 |

The temperature attainable in combustion is limited, among other factors, by the dissociation of the combustion products. If high temperatures are to be reached, the compounds formed by the combustion must be as stable as possible. Their stability is determined, among other factors, by the free enthalpy of formation, $\Delta G$ (see Table 2).

Table 2. Free enthalpy of formation $\Delta G$ [kcal/g-atom Zr], extrapolated to 4000 °K.

| Reaction | $\Delta G$ |
|---|---|
| $Zr + O_2 \rightarrow ZrO_2$ | −90 |
| $Zr + 4\ F \rightarrow ZrF_4$ | −160 |

Table 2 shows that reactions with fluorine can proceed at higher temperatures than those with oxygen.

Since elementary fluorine is difficult to handle, gaseous compounds with a high fluorine content are used as a source of fluorine. Some of these are thermally rather unstable and chemically rather inert under normal conditions, ($OF_2$: $\Delta H = +7.6$ kcal/mol; $NF_3$: $\Delta H = -27$ kcal/mol). Moreover, compounds of this type yield a larger number of free highly reactive atoms than does molecular fluorine per molecule in the course of dissociation. The bulb volume may therefore be reduced for the same amount of substance reacted. Examples are the enthalpies of formation, at 25 °C and 1 atm, of the reaction of zirconium with equal volumes of $O_2$, $F_2$, $NF_3$ and $OF_2$, as shown in Table 3.

Table 3. Enthalpy of formation $\Delta H$ [kcal] at 1 atm and 25 °C.

| Reaction | $\Delta H$ |
|---|---|
| $2\ O_2 + 2\ Zr \rightarrow 2\ ZrO_2$ | −516 |
| $2\ F_2 + 1\ Zr \rightarrow ZrF_4$ | −457 |
| $2\ NF_3 + 1.5\ Zr \rightarrow 1.5\ ZrF_4 + N_2$ | −630 |
| $2\ OF_2 + 2\ Zr \rightarrow ZrF_4 + ZrO_2$ | −729 |

The most important results of our experiments with fluorine reactions in flash lamps may be summarized as follows:

1. Fluorine as well as some fluorine compounds, *e.g.* $NF_3$ and $OF_2$, supply light in the course of the reaction with finely divided metals, *e.g.* Zr.

2. The color temperatures of the light emitted in the course of the fluorine reactions are up to 20 % higher than in the case of analogous oxygen reactions.

3. The quantities of light, calculated on the same amount of substance reacted, are up to 50 % larger than in the case of combustion with oxygen.

## A New Group of Co-carcinogens from Croton Oil [1]

By Prof. Dr. E. Hecker, H. Kubinyi, and Dr. H. Bresch

Max-Planck-Institut für Biochemie, München, and Biochemisches Institut am Deutschen Krebsforschungszentrum, Heidelberg (Germany)

In combination with biological tests for toxic, inflammatory and co-carcinogenic effects [1a], a substance group B [1b], which appears to be homogeneous in thin-layer chromatograms, can be separated chromatographically [2] from croton oil in addition to a substance group A [3]. By multiple counter current distribution B is separated into at least three components (B1, B2, and $B_X$), of which B1 and B2 were obtained pure.

B1 and B2 are colorless, optically active resins of the same Rf value, insoluble in water and soluble in nearly all organic solvents. B1: $C_{37}H_{58}O_8$, $[\alpha]_{578}^{26} = 54°$ (1.76 % in $CHCl_3$), $\lambda_{max} = 232$ and 335 mμ, $\varepsilon_{max} = 7000$ and 80 (in ethanol); IR-spectrum (in KBr): hydroxyl (2.95 μ), carbonyl (5.84 μ), C=C-double bonds (6.09; 6.14 μ); NMR-spectrum: $\delta = 0.9$; 1.3; 1.8; 2.3; 3.2; 3.9; 5.3; 5.6; 7.5 ppm (in $CCl_4$, internal standard: tetramethylsilane). B2: $C_{35}H_{54}O_8$, $[\alpha]_{578}^{26} = 50°$ (3.08 % in $CHCl_3$). The remaining spectral data agree within the limits of error with those of B1.

The two natural products are not aromatic; in addition to three free and two esterified hydroxy groups, each contains an α,β-unsaturated carbonyl group, which is not detectable with the usual reagents. One hydroxy group is esterified with (+)-*(S)*-2-methylbutyric acid, the other with lauric acid in the case of B1 and with capric acid in the case of B2. The third free hydroxy group of B1 and B2 may be esterified with pyridine/acetic anhydride and, on the basis of the NMR-spectra as well as of oxidation by $MnO_2$, can be regarded as primary and situated as in allyl alcohol. The resinous aldehyde obtained by oxidation yields a crystalline 2,4-dinitrophenylhydrazone (B1: $C_{43}H_{60}O_{11}N_4$, m.p. 108.5–109.5 °C; B2: $C_{41}H_{56}O_{11}N_4$, m.p. 119.5–120.5 °C). The two non-esterifiable hydroxy groups in B1 and B2 are tertiary. The natural products B1 and B2 are esters of the diterpenoid parent alcohol $C_{20}H_{28}O_6$ [3].

As is apparent from Table 1, the two substances show high and comparable biological activity with that of co-carcinogen A1 [3] in the inflammation test on the mouse ear (EE) and in the co-carcinogen test on the skin of the back of the mouse.

Table 1. Biological activity of the pure co-carcinogens B1 and B2. Tests according to [1a].

| Substance | E. E. (μg/ear) | Co-carcinogen test [a] | |
|---|---|---|---|
| | | μg/application [b] | papilloma/mouse [c] |
| B 1 | 0.009 | 10 | 5 |
| B 2 | 0.009 | 10 | 7 |
| A 1 | 0.009 | 10 | 9 |

[a] Carcinogen: 1 μMol 9,10-dimethylbenzanthracene.

[b] Application: twice weekly for 12 weeks. [c] After 12 weeks.

After our first communications [1a, 2] appeared, a biologically active product from croton oil has been described without detailed characterization [4] which on hydrogenation yields a fatty acid ester of a polyphenol containing capric acid, lauric acid, and 2-methylbutyric acid. The hydrogenated product possibly is a mixture of the substances B 1 and B 2 described above.

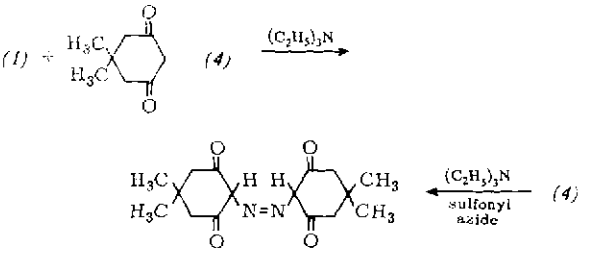
## Azo Coupling of α-Diazo-β-diketones with Non-phenolic Methylene Compounds

By Dr. M. Regitz and cand. chem. D. Stadler

Institut für organische Chemie
der Universität des Saarlandes, Saarbrücken (Germany)

Recently, *Severin* [1] reported on the azo-coupling of 2-diazodimedone *(1)* with highly reactive phenols, *e.g.* phloroglucinol; however, the dyestuffs he obtained were mostly amorphous and were difficult to purify [2].

We have found that readily crystallizable, purely aliphatic azo-compounds *(3)* are obtained with non-phenolic compounds containing an active methylene group when *(1)* or other α-diazo-β-diketones, *e.g.* 2-diazoindane-1,3-dione or 2-diazo-*peri*-naphthindane-1,3-dione, are treated with the methylene component *(2)* and potassium ethoxide in ethanol.



*(1)* *(2)* *(3)*

| *(2)* | *(3)* M.p. [°C] | Color | λmax [mμ] | ε [a] |
|---|---|---|---|---|
| Indane-1,3-dione | 196 | brown-violet | 446<br>246 | 26 500<br>25 300 |
| Diethyl malonate | 114–116 | yellow | 376<br>293 | 16 800<br>7 800 |
| Ethyl benzoylacetate | 96 | orange-brown | 392<br>287 | 15 200<br>10 700 |
| Ethyl cyanoacetate | 131 | yellow | 384<br>290 | 18 450<br>6 850 |
| Benzyl β-naphthyl ketone | 141 | yellow-orange | 384<br>295 | 12 300<br>16 300 |
| 1-Phenyl-3-methyl-pyrazol-5-one | 185 | red | 245<br>416 | 20 400<br>21 200 |

[a] In methylene chloride.

Symmetrical aliphatic azo compounds such as the orange-red derivative α,α'-azodimedone *(5)* are obtained by coupling *(1)* with dimedone *(4)*. However, since *(1)* can be obtained from *(4)* by diazo-group transfer using sulfonyl azides in a basic medium [3], and since it couples with *(4)* under the same conditions, *(5)* can also be obtained directly from dimedone by treating it with half of an equivalent of a sulfonyl azide in ethanol in the presence of triethylamine as base [4].

*(5)*

Dihydroresorcinol, 5,5-spiropentamethylenecyclohexane-1,3-dione, and 6,6-spiropentamethylenepyran-2,4-dione react analogously.

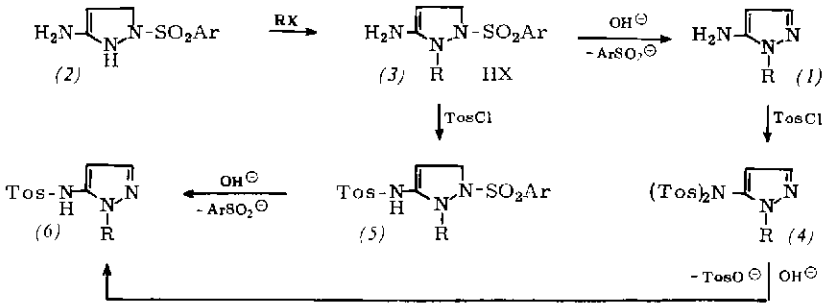
## Synthesis of 3(5)-Aminopyrazole and 1-Alkyl-5-aminopyrazoles [1]

By Dr. H. Dorn, Prof. Dr. G. Hilgetag, and Dipl.-Chem. A. Zubek

Institut für organische Chemie der Deutschen Akademie der Wissenschaften zu Berlin (Germany)



Up to the present, 1-alkyl-5-aminopyrazoles *(1)*, R = alkyl, could be obtained only by saponification and decarboxylation of 1-alkyl-5-amino-4-ethoxycarbonylpyrazoles, which are obtained by condensation of ethyl α-cyano-α-ethoxymethyleneacetate and alkylhydrazines [2].

A new synthetic route leading to *(1)*, R = alkyl, was discovered after we obtained salts of 1-alkyl-2-arenesulfonyl-5-amino-$\Delta^4$-pyrazolines *(3)* in very good yields from 3-amino-$\Delta^3$-pyrazoline and alkylating agents, *e.g.* particularly well with alkyl *p*-toluenesulfonates in dimethylformamide; the 3-amino-$\Delta^3$-pyrazoline is in turn readily accessible from hydrazine and acrylonitrile in water.

| Ar | R | X | M.p. [°C] |
|---|---|---|---|
| *p*-$H_3C$–$C_6H_4$– | $CH_3$– | TosO– | 206.5–207.5 |
| *p*-Cl–$C_6H_4$– | $CH_3$– | TosO– | 200–201 |
| $C_6H_5$– | $CH_3$– | TosO– | 188.5–190 |
| *p*-$H_3C$–$C_6H_4$– | $C_2H_5$– | TosO– | 175–176 |

Mild alkaline hydrolysis of each salt *(3)*, *e.g.* even with basic ion exchangers, affords 1 mole of an arenesulfinate and a 1-alkyl-5-aminopyrazole *(1)*. Correspondingly, elimination of 1 mole of sulfinate from non-alkylated monoarenesulfonyl derivatives *(2)*, which can be obtained in excellent yields from 3-amino-$\Delta^3$-pyrazoline and arenesulfonyl chlorides in methylene chloride plus triethylamine or even better in aqueous sodium hydrogen carbonate [*(2)*, Ar = $C_6H_5$, m.p. 167–168 °C; Ar = *p*-Cl–$C_6H_4$, m.p. 161–163 °C; Ar = *p*-$H_3C$–$C_6H_4$, m.p. 185–186 °C], gives almost quantitative yields of (3)5-aminopyrazole *(1)*, R = H, b.p. 155–157 °C/12 mm, m.p. 36–38 °C, a compound which was hitherto difficult to prepare [3, 4].

1-Methyl-5-aminopyrazole can be tosylated to give *(4)*, R = $CH_3$, m.p. 188–190 °C, the structure of which has been substantiated by the characteristic position of its sulfonyl absorption [5] in the infrared and by the synthesis [4] of analogous derivatives of *(1)* with two different arenesulfonyl residues. The salts *(3)* react with *p*-toluenesulfonyl chloride to give very good yields of 1-alkyl-2-arenesulfonyl-5-(*p*-toluenesulfonamido)-$\Delta^4$-pyrazolines *(5)*, Ar = *p*-$H_3C$–$C_6H_4$,

R = $CH_3$, m.p. 189–190 °C, which like *(3)* can also lose 1 mole of sulfinate. The structures of *(2)* and *(3)* are certified by the fact that alkaline cleavage of *(4)*, R = $CH_3$, and *(5)*, R = $CH_3$, leads to the same compound, *viz.* 1-methyl-5-(*p*-toluenesulfamido)pyrazole *(6)*, R = $CH_3$, m.p. 151.5 to 152.5 °C.

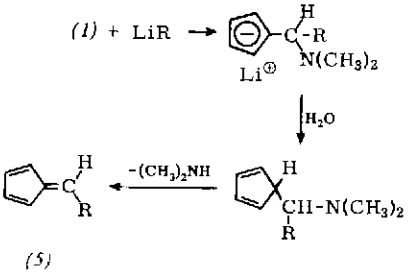
## A Simple Synthesis of Fulvene and Its 6-Alkyl Derivatives

By Dipl.-Chem. E. Sturm and Prof. Dr. K. Hafner



Institut für Organische Chemie
der Universität München (Germany)

The base-catalysed condensation of cyclopentadiene with formaldehyde or a homologue affords fulvene *(4)* or its 6-alkyl derivative *(5)* respectively, but only in yields of less than 5 % [1]. We have found that *(4)* is obtained in ca. 60 % yield from the "reductive deamination" of the readily accessible 6-dimethylaminofulvene *(1)* [2] with lithium aluminium hydride in ether.

The cyclopentadiene-metal compound first formed, which can be isolated, is converted on hydrolysis at 0 °C into the Mannich base *(3)*, which rapidly loses dimethylamine above 100 °C in high vacuum or during chromatography on alumina (neutral, activity grade II) with ether or n-pentane. On reaction with methyl iodide at 0 °C, *(3)* yields a quaternary salt which immediately splits out trimethylammonium iodide to give *(4)* which is isolated by distillation (b.p. ~5 °C/15 mm) as a pale yellow oil and is very sensitive to heat and oxygen. Its ultraviolet spectrum agrees with that given in the literature [1]. The NMR spectrum of *(4)* in $CCl_4$ shows a multiplet between 3.6 and 4.1 τ.

Compound *(1)* reacts similarly with organolithium compounds to form fulvenes of type *(5)* in yields of 80–90 %.

For example, 6-methylfulvene *(5)*, R = $CH_3$, is obtained in 81 % yield from *(1)* and methyl-lithium as a yellow oil, b.p. 19–21 °C/12 mm; ultraviolet spectrum in ethanol: $\lambda_{max}$ = 255 mμ (log ε = 4.24), 357 (2.50); NMR spectrum in $CCl_4$: multiplet between 3.7 and 4.1 τ *(5)*, doublet at 8.0 τ *(3)*. Numerous 6-arylfulvenes can be readily prepared in the same manner.

## Synthesis of 2,3-Diphenyl-1,1,4-trioxo-1,2,3-thiadiazolidines

By Prof. Dr. A. Mustafa, Dr. M. Kira, and H. Hanna

National Research Centre, Dokki, and
Faculty of Science, Cairo University, Giza (U.A.R.)

When *N'*-chloroacetylhydrazobenzene *(1)*, R = H, X = Cl [1], and potassium sulfite are boiled in ethanol/water (2:1) for 3 h under reflux, the potassium salt of sulfoacetylhydrazobenzene *(2)*, R = H, is formed with 95 % yield (colorless crystals, m.p. 245 °C, from aqueous ethanol). This salt was readily cyclized by phosphorus oxychloride to *(3)*, R = H, m.p. 150 °C, in about 50 % yield [2].

Similarly, α-bromobutyryl hydrazobenzene *(1)*, R = $C_2H_5$, X = Br [3], yielded 5-ethyl-2,3-diphenyl-1,1,4-trioxo-1,2,3 thiadiazolidine *(3)*, R = $C_2H_5$, m.p. 109 °C.

5-Aralkyl derivatives of *(3)* have been obtained in almost quantitative yields by catalytic hydrogenation (10 % Pd-charcoal; dioxane; room temperature; 10 h) of the yellow 5-arylidene derivatives *(4)* which are readily available by the condensation of aldehydes with the active methylene group of *(3)*, R = H. The following compounds were prepared:

*(4)*, $R' = C_6H_5-$, m.p. 176 °C
*(4)*, $R' = p\text{-}CH_3OC_6H_4-$, m.p. ca. 290 °C (decomp.)
*(4)*, $R' =$ 2-furyl, m.p. 183 °C
*(4)*, $R' = o\text{-}HOC_6H_4-$, m.p. 230 °C
*(4)*, $R' = C_6H_5-CH=CH-$, m.p. 197 °C
*(3)*, $R = C_6H_5-CH_2-$, m.p. 181 °C
*(3)*, $R = p\text{-}CH_3OC_6H_4-CH_2-$, m.p. ca. 290 °C (decomp.)
*(3)*, R = 2-furylmethyl, m.p. — 116 °C

Compounds *(3)*, R = H or alkyl, have anti-inflammatory activity. They are stable towards hydrazine and amines, whereas alkali hydroxide cleaves the ring and liberates hydrazobenzene. Also, the attempted alkylation of *(3)* with alkyl halide and NaOH resulted in the formation of hydrazobenzene.

## Gas-Chromatographic Separation and Analysis of Isomeric Halogenated Hydrocarbons

By Dr. Elisabeth Bendel, cand. phys. W. Meltzow, and Dr. Li-Hoan Kung

Institut für Technische Chemie der Technischen Hochschule Aachen (Germany)

After chlorination or bromination of high-molecular, straight-chain hydrocarbons with, for example, *N*-chloro- or *N*-bromosuccinimide, t-butyl hypochlorite or hypobromite [1] the isomeric chlorides of n-heptane, n-octane, n-decane and the isomeric bromides of n-heptane and n-octane were quantitatively separated by gas chromatography on a Ucon LB 550 X Golay column (200 m; internal diameter 0.5 mm). A capillary chromatograph with a flame-ionization detector was used. The carrier gas was helium (4.5 ml/min), and the temperatures used are shown in Table 1.

Table 1. Temperatures of flash heater, column, and detector.

| Isomers | Column | Detector | Flash heater |
|---|---|---|---|
| Chloro-n-heptanes | 70 °C | 70 °C | 170 °C |
| Bromo-n-heptanes | 90 °C | 90 °C | 170–175 °C |
| Chloro-n-octanes | 90 °C | 90 °C | 175–179 °C |
| Bromo-n-octanes | 90 °C | 90 °C | 230 °C |
| Chloro-n-decanes | 120 °C | 120 °C | 232 °C |

The retention times of the isomeric halogenated hydrocarbons and the resolution obtained for each individual pair of isomers are set out in Table 2.

The quantitative evaluation of the chromatograms was confirmed by the analysis of test mixtures. The maximum relative error found was about 5 %, so that the use of correction factors is unnecessary.

The gas-chromatographic analysis of the unstable bromo-n-decanes still presents difficulties.

Table 2. Retention times ($t_r$) and effective resolution ($\vartheta$) [*] for the isomeric halogenated hydrocarbons.

| Isomer X R | Chloro-n-heptanes | | Bromo-n-heptanes | | Chloro-n-octanes | | Bromo-n-octanes | | Chloro-n-decanes | |

## An External Magnetocatalytic Effect

By Doz. Dr. W. Haberditzl and Dipl.-Chem. Klaus Müller

Physikalisch-Chemisches Institut der Humboldt-Universität Berlin (Germany)

The existence of external magnetocatalytic effects, *i.e.* alterations of catalytic activity within external magnetic fields, has been the subject of much controversy. We have now detected such an effect with the enzyme glutamic dehydrogenase (GlDH).

GlDH catalyses the reaction:

$$\alpha\text{-Oxoglutarate} + NH_3 + DPNH \rightleftharpoons \text{Glutamate} + DPN + H_2O$$

The changes in the concentration of DPNH with time were followed by spectrophotometry [1], and the catalytic activity was calculated in units per ml [2]. The reaction mixture comprised 3 ml of 0.05 M triethanolamine buffer (pH 8.0), 0.045 ml of 0.01 M DPNH, 0.03 ml of 0.26 M EDTA, 0.1 ml of 3 M ammonium acetate, and 0.03 ml of $10^{-7}$ M GlDH. After addition of 0.06 ml of 0.4 M sodium α-oxoglutarate, the extinction of the solution at 366 mμ was measured at one-

minute intervals. After 5 min, the sample cell (light path 1 cm) was placed between the poles of an electromagnet in an inhomogeneous field (distance from poles 13.5 mm, magnetic field strength 15000 Gauss) for 40–50 min. The extinction was thereafter again measured at one-minute intervals for 5 min. A duplicate determination was carried out on a cuvette not placed within the magnetic field. There was generally a difference in temperature of 0.1 to 0.3 °C between the solutions within and ouside the magnetic field. The temperature dependence of the enzymatic activity was 1.5 units/°C at 25 °C and 1.8 units/°C at 27 °C.

In four replicate experiments, the activity of the GIDH inside the magnetic field was 12–15 % (in one series of experiments 7 %) less than that outside the magnetic field.

[2] *T. Bücher*, Z. Naturforsch. *8b*, 555 (1953). One unit is the amount of enzyme dissolved in 1 ml which alters the extinction at 366 mμ (light path: 1 cm) by 0.100 within 100 sec at 25 °C.

## Synthesis of Octabenzylcyclotetrastannane

By Priv.-Doz. Dr. W. P. Neumann and Dipl.-Chem. K. König

Institut für Organische Chemie
der Universität Gießen (Germany)

Catalytic condensation of dialkyltin dihydrides and diaryltin dihydrides gives rise to crystalline aliphatic [1] and aromatic [2] cyclostannanes containing five-, six-, or nine-membered rings. We have now succeeded in preparing an analogous compound with a four-membered ring, *viz.* octabenzylcyclotetrastannane. It is formed from dibenzyltin dihydride in almost quantitative yield at 50 °C in dimethylformamide, which also acts as catalyst, and a trace of dibenzyltin dichloride as co-catalyst; the product is very sensitive to air but crystallizes from toluene/ligroin as beautiful pale yellow prisms (m.p. 226–228 °C with partial decomposition). It is highly soluble in hot benzene but sparingly soluble in cold benzene. On degradation with iodine in benzene, it affords a quantitative yield of pure dibenzyltin diiodide. This reaction, together with its molecular weight (determined by osmometry), analyses, and spectra substantiate its structure.

When the condensation was carried out in pyridine, a crystalline mixture containing higher cyclic homologues was obtained; these probably included the five- and six-membered ring compounds. The ring size in the products formed depends not only on the catalyst used, but also on the nature of the organic substituent on the tin (cf. [1, 2]). Recently, the analogous octa-t-butyl compound was prepared by a different route as the first example of a cyclotetrastannane [3].

Our starting material, dibenzyltin dihydride, was hitherto unknown and was prepared from pure dibenzyltin dichloride using lithium aluminohydride in ether at 0 °C ($\nu_{SnH}$ at 1843 cm$^{-1}$, broad absorption); it was used without previous distillation. It ignites spontaneously on filter paper in contact with air.

## Preparation of Malonic Acid by Carboxylation of Acetic Acid

By Dr. B. Raecke

Forschungslaboratorium der Firma Henkel & Cie. GmbH.,
Düsseldorf (Germany)

The decarboxylation of malonic acid may be regarded as an equilibrium reaction. Salts of malonic acid can be produced from acetates and carbon dioxide if the hydrogen ions liberated during the reaction are removed [1].

The carboxylation proceeds especially smoothly with potassium acetate, which in the presence of potassium carbonate reacts with $CO_2$ under pressure and above 200 °C to give potassium malonate:

$$CH_3COOK + CO_2 + K_2CO_3 \longrightarrow KOOC{-}CH_2{-}COOK + KHCO_3$$

Suitable catalysts include finely powdered metals and metal oxides, especially iron and $Fe_2O_3$.

When anhydrous potassium acetate (30 g) is heated with anhydrous potassium carbonate (120 g) and iron powder (1 g) in an autoclave at 300 °C for 3 h at ca. 500 atm $CO_2$, pure malonic acid (ca. 24 g; 75.2 %) can be isolated from the reaction mixture.

Other carboxylic acids with hydrogen atoms in the α-position can also be carboxylated in this way, although the yields are considerably lower.

## A Simple Synthesis of Organic Di- and Polystannanes

By Priv.-Doz. Dr. W. P. Neumann and
Dipl.-Chem. B. Schneider

Institut für Organische Chemie
der Universität Gießen (Germany)

Organotin hydrides [1] can be condensed with organotin oxides, giving rise with surprising ease and occasionally even in an exothermic reaction either to symmetrical and unsymmetrical hexaalkyldistannanes [Equation (a)], or to the octaalkyltristannanes [Equation (b)] hitherto obtainable only with difficulty, or to polystannanes [Equation (c)]. Aryltin compounds react faster than the corresponding alkyltin compounds. When R = iso-$C_4H_9$, reaction (c) leads to a polydiisobutyltin polymer which still contains some Sn-O-Sn groups [2].

$$2\,R_3SnH + (R'_3Sn)_2O \longrightarrow 2\,R_3SnR'_3 + H_2O \qquad (a)$$

$$2\,R_3SnH + R_2SnO \longrightarrow R_3Sn{-}R_2Sn{-}SnR_3 + H_2O \qquad (b)$$

$$R_2SnH_2 + R_2SnO \longrightarrow 1/n\,(-R_2Sn{-}R_2Sn{-})n + H_2O \qquad (c)$$

| $R_3SnH$ R = | $(R'_3Sn)_2O$ R' = | Temp. [°C] | Product | B.p. [°C/mm] (M.p. [°C]) | Yield of pure product [%] |
|---|---|---|---|---|---|
| n-$C_4H_9$ | n-$C_4H_9$ | 110 | $(C_4H_9)_3Sn-Sn(C_4H_9)_3$ | 144/0.09 | 90 |
| $C_6H_5$ | $C_6H_5$ | 20 | $(C_6H_5)_3Sn-Sn(C_6H_5)_3$ | (232) | 89 |
| $C_6H_5$ | $C_2H_5$ | 25 | $(C_6H_5)_3Sn-Sn(C_2H_5)_3$ | $186/10^{-4}$ | 80 |
| $C_2H_5$ | $C_6H_5$ | 25 | $(C_6H_5)_3Sn-Sn(C_2H_5)_3$ | (16) | 73 |
| $C_2H_5$ | $C_2H_5$ | 130 | $(C_2H_5)_3Sn-Sn(C_2H_5)_3$ | 145/11 | 86 |
| iso-$C_4H_9$ | $C_2H_5$ | 110 | $(iso\text{-}C_4H_9)_3Sn-Sn(C_2H_5)_3$ | 75/0.11 | 42 [3] |
| $C_2H_5$ | $(C_2H_5)_2SnO$ | 110 | $(C_2H_5)_3Sn-(C_2H_5)_2Sn-Sn(C_2H_5)_3$ | $133/10^{-5}$ | 47 [3] |

Often a slow H–O exchange [Equation (d)] can be detected alongside the condensation reactions, *e. g.* by removal of the small amount of volatile triethyltin hydride formed:

$$2\ (iso\text{-}C_4H_9)_3SnH + [(C_2H_5)_3Sn]_2O \overset{60\,^\circ C}{\rightleftharpoons} [(iso\text{-}C_4H_9)_3Sn]_2O + 2\ (C_2H_5)_3SnH \qquad (d)$$

Oxygen is exchanged for hydrogen in hydrides much more slowly than deuterium [4] or halogen [5]; a complex can be assumed as transition state.

The exchange proceeds quickly at temperatures as low as 25 °C with dialkyltin dihydrides [Equation (e)]; the dialkyltin oxide precipitates almost quantitatively and can be filtered or centrifuged off.

$$R_2SnH_2 + (R'_3Sn)_2O \rightarrow 2\ R'_3SnH + R_2SnO \qquad (e)$$

where *e.g.* R = $C_2H_5$, iso-$C_4H_9$, and R' = $C_2H_5$, n-$C_4H_9$, $C_6H_5$.

When R = R' = $C_6H_5$, ligand exchange and the condensation reaction compete with each other; the final result is a mixture $(C_6H_5)_3Sn-[(C_6H_5)_2Sn]_n-Sn(C_6H_5)_3$.

The synthesis of Sn–Sn bonds according to Equation (f) has obviously much more scope than was hitherto envisaged.

$$R_3SnH + R'_3SnX \longrightarrow R_3Sn-SnR'_3 + HX \qquad (f)$$

In this reaction, X can be not only $-CF-CF_2$ [6], $-OR$ [7] (particularly $-OCH_3$ [Equation (g)] [2, 8]), $-NR-CHO$, and $-NR-NHR$ [9], but also, for example, halogen [Equation (h)], $-OSnR_3$, $-N(C_2H_5)_2$ [Equation (i)], or another electronegative residue. Organotin dihydrides also react readily in this manner. A few new examples may serve to illustrate this. All the substances were obtained in good yields and were characterized by their analyses, melting or boiling points, molecular weights, and infrared spectra.

$$(C_4H_9)_2SnH_2 + (C_4H_9)_2Sn(OCH_3)_2 \xrightarrow[-2\ CH_3OH]{20\,^\circ C} 2/n\ [(C_4H_9)_2Sn]_n \qquad (g)$$

crystalline, yellow, sensitive to air [3, 8]

$$(C_6H_5)_3SnH + (C_2H_5)_3SnCl + N(C_2H_5)_3 \xrightarrow{\text{exothermic}} (C_6H_5)_3Sn-Sn(C_2H_5)_3 + HN(C_2H_5)_3Cl \qquad (h)$$

$$(C_4H_9)_2SnH_2 + 2\ (C_2H_5)_3SnN(C_2H_5)_2 \xrightarrow{\text{exothermic}} 2\ HN(C_2H_5)_2 + (C_2H_5)_3Sn-(C_4H_9)_2Sn-Sn(C_2H_5)_3 \qquad (i)$$

B.p. 140 °C/$10^{-3}$ mm, $n_D^{20} = 1.5641$ [3, 8]

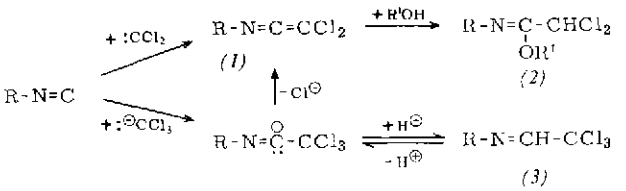
## α-Addition of Dichlorocarbene to Cyclohexyl Isonitrile

By Dr. A. Halleux



Union Carbide European Research Associates, Brussels (Belgium)

Because of their electronic structure, isonitriles should undergo nucleophilic reactions with dichlorocarbene to give, by α-addition, *N*-substituted dichloroketeneimines *(1)*.

A suspension of anhydrous potassium alcoholate R'OK, R' = $CH_3$, $C_2H_5$, $(CH_3)_3C$, in hexane was added to a solution of cyclohexyl isonitrile in hexane, and chloroform or ethyl trichloroacetate was then added dropwise to the vigorously stirred suspension. *N*-Cyclohexyldichloroacetimidate *(2)*, R = $C_6H_{11}$, was obtained from the reaction mixture in up to 75 % yield but no dichloroketeneimine *(1)* or trichloroethylidenecyclohexylamine *(3)* was isolated.

The imidates *(2)* [R = $CH_3$; b.p. 65 °C/$10^{-1}$ mm; $n_D^{25} = 1{,}4889$; R = $C_2H_5$: b.p. *ca.* 50 °C/$10^{-2}$ mm; R = $(CH_3)_3C$: b.p. 60–65 °C/$10^{-2}$ mm, decomposes to *N*-cyclohexyldichloroacetamide, m.p. 140 °C [1], on prolonged standing] were obtained pure by vacuum distillation or preparative gas-liquid chromatography and were characterized by elemental analysis, IR spectrum and acid hydrolysis.

Two reaction mechanisms are possible: either nucleophilic reaction of the isonitrile with dichlorocarbene or electrophilic reaction [2] with the trichloromethyl carbanion.

Compound *(1)* is also formed from trichloroethylideneimine *(3)*, prepared from the amine and chloral.

Competitive experiments in the presence of cyclohexene showed that the ratio of the products depends characteristically on the concentration of the added cyclohexene [3]. The relative reactivities of cyclohexene and cyclohexyl isonitrile were 1:6. The ratio of the products was determined by gas-liquid chromatography.

The results show that the reaction occurs exclusively *via* the carbene. Thus, the possibility that the reaction of cyclohexyl isonitrile with chloramine T, described by *Aumüller* [4], occurs *via* a nitrene cannot be excluded.

## A New Method for the Preparation of Phosphorus-Nitrogen Compounds [1]

By Dr. R. Schmutzler

E.I. duPont de Nemours & Co., Inc.,
Explosives Department, Experimental Station,
Wilmington, Del. (U.S.A.)

During the reaction of hexamethyldisiloxane and trimethylsilyl ethers with Lewis-acid phosphorus fluorides such as $RPF_4$ and $(C_6H_5)_2PF_3$ [2] cleavage of the Si—O bond and liberation of the trimethylsilyl groups as trimethylfluorosilane were observed.

Application of this principle to dialkylaminotrimethylsilanes allows the preparation of novel types of phosphorus-fluorine-nitrogen compounds [3]:

$$PF_5 + (CH_3)_3SiN(C_2H_5)_2 \xrightarrow[-78 \text{ to } +60^\circ C]{} (C_2H_5)_2NPF_4 + (CH_3)_3SiF \quad (1)$$

$$(C_2H_5)_2NPF_4 + (CH_3)_3SiN(C_2H_5)_2 \xrightarrow[150-170^\circ C]{} [(C_2H_5)_2N]_2PF_3 + (CH_3)_3SiF \quad (2)$$

$$H_5C_6PF_4 + (CH_3)_3SiN(CH_3)_2 \longrightarrow H_5C_6PF_3N(CH_3)_2 + (CH_3)_3SiF \quad (3)$$

$$H_5C_6PF_4 + \text{(N-Si(CH}_3\text{)}_3\text{ ring)} \longrightarrow H_5C_6PF_3N\text{(ring)} + (CH_3)_3SiF \quad (4)$$

The above method, which can be referred to as a controlled dialkylaminolysis of the phosphorus fluoride with $(CH_3)_3Si$ functioning as a "protecting group", is generally applicable. By reaction of $PF_5$ and fluorophosphoranes with *N*-substituted hexamethyldisilazanes, $[(CH_3)_3Si]_2NR$, four-membered P—N ring systems are formed [4]. Presumably there is a nucleophilic attack on the pentacoordinate phosphorus atom by the silazane-nitrogen atom. Nucleophilic reaction of the fluorine atom with silicon then cleaves the Si—N bond.

$$(CH_3)_3Si\text{-}NR_2 \xrightarrow{R'_nPF_{5-n}} (CH_3)_3Si\text{-}NR_2 \rightarrow (CH_3)_3SiF + R'_nPF_{4-n}NR_2$$

$$F\text{-}P(F_{4-n})(R'_n)$$

$n = 0, 1$; $R' =$ Alkyl or Aryl

The stereochemistry of the resulting tri- and tetrafluorophosphoranes was investigated by $^{19}F$- and $^{31}P$-NMR spectroscopy (see Table 1). The data for trifluorophosphoranes, as for dialkyl(diaryl)trifluorophosphoranes [5], were interpreted in terms of a trigonal bipyramidal model in which two fluorine atoms are in axial positions and one in an equatorial site. The $^{19}F$-NMR spectrum of $(C_2H_5)_2NPF_4$, in analogy with tetrafluorophosphoranes having hydrocarbon groups as substituents, consists of a simple doublet (P—F coupling) at room temperature, but is temperature-dependent, and at lower temperature the expected non-equivalence of the fluorine atoms is evident [6].

Table 1. Physical properties of compounds *(1)*—*(4)*.

| Compound | B.p. [°C/mm] | NMR Data $J_{P-F}$ [c] | $\delta$[p.p.m.] [a] $^{19}F$ | $^{31}P$ |

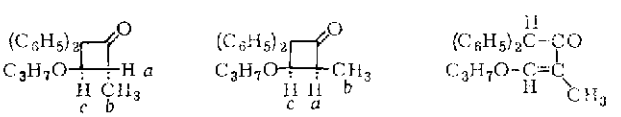
## Stereospecific Addition of Ketenes onto Enol Ethers

By Prof. Dr. R. Huisgen, Dipl.-Chem. L. Feiler, and Dr. G. Binsch



Institut für Organische Chemie der Universität München (Germany)

Ketenes react with enol ethers to form 3-alkoxycyclobutanones *(1)* [1—3] by addition in the electronically favored direction; the products are compatible with the occurrence of the resonance-stabilized intermediate *(2)*.

*(1)* *(2)*

Treatment of *trans*-propenyl propyl ether [4] with diphenylketene in absolute ether at 20 °C for seven days and removal of some ketene dimer gives an 86 % yield of *(3)*, m.p. 35 to 37 °C, $\nu_{C=O} = 1780$ cm$^{-1}$. The reaction of diphenylketene with *cis*-propenyl propyl ether [4] is complete after one hour and gives *(4)* in 85 % yield as an analytically pure oil, $\nu_{C=O} = 1778$ cm$^{-1}$. The NMR spectra of the crude products from both reactions do not indicate any mutual contamination of the adducts *(3)* and *(4)*, although 2.5 % of *(4)* in *(3)* and 3.8 % of *(3)* in *(4)* were readily detectable in synthetic mixtures. Competitive experiments revealed that the *cis*-enol ether reacts with diphenylketene 170 times faster than its *trans*-isomer.

*(3)* *(4)* *(5)*

The NMR spectra indicate that each of the two geometrically isomeric enol ethers has retained its original configuration in the adduct. A methyl group displaces the NMR signal of a *cis*-hydrogen on the adjacent carbon atom to higher field, and that of a *trans*-hydrogen to lower field; the doublet for the tertiary proton *c* appears at 5.62 $\tau$ for *(3)* and at 5.28 $\tau$ for *(4)*. The methyl doublet *b* lies at 8.74 and 8.77 $\tau$, respectively. $J_{ac}$ is 7.0 cps for the *trans*-adduct and 8.1 cps for the *cis*-

compound; however, *Karplus'* rule [5] does not strictly apply to four-membered rings.

In boiling xylene, both *(3)* and *(4)* are converted almost quantitatively into the same acyclic acylpropenyl propyl ether *(5)*. The structure of *(5)* was determined from elemental analysis, NMR and infrared spectra, and from acid hydrolysis to form 1,1-diphenylbutan-2-one.

Dimethylketene also adds onto both *trans*- and *cis*-propenyl propyl ether stereospecifically to yield diastereoisomeric cyclobutanones. Again the *cis*-form reacts faster. In the NMR spectra, the doublet for the tertiary proton on C-3 appears at 6.52 τ ($J_{ac}$ = 6.4 cps) in the *trans*-adduct and at 6.12 τ ($J_{ac}$ = 8.3 cps) in the *cis*-adduct.

The stereoselective *cis*-addition renders the formation of an intermediate such as *(2)* improbable. We assume that a one-stage multicentered cycloaddition takes place.

## Pentakis(trifluorophosphine)iron(0) [1]

By Priv.-Doz. Dr. T. Kruck and Dipl.-Chem. A. Prasch

Anorganisch-Chemisches Laboratorium der Technischen Hochschule München (Germany)

Anhydrous ferrous iodide reacts with highly purified trifluorophosphine at 140 °C and 500 atm in the presence of copper powder (to trap the iodide) to give over 40 % yield of pale yellow crystals of pentakis(trifluorophosphine)iron(0).

$$FeI_2 + 2\,Cu + 5\,PF_3 \rightarrow Fe(PF_3)_5 + 2\,CuI$$

This reaction represents the first direct synthesis of a homogeneous trifluorophosphine-metal(0) complex. The compounds $Cr(PF_3)_6$, $Mo(PF_3)_6$, and $Ni(PF_3)_4$ isolated previously were all prepared by elimination reactions from preformed hexa- or tetra-coordinate metal(0) complexes [2]. The iron complex is volatile and is readily soluble in the usual organic solvents; it remains undecomposed for a short time even in moist air, and in this and in other respects is very similar to its analogue pentacarbonyliron [3]. The infrared spectrum of the diamagnetic complex contains ν(P–F) vibrations at 949 (w), 922 (vs), 907 (s) 894 (sh), and 858 (s) $cm^{-1}$ plus two other sharp bands at 2044 (w) and 2017 (w) $cm^{-1}$ [4]. These weak absorptions in the 5-μ-region are due to combination vibrations and are characteristic of trifluorophosphine-metal(0) complexes.

## A New Synthesis of Indigo

By Prof. Dr. E. Ziegler and Dr. Th. Kappe

Institut für Organische and Pharmazeutische Chemie der Universität Graz (Austria)

We have succeeded in obtaining indigo [1] in excellent yield and purity from 4-hydroxycarbostyril *(1)* which in turn is produced in 90–93 % yield by fusing malonodianilide with $NaCl/AlCl_3$ at 240–250 °C [1].

The dichloro compound *(2)*, obtained in practically quantitative yield by chlorination of *(1)* [2], exchanges its two atoms of chlorine readily for two methoxy groups on treatment with 2 moles of sodium methoxide in methanol at 50 °C, to give the ketal *(3)*, m.p. 165–165 °C, in 93 % yield. Hydrolysis of *(3)*, by refluxing it for 1 h in 2 N NaOH, causes ring opening and decarboxylation to give the dimethylacetal *(4)*, m.p. 100–102.5 °C, in 92 % yield. Treatment of *(4)* with dilute acid converts it rapidly and quantitatively *via* unisolable *o*-aminophenylglyoxal into indigo.

Starting from the dichloro compound *(2)*, indigo can be prepared in 90 % yield in a single run and in the same reaction vessel by treating *(2)* in series with methanolic sodium methoxide for 10 min at 50 °C, with boiling 2 N NaOH for 60 min, and finally with dilute mineral acid.

The principal advantage of this new procedure is that instead of merely *(1)*, various substituted 4-hydroxycarbostyrils, or the cyclic malonyl derivatives of α- and β-naphthylamine, 6-aminocoumarin, 9-aminophenanthrene, 1,2,3,4-tetrahydroquinoline, *etc.* can be used as starting materials. Benzidine or 1,2,3,4-tetrahydroquinoxaline thus give rise to indigoids of higher molecular weight in which the above series of reactions has taken place twice in the same molecule.

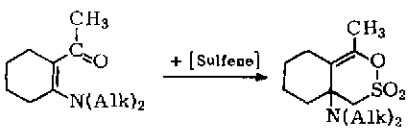
## Sulfene as a Dienophile

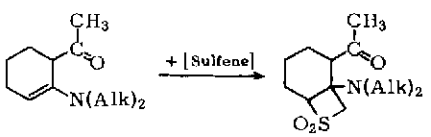
By Priv.-Doz. Dr. G. Opitz and Dipl.-Chem. E. Tempel

Chemisches Institut der Universität Tübingen (Germany)

Sulfene $H_2C{=}SO_2$ is an intermediate formed by abstraction of HCl from methanesulfonyl chloride with triethylamine [1,2]; it reacts with vinylogous carboxamides of type *(1)* in a kind of diene synthesis to form unsaturated 3-amino-δ-sultones *(2)* which exhibit a weak to medium olefin band in the



| | $R^1$ | $R^2$ | $R^3$ | $N(Alk)_2$ |
|---|---|---|---|---|
| *a* | $CH_3$ | $CH_3$ | H | Piperidino |
| *b* | $CH(CH_3)_2$ | H | H | Pyrrolidino |
| *c* | $CH_3$ | H | $CH_3$ | Dimethylamino |



infrared at 1674–1682 $cm^{-1}$ and sulfonate bands at 1360 and 1150 $cm^{-1}$. This cyclization corresponds to the formation of α-pyrones from vinylogous carboxamides and ketene [3].

1-Piperidino-2-methylbut-1-en-3-one *(1a)* reacts with methanesulfonyl chloride in the presence of triethylamine in ether at room temperature to give the β-amino-δ-sultone *(2a)*, in 80 % yield, as colorless crystals, m.p. 108–109 °C (from methanol). Analogously, 1-pyrrolidino-4-methylpent-1-en-3-one *(1b)* gives the β-aminosultone *(2b)*, m.p. 94–95 °C in 75 % yield. The trisubstituted ethylene bond in *(1a)* gives rise to an intensified C=C valence vibration in its infrared spectrum at 1681 $cm^{-1}$ and to a weak =C–H band at 3070 $cm^{-1}$. 2-Dimethylaminopent-2-en-4-one *(1c)*, which is obtained from acetylacetone and dimethylamine, gives only 7 % of the β-aminosultone *(2c)*, m.p. 91–92 °C.

With the aid of this new Diels-Alder reaction and the formation of β-aminotrimethylenesulfones [1] from simple alkenylamines and methanesulfonyl chloride plus triethylamine it can be shown that acylation of 1-dialkylaminocyclohexene with acetyl chloride and triethylamine leads to mixtures of vinylogous carboxamides *(3)* and their unconjugated isomers *(5)*.

*(3)* *(4)*

*(5)* *(6)*

The reaction of mesyl chloride plus triethylamine with *(3)* + *(5)*, $N(Alk)_2$ = pyrrolidino, produces 32 % *(4)*, m.p. 80 to 82 °C, and 8 % *(6)*, m.p. 133–134 °C; with *(3)* + *(5)*, $N(Alk)_2$ = piperidino, it produces 9 % *(4)*, m.p. 108–109 °C, and 57 % *(6)*, m.p. 118–119 °C, and with *(3)* + *(5)*, $N(Alk)_2$ = morpholino, it affords 5 % *(4)*, m.p. 153–155 °C, and 66 % *(6)*, m.p. 123–124 °C. It is easy to identify the β-aminotrimethylenesulfone derivatives *(6)* by their strong carbonyl band in the infrared.

## Rearrangement of Dibenzo[*c*,*g*]carbazole to Dibenzo[*a*,*g*]carbazole

By Dr. M. Zander and W. H. Franke

Rütgerswerke und Teerverwertung AG.,
Castrop-Rauxel (Germany)

During attempts to convert dibenzo[*c*,*g*]carbazole *(1)* into the unknown compound 1,12-iminoperylene by heating it with $AlCl_3$ in boiling benzene for 2.5 h or in an $AlCl_3$/NaCl melt at 140 °C for 7 min, we obtained, surprisingly, dibenzo[*a*,*g*]carbazole *(2)* in yields of 14 % ($AlCl_3$/benzene) and 25 % ($AlCl_3$/NaCl melt) instead.

Compound *(2)* was identified by comparing its melting point and ultraviolet, infrared, and phosphorescence spectra to those of an authentic sample [1]; the melting point of a mixture of the two materials showed no depression. Compound *(1)* used for the experiments was prepared from 2,2'-dihydroxy-1,1'-binaphthyl and $NH_3$ [2] and was pure, as

careful examination of its melting point and ultraviolet, infrared, and phosphorescence spectra indicated. The dibenzo[*a*,*g*]carbazole *(2)* must, therefore, have been formed by intramolecular rearrangement of *(1)*.

Although rearrangements of polynuclear aromatic hydrocarbons [3] such as benz[*a*]anthracene, dibenz[*a*,*h*]anthracene, picene, *etc.* are known, this is probably the first example of the rearrangement of a carbazole benzologue.

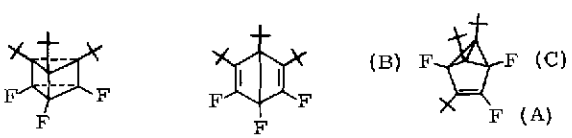
## Valence-Bond Isomers of (Substituted) Benzene

### Simultaneous Formation of Substituted Tetracyclohexane, Tricyclohexene, and Bicyclohexadiene by Spontaneous Trimerization of t-Butylfluoroacetylene [1]



By Dr. H. G. Viehe, Dipl.-Ing. R. Merényi, Dr. J. F. M. Oth, J. R. Senders [2], and P. Valange [2]

Union Carbide European Research Associates,
Brussels (Belgium)

t-Butylfluoroacetylene is an extremely reactive compound which undergoes exothermal oligomerization [3]. Of the trimeric products formed in this reaction, only 1,2,3-tri-t-butyltrifluorobenzene [3] is aromatic; all the others are derivatives of valence-bond isomers of benzene [4].

The component of this mixture which was easiest to purify by gas chromatography is the "prismane" derivative *(1)*, which melts at 187 °C and is stable up to 250 °C. Its infrared spectrum contains no C=C absorptions, and its ultraviolet spectrum in n-hexane down to 200 mμ shows only end absorption. Its NMR spectrum contains a singlet at −1.18 ppm for the t-butyl protons and another at +176 ppm for the fluorine atoms [5]. In contrast to *(2)* and *(3)*, compound *(1)* does not react with $Br_2$ in $CCl_4$ or with $O_3$ in petroleum ether at room temperature. An X-ray analysis of its structure is being made.

The derivative *(2)* of "Dewar benzene" is more sensitive and could be separated only by cautious crystallization, but even then only in admixture with some *(1)*. Brief heating at 100 °C suffices to convert *(2)* quantitatively into 1,2,3-tri-t-

*(1)* *(2)* *(3)*

⊣ = t-Butyl

butyltrifluorobenzene. However, the structure of *(2)* appears to be well established by the following findings: a sample containing about 30% *(1)* showed only end absorption in n-hexane down to 200 mμ but exhibited a C=C absorption in the infrared at 5.96 μ. The NMR spectrum of *(2)* [5] has two signals each for the protons and fluorine atoms, both with relative intensities of 2:1; the proton signals are at −1.2 and −1.12 ppm, the fluorine signals at +103 and +181 ppm. All the F F coupling constants are less than 2 cps.

The third component is a derivative *(3)* of tricyclo[2,1,1,$0^{5,6}$]-hex-2-ene, which we call benzvalene; this is a liquid, b.p. ca. 140 °C/11 mm (air bath), which is readily separated by column chromatography. It has a strong C=C absorption at 5.98 μ. Its ultraviolet spectrum has $\lambda_{max}$ = 232 mμ (ε = 2500) and 300 mμ (ε = 300); this makes a bicyclohexadiene structure highly improbable. The ultraviolet spectrum is readily explicable by the assumption of optimum conjugation between the cyclopropane ring and the double bond with the plane of each mutually at right angles [6]. The NMR spectrum of *(3)* [5] has two signals for t-butyl protons with intensity ratios of 1:2 (a doublet at −1.22 and a multiplet at −1.16 ppm) and three fluorine signals of equal intensity: a broad band at +102 (A), a doublet at +182 (B), and a quadruplet at +184 ppm (C). The respective coupling constants are $J_{AB} < 2$ cps, $J_{AC} = 4$ cps, and $J_{BC} = 10$ cps. Compound *(3)* gives rise to a liquid dibromide which has no maxima in its ultraviolet spectrum and no C=C absorption in the infrared. Debromination of this derivative with magnesium in tetrahydrofuran yields *(3)* again. When heated to 220 °C, *(3)* is transformed into 1,2,4-tri-t-butyltrifluorobenzene, m.p. 53–54 °C, which has a C–C band at 6.22 μ and ultraviolet maxima at 201, 238, and 297 mμ (ε = 25000, 6600, and 1500).

The NMR spectrum [5] of 1,2,4-tri-t-butyltrifluorobenzene contains an asymmetric multiplet centered around −1.45 ppm for the t-butyl protons and three signals of equal intensity for the fluorine, *viz.* a multiplet at +102 ppm, and two double multiplets for the *ortho*-fluoro substituents at +133 and +135 ppm. The latter signals give a value for $J_{FF\ ortho}$ of 16 cps.

# CONFERENCE REPORTS

## Second International Dyestuff Symposium [*]

April 21st to 24th, 1964 at Schloß Elmau (Germany)

From the lectures:

### The Solvent-Dependence of the Wave Number of Electronic Absorption Bands and its Physico-chemical Basis

*W. Liptay*, Würzburg (Germany)

The solvent-dependence of the wave numbers of absorption and emission bands is essentially determined by polarization and dispersion interactions between the dissolved molecule and the surrounding solvent molecules, provided that specific interactions, *e.g.* the formation of electron donor/electron-acceptor complexes or hydrogen bridge associates, can be excluded. The solvent properties of the medium are approximated by functions of the dielectric constant and of the refractive index.

For neutral, dipole-free, dissolved molecules, dispersion interactions are important. Starting from a generally valid relationship and using the Thomas-Reiche-Kuhn summation principle, an equation was obtained according to which the displacement of the absorption and emission bands for an electron transition between the ground state and any excited state must always be toward smaller wave numbers in a solution than in the gaseous state (bathochromic shift). If the wave functions of the dissolved molecule are approximated by Slater determinants, the following approximate equation is obtained for the displacement of the wave number of the absorption and emission bands by dispersion interactions:

$$\Delta\tilde{\nu} = -\frac{n^2-1}{2n^2+1}\,D'$$

$$D' = \frac{1}{a^3 hc}\,\frac{E_a}{(\bar{E}_n - E_a)\bar{E}_n}\left[\frac{3\hbar^2 e^2}{2m} + (2\bar{E}_n - E_a)\,\mu_{ag}^2\right]$$

where n is the refractive index of the solvent; $E_a$ and $\mu_{ag}$ are respectively the energy and transition moment of the excitation in question; a is an empirical constant of the order of magnitude of the molecular radius; $\bar{E}_n$ is a constant of the order of magnitude of the ionization energy of the dissolved molecule; $h = 2\pi\hbar$ is Planck's constant; e and m are the charge and mass of an electron; and c is the velocity of light. The bathochromic shift due to dispersion interactions is thus approximately a linear function of $(n^2-1)/(2n^2+1)$, and is determined by two terms. The first term depends only on the magnitudes of the energies, whilst the second also depends on the probability of transition of the band in question. To an approximation, therefore, the bathochromic shift increases with increasing intensity of the absorption and remains finite even for the weakest bands; this agrees well with experimental findings.

The band displacement of dissolved neutral molecules with a dipole moment is determined by both dispersion and polarization interactions. Classical and quantum mechanical treatments lead to identical results as regards the terms and show that the polarization component of the solvent-dependence of the absorption (emission) depends essentially on the dipole moment in the ground state (excited state) and on the change in dipole moment occurring during the excitation (emission). The calculation of the problem was carried out, taking the polarizability of the dissolved molecule completely into account for the first time. An increase in the dipole moment on excitation causes a bathochromic shift of the absorption, and a decrease causes a hypsochromic shift; the

magnitude of the latter depends on the dielectric constant and the refractive index of the solvent, and is superimposed on the bathochromic shift due to dispersion interactions. Various approximate equations which are suitable for application were discussed and applied to a few examples.

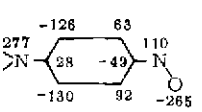
The solvatochromism of the merocyanine-type dyes has frequently been interpreted as being due to a change in their resonance. It was shown that the change in resonance and the polarization of the dissolved molecule are identical, and should therefore also be better described by this term. However, the strong solvatochromism of various merocyanines is not due to their polarizability, but to their large dipole moment in the ground state and the large change in the dipole moment during excitation. The anomalies in the dependence of the absorption bands on the dielectric constant, found by *Brooker*, are probably always due to associates, particularly hydrogen-bonded associates.

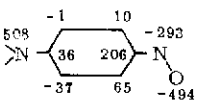
## Methods for Determining the Charge Distribution in Electronically Excited States

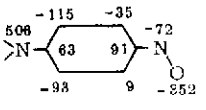
*H. Labhart*, Basel (Switzerland)

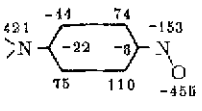
The main experimental methods for determining the charge distribution in electronically excited molecular states are summarized in Table 1. It can be seen that, with the exception of substituent effects, which permit the estimation of charge variations on the atoms of conjugated systems, all the methods solely yield the dipole moments in the excited states. However, these experimental dipole moments can be used to check theoretically determined atomic charges. By taking into account the configurational interaction between the nine lowest singly excited configurations, SCF Pariser-Parr-Pople calculations yielded charge distributions such as those given in Table 2 for *p*-nitrosodimethylaniline. Table 2 also shows a comparison of the theoretical and experimental dipole moments.

Table 2. Charge distributions and dipole moments of *p*-nitrosodimethylaniline.









| State | Charge distribution in $10^{-3}$ protonic charges | π-Dipole moment, calculated [Debye] | Total dipole moment, experimental [Debye] |
|---|---|---|---|
| Ground state |   | 5.96 | 6.45 |
| First excited π-π* state λ = 390 mμ |   | 17.7 | 13.5 |
| Second excited π-π* state λ = 300 mμ |   | 12.9 | — |
| Third excited π-π* state λ = 270 mμ |   | 14.8 | 13.4 |

Table 1. Experimental methods for determining the charge distribution in electronically excited states.

| Effect | Interpretation | Result | Notes |
|---|---|---|---|
| Influence of substituents on the spectrum | Perturbation of the π-electron system by inductive effects | Change in the atomic charges on optical excitement | Advantages: local charge variations<br>Disadvantages: perturbation often too great or mesomeric |
| Solvent effects on the absorption and fluorescence spectra | Stark effect in the reaction field of the solvent | Dipole moment in the lowest excited singlet state | Advantages: observation simple<br>Disadvantages: size of the reaction field uncertain; suitable only for fluorescent molecules |
| Band displacement in an external electric field | Stark effect of the partially oriented molecules in the applied field | Dipole moments in several excited singlet states | Advantages: also suitable for non-fluorescent molecules<br>Disadvantages: effect often small |
| Polarization of luminescence in an external electric field | Degree of orientation of excited molecules in the field | Dipole moments in the lowest excited singlet or triplet state | Advantages: dipole moments of triplet states can be determined<br>Disadvantages: luminescence essential |

It should be pointed out that, without calculation, it is impossible to predict such charge distributions in excited states, even qualitatively, by writing down resonance structures.

[*] All lectures together with discussion remarks will soon be published.

## The Dependence of the Color of Fluorescence on the Medium

*E. Lippert*, Stuttgart (Germany)

One of the characteristics of a good optical brightener is that its absorption spectrum begins with a very intense O–O transition near the long-wave end of the ultraviolet spectral region. It is to be expected that it will completely absorb the ultraviolet components of the incident daylight or artificial light, and that its fluorescent light is distributed over the violet and blue regions of the spectrum. The fluorescent color of fluorescent dyes must agree with their absorption color. In both cases, the quantum yield of the fluorescence should be close to unity. Competing mechanisms for the conversion of electronic excitation energy, which depend on the surrounding medium, should thus be excluded [1]. Consequently, for example, it cannot be concluded from the observation that a substance is only weakly fluorescent in solution that it is necessarily a poor optical brightener. The

[1] For a survey of these mechanisms see *E. Lippert* et al., Angew. Chem. *73*, 695 (1961).

color of the fluorescence also depends on the substrate, not only owing to the intermolecular interactions which also affect the absorption color, but also owing to the solvent-dependent relaxation effects which always occur during the life of the fluorescent excited state and which are based on the Franck-Condon principle and on the fact that the various electronic states of a system are associated with different charge distributions and equilibrium nuclear configurations. The consequent photophysical relaxation cycles for solutions of Dilthey-Wizinger dyes (structure: chromophore-aromatic system-auxochrome; *e.g.* *p*-amino-*p'*-nitrobiphenyl) were described.

### Influence of the Dielectric Properties of Solvents and Substrates on the Light Absorption and Photochemical Behavior of Cationic Dyes

*F. Feichtmayr* and *J. Schlag*, Ludwigshafen/Rhein (Germany)

A dye salt in solution and on solid substrates may either be dissociated into individual ions or exist in ion pairs. Furthermore, similarly charged ions of the dye may be present as the monomer or dimer, or in higher associates. For dyes deposited on solid substrates, little is known concerning the position of the equilibria between these states, since most methods of investigation can only be used in solution. For symmetrical triphenylmethane dyes, such as Crystal Violet and Victoria Blue, the forms of the dye salts taking part in the equilibria can be distinguished by their absorption spectra in the visible region. The equilibria for these dyes can therefore be spectroscopically investigated both in solution and on solid substrates.

It was found that, for such dyes in solution and on solid substrates, the dielectric properties of the surroundings of the dye stuff molecule determines the dissociation of the salts and the association of the dye cations. The dye salts are undissociated in non-polar media, and dissociated in polar media. Association of similarly charged dye ions occurs only in strongly polar media.

The photochemical stability of the dye salts depends on their state of dissociation and association. Dissociated salts are more stable towards light than undissociated salts. Furthermore, the "light-fastness" depends on the nature of the anion of the salt. In solution and on substrates in which the rate of diffusion of the reaction products is high, the rate of fading of the dye salt increases with the ease with which the anion can give up its electron, *i.e.* with decrease in the electron affinity of the anion. It is therefore concluded that the first step in the reaction involved in photochemical fading is an electron transition from the anion to the photoexcited dye cation. In substrates in which the anion and the dye cation cannot diffuse away from each other sufficiently rapidly after the electron transition, the "light-fastness" of the dye salt is no longer determined by the electron affinity of the anion. Here it increases with the activation energy for the secondary reaction of the free radical formed from the anion (detected by ESR spectroscopy) with the substrate (hydrogen abstraction).

### Relationship between the Constitution of Cationic Triphenylmethane Dyes and their Light-Fastness on Polyacrylonitrile

*R. F. Johnson*, *O. A. Stamm*, and *H. Zollinger*, Zürich (Switzerland)

In investigations on 20 triphenylmethane dyes of the type of Malachite Green (R = $CH_3$, X = H), Doebner's Violet (R = H, X = H), and 4-dimethylaminotriphenylcarbonium chloride, the acidity constants of the carbonium ion $\rightleftharpoons$ carbinol equilibrium, the light-fastness of the dyes on Orlon 42, Dacron 64, and mordanted and cyanoethylated cottons, and (for most of the dyes) the adsorption isotherms on Orlon 42 were measured. The standard affinities ($-\Delta_\mu^0$) were calculated from the Langmuir isotherms.

The $pK_a$ values and the light-fastness (blue scale) on Orlon 42 and on Dacron 64 of *m*- and *p*-substituted malachite-green derivatives follow the Hammett relationship for benzene derivatives, whilst their light-fastness on pretreated cotton does not. For standard affinities, an additional influence is presumably superimposed upon a simple Hammett relationship. Photolytic oxidation (according to *C. H. Giles*) is not the only interpretation for the observed Hammett relationship. It was concluded

1. that the much higher light-fastness of cationic dyes on polyacrylonitrile fibers than on pretreated cellulose fibers is not due to covalent fiber-dye bonding;

2. that free-radical formation from the excited state is compatible with the observed substituent effects;

3. that the difference in light-fastness is probably due to the nature of the fiber's counterion ($SO_3^\ominus$ and $-COO^\ominus$) and on the rate of recombination and/or of the secondary reactions of the free radicals initially formed;

4. that the Hammett relationship is of limited importance for final clarification of a bleaching mechanism.

### Changes in the Light-Fastness and Color of Organic Dyes on Various Substrates

*M. Pestemer*, Leverkusen (Germany) [*]

The light-fastness of dyes (*e.g.* triphenylmethane, anthraquinone, cyanine, phthalocyanin, and azo dyes) depends mainly on their bonding to the substrate and on their particle size. The color hues can vary very considerably with the substrate, particularly with polar dyes. Samples were shown of dyeings on wool, silk, cotton, acetate rayon, polyacrylonitrile, polyamide, polyester, and polypropylene fibers. Treatment to improve crease-resistance and wash-fastness also has a decisive influence on the competition between deactivation and chemical reaction of dye molecules which have been activated by light absorption. As a result of fiber treatment, dyes generally become more finely divided, with resulting deterioration of their light-fastness. The photochemical reaction also depends on the substrate and generally leads initially to reduction of dyestuffs on wool, silk, and gelatin, whilst on all other substrates it results in oxidation of the dyes. It was shown with examples how important the role of water may be in this reaction. For certain green combinations of blue phthalocyanin dyes and yellow 3-methyl-1-phenylpyrazolone azo dyes, the wet-fastness falls off rapidly compared with the light-fastness under normal conditions. The increased light-fastness of many cationic dyes (*e.g.* triphenyl methane, phenoxazine, and indole derivatives) on polyacrylonitrile is probably attributable to the chemical inertia of this fiber. Many polar azo dyes exhibit phototropism on fibers, *i.e.* "displacement" toward other color tones, which is reversed in the dark. Some phthalocyanin derivatives also exhibit phototropism as a result of treatment of the textiles with melamine-HCHO or urea-HCHO condensates to improve their crease-resistance.

### Study of Intermediates in Flash Photolysis

*G. Porter* and *A. D. Osborne*, Sheffield (England)

Flash photolysis was the first method which permitted concentration of intermediates by optical excitation to such an extent that they could be observed optically [1] (generally $10^{-5}$–$10^{-2}$ sec after the flash photolysis). Whereas the rate constant k can be calculated directly for photolysis which

[*] Based on contributions from Badische Anilin- und Soda-Fabrik, Ludwigshafen, Farbenfabriken Bayer, Leverkusen, and Farbwerke Hoechst, Frankfurt/Main-Höchst (Germany).

[1] *G. Porter*, Proc. Roy. Soc. (London), Ser. A *200*, 284 (1950).

proceed by first-order kinetics, only $k/\varepsilon$ is initially obtained for a second-order reaction. The extinction coefficient $\varepsilon$ of the intermediate can be determined from the decay time of the collision-controlled reaction in viscous media [2, 3]. A process which can occur with low activation energy at each collision with a luminescence extinguisher (Q) is: $T_1 + S_Q \rightarrow S_0 + T_Q$ ($T_1$ and $T_Q$: triplet states of the substrate and the extinguisher; $S_Q$ and $S_0$: singlet states of the extinguisher and the substrate). Thus, for example, benzophenone is deactivated by naphthalene as an extinguisher, its reduction to benzopinacol being prevented by the solvent.

The rate constant for a collision-controlled, second-order luminescence extinction is given by

$$k_Q = 8\,RT/200\,\eta \text{ [l/mole·sec]} \qquad (\eta = \text{viscosity})$$

Since the potential curve of any excited substituted aromatic compound (this is generally similar to its curve in the ground state) is intersected by the potential curve (repulsion term) of a free radical state, the aromatic compound can undergo cleavage at an exocyclic bond, *e.g.*

$$C_6H_5-CH_3 + h\nu \rightarrow C_6H_5-CH_2\cdot + H\cdot$$

This reaction is scarcely affected by the temperature and the solvent. On the other hand, the reaction, for example, of S* or T*-excited aldehydes and ketones with solvent molecules is strongly dependent on the solvent and temperature. Thus, the following reaction proceeds through an $n$-$\pi^*$ triplet state, and is completely suppressed below $-40\,^{\circ}C$:

$$(C_6H_5)_2C{=}O \xrightarrow{h\nu} [(C_6H_5)_2C{=}O] \xrightarrow{RH} (C_6H_5)_2\dot{C}-OH + R\cdot$$

Whereas the solvent radicals recombine rapidly, large radicals of the substance (*e.g.* 2,4,6-tri-t-butylphenoxyl and rhodamine-B radicals) may be stable for minutes or even hours in the absence of oxygen. Carbonyl compounds (benzaldehydes, benzophenones, anthraquinones) with hydroxyl or amino substituents in the *ortho*-position are completely resistant to photolysis owing to hydrogen bonding (such compounds are therefore used, as dye stabilizers, for example). On the other hand, some benzophenones and anthraquinones without these *ortho*-substituents sensitize fiber damage. As *Porter* and *Suppan* [4] found, the electron-donating substituent in the stable carbonyl compounds causes a long-wave charge-transfer triplet state. Owing to a $\delta$-charge, the carbonyl oxygen is no longer chemically reactive in the excited state.

## Classification of the Excited Electronic States of Organic Molecules with the Aid of the Degree of Polarization of the Fluorescence and Phosphoresence

*F. Dörr*, München (Germany)

The degree of polarization of the luminescence produced by selective excitation in the various absorption bands with polarized light yields information on the position and form of masked absorption bands, the relative orientation of transition moments, the symmetry of structural vibrations, and the effective mechanism of the triplet-singlet emission. These data are particularly useful for checking theoretical models, which generally give the number and the direction of the polarization of transitions with greater reliability than their energy and intensity.

Special examples: The appearance of a cross-polarized band during the photoisomerization of unbranched polymethine dyes led to the conclusion that a *trans* → *cis*-rearrangement had occurred. The first and second absorption bands of Malachite Green are polarized perpendicularly to each other. On the other hand, the first band of Crystal Violet is degenerate; the degree of polarization drops within the band from about 0.5 to zero. The high value of 0.5 does not agree with a threefold axis of symmetry and rules out a propeller form for the molecule. Two rings probably lie in one plane, while the third is twisted out of plane.

In phosphorescence, heavy substituents have a pronounced effect on the degree of polarization even when they affect the spectra only slightly.

## Current Ideas on Spectral Sensitization

*E. Klein* and *R. Matejec*, Leverkusen (Germany)

In photographic and electrophotographic processes, the primary process (formation of free charge carriers) is the same. Both processes can consequently be spectrally sensitized.

The classes of dyes which can be used for sensitization (particularly fluoresceins and cyanins) and the requirements placed on them (light absorption, adsorption, no desensitization, good sensitization) were discussed, together with the observed attendant effects (super-, anti-, and desensitization; formation of dye aggregates, crowding, singlet and triplet transitions).

The quantum yield of spectral sensitization generally decreases with decreasing temperature, and cannot be increased above a maximum value of $\varphi \approx 0.25$, even by supersensitization [*]. The main effect of supersensitization is to prevent reduction of this quantum yield at lower temperatures; this effect falls off only at very low temperatures ($T < -183\,^{\circ}C$). The relationship between absorption spectra, sensitization spectra, and photoconductivity spectra were discussed with examples (AgBr + sensitizer; AgBr + another dye; AgBr + sensitizer + supersensitizer; CdS + sensitizer; ZnO + sensitizer).

It was found from both photolytic investigations on AgBr and photoconduction measurements on ZnO that a sensitizer molecule is capable of effecting sensitization several times (in the limiting case, infinitely often). This discovery is extremely important for the mechanism of spectral sensitization. There are two main questions in the discussion of the mechanism of sensitization:

1. how can the dye in the photoconductor (or in the silver halide) initiate photophysical processes on absorption of an appreciably smaller quantum of energy than the specific absorption of the silver halide or the photoconductor?

2. are electrons or energy transferred from the sensitizer to the photoconductor?

The probable answer to the first question is that spectral sensitization is a surface process; however, the semiconductor surface certainly has a electronic structure different from that of the interior of the semiconductor (bending upwards of the electron bands; surface terms, *etc.*), so that, taking account of the probability of transition, the energy relationships found for spectral sensitization are different from those to be expected from the electronic structure of the interior of the semiconductor (*i.e.* from the distance between the valence band and the conductivity band).

With regard to the second question, barrier-layer effects indicate electron transfer. Estimation of the probability with which the electrons could "tunnel" through the potential barrier which is presumably present between the photoconductor and the dye shows that electron transfer may also be physically possible. On the other hand, energy transfer is indicated particularly by experiments in which the energy from a receiver dye absorbing the incident light is passed

[*] The term "supersensitization" refers to a "catalytic" increase in sensitization by very small amounts of foreign compounds.

through a layer of barium stearate about 200 Å thick or across several solvent molecules without radiation to a receiver substance which emits fluorescent light. Similar energy transfer phenomena are known to occur in systems such as anthracene/tetracene, and in the 'plastic scintillators' used in nuclear technology.

### Fiber Damage due to Anthraquinonoid Dyes

*F. Dörr*, München (Germany)

Yellow anthraquinone dyes dehydrogenate their substrate on exposure to light. The known dyes can be divided into two groups according to the electronic structure of their lowest excited state. In the first group, which included most yellow dyes, the lowest excited state is a triplet n-$\pi^*$ state in which a non-bonding, localized n-electron from the oxygen of the keto group passes into a delocalized $\pi^*$-orbital of the carbon skeleton. The free-radical electron remaining on the oxygen reacts with the surroundings. Almost all the dyes which cause active damage belong to this group. In the second group, the lowest triplet level of the delocalized $\pi$-electrons T($\pi$-$\pi^*$) is depressed below the T(n-$\pi^*$) level by the action of substituents. This group includes the inactive dyes.

This hypothesis is supported by the detection of n-$\pi^*$ absorption bands in dyes which cause damage, by the flash-spectroscopic detection of ketyl radicals in active benzophenone derivatives, and of semiquinone radicals in active anthraquinone derivatives. These radicals react further by second-order kinetics. They are absent from all the inactive compounds investigated. Flavanthrone, which belongs to the second group, is progressively reduced on cellophane to the semiquinone radical ion, when irradiated with light of 365 mμ wavelength in its second, weak absorption band. It is assumed that a T(n-$\pi^*$) state, which lies above the T($\pi$-$\pi^*$) level, can also react in the case of hindered deactivation.

## Modern Methods of Organic Analysis

A symposium under the above title organized by the Analytical Chemistry Sections of the Royal Dutch Chemical Society and the German Chemical Society was held in Eindhoven (Holland) from May 20th to 23rd, 1964.

From the lectures:

### Determination of Acetoacetic Acid in 0.1 ml of Blood

*F. Bahner*, Heidelberg (Germany)

Acetone is liberated from the acetoacetic acid in the blood sample and isolated by microdiffusion. Disadvantages of the Conway microdiffusion apparatus are that the diffusion cell is not gas-tight at 30–40 °C, and a temperature gradient cannot be maintained between the inner and outer chambers. In a new apparatus described, a temperature difference can be maintained between the two reacting solutions. Acetone reacts in alkaline solution with salicylaldehyde to form red 1,3-disalicylideneacetone. The reaction is influenced by 1. the reactant concentrations; 2. oxygen; 3. daylight; and 4. slow thermal dissociation of the disalicylideneacetone in alkaline solution; this last factor makes the final color dependent on temperature. Under appropriate conditions, $10^{-8}$ mole of acetone can be separated and determined.

### Improvement and Automation of the Determination of Creatinine

*K. Beyermann*, Mainz (Germany)

Creatinine can be separated rapidly and selectively by precipitation as its tetraphenyl borate complex in the presence of butylamine as carrier. The optimum conditions for precipitation (pH 3 ± 1, $10^4$-fold excess of tetraphenyl borate and $10^3$-fold excess of butylamine, room temperature) were determined by studies with [$^{14}$C]creatinine [1]. For $10^{-2}$–$10^3$ μg of creatinine per ml, the efficiency of isolation is 97–100 %. About 300 substances representing either normal constituents of biological materials or pharmaceutical preparations did not interfere. The few compounds which are coprecipitated do not interfere in practice with the subsequent determination. The precipitate is dissolved in dimethylformamide, and the red color produced by reaction between creatinine and picric acid is determined spectrophotometrically. Protein must first be separated off by precipitation with trichloroacetic acid; this results in a creatinine loss of less than 1 %. Other separation procedures (ion exchange, adsorption on Fuller's earth) gave lower recoveries. A fully automatic, programmed apparatus makes it possible to complete 10 creatinine determinations per hour.

[1] *K. Beyermann*, Z. analyt. Chem., in the press.

### Thin-Layer Chromatography on Silica Gel Impregnated with Silver Nitrate

*F. C. den Boer*, Vlaardingen (Holland)

Substances with C–C double bonds form complexes with silver ions. Hence olefinic substances can be separated on thin layers of silica gel previously impregnated with silver nitrate. The thin layers can be prepared quickly, and 0.1 to 100 mg of mixtures can be separated quickly, readily identified, and isolated quantitatively.

Typical analyses include the separation of the methyl esters of the fatty acids in soya oil having the same chain length but different numbers of double bonds, analysis of a mixture of the triglycerides of linoleic, oleic, and stearic acid, and the analysis of a mixture of acetylated methylsterols.

### Separation of Steryl Acetates by Thin-Layer Chromatography

*J. W. Copius-Peereboom*, Leiden (Holland)

Mixtures of animal and vegetable fats were analysed by identifying the sterol types present by means of a thin-layer chromatography reversed-phase technique on kieselguhr G impregnated with undecane (b.p. 190–220 °C). On development of the plates with acetic acid/acetonitrile (25:75), various steryl acetates, *e.g.* the acetates of β-sitosterol, stigmasterol, cholesterol, desmosterol, and $\Delta^{9(11)}$-dehydroergosterol, are separated into small semi-circular bands.

The rates of migration of sterols are characterized by their carbon numbers (Nc values), *i.e.* the number of carbon atoms minus the number of double bonds.

Unfortunately, in this system, certain sterol pairs have equal $R_F$ values, *e.g.* cholesterol and brassicasterol; ergosterol and 7-dehydrocholesterol. Such "critical pairs" of sterols were separated by adding 0.5 % bromine to the mobile phase according to the procedure of *Kaufmann*.

Critical pairs of sterols can also be separated on silica gel-G layers impregnated with silver nitrate. The acetates of various sterols are separated with chloroform/light petroleum/acetic acid (25:75:0.5) as solvent, *e.g.* the pairs: dihydrocholesterol/cholesterol, $\Delta^7$-cholesterol/cholesterol, $\Delta^7$-cholesterol/5-dihydroergosterol, lanosterol/agnosterol. Sterols with a greater number of ethylenic linkages display lower $R_F$ values in this system.

### Colorimetric Sub-micro Determination of Bromine in Organic Compounds

*T. R. F. W. Fennell* and *J. R. Webb*, Farnborough, Hants (England)

Sulfophthalein dyes in strongly acidic solution exhibit high intensity absorption in the 500–550 mμ spectral region. It was found that on treating bromide with bromate in the acidic dye solutions, a decrease of the absorption intensity occurred which was proportional to the amount of bromide present. Detailed investigations with several dyes showed that *o*-cresolsulfophthalein (cresol red) was most suitable for the determination of bromide.

By varying the initial concentration of dye, 2–10, 5–20, and 10–40 μg amounts of bromide were determined with standard deviations of 0.08, 0.12, and 0.16 μg respectively. Within these ranges, straight-line calibration curves were obtained. Apart from chloride and iodide, ions in the amounts that occur in sub-micro analyses do not interfere provided that oxidizing and reducing agents are absent.

### Analysis of Drugs in Biological Fluids by the Tropäolin Method

*A. Häussler* and *P. Hajdu*, Frankfurt/Main-Hoechst (Germany)

The formation of chloroform-soluble complexes with Tropäolin-00 (4-Phenylaminoazobenzene-4′-sulfonic acid) by many basic pharmaceuticals can be used for both qualitative and quantitative analysis [2]. Using an Autoanalyzer [3], a continuous record of reaction kinetics can be obtained by this method, *e.g.* of the ester hydrolysis of local anesthetics at low concentrations (10–50 μg/ml) in serum. The calculated reaction constants show that the rate of hydrolysis is strongly species-dependent. This finding is in agreement with the literature [4]. Complex formation can also be used to extract basic drugs selectively from body fluids. By fluorimetry of the extract, less than $10^{-6}$ g of drug material can be detected.

### Automatic Combination of Thin-Layer Chromatography and a Temperature-Programmed Gas-Chromatograph

*R. Kaiser*, Ludwigshafen/Rhein (Germany)

With increasing molecular weight, the uncertainty in the qualitative identification of compounds by gas chromatography increases sharply. Here automatic combination of a gas chromatograph and a thin-layer chromatograph can help. A thin-layer plate is attached to the adapted, strongly heated outlet of a temperature-programmed gas-chromatograph and is moved from one end to the other, the movement being controlled either by time or by recorder output. The material from each small gas-chromatographic peak, and the impurities between peaks, are deposited as individual spots or as a line by local cooling. Large peaks (relatively large quantities of material) are deposited in several spots on the start line. The thin-layer plate is then developed with a suitable mobile phase. In this way, the substances contained in the gas-chromatographic peaks are rechromatographed, but on the basis of different principles, so that better separations can be achieved. The developed thin-layer plates are treated with specific chemical reagents; the finished thin-layer chromatograms provide, in association with the gas chromatogram, an abundance of frequently surprising additional information.

### The Reaction of Nucleotides and Nucleic Acids with Diazonium Salts

*H. Kössel*, Munich (Germany)

As *Zillig* and *Verwoed* [5] showed by the example of the reaction of hydroxylamine with s-RNA, chemical methods are useful for the base-specific degradation or base-specific modification of nucleic acids for sequence analysis. The reaction of diazonium salts with nucleotides and nucleic acids was examined from this aspect.

The diazonium salts used were diazotized *p*-sulfanilic acid, diazotized 2,4-dichloroaniline, diazotized *p*-nitroaniline, and diazotized 4-nitroaniline-3-sulfonic acid, all in 3- to 10-fold excess at 2 °C. The reactions with the nucleotides guanylic acid (Gp), adenylic acid (Ap), and cytidylic acid (Cp) were readily followed by extinction measurements in the 370–440 mμ region and by high-voltage paper electrophoresis.

Gp, Ap, and Cp all reacted with diazotized *p*-sulfanilic acid, Gp quickly and quantitatively, but Cp only to the extent of about 20 %. Uridylic and thymidylic acids did not react. The pH optima were 10.2 (Gp) and 10.7 (Ap, Cp). The dyestuffs produced were not, or were only in small part, true azo compounds, but rather diazoamino derivatives with the structure $R^1-N=N-NH-R^2$; this was deduced from the following observations:

1. The dyes decompose in weakly acidic medium to reform the starting materials.

2. They show spectroscopic $pK_a$ values of 11.9 (Gp) and 9.0 (Ap, Cp).

3. Their formation is inhibited by formaldehyde, which reacts with amino groups.

The dye formed with Ap is the one most readily reconverted into the starting materials. Decomposition of the product from Gp gives some xanthidylic acid, the deamination product of guanylic acid.

Diazotized *p*-sulfanilic acid reacts correspondingly with RNA and DNA; cytidylic acid does not react. In contrast, *Beer* and *Mouchrianakis* [6] observed base-specific coupling of diazotized aminonaphthalenetrisulfonic acid with DNA.

Only the purine nucleotides react with the diazonium salts of 2,4-dichloroaniline, *p*-nitroaniline, and 4-nitroaniline, but again Gp reacts faster than Ap. The pH optimum for both nucleotides is 8.5 for all three diazonium salts.

### NMR-Spectroscopy for the Analysis of Organic Compounds with Known Functional Groups

*N. van Meurs*, Amsterdam (Holland)

High-resolution NMR spectra can be used a) to distinguish between primary, secondary, and tertiary monobasic acids and for quantitative analysis of binary mixtures of these

[2] *A. Häussler* and *P. Hajdú*, Arzneimittel-Forsch. *12*, 411 (1962).

[3] *A. Häussler* and *P. Hajdú*: Wandel in der chemischen Technik. Hanser, München 1963, p. 112.

[4] *R. Muschaweck*, Lokalanästhesie und Lokalanästhetika. Thieme, Stuttgart 1959, p. 103.

[5] *W. Zillig*, *D. W. Verwoed*, and *H. Kohlhage*, Hoppe-Seylers Z. Physiol. Chem. *332*, 184 (1963).

[6] *M. Beer* and *E. N. Mouchrianakis*, Proc. nat. Acad. Sci. U.S.A. *48*, 409 (1962).

acids, and b) to differentiate between primary, secondary, and tertiary monohydric alcohols and for the quantitative analysis of binary and ternary mixtures of these alcohols.

The three types of monobasic acids can be distinguished by the multiplet structure and intensity ratio of the α-$CH_2$ and α-CH proton resonance signals, provided that these do not overlap with the β-proton multiplets. The intensities of the signals are determined relative to that of the carboxylic proton resonance signal. For quantitative analysis of binary mixtures, the intensity ratio can be used.

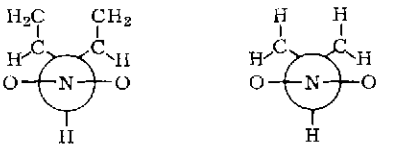
For the analysis of alcohols, the preparation of the sample constitutes an important part of the procedure, for it must ensure that any exchange of the hydroxyl protons comes to a standstill [7]. The three types of alcohol then show differences in the multiplicity of the hydroxyl signal and in its chemical shift. This depends on the solvent and the temperature.

A second procedure, based on comparison of peak heights gives results of similar absolute accuracy (±5 %) in suitable cases.

### Relations between Structure and Rate Constants for the Dissociation and Recombination of Carboxylic Acids

*H. W. Nürnberg*, Jülich (Germany)

The rate constants for the dissociation and recombination of 12 aliphatic and aromatic carboxylic acids in 1 M LiCl have been determined for the first time by a new electrochemical method termed "High Level Faradaic Rectification" [8].



With the kinetic data now available for a greater number of acids, the formulation of a correlation between the rate constants and the structure of the acid molecules and their anions is possible; previously such considerations had to be based solely on equilibrium constants. Normally, recombination depends only upon diffusion, and a common value ($k_r \approx 3.5 \times 10^{10}$ liter·mole$^{-1}$·sec$^{-1}$) is obtained for the rate constant for recombination in 1 M LiCl, since the diffusion coefficient of the hydrogen ion exerts the dominating influence. Consequently there is a linear relationship between the dissociation constant $k_d$ and the equilibrium constant. Hence, for acids with normal behavior, $k_d$ can be predicted from a knowledge of the equilibrium constant. The influence of structure with its inductive and mesomeric effects plays a part in determining the value of $k_d$. Deviations from normal behavior arise if recombination is retarded by steric effects, *e.g.* particularly by the formation of intramolecular hydrogen bridges in the anion (lactic acid, salicylic acid). With these acids, only kinetic measurements give complete information on the dissociation and recombination behavior. In addition, the stability constant of the intramolecular hydrogen bridges follows from a knowledge of $k_r$. Finally, evidence of the salt effect on the rate of dissociation and recombination can be obtained.

### Conformational Analysis of Nitrosteroids by Circular Dichroism

*G. Snatzke*, Bonn (Germany)

Nitrosteroids show a Cotton effect at 280 mμ, and sometimes their absorption band at 320 mμ also is circular dichroitic. Both bands involve $n \rightarrow \pi^*$ transitions, but only the first transition exhibits the symmetrical properties of carbonyl excitation. The rules found for ketones can thus be applied to the 280 mμ band with slight modifications [9].

For nitro compounds in which free rotation of the $NO_2$ group is hindered, the relationship between the circular dichroism and the axial or equatorial conformation of the $NO_2$ group has been deduced; a modified octant rule is applicable for nitro groups. The two planes of symmetry of the $NO_2$ group and a third plane perpendicular to them lying between the nitrogen atom and the two oxygen atoms divide the space around the molecule as in ketones; the contributions of the carbon atoms are, however, calculated with opposite signs. Measurements of the circular dichroism of *gem*-nitrohalogenosteroids at −188 °C support the rule given. From the results it follows that in unhindered nitrocyclohexanes the following conformations are energetically most favored:

Axial $NO_2$ group  equatorial $NO_2$ group

### Preparative Thin-Layer Chromatographic Separation of Phosphatides and Thin-Layer Chromatographic Identification of Their Hydrolysis Products

*O. W. Thiele* and *W. Wober*, Göttingen (Germany)

Phosphatides can be separated by thin-layer chromatography on silica gel-G with isobutyl ketone/formic acid/water (40:15:2). Staining agents which have proved generally applicable are: borate-buffered bromothymol blue solution for lipids; ninhydrin for primary amines; and Dragendorff's reagent, followed by ninhydrin on the same plate, for quaternary amines.

Since column-chromatographic separation of phosphatides seldom yields pure fractions, exclusive use of thin-layer chromatography on the preparative scale is of great value. The mixture is placed on the start line in a strip 18 cm long (0.1 mg/cm). After development of the chromatogram and staining of a narrow guide strip, the absorption material containing the desired fraction is scraped off the plate and extracted.

After hydrolysis of the phosphatides, fatty acids, amines, and phosphate esters (which alone are resistant to hydrolysis) are obtained. The fatty acids are separated by gas chromatography of their methyl esters. The amines are separated by thin-layer chromatography on silica gel-G with 96 % v/v ethanol/water (63:37), or n-butanol/glacial acetic acid/water (3:1:1), or n-propanol/34 % ammonia (67:33). For the identification of phosphate esters, a thin-layer chromatographic procedure on cellulose sheets is employed, using either an ammoniacal (*e.g.* 0.5 N ammonia/methanol, 2:3) or an acidic system (*e.g.* glacial acetic acid/n-propanol/water 1:2:1) as mobile phase. Compared with paper-chromatographic procedures, thin-layer chromatography on cellulose has the advantages of improved zone sharpness, clean applicability of phosphate reagents (Hanes-Isherwood spray reagent), and good resistance of the cellulose layers to aggressive spray reagents. [VB 819/147 IE]

German version: Angew. Chem. *76*, 691 (1964)

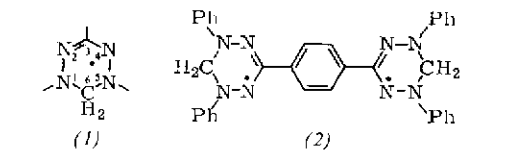
### Verdazyls and Related Nitrogen-Containing Free Radicals

*R. Kuhn*, Heidelberg (Germany)

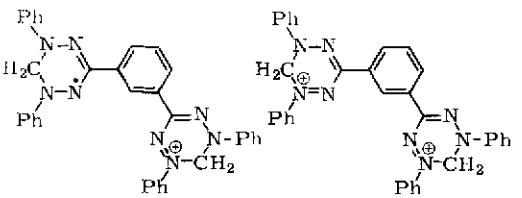
Verdazyls *(1)* [1] may be prepared from sugar phenylhydrazones; the solubility of such 1,5-diphenylverdazyls in polar solvents is improved by hydrophilic substituents in the 3-position (*T. Schwarz-Fischer*). The following compounds have been prepared: 3-[D-*gluco*-, 3-[D-*galacto*-, and 3-[D-

[7] Proton exchange is suppressed by careful neutralization of solvents and solutes.



[8] *H. W. Nürnberg* and *G. C. Barker*, Naturwissenschaften *51*, 191 (1964).

[9] *C. Djerassi*: Optical Rotatory Dispersion. McGraw-Hill, New York 1960.



[1] *R. Kuhn* and *H. Trischmann*, Mh. Chem. *95*, 457 (1964); Angew. Chem. *75*, 294 (1963); Angew. Chem. internat. Edit. *2*, 155 (1963).

*manno*-pentahydroxypentyl]-1,5-diphenylverdazyls, and 3-[D-*arabo*-, 3-[D-*rhamno*- and 3-[D-*xylo*-tetrahydroxybutyl]-1,5-diphenylverdazyls. Free radicals of this type affect the decomposition of $H_2O_2$ by catalase.

Combination of two 3-verdazylyl residues by a 1,3- or 1,4-phenylene bridge (*F. A. Neugebauer* and *H. Trischmann*) gives fully conjugated, planar, green biradicals with properties which correspond to those of the simple verdazyls. Examples of these compounds are 1,3-bis-[1,5-diphenyl-3-verdazylyl]benzene, m.p. 184–185 °C (decomp.), magnetic moment $\mu/\mu_B$ = 2.46 (found), $\lambda_{max}$ = 719 mμ (ε = 8200), and 1,4-bis-[1,5-diphenyl-3-verdazylyl]benzene *(2)*, m.p. 190–192 °C (decomp.), $\lambda_{max}$ = 732 mμ (ε = 7400). The ESR spectra of these biradicals (*K. H. Hausser* and *P. Fischer*) do not show the 9 lines characteristic of verdazyls; they indicate interaction between the two unpaired electrons (also observed with the *m*-compound). Reversible polarographic oxidation yields the diamagnetic, violet, divalent-cation *(4)* via the violet monoradical cation *(3)*, which gives a typical verdazyl ESR spectrum with 9 lines.

*(1)* *(2)*

*(3)* *(4)*

Ph = Phenyl

Some nitrogen-containing free radicals, arranged in order of decreasing dehydrogenating power, are: tetraphenylpyrryl > *N,N*-diphenyl-*N'*-picrylhydrazyl > 1,1,5,5-tetraphenyl-1,2,4,5-tetraazapentenyl, 1,1,5,5-hisbiphenylene-3-azapentadienyl > 1,3,5-triphenylverdazyl, 1,1,5,5-bisbiphenylene-2,3-diazapentadienyl. Each of the nitrogen radicals can abstract a hydrogen atom from the NH-compounds derived from radicals lower in this series, being thereby converted itself into the parent NH-compound.

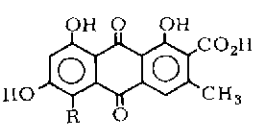
## Ergot Pigments

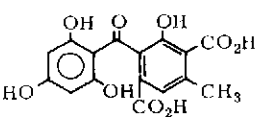
*B. Franck*, Kiel (Germany) [1].

The ergot pigments secalonic acid A, secalonic acid B, and ergoflavin are symmetrical dimerization products of the monomers *(1)*, *(2)*, and *(3)*, respectively, with a 2,2'- or 4,4'-bond [2, 3]. Three further similar, pale yellow pigments, which we denote as secalonic acid C, ergochrysin A, and ergochrysin B, have been isolated as pure crystalline individuals. Their analyses, infrared, ultraviolet, and NMR spectra, and specific rotations show them to be unsymmetrical dimerization products of *(1)*, *(2)*, and *(3)*.

*(1)*



*(2)*



*(3)*

Secalonic acid A: 1-1
Secalonic acid B: 2-2
Ergoflavin: 3-3
Secalonic acid C: 1-2
Ergochrysin A: 1-3
Ergochrysin B: 2-3

The anthraquinonecarboxylic acids endocrocin *(4)* and clavorubin, isolated in collaboration with *T. Reschke* [4], form a second group of ergot pigments. The structure of 3-methyl-1,5,6,8-tetrahydroxyanthraquinone-2-carboxylic acid *(5)* has now been determined for clavorubin, and confirmed by synthesis.

*(4)*, R = H
*(5)*, R = OH

*(6)*

Endocrocin is considered to be the biogenetic precursor both of the 80 natural anthraquinone pigments known so far and of the 6 pale yellow ergot pigments [5]. In contrast to the anthraquinone derivatives, however, the ergot pigments are derived from endocrocin *via* an oxidative ring cleavage *(4)* → *(6)* → *(1)*, *(2)*, or *(3)*, analogous to the Baeyer-Villiger oxidation. The six dimeric ergot pigments are subsequently formed from *(1)*, *(2)*, and *(3)* by phenol oxidation.

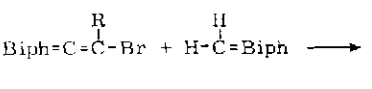
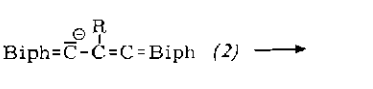
# SELECTED ABSTRACTS

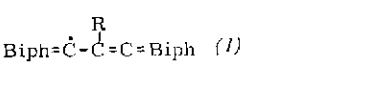
**Iron(III) siloxane compounds** are reported by *H. Schmidbaur*. Reaction of anhydrous $FeCl_3$ with three equivalents of sodium trimethylsiloxide in ether gives tristrimethylsiloxyiron(III), m.p. 179–181 °C, sublimation at 135–160 °C/1 mm, yield 40 %, in the form of yellow-green, waxy crystals which are readily soluble in inert organic solvents. Cryoscopic measurements show that the compound is dimeric in solution. Reaction either of this compound with 1 equivalent of alkali trimethylsiloxide or of $FeCl_3$ with 4 equivalents of alkali trimethylsiloxide gives good yields of alkali tetrakistrimethylsiloxyferrates(III). These are yellowish, finely crystalline, and, with the exception of the Li compound, hardly soluble in organic solvents. They decompose slowly above 200 °C, becoming brown in color. / Chem. Ber. *97*, 836 (1964) / – Ko. [Rd 948/268 IE]



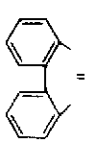
**Nuclear magnetic resonance spectra of new organolead compounds,** *viz.* trimethylcyclopentadienylplumbane *(1)*, dimethyldicyclopentadienylplumbane, and triethylcyclopentadienylplumbane, have been recorded by *H. P. Fritz* and *K. E. Schwarzhans*. The compounds were prepared from methyl- and ethylchloroplumbanes with cyclopentadienylsodium, under nitrogen in absolute benzene. The resultant yellow to green solutions are unstable, even under nitrogen. Only *(1)* could be obtained as a yellow crystalline solid, namely from absolute diethyl ether below 0 °C; it decomposed above +10 °C with deposition of a lead mirror. The NMR spectra of the methyl compounds show only one sharp signal, accompanied by two satellites, for the cyclopentadienyl and methyl protons. / J. organometallic Chemistry *1*, 297 (1964) / –Hz. [Rd 940/277 IE]



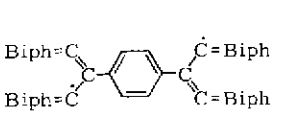
**Two stereoisomeric dimers of cyclobutadiene** have been synthesized by *C. D. Nenitzescu* et al. from *cis*-3,4-dichlorocyclobutene. Its reaction with sodium amalgam in ether at room temperature gives 46–51 % yields of *syn*-tricyclo[4,2,0,$0^{2,5}$]-octa-3,7-diene *(1)*, which is identical with a product previously obtained from 1,2,3,4-tetrabromocyclobutane (m.p. of the silver nitrate complex: 138–140 °C). If lithium amalgam



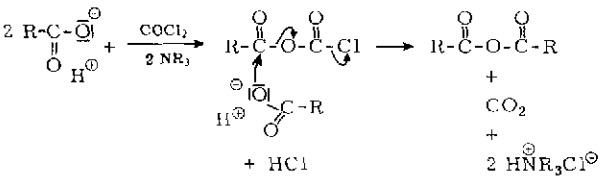
*(1)*   *(2)*



is used instead of sodium amalgam, a 55 % yield of the *anti*-compound *(2)* is obtained (m.p. of the silver nitrate complex: 148–152 °C). Both *(1)* and *(2)* can be largely purified by fractional distillation. Compound *(2)* can be obtained in pure form by conversion into its tetrabromide and re-elimination of the bromine. Ozonization of *(1)* gives *all-cis*-cyclobutane-1,2,3,4-tetracarboxylic acid, while *(2)* gives the *cis-trans-trans*-acid. With 2,5-diphenylbenzo[*c*]furan, *(1)* gives an adduct of m.p. 288–290 °C, and *(2)* gives an adduct of m.p. 252 °C. Both tricyclooctadienes are readily converted above 100 °C into cyclooctatetraene. The infrared spectra of *(1)* and *(2)* differ appreciably and point to deviations from the ideal molecular shape. / Chem. Ber. *97*, 382 (1964) / –W. [Rd 937/274 IE]

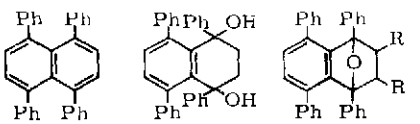


**Stable 2-aryl-1,3-bisdiphenyleneallyl radicals** *(2)* have been prepared by *R. Kuhn* and *F. A. Neugebauer*. Fluorene reacts as a nucleophile with diphenylenevinyl bromides in dimethylformamide in the presence of $KOCH_3$. HBr is eliminated with direct formation of the anions of acidic propene derivatives *(2)*, which are converted into the radicals with $K_3[Fe(CN)_6]$. The diradical *(3)* was obtained similarly.



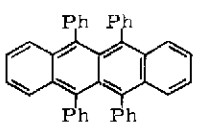
*(3)*

The radicals are stable toward hydroquinone, ascorbic acid, and $Na_2SO_3$. This stability is due to the strong electron-attraction of the fluorene, which is amplified by aryl substitution. Magnetic measurements have shown the radicals to be monomeric, even in the solid state, up to 77 °C. / Mh. Chem. *95*, 3 (1964) / –Rc. [Rd 941/278 IE]



**Reactions of *N*-bromobistrifluoromethylamine** have been investigated by *H. J. Emeleus* and *B. W. Tattershall*. When irradiated with ultraviolet light, $(CF_3)_2NBr$ *(1)* dissociates into $(CF_3)_2N\cdot$ and Br· radicals; the former can combine to form perfluorotetramethylhydrazine, $(CF_3)_2N{-}N(CF_3)_2$. Ultraviolet irradiation of a mixture of $(CF_3)_2NBr$ and $NO_2$ gave *inter alia* *O*-nitroso-*N*,*N*-bistrifluoromethylhydroxylamine $(CF_3)_2N{-}O{-}NO$. Compound *(1)* reacts with NO even at room temperature to form bistrifluoromethylnitrosamine $(CF_3)_2N{-}NO$. Reaction of *(1)* with CO at room temperature gives bistrifluoromethylcarbamyl bromide $(CF_3)_2N{-}CO$ Br. *(1)* adds onto olefins (ethylene and tetrafluoroethylene) and acetylene to form $(CF_3)_2N{-}CR_2{-}CR_2{-}Br$ (R = H, F) and $(CF_3)_2N{-}CH{=}CHBr$, respectively. The action of AgCN on *(1)* did not yield the expected *N*-cyano derivative but $CF_3{-}N{=}CF_2$; *(1)* plus $Ag_2CO_3$ gave perfluoroazomethane $CF_3{-}N{=}N{-}CF_3$. / Z. anorg. allg.Chem. *327*, 147 (1964) / Ko. [Rd 944/264 IE]

**A simple new synthesis of anhydrides** has been discovered by *H. Rinderknecht* and *Viktoria Ma*. Reaction of carboxylic acids with 0.5 mole of phosgene at room temperature in the presence of trialkylamines gives anhydrides, generally in yields of over 80 %. If the reaction is carried out in benzene, the solution of the anhydride can be used directly, after filtering off the insoluble trialkylamine hydrochloride. The reaction, which is suitable for the preparation of labile anhydrides such as nicotinic and isonicotinic anhydrides, is assumed to proceed as follows:



Helv. chim. Acta *47*, 162 (1964) / –Re. [Rd 942/279 IE]

**Bis-peri-tetraphenylnaphthalene** *(1)* has been synthesized for the first time by *C. Dufraisse* and *Y. Lepage* by four routes: alkali fusion of 1,4,6,7,10,11-hexaphenyl-5,12-naphthacenequinone; alkali fusion of 5,8,9,10-tetraphenyl-1,4-anthraquinone; from 5,8-diphenylnaphthoquinone → the 2,3-dihydro compound $\xrightarrow{C_6H_5Li}$ the tetraphenyl diol *(2)* $\xrightarrow{\text{dehydration}}$ *(1)*; and from tetraphenylisobenzofuran $\xrightarrow{\text{acrylic acid}}$ adduct *(3)* $\xrightarrow{\text{acetic acid/}H_2SO_4}$ *(1)* in 40 % yield. Compound *(1)*, m.p.

*(1)* *(2)* *(3)*

*(4)*

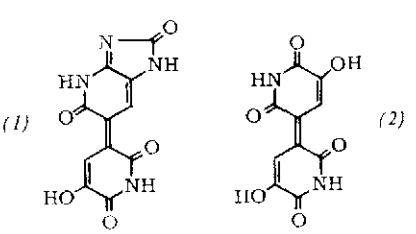
279–280 °C, is colorless and, in contrast to rubrene *(4)*, is not photo-oxidizable. C. R. hebd. Seances Acad. Sci. *258*, 1507 (1964) / –Ma. [Rd 950/270 IE]

**A simple synthesis of disecondary diarsines and alkali phenylarsides** has been described by *A. Tzschach* and *G. Pacholke*. Phenylarsine reacts with Li, Na, or K on heating in dioxane to give monoalkali phenylarsides *(1)* in 90 % yield. These

compounds are obtained as dioxane solvates and are extremely sensitive to air and hydrolysis. Their reaction

$$2M-AsH-C_6H_5 + X-(CH_2)_n-X \rightarrow \underset{(1)}{} \qquad n = 3,4$$

$$H_5C_6-AsH-(CH_2)_n-AsH-C_6H_5 \quad (2)$$



with α,ω-halogenoalkanes gives 60–70 % yields of the secondary arsines *(2)* as distillable oils which are converted by $CH_3I$ into crystalline arsonium salts

$[H_5C_6CH_3)_2As^{\oplus}-(CH_2)n-As^{\oplus}(CH_3)_2C_6H_5]\ 2\ I^{\ominus}$.

On reaction of *(1)*, M = K, with 1,2-dibromoethane, a bromine atom is first exchanged for a potassium atom. Since the resulting intermediates are very unstable, only ethylene, arsenobenzene, and phenylarsine could be detected. / Chem. Ber. *97*, 419 (1964) / –Re. [Rd 943/263 IE]

**The cause of the pyrophoric behavior of finely divided iron** has been investigated by *W. Feitknecht* and *A. Durtschi*. Their starting materials were samples of $Fe_3O_4$, $Fe_{3-x}O_4$, and ferric hydroxide; these were reduced in a current of hydrogen at 300–500 °C. α-$Fe_2O_3$ (formed from $Fe(OH)_3$ at 280 °C) and $Fe_{3-x}O_4$ are first reduced to $Fe_3O_4$, which is then directly reduced to Fe; FeO may also occur as an intermediate. Since the formation of iron nuclei is relatively slow, more coarsely crystalline oxides give roughly one Fe crystal from one $Fe_3O_4$ crystal at 300 °C, whereas with more finely crystalline material, even at 300 °C, each iron nucleus grows at the expense of several oxide crystals, so that particle growth results. Pyrophoric behavior is exhibited by all iron preparations with a specific surface area of more than about 3 $m^2/g$. Pyrophoric iron is inactivated by the action of a stream of gas consisting of nitrogen and a little oxygen; during inactivation, the temperature of the sample rises by about 10 °C and then remains constant for a time. The time of inactivation is proportional to the specific surface area. From the quantity of oxygen adsorbed, it is calculated that the thickness of the oxide layer is about 13 Å (about 6 layers of oxygen ions). The heat liberated during the formation of this primary oxide layer is estimated at 7.5 $cal/m^2$ of layer, *i.e.* sufficient to raise the temperature of 1 g of iron by about 70 °C. For a specific surface area of 3 $m^2/g$, this gives a temperature rise of about 210 °C. This agrees well with the experimental ignition temperature of iron with a specific surface area of 3 $m^2/g$ (240 °C). This ignition temperature is lower for more finely divided iron, and higher for coarser preparations. / Helv. chim. Acta *47*, 174 (1964) / –Ko. [Rd 946/266 IE]

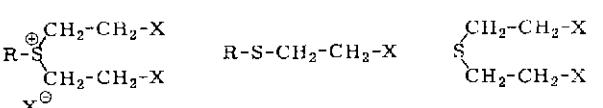
**The structure and synthesis of the blue dye from** *Corynebacterium insidiosum* was reported by *R. Kuhn, W. Blau, H. Bauer, H.-J. Knackmuss, D. A. Kuhn*, and *M. P. Starr*. The extracellularly produced dye particles were isolated by fractional sedimentation and reduced with $Na_2S_2O_4$ to the leuco compound, oxidation of which with oxygen gave the dye of structure *(1)*. Hydrolysis of *(1)* with HCl gave rise to $CO_2$, $NH_3$, and fragment *(2)*. Compound *(2)* was also obtained by synthesis from 2-hydroxy-5-aminopyridine and citrazinic acid (2,6-dihydroxyisonicotinic acid). The dye *(1)* itself was also synthesized starting from either 2-hydroxy-5-aminopyridine

*(1)* *(2)*

(reactions with $H_2SO_4$, urea, and $KBrO_3$) or citrazinic acid (reactions with $N_2O_3$, Sn/HCl, KNCO, and $O_2$). Both synthetic routes seem biosynthetically feasible. / Naturwissenschaften *51*, 194 (1964) / –Ma. [Rd 7/284 IE]

**Large quantities of xenon tetrafluoride** were prepared by *E. Schumacher* and *M. Schaefer* using a circulatory apparatus. A circulating pump blows a $Xe/F_2$ mixtures (molar ratio 1:3) at atmospheric pressure through a Monel-metal tube furnace filled with pieces of nickel plate heated at 560 °C. $XeF_4$ crystals separate out in a cold trap at 0 °C. Unreacted gas is recirculated to the tube furnace, if necessary, after addition of fresh feed gas. The apparatus delivers 11 g of $XeF_4$ per hour: the yield is over 97 % based on the xenon fed in. / Helv. chim. Acta *47*, 150 (1964) / –Ko. [Rd 945/265 IE]

**The synthesis of phosphorus nitride dichlorides** from $PCl_5$ and $NH_4Cl$ has been further investigated by *Margot Becke-Goehring* and *W. Lehr*. The $PCl_4^{\oplus}$ cation formed by dissociation of $PCl_5$ reacts with $NH_3$ (from $NH_4Cl$) to give $Cl_3P=N-H$, which rapidly undergoes further reaction with another $PCl_4^{\oplus}$ ion to yield the cation $[Cl_3P-N=PCl_3]^{\oplus}$ *(1)*, which can be isolated as its sparingly soluble hexachlorophosphate. In a similar manner, *(1)* gives rise to the higher homologue $[Cl_3P=N-PCl_2=N-PCl_3]^{\oplus}$ *(2)*. Reaction of *(2)* with $Cl_3P=NH$ leads successively to longer-chain cations $[Cl_3P=N-(PCl_2-N)n-PCl_3]^{\oplus}$ *(3)*, whose salts are considerably more soluble than those of *(1)* or *(2)*. On reaction with $NH_3$, *(2)* and *(3)* form chains with terminal NH groups *(4)*:



$$[Cl_3P=N-(PCl_2=N)_n-PCl_3]^{\oplus} + NH_3 \rightarrow$$

*(2)*: n = 1 *(3)*: n = 2, 3, ...

$$Cl_3P=N-(PCl_2=N)_n-PCl_2=NH + HCl + H^{\oplus} \quad (4)$$

Compounds *(4)* are stable when n is large, and are found in phosphorus nitride dichloride oils. When n = 1 or 2, *(4)* can eliminate HCl and undergo ring closure to form stable trimeric or tetrameric phosphorus nitride dichlorides. To prepare longer-chain phosphorus nitride dichloride oils selectively, the reaction is carried out in the molten state in a sealed tube. For preferential preparation of the trimer, the reaction is carried out in tetrachloroethane at the maximum possible dilution; the primary product is the cation *(2)*, and dilution favors ring closure of its secondary product *(4)*, n = 1. For preparation of the tetramer, the chloride of *(1)* is made first and then treated with $NH_4Cl$, the formation of trimer being thus completely suppressed. / Z. anorg. allg. Chem. *327*, 128 (1964) / Ko. [Rd 947/267 IE]

**Sulfonium salts exhibit high reactivity toward mercaptide ions** (at physiological pH values) as *A. Lüttringhaus* and *H. Machatzke* found in kinetic investigations employing polarographic methods. The alkylating properties of these sulfonium compounds can explain their cytostatic activity. The substances most effective against both Yoshida sarcoma in rats and Ehrlich carcinoma in mice have been found to be those of structure *(1)* which, on transalkylation of one ligand onto the SH compound, yields products *(2)*, and not the highly toxic sulfur mustard gas *(3)*.

*(1)* *(2)* *(3)*

X= Halogen

Since the cytostatic effect of the salts increases with their ability to block the SH group, it can be concluded that at least one of the principles of action of sulfonium salt cytostatics consists in blocking biologically important SH groups. The residue R affects the transport characteristics, the affinity for cell components, and the distribution behavior of the cytostatic compound. / Liebigs Ann. Chem. *671*, 165 (1964) / Sch. [Rd 951/271 IE]

**The dipole moments of isomeric 1,2,3,4,5,6-hexachlorocyclohexanes** were investigated by *C. Quivoron* and *J. Neel*. Seven of the 13 theoretically possible conformations with a chair carbon-skeleton are known, being those confirmations in which the partial structure of "2 axial chlorine atoms on the next-but-one carbon atoms" occurs only once or not at all. The dipole moments of these compounds cannot be calculated by simple vector addition of the partial moments, since mutual induction can cause the effective moment of the C Cl bond to vary by a factor of 2. By making allowances for the polarizability of the C–Cl bond and for a finite dipole moment of the C H bonds, the dipole moments of the 5 more readily available isomers (α to ε) can be calculated. The results agree well with the experimental values and help to assign conformations to the isomers. The dipole moments of the ϰ- and ϑ-isomers were predicted on the same basis. / J. Chim. physique *61*, 554 (1964) / –Hz. [Rd 8/285 IE]

**An instrument for estimating oxygen by gas-phase polarography** has been designed by *G. Halpert*, *A. C. Madsen*, and *R. T. Foley*. In it an oxygen concentration gradient is built up by diffusion through a semipermeable teflon membrane which is held under tension touching a microelectrode made of gold or platinum. The microelectrode is immersed together with a silver/silver chloride reference electrode in potassium chloride solution buffered at pH 6. Oxygen analyses can be carried out with an accuracy of 1 % between –20 and +80 °C at pressures down to 10 mm over a concentration range of 0.001 to 100 % $O_2$. / Rev. sci. Instruments *35*, 950 (1964) / –Hz. [Rd 108/295 IE]

# BOOK REVIEWS

**Gmelins Handbuch der anorganischen Chemie** (Gmelin's Handbook of Inorganic Chemistry), 8th completely revised edition. Published by the Gmelin-Institut für anorganische Chemie und Grenzgebiete in the Max-Planck-Gesellschaft zur Förderung der Wissenschaften. Initiated by *R. J. Meyer*, continued by *E. H. Erich Pietsch*. Verlag Chemie GmbH., Weinheim/Bergstrasse.

**System No. 52: Chromium:** Part A, Vol. 1 (Historical, Occurrence, Technology, Element [up to physical Properties]). 1962. IV, XX, 418 pp. 38 figs., cloth, DM 316.– (about $ 80. ). Revised by *M. Atterer*, *Anna Bohne-Neuber*, *G. Czack*, *R. Glauner*, *A. Hirsch*, *Erna Hoffmann*, *G. Huschke*, *Eleonore Kirchberg*, *Isa Kubach*, *H. Lehl*, *Gertrud Pietsch-Wilcke*, *N. Polutoff*, *F. Rex*, *K. Rumpf*, and *F. Seuferling*.

**System No. 52: Chromium:** Part A, Vol. 2 (Electrochemical Behavior, Chemical Behavior, Alloys), 1963. IV, XVIII, 312 pp., 111 figs., cloth, DM 241.– (about $ 61.–). Revised by *H. Balters*, *Marie-Luise Klaar*, *G. Krause*, *Margarete Lehl-Thalinger*, *K. Swars*, and *Hildegard Wendt*.

**System No. 52: Chromium:** Part B (Compounds [Excluding Complexes with Neutral Ligands]), 1962. IV, LXXIX, 942 pp., 74 figs., cloth, DM 715.– (about $ 180.–). Revised by *M. Atterer*, *H. Balters*, *H. Feicht*, *R. Glauner*, *A. Hirsch*, *H. K. Kugler*, *A. Kunze*, *Gertrud Pietsch-Wilcke*, *P. Stiess*, *K. Swars*, *Ursula Trobisch-Raussendorf*, *E. Ühlein*, and *Ursula Venzke-Sante*.

The volume "Chromium" of the foregoing 7th edition of "Gmelin" was published in 1912, and is thus more than half a century (!) out of date. So much the greater, therefore, is the pleasure with which chemists now receive the chromium volume of the 8th edition, of which Parts A (Elemental Chromium) and B (Compounds of Chromium) are now available (total price DM 1272. or about $ 320. ). An impressive indication of the advances made since time of the earlier edition is the fact that the principal chromium volume at that time contained 390 pp., and was compiled by a single writer, whereas even excluding Part C, which is now in preparation and which deals comprehensively with the chemistry of chromium complexes, the new System No. "Chromium" already comprises 1672 pp. and 223 figs., and its preparation has involved the cooperation of almost three dozen writers.

**Part A.** Part A (DM 557.– or about $ 140. –), which is published in two volumes with a total of 730 pp. and 149 figs., begins with sections (284 pp.) on the history (5 pp.), occurrence (186 pp.), technology (83 pp.), and toxicology (10 pp.) of chromium and its compounds. This is followed by a description of elemental chromium (446 pp.), divided as usual into chapters on its formation and preparation (9 pp.), physical properties (125 pp.), electrochemical behavior (204 pp.), chemical behavior (87 pp.), and alloys (21 pp.).

Chromium was discovered in Siberian crocoite ($PbCrO_4$) by the French chemist *Louis Nicolas Vauquelin* in 1797, and its name (from χρῶμα = color) was chosen on account of the magnificent colors of some of its compounds. Since the element is still relatively "young", its history requires only a few pages. This section is arranged according to the chromium-bearing minerals of the greatest importance to the history of the discovery of the metal, namely crocoite $PbCrO_4$, emerald $Be_3Al_2Si_6O_{18}$ (chromium oxide as coloring agent, discovery of beryllium by *Vauquelin*), ruby $Al_2O_3$ (chromium oxide as the coloring component), and chromite $FeCr_2O_4$.

The section on the occurrence of chromium begins with a discourse on its extraterrestrial occurrence, which has been the subject of many investigations, since the metal is easily detectable by its blue and green spectral lines. The sections dealing with the terrestrial occurrence are arranged under geochemistry, topography, and minerals. In the geochemical section, special attention should be called to the comprehensive tabular summaries of the chromium content of minerals, its diadochic relationships to other elements, and the formation and transformation of chromium deposits. The topographical survey begins with an economic statistics chart showing that the global production of chromium ore has now grown to almost 5 million tons per year, *i.e.* it has increased by a factor of about thirty since the beginning of the First World War. The topographical survey then goes on to consider workable deposits, particularly those in the six principal producing countries (the Soviet Union, The Union of South Africa, the Philippines, Southern Rhodesia, Turkey, and Albania), and ends with a comprehensive list of chromium minerals. This chapter is of particular importance since the economy of modern states, in peace or at war, is no longer conceivable without a suitable supply of chromium ore.

The importance of chromium in present-day economy becomes even more evident in the chapter on the technology of chromium and its inorganic compounds. This chapter deals in detail with the processing of the ores, the degradation of the principal technical chromium ore, *viz.* chrome iron ore $FeCr_2O_4$, the production of metallic chromium and its principal inorganic compounds [chromium(III) and chromium(VI) oxides, chromium(III) hydroxide, nitrate, chloride, sulfate, potassium chrome alum, and the alkali metal chromates and dichromates], and the preparation of the most important inorganic chrome pigments (chrome yellow, chrome red, chrome green, and many mixed pigments containing chromium). It presents an impressive picture of the technological processing and importance of chromium ores, about 50 % of which are used in metallurgy (chromium alloys), about 35 % in ceramics (refractory bricks), and about 15 % in the chemical industry (chromium compounds).

The section on toxicology deals with physiological damage caused by chromium compounds (symptoms, toxic doses, prophylaxis, therapy), on the basis of comprehensive technical literature.

Since the industrial production of chromium is dealt with earlier in the technology section, the section on the prepara-

tion of metallic chromium is confined to laboratory methods of obtaining chromium by reduction of chromium compounds, the production of special forms (*e.g.* powder, sponge, crystals, suspensions, sols), and the concentration and separation of chromium isotopes.

Under physical properties, treatment of the atom and the atomic nucleus is followed by a discussion of the crystallographic properties of the metal, which exists in several modifications. In connection with the production of a form of chromium which is ductile at normal temperature, interesting data are given on its structure and deformation, and on the effect of extraneous components in the lattice; these are discussed in detail in a special section. After a treatment of thermal and thermochemical data, the optical behavior of chromium is discussed at length, *e.g.* the reflectance of chromium mirrors, its optical line spectrum (arc spectrum, first to forteenth spark spectrum), and its X-ray spectrum.

In the section on its magnetic and electrical properties, particular attention is aroused *inter alia* by the discussions on the hitherto unexplained anomaly in its electrical resistance between 35 and 40 °C; this anomaly is also found in its elastic properties.

The chapter on the electrochemistry of Cr includes a report on the standard potentials of the various oxidation stages of chromium, the potentials of the metal with respect to 65 different solutions and melts, 54 electrochemical cells described in the literature, the behavior of chromium at the dropping mercury electrode, overvoltages on chromium, the behavior of chromium as an anode and cathode, and the electrolytic deposition of chromium. Special mention should be made of the discussions on the last two problems. As an element with a pronounced tendency towards both an "active" and a "passive" state, chromium has been the subject of numerous investigations on reductive activation and oxidative passivation and the causes of this phenomenon. It is on account of this phenomenon that active chromium can be regarded as a base Metal with a standard potential of −0.71 volt ($Cr/Cr^{III}$), lying between zinc and iron in the electrochemical series, whereas passive chromium is a noble metal with a standard potential of +1.33 volt ($Cr^{III}/Cr^{IV}$), lying between mercury and gold. As is shown by the discussions on the theory of passivity, the most obvious explanation of this phenomenon is still the formation and destruction of a film of chromium oxide on the surface of the metal. The detailed report on the electrolytic deposition of chromium (about three-quarters of the chapter on electrochemistry) is justified by the fact that chromium plating of metals, which was introduced some 40 years ago, is now one of the most important fields in electroplating and once revolutionized the plating industry as a result of the introduction of an entirely new type of bath (deposition from chromic acid solutions). The section is introduced by a comprehensive list of references arranged in chronological order, and then gives a detailed account of the nature and composition of chromium-plating baths, the influence of reaction conditions on the yield and quality of the chromium deposit, the action of bath additives, of bright, matt, black, and hard chromium-plating, of the anodes and cathodes used, the pre-treatment and after-treatment of the objects to be plated, special plating processes, and the properties and testing of the chromium deposit, the theoretical explanation of the phenomena always being included.

The special properties of chromium become evident in the chapter on its chemical behavior, as in that on its electrochemistry: *e.g.* its passivation by oxidizing agents and activation by reducing agents or agents which dissolve the surface layer, and the resulting difference in chemical behavior in the passive and active states; this difference is so great, in fact, that it was once assumed – erroneously – that chromium was allotropic. The section on the general reactions of chromium ions ($Cr^{2+}$, $Cr^{3+}$, $CrO_4^{2-}$, $Cr_2O_7^{2-}$) is particularly valuable. This section also deals with the redox transitions between these ions and with the analytically important reactions of chromium, so that – particularly in view of the volume on this subject in *Fresenius–Jander's* Handbuch der analytischen Chemie – the short section on the detection and determination of chromium can be confined to a comprehensive bibliography and a survey of the most sensitive reactions of chromium.

The last chapter of Part A, which deals with alloys of chromium, gives an account of its alloys with metals of system numbers lower than that of chromium, *i.e.* the metals Sb, Bi, Be, Ca, Zn, Cd, Hg, Ti, Zr, Hf, Th, Ge, Sn, Pb, V, Nb, and Ta, with special emphasis on the more thoroughly investigated systems with Sb, Be, Zn, Hg, Zr, and Ta. The alloys with Mg, Al, and rare earth metals are grouped with these metals, a departure from the Gmelin "last-place" principle. Alloys of chromium with metals of system numbers lower than that of antimony are dealt with under compounds of chromium in Part B of the "Chromium" volume, which is reviewed on below.

**Part B.** This part embraces all the "normal" compounds of chromium and all of its complexes with acidic ligands, including the related hydrates and aquo-complexes (*e.g.* the compounds $CrCl_3$, $[Cr(H_2O)_6]Cl_3$, $[CrCl_2(H_2O)_4]Cl{\cdot}2H_2O$, $K_3[CrCl_6]$); complexes with neutral ligands other than $H_2O$ (*e.g.* the ammoniates and ammine complexes) will form the subject of Part C, which has not yet been published. Part B includes information on compounds with non-metals (454 pp.) as well as on compounds with metals of system numbers lower than that of chromium (488 pp.). Thus the discussions cover the compounds of chromium with the non-metals: H (7 pp.), O (149 pp.), N (18 pp.), F, Cl, Br, I (120 pp.), S, Se, Te, Po (49 pp.), B (8 pp.), C, Si (85 pp.), P, As, Sb, Bi (18 pp.), and the chromates, acidochromates, and double salts of chromium with the metals Li, Na, K, Rb, and Cs – including the ammonium salts – (319 pp.), Be, Mg, Ca, Sr, and Ba (77 pp.), Zn, Cd, and Hg (40 pp.), Al, Ga, In, and Tl (13 pp.), Ti, Zr, Hf, and Th (5 pp.), Ge, Sn, and Pb (30 pp.), and V, Nb, and Ta (4 pp.). Compounds of chromium with more than one of the above elements are dealt with, as usual, under the element of highest system number. The compounds of chromium with the rare earths are excluded; in contrast to the "last-place" principle, these are discussed under the rare-earth metals.

The material dealt with is so extensive that the index alone fills no fewer than 79 pages. Consequently, only a few examples have been selected in the following paragraphs.

The account of the chromium/hydrogen system is particularly important with regard to the electrodeposition of chromium, since the mechanical properties of chromium plating are considerably influenced by the hydrogen content of the plating bath.

The chapter on oxygen compounds of chromium deals with the oxides CrO, $Cr_2O_3$, $CrO_2$, $CrO_3$, $CrO_4$, and $CrO_5$, the related aquo-oxides and aqueous solutions, and many intermediate oxides such as "$Cr_3O_4$" ($CrO_{1.3}$), "$Cr_5O_9$" ($CrO_{1.8}$), "$Cr_8O_{15}$" ($CrO_{1.9}$), "$Cr_4O_9$" ($CrO_{2.3}$), "$Cr_5O_{12}$" ($CrO_{2.4}$), "$Cr_2O_5$" ($CrO_{2.5}$), "$Cr_5O_{13}$" ($CrO_{2.6}$), "$Cr_3O_8$" ($CrO_{2.7}$), all of which require more detailed investigation. The majority of the text (over 80 %) is naturally concerned with the preparation and properties of the oxides $Cr_2O_3$ and $CrO_3$ and their systems with water, *i.e.* $Cr_2O_3{\cdot}nH_2O$ [*e.g.* $Cr(OH)_3$ and $CrO(OH)$] and $CrO_3{\cdot}nH_2O$ [*e.g.* $H_2CrO_4$, $H_2Cr_2O_7$, and polychromic acids $H_2Cr_nO_{3n+1}$].

Compounds of chromium with nitrogen include its nitrides, azides, amides, and nitrates; the nitrates are used as tanning agents.

Chromium halides and their aquo-complexes and hydrates are discussed in great detail since the literature on these compounds is very extensive. Besides compounds of trivalent chromium, those of monovalent (*e.g.* CrF, CrCl, CrBr, CrI), divalent (*e.g.* $CrF_2$, $CrCl_2$, $CrBr_2$), tetravalent (*e.g.* $CrF_4$, $CrCl_4$), pentavalent (*e.g.* $CrF_5$), and hexavalent chromium (*e.g.* $CrO_2F_2$, $CrO_2Cl_2$, $CrO_2Br_2$) are also discussed. Most of the chapter (over 75 % of the text) is occupied by the chlorine compounds. Particular mention should be made

of the sections on $CrCl_3$ hydrates and aqueous solutions of $CrCl_3$, which give occasion to deal comprehensively with the isomerism of the $CrCl_3$ hexahydrates ($[Cr(H_2O)_6]Cl_3$, $[CrCl(H_2O)_5]Cl_2 \cdot H_2O$, $[CrCl_2(H_2O)_4]Cl \cdot 2H_2O$) and the other hydrates of $CrCl_3$ (decahydrate $[CrCl_2(H_2O)_4]Cl \cdot 6H_2O$, tetrahydrate $[CrCl_2(H_2O)_4]Cl$, and trihydrate $[CrCl_3(H_2O)_3]$).

The section on the sulfur compounds of Cr deals with the sulfides and sulfates, such as CrS, $Cr_2S_3$, $CrSO_4$, $Cr_2(SO_4)_3$, and $H_2[CrO_3(SO_4)]$ ("chromosulfuric acid"). Particular attention is paid to chromium(III) sulfate $Cr_2(SO_4)_3$ (hydrates, acid sulfates, basic sulfates; problems of constitution), owing to its importance in chrome tanning.

The compounds of chromium with boron include chromium borides ($Cr_4B$, $Cr_2B$, $Cr_5B_3$, $Cr_3B_2$, CrB, $Cr_3B_4$, $CrB_2$, and $Cr_2B_5$) and chromium borates. Of particular interest here are the data on sintered hard metals based on CrB, since these alloys have recently become technically important.

The section on carbon compounds of Cr includes accounts of the chromium carbides $Cr_{23}C_6$ ("$Cr_4C$"), $Cr_7C_3$ ("$Cr_{15}C_2$"), and $Cr_3C_2$, chromium hexacarbonyl $Cr(CO)_6$, chromium carbonates, cyanides, and thiocyanates, and on chromium salts of carboxylic acids (formates, acetates, propionates, oxalates, malonates, tartrates, and citrates). Special mention should be made of the review on the preparation, properties, and derivatives of chromium hexacarbonyl, and on the chromium(III) acetates, which are important tanning agents.

Among the phosphorus compounds of Cr, the phosphides $Cr_3P$, $Cr_2P$, CrP, $Cr_2P_2$, and $CrP_2$, the chromium(III) phosphates $CrPO_4 \cdot nH_2O$, and adducts of chromium and phosphorus halides, such as $CrCl_3 \cdot PCl_5 = PCl_4[CrCl_4]$ are discussed.

More than half of Part B is now devoted in the following sections to the chromates, acidochromates, and chromium double salts of metals. This indicates the importance of these compounds in pure science and in industry, and shows the wide range of combinations that can be formed by chromium, for it occurs in various valence states, and forms chromates(III) and chromates(VI) with all metals, in some cases even chromates(V). The discussion here covers not only true chromates (and polychromates), but also acidochromates such as halogeno-, sulfato-, or oxalatochromates, and metal double salts of chromium, such as chrome alums. The major part (about 65 %) of the chapter is concerned with the Cr compounds of the alkali metals, particularly the compounds $Na_2CrO_4$, $K_2CrO_4$, $(NH_4)_2CrO_4$, $Na_2Cr_2O_7$, $K_2Cr_2O_7$, $(NH_4)_2Cr_2O_7$, and $KCr(SO_4)_2 \cdot 12H_2O$. Of these, sodium dichromate $Na_2Cr_2O_7$, which is produced industrially by alkali fusion of chrome iron ore, is important as the basis of all other compounds of chromium(VI), and chrome alum $KCr(SO_4)_2 \cdot 12H_2O$ is an important tanning agent. Mention should also be made of lead, zinc, and barium chromates, which are important chrome pigments. The latter have had keen competition in recent years from coal-tar dyes, which are non-toxic and extremely intensely colored, but chromates are involved indirectly as oxidizing agents in the manufacture of these coal-tar dyes.

To summarize, these three chromium volumes represent an impressive accomplishment by the Gmelin staff. The reference lists are complete up to the end of 1949, a closing date for literature perusal which was fixed in 1950, with the result that the "Gmelin" is no less than 15 years behind the present-day literature situation. An attempt has been made to alleviate this apparent deficiency by reference to more recent literature in particularly important cases; but this is only a makeshift remedy, which cannot replace exhaustive collation of the literature up to the time of publication of the volume. It must therefore be urgently requested that the decision taken in 1961 to introduce a "progressive closing date for literature screening" (complete reportage up to the year of publication of the volume in question) should be realized as soon as possible.

Translated by Express Translation Service, London

**Handbuch der Papierchromatographie** (Handbook of Paper Chromatography). Edited by *I. M. Hais* and *K. Macek*. Gustav Fischer Verlag, Jena 1963. Vol. I: Basis and Techniques. Translated from Czechoslovakian into German by *J. Liebster*. 2nd Edit., xv + 1069 pp., 235 illustrs., 178 tables, cloth, together DM 72.40 (about $ 18.50). Vol. III: Bibliography 1957–1960 and Applications. 1st Edit., xix + 700 pp., cloth, DM 40.90 (about $ 10.25).

Although since the appearance of the first edition the importance of paper chromatography has declined in favor of thin-layer chromatography, this consistent and painstaking revision of the standard handbook proves to be an important production. The additional procedures developed during the past five years in numerous laboratories, and not least in the author's own, have been harmoniously worked into the original highly successful work. The 225 pages of the general part in the first edition have been expanded to 263 – even though paper electrophoresis has been entirely neglected – and the specialized part has increased from about 500 pages to 640. The type used is unchanged, and the extreme care taken in production is noticeable throughout. Anyone using paper (or thin-layer) chromatography can save himself much time and vexation by having Hais-Macek in his laboratory. Anyone wanting a convenient introduction to further study of the literature used in the handbook will find this in Volume III, with its ca. 8300 pertinent literature references, a 100-page author index, and a 150-page subject index for 1957–1960. Furthermore, the price for this excellently produced volume is by no means excessive.

*Th. Wieland* [NB 186/84 IE]

**Die Nobelpreisträger der Chemie. Ein Kapitel Chemie-Geschichte** (Nobel Prize Winners in Chemistry. A Chapter in Chemical History), by *W. v. Bonin*. Heinz Moos Verlag, München 1963. 1st edit., 89pp., 69 portraits, half-linen, DM 14.80 (about $ 3.75).

As the highest scientific award, the Nobel Prize marks the great milestones of scientific discovery. *Wulf von Bonin* has skilfully and vividly reviewed these milestones in chemistry in the 45-page comprehensive text of the present book. It is pleasing to note that any national appraisement of the Nobel Prize was carefully avoided.

The text is followed by photographs of all the Nobel laureates in chemistry to date beginning with *Jacobus Henricus van't Hoff* and ending with *Guilio Natta* and *Karl Ziegler*.

This series of photographs gives rise to thoughtful reflection, although more care should have been devoted to the retouching (was it really necessary?). Altogether a volume to be recommended to many chemists.

# Recoil Reactions of Tritium with Organic Compounds

BY PROF. DR. F. SCHMIDT-BLEEK [*] AND PROF. DR. F. S. ROWLAND [**]
CHEMISTRY DEPARTMENT, THE UNIVERSITY OF KANSAS, LAWRENCE, KS. (U.S.A.)

*After "cooling", the hot tritium atoms formed above thermal energies by nuclear reactions abstract or replace hydrogen atoms, and replace substituents X (e.g. alkyl, $NH_2$, $NO_2$, OH, COOH, F, Cl, Br, or I) in organic compounds. Isotope effects have been observed for protonated vs. deuterated compounds in several hot reactions. Models and mechanisms are discussed for the abstraction and replacement, for specific reactions on certain carbon atoms, and for the isotope effects. These are based on steric, bond-energy, and kinetic considerations.*

## I. Introduction

In most chemical reactions, the necessary activation energy is obtained from an equilibrium distribution among all reactants; on the other hand, nuclear recoil processes produce highly energetic atoms within an otherwise unchanged system. In almost all nuclear transformations, recoil atoms, which are frequently radioactive, are generated with kinetic energies far above the energies of chemical bonds [1]. These atoms are not originally in thermal equilibrium with the surrounding medium, but must first be "cooled" into the range of chemical reaction energies before reaching a stable form *via* chemical reactions.

In 1934, *Szilard* and *Chalmers* first reported the chemical consequences of a nuclear reaction [1a]. They were able to show that neutron irradiation of liquid ethyl iodide led to water-extractable radioactive elemental iodine, *i.e.* a fraction of the $^{128}I$ formed by the nuclear reaction $^{127}I(n,\gamma)$ [1b] must have ruptured the original carbon-iodine bonds.

*Szilard* and *Chalmers* concluded that the recoil energy released in the nuclear reaction with iodine is sufficient to break its chemical bond to the carbon atom. Calculation of the energy released by this nuclear transformation shows that the recoiling atom can indeed escape its chemical binding and may be shot for many Ångstroms into the surrounding medium [2]. Many publications on the chemical consequences of nuclear reactions have appeared since these experiments with ethyl iodide. For such experiments, nuclear transformations on $^{3}He$, $^{6}Li$, $^{12}C$, $^{14}N$, $^{37}Cl$, $^{81}Br$, $^{127}I$, and many other isotopes have been utilized, and the reactions have been carried out with a large number of organic and inorganic compounds [3].

For the investigation of recoil reactions, those elements (isotopes) are especially useful which will give radioactive daughter isotopes in sufficient concentration and with convenient half-lives *via* nuclear transformations.

## II. Significance of Tritium Recoil Chemistry

The recoil chemistry of tritium is of special interest for several reasons. Tritium is the only radioactive isotope with the chemical properties of hydrogen. (Here we ignore isotope effects which are of minor importance in this connection.) Moreover, hydrogen is a component of most compounds and much is known about its thermal reactions. Table 1 shows that tritium can be

[1] In nuclear isomeric transitions, it is not the resulting recoil energy which is decisive but the high electronic excitation [3].

[1a] *L. S. Szilard* and *T. Chalmers*, Nature (London) *134*, 462 (1934).

[1b] $^{128}I$ is a $\beta$- and $\gamma$-emitter with a half-life of 25 min.

[2] *A. C. Wahl* and *N. A. Bonner*: Radioactivity Applied to Chemistry. Wiley, New York 1951.

[3] Chemical Effects of Nuclear Transformations. International Atomic Energy Authority, Vienna 1961, Vols. 1 and 2.

easily produced in good yields by neutron irradiation of $^6Li$ and $^3He$ for investigations in the solid, liquid, and gaseous phases. Modern methods of measurement permit the determination of the weak $\beta$-rays ($E_{max} \approx 0.018$ MeV) of tritium in practically every chemical form. Combination of gas-chromatographic separation with a flow proportional counter, for instance, allows precise quick measurements for both gas-phase and condensed-phase experiments [4–6]. It should be noted that "carrier-free" and therefore unweighably small amounts of radioactively labelled compounds can also be identified [7] since they have the same retention or elution times in separation columns as the analogous hydrogen compounds [*]. Investigations in solid compounds often require more complicated analyses [10].

Gas-phase recoil experiments with tritium are usually carried out in 10–30 ml ampoules made of quartz or Pyrex 1720 glass, containing a mixture of the substance to be investigated with $^3He$ at a partial pressure of 10–30 mm. A simple calculation shows that irradiation of 0.5 ml of $^3He$ (at STP) for 1 h in a neutron flux of $10^{11}$ n/cm²/sec (thermal neutrons) yields about $2.5 \times 10^{13}$ tritium atoms; this corresponds to ca. $2.5 \times 10^6$ decays per minute. It should be pointed out that double labelling is extremely improbable since about $10^7$ times fewer tritium atoms are produced than the number of parent molecules present during irradiation.

If lithium is to be used as the source of tritium, then about 10 % by weight of a lithium salt is mixed with the target substance. The natural abundance of $^6Li$ (about 7.5 %) permits the use of any lithium compound which is chemically inert in the investigated system, and which does not produce unwanted radioactivity from nuclear reactions with another element.

Table 1. The most important data on the nuclear reactions which are used as tritium sources for recoil experiments.

| Target isotope | $^6Li$ | $^3He$ |
|---|---|---|
| Natural abundance of the isotope [%] | ca. 7.5 | $1.3 \times 10^{-4}$ [*] |
| Nuclear reaction | $^6Li(n,\alpha)T$ | $^3He(n,p)T$ |
| Thermal neutron cross-section [barns] | 945 | 5400 |
| Tritium recoil energy [MeV] | 2.73 | 0.192 |
| Recoil energy of the emitted particle ($\alpha$ or p) [MeV] | 2.06 | 0.57 |

[*] Isotopically "pure" $^3He$ can be purchased (§ 150 per liter at STP); however, it must be purified from tritiated impurities for tritium-recoil experiments [53].

## III. Reactions of Hot and Thermal Tritium

Each recoil tritium atom is created with so much energy that it cannot undergo chemical reactions or compound formation immediately after its formation (see Table 1). Only after it has lost sufficient energy – first by ionic interactions [11], then by elastic and inelastic collisions with the medium – can the atom acquire a stable chemical form by chemical reaction.

In 1958, *Wolfgang* and co-workers [12,13] argued very convincingly that the recoil tritium atom is already electrically neutral at kinetic energies below 1000 eV. It may be assumed further that the reacting tritium atom is in the electronic ground state. None of the experimental results to date disagree with these hypotheses.

Why, then, have reactions other than those already well known for thermal hydrogen and deuterium atoms been postulated for recoil tritium atoms? Why is the term "hot" reaction used? Recoil experiments with tritium in methane [10,14] and cyclopropane [15] have shown that tritium atoms produced by nuclear transformations can replace hydrogen atoms in these compounds, or abstract hydrogen from them with formation of HT. These reactions are not observed for thermal deuterium atoms at these temperatures, and are typical of the "hot" reaction discussed below. Definitions for such hot reactions have been advanced by various authors [13,16]; to us the following appears to be clearest: *Hot reactions are brought about by energetic atoms which have never been in thermal equilibrium with their surroundings.*

The energy necessary for chemical reaction is exclusively (or almost exclusively) furnished by these atoms.

The following criteria are used to distinguish between hot reactions of a recoil atom and its thermal reactions:

1. Since the energy of reaction is furnished exclusively by the hot atom, hot reactions should to a first approximation be independent of temperature.

2. The yield of the products of hot reactions should not be influenced by the addition of small amounts of radical scavengers. Radical scavengers such as $O_2$, $I_2$, or NO eliminate thermalized recoil atoms and their reaction products (*e.g.* radicals produced by addition of tritium onto an olefin or by abstraction of hydrogen by thermal atoms).

3. The yield of hot reaction products should be influenced by moderators (inert gases); these should alter the energy distribution of the recoil atoms without taking part in the reactions.

If we define the probability of reaction (per collision) of a recoil atom with a reaction partner in the system

[15] *J. K. Lee, B. C. Musgrave*, and *F. S. Rowland*, Canad. J. Chem. *38*, 1756 (1960).

[16] *P. J. Estrup* and *R. L. Wolfgang*, J. Amer. chem. Soc. *82*, 2665 (1960).

as $P_i(E)$, then the value of $P_i(E)$ for a very energetic tritium atom will be zero. Collisions in an energy range well above 20 eV are much too energetic for the formation of a stable tritium bond (see Figure 1). The hot tritium atom becomes more and more moderated in energy by collision until it enters a range below $E_2$ in which it can form chemical bonds, *i.e.* $P_i(E) > 0$ within the limits $E_2 > E > E_1$. ($E_1$ is the minimum energy necessary for reaction; $E_1 > E_{thermal}$.)

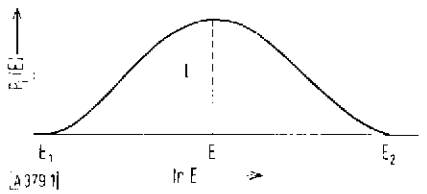

Fig. 1. Dependence of reaction probability of a hot reaction on the kinetic energy of the tritium atom.

We will return to this diagram later and indicate the dependence of the yield of hot reactions upon $P_i(E)$ and other parameters.

## IV. Prototype "Hot" Tritium Reactions in Organic Systems

### A. Substitution of Tritium for Hydrogen

In 1955, *Wolfgang*, *Rowland*, and *Turton* reported the first results of a tritium recoil experiment [17]. They observed the incorporation of tritium into glucose after thermal-neutron irradiation of a mixture of glucose and $Li_2CO_3$. Stepwise degradation of the irradiated compound showed that the distribution of tritium in the molecule was non-statistical.

*Rowland* and co-workers showed in 1959 [18] that the substitution of hydrogen by tritium at an asymmetrical carbon atom, *viz.* in crystalline L-(+)-alanine, occurred with almost complete retention of the configuration. Later, *Wolfgang* et al. [19] found over 90 % retention of configuration in gas-phase experiments with secondary butyl alcohol, and showed further that about 70 % of *cis*- and *trans*-dichloroethylene remained in the original conformation after the tritium hydrogen exchange [20]. These results imply a very rapid, direct exchange mechanism.

### B. Abstraction of Hydrogen by Tritium

In 1956/57, *Wolfgang*, *Rowland*, and co-workers, and *Willard* and co-workers [13,14,17,21,47] were able to show that abstraction of hydrogen plays as important a role in tritium-recoil systems as substitution reactions. Recoil experiments in liquid methane or ethane and in gaseous methane showed that the most important reaction products are HT and RT (RT = tritiated mother molecule). These authors showed further that the addition of radical scavengers to methane scarcely changed the yield of $CH_3T$ but lowered the yields of HT. Moreover, the postulated temperature independence as well as the influence of moderators ($^4He$) on the distribution of reaction products was experimentally demonstrated [12]. It has since been shown that the reactions

$$T + RH \rightarrow RT + H \quad \text{(a) (Substitution)}$$

and

$$T + RH \rightarrow R + HT \quad \text{(b) (Abstraction)}$$

are the most important ones for the formation of the products in almost all the systems that have been investigated: 5–60 % of the total tritium activity appears in labelled parent molecules, and in most cases more than 25 % is found as HT.

### C. Abstraction and Replacement of Larger Groups and Atoms

Recoil experiments with tritium and substituted benzoic acids showed that the extent of replacement of substituents X (X = $NH_2$, $NO_2$, OH, COOH, F, Cl, Br, and I) by tritium increases strongly as the binding energy of the group to the aromatic ring becomes smaller [23]. By analogy to Reactions (a) and (b), we can assume that the Reactions (c) and (d) are also involved in the formation of reaction products:

$$T + RX \rightarrow RT + X \quad \text{(c)}$$

$$T + RX \rightarrow R + TX \quad \text{(d)}$$

Since then, numerous investigations with alkyl halides have been carried out [24–29]. The replacement of alkyl groups in hydrocarbons by tritium [12,51,52,54] will be discussed in detail later.

### D. Tritium Addition to Double Bonds

*Urch* and *Wolfgang* were able to show in a series of experiments that hot tritium adds onto double bonds, and can result in geometric isomerization. Moreover, the formation of smaller olefins demonstrated the decomposition of excited radicals formed by the tritium addition [30,31].

### E. Formation and Decomposition of Excited Intermediates

In 1957, *Hoff* studied the recoil chemistry of tritium in liquid ethanol [32]. In order to explain the formation of the [$^3$H]acetaldehyde found as a reaction product, *Rowland* and *Hoff* suggested the formation and subsequent decomposition of an excited intermediate:

(e) $T + CH_3{-}CH_2{-}OH \rightarrow (CH_3{-}CHT{-}OH)^* + H$

(f) $(CH_3\ CHT\ OH)^* \rightarrow CH_3\ CTO + 2\,H$

Later, *J. K. Lee*, *Musgrave*, and *Rowland* [15,34] assumed similar excited intermediates in recoil experiments with cyclopropane, for they found that the yield of tritiated cyclopropane increased as the pressure in the irradiated ampoule was raised (collision stabilization). Subsequently, *E. K. C. Lee* [35] showed in a detailed investigation with cyclobutane that tritiated ethylene is formed as the result of the reaction sequence:

(g) $T + C_4H_8 \rightarrow (C_4H_7T)^* + H$

(h) $(C_4H_7T)^* \rightarrow CH_2{=}CH_2 + CH_2{=}CHT$

(i) $(C_4H_7T)^* + M \rightarrow C_4H_7T + M$

Applying known data on the unimolecular decomposition of cyclobutane [36,37], he was able to calculate from the observed pressure dependence of the yield of $C_2H_3T$ that the tritium atom in Reaction (g) transfers an average of 5 eV excitation energy to the cyclobutane product.

### F. Primary and Secondary Isotope Effects

If recoil tritium is allowed to react with $CH_3CD_3$ or $CH_2D_2$ [21,22,38], then about 30 % more HT than DT is formed with either compound. Furthermore, the experimental results obtained with the pairs of compounds $CD_4/CH_4$, $n\text{-}C_4D_{10}/n\text{-}C_4H_{10}$, $CD_3Cl/CH_3Cl$, and $CD_3F/CH_3F$ can be summarized as follows [27,29,38]:

1. For abstraction reactions [cf. Reaction (b)], the abstraction ratio of concentrations $[HT]/[DT] \approx 1.3$.

2. For the substitution of hydrogen isotopes [cf. Reaction (a)], the substitution ratio $[RH_{n-1}T]/[RD_{n-1}T] \approx 1.3$.

3. For the substitution of the group X in $CH_3X$ and $CD_3X$ [cf. Reaction (c)]. The substitution ratio $[CH_3T]/[CD_3T] \approx 1.4$.

This shows that:

a) An energetic tritium atom abstracts and replaces protium more easily than deuterium. The abstraction and substitution ratios are not very dependent upon the type of compound and are of about the same magnitude (primary isotope effect).

b) An energetic tritium atom replaces fluorine and chlorine more easily in a protonated than in a deuterated compound. The substitution ratio is about 1.4 (secondary isotope effect).

Explanation of these isotope effects is of great importance for an understanding of the reactions of hot tritium atoms. Satisfactory quantitative explanations for all the experimental data have not yet been found, but we shall discuss some aspects below.

## V. Reaction Models

1. The most frequent reactions of hot tritium atoms in organic systems are the substitution and the abstraction of hydrogen [Reactions (a) and (b)]. *Henchman, Urch,* and *Wolfgang* [20,31,33] proposed a steric model which depends upon the geometric properties of the compound for these reactions. They assumed that the formation of HT (abstraction of hydrogen) occurs preferentially if the tritium attacks the carbon-hydrogen bond almost co-axially. On the other hand, if the approach of the tritium to the carbon-hydrogen bond occurs at an oblique angle, the probability of reaction to form RT (substitution for hydrogen) is greater.

At these angles, the geometric arrangement of the reacting molecule could have an influence on the exchange of tritium for hydrogen, whereas the abstraction of hydrogen should be independent of molecular structure. By using an obstruction parameter $\Omega$, *Wolfgang* and co-workers developed Equation (1) for the relative frequency of abstraction and substitution.

$$\frac{[HT]}{[RT]} = \frac{n}{n_0 - n_1(1-\Omega) - n_2(1-\Omega)^2 + n_3(1-\Omega)^3} \qquad (1)$$

where $n$ = the number of hydrogen atoms in the compound

$n_0$ = the number of hydrogen atoms in methane

$n_1$, $n_2$, and $n_3$ = the number of primary, secondary and tertiary hydrogen atoms in compounds with more than 1 carbon atom.

Good agreement of experimental results with Equation (1) was found for a whole series of hydrocarbons with $\Omega = 0.45$.

In 1962 and 1963, experiments from our laboratory were published which questioned the exclusive steric dependence assumed by *Wolfgang* and co-workers. *Root* investigated the recoil chemistry of tritium in mixtures of n-butane and methane [39] and found that the ratio of the specific activities (per molecule) of n-butane to methane had the value of 2.3. Equation (1) predicted a value of 1.13, assuming equal abstraction probabilities for all the hydrogen atoms in both molecules.

As *E. K. C. Lee* later showed [35], the experimental values for the specific activities of cyclobutane/methane

[37] *C. T. Genaux, F. Kern*, and *W. D. Walters*, J. Amer. chem. Soc. *75*, 6196 (1953).

[38] *J. W. Root* and *F. S. Rowland*, J. Amer. chem. Soc. *85*, 1021 (1963).

[39] *J. W. Root* and *F. S. Rowland*, J. Amer. chem. Soc. *84*, 3027 (1962).

and cyclobutane/n-butane mixtures also did not agree with the values calculated from Equation (1). The compounds $CH_3-CD_2-CH_3$ and $CD_3-CH_2-CD_3$ were also exposed to energetic tritium atoms by *Breckenridge* and *Root* [40]; abstraction of hydrogen from the center carbon atoms was found to occur 1.4 times oftener than from the terminal carbon atoms, per C–H bond.

These and other experimental results [22] lead *Rowland* and co-workers to suggest that the characteristic differences in the ratio [HT]/[RT] for the various alkanes may depend not only on steric differences in the substitution reaction but also on differing probabilities of abstraction from compound to compound. This assumption led to the further conclusion that the binding energy of the carbon-hydrogen bond exerted an influence on the probability of formation of HT [*].

If one compares the relative yield of HT (yield per C–H bond) from different compounds with the bond dissociation energy of the C–H bond, Figure 2 is obtained.

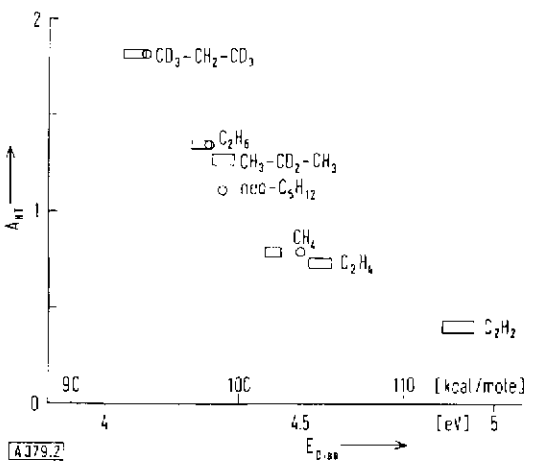

Fig. 2. Dependence of the relative yield $A_{TH}$ on the C–H bond dissociation energy $E_{Diss}$ of various hydrocarbons. The relative yield $A_{HT}$ is defined as the yield per C–H bond.
O: $E_{Diss}$ according to [48].
□: $E_{Diss}$ according to [49].

The fact that the measured points form a smooth curve indicates the dependence of the formation of HT upon the C–H bond dissociation energy.

Only stepwise degradation of the hot reaction products and location of the specific activity in the various positions in each molecule can decisively determine the extent to which differences in the substitution reactions contribute to the measured [HT]/[RT] ratios [**].

2. In the reactions of recoil tritium with many hydrocarbons, the tritium atom, after rupture of a carbon-carbon bond, attaches preferentially to the smaller fragment. Thus, for example, the ratio $[CH_3T]/[C_2H_5T]$ after irradiation of propane is 2.7 [20,41] and the ratio $[CH_3T]/[iso\text{-}C_4H_9T]$ from neopentane is 8.0 [20]. Similar selectivity of tritium incorporation has been observed for other compounds: substitution of tritium for fluorine occurs more easily in $CH_3F$ than in $CH_2F_2$ (the yield of $CH_3T$ from the former is larger than the yield of $CH_2TF$ from the latter) [25].

To account for these results, *Odum* and *Wolfgang* [26] proposed a reaction model that involves the inertia of the fragments produced in the reaction. This can be briefly explained for the molecules $CH_3Cl$ and $CH_2Cl_2$ (see Figure 3, a and d): after fission of a C–Cl bond by collision with the hot tritium atom (Figure 3, b and e), the $CH_3$ formed from $CH_3Cl$ can rotate quickly into a position favorable for bond formation with the tritium (Figure 3, c), whereas the $CH_2Cl$ formed from $CH_2Cl_2$ rotates more slowly because of its higher moment of inertia and allows sufficient time for the tritium atom to escape before $CH_2TCl$ can be formed.

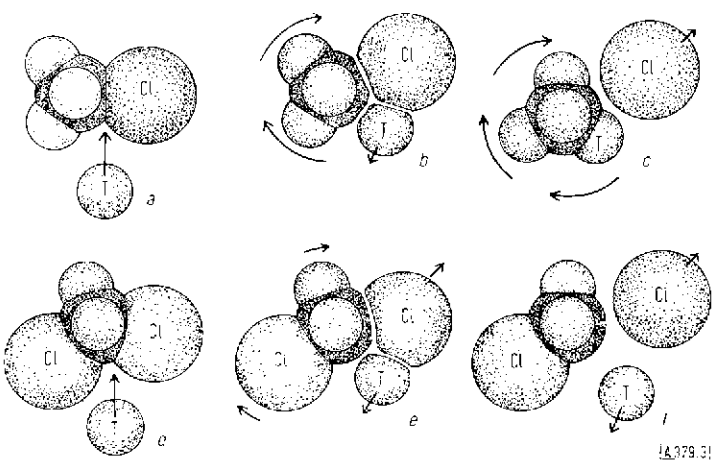

Fig. 3. Rotational inertia hypothesis of *Wolfgang* [36]. Substitution of Cl by T in $CH_3Cl$ and $CH_2Cl$.
b: Rotating $CH_3$ group
c: Formation of C–T bond
f: Failure to form a C–T bond
e: Rotating $CH_2Cl$ group.

As discussed above, the formation of excited intermediate compounds has now been shown in a series of investigations [15,34,35].

Since the instability of such intermediates is sure to affect the yield of some reaction products, dependence of the reaction products on pressure is expected, and a discussion of reaction mechanism is meaningful only after careful evaluation of the "original" yields of the hot reactions. Experimentally, the original yields can be obtained from investigations at high pressures (or in the liquid phase), where the excited species can undergo rapid collisional stabilization. In certain cases, *e.g.* with the $CH_3Cl$ system [28], the sum of the yields of collision-stabilized hot reaction products and their decomposition products is independent of the pressure. Such an indirect determination of the original yield can only be used when only few secondary products are formed, and when the radical decomposition products can be converted by a selective free-radical scavenger into a stable, radiochemically measurable form.

As a further test of the model proposed by *Wolfgang* and co-workers, *Schmidt-Bleek* examined a series of compounds of the type $n\text{-}C_3H_7X$ (X–$NH_2$, OH, F, Cl, or Br) [41]. The ratios $[C_2H_5T]/[CH_2TX]$ should be approximately 1.0 for n-propylamine, n-propyl alcohol, and n-propyl fluoride, if only the masses of the frag-

[40] *W. Breckenridge, J. W. Root*, and *F. S. Rowland*, J. chem. Physics *39*, 2374 (1963).

[*] Only the ratio [HT]/[RT] may be compared here because the absolute yield of HT or RT in different compounds can be influenced by variations in the energy spectrum of the tritium (see also Paragraphs 2 and 3).

[**] *Wolfgang* and co-workers recently investigated the distribution of recoil tritium in isobutane. They found that the ratio of tritium in the tertiary position to tritium in the primary position (per C–H bond) is 0.79 [J. chem. Physics *40*, 3730 (1964)].

[41] *F. Schmidt-Bleek*, unpublished results.

ments have an important influence on product formation. The observed value for $[C_2H_5T]/[CH_2TX]$ is about 10 for liquid n-propyl alcohol and 20 for liquid n-propylamine, while in gaseous n-propyl fluoride a pressure-independent (from 50 to 600 mm) ratio of 1.7 has been obtained.

These results have not yet been explained by a completely satisfactory reaction model. The rotational inertias of the reaction partners are certainly not the only important parameters for the formation of the reaction products. It is possible, for example, that the electron density of the various fragments is an important factor.

3. In Figure 1, the dependence of the probability of reaction of a hot tritium atom on its kinetic energy was illustrated. One of the main goals of recoil chemistry is to describe the kinetics of these hot reactions quantitatively.

In 1950, *Miller* and *Dodson* [42] expressed the reaction probability of a recoil atom in mathematical form for the first time. In 1960, *Estrup* and *Wolfgang* [43] applied the equations proposed by *Dodson* and co-workers to recoil tritium.

In the following, the mathematical treatment of *Wolfgang* and co-workers is briefly reviewed. For details we refer the reader to the original publications [43, 44].

If the total number of hot atoms present in the region $E_2-E_1$ (see Figure 1) is $N_s$, and their relative collision probabilities with molecules i is $f_i$, then the total number of atoms of reaction products $N_g$ is given by

$$N_g = N_s \sum_i \int_{E_1}^{E_2} f_i \, P_i(E) \, n(E) \, dE \qquad (2)$$

Equation (2) where n(E)dE is the number of collisions in the energy range E + dE to $E_1$, and $P_i(E)$ is the reaction probability of the hot atom per collision.

In order to calculate n(E), *Wolfgang* and co-workers made the following assumptions based upon theoretical calculations for the slowing down of fast neutrons [44a]:

(a) The energy loss per collision can be described by the relationships for collisions of elastic spheres.

(b) The original kinetic energy of the recoil atom is so high (see Table 1) that the tritium atom has already made many collisions before it reaches $E_2$. In this way, a statistically well-defined energy distribution can be formed between $E_2$ and $E_1$.

(c) $E_1$ is large compared to thermal energies.

As long as the probability of reaction of the hot tritium is zero [$P_i(E) = 0$], n(E) is given by Equation (3),

$$n(E) = -\frac{1}{\alpha E} \qquad (3)$$

where $\alpha$ is the average logarithmic energy loss per collision [*]:

$$\alpha = \ln(E_0/E) \qquad (4)$$

Since $P_i(E)$ is not zero between $E_2$ and $E_1$, the actual number of collisions in the energy range E + dE to E (see Equation 2) is less than $-1/\alpha E$.

$$n(E) = -\frac{1}{\alpha E}\left[1 - \sum_i \int_{E_2}^{E} f_i \, P_i(E) \, n(E) \, dE\right] \qquad (5)$$

Transformation of this expression and its insertion into Equation (2) finally gives for the relative yield $N_g/N_s$ of all hot products:

$$N_g/N_s = 1 - e^{-f \cdot I/\alpha} \qquad (6)$$

where

$$I = \int_{E_2}^{E_1} P_i(E) \, d\ln E \qquad (7)$$

*i.e.* the area under the curve in Figure 1.

Equation (6) is valid only if tritium encounters only the pure substance to be investigated as reaction partner, *i.e.* in a gaseous two-component system. On addition of a third collision partner, *e.g.* an inert "moderator", the relationships become more complicated. *Wolfgang* et al. gave the following approximate equation for the addition of inert gases:

$$N_g/N_s = 1 - \exp[-f_a I_a/\alpha_{ab}] \qquad (8)$$

in which the indices a and b stand for the starting material and the moderator, respectively. *Rowland* and *Coulter* [45] showed by Monte Carlo computer calculations that Equation (8) leads to satisfactory values only for the addition of helium.

It should be pointed out that the authors made several simplifying approximations during the derivation of these equations. For example, inelastic collisions, anisotropic scattering, and the dependence of the reaction cross-section on the energy of the colliding particles may have influences on the yield of hot reactions. However, good agreement was occasionally obtained between experimental results and the theoretical values [43]. The data available so far permit only approximate measurement of the magnitude of the area under the curve in Figure 1. The shape of this curve cannot yet be determined.

*Estrup* [45a] recently pointed out that quantitatively accurate measurements of I depend very strongly on the use of more realistic interaction potentials than those of the hard spherical models used so far. The effect is especially important in the calculations of $\alpha$ and f.

4. The kinetic model of hot tritium reactions described in paragraph 3 leads to several possible isotope effects. If the average energy loss of the tritium atom in a non-reacting collision in the energy range $E_2-E_1$ (see Figure 4) is different for isotopically substituted molecules, then the number of hot collisions of the tritium will be different in a given energy range. If we assume, for example, that a collision with RD leads to a greater energy loss for tritium than its collision with RH, then the tritium atom will undergo fewer collisions with RD and fewer reactions with RD than with RH within a comparable energy range. The yield from Reaction (k)

$$(k)\quad T + RD \rightarrow RT + D$$

would then be lower than that from Reaction (i).

$$(i)\quad T + RH \rightarrow RT + H$$

[45a] *P. Estrup*, J. chem. Physics *41*, 164 (1964).

This effect has been called a moderator isotope effect [29] (see Figure 4a).

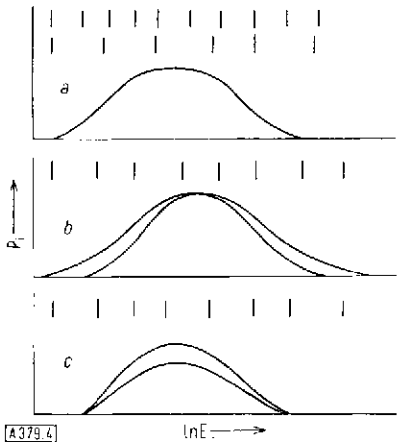

Fig. 4. Influence of various isotope effects on reaction probability and reaction energy of hot tritium atoms. (The short vertical lines signify energies at which collisions occur.)

a: Moderator effect (different energy losses for collisions with different molecules)

b: Probability-integral effect (different energy ranges for collisinns with different molecules).

c: Probability-integral effect (different probabilities of reaction for collisions with different molecules).

On the other hand, it is also possible that the energy ranges for Reactions (k) and (l) are different (see Figure 4b), or that differences occur in the probability of reaction of the tritium with isotopically different substances (see Figure 4c). These two effects are both included in the term "probability integral" isotope effects [27].

All three effects may exert influences on the reaction of the tritium and produce observable differences in the yields from isotopic molecules.

Experimentally, the moderator isotope effect can be distinguished from the probability integral isotope effect if the abstraction and substitution of protium and deuterium is measured simultaneously in a single molecule. In this way, the same energy spectrum of hot tritium is available for all reactions, and moderator isotope effects are excluded. The investigations of the compounds $CH_2D_2$ and $CH_3CD_3$ are good examples. For these two partially deuterated molecules, about 30 % more hydrogen than deuterium is abstracted; this led to the hypothesis that the effects illustrated in Figures 4b and 4c are also of decisive influence in other systems [39].

## VI. The Influence of Radiation Chemistry

Neutron irradiation of $^6Li$ and $^3He$ produces not only tritons but also high energy $\alpha$-partieles and protons. Moreover, each system is subjected to fast neutrons and $\gamma$-rays during irradiation in a nuclear reactor. Hence the danger exists that these accompanying irradiations may cause alterations which are difficult to separate from tritium recoil events. Also, each recoiling atom must itself dissipate its energy in the system, leaving a path of radiolysis products behind it.

For simplification, we might say that tritium can react with hydrocarbons in two distinctly different energy regions. In the "hot" zone extending from $E_2$ to $E_1$, the reactions we have described in detail occur. However, if the tritium escapes from this hot reaction zone without having formed a stable chemical bond, its further reactions are no longer separable from the well-known reactions of thermal hydrogen and deuterium atoms. Such reactions are chiefly addition to olefins and the abstraction of hydrogen.

The excited radicals formed by additions onto olefins ($H + CH_2{=}CH_2$, for example, leads to ethyl radicals with about 40 kcal/mole excitation energy) [46]) can undergo further abstraction reactions with molecules, or combination and disproportionation reactions with other radicals. The probabilities of these thermal reactions depend upon the equilibrium concentrations of the reactive components encountered by the tritium after passing through the hot reaction zone. It is obvious that the concentrations of many species will be different under different irradiation conditions. The influence of these radiation effects can be investigated by determining the dependence of the yields of hot products upon the total radiation dose and dose rate. The findings of various authors leave no doubt that the influence of radiation chemistry must be considered in all recoil experiments [3]. In our investigations, however, it is clear that the tritium reactions in the hot reaction zone are independent of the radiation damage at least so long as the concentration of the stable products formed by irradiation is so small that decomposition of the products is also kept within low limits. Furthermore, the addition of radical scavengers can control conditions such that the thermalized tritium atoms and radiation-damaged components are forced to react to give products which can easily be distinguished from products of recoil reactions. It has been demonstrated in many systems that this experimental technique leads to distributions of hot products which are independent of the radiation dose within wide limits [3].

## VII. Conclusion

Investigations of the chemical consequences of nuclear reactions aim at solution of the following problems:

1. How can the energy loss of the recoil atom be mathematically described in the hot reaction zone?

2. How large is the probability of reaction of the colliding particle in terms of its kinetic energy?

3. At what energies do recoil reactions occur?

4. What are the reaction mechanisms involved?

5. What products are formed when the excited labelled molecules decompose?

Scarcely any other recoil system appears to be as satisfactory for studying these problems as the recoil of tritium in organic molecules.

The decomposition of excited intermediates has been demonstrated in many experiments, and the products formed definitely determined. Quantitative estimation and comparison of the hot products formed in a large number of

[49] *R. R. Bernecker* and *F. A. Long,* J. physic. Chem. *65,* 1565 (1961).

systems have led to clarification of the reaction mechanisms entailed. Experiments in cyclobutane have shown that during hot exchange reactions tritium transfers an energy of about 5 eV from its kinetic energy to excitation of the product molecule. Finally, first approaches have been made to theoretical expressions for the reaction probability of energetic tritium atoms, as well as for their energy losses in collisions.

The investigations into recoil systems have required the development of radiogas-chromatographic measurement methods of high sensitivity. The techniques developed here are useful in many other areas of work: for example, as little as $10^9$ molecules of any tritiated compound can be determined with certainty in a gas stream.

For some time now, the problem has been considered of how tritium atoms (and other isotopes) can be produced with much smaller kinetic energies than those formed in nuclear transformations. Precise kinetic investigations of hot reactions would require tritium atoms with well defined energies between 20 and 1 eV. Attempts, for example, to accelerate $^{14}C$ ions onto a target with the help of specially constructed mass spectrometers have so far met with difficulties [3].

Experiments with shock waves are also not yet possible. In our laboratory, experiments are now proceeding on the use of photolytic decompositions (*e.g.* with Tl), following the successful experiments for producing deuterium and protium atoms [50]. The atoms formed by photolysis possess about 3 eV of energy and may lead to an increase in our knowledge of hot reactions. For the present, however, nuclear recoil systems offer the most promise for answering the questions given above.

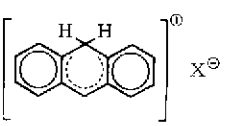
# Proton-Addition Complexes of Aromatic Hydrocarbons



BY PROF. DR. H.-H. PERKAMPUS [*] AND DR. E. BAUMGARTEN [**]

INSTITUT FÜR PHYSIKALISCHE CHEMIE UND ELEKTROCHEMIE
DER TECHNISCHEN HOCHSCHULE HANNOVER (GERMANY)

*The structures of proton-addition complexes of aromatic hydrocarbons were hitherto known only with respect to their stoichiometric compositions but can now be clarified by ultraviolet, infrared, and NMR spectroscopic methods. For example, it has been possible to prove by NMR soectroscopy that the expected addition of protons into 9,10-dimethyl-[a]benzanthracene actually does take place. Two isomeric proton adducts of toluene have been found by means of infrared spectra. On addition of protons, the ultraviolet spectra of aromatics change considerably; excellent agreement is sometimes observed between the band maxima calculated by quantum mechanics and those found by experiment.*

## I. Introduction

It has long been known that aromatic hydrocarbons form solid or liquid compounds with Lewis acids such as $AlCl_3$ in the presence of hydrogen halides [1]. It is also known that aromatic hydrocarbons yield carbonium ions in strong acids [2]. Proton-addition complexes are involved in both processes; *Gold* and *Tye* [3] have put forward certain proposals for the structures of these adducts, *e.g.*, the structure *(1)* for the anthracene complex.

*(1)* 

The pronounced interference with the aromatic system associated with the addition of protons gives rise to numerous striking properties of these complexes, *e.g.* their intense colors.

These complexes are of importance because similar entities must be assumed as intermediates in numerous electrophilic substitutions at aromatic rings [4], as was postulated relatively early on theoretical grounds [5]. *Brown* et al. [6] later

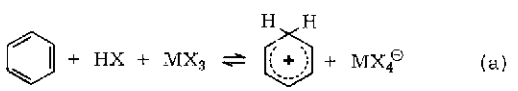
[6] *H. C. Brown* and *J. D. Brady*, J. Amer. chem. Soc. *74*, 3570 (1952).

reconsidered these assumptions, and initiated attempts to detect complexes appearing as intermediates in electrophilic substitution reactions.



In addition to proton-addition complexes, it is necessary to consider complexes arising by interactions between aromatic hydrocarbons and Lewis acids. Such complexes are primarily π-complexes according to *Dewar* [7], which, in *Mulliken*'s classification [8], must be designated as π-v-complexes. The complexes arise by a typical electron-donor/electron-acceptor mechanism, in which the donor has a π-electron system and the acceptor an electron deficiency (v = vacancy). Furthermore, sometimes complexes with a covalent bond between the aromatic hydrocarbon and the Lewis acid, without participation of protons, must be taken into account; like the proton-addition complexes, these should also be designated as σ-complexes.

Summing up, when the interaction of weak acids with aromatic hydrocarbons is disregarded, three types of complexes must be considered: 1. proton-addition complexes: aromatic hydrocarbon/HX/$MX_3$, 2. π-v-complexes: aromatic hydrocarbon/$MX_3$, and 3. σ-complexes: aromatic hydrocarbon/$MX_3$.

Only proton-addition complexes of the type aromatic hydrocarbon/HX/$MX_3$ will be discussed here.

## II. Composition of the Proton-Addition Complexes

The following equation holds formally for the formation of a proton-addition complex with participation of a Lewis acid.

$MX_3$ = $BF_3$, $AlCl_3$, $AlBr_3$, $GaCl_3$, $GaBr_3$

Equation (a) is idealized, since in reality Lewis acids are present partly as dimers, as follows from their solubilities in organic solvents [9–11] and from the Raman spectra of molten $AlCl_3$, $AlBr_3$, $AlI_3$, and $GaCl_3$ [12,13].

Consequently, the anion in Equation (a) may also be formulated as $M_2X_7^{\ominus}$. Because of this dimerization of Lewis acids, we find not only complexes of the composition benzene/HX/$MX_3$ = 1:1:1, but also 1:1:2 [14]. Different stoichiometric ratios may be found for various hydrocarbons, *e.g.* 3:1:2 and 1:1:2 for isolated crystalline mesitylene/HBr/$AlBr_3$, and 2:1:2 and 1:1:2 for 1,2,5-triethylbenzene/HBr/$AlBr_3$ [15]. Xylene complexes have the empirical composition $(Ar)_x \cdot Al_2Br_6 \cdot HBr$ with $x > 2$ [16]. On the other hand, *Lien, Shoemaker*, and *McCaulay* [17] found 1:1:1 complexes for the systems aromatic hydrocarbons/HF/$BF_3$. *Olah* et al. [18] confirmed these results by isolating complexes of various methylbenzenes with HF/$BF_3$ at low temperatures (see Table 1).

Table 1. Physical characteristics of some $ArH^+ \cdots BF_4^-$ complexes [18].

| Aromatic hydrocarbon (Ar) | log K [19] [a] | M. p. [°C] | Conductivity, [mho/cm] [c] | Color [d] | Empirical formula | $BF_4^-$ [%] calc. | $BF_4^-$ [%] found |
|---|---|---|---|---|---|---|---|

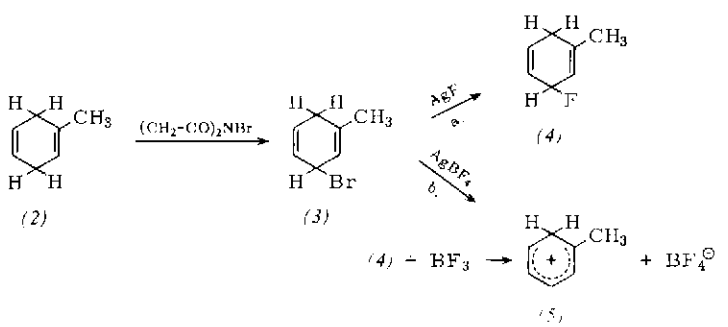
[a] The basicity constant [19] is defined as $[K] = \frac{[ArH^+]}{[Ar] \cdot [H^+]}$



[b] Calculated approximately in accordance with [45].

[c] At the melting point.

[d] Of the solid complex.

The analytical results given in the last column of Table 1 agree very well with expectations for 1:1:1 complexes. The melting points (partial dissociation begins at the melting point) show that the stability obviously increases with the basicity of the methylbenzenes.

The synthesis of a proton-addition complex described by *Olah* et al. [20] is of interest in this connection: 1-methyl-1,4-cyclohexadiene *(2)* was converted with the aid of *N*-bromosuccinimide into 1-methyl-3-bromo-1,4-

cyclohexadiene *(3)* which reacted with AgF to give the fluorine derivative *(4)*. $BF_3$ causes elimination of the fluorine anion from *(4)*, the products being a tetrafluoroborate anion and the proton-addition complex of toluene *(5)*.

Since replacement of bromine with fluorine by Route a presented difficulties, *(3)* was converted directly into *(4)* with $AgBF_4$ (Route b). Thus, a 1:1:1 composition has been established for this proton-addition complex aromatic hydrocarbon/HF/$BF_3$.

In order to clarify the complicated mode of interaction of aromatic hydrocarbons with Lewis acids such as $AlCl_3$ and $AlBr_3$ in the presence of halogen halides, *Lieser* and *Pfluger* investigated the formation of phases in the ternary systems toluene/HCl/$AlCl_3$ [21] and mesitylene/HCl/$AlCl_3$ [22] by vapor pressure measurements. Their results led to the conclusion that there are several phases with relatively large regions of homogeneity. Of these, the phase toluene:HCl:$AlCl_3$ = 6:1:2 is obviously favored in the toluene system. With mesitylene, the composition of the phase showing the orange color typical of proton-addition complexes was shown by conductivity measurements to be mesitylene: HCl:$AlCl_3$ = 4:1:2.

Here, as in other investigations, it turned out that generally more molecules of the aromatic hydrocarbon are fixed than are necessary for the formation of a proton addition complex. *Lieser* and *Pfluger* [21,22] therefore assumed that the molecules in excess are bound in a solvation sheath. The fact that the aromatic molecules present in excess in the complex are relatively free and therefore cannot be substantially involved in the interaction had already been discussed by *Luther* and *Pockels* [23] on the basis of ultraviolet spectra of the systems benzene/HCl(HBr)/$AlCl_3$($AlBr_3$) and toluene/HCl(HBr)/$AlCl_3$($AlBr_3$).

As *Perkampus* and *Baumgarten* [24] have shown for benzene, the changes in the infrared spectrum of benzene associated with the formation of proton-addition complexes are practically independent of the type of the Lewis acid. To illustrate this, the infrared spectra of some benzene/HX/$MX_3$ systems are shown schematically in Figure 1. These differ markedly from the spectrum of pure benzene but are identical with one another [*], proving that the anion exerts only a slight influence. Thus, it must be the addition of protons onto the aromatic hydrocarbon which is responsible for the marked effects during complex formation.

## III. Structure of the Proton-Addition Complexes

### 1. Proton Magnetic Resonance Spectra

The decisive factor in the addition of protons onto aromatic hydrocarbons is the transition of a trigonally $sp^2$-hybridized carbon atom into a tetragonally $sp^3$-hybridized one. Owing to this fact, any proton-addition complex can be detected directly from the nuclear magnetic resonance signals of its protons. *McLean, van der Waals*, and *Mackor* [25] investigated several mononuclear and polynuclear aromatic hydrocarbons and obtained direct proof of the structures formulated by *Gold* and *Tye* [3]. Figure 2 shows the proton magnetic resonance spectra of 9,10-dimethylbenz[*a*]anthracene and its proton-addition complex. The proton adds on in the 9-position. Figure 2a shows two bands for the methyl protons, indicating that the two $CH_3$ groups are no longer equivalent. As soon as the proton-addition complex is formed, the configuration $>CH-CH_3$ arises in the 9-position and one of the signals is strongly displaced as shown in Figure 2b.

The signals for the two methyl groups are easy to assign, since the neighboring single proton causes the signal for one of them to appear as a doublet and, conversely, the three protons of the methyl group cause the signal of the single proton to appear as a quadruplet. The quadruplet disappears in the corresponding deuteron-addition complex (cf. Fig. 2c), since the resonance frequency of the deuteron is located in a different region [26]. Finally, Figure 2d, which shows the PMR spectrum of 9,10-dihydro-9,10-dimethylanthracene, gives a reliable example of a $>CH-CH_3$ configuration. In this molecule the two methyl groups are equivalent, so that only a doublet appears for the $CH_3$ protons and a quadruplet for the CH proton. Similar results have been obtained for pentamethylbenzene, hexamethylbenzene, hexaethylbenzene, pyrene, and benzo[*c*]pyrene [25].

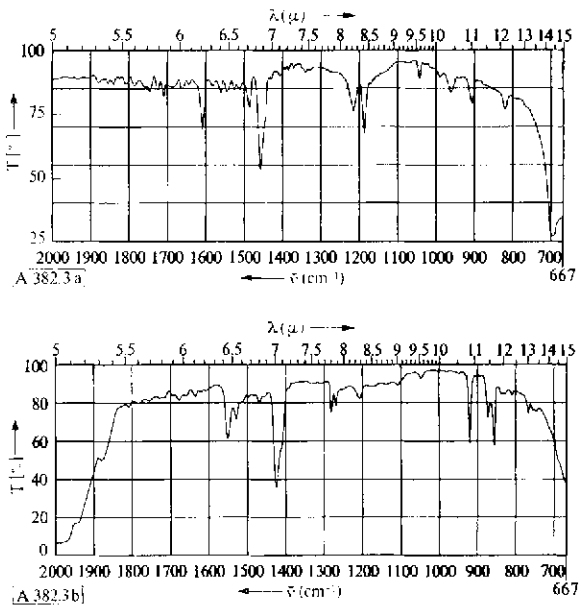
## 2. Infrared Spectra

Although infrared spectra are generally little affected by the medium, only few aromatic-proton complexes have been investigated by infrared spectroscopy, since the preparation of moisture-free samples and the development of a usable cell present great difficulties. We managed to overcome these difficulties by measuring the spectra of the solid complexes in high vacuum [27]. For this purpose, an evacuable cell for accomodating solids was employed; this cell could still be used at 60 °K, the temperature of solid nitrogen [28].

Figure 1 shows a schematic reproduction of the infrared spectra recorded for the ternary systems benzene/HCl/$AlCl_3$, benzene/HBr/$AlBr_3$, and benzene/HCl/$GaCl_3$ in the solid state at 77 °K [24] [*]. Compared with the infrared spectrum of crystalline benzene, numerous new bands appear, which can only be ascribed to C–C and C–H vibrations, since the Lewis acids used do not absorb in this region. Comparison of the spectrum with that of the complex perdeuterobenzene/DCl/$GaCl_3$ allows differentiation between the C–C and C–H vibrations. As can be seen from Figures 3a and 3b, the



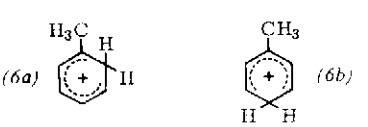


Fig. 3. Infrared spectrum of the solid proton-addition complex benzene/HCl/$GaCl_3$ (a) and the solid deuteron-addition complex perdeuterobenzene/DCl/$GaCl_3$ (b), at 77 °K.

position of some bands – those in the region from 1400 to 1600 $cm^{-1}$ – remain practically unchanged, while the bands of longer wavelength are bathochromically displaced [24].

Analysis of the infrared spectra shows that the new bands can be assigned to infrared-inactive (*i.e.* symmetry-forbidden) benzene vibrations. This means that the addition of the proton is associated with a lowering of the symmetry. Thus, the $D_{6h}$ symmetry of benzene is probably lowered to $C_{2v}$ symmetry in the complex.

With methylbenzenes [29], particularly marked changes occur on complex formation in the region between 670 and 900 $cm^{-1}$. According to *Bellamy* [30], the number and position of the bands in this region depend on the number of adjacent hydrogen atoms. The carbon atom to which the proton is added must be regarded as "substituted". Thus, two isomeric proton-addition complexes are conceivable for toluene, since its *ortho*- and *para*-positions have the same basicities.

[*] The proton-addition complex of benzene is only stable up to about 220 °K; this is probably why this complex had not previously been detected.

Table 2. Expected and observed γ-C–H vibrations of some proton-addition complexes of aromatic hydrocarbons.

| No. of neighboring "free" H atoms | 5 | 4 | 3 | 2 | 1 |
|---|---|---|---|---|---|
| | Regions of the C–H bands expected [cm$^{-1}$] | | | | |
| Complex | 730–770 (vs) 690–715 (s) | 735–770 (vs) | 750–810 (vs) 660–725 (m) | 800–860 (vs) 700–750 (m) | 860–900 (m) |
| Benzene·H$^+$ | 690 (vs) | | | | |
| Toluene·H$^+$ | | 742 (vs) | | 848 (vs) 709 (vs) | |
| *o*-Xylene·H$^+$ | | | 797 (m) 710 (s) | | |
| *m*-Xylene·H$^+$ | | | | 829 (s) 732 (s) | 875 (s) |
| *p*-Xylene·H$^+$ | | | | 857 (vs) 720 (s) | 873 (m) |
| Mesitylene·H$^+$ | | | | | 867 (m) |
| Hemimellito·H$^+$ | | | | 784 (vs) 729 (s) | |
| Pseudocumene·H$^+$ | | | | 824 (s) 734 (s) | 876 (m) 888 (m) |
| Durene·H$^+$ | | | | | 889 (m) |
| Hexamethylbenze·H$^+$ | – | – | | | – |

Symbols: m = medium strong; vs = very strong; s = strong

In the case of *(6a)*, characteristic bands for four, and in the case of *(6b)*, those for two neighboring hydrogen atoms should appear; toluene itself exhibits the bands for five neighboring H atoms. The proton-addition complex of toluene does in fact give bands indicating the existence of the two isomeric complexes *(6a)* and *(6b)* side by side.

A 382.4

Fig. 4. Structures of the proton-addition complexes of various methylbenzenes (from top left to bottom right: benzene, toluene, *m*-, *p*-, *o*-xylenes, mesitylene, hemellitol, pseudocumene, and durene).

As can be seen from Table 2, new bands appear in the regions of the γ-C–H vibrations for all the proton-addition complexes of methylbenzenes investigated so far. It is thus possible to establish the position of addition of the proton for each individual methylbenzene in a simple manner. The structures determind in this way, and also the isomeric complexes, can be seen from Figure 4. The positions of addition agree with the positions of the methylbenzenes that are most active for D/H exchange [31]. The changes appearing in the infrared spectrum of *p*-xylene (Fig. 5), on proton addition can be seen particularly clearly, since only one

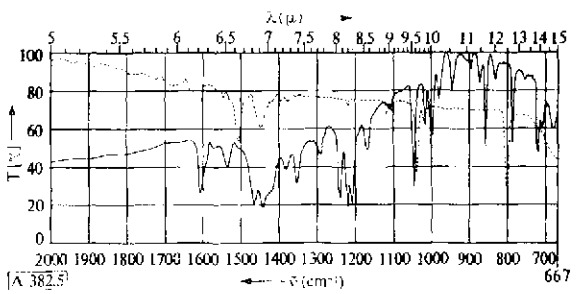

Fig. 5. Infrared spectrum of *p*-xylene (– – –) and its proton-addition complex (———) in the solid state at 77 °K. In the formation of the complex, tempering of the film of material with consequent displacement of the intensity background cannot be avoided.

proton-addition complex is produced. Comparison of the bands in the infrared spectrum of the proton-addition complex of *p*-xylene with the bands calculated for *p*-xylene [32,33] shows that the new bands correspond to the infrared-inactive vibrations of *p*-xylene [29]. Similar remarks apply to the proton-addition complexes of other methylbenzenes.

### 3. Ultraviolet Absorption Spectra

*Eley* and *King* [34] and *Reid* [35] were the first to investigate the ultraviolet spectra of some ternary (aromatic hydrocarbon/HX/$MX_3$) and binary (aromatic hydrocarbon/$MX_3$) systems. Since, however, their results ex-

[31] *E. L. Mackor, P. J. Smit,* and *J. H. van der Waals,* Trans. Faraday Soc. *53*, 1309 (1957).

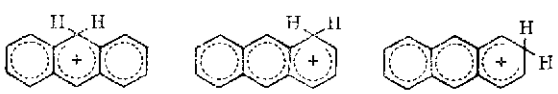
[33] *E. D. Schmid, J. Brandmüller,* and *J. Nonnenmacher,* Z. Elektrochem., Ber. Bunsenges. physik. Chem. *64*, 960 (1960).



[34] *D. D. Eley* and *P. J. King,* J. chem. Soc. (London) *1952*, 2577, 4972.

[35] *C. Reid,* J. Amer. chem. Soc. *76*, 3264 (1954).

hibited some contradictions and obscurities, *Luther* and *Pockels* [23] reinvestigated the spectra of the binary and ternary systems of benzene, toluene, and α- and β-methylnaphthalenes with $AlBr_3$, $AlCl_3$, HBr, and HCl. The results for the ternary systems were on the whole confirmed, but those for the binary systems were very different.

Over the last few years, *Hoijtink*, *Mackor*, *Dallinga* et al. studied the ultraviolet spectra of pure proton-addition complexes of aromatic hydrocarbons in hydrofluoric acid [36] and in trifluoroacetic acid/$H_2O$/$BF_3$ mixtures [37]. They also used ultraviolet spectroscopy to study the interaction in the binary systems aromatic hydrocarbon/Lewis acid in 1,2-dichloroethane as solvent [38]. Other investigations of the ultraviolet spectra of such binary systems [39–41] were carried out on thin films in high vacuum in the absence of solvent [42].

If a covalent C–H bond is formed during the addition of protons, the π-electron structure is profoundly changed. Thus, in the 9-anthracenium ion *(7a)* one π-electron pair of the aromatic hydrocarbon is claimed by the methylene group in the complex. *Mackor*, *Kruizinga*, and *Verrijn Stuart* [43,44] carried out quantum-mechanical calculations by the HMO and SCF methods [*] for this model, and found that structures *(7b)* and *(7c)* must also be taken into account.

*(7a)* *(7b)* *(7c)*

Comparison of the ultraviolet spectra calculated for the structures *(7a)–(7c)* with the measured spectrum of the anthracene adduct unambiguously indicates the *meso*-configuration *(7a)*, as was to be expected [36,43]. A long-wave band at about 25000 $cm^{-1}$ can be calculated for the benzene complex; *Luther* and *Pockels* [23] observed an intense band at 30000 $cm^{-1}$, *i.e.* greatly displaced towards the red as compared with the corresponding band in the benzene spectrum, and a shoulder at about 25000 $cm^{-1}$. A similar spectrum had previously been given by *Eley* and *King* [34]. When methyl substituents are present, the intense band is found at lower frequencies, but the appearance of the spectrum is unaltered (cf. Table 3).

Table 3. Position and intensity of the strongest band in the proton-addition complexes of benzene [23] and some of its methyl derivatives [38].

| Proton-addition complex | $\tilde{\nu}_{max}$ [$cm^{-1}$] | $\varepsilon_{max}$ |
|---|---|---|
| Benzene·$H^+$ | 30100 | |
| Mesitylene·$H^+$ | 28200 | 11000 |
| 1,2,3,5-Tetramethylbenzene·$H^+$ | 27400 | 7500 |
| Pentamethylbenzene·$H^+$ | 26550 | 9800 |

The ultraviolet spectrum of the binary system benzene/$AlCl_3$ measured in the solid state at low temperatures by *Perkampus* and *Kranz* [40,41] is also in agreement with that given by *Luther* and *Pockels* [23]. Since infrared measurements [24] have shown that, with intensively dried benzene, interaction can only be observed when hydrogen halide is present in addition to the Lewis acid, a proton-addition complex is also probably present in this case. Normally, the protons must arise from traces of water that may be present in the benzene or adsorbed on the cell walls.

As we have recently shown, interactions without participation of a proton can also be detected by infrared spectroscopy in binary systems aromatic hydrocarbon/Lewis acid. These interactions depend markedly on the donor strength of the aromatic hydrocarbon and on the acceptor strength of the Lewis acid [45]. However, benzene undergoes no interaction with $AlCl_3$. For this reason, the ultraviolet spectrum measured in the solid state must be ascribed to a ternary system, *i.e.* to a proton-addition complex.

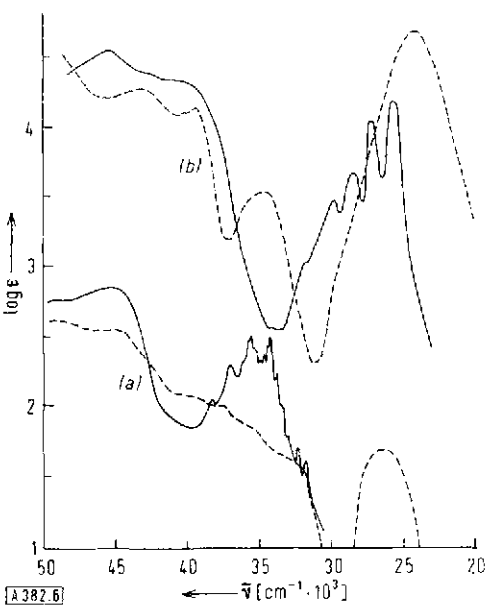


Fig. 6. Ultraviolet spectra of solid naphthalene (a), anthracene (b), and their solid $AlCl_3$ complexes. The extinction coefficients apply only to (b); for (a) only the extinctions were determined.
Pure hydrocarbon: (——); complex: ( – – ).

Figure 6 gives the absorption spectra for solid anthracene/$AlCl_3$ and naphthalene/$AlCl_3$ complexes [39]. As regards the positions of the bands, the two spectra agree surprisingly with those given by *Mackor* et al.

[36,43] for the proton-addition complexes. In the case of the naphthalene/$AlCl_3$ complex, moisture may have been present. However, for the anthracene/$BF_3$ complex in 1,2-dichloroethane as solvent, *Hoijtink*, *Mackor*, et al. [38] found a spectrum similar to that given in Figure 6 and to that of the proton-addition complex.

These authors exclude the participation of protons and assume a σ-complex with a structure similar to that of the proton-addition complex. According to *Mackor*, *Hofstra*, and *van der Waals* [46], the basicity [*] increases from naphthalene to anthracene by about eight powers of ten, so that a σ-complex between anthracene and a Lewis acid is quite conceivable. In tetracene and the still higher homologues of naphthalene, the basicity increases further, in proportion to the decrease in ionization energy [47]. It is therefore understandable that, under the same conditions as for anthracene, a σ-complex is also assumed for tetracene/$BF_3$ [38]. According to our own infrared measurements, σ-complexes can be detected in the products obtained from methylnaphthalenes, but not in that from naphthalene itself [48]; this is in harmony with the increased basicity of the methylnaphthalenes due to their methyl groups [19].

Table 4 gives the positions of the most intense bands of some proton-addition complexes as determined experimentally and calculated by *Mackor* et al. [36,37,43]. Occasionally, *e.g.* with benzo[*a*]pyrene and perylene, two carbonium ions are to be expected with approximately equal probability, so that the observed spectrum probably results from superposition of the spectra of these two [36]. The agreement of the experimental and theoretical values in Table 4 must be regarded as very good. This again shows that the model upon which the calculations were based, *viz.* the cation arising from an aromatic hydrocarbon by removal of an electron, has a relatively high probability. The light absorption of proton-addition complexes is therefore determined by the π-electron state of the positive aromatic ions.

The counterion, *i.e.* the anion, has only a small influence, comparable in its order of magnitude with solvent effects. Thus, according to *Luther* and *Pockels* [23], the ternary complexes benzene/HCl/$Al_2Cl_6$ and benzene/HBr/$Al_2Br_6$ and the complexes toluene/HCl/$Al_2Cl_6$ and toluene/HBr/$Al_2Br_6$ differ in the position of the maxima by only $\Delta\tilde{\nu} = 600$ cm$^{-1}$. *Kranz* [49] found a similar small effect for the systems anthracene/$AlCl_3$ and anthracene/$AlBr_3$ in the solid state, $\Delta\tilde{\nu}$ being only 300 cm$^{-1}$.

If we assume that the formulation of the binary complexes anthracene/$BF_3$ and tetracene/$BF_3$ in 1,2-dichloroethane as σ-complexes is correct [38], then it should be impossible to distinguish, by means of ultraviolet spectra alone, between a proton-addition complex and a σ-complex with a Lewis acid. Light absorption is therefore determined only by the π-electron system of the aromatic cation.

The mode of stabilization of the aromatic carbonium ions can, however, be deduced by comparing the ultraviolet absorption spectra of the free aromatic hydrocarbons with those of the proton-addition complexes. At least two effects must be taken into account [41]: the carbonium ion can be stabilized either by charge resonance or by aromatization of the ring systems, which are independent in the complex. In view of the almost equal polarities of the two states [50], the first effect implies convergence of the ground and excited states, *i.e.* the complex has a smaller energy of excitation than the free aromatic hydrocarbon. In contrast, the second effect should increase the difference between ground and excited states, since aromatization of the independent ring systems affects the ground and excited states differently, so that the complex has a greater excitation energy than the free hydrocarbon.

[50] *Th. Förster*, Z. Elektrochem., Ber. Bunsenges. physikal. Chem. *45*, 548 (1939).

Since with increasing linear annulation, as in the acenes, the second effect acquires significance [51], the opposing trends of the two effects become clearly expressed in the acenium ion series as the number of rings increases.

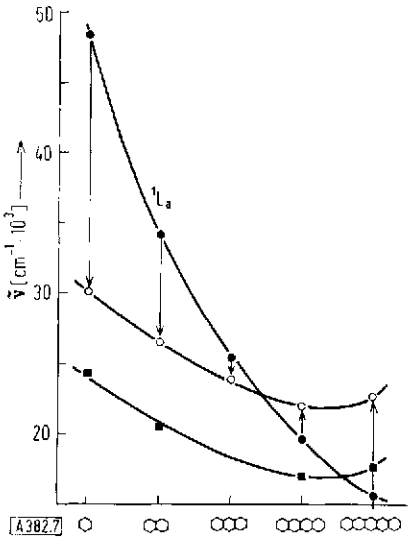

Fig. 7. Position of the bands (o) and pre-bands (■) of the proton-addition complexes and the $^1L_a$ bands (●) of acenes as a function of the number of rings. The spectra were measured at ca. 100 °K in the solid state.

In Figure 7, the maxima of the $^1L_a$ bands as well as the bands and pre-bands of the complexes are plotted for acenes as functions of the number of ring. The bathochromic shift of the absorption bands of the complexes relative to the $^1L_a$ bands of the free acenes decreases from benzene to anthracene; from tetracene onwards the main bands of the complexes have a hypsochromic shift relative to the $^1L_a$ bands. It is interesting to note that there must be some relationship between the main and pre-bands of the complexes, since the distances between the two bands remain practically constant.

The difference between the proton-addition complexes of anthracene and pentacene is the following: with anthracene, a resonance-stabilized carbonium ion is still present, whereas with pentacene, after addition of the proton, both naphthalene partial systems contribute substantially to the stabilization of the complex. In the first case, the positive charge is distributed over the whole molecule, whereas in the second it must be regarded as being localized in the center "dearomatized" ring. While the tendency to form separate aromatic ring systems follows from the reactivity of the acenes [51], and also from theory [52], charge resonance can be considered to occur in the complexes of various benz- and dibenzanthracenes (judging from their ultraviolet spectra) [39], and has been detected spectroscopically in the system 2-aminoanthracene/$AlCl_3$ [53]. In the solid state, 2-aminoanthracene and $AlCl_3$ form a complex the ultraviolet spectrum of which coincides with that of the anthracene/$AlCl_3$ complex. However, the ultraviolet spectrum of the 1-aminoanthracene/$AlCl_3$ complex is the same as that of free anthracene, *i.e.* here the $AlCl_3$ molecule adds onto the amino group. Thus, because of its auxochromic character, an amino group in the 2-position promotes charge resonance of the anthracenium ion.

It must be noted, however, that owing to great experimental difficulties, it is still impossible to provide a comprehensive description of the spectroscopic and energetic situation – *e.g.* in the form of a term scheme – for proton-addition complexes and for σ-complexes not involving a proton.

In summary, it has at least been possible to detect proton-addition complexes by means of ultraviolet spectroscopy. Since σ-complexes not involving protons give the same ultraviolet spectra, ultraviolet spectroscopic detection of these complexes is not definite. Other methods, *e.g.* infrared spectroscopy, are therefore required for this purpose [45,48].

## IV. Summary

From kinetic investigations it must be assumed that species of the type of the proton-addition complexes occur as intermediates in electrophilic substitution reactions of the benzene nucleus [54]. However, it is only when the structures of these intermediate cationic complexes become known that it will be possible to say something definite about the reaction mechanism. The present paper was primarily concerned with spectroscopic methods, since they yield information on the structure of proton addition complexes either directly or in combination with theoretical considerations. As has been shown, the results of PMR and ultraviolet spectroscopy complement one another without contradictions, so that, for example, the structures of the proton-addition complexes of the methylbenzenes given in Figure 4 can be taken as established.

*Our own investigations discussed in this review were supported by the Deutsche Forschungsgemeinschaft, the Verband der Chemischen Industrie, and the Max-Buchner-Forschungsstiftung, to whom we here express our thanks.*

# Gradient and Low-Temperature Thin-Layer Chromatography

BY PROF. DR. E. STAHL [*]

INSTITUT FÜR PHARMAKOGNOSIE DER UNIVERSITÄT DES SAARLANDES, SAARBRÜCKEN (GERMANY)

*The preparation and the use of gradient layers for thin-layer chromatography are described. On a gradient layer there are three flow surfaces, all differing in their separation behavior. It is therefore possible to determine, for example, the basicity and/or activity which gives the optimum separation for a mixture of substances. Gradient thin-layer chromatography was also carried out at low temperatures, after the effect of temperature on the separation of various mixtures had been studied.*

Thin-layer chromatography [1–6] on silica gel was first used for the separation of lipophilic substances. The method was next extended to hydrophilic substances, and new fine-grained inorganic and organic adsorbents were used. It was then found that the separation of amino acids was better, more sensitive, and more rapid, when it was carried out on fine-grained layers than on the fibrous paper [7].

Today a large number of adsorbents is available for thin-layer chromatography [8]. This is important, since a successful separation depends on the correct choice of both stationary and mobile phases. Whereas the stationary phase is more or less given in paper chromatography, the same is true for the mobile phase in gas chromatography. It is only in column and thin-layer chromatography that both phases can be widely varied.

We have attempted to find other methods of improving the efficiency of separation, and these attempts will be reported here, with the main emphasis on equipment.

## Influence of Temperature on the Separation

Temperature differences between 4 and 20 °C appear to have no appreciable influence on the developing time and the $R_f$ values [9] in thin-layer chromatography. However, according to *Malins* and *Mangold* [10], "low-temperature chromatography" (4–6 °C) on siliconized layers of silica gel G often gives a better separation of certain fatty acids. It still remained to be shown whether a change in temperature could lead to a general improvement of the separation in thin-layer chromatography.

We were interested in "low-temperature" thin-layer chromatography for the following reasons:

1. the possibility of using low-boiling solvents and liquefied gases as developing solvents;
2. thin-layer chromatography of volatile compounds which, under normal conditions, either completely or partly evaporate out of the layer;
3. "freezing-in" of excited molecular states during chromatography.

In order to carry out chromatography at constant temperature over a wider range (+50 to −50 °C), the conventional Desaga trough chamber was enclosed in a thermostatically controlled jacketing vessel (Fig. 1).

However, not only the chamber but also the plate supporting the layer should be at the desired temperature. It must therefore be suspended in the chamber in

Fig. 1. Thermostatically controlled "Kryobox" chamber for low-temperature thin-layer chromatography (Photograph: Desaga).

such a way that it does not dip into the solvent until it has reached the chosen temperature. At lower temperatures, this often requires 30 to 45 minutes. A striking feature of this equilibration is that it reduces the developing time by half without any noticeable change in the $R_f$ values. For example, the developing time for a 10 cm separation distance is 21 min if the plate is dipped into the solvent immediately, and only 9 min after temperature equilibration for 30 minutes. This may be due to the fact that the solvent vapor coats the particles of the adsorbing agent. Such a coated layer would then present only a small "frictional drag" to the solvent ascending in the capillaries.

It was found that ®Frigens can be used as developing solvents at lower temperatures. With Frigen 21 (monofluorodichloromethane, b.p. 8.9 °C) at −10 °C mixtures of geranyl acetate, asarone, carotol, and hydroxycaryophyllene could be nicely separated, which is otherwise difficult [11]. With other solvents the separation was less effective in this temperature range, and there was no separation at room temperature. According to *Hückel* et al. [12,13], low-temperature thin-layer chromatography is also suitable for the separation of terpenes. These authors separated terpene mixtures on alumina columns at −40 to −78 °C, using dimethyl ether (b.p. −23.6 °C) and propene (b.p. −47.0 °C) [*].

We therefore investigated the separation of mixtures of this type on layers of silica gel H using a 1:1 pentane-hexane mixture. It was found that the $R_f$ values decreased with falling temperatures (Fig. 2, left).

The readily volatile α-pinene apparently no longer evaporates off at lower temperatures and can be detected after separation. When more highly polar solvents such as methylene chloride and/or chloroform are used, the temperature effect is generally less pronounced (Fig. 2, right). Carotol constitutes an exception in that a clear separation from geranyl acetate is obtained only at low temperatures.

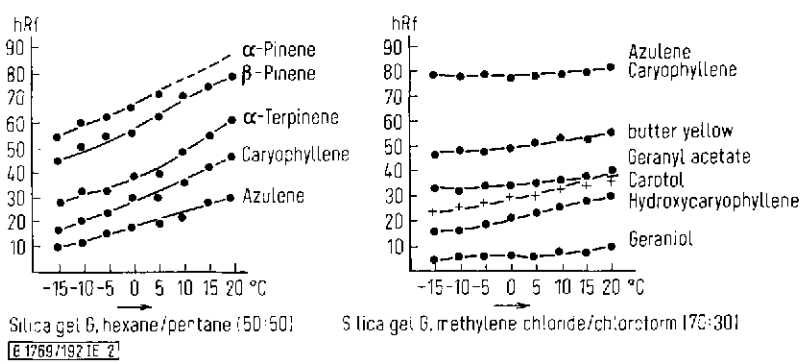

Fig. 2. Influence of temperature on the $R_f$ values of various substances. Note the separation of the geranyl acetate/carotol mixture.

[*] After completion of this manuscript, a paper was kindly sent to us by *C. Mathis* (Ph. D. Thesis, Strasbourg 1963), describing the separation of terpene hydrocarbons on silica gel/silver nitrate layers and on layers of silica gel G at −15 °C.

Low-temperature thin-layer chromatography is of great value for the separation of mixtures of sensitive natural products, *e.g.* carotenes and carotenoids; decomposition can be largely suppressed in such cases [14].

## Devices for the Production of a Gradient Layer

As a model, we first solved the problem of mixing a uniformly colored silica gel H suspension with one of another color, or an uncolored suspension, and then depositing the mixture in such a way that the layer shows a continuous gradation of color intensity.

### a) Division of Dissimilar Coating Materials (Fixing the Gradient)

A simple solution to the problem seemed to be the use of a rectangular trough divided diagonally into two compartments (Fig. 3 top). The colored suspension of the adsorbent could then be placed in one compartment, and the same volume of the uncolored suspension in the other. Corresponding to its function, we describe this simple device as a "divider box".

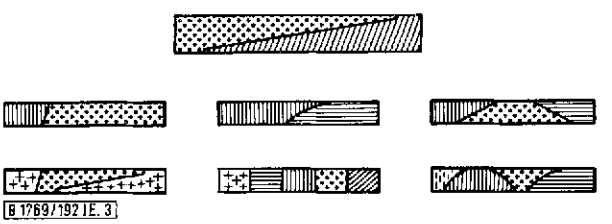

Fig. 3. Various forms of the divider box (viewed from above). The diagonal divider (top center) was preferred for the preparation of gradient layers.

It was found advantageous to make the partition removable, and to give it a certain shape at the ends. Any desired gradients can be achieved by different, non-diagonal arrangements of the partition, or by the use of several partitions (Fig. 3, lower part).

The next problem was to mix the suspensions present in the divider box in such a way, that the mixing effect occurred roughly transversely to the longitudinal axis of the divider and that the gradient was maintained. The simplest method would have been to remove the partition and carry out the mixing process in the divider box itself. However, the corners of the trough interfered with the mixing process, and a separate

[14] *E. Stahl*, Laboratory Practice *13*, 496 (1964).

cylindrical mixing vessel was therefore used. This raised the necessity of opening the base of the divider box in such a way that the two suspensions fall into the mixing vessel without mixing.

b) Mixing of the Coating Materials

Once again, there are a number of possibilities. The necessity of avoiding longitudinal mixing led us to divide the mixing vessel into numerous small compartments (Fig. 4). The disc-shaped partitions between

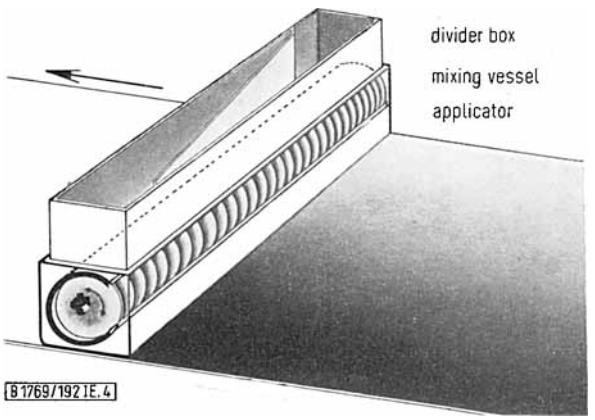

Fig. 4. Simplified semi-diagrammatic representation of the GM applicator during deposition of a gradient layer.

the compartments were fitted to a rotating shaft, which was turned by a hand-operated crank. The mixing effect could be intensified by making the mixer shaft execute a slight lifting motion with each rotation.

Other modes of mixing, *e.g.* by vibration, or (in the absence of partitions) by a kitchen twirl, an ointment mill, or rotating brushes, did not give the desired results.

c) Special Devices for Thin-Layer Chromatography

It was now necessary to adapt the divider box and the mixing vessel to the applicator which we had previously developed, in such a way, that the three processes (division, mixing, and application) could be carried out in one piece of equipment. For economic reasons, we looked for a solution which would make it possible to convert the standard applicator into the GM applicator (G = gradient, M = mixer) (Fig. 5) in a simple manner.

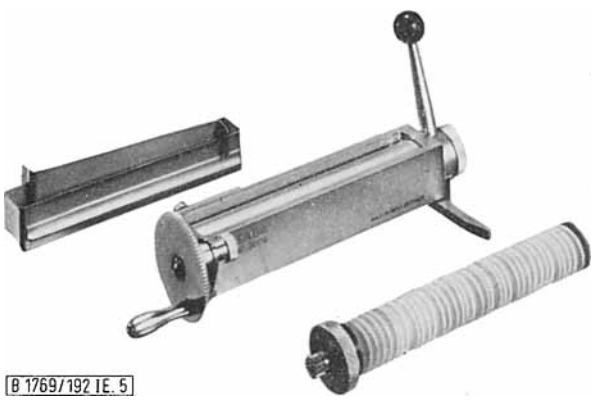

Fig. 5. Individual parts of the GM applicator.
Left: the attachable diagonal divider box; center: the actual applicator with cogwheel drive fitted; right: mixing shaft with thirty partition discs. (Photograph: Desaga).

With this in mind, the mixing shaft was located in the sleeve of a normal applicator for thin-layer chromatography, provided with a slit. The divider box can then be attached to this combined "mixer-applicator" (Fig. 6). The bottom of the divider box in this case is formed

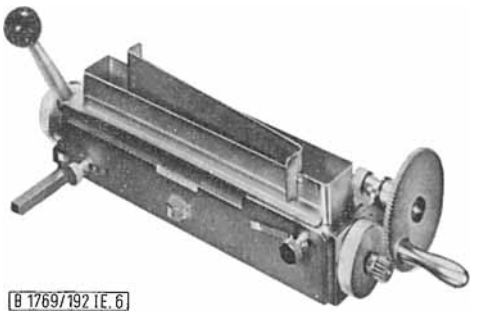

Fig. 6. Front view of the assembled GM applicator with layer-thickness adjustment. (Photograph: Desaga).

by the rotating sleeve of the applicator. The diagonal partition must be suitably mounted in the divider box. To fit the divider box, it was only necessary to enlarge the feed slot of the applicator block and the sleeve. The problem of admitting air during the coating process was solved by setting the sleeve slot correspondingly (Fig. 8 C).

In preparing the gradient layers (see operating instructions) it is necessary to observe the following points:

d) Adsorbents for the Gradient Layer and Testing the Layer

The particle size distributions of the adsorbents must correspond to the normal requirements for thin layer chromatography, and should not differ appreciably between the adsorbents mixed. Consistency of the coating material is of fundamental importance in the formation of the gradient layer. The method fails if the materials are too viscous or even pasty, while difficulties are encountered in sealing the equipment in the case of excessively thin or watery suspensions. The most suitable proportions for the mixture are easily determined in preliminary experiments.

In the case of colored layers it can be seen if the transition is continuous. For observing details we used the "Chromoscan" [*] automatically recording double-beam reflection densitometer. Fig. 7 shows that a practically stepless gradient was in fact achieved. However, colored adsorbents are not normally used in thin-layer chromatography. Since it may nevertheless be necessary to check the gradient, the following method was developed: An inorganic fluorescent tracer is added to one of the two adsorbents, and the continuity of the gradient is checked under an ultraviolet lamp after the layer has dried. An example is given in the following Section. If there is a pH gradient, the success of the preparation can be determined by spraying a strip with universal indicator.

[*] We should like to thank the manufacturers, Messrs. Joyce, Loebl and Company, Ltd., Gateshead-on-Tyne (England), and the distributors, Messrs. Kurt Hillerkus, Krefeld (Germany), for loan of the apparatus.

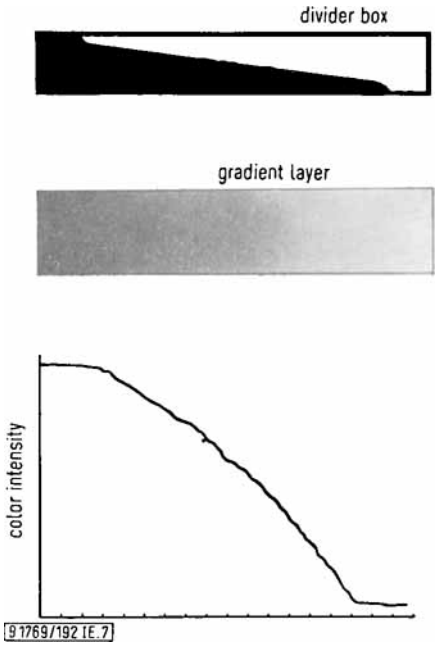

Fig. 7. Photometric test of a color-gradient layer (center), prepared with the GM applicator (diagonal divider box above). The densitometer curve (below) indicates a continuous change in the color intensity.

## Procedure

Numerous experiments have led to the following procedure for the use of the GM applicator [**].

### I. *Preparation of the coating material for five plates 20×20 cm²*

1a) Kieselguhr G ("Merck") for thin-layer chromatography (20 g) is shaken in a 100 ml wide-neck Erlenmeyer flask with 45 ml of distilled water, to form a uniform suspension.

1b) Silica gel $HF_{254}$ (18 g) is mixed with 45 ml of water in a second flask.

2. Portions of silica gel G (20 g each) are shaken with 45 ml of (a) 0.1 N potassium hydroxide solution and (b) 0.1 N orthophosphoric acid.

### II. *Preparation of the equipment*

The template of the basic Desaga apparatus must be perfectly horizontal since any tilting leads to undesirable longitudinal mixing in the gradient layer. The glass plates are then laid down in the usual manner and the GM applicator is placed on the 5 cm starting plate.

Assembling the GM applicator: (a) The mixing shaft is introduced into the rotating sleeve of the applicator and the threaded cover is screwed on. (b) The cogwheel crank drive is attached to the applicator by two screws. The drive wheel can be easily withdrawn and set at the required distance by means of a clamping bolt. The mixing shaft must turn freely in both directions. (c) The lever of the sleeve is turned so that the feed orifice is closed (see Fig. 8A). (d) The divider box housing with the diagonal partition is fitted and tested for leaks at the seating.

Filling the divider box: (a) The suspensions (see 1a and 1b) are placed one in each of the two compartments of the divider box. Care must be taken that the compartments are filled to the same level all over, and that the levels in the two compartments are equal. (b) The housing of the divider box is held firmly in position and the diagonal partition is carefully removed. (c) Still holding the housing firmly and pressing the applicator down on the starting plate, the sleeve is now brought into the filling position by means of the long tipping lever (Fig. 8B).

[**] Manufacturer: C. Desaga, Heidelberg (Germany).

### III. *Mixing process*

The crankshaft is rotated 30 to 40 times (ca. 30 seconds per turn) in both directions. The divider housing can now be removed. The applicator is firmly pressed down with the left hand, and the sleeve is turned to the original position (Fig. 8A). The outlet slot must, however, first be closed by bringing the adjustable front plate to the "O" position. The mixing is then repeated as described above by turning the crank.

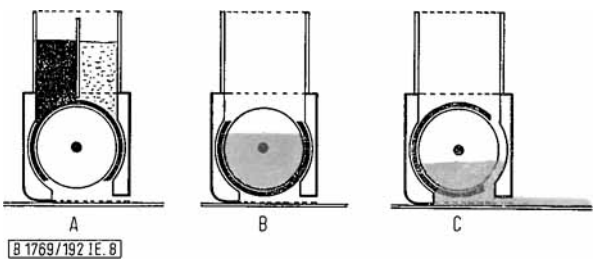

Fig. 8. Positions of the rotating sleeve of the GM applicator (cross-section) during the preparation of a gradient layer.

A. Two different adsorbents are placed in the two compartments of the divider box.

B. The partition has been removed and the sleeve is rotated by 180. The suspensions are mixed inside the sleeve.

C. During application the position of the sleeve is such that the compartments are accessible to air.

Since there must be no reduction in pressure in the compartment during the application process, the sleeve is placed in position "C" (Fig. 8C) by means of the tipping lever, which should then point upwards. This application position is easy to find owing to a built-in detent ball. Special care must be taken during tipping to ensure that the applicator is not raised, even partially, from the glass plate. The two setscrews are then loosened and the front plate is adjusted to the "open" position. The thickness of the layer should be adjusted on the scale to 0.35 mm.

### IV. *Coating the plates*

The application and drying of the gradient layers and chromatography on these layers are carried out in the usual manner (standard method [5]).

### V. *Control and presentation of results*

Before using the gradient layer, the quality of the gradient should be checked. In example 1.1a, a uniform decrease in the intensity of the green fluorescence must be observed, when the layer is examined in ultraviolet light (254 mμ). In the case of layers with a pH gradient, most of the chromatography surface is masked, and a narrow strip of the layer (above the later solvent front), which runs perpendicular to the direction of application, is sprayed with an indicator (pH 0 to 5 or pH 4 to 10) possibly diluted with acetone.

In the presentation of the results on gradient layers, all details, including the form of the divider box, the nature of the adsorbent suspension, and the method by which the quality of the layer was checked, must be given in order to ensure reproducibility. In diagrams the gradient should be indicated (see, for example, Figs. 10–12).

## Types and Applications of Gradient Layers

Using the procedure described above, it is possible to achieve a continuous transition between two sorption properties. It is easy to see, for example, the advantages of a gradient layer in which the sorption properties pass from active to inactive. In Fig. 9 the active part of the layer is represented by dark shading and the inactive part is light. It can be seen that, in contrast to the conventional uniform layers, a gradient layer offers three flow directions with different layer properties (Fig. 9A, B, C).

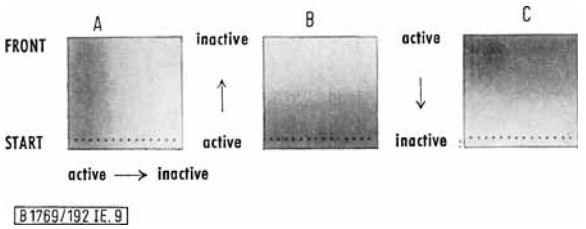

Fig. 9. The three possible applications of a gradient layer (ascending development). Shading and arrows indicate the gradient.

In case "A", which in our opinion will attract particular attention, we have numerous "open separating columns", all with slightly different properties, lying alongside one another. In the example chosen, the most active "columns" lie on the left, while the inactive ones are on the right. The different separation effects on a layer of this type can be demonstrated if a mixture of dyes is applied onto numerous starting points alongside one another (Fig. 10A). This also provides a rapid method of determining the ratio of adsorbents at which the best separation is achieved. We have used combinations of the following adsorbents:

| | |
|---|---|
| Silica gel | Kieselguhr |
| Alumina, basic | Glass powder |
| Alumina, neutral | Cellulose |
| Alumina, acidic | Cellulose derivatives |
| Magnesium silicate | Perlon |

With arrangement "A", it is also possible to determine rapidly whether and at what concentration a certain "impregnation" gives an improved separation. The "impregnant" is added to the water used in the preparation of the coating material. The following additives may be included: Acids and acid salts, bases and basic salts, buffer mixtures, silver nitrate and other heavy metal salts, polyethylene glycol, glycerol, and sugar. Solids can also be used in very finely powdered form.

The actual gradient of the layer is employed in chromatography using arrangements "B" and "C" (see Fig. 9). In this case the sorption property of the layer changes from the start to the front.

In classical column chromatography, use has already been made of columns arranged in series, packed with adsorbents of different strengths [15]. *Hesse* et al. [16] showed that active alumina columns can be made into a kind of gradient column (inactive-active) by sucking through a certain quantity of water vapor.

[15] *L. Gattermann*: Die Praxis des organischen Chemikers. 37th Edition, Walter de Gruyter, Berlin 1956.

Figure 10B shows the result of separating the dye mixture, already used for the chromatogram in Fig. 10A, now using arrangement "B" (flow direction from active to inactive). This is compared to "C", *i.e.* flow direction from inactive to active (Fig. 10C). Mixtures of substances with acidic or basic properties can be separated on pH-gradient layers.

## "Three-Dimensional" Thin-Layer Chromatography

The two-dimensional technique of chromatography consists in separating a mixture on a chromatogram and rechromatographing the zones in a direction perpendicular to the original one using another developing solvent. When the two-dimensional method is used on a gradient layer, the gradient always has an additional influence in one of the two flow directions, and so has the effect of another "dimension"; in such cases we can speak of a "three-dimensional" chromatogram.

However, since this expression does not coincide with the usual picture of a third dimension, and since two-dimensional chromatography is not carried out in every case, it is better to speak of chromatography on a gradient layer. It will therefore be necessary in future to differentiate between chromatography with "gradient elution", as described by *Wieland* and *Determann* [17] and "thin-layer chromatography on a gradient layer". In some cases it is even possible to combine the two methods. With regard to the "gradient elution" technique, which is undoubtedly gaining importance in thin-layer chromatography, the reader is referred to the "gradient" mixed batteries developed by *Peterson* and *Sober* [18].

## Further Uses and Outlook

Using the principle described above, it is also possible to set up chromatography columns in such a way, that the packing exhibits a gradient. Details of this arrangement and its possible uses will be reported later.

The difficulties in the preparation of gradient layers, as regards both apparatus and method, consumed more time than had been anticipated. It has therefore not yet been possible to study systematically a greater number of applications. The following examples have resulted from experiments which are still in progress.

Using gradient layers with a transition from basic to acidic alumina ("Woelm", thin-layer chromatography grade), it has been found that an optimum separation of alkaloid and amine mixtures could be achieved only at very definite mixing ratios of the two adsorbents. For the silver nitrate silica gel H layers which are frequently used we were able to determine the optimum $AgNO_3$ content by gradient-layer chromatography. A new method for the chromatographic characterization of basic, amphoteric, and acidic substances has been found in the use of acidic → basic silica gel G gradient layers.

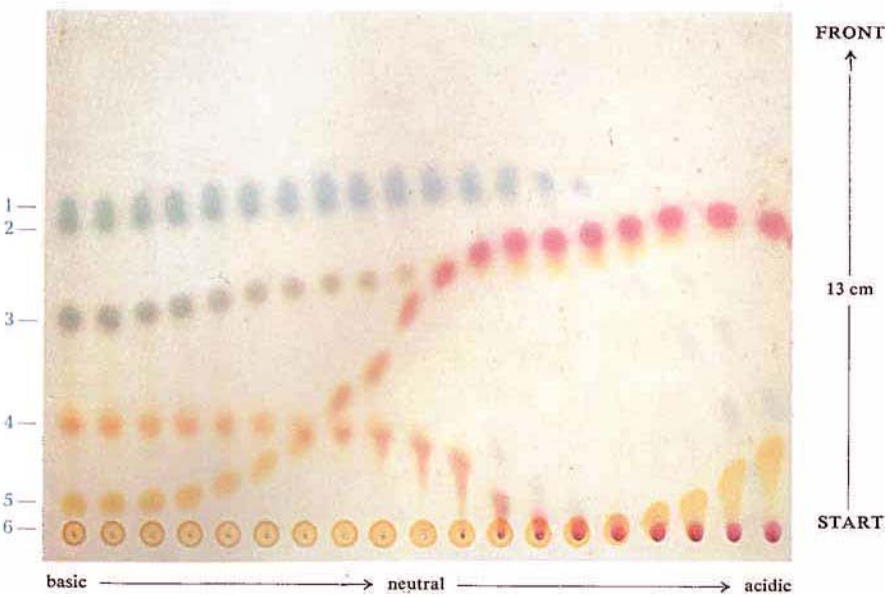

Fig. 11

Chromatogram C: Clean separation with the possibility of placing more strongly polar dyes in the lower part of the chromatogram.

The dyes are noted by figures:

1. Guaiazulene
2. Azobenzene
3. Sudan green
4. Ceres red
5. Ceres blue
6. Sudan red G
7. Indophenol
8. Ceres black.

Fig. 11. Separation of indicator dyes on a pH gradient layer (diagonal divider box) on silica gel G+ 0.1 N $H_3PO_4$ → silica gel G + 0.1 N KOH. Solvent: chloroform/acetone (50:50). Saturated chamber.

Note the form of the spots and the typical curves given by the individual indicator dyes on transition from basic to acidic.

1. Guaiazulene
2. Indophenol
3. α-Naphtholphthalein
4. Neutral red
5. Methyl red
6. Thymol blue.

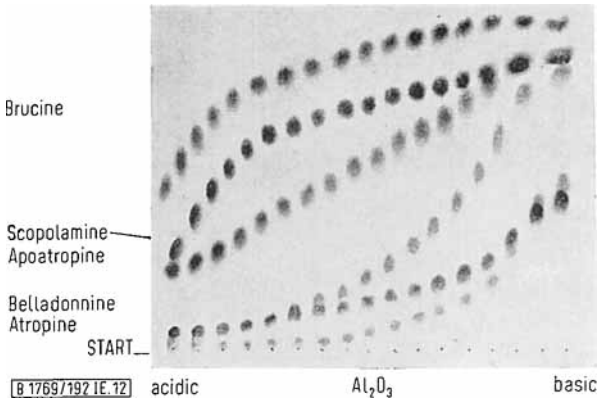

Fig. 12. Separation of a mixture of alkaloids on a gradient layer (diagonal divider box). Adsorbents: left: alumina, acidic, for thin-layer chromatography (Woelm) + 10 % gypsum; right: alumina, basic, for thin-layer chromatography (Woelm) + 10 % gypsum. Solvent: chloroform/methanol (95:5), chamber saturation. Flow distance: 15 cm. Below the spots for atropine a minor alkaloid (?) is seen.

As shown in Figs. 11 and 12, substance-specific curves, reminiscent of neutralization curves, are obtained.

The use of a gradient in the flow direction (Figs. 9, 10B, and C) offers considerable advantages, particularly in the separation of substances of different polarities. Whereas on a uniform layer of silica gel a carotene mixture from *Calendula* flowers could only be separated into seven zones, sixteen substances were recognized after chromatography on a gradient layer of kieselguhr-silica gel.

*I am grateful to J. Fuchs for his conscientious and able assistance with the experiments, to M. Kleinert of Messrs. Desaga for the careful production of equipment required, and to the Fonds der Chemischen Industrie for their support.*

# Old and New Processes of Multiplicative Distribution (Liquid-Liquid Extraction) [1]

## A Comparison of the Methods of Material Flow and the Mode of Action

BY PROF. DR. WERNER FISCHER
WITH THE COLLABORATION OF DR. K. BIESENBERGER, DR. J. HEPPNER, AND DR. U. NEITZEL

INSTITUT FÜR ANORGANISCHE CHEMIE
DER TECHNISCHEN HOCHSCHULE HANNOVER (GERMANY)

*A new process is described for the separation of mixtures of materials by multiplicative distribution, which is characterized by repeated addition of the mixture throughout the whole process and by material exchange during the countercurrent flow of finite amounts of one, and infinitesimally small amounts of the other phase. The intrinsic features of the mode of action of the old distribution processes and the new one are developed, and their relationship to one another is discussed. In this connection, an attempt is made to clarify the confused situation in the terminology of this field by introducing clearer definitions. Reflux and "displacement distribution", another new distribution process, are treated briefly in two final sections.*

### 1. Introduction

*Multiplicative distribution* consists of the separation of dissolved materials by distribution between two co-existing liquid phases which flow in countercurrent to one another, and which are thereby repeatedly brought into contact with one another for the exchange of materials. In the ideal case equilibrium is set up. For a complete description of such a process, we must know:

1. the substances to be separated and the solvents;

2. the manner in which the mixture to be separated and the solvents are introduced into the process, passed from one material-exchange to the next, and finally removed; the total of these operations will be called the *method or scheme of material flow*;

3. the amounts or volumes of substance for each of these individual steps; and

4. the apparatus used and other technical details.

In the present paper, we shall concentrate on item 2.

In any distribution process, definite quantities and concentrations of the dissolved materials are set up in all parts of the apparatus. This pattern of quantities or concentrations coming into being at a given moment of time will be called the quantity-based or concentration characteristic, or, for the sake of brevity, the *characteristic*.

### 2. Classification of the Methods of Material Flow

We classify the various methods of material flow somewhat differently from the proposals of *Hecker* and *Allemann* [2] and *Jübermann* [3]. We use as the *main*

*classification characteristics* the method of adding the mixture to be separated and the method by which the two liquid phases are brought to the material-exchange.

### a) Method of Adding the Mixture

The mixture to be separated (subsequently called the "mixture" for short) is *added* either only *once* at the beginning of the process (discontinuous distributions) or *continuously* throughout the whole process (continuous distributions).

With a *single* addition, the mixture is separated in the course of the multistage multiplicative distribution *into numerous fractions*, all of which differ from one another in their composition. Under the *continuous* addition regime, on the other hand, the distribution system attains a stationary condition after a certain time. Here the mixture can be split only *into two fractions* differing in composition.

In some types of processes with repeated addition of the mixture, *e.g.* in which the mixture is added batchwise after equal intervals but one or both solvents is fed continuously, only quasi-stationary conditions are attained. The state of the system is subjected to periodic variations, but it repeats exactly at corresponding times of different periods. The periods are also known as *cycles*.

### b) Method of Bringing the Phases to Material Exchange

*Either finite or infinitesimal amounts of the two phases arrive at the individual steps of the material exchange process* or the process of establishing equilibrium. In this, no account is taken of back-mixing, *i.e.* of transient retrograde motion of parts of one or both phases, or of the formation of finite working volumes ("hold up", see below) in the individual distributing elements.

In this classification, there are obviously three possibilities:

1. *Both phases* are fed in *finite amounts* and brought into equilibrium, and are subsequently separated again. This applies, for example, to work with separating funnels or decanting vessels.

2. *Infinitesimal amounts of both phases* are caused to undergo material exchange and are then separated. This procedure is approached, for example, in a column when both phases are fed in countercurrent to one another with good intermixing. The same situation exists, however, when one of the two phases – subdivided almost infinitesimally – is fixed and only the other phase moves, as is the case in partition chromatography. This shows that our classification principle is *not identical* with that for the *transport* of the phases.

3. At any given moment an *infinitesimal amount of one phase* is brought into equilibrium with a *finite amount of the second phase*, is separated, and is then brought into contact with the next finite portion of the second phase. This case can be realized, *e.g.* with mixer-settlers, if one phase undergoes no movement but is present in the individual mixer-settlers in finite amounts and remains there, while the other phase is continuously passed in sequence through all the mixer-settlers, without appreciable amounts of this phase being retained in the individual units.

### c) The Various Schemes of Material Flow

By combining the two classification characteristics, therefore, *six different schemes of material flow* are obtained (Table 1). For the processes arranged in columns 1 and 2 the names proposed by *Hecker* and *Allemann* [2] are used.

Table 1. Classification of the methods of material flow in multiplicative distribution processes.

| Addition of the mixture | Arriving for material exchange or establishment of equilibrium | | |
|---|---|---|---|
| | 1<br>finite amounts of both phases | 2<br>infinitely small amounts of both phases | 3<br>finite amounts of one phase and infinitely small amounts of the other phase |
| A: single portion (discontinuous processes) | A 1<br>Craig process | A 2<br>Partition chromatography (pure [4]) and Cornish process | A 3<br>Johnson process |
| B: repeated (continuous processes) | B 1<br>O'Keeffe process | B 2<br>van Dijck process | B 3<br>new process |

Since the criterion of column 3 was not taken into account in the older classifications [2,3], processes A2 and A3 have not previously been distinguished. This is desirable however, since these processes exhibit very different characteristics and very different separating effects as a result of their different methods of material flow [1]. It is therefore also desirable to give the two processes different names. Pure [4] "distribution chromatography" and the "Cornish process" apply to class A2, while for A3 we propose the name of the "Johnson process", since, out of a number of authors who developed this process independently of one another (besides *Johnson* they are *Kies* and *Davis* [5], *Weygand* [6], *Fischer* and *Jübermann* [7]), *Johnson* was the first [8] to give it an exhaustive description and mathematical treatment [9].

Process B3 in Table 1 differs from the Johnson process only in that the addition of the mixture is repeated. We have developed and described this previously unknown process [10]. (Exhaustive treatment in the next Section and by *F. Horn* [11].)

[4] By this is understood pure partition chromatography without complications due to adsorption *etc.*

[8] *J. D. A. Johnson*, J. chem. Soc. (London) *1950*, 1743.

[9] A short description of the principle of this process and the derivation of the fundamental equation will be found in the general review of distribution processes by *S. Stene*, Ark. Kemi, Mineralog., Geol., Ser. *A 18*, no. 18, pp. 39 et seq. (1944).

[10] *W. Fischer*, German Patent 1050731 (March 6th, 1956).

[11] *F. Horn*, Chemie-Ing.-Techn. *36*, 99 (1964).

Other known distribution processes can be regarded as variants of the six fundamental types of Table 1, in which either the conditions are specially chosen (*e.g.* various methods of withdrawing the substances in the Craig process, addition of mixture at one end instead of to a middle stage of the cascade in continuous processes) or the apparatus brings about certain deviations from the selected and to some extent idealized classification criteria (*e.g.* back-mixing, only approximately infinitesimal subdividing of a phase).

## 3. The New Process

### a) Procedure

The new process is periodically quasi-stationary. The operations during one period are shown schematically in Figure 1. The process is preferably carried out in mixer-settler devices; in the example of Figure 1, five distribution elements are used.

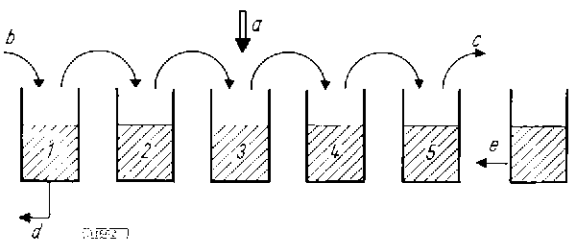

Fig. 1. Scheme of the new process.

1 to 5 mixer-settlers; a = introduction of an amount of mixture Z; b = introduction of the light phase $v_l$, in very small amounts $\Delta v_l$; c = removal of $\Sigma\Delta v_l = v_l$ with the amount of dissolved substance $m_{5,l}$; d = removal of an element at the end of the cycle with an amount of dissolved substance $m_{1,h}$ in a volume $v_h$; e = addition of an element at the end of a cycle with volume $v_h$.

At the beginning of the cycle, each mixer-settler contains a finite volume $v_h$ of the heavy phase, which remains in it as long as it takes part in the exchange; the whole cascade is free from the light phase. One of the distributing elements – the third in the example of Figure 1 – is supplied with an amount Z of the mixture to be separated. This can be added once at the beginning of the cycle, or gradually during the cycle. The light phase is added to element no. 1 in small (in the ideal case, infinitesimal) portions. Each of these portions is brought into equilibrium with the volume $v_h$, and is then immediately separated and transferred to the mixing chamber of the next unit, treated in a corresponding manner, and finally removed from element no. 5. When in this manner a certain volume $v_l$ of the light phase has been added and withdrawn continuously, the addition and removal of the finite volume $v_h$ of the heavy phase as a whole is carried out all at once. This is preferably performed by removing the mixer-settler no. 1 from the process, together with the heavy phase $v_h$ which it contains and the material dissolved in it, while a new mixer-settler containing a volume $v_h$ of pure heavy solvent is added at the other end of the distribution cascade. This completes the cycle.

The next cycle takes place in an analogous manner. In this, the previous mixer-settlers nos. 2 to 5 take over the roles of the previous nos. 1 to 4, and the newly added one the function of no. 5. Five stages are therefore in operation at any given time.

It is desirable to arrange the mixer-settlers in a circle or in two parallel lines close to one another. When more units are available than the number which must be operated simultaneously to obtain the required separating effect, and when all the units are provided with suitably arranged inlet and outlet conduits, the transition from one cycle to the next can be performed simply by operating suitable valves [10].

The process can be carried out in a similar way if the phases are treated in the reverse manner, with the light phase in finite portions and the heavy phase in infinitesimal portions.

It is impossible to achieve in practice the situation in which as presupposed above – only an infinitesimal amount of the continuously flowing phase is present in each mixer-settler. In actual fact, a finite "working volume" ("hold up") of this phase is necessary in the mixing and settling chambers. However, this affects the separating effect only slightly when the amount of material dissolved in this volume is small in comparison with the total amount of dissolved material present in the mixer-settler; cf. *Horn* [11]. A similar situation prevails in the Johnson process [12]. The following theoretical considerations are idealized throughout by the assumption of a vanishingly small working volume.

After a sufficiently large number of individual cycles under constant conditions, a quasi-stationary state is finally obtained. The concentration of the distributed materials for each stage can be calculated for this case [11], assuming constant distribution coefficients and the establishment of equilibrium at all stages; we also assume here that the mixture to be separated is introduced in the solvent-free state. *These three assumptions always apply, in what follows*, for the other processes as well, unless the contrary is expressly stated.

### b) Comparison with the O'Keeffe and van Dijck Processes

The result calculated in this way for the fractions removed from the two ends of a seven-stage distribution by the new process, with the addition of the mixture to be separated at the central (fourth) stage, are compared in Figure 2 with the situations in the O'Keeffe and van Dijck processes (which agree in their separating effects, cf. p. 798). The amounts of these end fractions are plotted logarithmically against the logarithm of the extraction factor

$$G = K \cdot \frac{v_l}{v_h} = \frac{c_l}{c_h} \cdot \frac{v_l}{v_h}$$

K being the partition coefficient, c the concentrations.

While the curves for B 1 and B 2 intersect at G = 1 and form mirror images of one another, this is not the case with the curves for the new process, which express the asymmetry of the flow of the two phases in this process. Moreover, the curves of the new process are steeper in their important sections. This means a better separating effect (cf. the following paragraph). This difference is particularly great at high values of G.

Figure 2 is also useful as a nomogram in the selection of the *operating conditions* for a given separating problem. If two substances a and b are to be separated, and the solvents have

[12] *W. Fischer* et al., Angew. Chem. 66, 319 (1954).

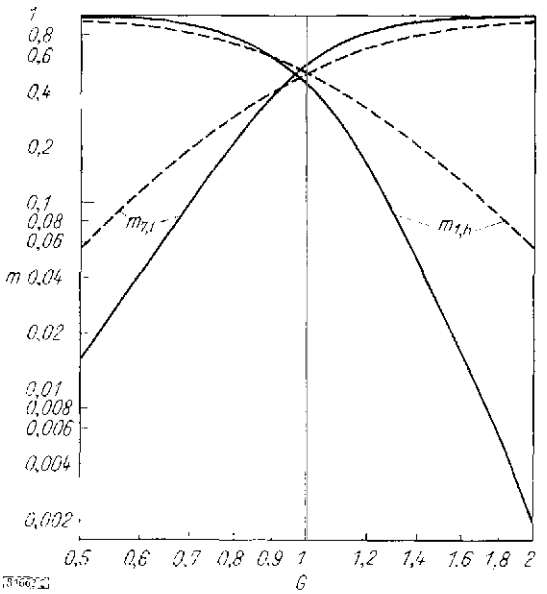

Fig. 2. *Amounts of the fractions* $m_{1,h}$ *and* $m_{7,l}$ *in fractions of the amount Z = 1 of material fed in as a function of the extraction factor G.*

Seven-stage distribution, addition of the material to be distributed to stage no. 4.

— — — O'Keeffe and van Dijck processes (B 1 and B 2)

——— new process (B 3), light phase infinitesimally subdivided.

been chosen, the partition coefficients $K_a$ and $K_b$ and the $G_a : G_b$ ratio are fixed. The absolute value of G can still be varied by the selection of $v_l : v_h$. If a rectangular aperture with a horizontal width of (log $G_a$–log $G_b$) is cut out of paper, its horizontal movement on Figure 2 corresponds to a change in $v_l : v_h$. It is then possible to read off from the ordinate the proportions of the two materials in the end fractions corresponding to any value of $v_l : v_h$ and thereby to determine the yield and purity of the separated products.

but with variations of the absolute magnitude of G; associated values for $G_a : G_b = 2$ are always adjacent to one another, while the absolute values of G decrease in the five double columns from left to right. In addition, Table 2 gives the so-called *migration ratio* or *rejection ratio* [14].

$$R = m_{7,l} : m_{1,h}.$$

In the bottom line of Table 2 is given the *overall separating effect* of the seven-stage cassade $T_{a,b} = R_a : R_b$.

*A comparison of the figures* of Table 2 shows the following facts (discussed exhaustively in [1]):

1. In processes B 1 and B 2, when the mixture is added at the central stage, a material with G = 1 (column 5a) is distributed equally in the two phases leaving the ends of the system: $m_{7,l} = m_{1,h} = 0.500$. The migration ratio R = 1.000. On the other hand, the new process operates unsymmetrically: a material with G = 1 migrates preferentially with the light phase: $m_{7,l} > m_{1,h}$ and $R > 1$.

2. If in processes B 1 and B 2 the values of G are chosen in such a way that $G_a = 1 : G_b$ (reciprocity rule), *i.e.* for our example $G_a = \sqrt{2} = 1.414$ and $G_b = 1 : \sqrt{2} = 0.707$, then $m_{7,l,a} = m_{1,h,b}$ and $m_{7,l,b} = m_{1,h,a}$. It can be seen from Table 2 (column 3, bottom) that material a is obtained in 80 % purity with 80 % yield with the light phase from stage 7, while material b is similarly obtained in 80 % purity with an 80 % yield with the heavy phase from stage 1. In order to arrive at the corresponding situation in the new process, we must make $G_a = 1.334$ and $G_b = 0.667$, *i.e.* the reciprocity rule does not apply to this case. However, as Table 2 (column 3, top) shows, both purity and yield are substantially higher, amounting to 92.3 % for a and b (cf. also R and T).

Table 2. Calculated figures for seven-stage distribution of two materials a and b under stationary conditions. Addition of the mixture in the amounts $Z_a = Z_b = 1$ to stage no. 4. The following relations hold for any two adjacent columns: $\beta = K_a : K_b = G_a : G_b = 2$.

I. Distribution according to the new process B 3; light phase infinitesimally subdivided.

| | 1 | | 2 | | 3 | | 4 | | 5 | |
|---|---|---|---|---|---|---|---|---|---|---|
| Material | a | b | a | b | a | b | a | b | a | b |
| G | 1.8 | 0.9 | 1.5 | 0.75 | 1.334 | 0.667 | 1.2 | 0.6 | 1.0 | 0.5 |
| $m_{7,l}$ | 0.995 | 0.362 | 0.971 | 0.150 | 0.923 | 0.077 | 0.830 | 0.042 | 0.541 | 0.015 |
| $m_{1,h}$ | 0.0052 | 0.638 | 0.029 | 0.850 | 0.077 | 0.923 | 0.170 | 0.958 | 0.459 | 0.985 |
| R | 191 | 0.567 | 33.5 | 0.177 | 12.0 | 0.083 | 4.88 | 0.0438 | 1.179 | 0.0152 |
| $T_{a,b}$ | 337 | | 190 | | 144 | | 111 | | 77 | |

II. Distribution according to the O'Keeffe process (B 1) or the van Dijck process (B 2).

| | 1 | | 2 | | 3 | | 4 | | 5 | |
|---|---|---|---|---|---|---|---|---|---|---|
| Material | a | b | a | b | a | b | a | b | a | b |
| G | 1.8 | 0.9 | 1.5 | 0.75 | 1.414 | 0.707 | 1.2 | 0.6 | 1.0 | 0.5 |
| $m_{7,l}$ | 0.913 | 0.396 | 0.835 | 0.240 | 0.800 | 0.200 | 0.675 | 0.115 | 0.500 | 0.0588 |
| $m_{1,h}$ | 0.087 | 0.604 | 0.165 | 0.760 | 0.200 | 0.800 | 0.325 | 0.885 | 0.500 | 0.941 |
| R | 10.50 | 0.656 | 5.06 | 0.316 | 4.00 | 0.25 | 2.074 | 0.1296 | 1.000 | 0.0625 |
| $T_{a,b}$ | 16 | | 16 | | 16 | | 16 | | 16 | |

The advantage of the new process is shown still more clearly by Table 2. In this Table are given some selected figures from Figure 2 for $m_{7,l}$ and $m_{1,h}$ for two substances with the constant separating factor

$\beta = K_a : K_b = G_a : G_b = 2$,

[13] This follows, for example, from calculations given by *Jübermann* [3] pp. 250–253, and by *Treybal* [14], formula 7.70 for $\varepsilon' = \varepsilon$ and $n' = n + 1$.

[14] *R. E. Treybal*: Liquid Extraction. 2nd Edit., McGraw Hill, New York 1963.

3. For separations by methods B 1 or B 2, the following relation holds [13] when the mixture is fed to the central stage ($\sigma$ = number of stages):

$$T_{a,b} = (G_a/G_b)^{(\sigma+1)/2}$$

and the overall separating effect is therefore independent of the absolute magnitudes of G (Table 2, II). On the other hand, in the new process the overall separating effect $T_{a,b}$ is much greater and depends not only on the ratio $G_a:G_b$ but also to a large extent on the absolute magnitudes of G (Table 2, I). This shows that *the new process is fundamentally different from those used hitherto.*

4. When the conditions are selected in accordance with the double column 3 of Table 2, the new process gives a separating effect $T_{a,b} = 144$, *i.e.* a figure which is somewhat greater than $(G_a/G_b)^7$. If it is desired to obtain the same separating effect by B 1 or B 2, thirteen or fourteen stages would have to be used, *i.e.* almost twice as many as in the new process.

*These differences*, shown here on the basis of a few examples, *are of general nature*, as *Horn* has pointed out [11]. This applies particularly to the finding that the new process requires only *half as many stages* as the older processes to obtain a given overall separating effect.

A further advantage of the new process is that it requires smaller volumes of solvents than the older processes to separate a given amount of a mixture with the same separating effect; cf. [1].

These theoretical results have been confirmed by a series of experiments [1, 10]. In these, the same separation was carried out both by the O'Keeffe process and by the new process in each case. An example is described here:

A 1:1 mixture of *succinic and oxalic acids* was distributed between *water* and *n-butanol* in seven stages with the addition of the mixture to stage 4. The temperature was 20 – 1 °C and $\beta = K_S:K_O = 1.03:0.57 = 1.81$. After stationary conditions had been achieved, figures for the overall separating effect T in the O'Keeffe distribution process varied between 8.6 and 9.4. They correspond to $\beta^{3.6}$ to $\beta^{3.8}$, while theoretically $\beta^4$ is expected. In the new process, the overall separating effect was between $30.6 = \beta^{5.8}$ and $34.8 = \beta^{6.0}$, while according to calculation $\beta^{6.9}$ would have been expected for idealized conditions. Thus, for both processes, the separating effect obtained was only slightly below the theoretical figures. However, above all, the experiments confirmed the expected improvement in the separation by the use of the new process.

## 4. Comparison of the Different Schemes of Material Flow, and Their Modes of Action

### a) Flow-Sheets

*Process A 1.* In the Craig process, which can be represented by a triangular scheme (Figure 3, top), the mixture to be separated is added in one portion at the apex D. At a given moment of time, the state of the apparatus is described by a horizontal row of the flow-sheet, *e.g.* by the row E–F, in which three distribution elements are in operation.

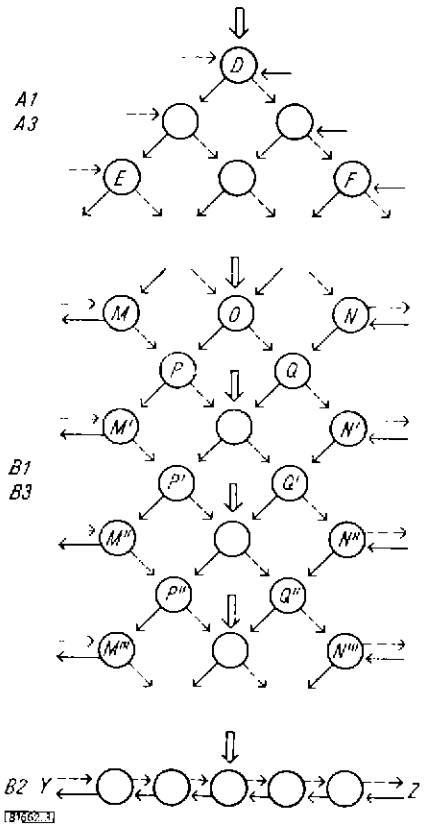

Fig. 3. Interrelationships of the various schemes of material flow. Each circle denotes one distribution operation. (For explanation, see text).
Broken arrows: light phase.
Full arrows: heavy phase.
Double line arrows: introduction of the mixture.

*Process A 3.* The Johnson process is represented in the triangular flow-sheet at the top of Figure 3 by a line D–F or D E, according to whether the heavy or the light phase is used in a state of finite subdivision. Here, as an example, we shall deal only with the first case. All the distribution elements from D to F are provided from the start with equal finite amounts of the heavy phase which remain in them during the whole process. The mixture is added to element D only once at the beginning of the process. The light phase then flows in infinitesimally small amounts successively through the individual distribution elements of the row D–F, until the desired degree of separation of the components has been achieved.

*Process B 1.* The O'Keeffe process is described by the central part of Figure 3. It is derived from the Craig process if fresh amounts of mixture are added regularly and the light and heavy phases are taken off from the ends, so that the number of stages in operation (see p. 796) remains constant. The horizontal rows M–N and P–Q together form one cycle, which is always repeated in the same manner.

*O'Keeffe* [15] worked with a doubled scheme, in such a way that two similar processes were carried out together with a displacement lasting half a cycle. This is only the mechanical

[15] *A. E. O'Keeffe, M. A. Dolliver*, and *E. T. Stiller*, J. Amer. chem. Soc. *71*, 2452 (1949).

addition of two individual processes completely separate from one another as regards materials, and consideration of the simple flow-sheet of the center of Figure 3 is therefore sufficient.

*Process B 2.* In the van Dijck process, the light and heavy phases flow continuously and simultaneously in opposite directions through all distribution elements of the series, while the mixture is likewise fed in continuously at a suitable point. The process can therefore be shown, for example, by the flow-sheet Y–Z at the bottom of Figure 3.

*Process B 3.* The *new process* is shown in Figure 3 by the oblique rows M–N″, M′–N‴, *etc.*, or by N–M″, N′–M‴, *etc.* according to whether the heavy or the light phase is used in the form of finite amounts, in a similar manner to the Johnson process (A 3). In the case where the heavy phase is divided into finite portions, the row M–N″ forms a cycle. When, after the addition of mixture, the necessary amount of light phase has been passed through the process in infinitesimal amounts, M is removed, P–N″ take the position of M′–Q″, and N‴ is added, as described above. This completes the cycle.

b) Definitions

Before the separating effects of the individual methods of material flow can be compared, some questions of nomenclature must be discussed, since considerable confusion exists in this respect. Here we wish to propose some definitions, particularly in view of the current efforts to arrive at an internationally uniform terminology in the field of distribution processes.

n = *Number of distribution steps.* A distribution step means an establishment of equilibrium with all the distribution elements simultaneously in operation. The term can only be used with respect to processes with two finitely subdivided phases, *i.e.* processes A 1 and B 1.

N = *Number of distribution cycles*; cf. p. 792. This term is meaningful only with continuous processes with at least one finitely subdivided phase, *i.e.* processes B 1 and B 3.

z = *Number of distribution elements* (also called elements, for short) of an apparatus. This number can obviously be given only for apparatus which consist of individual distribution elements, *i.e.* not for packed columns and the like.

$\sigma_{pr}$ = *Number of practical stages.* Again, we can speak of practical stages only in the case of an apparatus consisting of individual distribution elements. We define $\sigma_{pr}$ as the number of distribution elements traversed by the mobile phase from its introduction to its removal. If both phases are transported, the number of distribution elements traversed by each phase is the same. – In processes A 2, A 3, B 2, and B 3, so far as apparatus consisting of individual distribution elements are used, $\sigma_{pr} = z$. It must be particularly noted that this equality does not apply to the O'Keeffe and the Craig processes. In the latter case (*i.e.* in the Craig process), the number of practical stages in the above sense is generally not clear-cut, while there is no doubt about the number z of elements. Consequently the concept of stages should not be used in this case. In the O'Keeffe process, for the example given in the center of Figure 3, $\sigma_{pr} = 5$, while throughout only three (row M–N) or two (row P–Q) elements, alternately, are simultaneously filled and in operation.

$\sigma_{th}$ = *Number of theoretical stages* = number of practical stages which, with complete establishment of equilibrium *in each individual distribution operation, give the same* overall separation effect. as a process without individual distribution elements and/or without establishment of equilibrium.

We shall speak of the *separating power* of a process when we mean the separation achieved only in a general sense. As *measurable* magnitudes we propose the following:

1. The *separation factor*

$$\beta = K_a : K_b = G_a : G_b = \frac{c_{l,a} : c_{h,a}}{c_{l,b} : c_{h,b}} = \frac{c_{l,a} : c_{l,b}}{c_{h,a} : c_{h,b}}$$

As a material constant, it is *independent* of the type of multiplicative scheme of material flow used.

All measurable magnitudes for the change in the ratio of the amounts of two components of a mixture within a multiplicative distribution cascade that *depend* on the method of material flow, shall be called *separating effects.* We distinguish:

2. The *overall separating effect T* of a distribution cascade. It has already been defined on p. 794 as the quotient of the migration ratios R of two substances. If, in accordance with p. 794, the corresponding ratio of amounts is put for R and the last distribution element of the cascade is denoted by ω, we obtain the following expression for T, which can also be formulated with the concentrations:

$$T_{a,b} = R_a : R_b = \frac{m_{\omega,l,a} : m_{1,h,a}}{m_{\omega,l,b} : m_{1,h,b}} = \frac{m_{\omega,l,a} : m_{\omega,l,b}}{m_{1,h,a} : m_{1,h,b}} = \frac{c_{\omega,l,a} : c_{\omega,l,b}}{c_{1,h,a} : c_{1,h,b}}$$

Consequently, we may also regard $T_{a,b}$ as the ratio of the amounts or concentrations of the two materials a and b in the light phase of the last distribution element (= *purity ratio* of this fraction) divided by the corresponding purity ratio in the heavy phase of the first element.

3. We denote by the term *partial separating effect U* the quotient formed in the same way from the concentration ratio in any two distinct distribution elements i and j, now, however, within the *same phase* of the two elements:

$$U_{a,b} = \frac{c_{i,h,a} : c_{i,h,b}}{c_{j,h,a} : c_{j,h,b}}.$$

The quotient relating to the light phase is identical with that for the heavy phase under equilibrium conditions with a constant separation factor.

4. An important special case of the above, the *separating effect S from stage to stage*, is based on the definition of a stage given above, i and i-1 being neighboring stages:

$$S_{a,b} = \frac{c_{i,h,a} : c_{i,h,b}}{c_{i-1,h,a} : c_{i-1,h,b}}.$$

The separating effects defined in this way must be supplemented for a complete characterization of the separating power of a process or a plant by data on the *yield* (*i.e.* the fraction of the amount of a component added that is removed from the plant in enriched form), and on the *separating output*, by which is understood the amount of mixture passed through and subjected to a given separating effect, referred to the time or to the volumes of the two solvents. These two differently based forms of the separating output are connected with one another and with the rate of throughput of the solvents. The reciprocal of the separating output referred to volumes is also called the *solvent demand.*

c) Comparison of the Processes

*Process A 1.* Figure 4a gives the quantity-based characteristics of three distributed materials with different extraction factors G at a certain moment of the process for a *Craig distribution* (fundamental process) with a large number of distribution elements. It is noteworthy that the curves for the two materials with the reciprocal G values 0.1 and 10 are symmetrical to one another, and are precisely the same with respect to steepness and height [16].

It follows from the well-known calculations [17] of this method of working that between neighboring distribution elements in *simultaneous* operation (in Figure 3, top, these are the neighboring elements of a *horizontal* row, *e.g.* the row E–F), the separating effect, $U_{a,b} = \beta_{a,b}$. If $G_a = 1{:}G_b$, it follows similarly for the distribution operations *succeeding one another in time* of the *oblique* row D–F of Figure 3 that $U_{a,b} = \sqrt{\beta_{a,b}}$.

*Process A 2.* A description of this scheme is not necessary in order to understand the considerations predominating here. A comparative discussion of its mode of action is to be found in the German text [1].

*Process A 3.* The characteristics of the Johnson process differ in a quite definite manner from those of the Craig process, as shown by Figure 4b on the basis of the separation of a ternary mixture at a given moment of time. With increasing magnitude of the extraction factor G, the curves become flatter and broader, and reciprocal G figures do not yield curves of the same steepness and height, as in the Craig process. For the separating effect from stage to stage, *e.g.* in row D–F of Figure 3, we have $S_{a,b} = \beta_{a,b}$ [12].

*Comparison of A 1 and A 3.* We again consider a Johnson process in which the heavy phase is present in a state of finite subdivision in stages D–F of Figure 3 and the light phase flows uniformly without the formation of a finite working volume. With this, we compare a fundamental process of the Craig method, in which decantation vessels may be used. In this case again each portion of the heavy phase is associated with a definite distribution element and the light solvent forms the mobile phase, which however is transferred in batches.

[16] See, for example, *O. Jübermann* [3], p. 261.

[17] See, for example, *E. Hecker*: Verteilungsverfahren im Laboratorium. Verlag Chemie, Weinheim 1955.

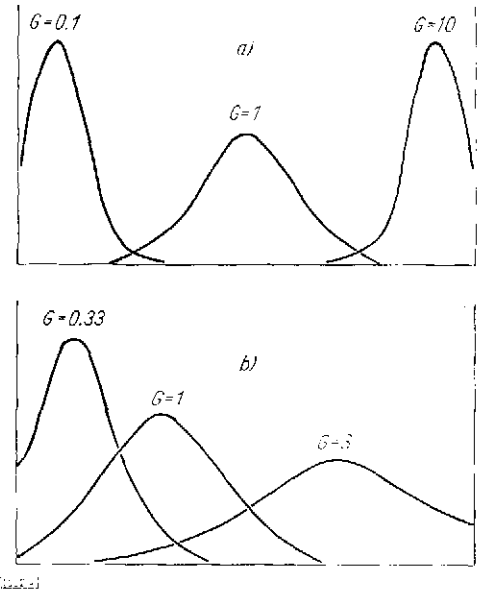

Fig. 4. Example showing the characteristics
a) of the Craig process (A 1); b) of the Johnson process (A 3).
Abscissa: Number of the distribution elements.
Ordinate: Content of the distribution elements, m.

We can now alter to some extent the temporal sequence of the individual operations in the Craig process without changing the principle, by first passing only one portion of the light phase through all three distribution elements from D to F. All three elements are then again free of the light phase, and the state is comparable with that of the Johnson process after the same amount of light phase has been passed through. As is well known [18], the extraction effect, and therefore the separation effect, are increased when a given volume of the extracting solvent is used in the form of separate small portions. It therefore becomes understandable that in process A 1 the separating effect between two neighboring elements of row D–F is only $\sqrt{\beta}$ while in process A 3 it is $\beta$. In the normal Craig process, two further portions of light phase have been brought into operation in the meantime, so that the three elements are then in the state E–F. The separating effect between neighboring elements has then increased to $\beta$ in the Craig process as well, which, as compared with row D–F, arises from the fact that the heavy phase which has been placed in D has now been treated with three times the volume corresponding to the Johnson process, the middle element with twice the volume, and only the element F with the same volume. The Craig process therefore achieves the advantage of the Johnson process by pursuing the separating operation partially, *i.e.* in the flow-sheet of Figure 3 towards the left-hand end in increasing degree. Mathematical treatment of the cases shows that the disadvantage for the separating effect between neighboring elements resulting from establishment of equilibrium with finite portions of the light phase is just compensated by the partial pursuit of the process. This result is not obvious.

Thus, using an equal number of distribution elements, processes A 1 and A 3 give the same separating effect but possess different characteristics. Furthermore,

[18] See, for example, *O. Jübermann* [3], pp. 234–235.

process A 3 has a smaller solvent demand for the same output [19].

*Processes B 1 and B 2.* The van Dijck process B 2 can be carried out in columns or in *mixer-settlers*. We shall first consider the second case In operation, mixers and settlers contain certain working volumes ("hold up") of the two phases, their amounts and concentrations in each distribution element being constant in time under stationary conditions. The magnitudes of the working volumes are obviously irrelevant to theoretical considerations with idealized conditions, and are to be chosen only according to practical points of view (*e.g.* the velocity of mass transfer and the rate of settling). For these reasons, in the idealized calculation of the concentration characteristics it is possible to leave the working volumes out of consideration. The van Dijck process is then considered as if infinitesimal amounts of the two phases were brought directly to mass exchange with one another – in the ideal case, brought into equilibrium – and then separated, and passed to the subsequent stages. On the one hand this justifies the classification of the van Dijck process, when carried out in mixer-settlers, in our category B 2. On the other hand, these considerations show that the idealized van Dijck process can be regarded as an O'Keeffe process with the feed and transport of infinitesimal amounts of all the participating materials, from which it follows that the characteristics, the separating effects, the yields, and generally the entire separating power of the two processes are identical, provided all other experimental conditions are equal.

If, on the other hand, the van Dijck process is carried out in a *column* (without back-mixing), the scheme of material flow corresponds completely to the conditions of our category B 2. However, in general, the time of contact of two infinitesimal portions of the two phases is so short that their concentrations will remain further from equilibrium than in mixer-settlers.

The calculation is most simply carried out by the use of a fictitious "height equivalent to a theoretical stage", by analogy with rectification. Thus the calculation of the van Dijck process in a column and its conception within the framework of our considerations leads back to the method of working with mixer-settlers sketched above, and the same conclusions follow.

When $G_a$ is chosen as equal to $1/G_b$ in the van Dijck process [20], the relation $S_{a,b} = \sqrt{\beta_{a,b}}$ holds [21,22] for the separating effect from (theoretical) stage to stage in row Y–Z of Figure 3. The same applies in the O'Keeffe process for neighboring stages, *i.e.* in Figure 3 for the row M–P–O–Q–N.

*Process B 3.* The *new process* has already been compared with processes B 1 and B 2 above. Figure 5 shows in addition a comparison of the quantity-based characteristics for a seven-stage distribution with the addition of the mixture to the middle stage for two materials with $G_a = 2$ and $G_b = 1/G_a = 0.5$, *i.e.* $\beta = 4$. The symmetrical character of the O'Keeffe procedure is reflected in the fact that the curve for the content of material a in the light phase in the individual stages forms a mirror image of that for material b in the heavy phase. The unsymmetrical flow of the phases in the new process leads to curves which deviate markedly from a mirror-image relationship; the material with $G_b = 0.5$ is somewhat held up in the first stages, while in particular the material with $G_a = 2$ is greatly displaced towards higher-numbered stages as compared with the O'Keeffe process.

While in the O'Keeffe distribution in the case under consideration the separating effect between neighboring stages $S_{a,b} = \sqrt{\beta} = 2$ and is constant, with the new process it is on average somewhat more than 4, *i.e.* somewhat larger than $\beta$, and varies from one pair of stages to another in a characteristic manner [1].

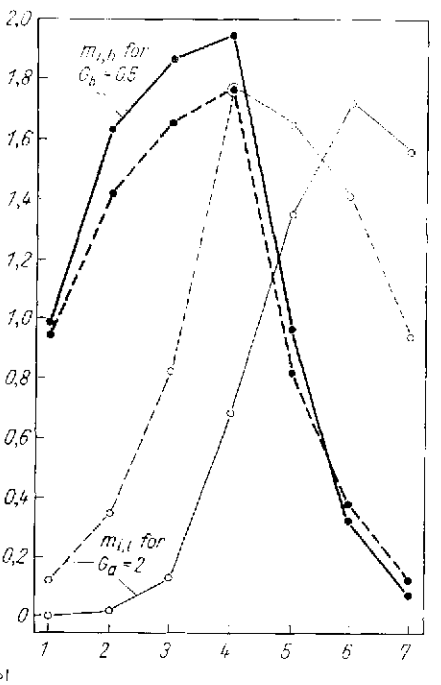

Fig. 5. Examples of the quantity-based characteristics at the end of a cycle in seven-stage distribution.

- - - - - O'Keeffe process (B 1).

—— New process (B 3), light phase infinitesimally subdivided.

Addition of the material to be distributed in an amount of Z = 1 per cycle to stage 4.

Abscissa: stage no. i.

Ordinate: amount of distributed material in the heavy phase $m_{i,h}$ and in the light phase $m_{i,l}$ of stage i.

*Summarizing*, it can be stated that the *new process*, at the same yield and with a smaller consumption of solvent, requires only about half as many stages to obtain a given overall separating effect as the O'Keeffe and van Dijck processes. Its characteristics distinguish it markedly from the other two processes. The separating effect from stage to stage varies with the position of the stages within the cascade, and the overall separating effect rises with the absolute values of K at a constant

[19] *O. Jübermann* [3], pp. 276 et seq.

[20] In the German text [1], on p. 95 and in Table 5, this prerequisite was erroneously omitted.

[21] According to *O. Jübermann* [3], pp. 243–244, and 250, or according to *R. E. Treybal* [14] using equation 7.84.

[22] With addition of the mixture to the middle stage, the following expression holds for the average separating effect from stage to stage: $S = T^{1/(\sigma+1)} \sqrt{\beta}$, even if $G_a \neq 1/G_b$.

value of $\beta_{a,b} = K_a : K_b$. These phenomena also differentiate the new process from the Johnson process with which it otherwise has much in common, particularly in the method of the flow of phases.

## 5. Reflux

If in processes B 1 or B 2 complete reflux of the dissolved material at both ends of the cascade is used, the relation $S_{a,b} = \beta_{a,b}$ holds [23,24] for the separating effect from stage to stage under stationary conditions; it is therefore greater by a power of two than in the absence of reflux.

A corresponding situation exists [1] when the new process B 3 is carried out with complete reflux. The separating effect from stage to stage is thereby again squared and, on average, becomes equal to $\beta^2$. This superior separating effect, which was previously shown in the Johnson process and in the new process without reflux, is obviously characteristic for the third method of phase flow (Table 1).

## 6. Displacement Distribution [25]

When certain extreme deviations from the Nernst distribution law exist (cf. Figure 6), peculiar phenomena may arise in multiplicative distribution.

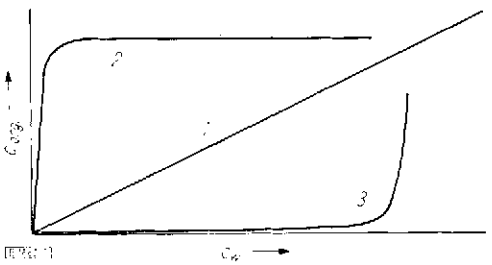

Figure 6. Distribution isotherms.
Curve 1: Nernst distribution law.
Curves 2 and 3: Extreme cases which can lead to displacement distribution.
c = Concentration, w = aqueous phase, org = organic solvent phase.

In the first place, these cases often offer a convenient possibility of working with reflux at both ends of the distribution cascade. An example of this is given by extractions of complexes by the scheme:

$$MCl_w + HX_{org} = MX_{org} + HCl_w,$$

when the chloride ion is present only in the aqueous solution and the complex-forming agent X only in the organic solution. The marked dependence of these equilibria on the hydrogen ion concentration of the aqueous phase permits reflux to be carried out: if the pH is kept high at that end of the cascade at which the organic solvent and the complex-forming agent are added, the metal M can be transferred here completely from the aqueous to the organic phase; if aqueous acid is fed at the other end of the cascade, the reverse process can be brought about there.

A further feature appears under these conditions. The extraction from the aqueous phase follows the peculiar Curve 2 in Figure 6 and leads to a saturation of the organic solvent with the metal M, the height of which is determined by the predetermined concentration of X but is independent of the metal concentration in the aqueous phase.

If, with a multistage distribution cascade, it is arranged that the aqueous phase of all stages with the exception of the first and the last contains the same concentration of MCl, the organic phase flows past the aqueous phase without a change occurring in the concentration of the metal in the two phases. If a mixture of several metals is present, the same applies for their total (equivalent) concentration; but in the middle stages there is an interphase exchange of the individual metals with one another, corresponding to the different stabilities of their X-complexes. Thus, there is a rectangular concentration characteristic for the sum of the metals within which the various metals separate from one another in the course of the process as individual bands. The picture is thus substantially analogous to displacement chromatography, and the reason is the same: extreme positions of the equilibria at the front of the mixture and at the front of the eluent, combined with saturation phenomena. Because of this analogy, we propose for multiplicative distribution processes with rectangular concentration characteristics the name *displacement distribution*.

When the extreme shape of the equilibrium isotherms is given, this type of distribution can be carried out with all three different methods of phase flow (p. 792). It differs from a distribution in a system for which the Nernst distribution law holds by the fact that in this latter case – even with complete reflux – there are no rectangular concentration characteristics, the concentration varying from stage to stage. In case the Nernst distribution law applies, discontinuous multiplicative distribution corresponds to elution chromatography.

The occurrence of displacement distribution is not restricted to the complex equilibria mentioned [1]. We have also observed cases in which distribution isotherms of the shape of Curve 3 in Figure 6 lead to displacement distribution [1].

We have applied displacement distribution particularly to the scheme of the new process B 3, and have obtained very good separating effects under these conditions – particularly with partial reflux. A theoretical treatment of the problem on a digital computer with simplified assumptions made by *M. Krüger* on the basis of preliminary work by *U. Neitzel* showed that the separating effects from stage to stage vary in a complex manner with the position of the stages within the cascade, the magnitude of the reflux, and the ratio of the amounts of the components to be separated, but are sometimes even greater than for the new process B 3 when the distribution law applies. This and the associated experiments will be reported in detail elsewhere.

[23] If in [3] ${}_1A_S = A$ and ${}_nA_R = a$ are put in Figure 10b, p. 242, the above result follows from the equations on pp. 243–244. Similarly from [14], equation 7.62.

[24] This relation also holds when $G_a = 1/G_b$.

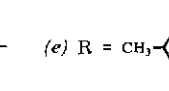
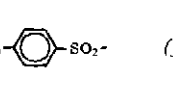
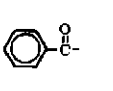
## Detection of a Heterocyclic Nucleophilic Carbene [*]







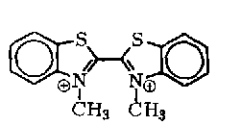
By Dr. H. Quast and Prof. Dr. S. Hünig

Chemisches Institut der Universität Würzburg (Germany)

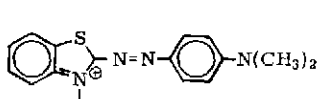
After it has not been proven so far that tetra-aminoethylenes dissociate into nucleophilic carbenes [1–3], numerous reactions which have been ascribed to nucleophilic carbenes [4] probably must be given a new interpretation. Since a yellow crystalline substance recently described [5,6] is not *(1)* but its "dimer" *(2)* [7], there are no reactions known – apart from the rapid exchange of the protons on the α-carbon atom of quaternary heterocycles [8] and the formation of dimers of type *(2)* [3–6,9] – which definitely proceed *via* a carbene and not *via* its dimer.

*(4-7)* *(a)* R =  *(b)* R =  *(c)* R = 

*(d)* R =  *(e)* R =  *(f)* R = 



We have now succeeded in producing a short-lived nucleophilic carbene *(1)* by deprotonation of 3-methylbenzthiazolium salts *(3)*, *e.g.* in acetonitrile with triethylamine or diisopropylethylamine [10], and in differentiating it by means of its reactions from its dimer *(2)* which is also formed under comparable conditions [5,6]. Compound *(2)* is obtained in 70–75 % yield from *(3)* with sodium hydride in dioxan under nitrogen and reacts with 2 moles of the azidinium salt *(4a,b)* [11] or with 1 mole of *p*-toluenesulfonylazide *(4e)* in acetonitrile at 5 °C to give 1 mole of nitrogen and mixtures of compounds *(5)* and *(6)*, *e.g.* 21 % *(5a)* + 41 % *(6a)*, 14 % *(5b)* + 50 % *(6b)*, or 45 % *(5e)* + 79 % *(6e)*. The less reactive compound *(4d)* gives only 1.3 moles of *(6d)* and 1.5 moles of nitrogen.



In contrast, uniform products are isolated when *(1)* is prepared from *(3)* in the presence of the azides *(4)*: compounds *(4a)*, *(4b)*, and *(4c)* undergo a very rapid reaction to form almost exclusively triazacyanines [11], *viz.* 75–80 % *(5a)*, 69 % *(5b)*, and 32 % *(5c)*, whereas *(4d)*, *(4e)*, and *(4f)* yield 70–80 % nitrogen and only the corresponding compounds containing only one N-atom in the chain [12], *viz.* 53 % *(6d)*, 62 % *(6e)*, and 44 % *(6f)*.

The products of the reactions with the carbene *in situ* show that the course of the reaction is decisively influenced by the electrophilicity of the azide. It is only with the strongly electrophilic azidinium salts *(4a)–(4c)* that the products expected from a reaction which traps the carbene *(1)* are actually obtained. The less reactive azides *(4d)*, *(4e)*, and *(4f)* are apparently unable to capture *(1)* in the presence of *(3)*. Since the dimer *(2)* is readily formed under the reaction conditions used [5,6], it must be assumed that the reaction with *(4e)* and *(4d)* proceeds *via (2)*.

The reaction of *(2)* with azides is understandable if it is assumed that an adduct *(7')*, or more probably *(7)*, is formed, and then decomposes by loss of nitrogen to form *(6)*. Just as in the decomposition of the adducts of electrophiles with tetra-aminoethylene [3], a carbene must be formed here too. The fate of this carbene is again determined by the most reactive electrophile present. The yield of nitrogen, the relative proportions of the products formed, and the observation that no iminodiazosulfone *(5e)* is formed from *(2)* and *(4e)* when *(2)* is produced directly in the solution from *(3)* prove that *(7)* cannot be transformed directly into *(5)* here.

In the reaction of *(2)* with 2 moles of a benzenediazonium fluoroborate (*p*-$NO_2$, *p*-$CH_3$, *p*-$N(CH_3)_2$), only 1 mole of nitrogen and the compound with two electrons less, *i.e. (8)* [13], could be isolated (43 %, 26 %, 22 % yields). Although

*(8)* 

*(9)*

*(9)* [14] is expected by reaction with *(1)* [6], only traces are formed. The red-brown color of the solutions is partially

due to the presence of unstable radical ions with an oxidation stage intermediate between that of *(2)* and *(8)* [13].

## Synthesis of Tris(pentafluorophenyl)arsine, -stibine, and -phosphine and of Pentafluorophenyltrimethylsilane

By Dipl.-Chem. M. Fild, Prof. Dr. O. Glemser, and cand. chem. G. Christoph

Anorganisch-Chemisches Institut
der Universität Göttingen (Germany)

To prepare the title compounds, pentafluorophenylmagnesium bromide [1] is made by the reaction of pentafluorobromobenzene with magnesium in ether, and the corresponding amounts of $AsCl_3$, $SbCl_3$, $PSCl_3$, or $(CH_3)_3SiCl$ are added dropwise at −10 to −20 °C with vigorous stirring. The solution is then allowed to warm up to room temperature over 4 h and stirring is continued for a further 2 h. The mixture is then cooled to 0 °C, ice-water is added, and 3 N HCl is stirred in until the solution is acidic. The ether phase is separated off, dried, and the solvent distilled off; the residue is then recrystallized from methanol or petroleum ether. Each product was characterized by elemental analysis, molecular-weight estimation, and infrared spectra.

*Trispentafluorophenylarsine*, $As(C_6F_5)_3$: colorless platelets, m.p. 106 °C, 39 % yield. Infrared spectrum [2]: 6.08 (s); 6.58 (vs); 6.73 (vs); 7.20 (s); 7.75 (s); 7.75 (s); 9.22 (vs); 10.25 μ (vs).

*Trispentafluorophenylstibine*, $Sb(C_6F_5)_3$: colorless needles, m.p. 74 °C, 32 % yield. Infrared spectrum [2]: 6.08 (s); 6.58 (vs), 6.76 (vs), 7.23 (s), 7.78 (s), 9.20 (vs), and 10.31 μ (vs).

With $PSCl_3$ the reaction does not give $(C_6F_5)_3PS$, but instead leads to the known compound $(C_6F_5)_3P$ [3] in 25 % yield. Although the phosphine and arsine derivatives are stable towards water, caustic soda, and methanol, $Sb(C_6F_5)_3$ is slowly hydrolysed with loss of its pentafluorophenyl groups; on the other hand, the compounds are thermally remarkably stable.

With trimethylchlorosilane, the reaction affords pentafluorophenyltrimethylsilane, $(CH_3)_3SiC_6F_5$, as a colorless liquid, b.p. 60 °C/14 mm, in 42 % yield. Its infrared spectrum [2] has bands at 6.10 (s), 6.61 (vs), 6.82 (vs), 7.96 (vs), 9.21 (vs), 10.31 (vs), 11.80 (vs), and 12.31 μ (vs). Analogous experiments with dichlorodimethylsilane and methyltrichlorosilane yielded only polymeric products.

## Quinonoid Diazo Compounds

By Doz. Dr. Th. Severin and Apotheker J. Dahlström

Institut für Pharmazeutische Chemie und Lebensmittelchemie der Universität Marburg/Lahn (Germany)

Recently *Hartzler* [1] described the preparation of 3-diazo-6-dicyanomethylene-1,4-cyclohexadiene from *p*-aminophenylmalodinitrile. This has induced us to report some of our own syntheses of quinonoid diazo compounds. We obtained compounds *(5a)* and *(5b)* by the route indicated in the formulae.

2-(*p*-Nitrophenyl)dimedone *(2b)*, m.p. 231 °C, is obtained in 55 % yield by refluxing *p*-nitrofluorobenzene *(1b)* with the sodium salt of dimedone (5,5-dimethylcyclohexane-1,3-dione) for 4 h in dimethylformamide. 2-(2-Nitro-4-aminophenyl)dimedone *(3a)*, m.p. 202 °C, is formed in 51 % yield by reducing one nitro group of 2-(2,4-dinitrophenyl)dimedone *(2a)* [2] by passing $H_2S$ through a boiling solution of *(2a)* in ethanol/conc. ammonia (50:1) for 24 h. In order to procure compound *(3b)*, m.p. 218 °C, compound *(2b)* is dissolved in 2 N NaOH at 90 °C and treated with sodium dithionite until colorless; the yield is 75 %. When the hydrochlorides of *(3a)* and *(3b)* are treated with amyl nitrite in acetic acid and ether is then added, the yellow diazonium salt *(4a)* [diazo band at 2270 $cm^{-1}$] and the pale yellow salt *(4b)* [diazo band at 2260 $cm^{-1}$] are precipitated in 72 % and 67 % yields, respectively. The salt *(4a)* reacts with hypophosphorous acid to give 2-(*o*-nitrophenyl)dimedone [3]. This proves that it is the *para*-nitro group in *(2a)* that has been reduced.

Addition of $NaHCO_3$ to an aqueous solution of *(4a)* precipitates the red quinonoid diazo compound *(5a)* [diazo band at 2220 $cm^{-1}$] in 63 % yield. In contrast to the diazodicyanomethylene compound prepared by *Hartzler*, *(5a)* can be recrystallized from methanol by addition of ether and gives good results for its elemental analysis even after 24 h. On heating, it decomposes slowly without melting. The diazo compound *(5b)* is much less stable than *(5a)*. It is not precipitated by $NaHCO_3$ but can be extracted from its aqueous solution with methylene chloride or ethyl acetate. It decomposes within a few minutes and has, therefore, not yet been isolated in the solid form. If hydrogen chloride is passed into a fresh extract of *(5b)* in methylene chloride, *(4b)* is reformed. Compound *(5b)* also couples with β-naphthol to give an azo dye.

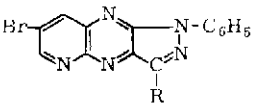
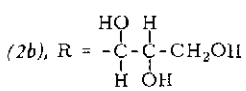
## Azaflavazole Derivatives — New Heterocycles



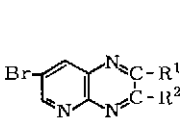
By Prof. Dr. G. Henseke and Dipl.-Chem. D. Lehmann

Institut für Organische Chemie der
Bergakademie Freiberg/Sachsen (Germany)



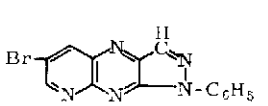
We have obtained azaflavazoles by three different routes. 2,3-Diamino-5-bromopyridine condenses with 1-phenyl-3-methyl-4,5-dioxopyrazoline in water slightly acidified with acetic acid to give the anil *(1)*, m.p. 218–220 °C (decomp.), as red brown crystals from aqueous acetic acid. When heated briefly in 1 N NaOH, the latter affords an 80 % yield of 6-bromo-3-methyl-1-phenyl-4-azaflavazole *(2a)* [1] as yellow prisms, m.p. 223–224 °C from ethanol.

*(1)*



*(2a)*, R = $CH_3$; *(2c)*, R = $CO_2H$

*(2b)*, R = $-C(H)(OH)-C(H)(OH)-CH_2OH$



The reaction of 2,3-diamino-5-bromopyridine with dehydro-L-ascorbic acid and phenylhydrazine [2] at 25 °C leads to 20 % of the azaquinoxaline *(3a)* as red prisms, m.p. 281 to 283 °C (decomp.) from methanol; when *(3a)* is heated with 0.01 N NaOH, it is transformed quantitatively into 6-bromo-3-[L-*threo*-1,2,3-trihydroxypropyl]-1-phenyl-4-azaflavazole *(2b)*, yellow needles, m.p. 214–216 °C (decomp.) from ethanol.

*(3a)*, $R^1$ = OH; $R^2$ = $-C(H)(OH)-C(H)(OH)-CH_2OH$

*(3b)*, $R^1$ = $-CH=N-NH-C_6H_5$; $R^2$ = H

Dehydrogenative cyclization with phenylhydrazine of 7-bromo-5-azaquinoxaline-2-carboxaldehyde phenylhydrazone *(3b)* in water weakly acidified with mineral acid gives a 50 % yield of 5-bromo-1-phenyl-7-azaflavazole *(4)* as yellow prisms, m.p. 247–248 °C from ethanol.

*(4)*

Oxidation with alkaline peroxide at 30 °C of the aldehyde prepared from *(2b)* led to 6-bromo-1-phenyl-4-azaflavazole-3-carboxylic acid *(2c)*, yellow prisms, m.p. 268–270 °C from dioxan.

## Reversibility of the Dissociation of Glutamate Dehydrogenase from Beef Liver into Its Polypeptide Chains [1]

By Dr. H. Sund

Chemisches Laboratorium
der Universität Freiburg/Breisgau (Germany)

In its native, associated state, glutamate dehydrogenase from beef liver is a prolate particle with a particle weight of $2\times10^6$. If it is considered as an ellipsoid of revolution, then its major and minor axes are about 930 and 70 Å long, respectively [2]. This particle is in a reversible, spontaneously attained equilibrium with subunits having particle weights of $1\times10^6$, $0.5\times10^6$, and $0.25\times10^6$, all of which exhibit enzymatic activity. Further cleavage into the polypeptide chains occurs in the presence of urea or long-chain alkyl sulfates or at pH values above 10 or below 4; this change is accompanied by loss of the native chain conformation and the enzymatic activity, and so far has been found to be always irreversible [2–7].

We have now succeeded in showing that this dissociation, too, is in fact reversible. Incubation of glutamate dehydrogenase in the presence of mercaptoethanol at pH 2.0–2.2 leads to complete inactivation of the enzyme. Subsequent dialysis against mercaptoethanol at pH 7.6 effects extensive reactivation: specific activity [8] before denaturation with acid: 6200 $min^{-1}$, after denaturation: 10 $min^{-1}$, after renaturation by dialysis at pH 7.6: 4500 $min^{-1}$. These results show that glutamate dehydrogenase from beef liver contains in its amino-acid sequence the information required for the chain conformation of the native, catalytically active enzyme protein.

## Explosion during the Oxidation of Tetralin with Hydrogen Peroxide in Acetone (Comments)

By Prof. Dr. W. Treibs, Heidelberg (Germany)

*H. Seidl* recently reported [1] on an explosion which occurred during the preparation of tetralone from tetralin in acetone using hydrogen peroxide.

Since publication of the original procedure [2], this method has been used in numerous experiments for oxidizing open-

chain and cyclic olefins and ketones, as well as terpenes and sesquiterpenes without any accidents. Since the description of the original procedure was rather terse, detailed instructions are given here for the production of α-tetralone.

One gram of vanadium pentoxide is placed in a beaker and a total of 30 ml of 10 % hydrogen peroxide is added in portions. Strong effervescence occurs and heat is liberated. The product is a green-brown voluminous mass, which is dissolved in 100 ml of a 20:80 v/v mixture of 10 % $H_2O_2$ and acetone. The solution is filtered and added to a solution of 500 g of tetralin in 5 l of acetone. The reaction mixture is stirred or shaken and 30–40 % $H_2O_2$ is added in portions of 50 ml, keeping the temperature at 30–40 °C; before each new addition, the color of the mixture should be allowed to change from yellow-red to green or brown-green. If the mixture separates into two phases, enough acetone is added to make the solution homogenous again. The oxidation is complete when the color change occurs only slowly. A little fresh tetralin is then added, and the whole is boiled for 1 h under reflux. The solvent is then distilled off, and the residue is separated in a separating funnel. The lower, aqueous phase is extracted with ether, and the extract is added to the upper, organic phase, which is then shaken with 100 ml of 2 N sodium hydroxide and washed thrice with 100 ml portions of distilled water. The ether is removed, and the residue is fractionated *in vacuo* on an oil bath.

The acetone used as solvent in the reaction is distilled beforehand from $KMnO_4$. Pure methanol can also be used as solvent, but after dilution with $H_2O_2$ it has less dissolving power than acetone. *Mineral acids must not be present, not even in traces.*

## Formation of 1-Benzyl-2,3-diphenylindanes from Stilbene in the Presence of Tin Tetrachloride under the Influence of γ-Radiation

By Dr. M. Salzwedel, V. Werner, and Priv.-Doz. Dr. D. Schulte-Frohlinde

Strahlenchemisches Laboratorium, Kernforschungszentrum Karlsruhe (Germany)

Irradiation of *cis*- or *trans*-stilbene in the presence of tin tetrachloride with γ-rays from $^{60}Co$ [1] led to trimers plus three isolable dimers *(1)–(3)*:

*(1)* *(2)* *(3)*

| | Mol. wt. | M.p. [°C] | $\lambda_{max}$ [mμ] |
|---|---|---|---|
| *(1)* | 360 | 99–100 | 274 |
| *(2)* | 360 | 114–115 | 275 |
| *(3)* | 360 | 147–148 | 281 |

The G value for the consumption of the stilbene in an equimolar mixture with tin tetrachloride was 105; the G value for the formation of the mixture of isomers was calculated to be 31.5 on complete reaction. The ultraviolet, infrared, mass and proton magnetic resonance spectra of the dimers as well as the products of their oxidative degradation [benzoic acid, *o*-benzoylbenzoic acid, anthraquinone, 2,3-diphenyl-$\Delta^2$-inden-1-one, and (*o*-benzoylphenyl)benzoylbenzylmethane] indicate that they are the stereoisomers *(1)–(3)* of 1-benzyl-2,3-diphenylindane.

## Damped Oscillation of the Enzyme Synthesis in Yeast

By Dr. W. Bernhardt, cand. med. K. Panten, and Prof. Dr. H. Holzer [1]

Biochemisches Institut der Universität Freiburg/Breisgau (Germany)

When a disturbance enters a feedback system, the transition from the regulator's initial output to the new level consists of either a sudden jump, an asymptotic change, or a damped oscillation, depending on the nature of the feedback system.

While studying the regulation of DPN-dependent glutamate dehydrogenase (DPN-GluDH) [2] in yeast, we found that damped oscillations of the rate of enzyme synthesis can occur. Synthesis of the enzyme is repressed by ammonium ions [3,4]. When repressed cells are transferred to a medium containing glutamic acid as source of nitrogen, DPN-GluDH is synthesized as a result of "derepression". After some time, a new stationary content of DPN-GluDH, which is five to ten times higher, is attained. As is shown in Figure 1, the transition

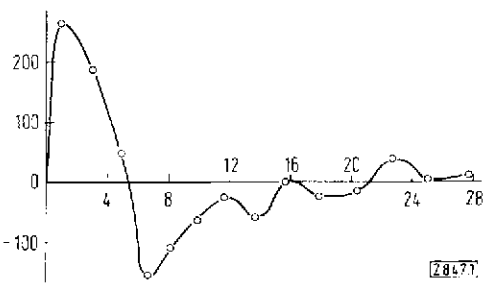

Fig. 1. Rate of change in the specific activity of DPN-dependent glutamate dehydrogenase in logarithmically growing cells of *Saccharomyces cerevisiae* R 59. The cells were grown on a medium with $NH_4^{\oplus}$ as sole source of nitrogen (for details see [4]), depleted of nitrogen and glucose for 3 h, and then administered L-glutamic acid and glucose at time zero.

Ordinate: Change in the specific activity per hour [activity units × (mg protein)$^{-1}$ × h$^{-1}$]. For definition of activity units see [4].

Abscissa: Time [h].

from the low to the high rate of synthesis of the enzyme proceeds by oscillations. These oscillations probably occur because the enzyme synthesis is part of a feedback system in which the ammonium ion acts as "co-repressor". The transition does not occur in a sudden jump or asymptotically because the feedback system has a time lag. This time lag is due to mainly two factors: 1. $NH_4^{\oplus}$ is released only slowly from the glutamic acid corresponding to the slow accumulation of DPN-GluDH; 2. free ammonium ions accumulate in the medium only after the $NH_4^{\oplus}$-dependent nitrogen reserves have been replenished. This interpretation is supported by our finding that oscillations occur only when nitrogen-deficient yeast cells are used for the experiments.

While the frequencies of oscillations observed for DPNH [5,6] and fermentation metabolites [7] are of the order of 1 min$^{-1}$, that for the enzyme synthesis is about 0.1–0.2 h$^{-1}$. Oscilla-

tions of this type may be involved in the mechanism of "biological clocks" [8], the periodicities of which lie in the range of hours or days.

## A New Synthesis of Quinoline Derivatives

By Dr. Richard R. Schmidt

Institut für Organische Chemie der Technischen Hochschule Stuttgart (Germany)

The high reactivity of phenylacetylene when treated with aromatic acid chlorides and Lewis acids [1,2] led us to expect that the use of aromatic *N*-phenylimide chlorides *(1)* would result in the formation of 2,4,6-triaryl-*N*-phenylpyridinium compounds. However, the course of the reaction corresponded to the quinazoline synthesis discovered by *Meerwein* et al. [3] and thus afforded quinolinium salts *(3)*. Electrophilic substitution on the benzene ring apparently proceeds faster than the further addition of a molecule of phenylacetylene onto the expected intermediate *(2)*.

The reaction is carried out in anhydrous chloroform and is strongly exothermic. The phenylacetylene is therefore added to the reaction mixture at a rate which just keeps the chloroform refluxing gently. After cooling, the quinolinium salt *(3)* produced is filtered off, washed with chloroform, and treated with 1:1 aqueous ammonia. The quinoline derivative *(4)* formed is

| Compound | M.p. [°C] | Yield [%] based on *(1)* |
|---|---|---|
| *(4a)*, Ar = Phenyl | 112 (112 [4]) | 56 |
| *(4b)*, Ar = *p*-Tolyl | 106 | 68 |
| *(4c)*, Ar = *p*-Chlorophenyl | 104 | 69 |
| *(4d)*, Ar = *p*-Nitrophenyl | 160 | 70 |

extracted with toluene. Comparison of the product *(4a)* with an authentic sample of 2,4-diphenylquinoline [4] confirmed the course of reaction.

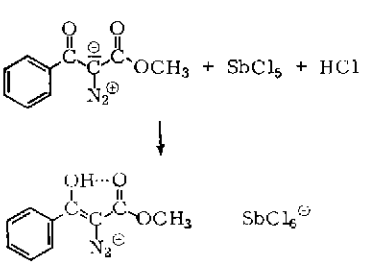
## Stable Aliphatic Diazonium Ions [1]

By Dr. K. Bott

Institut für Organische Chemie der Universität München (Germany)



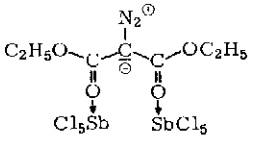
a) When triethyloxonium hexachloroantimonate is allowed to react with excess diazoacetic ester in ethylene dichloride the carbonyl oxygen of the ester is alkylated. The product, 2,2-diethoxyethylenediazonium hexachloroantimonate *(1)*, is stable at room temperature and is isolated by precipitation with carbon tetrachloride to give an about 50 % yield of the pure material as colorless crystals, m.p. 115 °C (decomp.).

*(1)*

The structure of *(1)* follows from its elemental analysis and its infrared spectrum. There is no absorption in the carbonyl region, and the N ⁻ N valence vibration of the diazo group is displaced to higher frequencies relative to that of diazoacetic ester, as is to be expected for a diazonium salt. This band is resolved and has two sharp peaks at 2180 and 2160 $cm^{-1}$, respectively.

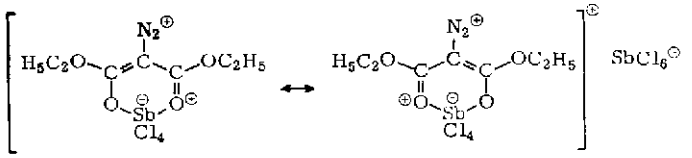
b) When hydrogen chloride is bubbled through an equimolar solution of methyl benzoyldiazoacetate and antimony pentachloride in methylene chloride, the diazonium salt *(2)*, which

*(2)*



is derived from the enol form of methyl benzoylacetate, crystallizes out as colorless needles, m.p. 114 °C (decomp.) in a sealed tube; the yield is 78 %.

The chlorine and antimony analyses of *(2)* conform with the proposed formula. Its small HCl vapor pressure and the stability of its diazonium group are suggestive of a hydrogen-bridged chelate. The absorption maximum of the N≡N valence vibration lies at 2180 $cm^{-1}$.



Reaction of *(2)* with a stoichiometric amount of triethylamine in methylene chloride reconverts it quantiatively into methyl benzoyldiazoacetate plus triethylammonium hexachloroantimonate.

c) When a solution of equimolar amounts of antimony pentachloride and diazomalonic ester in methylene chloride is saturated with HCl gas and carbon tetrachloride is added, a substance crystallizes out which surprisingly consists of two

moles of antimony pentachloride and one mole of diazomalonic ester. When the components are used in stoichiometric proportions, the same product is obtained in better yield (73 %) as colorless needles, m.p. 107–108 °C (decomp.) in a sealed tube.

(3)

(4)

Of the two possible structures (3) and (4) for this compound, the second is supported by the results of conductivity measurements in liquid $SO_2$ because the diazonium chelate (4) has salt-like character [2]. There is a sharp diazonium band in the infrared at 2220 $cm^{-1}$.

Received, October 23rd, 1964 [Z 844/671 IE]
German version: Angew. Chem. 76, 992 (1964)

[1] The preparation of a stable non-aromatic diazonium ion was described by *H. Reimlinger*, Angew. Chem. *75*, 788 (1963); Angew. Chem. internat. Edit. *2*, 482 (1963).

## Triphenylphosphineazine $Ph_3P{=}N{-}N{=}PPh_3$ [1]

By Prof. Dr. R. Appel and Dr. R. Schöllhorn

Anorganisch-Chemisches Institut der Universität Bonn (Germany)

The action of dibromotriphenylphosphorane on hydrazine [2] yields hydrazinotriphenylphosphonium bromide (1). It was observed by *Zimmer* [3] and independently by us [4] that deprotonation of (1) with sodium amide in liquid ammonia yields *N*-aminotriphenylphosphineimine (2), m.p. 116 to 120 °C (decomp.), which can also be designated as triphenylphosphine hydrazone.

$$[Ph_3P{-}NHNH_2]\,Br \xrightarrow{+\ NaNH_2} Ph_3P{=}N{-}NH_2 + NaBr + NH_3$$

(1) (2)

When (2) reacts with ketones, it does not yield phosphazines, but instead, oxygen exchange occurs and triphenylphosphine oxide and the hydrazones of the ketones are formed.

We found that the second amino group of the hydrazine also reacts with dihalogenotriphenylphosphoranes when these are heated with hydrazine dihydrochloride to 180–200 °C.

$$2\ Ph_3PCl_2 + N_2H_4{\cdot}2\ HCl \rightarrow [Ph_3PNHNHPPh_3]Cl_2 + 4\ HCl$$

(3), 80 %

Compound (3) decomposes quantitatively above its melting point (265 °C) to form triphenylphosphine, nitrogen, and hydrogen chloride. Deprotonation of (3) with strong bases such as alkali metal amides or potassium t-butoxide affords triphenylphosphineazine (4). Oxidation of (2) with elemental bromine also yields (4).

$$Ph_3P{=}N{-}N{=}PPh_3 \qquad (4)$$

Triphenylphosphineazine forms garnet red crystals, m.p. 184 °C, which dissolve readily in benzene, tetrahydrofuran, alcohols, and cyclohexane. Its solution in cyclohexane has an absorption maximum at 400 mμ. The substance is diamagnetic and is stable under nitrogen, but reacts rapidly with atmospheric oxygen to give triphenylphosphine oxide and nitrogen. When heated above its melting point, it decomposes quantitatively into triphenylphosphine and nitrogen. It reacts with hydrogen chloride to reform (3), and with methyl iodide to give only the monomethyl derivative, m.p. 140 °C (decomp.).

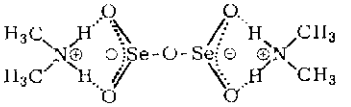
## Aminolysis of Selenium Dioxide [1]

By Doz. Dr. R. Paetzold and Dipl.-Chem. E. Rönsch



Institut für Anorganische Chemie der Universität Jena (Germany) and

Institut für Anorganische und Anorganisch-Technische Chemie der Technischen Universität Dresden (Germany)

Ammonolysis of selenium dioxide results in numerous products (including selenium nitride and elemental selenium) owing to redox and condensation reactions [2,3]; this makes it difficult to identify the primary solvolysis reactions. When dimethylamine is used instead of ammonia, the reaction should come to a standstill directly after the solvolysis.

We treated selenium dioxide at −20 °C with pure dimethylamine and with its solution in ether. Complete reaction occurs at a molar ratio $SeO_2:(CH_3)_2NH$ of 3:4. In both experiments the selenium dioxide dissolves with formation of two liquid phases.

The heavier phase is a thick resin which melts at about −35 °C. It is readily soluble in water, slightly soluble in alcohol, but insoluble in all organic solvents. Its Se content is 27.8 % and its $(CH_3)_2N$ content is 48.1 %. No N–H valence bands from isolated $(CH_3)_2NH_2^{\oplus}$ ions can be detected in the infrared spectrum, but there are strong broad bands from N–H···O= bridges with maxima at 2450, 2780, and 2970 $cm^{-1}$. The bands for the $SeO_2$ valence vibrations lie about 30 $cm^{-1}$ lower than those in the spectra of alkali diselenites [4]. This information indicates the structure shown in Formula (1).

(1)

In order to confirm these results, we also prepared dimethylammonium diselenite by reaction of an aqueous solution of $H_2SeO_3$ with dimethylamine in a molar ratio of 1:1. It has the same properties (melting point, Se and $(CH_3)_2N$ contents, infrared spectrum) as compound (1).

A colorless crystalline compound, m.p. 42 °C, can be separated from the lighter phase at −20 °C. Another component, a liquid boiling at 32.5 °C/14 mm, can be isolated at room temperature. The selenium and $(CH_3)_2N$ analyses as well as the infrared spectrum of the crystalline product indicate a formula $[(CH_3)_2N]_2SeO$; the data for the liquid suggest the

formula $[(CH_3)_2N]_2Se$. The solid is thermolabile, being converted with loss of oxygen into the liquid $[(CH_3)_2N]_2Se$. We have also prepared the solid $[(CH_3)_2N]_2SeO$ from $ScOCl_2$ and dimethylamine [5].

$[(CH_3)_2N]_2SeO$ and $[(CH_3)_2NH_2]_2Se_2O_5$ *(1)* are always formed together in a 1:1 molar ratio. Thus, the following equation can be written for the aminolysis of selenium dioxide:

$$3\ SeO_2 + 4\ (CH_3)_2NH \rightarrow [(CH_3)_2N]_2SeO + [(CH_3)_2NH_2]_2Se_2O_5$$

It therefore appears that not every Se-O-Se bridge in the selenium dioxide undergoes aminolysis. Terminal anionic groups apparently increase the stability of adjacent Se-O-Se bridges towards solvolysis. This interpretation is supported by the fact that the diselenites $(NH_4)_2Se_2O_5$ and $K_2Se_2O_5$ are resistant to liquid dimethylamine at room temperature and even to liquid ammonia.

## Indications of the Transient Occurrence of 3,4-Dehydropyridine N-Oxide and 3,4-Dehydroquinoline N-Oxide

By Doz. Dr. Th. Kauffmann and cand. chem. R. Wirthwein

Institut für Organische Chemie der Technischen Hochschule Darmstadt (Germany)

The reaction of 2-chloropyridine *N*-oxide with $KNH_2$ in liq. ammonia leads mainly to undefined products plus 5 % 2-aminopyridine *N*-oxide and 1 % 3-aminopyridine *N*-oxide; the latter two products are suggestive of the intermediate occurrence of 3,4-dehydropyridine *N*-oxide *(1)*. In contrast, 3-chloropyridine *N*-oxide yields only the 3-amino compound [1]. We heated 3-chloropyridine *N*-oxide for 8 days with piperidine in anhydrous benzene at 100 °C and obtained ca. 80 % of the starting material, non-identified products, and 3-piperidinopyridine *N*-oxide (82 % [2]; picrate has m.p. 189 °C), plus 4 % [2] 4-piperidinopyridine *N*-oxide (m.p. of picrate 153–154 °C), but could not detect the 2-piperidino isomer. Analogously, when 3-bromoquinoline *N*-oxide was heated with piperidine at 115 °C for three days, 22 % [2] 4-piperidinoquinoline *N*-oxide [3] (m.p. of picrate 132–133 °C) was isolated in addition to a small amount of starting material, non-identified products, and 3-piperidinoquinoline *N*-oxide (20 % [2]; m.p. of picrate 165–166 °C), but again no 2-piperidino isomer was found.

The formation of the 4-piperidino compounds indicates an elimination/addition mechanism for the substitution proceeding via the heterocyclic *N*-oxides *(2)* and *(3)* [4].

*(1)* *(2)* *(3)*

In contrast to the 3-halogeno compounds, 2- and 4-chloropyridine *N*-oxides and 4-chloroquinoline *N*-oxide appear to react completely according to the normal addition/elimination mechanism [5] when heated in piperidine to about 100 °C, for only the "non-rearranged" substitution products, *viz.* 2-piperidinopyridine *N*-oxide (m.p. 124.5–125.5 °C), 4-piperidinopyridine *N*-oxide, and 4-piperidinoquinoline *N*-oxide are formed in almost quantitative yield.

## A Simple Nitrovinylation Reaction

By Doz. Dr. Th. Severin and Apotheker B. Brück

Institut für Pharmazeutische Chemie und Lebensmittelchemie der Universität Marburg/Lahn (Germany)

β-Dimethylaminonitroethylene *(2)* can be readily prepared from nitromethane and dimethylformamide diethylacetal [1]. We have found that *(2)* reacts with C–H-acidic compounds *(1)* in the presence of alkoxides by elimination of dimethylamine to give salts of substituted nitropropenes *(3)*.

*(1)* *(2)*

*(3a)*, X = $CO_2CH_3$ Y = $CO_2CH_3$
*(3b)*, X = CN Y = CN
*(3c)*, X = CN Y = $C_6H_5$
*(3d)*, X = $CH_3CO$ Y = H

Stoichiometric amounts of the reactants are heated together in ethanol for 3–5 min at about 70 °C. Compound *(3d)* is made preferably by adding a hot solution of potassium ethoxide in ethanol to a refluxing solution of *(2)* in acetone. The yields are always over 75 %. The products are purified by recrystallization from methanol, ethanol, or acetonitrile. Analogous reaction of *(2)* with phenylmagnesium bromide affords ω-nitrostyrene in 50 % yield. The action of acids on the salts *(3a)–(3d)* produces unstable oils, which are difficult to purify. 1,1-Disubstituted 3-nitropropenes have already been prepared by the reaction of nitromethane with ethoxymethylene derivatives of some β-dicarbonyl compounds [2].

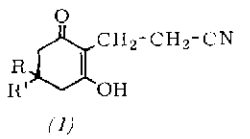
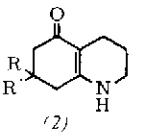
## Synthesis of 5-Oxo-octahydroquinolines and Their Reduction with Lithium Aluminum Hydride



By Dr. H. Reinshagen [1]

Institut für Organische Chemie
der Technischen Hochschule Darmstadt (Germany)



When dissolved in aqueous ammonia, 2-(β-cyanoethyl)-4,5-dihydroresorcinol *(1a)* and its derivatives *(1b)* and *(1c)* [2,3] rapidly absorb 2 moles of hydrogen over Raney nickel, being thereby converted into the corresponding primary amines, which are not isolated but undergo spontaneous dehydration to form 5-oxo-$\Delta^{9(10)}$-octahydroquinoline *(2a)* and its 7-methyl *(2b)* and 7,7-dimethyl derivatives *(2c)* in yields of 95–98 %. On the basis of their infrared spectra in KBr and of their NMR spectra, these new vinylogous amides are in the form of enol betaines *(4)* in the solid state, but occur as mixtures of the forms *(2)* and *(3)* in chloroform.

Ketones *(2a)* and *(2b)* react with methyl iodide to give the hydroiodides of the *O*-methylated bases [4].

Reduction of *(2a)* with excess lithium aluminum hydride produces $\Delta^{1(9)}$-octahydroquinoline *(5)*; analogous reduction of *(2b)* and *(2c)* yields the $\Delta^{5(10)}$-octahydroquinoline derivatives *(6)*. Hydrogenation of the hydrobromides of the bases *(5)* and *(6)* with $Pd/BaSO_4$ in water or ethanol affords mixtures of *cis*- and *trans*-decahydroquinoline, of the 7-methyl derivatives, and of the 7,7-dimethyl derivatives, respectively.

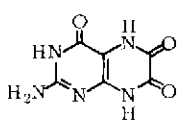
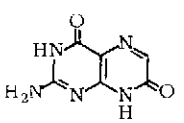
# CONFERENCE REPORTS

## Colloquium in Honor of H. Bredereck



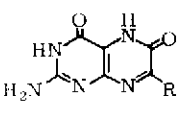
A colloquium was held on May 29th, 1964 in Stuttgart (Germany) on the occasion of the 60th birthday of Professor *Hellmut Bredereck*.

From the lectures:

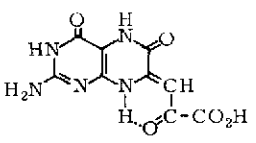


### Recent Work on Natural Pteridines

*W. Pfleiderer*, Stuttgart (Germany)

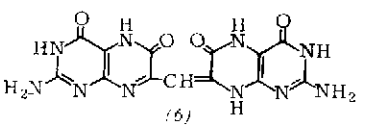


The best-known wing pigments of the *Pieridae* butterflies are the colorless compounds leucopterin *(1)* and isoxanthopterin *(2)*, the yellow compounds xanthopterin *(3)* and chrysopterin *(4)*, and the orange compound erythropterin *(5)*.

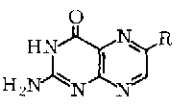


*(1)*

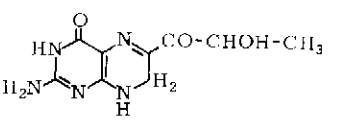
*(2)*



*(3)*, R = H
*(4)*, R = $CH_3$



*(5)*



Since pure erythropterin is orange, the observation that the pierid *Appias nero* native to Java and Ceylon has intensely red wings initiated thorough investigations of the constituents of the wing pigments of tropical and indigenous butterflies. It was found that the deep pigmentation of *A. nero* was due to the presence of the dark-red compound pterorhodin *(6)*.

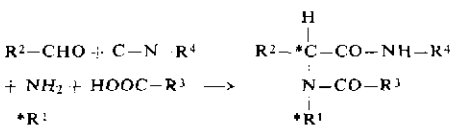
*(6)*

*(7)*, R = H
*(8)*, R = $CO_2H$

*(9)*

Two further compounds, *viz.* pterin *(7)* and pterin-6-carboxylic acid *(8)*, were isolated from the wings of *A. nero*; in addition, a very labile, yellow-fluorescent substance was separated from the other pteridines, concentrated, and identified as sepiapterin *(9)*. A number of other blue-fluorescent compounds were also detected but, owing to their low concentration, could not be isolated; their fluorescence and $R_f$ values indicate that they are 6-polyhydroxyalkylpterins. These compounds and *(9)* are probably intermediates in the conversion of purine-type pteridine precursors into the wing pigments, thus supporting the biogenetic scheme proposed by *Weygand* et al.

Sepiapterin and other pterins were also detected in the South American pierid *Catopsilia argante* and in the orange-tip butterfly *Euchloe cardamines*.



Chromatographic separation of the pigments from the brimstone butterfly (*Gonepteryx rhamni*) showed that the chrysopterin *(4)* isolated from this source in 1936 was not a natural butterfly pigment but was a hydrolysis product from the erythropterin which is located in its discoidal spot.

## Asymmetric Induction during the Synthesis of Amino Acids by the Passerini-Ugi Reaction

*H. Herlinger, D. Rücker,* and *H. Kleimann,*
Stuttgart (Germany)

In the presence of asymmetrically inducing components, such as optically active carbonyl compounds or primary amines, the Ugi variant of the Passerini reaction [1, 2] gives optically active amino-acid derivatives. On asymmetric 1,3-induction with D-(+)-α-methylbenzylamine in the system isobutyraldehyde/benzoic acid/t-butyl isocyanide at −70 °C with concentrations of 1 mole/kg of each of the components in methanol (reaction conditions A), a conformationally determined difference of 0.7–1.0 kcal/mole between the free energies of activation of the diastereoisomeric transition states results in formation of predominantly the L-(+)-valine derivative *(1)*. At 0 °C with concentrations of 0.1 mole/kg (reaction conditions B), however, the D-(−)-valine derivative *(2)* is formed in preponderance. Application of this synthetic method to n-butyraldehyde and L-(−)- or D-(+)-α-methylbenzylamine under reaction conditions A gives the D-(−)- and L-(+)-norvaline derivatives *(3)* and *(5)*, respectively. Under reaction conditions B, the L-(+)- and D-(−)-norvaline derivatives *(4)* and *(6)* are formed predominantly.

On combined asymmetric 1,2- and 1,3-induction, the D-(−)-*allo*-isoleucine derivatives *(7)* and *(10)*, and the L-(+)-isoleucine derivatives *(8)* and *(9)* were prepared from L-(+)-methylethylacetaldehyde and L-(−)- or D-(+)-α-methylbenzylamine, respectively. The reactions give yields of 90–95% and are 70–75% stereospecific. The pure amino-acid derivatives can be readily isolated from the diastereoisomeric mixtures by crystallization from high-boiling petroleum ether. The L-(+)- and D-(−)-amino acids can be obtained by hydrolysis with ca. 15% hydrochloric acid.

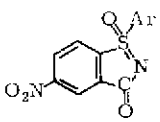
## Heterocyclic Compounds with Endocyclic Sulfur-Nitrogen Double Bonds

*A. Wagner,* Stuttgart (Germany)



*N*-(*o*-Tolylthiophenyl)-*O*-ethylisourea hydrochloride can be cyclized by dehydrogenation with bromine and sodium methoxide in absolute methanol to give 1-tolyl-3-ethoxy-1*H*-1,2,4-benzothiadiazine *(1)*. In contrast to 1-substituted 1*H*-1,2,4-benzothiadiazin-3-ones, *(1)* is not hydrolysed by aqueous acids or alkalis. 1-Substituted 1*H*-1,3,2-benzodithiazole 3,3-dioxides can be oxidized with potassium permanganate to the corresponding 1-substituted 1*H*-1,3,2-benzodithiazole 1,3,3-trioxides *(2)*, X = $NO_2$, H, or Hal. The S=N double bonds in *(2)* are stable to hydrolysis. The 1-phenyl derivatives of *(2)* can be converted with nitrating mixture at 100 °C into the 1-(*m*-nitrophenyl) derivatives in good yield. The sulfoximino group is thus *meta*-directing. When in *(2)* X = $NO_2$ or Cl, it can be replaced by nucleophilic reagents ($RO^-$, $RS^-$, $N_3^-$, $NH_2R$, or $NH_2NH_2$). Similarly, 5-nitro-1-aryl-1*H*-benzisothiazol-3-one 1-oxides *(3)* can be nitrated in the aryl residue with nitrating mixture in the position *meta* to the sulfoximino group. Compounds *(3)* usually react with alkoxides with ring opening and formation of 2-alkoxy-5-nitrobenzamides; only small amounts of 5-alkoxy-1-aryl-1*H*-benzisothiazol-3-one 1-oxides [*(3)* with $NO_2$ replaced by RO] are formed by this reaction.

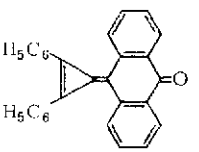
## Investigations on Cyclopropenes



*B. Föhlisch,* Stuttgart (Germany)

As part of a series of experiments directed towards synthesis of compounds containing the methylenecyclopropene structure, preliminary experiments on the preparation of bicyclo-[3,1,0]hexa-1,3,5-triene *(1)* were carried out. Hofmann degradation of the quaternary ammonium salt derived from 6-aminobicyclo[3,1,0]hex-2-ene and methyl iodide resulted in destruction of the bicyclic ring system to give benzene [1]. Similarly, thermal decomposition of trimethyl(bicyclo[3,1,0]-hex-6-yl)ammonium hydroxide gave 1,3-cyclohexadiene.

Substituted tetraarylcyclopropenes were obtained by alkylation of activated aromatic compounds with triphenylcyclopropenylium bromide. An example of the reaction of disubstituted cyclopropenylium salts with aromatic compounds is the reaction of anthrone with diphenylcyclopropenylium salts; this gives rise to 10-(diphenylcyclopropenylidene)anthrone *(2)* – a stable compound with a methylenecyclopropene structure.

## Heterocyclic Diazo-azo Compounds as a Source of Nucleophilic Carbenes [*]

*H. Balli*, Marburg/Lahn (Germany)

Heterocyclic-diazo-azo compounds (tetrazo compounds) *(2)*, a new class of mesomeric compounds of the benzthiazole series, can be prepared from the azidinium salts *(1)* [1] and lithium azide at ca. −50 °C.

The "azohomologous" diazo compounds *(2)*, which are explosive in the dry state at room temperature, are protonated by $HBF_4$ at −50 °C with elimination of nitrogen (2 $N_2$) to give the benzthiazolium salts *(5)*. At ca. −10 °C in tetrahydrofuran or dimethylformamide, compounds *(2)* undergo controlled decomposition to give the nucleophilic heterocyclic carbenes *(3)*; these can be trapped by tetracyanoethylene, azidinium salts *(1)*, and diazonium salts to give respectively, cyclopropane derivatives, triazatrimethinecyanines [2,3] and quaternary heterocyclic azo dyes [3,4].

The kinetics of the process *(1)* → *(2)* → *(3)* → triazatrimethinecyanine (X = H) confirm the existence of the short-lived intermediate *(3)* (cf. in contrast [4]). As shown in the case of X = $NO_2$, a true dimerisation of the nucleophilic carbenes, *(3)* → *(4)*, could not be observed (cf. in contrast [4]). Compound *(4)* may be readily prepared *via (5)* or *(6)*. The configuration of *(4)* is unknown.

## Electrochemical Reactions at Semiconductor Surfaces

*H. Gerischer*, München (Germany)

The role that the bonding state of the electrons in a solid plays in the mechanism of surface reactions may be most clearly followed when the electrons are direct reactants. This can be demonstrated by electrochemical reactions such as anodic dissolution, cathodic evolution of hydrogen, or other redox reactions at the surfaces of semiconductors. During anodic dissolution of Ge, Si, and GaAs, holes are consumed in the rate-determining step, *i.e.* the release of surface atoms is initiated by donation of the bonding electrons to vacant electronic states in the valence band. In germanium, some of the four electrons per surface atom, which are given free from bonding states during oxidation, are transferred to the conduction band. In semiconductors with a larger band gap, *e.g.* Si or GaAs, the latter step is no longer possible and the release of atoms from the lattice results solely by uptake of holes.

In redox reactions one can discriminate between electron transfers involving either electrons of the conduction band or electrons of the valence band. For example, electrons from the conduction band are consumed during cathodic hydrogen discharge at all the three semiconductors mentioned. On the other hand, reduction of $Fe^{3+}$ ions at these semiconductors takes place by uptake of electrons from the valence band.

Comparison of the work functions for the emission of electrons from the conduction band, the valence band, and the components of the redox system suggests that electron exchange in the conduction band should be favored in redox systems with reducing properties, *i.e.* with a negative redox potential and a correspondingly lower electron affinity. Electron exchange in the valence band is preferred for redox systems with high redox potential, *i.e.* with a greater electron affinity. This theoretically expected result is confirmed by experimental findings.

[GDCh-Ortsverband Freiburg-Südbaden (Germany), July 10th, 1964] [VB 843/162 IE]

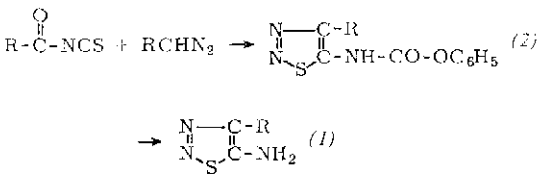
# SELECTED ABSTRACTS



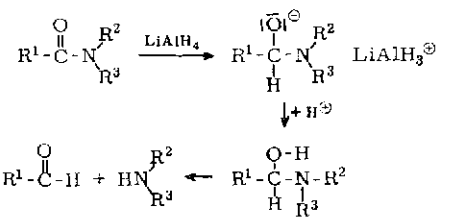
**Isocyanates of sulfuric acid react with dimethyl sulfoxide,** according to *R. Appel* and *H. Rittersbacher*, to form sulfuryldimethylsulfimines with elimination of $CO_2$. Amine oxides form adducts with sulfuryl di-isocyanate, which can be split up into their components again by chemical means. A colorless oil, which decomposes explosively above 0 °C, can be isolated from the reaction of the isocyanates of sulfuric acid with dimethyl sulfoxide under mild conditions below 0 °C. Sulfurylbisdimethylsulfimine *(1)*, m.p. 177 °C, is formed in 54 % yield, with evolution of $CO_2$ and heat, when sulfuryl di-isocyanate is treated with dimethyl sulfoxide at 20 °C.

$$O_2S(NCO)_2 + 2\ OS(CH_3)_2 \rightarrow (CH_3)_2S{=}N{-}SO_2{-}N{=}S(CH_3)_2$$
*(1)*

Dimethylsulfiminosulfuric acid, m.p. 171 °C, is formed in 75 % yield by hydrolysis of the product obtained from chlorosulfonyl isocyanate and dimethyl sulfoxide. The adduct of pyridine *N*-oxide and sulfuryl di-isocyanate melts at 138 to 139 °C, the trimethylamine *N*-oxide adduct melts at 68 °C. Water decomposes the adducts, occasionally with the appearance of flames, to give sulfamide, $CO_2$, and the *N*-oxide. / Chem. Ber. *97*, 852 (1964) / −W. [Rd 996/280 IE]

**The adsorption of cyanine dyes onto silver halides** has been investigated by *J. F. Padday*. The surface occupied by dyestuff molecules adsorbed on different silver halides is not always the same; this causes problems in the use of such dyes for estimating surface areas. The absorption spectrum of the adsorbed dyestuff also depends on the silver halide carrier and furthermore on the degree of coverage of the surface. Different absorption bands were found which can be ascribed to monomeric (M bands), dimeric (D or H bands), and polymeric (J bands) species of the dyestuff. The occurrence of H or J bands depends practically exclusively on the conditions of adsorption, and not upon the degree of coverage of the surface. It is therefore concluded that the association theory must be reexamined. / Trans. Faraday Soc. *60*, 1325 (1964) / −Hz. [Rd 113/300 IE]

**5-Amino-1,2,3-thiadiazoles** were prepared by *J. Goerdeler* and *G. Gnad*, by treating acyl isothiocyanates with diazoalkanes and carefully deacylating the *N*-phenoxycarbonylamines *(2)* thus obtained with weak bases in aqueous acetone. Other acyl groups cannot be removed without changing the structure of the ring. The parent compound *(1)* [R = H], m.p. 152 °C, is made by careful hydrolysis of 5-phenoxycarbonylaminothiadiazole. Other diazoalkanes give *(1)* with substituents in the 4-position, *e.g.* 4-methyl-1,2,3-thiadiazole, (m.p. 120 °C) and 4-ethoxycarbonyl-1,2,3-thiadiazole, m.p. 126 °C,



which were obtained from diazoethane and diazoethyl acetate, respectively. The amino group can be sulfonated, acylated, nitrosated, and diazotized. Some 5-substituted 1,2,3-thiadiazoles were obtained via the diazotized compounds. / Tetrahedron Letters *1964*, 795 / –W. [Rd 997/281 IE]

**Streptomycin alters the mechanism by which the messenger code is red,** according to *J. Davies, W. Gilbert*, and *L. Gorini*. During polypeptide synthesis *in vitro* with the system of *Matthaei* and *Nirenberg*, streptomycin exerts an inhibitory effect on protein synthesis by upsetting the mechanism by which the base sequence in the messenger RNA at the ribosomes is translated into the amino-acid sequence of the protein. The incorporation of phenylalanine into acid-insoluble material by the synthetic messenger polyuridylic acid is inhibited 50–75 % by streptomycin, whereas the incorporation of isoleucine (code UUA, UAA, CAU) is increased up to twentyfold. This effect depends upon the magnesium-ion concentration. The site of reaction of the streptomycin is the 30-S subunit of the 70-S ribosome. A cell-free system containing 30-S subunits from streptomycin-resistant bacteria does not exhibit this effect. Ribosomes which are resistant to streptomycin are not necessarily resistant to kanamycin and to neomycin although these substances act like streptomycin. The translating mechanism requires a specific conformation of the center on the ribosomes which attaches the transfer RNA to the messenger RNA. Streptomycin can probably modify this center in such a way that the "wrong" transfer RNA is accepted thus leading to incorporation of the "wrong" amino acid, *i.e.* U is read off as A, for example. Mutations can apparently alter the ribosome in such a way that it becomes insensitive to streptomycin or even requires streptomycin. / Proc. nat. Acad. Sci. U.S.A. *51*, 883 (1964) / –Sch.

[Rd 142/329 IE]

**Lithium aluminum hydride cleaves proline linkages in peptides,** as *M. A. Ruttenberg, T. E. King*, and *L. C. Craig* discovered when they treated peptides containing proline with $LiAlH_4$ in tetrahydrofuran. Tertiary amides are reduced much faster than primary or secondary amides under these conditions which do not lead to racemization. Complete solubility of the peptide in the anhydrous solvent does not appear to be necessary. The yields of cleavage products lie between 30 and 100 %. The products are a peptide with *N*-terminal proline and a peptide with a *C*-terminal aldehyde group, probably formed by the following reactions:

/ Biochemistry *3*, 758 (1964) / –Sch. [Rd 135/322 IE]

# BOOK REVIEWS

**Gmelins Handbuch der anorganischen Chemie** (Gmelin's Handbook of Inorganic Chemistry), 8th completely revised edition. Published by the Gmelin-Institut für anorganische Chemie und Grenzgebiete in the Max-Planck-Gesellschaft zur Förderung der Wissenschaften. Initiated by *R. J. Meyer*, continued by *E. H. Erich Pietsch*. Verlag Chemie, GmbH, Weinheim/Bergstr.

**System No. 34: Mercury.** Part A, Vol. 2 (Electrochemistry. Chemical Behavior. Alloys). 1962, IV, XL, 709 pp., 285 figs., cloth, DM 534.– (about $135.–). Revised by *Erna Brennecke, Gertrud Glauner-Breitinger, Vera Haase, A. Kunze, K. Rehfeld, Ph. Stiess, K. Swars*, and *Ursula Trobisch-Raussendorf*.

Vol. A1 (466 pp., 53 figs.), which was published in 1960, dealt with the history, occurrence, preparation, and physical properties of mercury; the present Volume A2 (709 pp., 285 figs.) is concerned with its electrochemistry (316 pp.), chemical behavior (102 pp.), and alloys (291 pp.).

The chapter on the electrochemistry of mercury is naturally particularly comprehensive and comprises about 45 % of the present Volume. It opens with a discussion of the normal potentials of the redox systems $Hg/Hg_2^{2+}$, $Hg/Hg^{2+}$, and $Hg_2^{2+}/Hg^{2+}$ in aqueous and non-aqueous solutions; this is followed by sections on the position of mercury in the electrochemical series, its electrolytic solution pressure, its ion mobility, and its potentials with respect to 65 electrodes and over 214 galvanic cells described in the literature. Detailed consideration is given to mercury electrodes (such as $Hg/Hg_2O$, Hg/HgO, $Hg/Hg_2X_2$ [1], $Hg/HgX_2$ [1], $Hg/Hg_2(I_2O_3)$, Hg/HgS, $Hg/HgSO_4$, and $Hg/Hg_2CO_3$), and in particular to the $Hg/Hg_2Cl_2$ electrode (calomel electrode), the most important reference electrode. The section on the electrocapillary curves of mercury deals with both experimental results in aqueous and non-aqueous media and their theoretical interpretation.

In the section on the capacity and structure of the Hg/solution phase-boundary layer, consideration is also given, in view of the fundamental importance of this problem, to papers which appear essential to the presentation of the theory although they deal with other electrode metals. This section is supplemented and illustrated by many figures, descriptions of the methods of determining the phase-boundary capacity, and many individual data on measured specific capacities of Hg electrodes. The discussion of the mercury dropping electrode (polarography) does not attempt to give a complete account of all the available data, in view of the explosive increase in the pertinent literature over the past few years. Instead, reference is made to the review literature, and special attention is given to the behavior of mercury salts at the mercury dropping electrode, with quotation of the appropriate half-wave potentials. The details given of investigations of the hydrogen (deuterium) overvoltage on mercury are justified by the technical importance of this phenomenon. In this connection, and in connection with the theory of overvoltage, the behavior of mercury as an anode and a a cathode is considered. A discussion of the electro-

[1] X = F, Cl, Br, or I.

lytic deposition of mercury, which is of theoretical interest although it has no industrial importance, deals with deposition from solutions and melts. Finally, the mercury coulometer (voltameter), which is used to measure quantities of electricity, is discussed.

The chapter on the chemical behavior of mercury is subdivided into sections on elemental mercury and mercury ions ($Hg_2^{2+}$, $Hg^{2+}$). In both cases, the behavior towards both elements and inorganic and organic compounds is discussed. Particular mention should be made of the discussion of the behavior of metallic mercury toward acids, the general considerations on the existence of the characteristic diatomic Hg(I) ion $Hg_2^{2+}$, and its formation from and disproportionation into Hg + $Hg^{2+}$, and of the data on the degree of dissociation and complex formation of Hg(II) compounds. Among the ionic reactions of mercury, those which are suitable for analytical purposes are discussed in detail, so that a special chapter on the detection and determination of mercury has proved unnecessary, particularly in view of the "Fresenius-Jander" volumes on this subject.

The chapter on alloys of mercury is very extensive (more than 40 % of the volume) in view of the wide practical importance of amalgams. In accordance with the Gmelin "last-place" principle, all the alloys of mercury with metals of System Numbers lower than that of mercury are discussed, *i.e.* alloys with the metals Sb and Bi from the 5th main group, with Li, Na, K, Rb, and Cs from the first main group (including ammonium amalgam), with the metals Be, Ca, Sr, and Ba from the 2nd main group, and with Zn and Cd from the 2nd sub-group. Contrary to the Gmelin principle, the Tl alloys are also included here, and the Mg alloys, which should be dealt with here, are discussed earlier in the System No. "Magnesium." Alloys with metals of System Nos. higher than that of Hg are dealt with in the relevant System Numbers. Thus, data on alloys with Al, Ga, In, Ge, Ti, Zr, Th, Cr, Mo, W, U, Re, Fe, Co, Ni, platinum metals, and Au appear in volumes which have already been published, whilst the data on alloys of mercury with Ra, Ac, the rare earths, Sn, Pb, Hf, V, Nb, Ta, Pa, Mn, Tc, Cu, Ag, and the transuranium elements are still forthcoming. The chapter on amalgams includes phase diagrams and information on the formation and production, physical properties, and electrochemical behavior of the alloys and on intermetallic compounds and multicomponent alloys.

**System No. 58: Cobalt.** Part B, Supplement, Vol. 1 [Cobalt(I) and Cobalt(II) Compounds]. 1963, IV, XVIII, 314 pp., 48 figs., cloth, DM 241. (about $61.–). Revised by *K.-Ch. Buschbeck, H. Feicht, R. Gagarin, G. Krause, Irmingard Kreuzbichler, H. Lehl, W. Schaffernicht,* and *Edith Schleitzer-Steinkopf.*

This supplement, which is published in two volumes, is a continuation of the main volume "Cobalt, Part B" (376 pp., 2 figs.), which appeared in 1930. It embraces all the literature up to the end of 1949, with extensive supplements for the period 1950–1960, taking account of the developments right up to the present. This Volume 1 (314 pp., 48 figs.) deals with the complexes of mono- and divalent cobalt with neutral and inner complex-forming ligands; complexes of trivalent cobalt will be the subject of the second volume, which is still forthcoming. Recent literature on compounds of cobalt with acidic ligands (including aquo-complexes and hydrates) has already been evaluated in the supplement volume "Cobalt, Part A" (886 pp., 188 figs.) published in 1961 to bring the main volume "Cobalt, Part A" (502 pp., 32 figs.), published in 1931/32, up to date.

The supplement Volume B 1 which is reviewed here begins with short introductions and observations (5 pp.) on recent reviews (monographs, congress reports), on the arrangement of the material, and on general questions such as complex-formation constants, thermodynamic data, chelation effects, stability series, light absorption, and magnetic properties.

This is followed by a discourse on Co(I) complexes, which have only recently become known, so this only occupies 5 pp. The majority of the complexes are isocyanides of the type $[Co(RNC)_5]X$ containing the $[Co(RNC)_5]^{\oplus}$ cation, which is isoelectronic with $Fe(CO)_5$.

The major part of the volume (304 pp.) is devoted to Co(II) complexes. These are subdivided according to the complexing ligands, inorganic ligands ($H_2O$ [2], $NH_3$, $N_2H_4$) being dealt with first in 13 pp.; the remaining 291 pp. are devoted to organic ligands (compounds containing nitrogen, oxygen, sulfur, selenium, phosphorus, and arsenic). The discussions cover not only substances which have been isolated, but also those which have only been characterized by their stability constants. The data include all the factual material published to date, *i.e.* the structure, preparation, and physical and chemical properties, as well as the theoretical ideas proposed to explain the properties.

The organic ligands are subdivided into monoamines, diamines, polyamines, heterocycles with the heteroatoms O, N, and S (which are in turn subdivided according to the number of heteroatoms), alcohols, ethers, aldehydes, ketones, quinones, amino alcohols, amino acids, amine-*N*-polyacetic acids, cyanides, isocyanides, Schiff bases, azo compounds, formazans, oximes, urea, compounds containing sulfur and selenium, phosphines, and arsines. The widely studied complexes with ethylenediamine, phthalocyanine, pyridine, bipyridyl, quinoline, phenanthroline, histidine, acetylacetone, ethylenediaminetetraacetic acid, isocyanides, bis-*N*,*N'*(salicylidene)-ethylenediamine, dimethylglyoxime, dimethyl sulfoxide, phosphines, and arsines are discussed in particular detail. In the case of tetracoordinated cobalt complexes, consideration is given to the questions of their tetrahedral or planar structure and of their ability to take up oxygen reversibly. Their light absorption and optical activity are also considered.

Since it is difficult to find a given compound in the confusing superabundance of complexes discussed, the second volume of the supplement, which is due to appear in the near future, will contain indices of the ligands, arranged both alphabetically and according to their empirical formulae, an innovation which will be highly welcome.

**System No. 60: Copper.** Part D (Electrical Properties of Copper Oxides). 1963, IV, X, 168 pp., 136 figs., cloth, DM 134.– (about $ 34.–). Revised by *W. A. v. Meyeren* and *H.-G. Wuttke.*

Here 152 pp. and 126 figs. are devoted to Cu(I) oxide, and 16 pp. and 10 figs. to Cu(II) oxide. Apart from the electrical behavior proper, the thermoelectrical and photoelectrical properties are discussed. The discussion of CuO has for no apparent reason been inserted in the middle of the material on $Cu_2O$, under a heading which, owing to the size of the type, gives the false impression that all the subsequent material is a sub-chapter of the chapter "Copper(II) Oxide". It would have been better here to add the short CuO section at the end of the complete discussion of $Cu_2O$, as a final chapter to Part D.

The data on copper(I) oxide are divided – apart from discussions of its general electrical data (such as dielectric constants and contact potential), thermoelectric behavior (thermoelectric force, Peltier heat), and photoelectric behavior (photoemissive and photoconductive effects) – into two subchapters: "Electrical Conductivity of Copper(I) Oxide with Homogeneous Defect Distribution" (59 pp.) and "Electrical Conductivity of Copper(I) Oxide with Non-homogeneous Defect Distribution" (76 pp.).

The first subchapter (homogeneous defect distribution) deals with investigations which were of fundamental importance to the development of the theory and technology of semiconductors during the past decades, since $Cu_2O$ – or $Cu_xO$ ($x \ll 2$) – can be obtained relatively easily, in comparison with Se, the second standard substance for the investigation of semiconductors, from a metal which is readily obtainable in a

[2] The ligand $H_2O$ is only referred to, since the aquo-complexes of divalent cobalt are included in the supplementary volume "Cobalt, Part A" as Co(II) salts containing water of hydration.

state of high purity. The fact that, during the Second World War, the roles of Se and $Cu_xO$ as standard semiconductors were to a large degree taken over by Ge and Si in no way detracts from the importance of these investigations. The electrical conductivity at room temperature and at higher and lower temperatures is first discussed; the point of inflexion and other anomalies of the conductivity-temperature curve are indicated, and the mathematical representation of the temperature-dependence and the use of the temperature-dependence (resistance thermometer, high-resistance bolometer, pyroelectric conductor) are given. Considerable space is then devoted to the influence of the conditions of preparation of $Cu_xO$ on its electrical properties: the course of oxidation of Cu to $Cu_xO$ and CuO, dependence of the electrical conductivity on various factors (such as heat treatment, aging in air, packing density, grain size, layer thickness, mechanical surface-treatment, the action of pressure, surrounding gaseous and liquid media, stoichiometric composition, admixtures, electrodes, field strength), breakdown problems, surface conductivity, contact resistance (coherer effect, microphone effect), and magnetic resistance variation. This part is completed by observations on the mechanism of electrical conductivity according to the energy band model.

The second subchapter (non-homogeneous defect distribution) is concerned with the important field of the $Cu_2O$ rectifier, *i.e.* the rectification of alternating current at a $Cu_2O$–Cu contact, a phenomenon which was observed over 90 years ago but which was only applied technically and correctly interpreted theoretically at a much later date. This part deals first with the behavior of rectifier plates toward d.c. and a.c., the circuits and efficiency in the rectification of a.c., the loading capacity, reversible and irreversible changes under load, and the influence of moisture, impurities, and the conditions of production. This is followed, owing to the practical importance of the $Cu_2O$ rectifier, by detailed data on the production technology (pretreatment of Cu and oxidation to $Cu_2O$, annealing and cooling of the $Cu_2O$ layer, removal of the CuO surface layer, application of the counter-electrode to the CuO-free $Cu_2O$ surface, protection against moisture, production of rectifier assemblies), which is in turn followed by a section on fields of application (electroplating, battery chargers, a.c. ammeters and voltameters, telephone and signal equipment, radio engineering). Finally, the advantages and disadvantages of the $Cu_2O$ rectifier compared with Se rectifiers, which have gained ground in the past two decades, and the mechanism and theory of dry contact rectification are discussed.

The short chapter on copper(II) oxide deals, as that on copper(I) oxide, with the electrical and thermoelectric properties, and then gives an interpretation of its electrical volume conduction and surface conduction on the basis of the energy band model.

With the present Volume D, which completely covers the literature up to the end of 1959 and which, owing to the participation of only two (temporary) workers at the Gmelin Institute, has a peculiarly complete monograph-like character, the System No. "Copper" now reaches the impressive total of 2609 pp. and 657 figs. (total price DM 1645.– or about $415. -). This does not include the extensive volumes on complexes (Part B3) and alloys (Part C) of copper, and in the case of the previously published volumes of Part A (History. Occurrence. The Element) and B (Compounds of Copper), the work which has been published in the 15 years which have passed since the deadline for literature evaluation (1949) still awaits evaluation.

This shows that the extensiveness of reports on the individual elements is growing with time in a most alarming manner. It is consequently becoming increasingly difficult and time-consuming to find rapidly and completely the information on certain facts which, owing to the Gmelin classification of the substances and the Gmelin "last-place" principle, are inevitably dispersed throughout various sections of a System Number or even over various System Numbers. It is therefore appropriate to suggest that a detailed alphabetical subject and compound index (available as a separate part) should be added to each System Number on its completion; this should give references not only to the text of the System Number in question, but also cross-references to the relevant places in other System Numbers. In the reviewer's opinion, this would even further enhance the practical value of Gmelin's Handbook.

*E. Wiberg* [NB 232/94 IE]

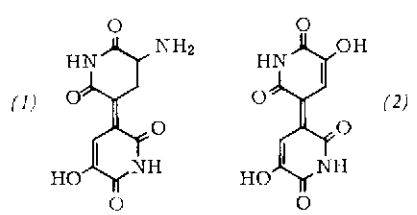
## Errata

A. In the paper "Immunochemistry", Angew. Chem. internat. Edit. *3*, 591 (1964), the following corrections must be made:

p. 591, right column, paragraph 4, line 6/7 read: 3-*O*-methylgalactose, insted of: 3-*O*-methylfucose.



p. 591, right column, paragraph 5, line 2 read: moderate blood-group A specificity, instead of high blood-group A specificity. Here it should be mentioned, that only virus grown on chick embryos was investigated. Since chickens contain blood group A-like Forssman antigens, it is likely that the virus has incorporated this material from the host as part of its surface structure.

B. In the paper "Metallo Complexes", Angew. Chem. internat. Edit. *3*, 686 (1964), the following corrections must be made:

p. 690, right column, Section 3, first line of third paragraph: omit the words "In the first sphere".

p. 690/691: In Section 3 the notation " ... mercury(I)-..." which appears seven times in names of complexes must be changed to read "...mercuro(II)-...".

C. On p. 765, left column, last abstract, the formulae should read:

according to *R. Kuhn, H. Bauer, H.-J. Knackmuss, D. A. Kuhn*, and *M. P. Starr*, Naturwissenschaften *51*, 409 (1964).

# SUBJECT INDEX

FP = Full paper (review article) CR = Conference report
SC = Short communication LA = Literature abstract
G.E. = Reference to the German Edition of Angewandte Chemie. References are given for Review Articles, Short Communications, and Conference Reports only.

ABSORPTION BANDS, Solvent-dependence of the wave number of electronic ~ and its physicochem. basis (CR) 756 [G.E. *76*, 819 (1964)]

Absorption coefficient, Scattering and ~-s in diffuse reflection of powdered materials (CR) 321 [G.E. *76*, 308 (1964)]

Acetaldehyde, Substrate of alcohol dehydrogenase (LA) 659

Acetic acid, Prepn. of malonic acid by carboxylation of ~ (SC) 751 [G.E. *76*, 893 (1964)]

Acetoacetic acid, Determin. of ~ in 0.1 ml of blood (CR) 761 [G.E. *76*, 688 (1964)]

Acetoxyacetate, Addn. of methyl ~ onto olefins by a free-radical mechanism (SC) 635 [G.E. *76*, 713 (1964)]

Acetylcholine esterase, Bis-[(4-hydroxy-iminomethylpyridinio)methyl] ether dichloride, a reactivator of ~ (LA) 595

Acetylene, New type of mesoionic aromatic compd. and its 1,3-dipolar cycloaddn. reacns. with ~ derivs. (SC) 136 [G.E. *76*, 185 (1964)]

Electrophilically induced cyclodimerization of methyl-~ by HBr (SC) 697 [G.E. *76*, 782 (1964)]

Formation of 1,2,3-tri-t-butyltrifluorobenzene by spontaneous trimerization of t-butylfluoro-~ (SC) 747 [G.E. *76*, 889 (1964)]

Valence-bond isomers of (substd.) benzene (SC) 756 [G.E. *76*, 922 (1964)]

Isolation, identification, and synth. of isomeric hexenediynes from electric-arc ~ (LA) 242

See also alkynes

Acetylenedicarboxylic esters, Reacn. of alkylidenetriphenylphosphoranes with ~ (SC) 512 [G.E. *76*, 569 (1964)]

Acid-base catalysis, Proton transfer, ~, and enzymatic hydrol. (FP) 1 [G.E. *75*, 489 (1963)]

Acidic compds., New class of ~ and their use in the synth. of cyclopropane derivs. (CR) 240 [G.E. *76*, 107 (1964)]

Acidity, Structure and ~ of org. compds. (FP) 661 [G.E. *76*, 772 (1964)]

Acids, Differentiation of strong ~ by conductometric titration in glacial acetic acid (SC) 225 [G.E. *76*, 184 (1964)]

Acridines, Photochemistry and spectroscopy of ~ (CR) 388 [G.E. *76*, 306 (1964)]

Acrolein polymers (FP) 416 [G.E. *76*, 357 (1964)]

Acrylates, Aryl rearr. in the thermolysis of β-arylated α-halogeno-~ (SC) 445 [G.E. *76*, 495 (1964)]

Activation analysis, Determin. of Li by ~ (CR) 139 [G.E. *75*, 1130 (1963)]

Acyldiazoalkanes, Capture of benzynes by ~ (SC) 67 [G.E. *76*, 98 (1964)]

Acylheterocumulenes, New observations on ~ (CR) 594 [G.E. *76*, 654 (1964)]

Adsorption phenomena at gas/solid interfaces at low gas pressures (CR) 321 [G.E. *76*, 308 (1964)]

Aescin, Constitution of the horse-chestnut saponin ~ (CR) 152 [G.E. *75*, 1127 (1963)]

Alcohol dehydrogenase, Substrate of ~ (LA) 659

Rate-determining step of the reacn. catalysed by ~ from yeast (LA) 710

Alcohols, Differentiation of primary, secondary, and tertiary ~ by near infrared spectroscopy (SC) 309 [G.E. *76*, 271 (1964)]

Aldehyde hemihydrates (LA) 451

Aldehyde hydrazones, Dimeric ~ (SC) 63 [G.E. *75*, 1204 (1963)]

Aldehyde phenylhydrazones, Structure of the "tetrazanes" produced from alkoxycarbonylazo compds. and ~ (SC) 693 [G.E. *76*, 684 (1964)]

Aldehydes, New synths. of ~ and carboxylic acids using α-halogen ethers (CR) 144 [G.E. *75*, 1118 (1963)]

Addn. of secondary *N*-trimethylsilylamides onto ~ (SC) 514 [G.E. *76*, 648 (1964)]

Aldoses, Cinnoline compds. as by-products in the formation of osazones from ~ (CR) 144 [G.E. *75*, 1126 (1963)]

Alfalfa, Investigations on the biosynth. of coumestrol in ~ (CR) 143 [G.E. *75*, 1126 (1963)]

Alicyclic systems, Synth. of higher ~ (LA) 243

Alkali amides, Amides of the alkali and the alkaline earth metals (FP) 471 [G.E. *76*, 290 (1964)]

Alkali carbonyls, Structure of the so-called ~ (CR) 152 [G.E. *75*, 1116 (1963)]

Alkaline earth amides, Amides of the alkali and the alkaline earth metals (FP) 471 [G.E. *76*, 290 (1964)]

Alkaloids, Oxidative condensation of quaternary phenolic bases (FP) 192 [G.E. *75*, 957 (1963)]

Alkenylamines, Prepn. of thioamides from ~ and sulfur at room temperature (SC) 705 [G.E. *76*, 861 (1964)]

Ring synth. using ~ and ketene-*N*,*N*-acetals (CR) 149 [G.E. *75*, 1122 (1963)]

Cycloaddns. of ~ and 1,1-bisdialkylaminoethylenes (CR) 708 [G.E. *76*, 724 (1964)]

Synth. of trithiones from ~, $CS_2$ and S (LA) 521

β-Alkoxyacrylyl chlorides, Synths. with ~ (SC) 230 [G.E. *76*, 188 (1964)]

Alkoxycarbonylazo compds., Structure of the "tetrazanes" produced from ~ and aldehyde phenylhydrazones (SC) 693 [G.E. *76*, 684 (1964)]

Alkoxydiazenium salts (CR) 151 [G.E. *75*, 1111 (1963)]

1-Alkyl-5-aminopyrazoles, Synth. of 3(5)-aminopyrazole and ~ (SC) 748 [G.E. *76*, 920 (1964)]

Alkylgallium derivs. (CR) 149 [G.E. *75*, 1115 (1963)]

Alkylidenephosphoranes, Reacn. of ~ with C=C and C=N double bonds (CR) 140 [G.E. *75*, 1117 (1963)]

Alkylidenetriphenylphosphoranes, Reacn. of ~ with acetylenedicarboxylic esters (SC) 512 [G.E. *76*, 569 (1964)]

*N*-Alkylisothiazolidin-3-one, Synth. from ω-chlorosulfenylalkylcarbonyl chlorides (SC) 67 [G.E. *76*, 51 (1964)]

Alkyl phosphates, New synth. of mono-~ (LA) 323

*N*-Alkylpyrroles, New synth. of ~ (SC) 510 [G.E. *76*, 536 (1964)]

*N*-Alkyltetrahydro-1,2-thiazin-3-one, Synth. from ω-chlorosulfenylalkylcarbonyl chlorides (SC) 67 [G.E. *76*, 51 (1964)]

Alkyl vinyl ethers, Formation of bis-(β-chloro-β-alkoxyethyl)sulfoxides by addn. of thionyl chloride onto ~ (SC) 373 [G.E. *76*, 435 (1964)]

Alkynes, Photolysis of 1-tosylamino-1,2,3-triazole anions; a new synth. of ~ (SC) 138 [G.E. *76*, 144 (1964)]

Synth. of alkynylamines by nucleophilic substitution of halogeno-~ (SC) 506 [G.E. *76*, 537 (1964)]

Alkynylamines from halogeno-~ and tert. amines (SC) 582 [G.E. *76*, 537 (1964)]

See also Acetylene

Alkynylamines, Synth. of ~ by nucleophilic substitution of halogenoalkynes (SC) 506 [G.E. *76*, 537 (1964)]

Addn. reacns. of ~ (SC) 581 [G.E. *76*, 571 (1964)]

~ from halogenoalkynes and tert. amines (SC) 582 [G.E. *76*, 537 (1964)]

Peptide synths. with ~ (SC) 582 [G.E. *76*, 572 (1964)]

Allylbiscyclopentadienyltitanium(III) and -vanadium(III) (SC) 311 [G.E. *76*, 274 (1964)]

Allylbiscyclopentadienylvanadium(III), Allylbiscyclopentadienyltitanium(III), and ~ (SC) 311 [G.E. *76*, 274 (1964)]

Aluminum compds., Complex formation with organo-~ (FP) 107 [G.E. *75*, 1090 (1963)]

Stable free radicals with B–N and Al–N bonds (SC) 514 [G.E. *76*, 649 (1964)]

Prepn. of anhydrous potassium hexathiocyanatoaluminate and its behavior in liq. $NH_3$ (SC) 586 [G.E. *76*, 647 (1964)]

Dehalogenation of ethylaluminum sesquichlorides with Na (SC) 635 [G.E. *76*, 712 (1964)]

t-Butyl-~ (SC) 640 [G.E. *76*, 817 (1964)]

Trimethylsiloxychloroalane, a crystalline, distillable compd. with a four-membered ring structure (CR) 151 [G.E. *75*, 1115 (1963)]

Reacns. of halogenomethyl-~ with azomethines and *N*-heterocycles (CR) 649 [G.E. *76*, 587 (1964)]

Aluminum halides, Complexes of organotin compds. with ~ (SC) 385 [G.E. *76*, 379 (1964)]

Amadori rearr., Mechanism of osazone formation and of the ~ (CR) 320 [G.E. *76*, 307 (1964)]

Ambident anions, Relations between structure and reactivity of ambifunctional nucleophilic compds. (FP) 560 [G.E. *76*, 412 (1964)]

Ambident cations, Modes of reacn. of ~ (FP) 548 [G.E. *76*, 400 (1964)]

Amidase, Cleavage of the f-amide bond in cyanocobalamin analogues by *Propionibacterium Shermanii* (SC) 308 [G.E. *76*, 272 (1964)]

Amide acetals, Reacn. of ~ with isocyanates, the synth. of parabanic acid *O,N*-acetals (SC) 704 [G.E. *76*, 861 (1964)]

Amide bond, Cleavage of the f-~ in cyanocobalamin analogues by *Propionibacterium Shermanii* (SC) 308 [G.E. *76*, 272 (1964)]

Amides of the alkali and the alkaline earth metals (FP) 471 [G.E. *76*, 290 (1964)]

Amines, Synth. of new organoarsenic and organophosphorus ~ (SC) 702 [G.E. *76*, 787 (1964)]

A new synth. of sec. and tert. ~ (LA) 405

Amino acid, Investigations of the racemization of L-~ derivs. (CR) 142 [G.E. *75*, 1125 (1963)]

Asymmetric induction during the synth. of ~-s by the Passerini-Ugi reacn. (CR) 808 [G.E. *76*, 757 (1964)]

New method of peptide synth. using ~ derivs. of saccharin (LA) 451

Novel stereospecific synth. of optically active α-~-s (LA) 710

~sequences in phosvitin (CR) 645 [G.E. *76*, 574 (1964)]

2-Amino-4-aryl-5-bromothiazole, Thiazolizations using 2-hydroxy- or ~ (CR) 147 [G.E. *75*, 1121 (1963)]

Aminoboranes, Recent developments in the chemistry of ~ (FP) 86 [G.E. *76*, 165 (1964)]

Structural investigations of phenylated ~ (CR) 140 [G.E. *75*, 1106 (1963)]

Aminoboron azides (SC) 315 [G.E. *76*, 343 (1964)]

Aminohalogenoboranes, Bis(trimethylsilyl)-~ (SC) 633 [G.E. *76*, 499 (1964)]

Amino isocyanides (CR) 647 [G.E. *76*, 580 (1964)]

Aminolysis of selenium dioxide (SC) 805 [G.E. *76*, 992 (1964)]

3(5)-Aminopyrazole, Synth. of ~ and 1-alkyl-5-aminopyrazoles (SC) 748 [G.E. *76*, 920 (1964)]

5-Amino-1,2,3-thiadiazoles (LA) 810

Aminosulfanes, Prepn. of new *N*-silyl-~ by nucleophilic rupture of S S bonds (CR) 150 [G.E. *75*, 1115 (1963)]

Ammonia, Effect of liq.~ on phosphoric esters (LA) 155

Ampicillin, Synth. of 6-[(D-α-amino-α-phenylacetyl)amino]-penicillanic acid using β-dicarbonyl compds. as amino-protecting groups (SC) 439 [G.E. *76*, 342 (1964)]

Analysis, Modern methods of org. ~ (CR) 760 [G.E. *76*, 688 (1964)]

Androstane, Recent advances in the synth. of 19-norsteroids (FP) 353 [G.E. *76*, 249 (1964)]

Anhydrides, Simple new synth. of ~ (LA) 764

Anions, Relations between structure and reactivity of ambifunctional nucleophilic compds. (FP) 560 [G.E. *76*, 412 (1964)]

Anthranilic acid, Detection of a nitrogen-free precursor of ~ in the biosynthesis of tryptophan by *Saccharomyces cerevisiae* (SC) 66 [G.E. *76*, 51 (1964)]

Anthranil systems, A general rearr. of heterocycles, and novel synth. of the benzotriazole, benzofurazan, and ~ (SC) 693 [G.E. *76*, 816 (1964)]

Anthraquinonoid dyes, Fiber damage due to ~ (CR) 760 [G.E. *76*, 822 (1964)]

Antibodies, Hapten-binding ~ (LA) 450

Antimony compds., Tristriphenylstannylarsine, -stibine, and -bismuthine (SC) 316 [G.E. *76*, 344 (1964)]

Superconductivity in $In_3SbTe_2$ (SC) 588 [G.E. *76*, 651 (1964)]

Antimony pentachloride, Reacn. of silyl azides with ~ (SC) 444 [G.E. *76*, 380 (1964)]

Apamin, a polypeptide from bee venom (LA) 658

Aprotic solvents, Behavior of some indicators in ~ (CR) 239 [G.E. *76*, 106 (1964)]

Aromatic character, Structure and ~ of non-benzenoid cyclically conjugated systems (FP) 165 [G.E. *75*, 1041 (1963)]

Aromatic hydrocarbons, Proton-addn. complexes of ~ (FP) 776 [G.E. *76*, 965 (1964)]

Aromatic systems, Investigations on ~ (CR) 319 [G.E. *76*, 276 (1964)]

Aroxyl radicals, A simple EPR method for measuring the g-factors of free radicals, applied to substd. aroxyls (CR) 656 [G.E. *76*, 610 (1964)]

5,12-Diphenyl-7-oxyldinaphtho[1,2-*b*:2',3'-*d*]furan (LA) 595

Arsenic, Bonding in intermetallic phases of the Ni-As type (CR) 322 [G.E. *76*, 353 (1964)]

Arsenic compds., Complexes of tetradentate ligands containing phosphorus and arsenic (FP) 453 [G.E. *76*, 621 (1964)]

Synth. of new organoarsenic and organophosphorus amines (SC) 702 [G.E. *76*, 787 (1964)]

Free thio acids of phosphorus and arsenic (LA) 392

Arsenic(V) oxide, Structure of $As_2O_5 \cdot 3H_2O$ (SC) 638 [G.E. *76*, 714 (1964)]

Arsides, Simple synth. of disec. diarsines and alkali phenylarsides (LA) 764

Arsines, New method for preparing trialkyl-~ and trialkylstibines (SC) 66 [G.E. *76*, 99 (1964)]

Bis(trimethylsilyl) aminodimethylarsine and tris(dimethylarsino)amine (SC) 137 [G.E. *76*, 144 (1964)]

Prepn. of volatile mixed hydrides of phosphorus, arsenic, nitrogen, and germanium, and of triphosphine and triarsine (SC) 703 [G.E. *76*, 860 (1964)]

Simple synth. of disec. di-~ and alkali phenylarsides (LA) 765

Arthropods, Defensive substances of the ~, their isoln. and identification (FP) 73 [G.E. *75*, 762 (1963)]

Arylcyanophenols and 2,4,6-tricyanophenol (SC) 384 [G.E. *76*, 433 (1964)]

Aryl rearr. in the thermolysis of β-arylated α-halogenoacrylates (SC) 445 [G.E. *76*, 495 (1964)]

Arynes, Investigations on heterocyclic ~ (CR) 650 [G.E. *76*, 590 (1964)]

Assimilation, Reduction of DPN during carbonic-acid ~ (LA) 658

~ of carbon from carbonates (LA) 710

Astrochemistry, Chemical composition of the stars (FP) 481 [G.E. *76*, 281 1964)]

Asymmetric induction during the synth. of amino acids by the Passerini-Ugi reacn. (CR) 808 [G.E. *76*, 757 (1964)]

Austrian chemists, Joint meeting of Swiss and ~ (CR) 238 [G.E. *76*, 105 (1964)]

Autoxidation, New diarylketenes and their ~ (CR) 650 [G.E. *76*, 589 (1964)]

Azabicyclononatriene, Rearr. of 9-azabicyclo[6,1,0]nonatriene to 4-azabicyclo[5,2,0]nonatriene (SC) 582 [G.E. *76*, 569 (1964)]

Azaflavazole derivs., new heterocycles (SC) 802 [G.E. *76*, 955 (1964)]

6-Azapteridines, Synth. of pyrimido[4,5-*e*]-as-triazines (~) (SC) 312 [G.E. *76*, 342 (1964)]

Azide chlorides, Prepn. and properties of ~ (CR) 142 [G.E. *75*, 1110 (1963)]

Azidinium salts, Introduction of diazo groups into reactive methylene compds. by ~ (CR) 644 [G.E. *76*, 573 (1964)]

Azidoformates, Photochem. decomposition of alkyl ~ in aliphatic alcohols (SC) 589 [G.E. *76* 681 (1964)]

Azlactones as 1,3-dipoles; new pyrrole synth. (SC) 135 [G.E. *76*, 185 (1964)]

Azo compds., Relationship between the color and constitution of ~ (CR) 645 [G.E. *76*, 575 (1964)]

Synth. of aliphatic azo and diazo compds. from active methylene compds and sulfonyl azides (CR) 654 [G.E. *76*, 601 (1964)]

Azo coupling of α-diazo-β-diketones with non-phenolic methylene compds. (SC) 748 [G.E. *76*, 920 (1964)]

Azodicarboxylic esters, 1,4-(*N,O*)-Cycloaddns. of ~ (CR) 646 [G.E. *76*, 579 (1964)]

1-Azo-1-hydrazinoalkane, Structure of the "tetrazanes" produced from alkoxycarbonylazo compds. and aldehyde phenylhydrazones (SC) 693 [G.E. *76*, 684 (1964)]

Azomethines, Reacns. of the halogenomethylaluminum compds. with ~ and N-heterocycles (CR) 649 [G.E. *76*, 587 (1964)]

BACTERIA, Biosynth., structure, and biological action of the lipids of the tubercle bacillus (FP) 393 [G.E. *76*, 241 (1964)]

Structure and synth. of the blue dye from *Corynebacterium insidiosum* (LA) 765, 812

Bacteriophages, Electron spin resonance measurements on irradiated ~ and their nucleic acids (CR) 241 [G.E. *76*, 233 (1964)]

Bee venom, Apamin, a polypeptide from ~ (LA) 658

Benzaldehydes, Synth. of substd. benzoic acids, benzonitriles, and ~ (LA) 595

Benz[*a*]anthrone, New synth. of derivs. of ~ and dibenz[*a,d*]anthrone (SC) 316 [G.E. *76*, 301 (1964)]

Benzene, Cyclopentadienyl(~)molybdenum (SC) 134 [G.E. *76*, 98 (1964)]

A crystalline deriv. of "Dewar ~" (SC) 695 [G.E. *76*, 716 (1964)]

Valence-bond isomers of (substd.) ~ (SC) 756 [G.E. *76*, 922 (1964)]

Optically excited electron states of mono- and disubstd. ~ derivs. (LA) 71

A localized bond between a substd. ~ and a transition metal (LA) 323

Benzhydroxamic acid, Stability constants of Fe(III) with ~ and acethydroxamic acid (LA) 71

Benzisothiazole, Heterocyclic compds. with endocyclic S=N double bonds (CR) 808 [G.E. *76*, 758 (1964)]

Benzodioxolone - *N,N* - diethylimidinium chloride, Synth. and reacns. of ~ (SC) 511 [G.E. *76*, 534 (1964)]

Benzodithiazole, Heterocyclic compds. with endocyclic S=N double bonds (CR) 808 [G.E. *76*, 758 (1964)]

Benzofurazan, General rearr. of heterocycles, and novel synth. of the benzotriazole, ~, and anthranil systems (SC) 693 [G.E. *76*, 816 (1964)]

Benzoic acids, Synth. of substd. ~, benzonitriles, and benzaldehydes (LA) 595

Benzonitriles, Synth. of substd. benzoic acids, ~, and benzaldehydes (LA) 595

Benzo[*a*]quinolizinium salts from 3,4-dihydroxyphenethylamine hydrobromide and acetoacetaldehyde, a possibly biogenetic-type cyclization (SC) 507 [G.E. *76*, 534 (1964)]

Benzoquinolones, Synth. with β-alkoxyacrylyl chlorides (SC) 230 [G.E. *76*, 188 (1964)]

Benzothiadiazine, Heterocyclic compds. with endocyclic S=N double bonds (CR) 808 [G.E. *76*, 758 (1964)]

Benzotriazinones, Reacn. of ~ with isocyanates (SC) 378 [G.E. *76*, 437 (1964)]

Benzotriazole, General rearr. of heterocycles, ~ and novel synth. of the ~ benzofurazan, and anthranil systems (SC) 693 [G.E. *76*, 816 (1964)]

Benzvalene, Simultaneous formation of substd. tetracyclohexane, tricyclohexene, and bicyclohexadiene by spontaneous trimerization of t-butylfluoroacetylene (SC) 755 [G.E. *76*, 922 (1964)]

Benzyl alcohols, *N,N*-Dimethylformamide dineopentylacetal: a reagent for esterifying carboxylic acids with ~ (SC) 62 [G.E. *75*, 1176 (1963)]

Benzyl azide, Pyrolysis of ~ in the gas phase (SC) 309 [G.E. *76*, 272 (1964)]

1-Benzyl-2,3-diphenylindanes, Formation of ~ from stilbene in the presence of tin tetrachloride under the influence of γ-radiation (SC) 803 [G.E. *76*, 989 (1964)]

Benzynes, Capture of ~ by acyldiazoalkanes (SC) 67 [G.E. *76*, 98 (1964)]

Bicyclohexadiene, Simultaneous formation of substd. tetracyclohexane, tricyclohexene, and ~ by spontaneous trimerization of t-butylfluoroacetylene (SC) 755 [G.E. *76*, 922 (1964)]

Bicyclononanol, Bicyclo[3,3,1]nonan-2-ol from 4-cyclooctenylmethyl toluenesulfonate (SC) 583 [G.E. *76*, 572 (1964)]

Bicyclooctadiene, Photolysis of bicyclo-[4,2,0]octa-2,4-diene, cycloocta-1,3,5-triene and cycloocta-1,3,6-triene (SC) 440 [G.E. *76*, 378 (1964)]

Bicyclooctatriene, Valence-bond tautomerism of cyclooctatetraene (FP) 83 [G.E. *76*, 36 (1964)]

Bicyclo[4,2,0]octa-2,4,7-triene (SC) 442 [G.E. *76*, 432 (1964)]

Biochemical societies, Federation of European ~ (CR) 447 [G.E. *76*, 503 (1964)]

Biosynthesis, Detection of a nitrogen-free precursor of anthranilic acid in the ~ of tryptophan by *Saccharomyces cerevisiae* (SC) 66 [G.E. *76*, 51 (1964)]

Investigations on the ~ of coumestrol in alfalfa (CR) 143 [G.E. *75*, 1126 (1963)]

Bis-(β-chloro-β-alkoxyethyl)sulfoxides, Formation of ~ by addn. of thionyl cloride onto alkyl vinyl ethers (SC) 373 [G.E. *76*, 435 (1964)]

1,1-Bisdialkylaminoethylenes, Cycloaddns. of alkenylamines and ~ (CR) 708 [G.E. *76*, 724 (1964)]

Bisdiphenyleneallyl radicals, Stable 2-aryl-1,3-bisdiphenyleneallyl radicals (LA) 764

Bisdithione complexes of transition metals (SC) 381 [G.E. *76* 345 (1964)]

Bis-[(4-hydroxyiminomethylpyridinio)-methyl] ether *dichloride* (LA) *595*

Bismuthine, Tristriphenylstannylarsine, -stibine, and -~ (SC) 316 [G.E. *76*, 344 (1964)]

Bis(trifluorophosphine)dinitrosyliron, Tris-(trifluorophosphine)nitrosylcobalt and ~ (SC) 700 [G.E. *76*, 787 (1964)]

Bis(trimethylsilyl)aminodimethylarsine, ~ and tris(dimethylarsino)amine (SC) 137 [G.E. *76*, 144 (1964)]

Blood, Determn. of acetoacetic acid in 0.1 ml of ~ (CR) 761 [G.E. *76*, 688 (1964)]

Boltzmann occupation of the energy terms of atoms and molecules (CR) 388 [G.E. *76*, 306 (1964)]

Book reviews

Fresh water from the sea 72

Analyse der Metalle (Analysis of Metals) 72

Atlas d'equilibres électrochimiques 25 °C 156

Brederеck, Colloquium in honor of H. ~ (CR) 807 [G.E. *76*, 757 (1964)]

Bromine, Colorimetric sub-micro determin. of ~ in org. compds. (CR) 761 [G.E. *76*, 688 (1964)]

*N*-Bromobistrifluoromethylamine, Reacns. of ~ (LA) 764

Bromobullvalene, Molecules with rapid reversible valence isomerism. – Synth. and properties of ~ and alkyl bullvalyl ethers (CR) 656 [G.E. *76*, 607 (1964)]

Bullvalene, Iron carbonyl complexes of the dimers of cyclooctatetraene and ~ (SC) 509 [G.E. *76*, 498 (1964)]

Bullvalyl ethers, Molecules with rapid reversible valence isomerism. – Synth. and properties of bromovullvalene and alkyl ~ (CR) 656 [G.E. *76*, 607 1964)]

Butadienes, Geometrically isomeric pairs with preferred cis-configuration among substd. ethylenes and 1,3-~ (CR) 152 [G.E. *75*, 1124 (1963)]

t-Butylaluminum compds. (SC) 640 [G.E. *76*, 817 (1964)]

t-Butylfluoroacetylene, Formation of 1,2,3-tri-t-butyltrifluorobenzene by spontaneous trimerization of ~ (SC) 746 [G.E. *76*, 889 (1964)]

Simultaneous formation of substd. tetracyclohexane, tricyclohexene, and bicyclohexadiene by spontaneous trimerization of t-butylfluoroacetylene (SC) 755 [G.E. *76*, 922 (1964)]

CALCIUM, Method for the micro-determination of $Mg^{2+}$ and $Ca^{2+}$ in tissues (LA) 70

Caprolactam hydroperoxide (LA) 390

Carbenes, Low-energy ~ (SC) 65 [G.E. *75*, 1204 (1963)]

Formation and reacns. of dimethylsilylene, a silicon-analogue of the ~ (SC) 226 [G.E. *76*, 270 (1964)]

Existence of a tungsten carbonyl carbene complex (SC) 580 [G.E. *76*, 645 (1964)]

α-Addn. of dichlorocarbene to cyclohexyl isonitrile (SC) 753 [G.E. *76*, 889 (1964)]

Detection of a heterocyclic nucleophilic ~ (SC) 800 [G.E. *76*, 989 (1964)]

Steric effects in carbene reacns. (CR) 651 [G.E. *76*, 591 (1964)]

Heterocyclic diazo-azo compds. as a source of nucleophilic ~ (CR) 809 [G.E. *76*, 995 (1964)]

Carbodiimides, *N*-Sulfonyl-~ (SC) 639 [G.E. *76*, 781 (1964)]

Carbohydrates, Cyclization of dialdehydes with nitromethane (FP) 211 [G.E. *76*, 84 (1964)]

Carbon, Surface oxides of ~ (FP) 669 [G.E. *76*, 742 (1964)]

Carbonates, Assimilation of carbon from ~ (LA) 710

Carbon compds., Attempts to prepare $C_6O_6$ (CR) 150 [G.E. *75*, 1123 (1963)]

Carbon tetrachloride, Explosion of a mixture of triethylaluminum and ~ (SC) 65 [G.E. *75*, 1205 (1963)]

Carbonyl chlorides, Rearr. of vinylogous ~ (CR) 317 [G.E. *76*, 276 (1964)]

Carbonyl olefination, Synth. of naturally occurring unsaturated fatty acids by sterically controlled ~ (FP) 250 [G.E. *76*, 113 (1964)]

Carbonyls, Photochem. substitutions on metal ~ and their derivs. (FP) 730 [G.E. *76*, 873 (1964)]

Existencene of a tungsten carbonyl carbene complex (SC) 580 [G.E. *76*, 645 (1964)]

*N*-Carbonylsulfamyl chloride, Reacns. of ~ with dienes (CR) 649 [G.E. *76*, 587 (1964)]

Carboranes, Formation of org. ~ (SC) 515 [G.E. *76*, 650 (1964)]

Carbostyrils, Synth. with β-alkoxyacrylyl chlorides (SC) 230 [G.E. *76*, 188 (1964)]

Carboxylase, Deaminothiamine pyrophosphate, a strong ~ inhibitor (SC) 227 [G.E. *76*, 226 (1964)]

Carboxylation, Prepn of malonic acid by ~ of acetic acid (SC) 751 [G.E. *76*, 893 (1964)]

Carboxylic acids, *N*,*N*-Dimethylformamide dineopentylacetal: a reagent for esterifying ~ with benzyl alcohols (SC) 62 [G.E. *75*, 1176 (1963)]

New synths. of aldehydes and ~ using α-halogen ethers (CR) 144 [G.E. *75*, 1118 (1963)]

Isomerization of cyclic mono- and diolefins during the Koch carboxylic acid synth. (CR) 148 [G.E. *75*, 1122 (1963)]

Relations between structure and rate constants for the dissociation and recombination of ~ (CR) 762 [G.E. *76*, 689 (1964)]

Carotenoids, Keto-~ in crustaceae (LA) 595

Catalysis, Proton transfer, acid-base ~, and enzymatic hydrol. (FP) 1 [G.E. *75*, 489 (1963)]

Coordination chemistry and ~ (FP) 185 [G.E. *76*, 28 (1964)]

Elimination of HCl from gaseous *cis*- and *trans*-chlorostilbene (SC) 135 [G.E. *76*, 184 (1964)]

Elimination of HCl from gaseous 2,3-dichlorobutane on $CaCl_2$, CaO, and $Al_2O_3$ (SC) 584 [G.E. *76*, 645 (1964)]

Catalysts, Mechanism of the action of organometallic ~ (FP) 93 [G.E. *75*, 805 (1963)]

Catena compds., Prepn. of ~ by directed synth. (FP) 546 [G.E. *76*, 567 (1964)]

Cathode, Hollow ~ as a light source for emission spectrography in the vacuum ultraviolet region (CR) 388 [G.E. *76*, 306 (1964)]

Cation-exchanger, Peat as a ~ in the purification of radioactive sewage (LA) 658

Cations, Modes of reacn. of ambident ~ (FP) 548 [G.E. *76*, 400 (1964)]

Cesium compds., Crystal structure of rubidium and cesium hexachloro-,-bromo- and -iodorhenates(IV) (SC) 445 [G.E. *76*, 497 (1964)]

Charge distribution, Methods for determining the ~ in electronically excited states (CR) 757 [G.E. *76*, 819 (1964)]

Charge-transfer band, Contribution of an intermolecular ~ to the optical activity of electron-donor/acceptor complexes (SC) 307 [G.E. *76*, 228 (1964)]

Chelates, Imidophosphinatometal ~, neutral complexes with carbon-free chelate rings (SC) 704 [G.E. *76*, 860 (1964)]

Chelate complexes of Pu with 8-hydroxyquinoline (CR) 145 [G.E. *75*, 1113 (1963)]

Stable chelate diazonium salt (LA) 391

Chelating agents, Structure and specificity of org. ~ (FP) 325 [G.E. *76*, 76 (1964)]

Chemiluminescent compds., 7-Dialkylaminonaphthalene-1,2-dicarboxylic hydrazides – new strongly ~ (SC) 637 [G.E. *76*, 686 (1964)]

Chemistry lecturers, Meeting of West German ~ (CR) 644 [G.E. *76*, 573 (1964)]

Chemotherapy, Third international congress of ~ (CR) 233 [G.E. *75*, 1178 (1963)]

Chlorine, Reacns. of compds. with electropositive ~ (CR) 448 [G.E. *76*, 385 (1964)]

Chlorins, Acetylation reacns. of ~, a contribution to the Munich chlorophyll chemistry (CR) 322 [G.E. *76*, 383 1964)]

γ-Chlorocaproic acid, Conversion of succinyl dichloride into ~ (SC) 584 [G.E. *76*, 646 (1964)]

Chloroethylenes, Prepn. and reacns. of ~ (CR) 651 [G.E. *76*, 592 (1964)]

Chlorofluorodiazine, Prepn. of *difluoro*diazine and the existence of ~ (SC) 701 [G.E. *76*, 713 (1964)]

Chloronitrate, Application of ~ for the prepn. of oxide fluorides (CR) 142 [G.E. *75*, 1110 (1963)]

Chlorophyll chemistry, Acetylation reacns. of chlorins, a contribution to the Munich ~ (CR) 322 [G.E. *76*, 383 (1964)]

Chlorostilbene, Elimination of HCl from gaseous *cis*- and *trans*-~ (SC) 135 [G.E. *76*, 184 (1964)]

ω-Chlorosulfenylalkylcarbonyl chlorides (SC) 67 [G.E. *76*, 51 (1964)]

Chlorotriazines, Synth. of halogenoalkyl-dichloro-s-triazines and bis(halogenoalkyl)-~ (SC) 378 [G.E. *76*, 437 (1964)]

Cholegenin, Constitution of a ~ analogue from the vegetable kingdom (CR) 152 [G.E. *75*, 1128 (1963)]

Chromatographic sepns. on porous gels (FP) 608 [G.E. *76*, 635 (1964)]

Chromatography, see Gas chromatography, Gel chromatography, Thin-layer chromatography

Cinnoline compds. as by-products in the formation of osazones from aldoses (CR) 144 [G.E. *75*, 1126 (1963)]

Circular dichroism, Conformational analysis of nitrosteroids by ~ (CR) 762 [G.E. *76*, 690 (1964)]

Cobalt compds., Rhenium-cobalt enneacarbonyl (SC) 701 [G.E. *76*, 786 (1964)]

Separation of the geometric isomers of cobalt complexes (LA) 390

Cocarcinogens, Cocarcinogen A 1 – the first pure, highly active constituent of croton oil (SC) 227 [G.E. *76*, 225 (1964)]

A new group of ~ from croton oil (SC) 747 [G.E. *76*, 890 (1964)]

Code, Determn. of the sequence of a ~ triplet (SC) 589, 660 [G.E. *76*, 716, 800 (1964)]

Coding with mono- and polytrinucleotides (SC) 590 [G.E. *76*, 717 (1964)]

Streptomycin alters the mechanism by which the messenger ~ is read (LA) 810

Color, Relationship between the ~ and constitution of azo compds. (CR) 645 [G.E. *76*, 575 (1964)]

Complexes, Formation of ~ with organoaluminum compounds (FP) 107 [G.E. *75*, 1090 (1963)]

Metallo-~ (FP) 686, 812 [G.E. *76*, 697 (1964)]

~ of tetradentate ligands containing phosphorus and arsenic (FP) 453 [G.E. *76*, 621 (1964)]

Proton-addn. ~ of aromatic hydrocarbons (FP) 776 [G.E. *76*, 965 (1964)]

Characterization and stabilization of dithiobenzil by complex formation (SC) 133 [G.E. *76*, 143 (1964)]

Contribution of an intermolecular charge-transfer band to the optical activity of electron-donor/acceptor ~ (SC) 307 [G.E. *76*, 228 (1964)]

Tricyanomethanido metal ~ containing carbon monoxide and nitric oxide (SC) 380 [G.E. *76*, 346 (1964)]

Bis-dithione ~ of transition metals (SC) 381 [G.E. *76*, 345 (1964)]

~ of organotin compds. with aluminum halides (SC) 385 [G.E. *76*, 379 (1964)]

Trisdithiobenzilmetal ~ (SC) 639 [G.E. *76*, 715 (1964)]

Water-stable, cationic ~ of silicic acid with 1-hydroxypyridine *N*-oxide (SC) 698 [G. E.*76*, 818 (1964)]

Imidodiphosphinatometal chelates, neutral ~ with carbon-free chelate rings (SC) 704 [G.E. *76*, 860 (1964)]

Chelate ~ of Pu with 8-hydroxyquinoline (CR) 145 [G.E. *75*, 1113 (1963)]

Structure of anomalous oxalato ~ of Pt (CR) 147 [G.E. *75*, 1114 (1963)]

Method for the prepn. of complex compds. of elements in higher valence states (CR) 149 [G.E. *75*, 1111 (1963)]

Formation of ~ with polymolybdate ions (CR) 320 [G.E. *76*, 236 (1964)]

Trifluorophosphinyl ~ of transition metals (CR) 652 [G.E. *76*, 593 (1964)]

Stability constants of 1:1, 1:2, and 1:3 ~ of Fe(III) with benzhydroxamic acid (LA) 71

Steric configuration of 1:2 metal-dye ~ (LA) 155

Separation of the geometric isomers of cobalt ~ (LA) 390

Complexing agents, Structure and specificity of org. chelating agents (FP) 325 [G.E. *76*, 76 (1964)]

Conductometric titration, Differentiation of strong acids by ~ in glacial acetic acid (SC) 225 [G.E. *76*, 184 (1964)]

Configuration, Geometrically isomeric pairs with preferred *cis*-~ among substd. ethylenes and 1,3-butadienes (CR) 152 [G.E. *75*, 1124 (1963)]

Conformational analysis, Modern problems of stereochemistry (CR) 516 [G.E. *76*, 501 (1964)]

~ of nitrosteroids by circular dichroism (CR) 762 [G.E. *76*, 690 (1964)]

Conformational mobility, Proton resonance investigations on the ~ of cyclic di- and trisulfides (CR) 650 [G.E. *76*, 590 (1964)]

Contraction cycle, Energetics of the ~ in muscle (CR) 321 [G.E. *76*, 308 (1964)]

Coordination chemistry and catalysis (FP) 185 [G.E. *76*, 28 (1964)]

Coordination numbers, Changes in the ~ of Ni(0) and Ni(I) compds. (CR) 648 [G.E. *76*, 586 (1964)]

Corrinoids, New chemical and biochemical developments in the vitamin $B_{12}$ field (FP) 200 [G.E. *75*, 1145 (1963)]

Corrin system, Synthetic route to the ~ (FP) 490 [G.E. *76*, 393 (1964)]

Coumestrol, Investigations on the biosynth. of ~ in alfalfa (CR) 143 [G.E. *75*, 1126 (1963)]

Creatine kinase, Isoenzymes of ~ (LA) 709

Creatinine, Improvement and automation of the determin. of ~ (CR) 760 [G.E. *76*, 688 (1964)]

Croton oil, Cocarcinogen A 1 – the first pure, highly active constituent of ~ (SC) 227 [G.E. *76*, 225 (1964)]

A new group of cocarcinogens from ~ (SC) 747 [G.E. *76*, 890 (1964)]

Crystal growth of compds. with incongruent melting point (CR) 141 [G.E. *75*, 1133 (1963)]

Crystal surface, Quantum chemistry of the ~ (FP) 496 [G.E. *76*, 365 (1964)]

Cyanamides, Interaction of disubstd. ~ with phosgene and oxalyl chloride (SC) 694 [G.E. *76*, 714 (1964)]

Cyanine dyes, Hindered internal rotation in ~ (SC) 306 [G.E. *76*, 275 (1964)]

Dependence of the electron excitation of open-chain ~ on the valence angle of their nitrogen atoms (SC) 374 [G.E. *76*, 187 (1964)]

Adsorption of ~ onto silver halides (LA) 809

Cyanocarbon chemistry, Recent developments in ~ (CR) 241 [G.E. *76*, 275 (1964)]

Cyanocobalamin, Cleavage of the f-amide bond in ~ analogues by *Propionibacterium Shermanii* (SC) 308 [G.E. *76*, 272 (1964)]

Cyclization, Unusual ~ of a steroid *N*-chloroamine (SC) 633 [G.E. *76*, 752 (1964)]

Cycloaddition, Azlactones as 1,3-dipoles; a new pyrrole synth. (SC) 135 [G.E. *76*, 185 (1964)]

A new type of mesoionic aromatic compd. and its 1,3-dipolar ~ reacns. with acetylene derivs. (SC) 136 [G.E. *76*, 185 (1964)]

Carbocyclic and heterocyclic four-membered rings from tetramethoxyethylene by ~ (SC) 380 [G.E. *76*, 346 (1964)]

1,4-Dipolar ~ onto diisonitriles (SC) 446 [G.E. *76*, 500 (1964)]

1,4-(*N*,*O*)-~ of azodicarboxylic esters (CR) 646 [G.E. *76*, 579 (1964)]

~ with isocyanates as 1,4- and 1,2-dipoles (CR) 652 [G.E. *76*, 596 (1964)]

~ of alkenylamines and 1,1-bisdialkylaminoethylenes (CR) 708 [G.E. *76*, 724 (1964)]

Cycloalkenes, Autoxidative ring closure of ω,ω-bis(triphenylphosphorylidene)-alkanes (SC) 226 [G.E. *76*, 226 (1964)]

Cyclobutadiene, Two stereoisomeric dimers of ~ (LA) 764

Cyclobutane derivs., Prepn. of condensed ~ and spiro-cyclopropane compds. by homoallylic rearr. (SC) 698 [G.E. *76*, 783 (1964)]

Cyclobutanones, Ring-opening of β-dialkylamino-~ (CR) 653 [G.E. *76*, 598 (1964)]

Cyclodecadienes, Valence-bond isomerizn. of *cis,trans*-cyclodeca-1,5-dienes (SC) 702 [G.E. *76*, 859 (1964)]

Cyclodecapentaene, The ~ system (SC) 228 [G.E. *76*, 145 (1964)]

Substitution of 1,6-methano-~ (SC) 642 [G.E. *76*, 784 (1964)]

~-s with a 1,6-heteroatomic bridge (SC) 642 [G.E. *76*, 785 (1964)]

Attempted synth. of ~-s by valence-bond isomerizn. of 9,10-dihydronaphthalenes (SC) 643 [G.E. *76*, 786 (1964)]

Cyclodimerization, Electrophilically induced ~ of methylacetylene by hydrogen bromide (SC) 697 [G.E. *76*, 782 (1964)]

Cycloheptatriene, Proof of a norcaradiene-~ valence-bond tautomerism by NMR spectroscopy (SC) 443 [G.E. *76*, 432 (1964)]

Cyclohexadiene, 1-Methylene-2,5-~ (SC) 62 [G.E. *75*, 1177 (1963)]

Photochemical valence isomerizn. of 1,3-~ derivs. (CR) 653 [G.E. *76*, 600 (1964)]

Cyclohexane, Homolytic hydrogen transfer in a ~ (LA) 522

Cyclohexyl isonitrile, α-Addn. of dichlorocarbene to ~ (SC) 752 [G.E. *76*, 889 (1964)]

Cyclooctatetraene, Valence tautomerism of ~ (FP) 83 [G.E. *76*, 36 (1964)]

Coordination chemistry and catalysis (FP) 185 [G.E. *76*, 28 (1964)]

Iron carbonyl complexes of the dimers of ~ and bullvalene (SC) 509 [G.E. *76*, 498 (1964)]

Cyclooctatriene, Photolysis of bicyclo-[4,2,0]octa-2,4-diene, cycloocta-1,3,5-triene and cycloocta-1,3,6-triene (SC) 440 [G.E. *76*, 378 (1964)]

Cyclooctenylmethyl toluenesulfonate, Bicyclo[3,3,1]nonan-2-ol from 4-~ (SC) 583 [G.E. *76*, 572 (1964)]

Cyclopentadiene, Dicyclopentadienyleuropium (SC) 132 [G.E. *76*, 52 (1964)]

Cyclopentadienyl(benzene)molybdenum (SC) 134 [G.E. *76*, 98 (1964)]

Tetrachlorodiazo-~ from hexachloro-~ (SC) 379 [G.E. *76*, 431 (1964)]

1,5-Hydrogen shifts in ~ and indene (CR) 654 [G.E. *76*, 602 (1964)]

Cyclopentene, Stereospecific homopolymerization of (FP) 723 [G.E. *76*, 765 (1964)]

Cyclopropane, Prepn. of condensed cyclobutane derivs. and spiro-~ compds. by homoallylic rearr. (SC) 698 [G.E. *76*, 783 (1964)]

Investigations on ~ compds. (CR) 144 [G.E. *75*, 1119 (1963)]

A new class of acidic compds. and their use in the synth. of ~ derivs. (CR) 240 [G.E. *76*, 107 (1964)]

Investigations on ~ compds. (CR) 317 [G.E. *76*, 235 (1964)]

Cyclopropene, Synth. of a methylene-~ deriv. (SC) 699 [G.E. *76*, 784 (1964)]

Investigations on ~-s (CR) 808 [G.E. *76*, 758 (1964)]

Cyclotetrastannane, Synth. of octabenzyl-~ (SC) 751 [G.E. *76*, 892 (1964)]

Cysteamine, Degradn. of DNA by ~ or L-cysteine (LA) 658

Cysteine, Degradn. of DNA by cysteamine or L-~ (LA) 658

Cytidine diphosphate glucose, Enzymatic reacns. on ion-exchange thin-layer plates (SC) 442 [G.E. *76*, 494 (1964)]

Cytohaemin, Constitution of ~ (LA) 243

Cytosine, Relationship between the molar extinction coefficient ε of DNA and the guanine and ~ content (LA) 658

DEAMINASE, Biochemistry of yeast threonine ~ (FP) 101 [G.E. *75*, 894 (1963)]

Deaminococarboxylase, Deaminothiamine pyrophosphate, a strong carboxylase inhibitor (SC) 227 [G.E. *76*, 226 (1964)]

Deaminothiamine pyrophosphate, a strong carboxylase inhibitor (SC) 227 [G.E. *76*, 226 (1964)]

Decarbobenzoxylation with liquid hydrogen bromide (LA) 155

Defensive substances of the arthropods, their isoln. and identification (FP) 73 [G.E. *75*, 762 (1963)]

Dehalogenation, Course of the ~ of ethylaluminum sesquichlorides with sodium (SC) 635 [G.E. *76*, 712 (1964)]

Reductive ~-s using tert. phosphines (CR) 145 [G.E. 75, 1119 (1963)]

Dehydration, Catalytic ~ with elemental boron (CR) 644 [G.E. 76, 574 (1964)]

Dehydrobenzene, Detection of ~ in the gas phase (CR) 145 [G.E. 75, 1119 (1963)]

Dehydropyridine *N*-oxide, Indications of the transient occurrence of 3,4-~ and 3,4-dehydroquinoline *N*-oxide (SC) 806 [G.E. 76, 993 (1964)]

Dehydroquinoline *N*-oxide, Indications of the transient occurrence of 3,4-dehydropyridine *N*-oxide and 3,4-~ (SC) 806 [G.E. 76, 993 (1964)]

Deoxyribonucleic acid, Bonding of dyes to ~ (CR) 648 [G.E. 76, 584 (1964)]

Relationship between the molar extinction coefficient ε of ~ and the guanine and cytosine content (LA) 658

Degradn. of ~ by cysteamine or L-cysteine (LA) 658

See also Nucleic acid

Desulfurization, Ring contractions by ~ leading to pyridazines and pyrazoles (LA) 451

Dewar benzene, Crystalline deriv. of ~ (SC) 695 [G.E. 76, 716 (1964)]

Simultaneous formation of substd. tetracyclohexane, tricyclohexene, and bicyclohexadiene by spontaneous trimerization of t-butylfluoroacetylene (SC) 755 [G.E. 76, 922 (1964)]

Dialdehydes, Cyclization of ~ with nitromethane (FP) 211 [G.E. 76, 84 (1964)]

β-Dialkylaminocyclobutanones, Ring-opening of ~ (CR) 653 [G.E. 76, 598 (1964)]

7-Dialkylaminonaphthalene-1,2-dicarboxylic hydrazides – new strongly chemiluminescent compds. (SC) 637 [G.E. 76, 686 (1964)]

Dialkylaminotrifluorophosphoranes, Alkyl(aryl)-~ and -fluorophosphines (SC) 513 [G.E. 76, 570 (1964)]

Dialkyldiazacyclopropanes, Thermal dehydrogenation of *C,C*-~ (SC) 229 [G.E. 76, 229 (1964)]

Diamines, Synths. of α,ω-~ via pseudonitrosites, nitroximes, and furoxans (CR) 651 [G.E. 76, 591 (1964)]

2,6-Diamino-2,6-dideoxy-D-gulose, New synth. of oxazolidones and the prepn. of ~ (SC) 379 [G.E. 76, 377 (1964)]

Diaroyl peroxides, Reacn. of diazo compds. with ~ (CR) 143 [G.E. 75, 1118 (1963)]

Diarsines, Simple synth. of disec. ~ and alkali phenylarsides (LA) 764

Diaryldiazomethanes, Reacns. of ~ with halogeno compds. (SC) 313 [G.E. 76, 343 (1964)]

Diaryldichloromethanes, Reacn. of potassium xanthate with ~, a new thioketone synth. (SC) 225 [G.E. 76, 98 (1964)]

Diarylketenes, New ~ and their autoxidation (CR) 650 [G.E. 76, 589 (1964)]

Diazacyclopropanes, see Diaziridines

Diazenium salts, Alkoxy-~ (CR) 151 [G.E. 75, 1111 (1963)]

Diaziridines, Three-membered rings containing two hetero-atoms (FP) 333 [G.E. 76, 197 (1964)]

Thermal dehydrogenation of *C,C*-dialkyldiazacyclopropanes (SC) 229 [G.E. 76, 229 (1964)]

Diazirines, Three-membered rings containing two hetero-atoms (FP) 333 [G.E. 76, 197 (1963)]

A simple synth. of cyclodiazomethane (LA) 522

Diazoalkanes, Capture of benzynes by acyl-~ (SC) 67 [G.E. 76, 98 (1964)]

Diazo-azo compds., Heterocyclic ~ as a source of nucleophilic carbenes (CR) 809 [G.E. 76, 995 (1964)]

Diazo compds., Quinonoid ~ (SC) 801 [G.E. 76, 954 (1964)]

Reacn. of ~ with diaroyl peroxides (CR) 143 [G.E. 75, 1118 (1963)]

Diazocyclopentadiene, Tetrachloro-~ from hexachlorocyclopentadiene (SC) 379 [G.E. 76, 431 (1964)]

α-Diazo-β-diketones, Azo coupling of ~ with non-phenolic methylene compds. (SC) 748 [G.E. 76, 920 (1964)]

Diazo groups, Introduction of ~ into reactive methylene compds. by azidinium salts (CR) 644 [G.E. 76, 573 (1964)]

Diazomethane, Reacns. of diaryl-~-s with halogenocompds. (SC) 313 [G.E. 76, 343 (1964)]

Prepn. of polymethylene by the reacn. of ~ with diborane (SC) 447 [G.E. 76, 495 (1964)]

Olefination of $N_2O$ and other attempts to synthesize ~ (CR) 655 [G.E. 76, 603 (1964)]

Diazonium groups, Substitution of aliphatic ~ (CR) 146 [G.E. 75, 1120 (1963)]

Diazonium salts, Stable aliphatic ~ (SC) 804 [G.E. 76, 992 (1964)]

Reacn. of nucleotides and nucleic acids with ~ (CR) 761 [G.E. 76, 689 (1964)]

Stable chelate ~ (LA) 391

Dibenz[*a,d*]anthrone, New synth. of derivs. of benz[*a*]anthrone and ~ (SC) 316 [G.E. 76, 301 (1964)]

Dibenzocarbazole, Rearr. of dibenzo[*c,g*]carbazole to dibenzo[*a,g*]carbazole (SC) 755 [G.E. 76, 922 (1964)]

Dibenzonaphthyridones, New synth. of dibenzo[*b,g*]-[1,8]naphthyridones (SC) 583 [G.E. 76, 646 (1964)]

Diborane, Prepn. of polymethylene by the reacn. of diazomethane with ~ (SC) 447 [G.E. 76, 495 (1964)]

Diboron compds., Disproportionation reacns. of ~ (CR) 148 [G.E. 75, 1114 (1963)]

Dibromovalerate, α,δ-Dibromovaleryl bromide and methyl α,δ-~ (SC) 63 [G.E. 75, 1205 (1963)]

α,δ-Dibromovaleryl bromide and methyl α,δ-dibromovalerate (SC) 63 [G.E. 75, 1205 (1963)]

Dichlorobutane, Elimination of HCl from gaseous 2,3-~ on $CaCl_2$, CaO, and $Al_2O_3$ (SC) 584 [G.E. 76, 645 (1964)]

Dichlorocarbene, α-Addn. of ~ to cyclohexyl isonitrile (SC) 752 [G.E. 76, 889 (1964)]

Dichloromaleyl dichloride (SC) 316 [G.E. 76, 303 (1964)]

Dichloromethyl-lithium and trichloromethyl-lithium (SC) 513 [G.E. 76, 536 (1964)]

Dichlorophenolindophenol, Non-enzymatic reduction of methylene blue and 2,6-~ by reduced di- and triphosphopyridine nucleotides (SC) 587 [G.E. 76, 571 (1964)]

Dicyclopentadienyleuropium (SC) 132 [G.E. 76, 52 (1964)]

Dielectric properties, Influence of the ~ of solvents and substrates on the light absorption and photochem. behavior of cationic dyes (CR) 758 [G.E. 76, 820 (1964)]

Diels-Alder reacn., Sulfene as a dienophile (SC) 754 [G.E. 76, 921 (1964)]

~ with nitroso compds. (CR) 146 [G.E. 75, 1120 (1963)]

Dienes, Hydrostannation of conjugated ~ (SC) 133 [G.E. 76, 52 (1964)]

Reacns. of *N*-carbonylsulfamyl chloride with ~ (CR) 649 [G.E. 76, 587 (1964)]

Dienophile, Sulfene as a ~ (SC) 754 [G.E. 76, 921 (1964)]

Dienylation reacns., Novel ~ (CR) 153 [G.E. 75, 1124 (1963)]

Diethylselenothiophosphinic acid, Derivs. of ~ (SC) 507 [G.E. 76, 496 (1964)]

Diffuse reflection, Scattering and absorption coefficients in ~ of powdered materials (CR) 321 [G.E. 76, 308 (1964)]

Diffusion, Fundamental aspects of ~ processes (FP) 713 [G.E. 76, 473 (1964)]

Diflavylenes, Synth. and properties of substd. ~ and quercetylenes (CR) 140 [G.E. 75, 1124 (1963)]

Difluorodiazine, Prepn. of difluorodiazine and the existence of chlorofluorodiazine (SC) 701 [G.E. 76, 713 (1964)]

Dihydronaphthalenes, Attempted synth. of cyclodecapentaenes by valence-bond isomerizn. of 9,10-~ (SC) 643 [G.E. 76, 786 (1964)]

7,14-Dihydrotriphendithiazine bis-*S*-oxides (SC) 375 [G.E. 76, 436 (1964)]

Diisonitriles, 1,4-Dipolar cycloaddn. onto ~ (SC) 446 [G.E. 76, 500 (1964)]

Diisonitrilomethane, Synth. of 1,1-~ (SC) 382 [G.E. 76, 440 (1964)]

Dimeric aldehyde hydrazones (SC) 63 [G.E. 75, 1204 (1963)]

Dimerization during the cyclization of proline peptides (SC) 64 [G.E. 75, 1206 (1963)]

Dimethylformamide-onium salts (SC) 377 [G.E. 76, 435 (1964)]

*N,N*-Dimethylformamide dineopentylacetal: a reagent for esterifying carboxylic acids with benzyl alcohols (SC) 62 [G.E. 75, 1176 (1963)]

Dimethylsilylene, Formation and reacns. of ~, a silicon-analogue of the carbenes (SC) 226 [G.E. 76, 270 (1964)]

Dimethyl sulfoxide, Isocyanates of sulfuric acid react with ~ (LA) 809

Dinucleotides, Synth. of ribo-~ with terminal 3'-phosphate groups (SC) 374 [G.E. 76, 435 (1964)]

5,12-Diphenyl-7-oxyldinaphtho[1,2-*b*:2',3'-*d*]furan (LA) 595

2,3-Diphenyl-1,1,4-trioxo-1,2,3-thiadiazolidines, Synth. of ~ (SC) 749 [G.E. 76, 919 (1964)]

Dipole moment of isomeric 1,2,3,4,5,6-hexachlorocyclohexanes (LA) 766

Disilylamides, Formation and properties of alkali ~ (CR) 646 [G.E. 76, 577 (1964)]

Displacement reaction, Novel intramolecular ~ (CR) 240 [G.E. 76, 107 (1964)]

Disproportionation reacns. of diboron compds. (CR) 148 [G.E. 75, 1114 (1963)]

Dissociation, Relations between structure and rate constants for the ~ and recombination of carboxylic acids (CR) 762 [G.E. *76*, 689 (1964)]

Distribution, Old and new processes of multiplicative ~ (liq.-liq. extraction) (FP) 791

Disulfur monoxide, Prepn. of pure ~ (SC) 61 [G.E. *76*, 97 (1964)]

1,3-Dithiacyclopentene-2-thione, Synth. of 1,3-dithiole-2-thione isotrithione (SC) 134 [G.E. *76*, 143 (1964)]

1,2-Dithiacyclopenten-3-one, Alkaline cleavage of ~ (CR) 645 [G.E. *76*, 575 (1964)]

Dithione (~) (LA) 71

Dithiobenzil, Characterization and stabilization of ~ by complex formation (SC) 133 [G.E. *76*, 143 (1964)]

Tris-~-metal complexes (SC) 639 [G.E. *76*, 715 (1964)]

1,6-Dithio-D-glucose, Prepn. of ~ (SC) 62 [G.E. *76*, 50 (1964)]

1,3-Dithiole-2-thione, Synth. of ~ (isotrithione) (SC) 134 [G.E. *76*, 143 (1964)]

Dithiols, Condensation of methyldichlorophosphine with ~ (SC) 586 [G.E. *76*, 648 (1964)]

Dithione, Bis-~ complexes of transition metals (SC) 381 [G.E. *76*, 345 (1964)]

~ (1,2-dithiacyclopenten-3-one) (LA) 71

Drugs, Analysis of ~ in biological fluids by the tropäolin method (CR) 761 [G.E. *76*, 688 (1964)]

Dyes, New reactive ~ (FP) 408 [G.E. *76*, 423 (1964)]

Hindered internal rotation in cyanine ~ (SC) 306 [G.E. *76*, 270 (1964)]

Dependence of the electron excitation of open-chain cyanine ~ on the valence angle of their nitrogen atoms (SC) 374 [G.E. *76*, 187 (1964)]

Bonding of ~ to deoxyribonucleic acid (CR) 648 [G.E. *76*, 584 (1964)]

Second international dyestuff symposium (CR) 756 [G.E. *76*, 819 (1964)]

Influence of the dielectric properties of solvents and substrates on the light absorption and photochem. behavior of cationic ~ (CR) 758 [G.E. *76*, 820 (1964)]

Changes in the light-fastness and color of org. ~ on various substrates (CR) 758 [G.E. *76*, 821 (1964)]

Relationship between the constitution of cationic triphenylmethane ~ and their light-fastness on polyacrylonitrile (CR) 758 [G.E. *76*, 821 (1964)]

Fiber damage due to anthraquinonoid ~ (CR) 760 [G.E. *76*, 822 (1964)]

Steric configuration of 1:2 metal-dye complexes (LA) 155

Structure and synth. of the blue dye from *Corynebacterium insidiosum* (LA) 765, 812

ELECTROCHEMICAL reacns. at semiconductor surfaces (CR) 809 [G.E. *76*, 759 (1964)]

Electrode, Theories of the glass ~ (FP) 36 [G.E. *76*, 39 (1964)]

Electron affinity of org. molecules (FP) 761 [G.E. *76*, 326 (1964)]

Electron configuration of tetravalent and trivalent uranium (LA) 70

Electron-donor/acceptor complexes, Contribution of an intermolecular charge-transfer band to the optical activity of ~ (SC) 307 [G.E. *76*, 228 (1964)]

Electron excitation, Dependence of the ~ of open-chain cyanine dyes on the valence angle of their nitrogen atoms (SC) 374 [G.E. *76*, 187 (1964)]

Electron proton resonance, Simple ~ method for measuring the g-factors of free radicals, applied to substd. aroxyls (CR) 656 [G.E. *76*, 610 (1964)]

Electron spin resonance measurements on irradiated bacteriophages and their nucleic acids (CR) 241 [G.E. *76*, 233 (1964)]

Electron states, Optically excited ~ of mono- and disubstd. benzene derivs. (LA) 71

Electropositive chlorine, Reacns. of compds. with ~ (CR) 448 [G.E. *76*, 385 (1964)]

Elimination of HCl from gaseous *cis*- and *trans*-chlorostilbene (SC) 135 [G.E. *76*, 184 (1964)]

Enamines, Prepn. of thioamides from alkenylamines and sulfur at room temperature (SC) 705 [G.E. *76*, 861 (1964)]

Ring synth. using ~ and ketene-*N*,*N*-acetals (CR) 149 [G.E. *75*, 1122 (1963)]

Cycloaddns. of alkenylamines and 1,1-bisdialkylaminoethylenes (CR) 708 [G.E. *76*, 724 (1964)]

Synth. of trithiones from ~, $CS_2$ and S (LA) 521

Endiol ethers, Photochemical synth. of ~ from thiocarboxylic *O*-esters (SC) 641 [G.E. *76*, 687 (1964)]

Energy-rich compds., *S*-Phosphorylated thiols, a new class of ~ (LA) 71

Energy terms, Boltzmann occupation of the ~ of atoms and molecules (CR) 388 [G.E. *76*, 306 (1964)]

Energy transformations, Reversibility of ~ in the respiratory chain (FP) 54 [G.E. *75*, 900 (1963)]

Enol ethers, Stereospecific addn. of ketenes onto ~ (SC) 753 [G.E. *76*, 893 (1964)]

Enolization of γ-lactones (SC) 375 [G.E. *76*, 376 (1964)]

Enol phosphate, Phosphonic ester/~ rearr. (SC) 443 [G.E. *76*, 494 (1964)]

*cis*-β,γ-Enoyl-coenzyme A, Metabolism of ~ compds. (SC) 386 [G.E. *76*, 440 (1964)]

*cis*-β,γ-Enoyl hydrase, Metabolism of *cis*-β,γ-enoyl-coenzyme A compds. (SC) 386 [G.E. *76*, 440 (1964)]

Enzymatic hydrolysis, Proton transfer, acid-base catalysis, and ~ (FP) 1 [G.E. *75*, 489 (1963)]

Enzymatic reactions on ion-exchange thin-layer plates (SC) 442 [G.E. *76*, 494 (1964)]

Enzyme synth., Damped oscillation of the ~ in yeast (SC) 803 [G.E. *76*, 990 (1964)]

Equilibrium and nonequilibrium in the glycolysis system (FP) 426 [G.E. *75*, 881 (1963)]

Ergot pigments (CR) 764 [G.E. *76*, 759 (1964)]

Erysotrine, Total synth. of ~ (SC) 588 [G.E. *76*, 651 (1964)]

Eserine, New synth. of the ~ skeleton (SC) 641 [G.E. *76*, 787 (1964)]

Esterification, *N*,*N*-Dimethylformamide dineopentylacetal: a reagent for esterifying carboxylic acids with benzyl alcohols (SC) 62 [G.E. *75*, 1176 (1963)]

Estrone, Recent advances in the synth. of 19-norsteroids (FP) 353 [G.E. *76*, 249 (1964)]

Ethers, Photocyanation of saturated ~ (LA) 71

Ethylaluminum sesquichlorides, Dehalogenation of ~ with Na (SC) 635 [G.E. *76*, 712 (1964)]

Ethylenes, Geometrically isomeric pairs with preferred *cis*-configuration among substd. ~ and 1,3-butadienes (CR) 152 [G.E. *75*, 1124 (1963)]

European biochemical societies, Federation of ~ (CR) 447 [G.E. *76*, 503 (1964)]

Europium, Dicyclopentadienyl-~ (SC) 132 [G.E. *76*, 52 (1964)]

~ as an alkaline earth metal (SC) 704 [G.E. *76*, 862 (1964)]

Systematic examination of the system $EuO-Eu_2O_3$ (CR) 139 [G.E. *75*, 1109 (1963)]

Excited electronic states, Classification of the ~ of org. molecules with the aid of the degree of polarization of the fluorescence and phosphorescence (CR) 759 [G.E. *76*, 822 (1964)]

Methods for determining the charge distribution in ~ (CR) 757 [G.E. *76*, 819 (1964)]

Explosion, of a mixture of triethylaluminum and $CCl_4$ (SC) 65 [G.E. *75*, 1205 (1963)]

~ during the oxidn. of tetralin with hydrogen peroxide in acetone (SC) 640 [G.E. *76*, 716 (1964)]

~ during the oxidn. of tetralin with hydrogen peroxide in acetone (Comments) (SC) 802 [G.E. *76*, 990 (1964)]

Extraction, Old and new processes of multiplicative distribution (liq.-liq. ~) (FP) 791

FATTY ACIDS, Synth. of naturally occurring unsaturated ~ by sterically controlled carbonyl olefination (FP) 250 [G.E. *76*, 113 (1964)]

Federation of European biochemical societies (CR) 447 [G.E. *76*, 503 (1964)]

Synth. of polyunsaturated ~ in microorganisms (LA) 450

Ferrocene, Absolute configuration of 1,2-(α-oxotetramethylene)-~ (SC) 512 [G.E. *76*, 570 (1964)]

Fiber damage due to anthraquinonoid dyes (CR) 760 [G.E. *76*, 822 (1964)]

Fibers, Chemistry of new heat-resistant films and ~ (FP) 460 [G.E. *76*, 484 (1964)]

Films, Chemistry of new heat-resistant ~ and fibers (FP) 460 [G.E. *76*, 484 (1964)]

Flash lamps, Generation of light by fluorine reacns. in ~ (SC) 747 [G.E. *76*, 890 (1964)]

Flash photolysis, Study of intermediates in ~ (CR) 758 [G.E. *76*, 821 (1964)]

Fluoranthene derivs., Synth. of ~ from monoethyl 4,4-(*o*,*o*-biphenylene)itaconate (SC) 587 [G.E. *76*, 648 (1964)]

Fluorescence, Dependence of the color of ~ on the medium (CR) 757 [G.E. *76*, 820 (1964)]

Classification of the excited electronic states of org. molecules with the aid of the degree of polarization of the ~ and phosphorescence (CR) 759 [G.E. 76, 822 (1964)]

Fluorine, New method for the determn. of ~ (FP) 424 [G.E. 76, 532 (1964)]

Fluorine reactions, Generation of light by ~ in flash lamps (SC) 747 [G.E. 76, 890 (1964)]

Fluorosilane, Racemization of an optically active ~ (LA) 244

Formyl chloride (SC) 132 [G.E. 75, 1203 (1963)]

Formylpyruvic acid, Role of ~ in the Warren reaction (LA) 390

Fragmentation, ~-s in the imidazoline series (CR) 139 [G.E. 75, 1116 (1963)]

~ of substd. pyrrolidinium salts (CR) 141 [G.E. 75, 1117 (1963)]

Five- and seven-center ~ of γ-oximino ketones (CR) 239 [G.E. 76, 106 (1964)]

Free radicals, See Radicals

Friedländer synth., Improvement of the ~ (LA) 522

Fuel cells, Methanol/air ~ (CR) 322 [G.E. 76, 382 (1964)]

Fulvene, A simple synth. of ~ and its 6-alkyl derivs. (SC) 749 [G.E. 76, 863 (1964)]

Furfuryloxycarbonyl group, an *N*-protecting group for peptide synth. (SC) 307 [G.E. 76, 271 (1964)]

Furoxans, Syntheses of α,ω-diamines via pseudonitrosites, nitroximes, and ~ (CR) 651 [G.E. 76, 591 (1964)]

GALLIUM COMPDS., A simple route to organo-~ (SC) 696 [G.E. 76, 752 (1964)]

Cleavage of siloxanes with gallium trichloride (SC) 696 [G.E. 76, 753 (1964)]

Alkylgallium derivs. (CR) 149 [G.E. 75, 1115 (1963)]

Gas chromatography, Gas-chromatographic sepn. and analysis of isomeric halogenated hydrocarbons (SC) 750 [G.E. 76, 891 (1964)]

Automatic combination of thin-layer chromatography and a temperature-programmed gas-chromatograph (CR) 761 [G.E. 76, 689 (1964)]

New method for identifying substances by ~ (LA) 243

Porous glasses as stationary phases in adsorption ~ (LA) 244

Inorg. salts as the stationary phase in ~ (LA) 451

Gel chromatography, Chromatographic sepns. on porous gels (FP) 608 [G.E. 76, 635 (1964)]

Genetic code, Determn. of the sequence of a code triplet (SC) 589, 600 [G.E. 76, 716, 800 (1964)]

Coding with mono- and polytrinucleotides (SC) 590 [G.E. 76 717 (1964)]

Streptomycin alters the mechanism by which the messenger code is red (LA) 810

German chemical society, Hauptversammlung der Gesellschaft Deutscher Chemiker (general meeting of the ~) (CR) 139 [G.E. 75, 1106 (1963)]

German chemistry lecturers, Meeting of West ~ (CR) 644 [G.E. 76, 573 (1963)]

Germanium compds., Methylgermylamines (SC) 231 [G.E. 76, 229 (1964)]

Prepn. of silylgermanes (SC) 314 [G.E. 76, 302 (1964)]

Structure and properties of trihalogenogermane etherates (SC) 508 [G.E. 76, 498 (1964)]

New synth. of germylsilane (SC) 586 [G.E. 76, 649 (1964)]

Synth. and cleavage of a six-membered germanium-nitrogen ring (SC) 637 [G.E. 76, 686 (1964)]

Prepn. of volatile mixed hydrides of phosphorus, arsenic, nitrogen, and germanium, and of triphosphine and triarsine (SC) 703 [G.E. 76, 860 (1964)]

New heterocycles containing Ge and Si (CR) 153 [G.E. 75, 1116 (1963)]

Polymerization of germanic acid (CR) 239 [G.E. 76, 106 (1964)]

Some bicyclic heterocycles (CR) 657 [G.E. 76, 615 (1964)]

Five-membered heterocyclics containing Si, Ge, or Sn (LA) 242

Gesellschaft Deutscher Chemiker, Hauptversammlung der ~ (general meeting of the German chemical society) (CR) 139 [G.E. 75, 1106 (1963)]

Glass electrode, Theories of the ~ (FP) 36 [G.E. 76, 39 (1964)]

Glasses, Hydrogen fluoride ~ (SC) 376 [G.E. 76, 343 (1964)]

Structure of silicate ~ (CR) 154 [G.E. 76, 233 (1964)]

Structure of ~ (CR) 520 [G.E. 76, 538 (1964)]

Porous ~ as stationary phases in adsorption gas chromatography (LA) 244

Glucose, Prepn. of 1,6-dithio-D-~ (SC) 62 [G.E. 76, 50 (1964)]

Glutamate dehydrogenase, Reversibility of the dissociation of ~ from beef liver into its polypeptide chains (SC) 802 [G.E. 76, 954 (1964)]

Damped oscillations of the enzyme synth. in yeast (SC) 803 [G.E. 76, 990 (1964)]

Glycols, Investigations on highly substd. ~ (CR) 242 [G.E. 76, 235 (1964)]

Glycolysis, Equilibrium and nonequilibrium in the ~ system (FP) 426 [G.E. 75, 881 (1963)]

Glycoside, Triandrin, a new phenolic ~ (LA) 70

Glycosylcarbamides, Triphenylphosphine *N*-acetylglycosylimides and *N,N'*-bis-(acetylglycosyl) carbodiimides (SC) 228 [G.E. 76, 227 (1964)]

Glycosylcarbodiimides, Triphenylphosphine *N*-acetylglycosylimides and *N,N'*-bis(acetylglycosyl)carbodiimides (SC) 228 [G.E. 76, 227 (1964)]

Glycosylimides, Triphenylphosphine *N*-acetyl-~ and *N,N'*-bis(acetylglycosyl)-carbodiimides (SC) 228 [G.E. 76, 227 (1964)]

Gradient thin-layer chromatography, Low temperature and ~ (FP) 784

Guanine, Relationship between the molar extinction coefficient ε of DNA and the ~ and cytosine content (LA) 658

Gulose, New synth. of oxazolidones and the prepn. of 2,6-diamino-2,6-dideoxy-D-~ (SC) 379 [G.E. 76, 377 (1964)]

HALOGENATED HYDROCARBONS, Gas-chromatographic sepn., and analysis of isomeric ~ (SC) 750 [G.E. 76, 891 (1964)]

Halogen compds., Reacns. of diaryldiazomethanes with ~ (SC) 313 [G.E. 76, 343 (1964)]

α-Halogen ethers, New synths. of aldehydes and carboxylic acids using ~ (CR) 144 [G.E. 75, 1118 (1963)]

Halogenoacrylates, Aryl rearr. in the thermolysis of β-arylated α-~ (SC) 445 [G.E. 76, 495 (1964)]

Halogenoalkynes, Synth. of alkynylamines by nucleophilic substitution of ~ (SC) 506 [G.E. 76, 537 (1964)]

Alkynylamines from ~ and tertiary amines (SC) 582 [G.E. 76, 537 (1964)]

Halogenoboranes, Bis(trimethylsilyl)-amino-~ (SC) 633 [G.E. 76, 499 (1964)]

Halogenoethylsulfonium salts, Sulfonium salts with alkyl and β-halogenoethyl ligands (LA) 70

Halogenomethylaluminum compds., Reacns. of ~ with azomethines and N-heterocycles (CR) 649 [G.E. 76, 587 (1964)]

Halogenosilanes, Reacns. of metal-substd. hydrides with ~ (CR) 644 [G.E. 76, 573 (1964)]

Heat-resistant films and fibers, Chemistry of new ~ (FP) 460 [G.E. 76, 484 (1964)]

Heavy metal compds., Recent investigations on the structure of ~ (CR) 70 [G.E. 76, 151 (1964)]

Helium, Prepn. of ~ from lithium deuteride by thermonuclear fusion (CR) 644 [G.E. 76, 574 (1964)]

Hemoglobin, Federation of European biochemical societies (CR) 447 [G.E. 76, 503 (1964)]

Heterocumulenes, New observations on acyl-~ (CR) 594 [G.E. 76, 654 (1964)]

Heterocycles, General rearr. of ~, and novel synth. of the benzotriazole, benzofurazan, and anthranil systems (SC) 693 [G.E. 76, 816 (1964)]

Heterocyclic arynes, Investigations on ~ (CR) 650 [G.E. 76, 590 (1964)]

Heterosiloxanes, New types of low molecular-weight ~ (CR) 241 [G.E. 76, 234 (1964)]

Hexacarbon hexoxide, Attempts to prepare ~ (CR) 150 [G.E. 75, 1123 (1963)]

Hexachlorocyclohexanes, Dipole moment of isomeric 1,2,3,4,5,6-~ (LA) 766

Hexachlorocyclopentadiene, Tetrachlorodiazocyclopentadiene from ~ (SC) 379 [G.E. 76, 431 (1964)]

Hexathiocyanatoaluminate, Prepn. of anhydrous potassium ~ and its behavior in liq. $NH_3$ (SC) 586 [G.E. 76, 647 (1964)]

Hexathiocyanatotitanate, Prepn. of potassium ~-(IV) and its behavior in liq. $NH_3$ (SC) 315 [G.E. 76, 304 (1964)]

Hexenediynes, Isolation, identification, and synth. of isomeric ~ from electric-arc acetylene (LA) 242

3-Hexen-2-one, Prepn. of ~ from 1-methoxybut-1-en-3-one (SC) 695 [G.E. 76, 817 (1964)]

Homoallylic rearr., Prepn. of condensed cyclobutane derivs. and spiro-cyclopropane compds. by ~ (SC) 698 [G.E. 76, 783 (1964)]

Homopolymerization, Stereospecific ~ of cyclopentene (FP) 723 [G.E. 76, 765 (1964)]

Hydrazide, Reacns. of sodium ~ with org. compds. (FP) 342 [G.E. 76, 206 (1964)]

Hydrazine, Reacns. of ~ and alkyl-substd. ~-s with pyrimidines (SC) 379 [G.E. *76*, 378 (1964)]

1-Hydrazinophthalazine, Mechanism of the protection by ~ against radiation (LA) 71

Hydrazones, Dimeric aldehyde ~ (SC) 63 [G.E. *75*, 1204 (1963)]

Hydrides, Prepn. of volatile mixed ~ of phosphorus, arsenic, nitrogen, and germanium, and of triphosphine and triarsine (SC) 703 [G.E. *76*, 860 (1964)]

Reacns. of metal-substd. ~ with halogenosilanes (CR) 644 [G.E. *76*, 573 (1964)]

Hydrocarbon, Proton-addn. complexes of aromatic ~-s (FP) 776 [G.E. *76*, 965 (1964)]

A stable radical-cation of a ~ (SC) 701 [G.E. *76*, 818 (1964)]

Hydrogen bromide, Electrophilically induced cyclodimerization of methylacetylene by ~ (SC) 697 [G.E. *86*, 782 (1964)]

Studies of the tetrahydrate of ~ $H_9O_4Br$ (CR) 389 [G.E. *76*, 307 (1964)]

Decarbobenzoxylation with liq. ~ (LA) 155

Hydrogen chloride, Elimination of ~ from gaseous 2,3-dichlorobutane on $CaCl_2$, CaO, and $Al_2O_3$ (SC) 584 [G.E. *76*, 645 (1964)]

Hydrogen fluoride glasses (SC) 376 [G.E. *76*, 343 (1964)]

Hydrogen halides, Polar addn. of ~ onto olefins (FP) 245 [G.E. *76*, 320 (1964)]

Hydrogen peroxide, Explosion during the oxidn. of tetralin with ~ in acetone (SC) 640 [G.E. *76*, 716 (1964)]

Explosion during the oxidn. of tetralin with ~ in acetone (Comments) (SC) 802 [G.E. *76*, 990 (1964)]

Reacn. between $P_2O_5$ and ~ (LA) 391

1,5-Hydrogen shifts in cyclopentadiene and indene (CR) 654 [G.E. *76*, 602 (1964)]

Hydrogen transfer, Homolytic ~ in a cyclohexane (LA) 522

Hydrolysis, Proton transfer, acid-base catalysis, and enzymatic ~ (FP) 1 [G.E. *75*, 489 (1963)]

Selective ~ of pyrophosphate bonds in polynucleotides (SC) 439 [G.E. *76*, 439 (1964)]

Hydrostannation of conjugated dienes (SC) 133 [G.E. *76*, 52 (1964)]

Hydrothermal sintering (SC) 133 [G.E. *76*, 52 (1964)]

2-Hydroxy-4-aryl-5-bromothiazole, Thiazolizations using ~ or 2-amino-4-aryl-5-bromothiazole (CR) 147 [G.E. *75*, 1121 (1963)]

Hydroxylamine derivs., Isomerism of ~ (CR) 153 [G.E. *76*, 233 (1964)]

Hydroxylammonium chloride, Reacn. of $PCl_5$ with ~ (LA) 391

Hydroxylation, Radiochemical ~ of phenolic compds. (SC) 640 [G.E. *76*, 752 (1954)]

5-Hydroxymethyluracil nucleosides, Simple synth. of natural and artificial ~ (SC) 66 [G.E. *76*, 50 (1964)]

4-Hydroxy-5-nitropyrimidines, Synth. of ~ (SC) 703 [G.E. *76*, 860 (1964)]

Hydroxyphthalides, New synth. of ~ (CR) 390 [G.E. *76*, 384 (1964)]

1-Hydroxypyridine *N*-oxide, Water-stable cationic complexes of silicic acid with ~ (SC) 698 [G.E. *76*, 818 (1964)]

8-Hydroxyquinoline, Chelate complexes of Pu with ~ (CR) 145 [G.E. *75*, 1113 (1963)]

IATROCHEMISTS, Chinese ~ in the middle ages prepared mixtures of steroid hormones (LA) 450

Imidazoline, Fragmentations in the ~ series (CR) 139 [G.E. *75*, 1116 (1963)]

Imidodiphosphinatometal chelates, neutral complexes with carbon-free chelate rings (SC) 704 [G.E. *76*, 860 (1964)]

Immunochemistry (CR) 591, 812 [G.E. *76*, 721, 995 (1964)]

Indanes, Formation of 1-benzyl-2,3-diphenyl-~ from stilbene in the presence of tin tetrachloride under the influence of $\gamma$-radiation (SC) 803 [G.E. *76*, 989 (1964)].

Indene, 1,5-Hydrogen shifts in cyclopentadiene and ~ (CR) 654 [G.E. *76*, 602 (1964)]

Indicators, Behavior of some ~ in aprotic solvents (CR) 239 [G.E. *76*, 106 (1964)]

Indigo, New synth. of ~ (SC) 754 [G.E. *76*, 921 (1964)]

Indium compds., Superconductivity in $In_3SbTe_2$ (SC) 588 [G.E. *76*, 651 (1964)]

Indolines, Restricted resonance in new ~ with fixed nitrogen torsion angles (CR) 647 [G.E. *76*, 581 (1964)]

Inert gases, Valence compds. of the ~ (FP) 538 [G.E. *76*, 455 (1964)]

Information, Chem. storage and processing of ~ in biological systems (CR) 706 [G.E. *76*, 718 (1964)]

Problem of ~ transfer in chemistry (LA) 710

Infrared spectroscopy, Differentiation of primary, secondary, and tertiary alcohols by near ~ (SC) 309 [G.E. *76*, 271,(1964)]

Solvent effects on the position of the first overtone of the O H valence vibration (SC) 694 [G.E. *76*, 715 (1964)]

Insects, Defensive substances of the arthropods, their isoln. and identification (FP) 73 [G.E. *75*, 762 (1963)]

Interfaces, Adsorption phenomena at gas/solid ~ at low gas pressures (CR) 321 [G.E. *76*, 308 (1964)]

Interferon, Joint meeting of Swiss and Austrian chemists (CR) 238 [G.E. *76*, 105 (1964)]

Mol. wt. of ~ (LA) 658

Intermetallic phases, Bonding in ~ of the Ni–As type (CR) 322 [G.E. *76*, 353 (1964)]

International congress of chemotherapy, Third ~ (CR) 233 [G.E. *75*, 1178 (1963)]

Intramolecular free-radical reacns. (FP) 525 [G.E. *76*, 518 (1964)]

Iron, Cause of the pyrophoric behavior of finely divided ~ (LA) 765

Iron compds., Iron carbonyl complexes of the dimers of cyclooctatetraene and bullvalene (SC) 509 [G.E. *76*, 498 (1964)]

Pentakis(trifluorophosphine)iron (SC) 754 [G.E. *76*, 893 (1964)]

Stability constants of 1:1, 1:2 and 1:3 complexes of Fe(III) with benzhydroxamic acid (LA) 71

Iron(III) siloxane compds. (LA) 763

Isocyanates, Reacn. of benzotriazinones with ~ (SC) 378 [G.E. *76*, 437 (1964)]

Reacn. of amide acetals with ~. Synth. of parabanic acid *O,N*-acetals (SC) 704 [G.E. *76*, 861 (1964)]

Reacn. of vinyl ethers and ketene acetals with ~ and *N*-sulfinyl compds. (CR) 142 [G.E. *75*, 1117 (1963)]

Cycloaddns. with ~ as 1,4- and 1,2-dipoles (CR) 652 [G.E. *76*, 596 (1964)]

~ of sulfuric acid react with dimethyl sulfoxide (LA) 809

Isocyanides, Amino ~ (CR) 647 [G.E. *76*, 580 (1964)]

Contribution to the chemistry of ~ (CR) 647 [G.E. 583 (1964)]

Preliminary studies on peptide syntheses from ~ (CR) 656 [G.E. *76*, 613 (1964)]

Isoenzymes of creatine kinase (LA) 709

Isoindoles, Prepn. of *N*-alkyl-~ from *N*-alkylisoindoline *N*-oxides (SC) 639 [G.E. *76*, 682 (1964)]

New synth. of *N*-alkyl-~ (LA) 522

Isoindoline *N*-oxides, Prepn. of *N*-alkylisoindoles from *N*-alkyl-~ (SC) 639 [G.E. *76*, 682 (1964)]

Isomerization of cyclic mono- and diolefins during the Koch carboxylic acid synth. (CR) 148 [G.E. *75*, 1122 (1963)]

Isomers, Relative reactivities of positional and geometric ~ of high mol.wt. n-olefins (CR) 647 [G.E. *76*, 580 (1964)]

Isoquinoline, Synth. of the ~ system from *o*-phthalaldehyde and nitromethane (SC) 224 [G.E. *76*, 50 (1964)]

Isothiazolidinone, $\omega$-Chlorosulfenylalkylcarbonyl chlorides (SC) 67 [G.E. *76*, 51 (1964)]

Isothioamide groups, Condensation of active methylene compds. with ~ (SC) 640 [G.E. *76*, 781 (1964)]

Isothiocyanates (CR) 317 [G.E. *76*, 276 (1964)]

Isotrithione, Synth. of 1,3-dithiole-2-thione (~) (SC) 134 [G.E. *76*, 143 (1964)]

KETENE ACETALS, Reacn. of vinyl ethers and ~ with isocyanates and *N*-sulfinyl compds. (CR) 142 [G.E. *75*, 1117 (1963)]

Ring synth. using enamines and ketene-*N,N*-acetals (CR) 149 [G.E. *75*, 1122 (1963)]

Ketenes, Stereospecific addn. of ~ onto enol ethers (SC) 753 [G.E. *76*, 893 (1964)]

New diaryl-~ and their autoxidation (CR) 650 [G.E. *76*, 589 (1964)]

Ketocarotenoids in crustaceae (LA) 595

Ketones, Course of the Willgerodt-Kindler reacn. of alkyl aryl ~ (FP) 19 [G.E. *75*, 1050 (1963)]

Kindler reacn., Course of the Willgerodt-~ of alkyl aryl ketones (FP) 19 [G.E. *75*, 1050 (1963)]

Koch carboxylic acid synth., Isomerizn. of cyclic mono- and diolefins during the ~ (CR) 148 [G.E. *75*, 1122 (1963)]

Krypton, Valence compds. of the inert gases (FP) 538 [G.E. *76*, 455 (1964)]

LACTONES, Enolization of $\gamma$-~ (SC) 375 [G.E. *76*, 376 (1964)]

Lactose, Biological utilization of ~ (CR) 449 [G.E. *76*, 383 (1964)]

Lead compds., Existence and constitution of ternary compds. between PbO, $SiO_2$, and Pb halides (CR) 148 [G.E. *75*, 1111 (1963)]

NMR spectra of new organo-~ (LA) 764

Lead electrode, Refining of Ti and Ti alloys by melt electrolysis using a liquid ~ (CR) 147 [G.E. *75*, 1114 (1963)]

Levafix dyes, New reactive dyes (FP) 408 [G.E. *76*, 423 (1964)]

Light, Generation of ~ by fluorine reacns. in flash lamps (SC) 748 [G.E. *76*, 890 (1964)]

Hollow cathode as a ~ source for emission spectrography in the vacuum ultraviolet region (CR) 388 [G.E. *76*, 306 (1964)]

Light-fastness, Changes in the ~ and color of org. dyes on various substrates (CR) 758 [G.E. *76*, 821 (1964)]

Relationship between the constitution of cationic triphenylmethane dyes and their ~ on polyacrylonitrile (CR) 758 [G.E. *76*, 821 (1964)]

Lipids, Biosynth., structure, and biological action of the ~ of the tubercle bacillus (FP) 393 [G.E. *76*, 241 (1964)]

Liquid-liquid extraction, Old and new processes of multiplicative distribution (~) (FP) 791

Lithium, Determin. of ~ by activation analysis (CR) 139 [G.E. *75*, 1130 (1963)]

Lithium compds., Mechanism of the action of organometallic catalysts (FP) 93 [G.E. *75*, 805 (1963)]

Dichloromethyl-Li and trichloromethyl-Li (SC) 513 [G.E. *76*, 536 (1964)]

Prepn. of He from LiD by thermonuclear fusion (CR) 644 [G.E. *76*, 574 (1964)]

Lysozymes, Recent developments in the study of ~ (FP) 28 [G.E. *76*, 20 (1964)]

MAGNESIUM, Method for the microdetermination of $Mg^{2+}$ and $Ca^{2+}$ in tissues (LA) 70

Magnetic susceptibility, Determn. of the ~ of org. compds. from proton resonance (SC) 440 [G.E. *76*, 496 (1964)]

Magnetocatalytic effect, External ~ (SC) 750 [G.E. *76*, 891 (1964)]

Malonic acid, Prepn. of ~ by carboxylation of acetic acid (SC) 751 [G.E. *76*, 893 (1964)]

Mass-spectroscopy of inorganic systems at high temperatures (CR) 153 [G.E. *76*, 150 (1964)]

Mercaptide ions, Reactivity of sulfonium salts toward ~ (LA) 765

Mercury, Recent investigations on the structure of heavy-metal compds. (CR) 70 [G.E. *76*, 151 (1964)]

Mesitylenecarboxamides, Rotational isomers of ~ (CR) 652 [G.E. *76*, 595 (1964)]

Mesoionic aromatic compds., New type of ~ and its 1,3-dipolar cycloaddn. reacns. with acetylene derivs. (SC) 136 [G.E. *76*, 185 (1964)]

Metabolism, Equilibrium and nonequilibrium in the glycolysis system (FP) 426 [G.E. *75*, 881 (1963)]

~ of *cis*-β,γ-enoyl-coenzyme A compds. (SC) 386 [G.E. *76*, 440 (1964)]

Metalating agent, Naphthalene magnesium, a new ~ (LA) 243

Metalcarbonyls, Photochem. substitutions on ~ and their derivs. (FP) 730 [G.E. *76*, 873 (1964)]

Metal-dye complexes, Steric configuration of 1:2-~ (LA) 155

Metallo-complexes (FP) 686, 812 [G.E. *76*, 697 (1964)]

1,6-Methanocyclodecapentaene, The cyclodecapentaene system (SC) 228 [G.E. *76*, 145 (1964)]

Substitution of ~ (SC) 642 [G.E. *76*, 784 (1964)]

Methanol/air fuel cells (CR) 322 [G.E. *76*, 382 (1964)]

1-Methoxybut-1-en-3-one, Prepn. of 3-hexen-2-one from ~ (SC) 695 [G.E. *76*, 817 (1964)]

Methylacetylene, Electrophilically induced cyclodimerization of ~ by HBr (SC) 697 [G.E. *76*, 782 (1964)]

Methyldichlorophosphine, Condensation of ~ with dithiols (SC) 586 [G.E. *76*, 648 (1964)]

Methylene blue, Non-enzymatic reduction of ~ and 2,6-dichlorophenolindophenol by reduced di- and triphosphopyridine nucleotides (SC) 587 [G.E. *76*, 571 (1964)]

Methylene compds., Condensation of active ~ with isothioamide groups (SC) 640 [G.E. *76*, 781 (1964)]

Introduction of diazo groups into reactive ~ by azidinium salts (CR) 644 [G.E. *76*, 573 (1964)]

Synth. of aliphatic azo and diazo compds. from active ~ and sulfonyl azides (CR) 654 [G.E. *76*, 601 (1964)]

Azo coupling of α-diazo-β-diketones with non-phenolic ~ (SC) 748 [G.E. *76*, 920 (1964)]

1-Methylene-2,5-cyclohexadiene (SC) 62 [G.E. *75*, 1177 (1963)]

Methylenecyclopropane, Synth. of a ~ deriv. (SC) 699 [G.E. *76*, 784 (1964)]

Methylenephosphoranes, Cyclic ~ (CR) 147 [G.E. *75*, 1121 (1963)]

Methylgermylamines (SC) 231 [G.E. *76*, 229 (1964)]

Molybdenum, Cyclopentadienyl(benzene)-~ (SC) 134 [G.E. *76*, 98 (1964)]

Monoalkyl phosphates, New synth. of ~ (LA) 323

Multiplicative distribution, Old and new processes of ~ (liq.-liq. extraction) (FP) 791

Muscle, Energetics of the contraction cycle in ~ (CR) 321 [G.E. *76*, 308 (1964)]

NAPHTHALENE, Bis-peri-tetraphenyl-~ (LA) 765

7-Dialkylamino-~-1,2-dicarboxylic hydrazides, – new strongly chemiluminescent compds. (SC) 637 [G.E. *76*, 686 (1964)]

~ magnesium, a new metalating agent (LA) 243

Neuroscience research foundation, Chem. storage and processing of information in biological systems (CR) 706 [G.E. *76*, 718 (1964)]

Neutron, Structure of the proton and the ~ (FP) 597 [G.E. *76*, 513 (1964)]

Nickel, Bonding in intermetallic phases of the Ni–As type (CR) 322 [G.E. *76*, 353 (1964)]

Nickel compds., Changes in the coordination numbers of Ni(0) and Ni(I) compds. (CR) 648 [G.E. *76*, 586 (1964)]

Niobium compds., New modifications of $Nb_2O_5$ (SC) 511 [G.E. *76*, 536 (1964)]

Reacns. with single crystals of Nb oxides (SC) 634 [G.E. *76*, 685 (1964)]

Compds. of Nb with elements of the 5th and 6th main groups (CR) 150 [G.E. *75*, 1134 (1963)]

Nitrile oxides, Aliphatic ~ (SC) 383 [G.E. *76*, 440 (1964)]

Stable aromatic ~ (SC) 585 [G.E. *76*, 682 (1964)]

α-Nitroacrylic ester, Investigations of α-nitro-β-alkoxypropionic esters; ~ as intermediate (CR) 144 [G.E. *75*, 1118 (1963)]

α-Nitro-β-alkoxypropionic esters, Investigations of ~; α-nitroacrylic ester as intermediate (CR) 144 [G.E. *75*, 1118 (1963)]

Nitrogen compds., Dependence of the electron excitation of open-chain cyanine dyes on the valence angle of their nitrogen atoms (SC) 374 [G.E. *76*, 187 (1964)]

Prepn. of fluorinated Si-~ using $SiF_4$ (SC) 446 [G.E. *76*, 497 (1964)]

Compds. containing the Si–N–B-linkage (SC) 509 [G.E. *76*, 500 (1964)]

A new type of P-~ with pentavalent P (SC) 590 [G.E. *76*, 686 (1964)]

Synth. and cleavage of a six-membered Ge-~ (SC) 637 [G.E. *76*, 686 (1964)]

Prepn. of volatile mixed hydrides of phosphorus, arsenic, nitrogen, and germanium and of triphosphine and triarsine (SC) 703 [G.E. *76*, 860 (1964)]

New method for the prepn. of P-~ (SC) 753 [G.E. *76*, 894 (1964)]

Prepn. of Ti-~ by addn. and substitution reacns. (CR) 141 [G.E. *75*, 1109 (1963)]

Reactivity of the P=N double bond (CR) 141 [G.E. *75*, 1109 (1963)]

Recent investigations of inorg. halogen-~ (CR) 449 [G.E. *76*, 386 (1964)]

Nitrogen radicals, Verdazyls and related nitrogen-containing free radicals (CR) 763 [G.E. *76*, 691 (1964)]

Nitromethane, Cyclization of dialdehydes with ~ (FP) 211 [G.E. *76*, 84 (1963)]

Synth. of the isoquinoline system from *o*-phthalaldehyde and ~ (SC) 224 [G.E. *76*, 50 (1964)]

Nitronic acids, Possibility of the existence of dialkyl- and diacyl-~ (LA) 156

*o*-Nitrophenylsulfenylimine radical (SC) 373 [G.E. *76*, 376 (1964)]

Nitropyrimidines, Synth. of 4-hydroxy-5-~ (SC) 703 [G.E. *76*, 860 (1964)]

Nitroso compds., Diels-Alder syntheses with ~ (CR) 146 [G.E. *75*, 1120 (1963)]

New type of base-catalysed rearr. of ~ (LA) 709

Nitrosteroids, Conformational analysis of ~ by circular dichroism (CR) 762 [G.E. *76*, 690 (1964)]

Nitrous acid, Solutions of pure ~ (LA) 323

Nitrovinylation reacn., Simple ~ (SC) 806 [G.E. *76*, 993 (1964)]

Nitroximes, Syntheses of α,ω-diamines via pseudonitrosites, ~, and furoxans (CR) 651 [G.E. *76*, 591 (1964)]

NMR spectroscopy, Determn. of the magnetic susceptibility of org. compds. from proton resonance (SC) 440 [G.E. *76*, 496 (1964)]

Proof of a norcaradiene-cycloheptatriene valence tautomerism by ~ (SC) 443 [G.E. *76*, 432 (1964)]

Proton resonance investigations on the conformational mobility of cyclic di- and trisulfides (CR) 650 [G.E. 76, 590 (1964)]

~ for the analysis of org. compds. with known functional groups (CR) 761 [G.E. 76, 689 (1964)]

~ of new organolead compds. (LA) 764

Noble-gas compds., Valence compds. of the inert gases (FP) 538 [G.E. 76, 455 (1964)]

Noble-metal compds., Recent investigations into the structures of ~ (CR) 519 [G.E. 76, 690 (1964)]

Nonequilibrium, Equilibrium and ~ in the glycolysis system (FP) 426 [G.E. 75, 881 (1963)]

Norcaradiene, Proof of a ~-cycloheptatriene valence tautomerism by NMR spectroscopy (SC) 443 [G.E. 76, 432 (1964)]

19-Norsteroids, Recent advances in the synth. of ~ (FP) 353 [G.E. 76, 249 (1964)]

Nuatigenin, Constitution of a cholegenin analogue from the vegetable kingdom (CR) 152 [G.E. 75, 1128 (1963)]

Nucleic acids, Electron spin resonance measurements on irradiated bacteriophages and their ~ (CR) 241 [G.E. 76, 233 (1964)]

Chem. storage and processing of information in biological systems (CR) 706 [G.E. 76, 718 (1964)]

Reacn. of nucleotides and ~ with diazonium salts (CR) 761 [G.E. 76, 689 (1964)]

Nucleophilic carbene, Detection of a heterocyclic ~ (SC) 800 [G.E. 76, 989 (1964)]

Heterocyclic diazo-azo compds. as a source of ~-s (CR) 809 [G.E. 76, 995 (1964)]

Nucleophilic compds., Relations between structure and reactivity of ambifunctional ~ (FP) 560 [G.E. 76, 412 (1964)]

Nucleoside diphosphates, Simple method for preparing ~ (SC) 634 [G.E. 76, 683 (1964)]

Nucleosides, Simple synth. of natural and artificial 5-hydroxymethyluracil-~ (SC) 66 [G.E. 76, 50 (1964)]

Nucleotides, Synth. of ribodi-~ with terminal 3'-phosphate groups (SC) 374 [G.E. 76, 435 (1964)]

Coding with mono- and polytri-~ (SC) 590 [G.E. 76, 717 (1964)]

Reacn. of ~ and nucleic acids with diazonium salts (CR) 761 [G.E. 76, 689 (1964)]

OCTABENZYLCYCLOTETRASTANNANE, Synth. of ~ (SC) 751 [G.E. 76, 892 (1964)]

Octahydroquinolines, Synth. of 5-oxo-~ and their reduction with lithium aluminum hydride (SC) 807 [G.E. 76, 994 (1964)]

Olefination, Synth. of naturally occurring unsaturated fatty acids by sterically controlled carbonyl ~ (FP) 250 [G.E. 76, 113 (1964)]

~ of $N_2O$ and other attempts to synthesize diazomethane (CR) 655 [G.E. 76, 603 (1964)]

Olefins, Polar addn. of hydrogen halides onto ~ (FP) 245 [G.E. 76, 320 (1964)]

Addn. of methyl acetoxyacetate onto ~ by a free-radical mechanism (SC) 635 [G.E. 76, 713 (1964)]

Reacn. of alkylidenephosphoranes with C=C and C=N double bonds (CR) 140 [G.E. 75, 1117 (1963)]

Isomerization of cyclic mono- and di-~ during the Koch carboxylic acid synth. (CR) 148 [G.E. 75, 1122 (1963)]

Relative reactivities of positional and geometric isomers of high mol.wt. n-~ (CR) 647 [G.E. 76, 580 (1964)]

New stereospecific synth. of ~ from 1,2-dioles (LA) 451

Onium salts, Dimethylformamide-~ (SC) 377 [G.E. 76, 435 (1964)]

Prepn. and properties of organometallic ~ complexes (CR) 142 [G.E. 75, 1112 (1963)]

Optical activity, Contribution of an intermolecular charge-transfer band to the ~ of electron-donor/acceptor complexes (SC) 307 [G.E. 76, 228 (1964)]

Radiochemical polymerizn. of some optically active monomers (CR) 151 [G.E. 75, 1135 (1963)]

Organometallic catalysts, Mechanism of the action of ~ (FP) 93 [G.E. 75, 805 (1963)]

Organometallic compds., Monovalent reacns. on ~ (CR) 654 [G.E. 76, 601 (1964)]

Osazones, Cinnoline compds. as by-products in the formation of ~ from aldoses (CR) 144 [G.E. 75, 1126 (1963)]

Mechanism of ~ formation and of the Amadori rearr. (CR) 320 [G.E. 76, 307 (1964)]

Oscillation, Damped ~ of the enzyme synth. in yeast (SC) 803 [G.E. 76, 990 (1964)]

Osmium compds., Szilard-Chalmers process in $K_2ReBr_6/K_2OsCl_6$ mixed crystals (CR) 148 [G.E. 75, 1132 (1963)]

Oxalato complexes, Structure of anomalous ~ of Pt (CR) 147 [G.E. 75, 1114 (1963)]

Oxalyl chloride, Interaction of disubstd. cyanamides with phosgene and ~ (SC) 694 [G.E. 76, 714 (1964)]

1-Oxa-2-silacyclopentane, Synth. and polymerization of ~ derivs. (CR) 146 [G.E. 75, 1114 (1963)]

Oxaziranes, Three-membered rings containing two hetero-atoms (FP) 333 [G.E. 76, 197 (1964)]

Oxazolidones, New synth. of ~ and the prepn. of 2,6-diamino-2,6-dideoxy-D-gulose (SC) 379 [G.E. 76, 377 (1964)]

Oxepin, Synth. of an ~ deriv. (SC) 510 [G.E. 76, 535 (1964)]

Oxidative condensation of quaternary phenolic bases (FP) 192 [G.E. 75, 957 (1963)]

Oxide fluorides, Applicn. of chloronitrate for the prepn. of ~ (CR) 142 [G.E. 75, 1110 (1963)]

Oxide iodides, New synth. of ~ (CR) 646 [G.E. 76, 578 (1964)]

Oxides, Reacn. of ~ with $H_2O$ at high pressures and temperatures (FP) 47 [G.E. 75, 949 (1963)]

Transport processes and equilibria in the reduction of ~ (CR) 320 [G.E. 76, 307 (1964)]

γ-Oximino ketones, Five- and seven-center fragmentation of ~ (CR) 239 [G.E. 76, 106 (1964)]

5-Oxo-octahydroquinolines, Synth. of ~ and their reduction with lithium aluminum hydride (SC) 807 [G.E. 76, 994 (1964)]

1,2-(α-Oxotetramethylene)ferrocene, Absolute configuration of ~ (SC) 512 [G.E. 76, 570 (1964)]

Oxygen, New cell for the electrochem. determn. of ~ (LA) 659

Instrument for estimating ~ by gas-phase polarography (LA) 766

PARABANIC ACID, Reacn. of amide acetals with isocyanates, the synth. of ~ *O,N*-acetals (SC) 704 [G.E. 76, 861 (1964)]

Passerini-Ugi reacn., Asymmetric induction during the synth. of amino acids by the ~ (CR) 808 [G.E. 76, 757 (1964)]

Peat as a cation-exchanger in the purification of radioactive sewage (LA) 658

Penicillamine amide, Synth. of ~ and penicillamine thioamide from thiazolidine-4-carboxamides and -4-thiocarboxamides (SC) 313 [G.E. 76, 273 (1964)]

Penicillamine nitrile (LA) 595

Penicillamine thioamide, Synth. of penicillamine amide and ~ from thiazolidine-4-carboxamides and -4-thiocarboxamides (SC) 313 [G.E. 76, 273 (1964)]

Penicillanic acid, Synth. of 6-[(D-α-amino-α-phenylacetyl)amino]-~ using β-dicarbonyl compds. as amino-protecting groups (SC) 439 [G.E. 76, 342 (1964)]

Pentafluoro-orthotelluric acid (SC) 383 [G.E. 76, 379 (1964)]

Pentafluorophenyltrimethylsilane, Synth. of tris(pentafluorophenyl)arsine, -stibine, and -phosphine and of ~ (SC) 801 [G.E. 76, 954 (1964)]

Peptides, Dimerization during the cyclization of proline ~ (SC) 64 [G.E. 75, 1206 (1963)]

Furfuryloxycarbonyl group, an *N*-protecting group for ~ synth. (SC) 307 [G.E. 76, 271 (1964)]

~ syntheses with alkynylamines (SC) 582 [G.E. 76, 572 (1964)]

Chemical synth. of poly-~ and the hydrodynamic properties of their solns. (CR) 389 [G.E. 76, 381 (1964)]

Preliminary studies on ~ syntheses from isocyanides (CR) 656 [G.E. 76, 613 (1964)]

New method of ~ synth. using amino acid derivs. of saccharin (LA) 451

Lithium aluminum hydride cleaves proline linkages in ~ (LA) 810

Perbromoallene, Tribromoallene and ~ (SC) 382 [G.E. 76, 379 (1964)]

Peroxyesters, The peroxyester reacn. (FP) 269 [G.E. 76, 218 (1964)]

Novel decomposition of ~ (CR) 150 [G.E. 75, 1122 (1963)]

Pharmaceutical exhibition, Therapy congress and ~ (CR) 68 [G.E. 76, 55 (1964)]

Phenolic bases, Oxidative condensation of quaternary ~ (FP) 192 [G.E. 75, 957 (1963)]

Phenolic compds., Radiochemical hydroxylation of ~ (SC) 640 [G.E. 76, 752 (1964)]

Phenols, Substd. ~ (LA) 71

Phenoxycyclopropanes, Synth. of ~ (LA) 156

Phenylarsides, Simple synth. of disecondary diarsines and alkali ~ (LA) 764

Phenyl t-butylnitroxide, a new free radical (LA) 323

Phenyl cyanate (SC) 311 [G.E. *76*, 303 (1964)]

Phenyl migration, Stereochemical criterion for ~ by a free-radical mechanism (CR) 655 [G.E. *76*, 602 (1964)]

Phosgene, Interaction of disubstd. cyanamides with ~ and oxalyl chloride (SC) 694 [G.E. *76*, 714 (1964)]

Phosphacyanines, a new class of compds. containing trivalent P (SC) 384 [G.E. *76*, 433 (1964)]

2-Phospha-1,3-diazetidinones, a new class of compds. (SC) 585 [G.E. *76*, 647 (1964)]

Phosphates, New synth. of monoalkyl ~ (LA) 323

Phosphatides, Preparative thin-layer chromatographic sepn. of ~ and thin-layer chromatographic identification of their hydrolysis products (CR) 762 [G.E. *76*, 690 (1964)]

Phosphazenes, Reactivity of the P=N double bond (CR) 141 [G.E. *75*, 1109 (1963)]

Phosphine, New method for the formation of P–P bonds (SC) 64 [G.E. *75*, 1205 (1963)]

Triphenyl-~ *N*-acetylglycosylimides and *N,N'*-bis(acetylglycosyl)carbodiimides (SC) 228 [G.E. *76*, 227 (1964)]

Alkyl(aryl)dialkylaminofluorophosphoranes and -fluoro-~-s (SC) 513 [G.E. *76*, 570 (1964)]

Condensation of methyldichloro-~ with dithiols (SC) 586 [G.E. *76*, 648 (1964)]

Reductive dehalogenations using tert. ~-s (CR) 145 [G.E. *75*, 1119 (1963)]

Phosphonic ester/enol phosphate rearr. (SC) 443 [G.E. *76*, 494 (1964)]

Phosphonium salts, Formation of the second kind (FP) 737 [G.E. *76*, 944 (1964)]

New approach to tetraaryl-~ (SC) 231 [G.E. *76*, 187 (1964)]

Phosphoranes, Autoxidative ring closure of ω,ω-bis(triphenylphosphorylidene)-alkanes (SC) 226 [G.E. *76*, 226 (1964)]

Reacn. of alkylidenetriphenyl-~ with acetylenedicarboxylic esters (SC) 512 [G.E. *76*, 569 (1964)]

Alkyl(aryl)dialkylaminofluoro-~ and -fluorophosphines (SC) 513 [G.E. *76*, 570 (1964)]

Reacn. of alkylidene-~ with C=C and C=N double bonds (CR) 140 [G.E. *75*, 1117 (1963)]

Cyclic methylene-~ (CR) 147 [G.E. *75*, 1121 (1963)]

Phosphorescence, Influence of heavy atoms on the polarization of triplet-singlet ~ of org. compds. (SC) 387 [G.E. *76*, 305 (1964)]

Classification of the excited electronic states of org. molecules with the aid of the degree of polarization of the fluorescence and ~ (CR) 759 [G.E. *76*, 822 (1964)]

Phosphoric esters, Effect of liquid $NH_3$ on ~ (LA) 155

Phosphorus, Reacn. of white ~ with free radicals from γ-radiolysed org. liquids (CR) 709 [G.E. *76*, 718 (1964)]

Phosphorus amines, Synth. of new organoarsenic and organo-~ (SC) 702 [G.E. *76*, 787 (1964)]

Phosphorus compds., Complexes of tetradentate ligands containing P and As (FP) 453 [G.E. *76*, 621 (1964)]

New method for the formation of P–P bonds (SC) 64 [G.E. *75*, 1205 (1963)]

New type of nitrogen-~ with pentavalent P (SC) 590 [G.E. *76*, 686 (1964)]

Prepn. of volatile mixed hydrides of phosphorus, arsenic, nitrogen, and germanium, and of triphosphine and triarsine (SC) 703 [G.E. *76*, 860 (1964)]

New method for the prepn. of nitrogen-~ (SC) 753 [G.E. *76*, 894 (1964)]

Reactivity of the P=N double bond (CR) 141 [G.E. *75*, 1109 (1963)]

Formation of novel organotin-~ by reacns. of tetraphenyltin with elemental P (CR) 151 [G.E. *75*, 1116 (1963)]

Some bicyclic heterocycles (CR) 657 [G.E. *76*, 615 (1964)]

Free thio acids of P and As (LA) 392

Phosphorus nitride dichlorides, Synth. of ~ (LA) 765

Phosphorus oxides, Prepn. of P(III) and P(III/V) oxides (SC) 232 [G.E. *76*, 229 (1964)]

Reacn. between phosphorus pentoxide and hydrogen peroxide (LA) 391

Phosphorus pentachloride, Reacn. of ~ with hydroxylammonium chloride (LA) 391

Phosphorus peroxide, Improved synth. of ~ (LA) 323

Phosphorus selenide halides, New phosphorus sulfide and ~ (CR) 140 [G.E. *75*, 1109 (1963)]

Phosphorus sulfide halides, New ~ and selenide halides (CR) 140 [G.E. *75*, 1109 (1963)]

*S*-Phosphorylated thiols, a new class of energy-rich compds. (LA) 71

Phosphorylating agents, Design of ~ (FP) 678 [G.E. *76*, 704 (1964)]

Phosphorylides, Intermediates of the Wittig reacn. with non-stabilized ~ (SC) 636 [G.E. *76*, 683 (1964)]

Phosvitin, Amino-acid sequences in ~ (CR) 645 [G.E. *76*, 574 (1964)]

Photochemical decomposition of alkyl azidoformates in aliphatic alcohols (SC) 589 [G.E. *76*, 681 (1964)]

Photochemical reacns. of steroids (CR) 318 [G.E. *76*, 275 (1964)]

Photochemical substitutions on metal carbonyls and their derivs. (FP) 730 [G.E. *76*, 873 (1964)]

Photochemical synth. of endiol ethers from thiocarboxylic *O*-esters (SC) 641 [G.E. *76*, 687 (1964)]

Photochemical valence-bond isomerizn. of 1,3-cyclohexadiene derivs. (CR) 653 [G.E. *76*, 600 (1964)]

Photochemistry and spectroscopy of acridines (CR) 388 [G.E. *76*, 306 (1964)]

Photocyanation of saturated ethers (LA) 71

Photolysis, of 1-tosylamino-1,2,3-triazole anions; a new synth. of alkynes (SC) 138 [G.E. *76*, 144 (1964)]

~ of bicyclo[4,2,0]octa-2,4-diene, cyclooctа-1,3,5-triene and cycloocta-1,3,6-triene (SC) 440 [G.E. *76*, 378 (1964)]

Study of intermediates in flash ~ (CR) 758 [G.E. *76*, 821 (1964)]

Phototropy, Phenomenon of ~ (FP) 570 [G.E. *76*, 463 (1964)]

*o*-Phthalaldehyde, Synth. of the isoquinoline system from ~ and nitromethane (SC) 224 [G.E. *76*, 50 (1964)]

Phthalides, New synth. of hydroxy-~ (CR) 390 [G.E. *76*, 384 (1964)]

Plant products (CR) 593 [G.E. *76*, 723 (1964)]

Platinum, Structure of anomalous oxalato complexes of ~ (CR) 147 [G.E. *75*, 1114 (1963)]

Plumbosiloxanes, Hexaalkyl-~ (LA) 522

Plutonium, Chelate complexes of ~ with 8-hydroxyquinoline (CR) 145 [G.E. *75*, 1113 (1963)]

Polarization, Influence of heavy atoms on the ~ of triplet-singlet phosphorescence of org. compds. (SC) 387 [G.E. *76*, 305 (1964)]

Classification of the excited electronic states of org. molecules with the aid of the degree of ~ of the fluorescence and phosphorescence (CR) 759 [G.E. *76*, 822 (1964)]

Polarography, Instrument for estimating oxygen by gas-phase ~ (LA) 766

Polyacrolein, Acrolein polymers (FP) 416 [G.E. *76*, 357 (1964)]

Polyacrylonitrile, Relationship between the constitution of cationic triphenylmethane dyes and their light-fastness on ~ (CR) 758 [G.E. *76*, 821 (1964)]

Polyenes, New types of ~ with cyclic cross-conjugated bond systems (CR) 319 [G.E. *76*, 235 (1964)]

Polymerization, Stereospecific homo-~ of cyclopentene (FP) 723 [G.E. *76*, 765 (1964)]

Radiochemical ~ of some optically active monomers (CR) 151 [G.E. *75*, 1135 (1963)]

Polymers, Chemistry of new heat-resistant films and fibers (FP) 460 [G.E. *76*, 484 (1964)]

Polymethylene, Prepn. of ~ by the reacn. of diazomethane with diborane (SC) 447 [G.E. *76*, 495 (1964)]

Polymolybdate ions, Complex formation with ~ (CR) 320 [G.E. *76*, 236 (1964)]

Polymorphism, Thermochemistry and ~ of Se (CR) 143 [G.E. *75*, 1110 (1963)]

Polynucleotides, Selective hydrol. of pyrophosphate bonds in ~ (SC) 439 [G.E. *76*, 439 (1964)]

Polypeptide, Reversibility of the dissociation of glutamate dehydrogenase from beef liver into its ~ chains (SC) 802 [G.E. *76*, 954 (1964)]

Chemical synth. of ~-s and the hydrodynamic properties of their solns. (CR) 389 [G.E. *76*, 381 (1964)]

Polysilazane, Equilibration of cyclic silazanes and isoln. of a linear ~ (SC) 516 [G.E. *76*, 650 (1964)]

Polystannanes, Simple synth. of org. di- and ~ (SC) 751 [G.E. *76*, 892 (1964)]

Poly(vinyl alcohol), Size of the solvation sheath of ~ in aqu. solns. (CR) 519 [G.E. *76*, 441 (1964)]

Potassium, Experiments with ~ needles (CR) 519 [G.E. *76*, 653 (1964)]

Potassium compds., Organosodium and organo-~ (FP) 287, 362 [G.E. *76*, 124, 258 (1964)]

Potassium hexathiocyanatoaluminate, Prepn. of anhydrous ~ and its behavior in liq. $NH_3$ (SC) 586 [G.E. *76*, 647 (1964)]

Potassium methoxide, Crystal structure of ~ (LA) 391

Preparative org. chemistry, New methods of ~ (FP) 211, 250, 401 [G.E. 76, 84, 113, 313 (1964)]

Prismane, Simultaneous formation of substd. tetracyclohexane, tricyclohexene, and bicyclohexadiene by spontaneous trimerization of t-butylfluoroacetylene (SC) 755 [G.E. 76, 922 (1964)]

Proline, Dimerization during the cyclization of ~ peptides (SC) 64 [G.E. 75, 1206 (1963)]

Lithium aluminum hydride cleaves ~ linkages in peptides (LA) 810

Promethium and some of its compds. (CR) 657 [G.E. 76, 614 (1964)]

Protein synth., Effect of X-rays on the ~ in vitro (SC) 636 [G.E. 76, 685 (1964)]

Proton, Structure of the ~ and the neutron (FP) 597 [G.E. 76, 513 (1964)]

Proton-addition complexes of aromatic hydrocarbons (FP) 776 [G.E. 76, 965 (1964)]

Protonic states in chemistry (FP) 157 [G.E. 76, 1 (1964)]

Proton transfer, acid-base catalysis, and enzymatic hydrol. (FP) 1 [G.E. 75, 489 (1963)]

Pseudonitrosites, Syntheses of α,ω-diamines via ~, nitroximes, and furoxans (CR) 651 [G.E. 76, 591 (1964)]

Pteridines, Recent developments in the chemistry of ~ (FP) 114 [G.E. 75, 993 (1963)]

Recent work on natural ~ (CR) 807 [G.E. 76, 757 (1964)]

Pyrazoles, Synth. of 3(5)-aminopyrazole and 1-alkyl-5-amino-~ (SC) 749 [G.E. 76, 920 (1964)]

Ring contractions by desulfurization leading to pyridazines and ~ (LA) 451

Pyrazol-3-ones, Synth. with β-alkoxyacrylyl chlorides (SC) 230 [G.E. 76, 188 (1964)]

Pyridazines, Ring contractions by desulfurization leading to ~ and pyrazoles (LA) 451

Pyridine, Synth. of ~ derivs. from aminobutenone and aldehydes (LA) 450

Pyridine nucleotides, Non-enzymatic reduction of methylene blue and 2,6-dichlorophenolindophenol by reduced di- and triphospho-~ (SC) 587 [G.E. 76, 571 (1964)]

Pyrimidine, Reacns. of hydrazine and alkylsubstd. hydrazines with ~-s (SC) 379 [G.E. 76, 378 (1964)]

Synth. of 4-hydroxy-5-nitro-~-s (SC) 703 [G.E. 76, 860 (1964)]

Heterocyclic steroids in which ring A is replaced by a ~ ring (LA) 155

Pyrimido[4,5-*e*]-as-triazines, Synth. of ~ (6-azapteridines) (SC) 312 [G.E. 76, 342 (1964)]

Pyrolysis of benzyl azide in the gas phase (SC) 309 [G.E. 76, 272 (1964)]

Pyrophoric behavior, Cause of the ~ of finely divided iron (LA) 765

Pyrophosphate, Selective hydrol. of ~ bonds in polynucleotides (SC) 439 [G.E. 76, 439 (1964)]

Pyrrole, Azlactones as 1,3-dipoles. A new ~ synth. (SC) 135 [G.E. 76, 185 (1964)]

New synth. of *N*-alkyl-~-s (SC) 510 [G.E. 76, 536 (1964)]

Pyrrole-2-carboxylic acid, New synth. of ~ (SC) 382 [G.E. 76, 439 (1964)]

Pyrrolidinium salts, Fragmentation of substd. ~ (CR) 141 [G.E. 75, 1117 (1963)]

Pyrylium salts, New synth. of ~ (SC) 387 [G.E. 76, 437 (1964)]

QUANTUM CHEMISTRY of the crystal surface (FP) 496 [G.E. 76, 365 (1964)]

Quercetylenes, Synth. and properties of substd. diflavylenes and ~ (CR) 140 [G.E. 75, 1124 (1963)]

Quinoline derivs., New synth. of ~ (SC) 804 [G.E. 76, 991 (1964)]

Quinolizinium salts, Benzo[a]-~ from 3,4-dihydroxyphenethylamine hydrobromide and acetoacetaldehyde, a possibly biogenetic-type cyclization (SC) 507 [G.E. 76, 534 (1964)]

*p*-Quinols, Rearrs. of ~ in trifluoroacetic anhydride (SC) 229 [G.E. 76, 227 (1964)]

Quinones, Synth. with nascent ~ (FP) 401 [G.E. 76, 313 (1964)]

Quinonoid diazo compds. (SC) 801 [G.E. 76, 954 (1964)]

RACEMIZATION, Investigations of the ~ of L-amino acid derivs. (CR) 142 [G.E. 75, 1125 (1963)]

~ of an optically active fluorosilane (LA) 244

Radiation, Mechanism of the protection by 1-hydrazinophthalazine against ~ (LA) 71

Formation of 1-benzyl-2,3-diphenylindanes from stilbene in the presence of tin tetrachloride under the influence of γ-~ (SC) 803 [G.E. 76, 989 (1964)]

Radicals, Intramolecular free-radical reacns. (FP) 525 [G.E. 76, 518 (1964)]

Free ~ and free-radical reacns. of monovalent and divalent sulfur (FP) 602 [G.E. 76, 629 (1964)]

Tetraazapentenyl ~ (SC) 232 [G.E. 76, 230 (1964)]

*o*-Nitrophenylsulfenylimine ~ (SC) 373 [G.E. 76, 376 (1964)]

Stable free ~ with B–N and Al–N bonds (SC) 514 [G.E. 76, 649 (1964)]

Addn. of methyl acetoxyacetate onto olefins by a free-radical mechanism (SC) 635 [G.E. 76, 713 (1964)]

Stable radical-cation of a hydrocarbon (SC) 701 [G.E. 76, 818 (1964)]

Monovalent reacns. on organometallic compds. (CR) 654 [G.E. 76, 601 (1964)]

Stereochemical criterion for phenyl migration by a free-radical mechanism (CR) 655 [G.E. 76, 602 (1964)]

A simple EPR method for measuring the g-factors of free ~, applied to substd. aroxyls (CR) 656 [G.E. 76, 610 (1964)]

Reacn. of white phosphorus with free ~ from γ-radiolysed org. liquids (CR) 709 [G.E. 76, 718 (1964)]

Verdazyls and related nitrogen-containing free ~ (CR) 763 [G.E. 76, 691 (1964)]

New free radical ions (LA) 243

Phenyl-t-butylnitroxide, a new free radical (LA) 323

5,12-Diphenyl-7-oxyldinaphtho[1,2-*b*:2',3'-*d*]furan (LA) 595

Stable 2-aryl-1,3-bisdiphenyleneallyl ~ (LA) 764

Radioactive sewage, Peat as a cation-exchanger in the purification of ~ (LA) 658

Radiochemical hydroxylation of phenolic compds. (SC) 640 [G.E. 76, 752 (1964)]

Radiochemical polymerization of some optically active monomers (CR) 151 [G.E. 75, 1135 (1963)]

Radiolysis, Reacn. of white phosphorus with free radicals from γ-radiolysed org. liquids (CR) 709 [G.E. 76, 718 (1964)]

Raman colloquium (CR) 518 [G.E. 76, 616 (1964)]

Reactive dyes, New ~ (FP) 408 [G.E. 76, 423 (1964)]

Reactivities, Relative ~ of positional and geometric isomers of high mol.wt. n-olefins (CR) 647 [G.E. 76, 580 (1964)]

Rearrangements, of *p*-quinols in trifluoroacetic anhydride (SC) 229 [G.E. 76, 227 (1964)]

Phosphonic ester/enol phosphate ~ (SC) 443 [G.E. 76, 494 (1964)]

Aryl ~ in the thermolysis of β-arylated α-halogenoacrylates (SC) 445 [G.E. 76, 495 (1964)]

General rearr. of heterocycles, and novel synth. of the benzotriazole, benzofurazan, and anthranil systems (SC) 693 [G.E. 76, 816 (1964)]

Prepn. of condensed cyclobutane derivs. and spirocyclopropane compds. by homoallylic ~ (SC) 698 [G.E. 76, 783 (1964)]

~ of dibenzo[*c*,*g*]carbazole to dibenzo[*a*,*g*]carbazole (SC) 755 [G.E. 76, 922 (1964)]

~ of vinylogous carbonyl chlorides (CR) 317 [G.E. 76, 276 (1964)]

New type of base-catalysed ~ of nitroso groups (LA) 709

Recoil atoms, Chemical reacns. with (n,γ)-, β-, and fission ~ (CR) 389 [G.E. 76, 307 (1964)]

Recoil reacns. of tritium with org. compds. (FP) 769 [G.E. 76, 901 (1964)]

Recombination, Relations between structure and rate constants for the dissociation and ~ of carboxylic acids (CR) 762 [G.E. 76, 689 (1964)]

Reducing action of triethylaluminum (SC) 65 [G.E. 76, 1206 (1963)]

Resonance, Restricted ~ in new indolines with fixed nitrogen torsion angles (CR) 647 [G.E. 76, 581 (1964)]

Respiration, Constitution of cytohaemin (LA) 243

Respiratory chain, Reversibility of energy transformations in the ~ (FP) 54 [G.E. 75, 900 (1963)]

Reversibility of energy transformations in the respiratory chain (FP) 54 [G.E. 75, 900 (1963)]

Rhenates, Crystal structure of rubidium and cesium hexachloro-, -bromo-, and iodo-~-(IV) (SC) 445 [G.E. 76, 497 (1964)]

Rhenium-cobalt enneacarbonyl (SC) 701 [G.E. 76, 786 (1964)]

Rhenium compds., Szilard-Chalmers process in $K_2ReBr_6/K_2OSCl_6$ mixed crystals (CR) 148 [G.E. 75, 1132 (1963)]

Rhodium, Localized bond between a substd. benzene and a transition metal (LA) 323

Ribodinucleotides, Synth. of ~ with terminal 3'-phosphate groups (SC) 374 [G.E. 76, 435 (1964)]

Ribonuclease, Federation of European biochemical societies (CR) 447 [G.E. 76, 503 (1964)]

Rifamycins, Constitution of ~ (CR) 154 [G.E. 76, 193 (1964)]

Ring closure, Autoxidative ~ of ω,ω-bis-(triphenylphosphorylidene)alkanes (SC) 226 [G.E. 76, 226 (1964)]

Ring contractions by desulfurization leading to pyridazines and pyrazoles (LA) 451

Ring-opening of β-dialkylaminocyclobutanones (CR) 653 [G.E. 76, 598 (1964)]

Ring synth., using enamines and ketene-*N*,*N*-acetals (CR) 149 [G.E. 75, 1122 (1963)]

Rotation, Hindered internal ~ in cyanine dyes (SC) 306 [G.E. 76, 270 (1964)]

Rotational isomers of mesitylenecarboxamides (CR) 652 [G.E. 76, 595 (1964)]

Rubidium compds., Crystal structure of rubidium and cesium hexachloro-, -bromo-, and -iodorhenates(IV) (SC) 445 [G.E. 76, 497 (1964)]

SACCHARIN, New method of peptid synth. using amino acid derivs. of ~ (LA) 451

Saponin, Constitution of a cholegenin analogue from the vegetable kingdom (CR) 152 [G.E. 75, 1128 (1963)]

Scattering and absorption coefficients in diffuse reflection of powdered materials (CR) 321 [G.E. 76, 308 (1964)]

Scheibe, Colloquium in honor of G. ~ (CR) 387 [G.E. 76, 305 (1964)]

Secalonic acids, Diastereomeric ~ (SC) 441 [G.E. 76, 438 (1964)]

Structure of ~ A and B (SC) 441 [G.E. 76, 438 (1964)]

Selenide halides, New phosphorus sulfide and ~ (CR) 140 [G.E. 75, 1109 (1963)]

Selenium, Thermochemistry and polymorphism of ~ (CR) 143 [G.E. 75, 1110 (1963)]

Selenium dioxide, Aminolysis of ~ (SC) 805 [G.E. 76, 992 (1964)]

Selenothiophosphinic acid, Derivs. of diethyl-~ (SC) 507 [G.E. 76, 496 (1964)]

Semiconductor surfaces, Electrochem. reacns. at ~ (CR) 809 [G.E. 76, 759 (1964)]

Sensitization, Current ideas on spectral ~ (CR) 759 [G.E. 76, 822 (1964)]

Sesquifulvalene, New types of polyenes with cyclic cross-conjugated bond systems (CR) 319 [G.E. 76, 235 (1964)]

Shikimic acid, New synth. of ~ (LA) 658

Silacyclopentane, Synth. and polymerization of 1-oxa-2-~ derivs. (CR) 146 [G.E. 75, 1114 (1963)]

Siladithiacyclopentane, Five-membered heterocyclics containing Si, Ge, or Sn (LA) 242

Silanes, New synth. of germylsilane (SC) 586 [G.E. 76, 649 (1964)]

Reacns. of metal-substd. hydrides with halogeno-~ (CR) 644 [G.E. 76, 573 (1964)]

Racemization of an optically active fluorosilane (LA) 244

Silanolates, Double ~ of the alkali metals (SC) 697 [G.E. 76, 753 (1964)]

Silazanes, Equilibriation of cyclic ~ and isoln. of a linear polysilazane (SC) 516 [G.E. 76, 650 (1964)]

Silicate glasses, Structure of ~ (CR) 154 [G.E. 76, 233 (1964)]

Silicic acid, Water-stable, cationic complexes of ~ with 1-hydroxypyridine *N*-oxide (SC) 698 [G.E. 76, 818 (1964)]

Silicium, New heterocycles containing Ge and ~ (CR) 153 [G.E. 75, 1116 (1963)]

Silicon compds., Conversion of Si–O into Si–N bonds (SC) 135 [G.E. 76, 99 (1964)]

Bis(trimethylsilyl) aminodimethylarsine and tris(dimethylarsino)amine (SC) 137 [G.E. 76, 144 (1964)]

Reacns. of halides of group IV elements with trifluoroacetic acid (SC) 376 [G.E. 76, 376 (1964)]

Prepn. of fluorinated Si–N compds. using $SiF_4$ (SC) 446 [G.E. 76, 497 (1964)]

Compds. containing the Si–N–B linkage (SC) 509 [G.E. 76, 500 (1964)]

The existence and constitution of ternary compds. between PbO, $SiO_2$, and Pb halides (CR) 148 [G.E. 75, 1111 (1963)]

Trimethylsiloxychloroalane, a crystalline, distillable compd. with a four-membered ring structure (CR) 151 [G.E. 75, 1115 (1963)]

Synth. with *N*-metalated nitrogen-~ (CR) 318 [G.E. 76, 234 (1964)]

Some bicyclic heterocycles (CR) 657 [G.E. 76, 615 (1964)]

New types of cyclic ~ (LA) 521

Volumetric determn. of Si (LA) 658

Silicon difluoride $[SiF_2]_x$ (SC) 700 [G.E. 76, 781 (1964)]

Silicon diiodide $[SiI_2]_x$ (SC) 699 [G.E. 76, 782 (1964)]

Silicon tetrafluoride, Prepn. of fluorinated Si–N compds. using ~ (SC) 446 [G.E. 76, 497 (1964)]

Siloxanes, Sensitivity of the siloxane linkage towards acidolytic cleavage (SC) 310 [G.E. 76, 273 (1964)]

Cleavage of ~ with $GaCl_3$ (SC) 696 [G.E. 76, 753 (1964)]

New types of low molecular-weight hetero-~ (CR) 241 [G.E. 76, 234 (1964)]

Hexaalkylplumbo-~ (LA) 522

Properties of alkylstannosiloxanes, alkyl-~ and alkylstannoxanes (LA) 523

Iron(III) siloxane compds. (LA) 763

Silver halides, Adsorption of cyanine dyes onto ~ (LA) 809

Silver nitrate, Thin-layer chromatography on silica gel impregnated with ~ (CR) 760 [G.E. 76, 688 (1964)]

Silylamides, Addn. of sec. *N*-trimethyl-~ onto aldehydes (SC) 514 [G.E. 76, 648 (1964)]

Formation and properties of alkali di-~ (CR) 646 [G.E. 76, 577 (1964)]

Silylamines, Nucleophilic substitutions on ~ (CR) 649 [G.E. 76, 588 (1964)]

Silylaminohalogenoboranes, Bis(trimethylsilyl)aminohalogenoboranes (SC) 633 [G.E. 76, 499 (1964)]

Silylaminosulfanes, Prepn. of new *N*-~ by nucleophilic cleavage of S–S bonds (CR) 150 [G.E. 75, 1115 (1963)]

Silyl azide, Reacn. of ~ with antimony pentachloride (SC) 444 [G.E. 76, 380 (1964)]

Reacn. of triphenyl-~ with triethyloxonium tetrafluoroborate (SC) 444 [G.E. 76, 381 (1964)]

Silylene, Formation and reacns. of dimethyl-~, a silicon-analogue of the carbenes (SC) 226 [G.E. 76, 270 (1964)]

Silylgermanes, Prepn. of ~ (SC) 314 [G.E. 76, 302 (1964)]

Single crystals, Reacns. with ~ of niobium oxides (SC) 634 [G.E. 76, 685 (1964)]

Sintering, Hydrothermal ~ (SC) 133 [G.E. 76, 52 (1964)]

Sodium compds., Organo-~ and organopotassium compds. (FP) 287, 362 [G.E. 76, 124, 258 (1964)]

Sodium hydrazide, Reacns. of ~ with org. compds. (FP) 342 [G.E. 76, 206 (1964)]

Solvation sheath, Size of the ~ of poly(vinyl alcohol) in aqu. solns. (CR) 519 [G.E. 76, 441 (1964)]

Solvent effects, on the position of the first overtone of the O–H valence vibration (SC) 694 [G.E. 76, 715 (1964)]

Solvent-dependence of the wave number of electronic absorption bands (CR) 756 [G.E. 76, 819 (1964)]

Spectroscopy, Differentiation of primary, secondary, and tertiary alcohols by near infrared ~ (SC) 309 [G.E. 76, 271 (1964)]

Hollow cathode as a light source for emission spectrography in the vacuum ultraviolet region (CR) 388 [G.E. 76, 306 (1964)]

Photochemistry and ~ of acridines (CR) 388 [G.E. 76, 306 (1964)]

Solvent-dependence of the wave number of electronic absorption bands and its physico-chem. basis (CR) 756 [G.E. 76, 819 (1964)]

See also Infrared spectroscopy, Mass spectroscopy, NMR spectroscopy

Spiro-cyclopropane compds., Prepn. of condensed cyclobutane derivs. and ~ by homoallylic rearr. (SC) 698 [G.E. 76, 783 (1964)]

Stability constants of 1:1, 1:2 and 1:3 complexes of Fe(III) with benzhydroxamic acid (LA) 71

2-Stanna-1,3-dithiacyclopentane, Five-membered heterocyclics containing Si, Ge, or Sn (LA) 242

Stannanes, Synth. of octabenzylcyclotetra-~ (SC) 751 [G.E. 76, 892 (1964)]

Simple synth. of org. di- and poly-~ (SC) 751 [G.E. 76, 892 (1964)]

Stannosiloxanes, Properties of alkyl-~, alkylsiloxanes and alkylstannoxanes (LA) 523

Stannoxanes, Properties of alkylstannosiloxanes, alkylsiloxanes and alkyl-~ (LA) 523

Stannylboranes, Triethyl-~ (SC) 377 [G.E. 76, 377 (1964)]

Stars, Chemical composition of the ~ (FP) 481 [G.E. 76, 281 (1964)]

Stereochemistry, Modern problems of ~ (CR) 516 [G.E. 76, 501 (1964)]

Stereoelectronics, Modern problems of stereochemistry (CR) 516 [G.E. 76, 501 (1964)]

Steroids, Recent advances in the synth. of 19-nor-~ (FP) 353 [G.E. 76, 249 (1964)]

Intramolecular free-radical reacns. (FP) 525 [G.E. *76*, 518 (1964)]

Unusual cyclization of a steroid *N*-chloroamine (SC) 633 [G.E. *76*, 752 (1964)]

Novel intramolecular displacement reacn. (CR) 240 [G.E. *76*, 107 (1964)]

Photochemical reacns. of ~ (CR) 318 [G.E. *76*, 275 (1964)]

Sepn. of steryl acetates by thin-layer chromatography (CR) 760 [G.E. *76*, 688 (1964)]

Conformational analysis of nitro-~ by circular dichroism (CR) 762 [G.E. *76*, 690 (1964)]

Heterocyclic ~ in which ring A is replaced by a pyrimidine ring (LA) 155

Chinese iatrochemists in the middle ages prepared mixtures of steroid hormones (LA) 450

Stibines, New method for preparing trialkylarsines and trialkyl-~ (SC) 66 [G.E. *76*, 99 (1964)]

Stilbene, Formation of 1-benzyl-2,3-diphenylindanes from ~ in the presence of tin tetrachloride under the influence of γ-radiation (SC) 803 [G.E. *76*, 989 (1964)]

Streptomycin alters the mechanism by which the messenger code is red (LA) 810

Substitution of aliphatic diazonium groups (CR) 146 [G.E. *75*, 1120 (1963)]

Succinyl dichloride, Conversion of ~ into γ-chlorocaproic acid (SC) 584 [G.E. *76*, 646 (1964)]

Sulfamyl chloride, Reacns. of *N*-carbonyl-~ with dienes (CR) 649 [G.E. *76*, 587 (1964)]

Sulfanes, Prepn. of new *N*-silylamino-~ by nucleophilic rupture of S-S bonds (CR) 150 [G.E. *75*, 1115 (1963)]

Sulfene as a dienophile (SC) 754 [G.E. *76*, 921 (1964)]

Sulfenic acid, Products of the thermolysis of ~ derivs. (SC) 705 [G.E. *76*, 861 (1964)]

Sulfides, Proton resonance investigations on the conformational mobility of cyclic di- and tri-~ (CR) 650 [G.E. *76*, 590 (1964)]

Reacns. of ~ in molten salts (LA) 522

Sulfinyl compds., Reacn. of vinyl ethers and ketene acetals with isocyanates and *N*-~ (CR) 142 [G.E. *75*, 1117 (1963)]

Sulfonium salts, with alkyl and β-halogenoethyl ligands (LA) 70

~ exhibit high reactivity toward mercaptide ions (LA) 765

Sulfonyl azides, Synth. of aliphatic azo and diazo compds., from active methylene compds. and ~ (CR) 654 [G.E. *76*, 601 (1964)]

*N*-Sulfonylcarbodiimides (SC) 639 [G.E. *76*, 781 (1964)]

Sulfoxides, Formation of bis-(β-chloro-β-alkoxyethyl)-~ by addn. of thionyl chloride onto alkyl vinyl ethers (SC) 373 [G.E. *76*, 435 (1964)]

Sulfur, Prepn. of thioamides from alkenylamines and ~ at room temperature (SC) 705 [G.E. *76*, 861 (1964)]

Sulfur compds., Free radicals and free-radical reacns. of monovalent and divalent sulfur (FP) 602 [G.E. *76*, 629 (1964)]

Prepn. of pure $S_2O$ (SC) 61 [G.E. *76*, 97 (1964)]

New phosphorus sulfide and selenide halides (CR) 140 [G.E. *75*, 1109 (1963)]

Some bicyclic heterocycles (CR) 657 [G.E. *76*, 615 (1964)]

Sulfuric acid, Radiation-induced formation of ~ in the system $SO_2/O_2/H_2O$ (CR) 655 [G.E. *76*, 607 (1964)]

Sulfur ylides, Reacns. of ~ (CR) 148 [G.E. *75*, 1121 (1963)]

Superconductivity in $In_3SbTe_2$ (SC) 588 [G.E. *76*, 651 (1964)]

Surface, Quantum chemistry of the crystal ~ (FP) 496 [G.E. *76*, 365 (1964)]

Surface area, Routine measurements of the ~ of finely divided materials (LA) 323

Surface chemistry, Chemistry of $TiO_2$ surfaces (CR) 646 [G.E. *76*, 576 (1964)]

Surface oxides of carbon (FP) 669 [G.E. *76*, 742 (1964)]

Swiss chemists, Joint meeting of ~ and Austrian chemists (CR) 238 [G.E. *76*, 105 (1964)]

Szilard-Chalmers-process in $K_2ReBr_6$/$K_2OsCl_6$ mixed crystals (CR) 148 [G.E. *75*, 1132 (1963)]

TELLURIC ACID, Pentafluoro-ortho-~ (SC) 383 [G.E. *76*, 379 (1964)]

Tellurium compds., Superconductivity in $In_3SbTe_2$ (SC) 588 [G.E. *76*, 651 (1964)]

Terpene phosphate, Biogenetic-type cyclization of a ~ (SC) 310 [G.E. *76*, 301 (1964)]

Tetraarylphosphonium salts, New approach to ~ (SC) 231 [G.E. *76*, 187 (1964)]

Tetraazafluorene, Synth. of the 1,5,8a,9-~ system (CR) 654 [G.E. *76*, 601 (1964)]

Tetraazapentalene, Identification of an aromatic non-benzenoid ring sytsem by X-ray analysis (LA) 71

Tetraazapentenyl radicals (SC) 232 [G.E. *76*, 230 (1964)]

Tetrachlorodiazocyclopentadiene from hexachlorocyclopentadiene (SC) 379 [G.E. *76*, 431 (1964)]

Tetracyanoethylene oxide (LA) 242

Tetracyclohexane, Valence-bond isomers of (substd.) benzene (SC) 755 [G.E. 922 (1964)]

2,3,5,6-Tetrahydro-7-arylimidazo[2,1-*b*]-thiazolium salts, Formation and behavior of ~ (SC) 308 [G.E. *76*, 301 (1964)]

Tetrahydrothiazinone, ω-Chlorosulfenylalkylcarbonyl chlorides (SC) 67 [G.E. *76*, 51 (1964)]

Tetrakis(dimethylamino)ethylene, Chemistry of ~ (CR) 152 [G.E. *75*, 1112 (1963)]

Tetralin, Explosion during the oxidn. of ~ with hydrogen peroxide in acetone (SC) 640 [G.E. *76*, 716 (1964)]

Explosion during the oxidn. of ~ with hydrogen peroxide in acetone (Comments) (SC) 802 [G.E. *76*, 990 (1964)]

Tetramethoxyethylene, Carbocyclic and heterocyclic four-membered rings from ~ by cycloaddn. (SC) 380 [G.E. *76*, 346 (1964)]

Tetramethylurea as a solvent and reagent (FP) 260 [G.E. *75*, 1059 (1963)]

Tetraphenylnaphthalene, Bis-peri-~ (LA) 764

Tetraphenyltin, Formation of novel organotin-phosphorus compds. by reacns. of ~ with elemental phosphorus (CR) 151 [G.E. *75*, 1116 (1963)]

Tetraphosphorus heptasulfide, Alcoholysis of ~ $P_4S_7$ (SC) 314 [G.E. *76*, 344 (1964)]

Tetrazanes, Structure of the "~" produced from alkoxycarbonylazo compds. and aldehyde phenylhydrazones (SC) 693 [G.E. *76*, 684 (1964)]

Theophylline 9(*N*)-glycoside, Synth. of the first ~ (SC) 638 [G.E. *76*, 713 (1964)]

Theories of the glass electrode (FP) 36 [G.E. *76*, 39 (1964)]

Therapy congress and pharmaceutical exhibition (CR) 68 [G.E. *76*, 55 (1964)]

Thermochemistry and polymorphism of Se (CR) 143 [G.E. *75*, 1110 (1963)]

Thermonuclear fusion, Prepn. of He from LiD by ~ (CR) 644 [G.E. *76*, 574 (1964)]

1-Thianaphthalenium salts, New synth. of ~ (CR) 143 [G.E. *75*, 1117 (1963)]

Thiazinone, ω-Chlorosulfenylalkylcarbonyl chlorides (SC) 67 [G.E. *76*, 51 (1964)]

Thiazolidine, Synth. of 2,3-diphenyl-1,1,4-trioxo-1,2,3-~-s (SC) 749 [G.E. *76*, 919 (1964)]

Thiazolidinecarboxamides, Synth. of penicillamine amide and penicillamine thioamide from thiazolidine-4-carboxamides and -4-thiocarboxamides (SC) 313 [G.E. *76*, 273 (1964)]

Thiazolidinethiocarboxamides, Synth. of penicillamine amide and penicillamine thioamide from thiazolidine-4-carboxamides and -4-thiocarboxamides (SC) 313 [G.E. *76*, 273 (1964)]

Thiazolizations using 2-hydroxy- or 2-amino-4-aryl-5-bromothiazole (CR) 147 [G.E. *75*, 1121 (1963)]

Thin-layer chromatography, Gradient and low-temperature ~ (FP) 784

Enzymatic reacns. on ion-exchange thin-layer plates (SC) 442 [G.E. *76*, 494 (1964)]

~ on silica gel impregnated with silver nitrate (CR) 760 [G.E. *76*, 688 (1964)]

Sepn. of steryl acetates by ~ (CR) 760 [G.E. *76*, 688 (1964)]

Automatic combination of ~ and a temperature-programmed gas-chromatograph (CR) 761 [G.E. *76*, 689 (1964)]

Preparative thin-layer chromatographic sepn. of phosphatides and thin-layer chromatographic identification of their hydrolysis products (CR) 762 [G.E. *76*, 690 (1964)]

Thio acids, Free ~ of phosphorus and arsenic (LA) 392

Thioamides, Prepn. of ~ from alkenylamines and sulfur at room temperature (SC) 705 [G.E. *76*, 861 (1964)]

Thiocarboxylic *O*-esters, Photochemical synth. of endiol ethers from ~ (SC) 641 [G.E. *76*, 687 (1964)]

Thiocyanatoaluminate, Prepn. of anhydrous potassium hexa-~ and its behavior in liq. $NH_3$ (SC) 586 [G.E. *76*, 647 (1964)]

Thioketones, Aliphatic ~ (FP) 277 [G.E. *76*, 157 (1964)]

Reacn. of potassium xanthate with diaryldichloromethanes, a new ~ synth. (SC) 225 [G.E. *76*, 98 (1964)]

Thiols, *S*-Phosphorylated ~, a new class of energy-rich compds. (LA) 71

Thionyl chloride, Formation of Bis-(β-chloro-β-alkoxyethyl)sulfoxides by addn. of ~ onto alkyl vinyl ethers (SC) 373 [G.E. *76*, 435 (1964)]

Thiophene, Synth. of higher alicyclic systems (LA) 243

Thiosulfuric acid, Prepn. and rate of decomposition of ~ (LA) 391

Thorium compds., Reacns. of halides of group IV elements with trifluoroacetic acid (SC) 376 [G.E. *76*, 376 (1964)]

Threonine deaminase, Biochemistry of yeast ~ (FP) 101 [G.E. *75*, 894 (1963)]

Tin compds., Hydrostannation of conjugated dienes (SC) 133 [G.E. *76*, 52 (1964)]

Prepn. of trimethyltin methoxide (SC) 138 [G.E. *76*, 145 (1964)]

Tristriphenylstannylarsine, -stibine, and -bismuthine (SC) 316 [G.E. *76*, 344 (1964)]

Complexes of organo-~ with aluminum halides (SC) 385 [G.E. *76*, 379 (1964)]

Formation of novel organotin-phosphorus compds. by reacns. of tetraphenyltin with elemental P (CR) 151 [G.E. *75*, 1116 (1963)]

Some bicyclic heterocycles (CR) 657 [G.E. *76*, 615 (1964)]

Tissues, Method for the micro-determination of $Mg^{2+}$ and $Ca^{2+}$ in ~ (LA) 70

Titanium compds., Crystal structure of titanium phosphide $Ti_5P_3$ (SC) 231 [G.E. *76*, 187 (1964)]

Allylbiscyclopentadienyltitanium(III) and -vanadium(III) (SC) 311 [G.E. *76*, 274 (1964)]

Synth. and crystal structure of titanium(III) tetrametaphosphate and polyphosphate (SC) 315 [G.E. *76*, 303 (1964)]

Prepn. of potassium hexathiocyanatotitanate(IV) and its behavior in liquid $NH_3$ (SC) 315 [G.E. *76*, 304 (1964)]

Reacns. of halides of group IV elements with trifluoroacetic acid (SC) 376 [G.E. *76*, 376 (1964)]

Prepn. of Ti-N compds. by addn. and substitution reacns. (CR) 141 [G.E. *75*, 1109 (1963)]

Refining of Ti and Ti alloys by melt electrolysis using a liquid Pb electrode (CR) 147 [G.E. *75*, 1114 (1963)]

Titanium dioxide, Chemistry of ~ surfaces (CR) 646 [G.E. *76*, 576 (1964)]

Titanium oxide iodide, New synth. of ~ (CR) 646 [G.E. *76*, 578 (1964)]

Titration, Differentiation of strong acids by conductometric ~ in glacial acetic acid (SC) 225 [G.E. *76*, 184 (1964)]

Torsion angles, Restricted resonance in new indolines with fixed nitrogen ~ (CR) 647 [G.E. *76*, 581 (1964)]

1-Tosylamino-1,2,3-triazole, Photolysis of ~ anions; a new synth. of alkynes (SC) 138 [G.E. *76*, 144 (1964)]

Transacylations using α-hydroxypyridyl phosphates and carboxylates (LA) 451

Transition metals, Trifluorophosphinyl complexes of ~ (CR) 652 [G.E. *76*, 593 (1964)]

Transport processes and equilibria in the reduction of oxides (CR) 320 [G.E. *76*, 307 (1964)]

Trialkylarsines, New method for preparing ~ and trialkylstibines (SC) 66 [G.E. *76*, 99 (1964)]

Trialkylstibines, New method for preparing trialkylarsines and ~ (SC) 66 [G.E. *76*, 99 (1964)]

Triandrin, a new phenolic glycoside (LA) 70

Triarsine, Prepn. of volatile mixed hydrides of phosphorus, arsenic, nitrogen, and germanium, and of triphosphine and ~ (SC) 703 [G.E. *76*, 860 (1964)]

1,3,4-Triaza-2,5-diborolidines (SC) 506 [G.E. *76*, 535 (1964)]

Triazines, Synth. of pyrimido[4,5-*e*]-as-~ (6-azapteridines) (SC) 312 [G.E. *76*, 342 (1964)]

Synth. of halogenoalkyldichloro-s-~ triazines and bis(halogenoalkyl)chloro-~ (SC) 378 [G.E. *76*, 437 (1964)]

Triazoles, Photolysis of 1-tosylamino-1,2,3-~ anions; a new synth. of alkynes (SC) 138 [G.E. *76*, 144 (1964)]

Tribromoallene and perbromoallene (SC) 382 [G.E. *76*, 379 (1964)]

1,2,3-Tri-t-butyltrifluorobenzene, Formation of ~ by spontaneous trimerization of t-butylfluoroacetylene (SC) 746 [G.E. *76*, 889 (1964)]

Trichloromethyl-lithium, Dichloromethyl-lithium and ~ (SC) 513 [G.E. *76*, 536 (1964)]

Tricyanomethanido metal complexes containing carbon monoxide and nitric oxide (SC) 380 [G.E. *76*, 346 (1964)]

2,4,6-Tricyanophenol, Arylcyanophenols and ~ (SC) 384 [G.E. *76*, 433 (1964)]

Tricyclohexene, Simultaneous formation of substd. tetracyclohexane, ~, and bicyclohexadiene by spontaneous trimerization of t-butylfluoroacetylene (SC) 755 [G.E. *76*, 922 (1964)]

*Tricyclo*[4,2,0,$0^{2,5}$]*octa*-3,7-*diene*, Two stereoisomeric dimers of cyclobutadiene (LA) 764

Triethylaluminum, Explosion of a mixture of ~ and $CCl_4$ (SC) 65 [G.E. *75*, 1205 (1963)]

Reducing action of ~ (SC) 65 [G.E. *75*, 1206 (1963)]

*Triethyloxonium tetrafluoroborate*, Reacn. of triphenylsilyl azide with ~ (SC) 444 [G.E. *76*, 381 (1964)]

Triethylstannylboranes (SC) 377 [G.E. *76*, 377 (1964)]

Trifluoroacetic acid, Reacns. of halides of group IV elements with ~ (SC) 376 [G.E. *76*, 376 (1964)]

*Trifluorophosphine*, Tris(~)nitrosylcobalt and Bis(~)dinitrosyliron (SC) 700 [G.E. *76*, 787 (1964)]

Pentakis(~)iron (SC) 754 [G.E. *76*, 893 (1964)]

Trifluorophosphinyl complexes of transition metals (CR) 652 [G.E. *76*, 593 (1964)]

*Trihalogenogermane etherates*, Structure and properties of ~ (SC) 508 [G.E. *76*, 498 (1964)]

Trimethylsiloxychloroalane, a crystalline, distillable compd. with a four-membered ring structure (CR) 151 [G.E. *75*, 1115 (1963)]

*N*-Trimethylsilylamides, Addn. of sec. ~ onto aldehydes (SC) 514 [G.E. *76*, 648 (1964)]

Trimethyltin methoxide, Prepn. of ~ (SC) 138 [G.E. *76*, 145 (1964)]

Triphenylamine, *Inversion of the* ~ molecule (SC) 230 [G.E. *76*, 186 (1964)]

Triphenylmethane dyes, Relationship between the constitution of cationic ~ and their light-fastness on polyacrylonitrile (CR) 758 [G.E. *76*, 821 (1964)]

2,4,6-Triphenylphenoxyl, Constitution of the dimer of ~ (SC) 385 [G.E. *76*, 434 (1964)]

Triphenylphosphineazine (SC) 805 [G.E. *76*, 991 (1964)]

Triphenylsilyl azide, Reacn. of ~ with triethyloxonium tetrafluoroborate (SC) 444 [G.E. *76*, 381 (1964)]

Triphosphine, Prepn. of volatile mixed hydrides of phosphorus, arsenic, nitrogen, and germanium, and of ~ and triarsine (SC) 703 [G.E. *76*, 860 (1964)]

Tris(biphenylenevinyl)methane (SC) 137 [G.E. *76*, 146 (1964)]

Tris(dibenzofulvenyl)methane, Tris(biphenylenevinyl)methane (SC) 137 [G.E. *76*, 146 (1964)]

Tris(dibenzofulvenyl)anion, an extremely stable colored carbanion (SC) 312 [G.E. *76*, 302 (1964)]

Tris(dimethylarsino)amine, Bis(trimethylsilyl)aminodimethylarsine and ~ (SC) 137 [G.E. *76*, 144 (1964)]

Trisdithiobenzilmetal complexes (SC) 639 [G.E. *76*, 715 (1964)]

Tris(pentafluorophenyl)arsine, Synth. of ~, -stilbine, and -phosphine and of pentafluorophenyltrimethylsilane (SC) 801 [G.E. *76*, 954 (1964)]

Tris(pentafluorophenyl)phosphine, Synth. of tris(pentafluorophenyl)arsine, -stibine, and ~ and of pentafluorophenyltrimethylsilane (SC) 801 [G.E. *76*, 954 (1964)]

Tris(pentafluorophenyl)stibine, Synth. of tris(pentafluorophenyl)arsine, ~, and -phosphine and of pentafluorophyltrimethylsilane (SC) 801 [G.E. *76* 954 (1964)]

Tris(trifluorophosphine)nitrosylcobalt and Bis(trifluorophosphine)dinitrosyliron (SC) 700 [G.E. *76*, 787 (1964)]

Tristriphenylstannylarsine, -stibine, and -bismuthine (SC) 316 [G.E. *76*, 344 (1964)]

Tristriphenylstannylbismuthine, Tristriphenylstannylarsine, -stibine, and ~ (SC) 316 [G.E. *76*, 344 (1964)]

Tristriphenylstannylstibine, Tristriphenylstannylarsine, ~, and -bismuthine (SC) 316 [G.E. *76*, 344 (1964)]

1,2,4-Trithia-3,5-diborolanes (SC) 637 [G.E. *76*, 687 (1964)]

Trithiones, Synth. of ~ from enamines, carbon disulfide and sulfur (LA) 521

Tritium, Recoil reacns. of ~ with org. compds. (FP) 769 [G.E. *76*, 901 (1964)]

Tropäolin, Analysis of drugs in biological fluids by the ~ method (CR) 761 [G.E. *76*, 688 (1964)]

Tropylium salts, Prepn. and investigation of substd. ~ (CR) 145 [G.E. *75*, 1119 (1963)]

Tryptophan, Detection of a nitrogen-free precursor of anthranilic acid in the biosynthesis of ~ by *Saccharomyces cerevisiae* (SC) 66 [G.E. *76*, 51 (1964)]

Tubercle bacillus, Biosynth., structure, and biological action of the lipids of the ~ (FP) 393 [G.E. *76*, 241 (1964)]

Tungsten carbonyl carbene complex, On the existence of a ~ (SC) 580 [G.E. *76*, 645 (1964)]

Tunnel effect, Protonic states in chemistry (FP) 157 [G.E. *76*, 1 (1964)]

URANIUM, Electron configuration of tetravalent and trivalent ~ (LA) 70

VALENCE ANGLE, Dependence of the electron excitation of open-chain cyanine dyes on the ~ of their nitrogen atoms (SC) 374 [G.E. *76*, 187 (1964)]

Valence-bond isomerizn., Attempted synth. of cyclodecapentaenes by ~ of 9,10-dihydronaphthalenes (SC) 643 [G.E. *76*, 786 (1964)]

~ of *cis,trans*-cyclodeca-1,5-dienes (SC) 702 [G.E. *76*, 859 (1964)]

Photochemical ~ of 1,3-cyclohexadiene derivs. (CR) 653 [G.E. *76*, 600 (1964)]

Valence-bond isomers of (substd.) benzene (SC) 755 [G.E. *76*, 922 (1964)]

Valence-bond tautomerism, of cyclooctatetraene (FP) 83 [G.E. *76*, 36 (1964)]

Proof of a norcaradiene-cycloheptatriene ~ by NMR spectroscopy (SC) 443 [G.E. *76*, 432 (1964)]

Vanadium, Allylbiscyclopentadienyltitanium(III) and -~-(III) (SC) 311 [G.E. *76*, 274 (1964)]

Vaporization equilibria, Mass-spectroscopy of inorg. systems at high temperatures (CR) 153 [G.E. *76*, 150 (1964)]

Venom, Most potent animal ~ known (LA) 242

Verdazyls and related nitrogen-containing free radicals (CR) 763 [G.E. *76*, 691 (1964)]

Vinyl ethers, Reacn. of ~ and ketene acetals with isocyanates and *N*-sulfinyl compds. (CR) 142 [G.E. *75*, 1117 (1963)]

Vitamin $B_{12}$, New chemical and biochemical developments in the ~ field (FP) 200 [G.E. *75*, 1145 (1963)]

Synthetic route to the corrin system (FP) 490 [G.E. *76*, 393 (1964)]

Vomicine, Synth. of ~ (CR) 150 [G.E. *75*, 1127 (1963)]

WARREN REACN., Role of formylpyruvic acid in the ~ (LA) 390

Water, Reacn. of oxides with ~ at high pressures and temperatures (FP) 47 [G.E. *75*, 949 (1963)]

West German chemistry lecturers, Meeting of ~ (CR) 644 [G.E. *76*, 573 1964)]

Willgerodt-Kindler reacn., Course of the ~ of alkyl aryl ketones (FP) 19 [G.E. *75*, 1050 (1963)]

Wittig reacn., Intermediates of the ~ with non-stabilized phosphorylides (SC) 636 [G.E. *76*, 683 (1964)]

XANTHATE, Reacn. of potassium ~ with diaryldichloromethanes, a new thioketone synth. (SC) 225 [G.E. *76*, 98 (1964)]

Xenic acid, Salts of ~ (LA) 323

Xenon, Valence compds. of the inert gases (FP) 538 [G.E. *76*, 455 (1964)]

Xenon tetrafluoride, Prepn. of large quantities of ~ (LA) 765

X-rays, Effect of ~ on the protein synth. in vitro (SC) 636 [G.E. *76*, 685 (1964)]

Identification of an aromatic nonbenzenoid ring system by ~ analysis (LA) 71

YEAST THREONINE DEAMINASE, Biochemistry of ~ (FP) 101 [G.E. *75*, 894 (1963)]

Ylides, Reacns. of sulfur ~ (CR) 148 [G.E. *75*, 1121 (1963)]

ZIRCONIUM, Reacns. of halides of group IV elements with trifluoroacetic acid (SC) 376 [G.E. *76*, 376 (1964)]
