# Proton Transfer, Acid-Base Catalysis, and Enzymatic Hydrolysis

## PART 1: ELEMENTARY PROCESSES [*]

BY DR. M. EIGEN

MAX-PLANCK-INSTITUT FÜR PHYSIKALISCHE CHEMIE, GÖTTINGEN (GERMANY)

*Dedicated to Dr. W. Foerst on the occasion of his 65th birthday*

*The proton occupies a special position as a promoter and mediator in chemical reactions occurring in solution. Many reactions in organic chemistry are catalysed by acids or bases; likewise, most enzymes contain active groups which promote acid-base catalysis. To understand the reaction mechanisms involved, it is necessary to identify the elementary steps as well as their course in time. Systematic investigation of these elementary steps has become possible only with the development of new methods for studying very fast reactions. The present paper reviews the information obtained in this type of investigation. The result is a relatively complete picture of the elementary proton transfer mechanisms and a comprehensive description of the modes and laws of acid-base and enzymatic catalysis.*

### 1. Structural Prerequisites for Proton Transport in Aqueous Media

The state of the (solvated) proton in aqueous media may be described in terms of four structural species:

the elementary proton, $H^+$

the hydronium ion, $H_3O^+$ (primary hydration)

the complex ion $H_9O_4^+$, (secondary hydration), and a tertiary hydration at the periphery of the complex.

Figure 1 shows the model of such a hydrate complex which has been described in detail in previous papers [1–3].

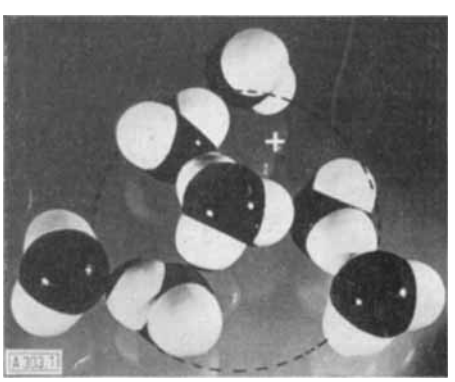

Fig. 1. Model of a $H^+$ hydrate complex containing the structural units $H_3O^+$ (center), $H_9O_4^+$ (within the circle) and with tertiary hydration (outside the circle). The pyramidal arrangement fits into the structure of hexagonal ice. Additional H-bridging between the secondary $H_2O$ molecules [4] would be possible only by outward displacement of bridge protons from the O–O bond direction.

The different structural species can be identified experimentally (literature see Table 1).

[*] Part II (Catalytic Mechanisms) will appear shortly in this journal.

The proton, being an elementary particle, differs from all other ions that are stable in aqueous solutions in that it lacks an electron shell. Its conduction properties (*e.g.* in ice crystals, see below), in particular, are in many respects similar to those of the electron. It differs from the latter, however, by its substantially greater mass, which has a decisive effect on its wave character (tunnel effect in proton transfer). Table 2 gives a comparison of the most important basic characteristics of the proton, the electron, and the $Li^+$ ion.

Table 2. Basic properties of the electron, proton and $Li^+$ ion

| | Radius [cm] | Mass number $[m/m_p]$ | De Broglie wavelength [cm] [a] |
|---|---|---|---|
| Electron | $1.42\times10^{-13}$ [b] | 1/1836 | $6.2\times10^{-7}$ |
| Proton | $\sim2\times10^{-13}$ | 1 | $1.5\times10^{-8}$ |
| $Li^+$ ion | $7.8\times10^{-9}$ | 7 | $5.5\times10^{-9}$ |

[a] $\lambda = \frac{h}{\sqrt{2mE}}$; refers to a particle kinetic energy of 3/2 kT (T = 300 °K) in a potential free space.

[b] "Classical" electron radius: $e^2/2\,m_e c^2$.

## $H_3O^+$ (Hydronium Ion)

Because of its small radius, the proton can come into close contact with polar molecules and also exert a strong polarizing effect. Thus, in water, it does not exist as an isolated elementary particle, but adds onto a molecule of $H_2O$, forming a covalent bond.

The existence of the molecule-ion $H_3O^+$ in ionized water vapor can be demonstrated by mass spectrometry. Thus, using a field emission ion source, *Beckey* [5] was able to show that the mass spectrum of an $H_2O$–$D_2O$ mixture exhibits four peaks, one mass unit apart from each other. These peaks can be assigned to the ions $H_3O^+$, $H_2DO^+$, $HD_2O^+$, and $D_3O^+$ (Figure 2). The symmetrical structure of the $H_3O^+$ ion is reflected in the nuclear magnetic resonance spectrum shown in Figure 3.

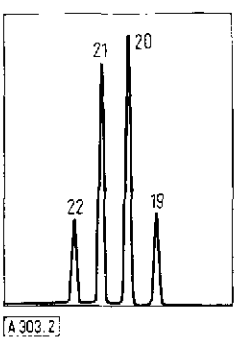

Fig. 2. Field emission mass spectrum of a mixture of $H_2O$ and $D_2O$ recorded by *Beckey* [5]. The appearance of four peaks proves the existence of $H_3O^+$. If $H_2O^+$ were the ionization product, then only 3 peaks would be observed. In this experiment, proof of the existence of $H_3O^+$ is given without absolute calibration of the mass scale.

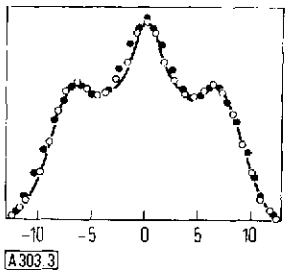

Fig. 3. Nuclear magnetic resonance spectrum of $H_3O^+$ in crystals of $HNO_3$ monohydrate at 90 °K (*Richards* and *Smith* [6]). The full line was calculated for distribution of a proton over the apices of an equilateral triangle (side length = 1.72 Å).

Abscissa: Magnetic field strength [gauss].

## $H_9O_4^+$ (Secondary Hydration)

The symmetrical distribution of the excess positive charge among the three protons in the hydronium ion allows formation of very stable hydrogen bridges to the neighboring $H_2O$ molecules. The proton possesses a very high mobility within this molecular complex. Thus, its localization in the central $H_3O^+$ portion simply expresses a maximum in its probability of position.

The existence of the $H_9O_4^+$ complex and its remarkable stability compared to the other complexes can also be demonstrated directly by mass spectrometry [5]. Thus, *Knewstubb* and *Tickner* [7] were able to show that a pronounced $H_9O_4^+$ frequency maximum occurs in the equilibrated ionization products formed in a glow discharge (Figure 4).

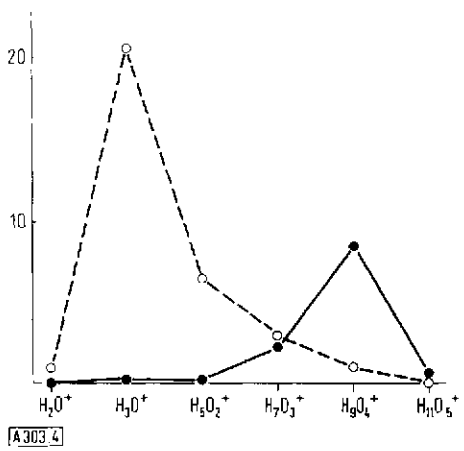

Fig. 4. Mass spectrometric frequency distribution of $H^+$ hydrate complexes in a glow discharge according to *Knewstubb* and *Tickner* [7].

○ - - - ○ Cathode distance: 1.5 cm; ●—● cathode distance: 6 cm. In the vicinity of the cathode, the equilibrium is markedly disturbed. Significant amounts of $H_3O^+$ (and small amounts of $H_2O^+$) are found only in this zone. Under normal conditions (greater cathode distance), $H_9O_4^+$ exhibits the greatest stability.

Ordinate: relative frequency [arbitrary units].

## Tertiary Hydration

Additional (relatively labile) hydrogen bridges, similar to those between $H_2O$ molecules in the liquid phase, are formed at the periphery of the $H_9O_4^+$ complex. The directed formation and breaking of these bonds results in "structural diffusion" of the entire hydrate complex. This diffusion is the rate-limiting step in the drift mobility of the proton in aqueous solution. The tertiary hydration shows strong dependence on temperature between 0 °C and 150 °C. Thus, it becomes particularly evident in the temperature dependence of the apparent molar heats of strong acids [1].

Similar structural relationships exist for the defect proton [8]; here, the hydroxyl ion $HO^-$ corresponds to the hydronium ion, and the (probably less stable) structural species $H_7O_4^-$ to the secondary hydrate complex $H_9O_4^+$.

## Mechanism of Proton Transport

The conductance in liquid $H_2O$ due to excess protons and defect protons may be explained by two possible mechanisms: a) The rate-determining step involves proton transfer from $H_3O^+$ to an $H_2O$ molecule of the secondary hydrate structure. Then the transformation within the tertiary structure (transition to the secondary and formation of a new tertiary hydrate structure) is complete before the proton jumps back into its previous central position.

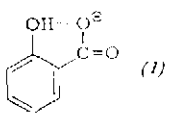
b) Structural rearrangement (structural diffusion) presents the rate-limiting step. In this case, the proton will frequently oscillate between the primary and the secondary structure before the center of the complex is shifted by the length of one hydrogen bridge.

Direct decision as to which of the two mechanisms is dominant can be obtained by comparing the drift mobility of the proton in water and ice. Mechanism a) predominates in ice, at least for small proton concentrations, when the disorientation of the lattice caused by proton jumps can be neglected; in this case, the perfect tetrahedral hydrogen bridge structure is ideal for proton transfer.

Proton mobility in ice crystals has been determined directly by methods based on reaction kinetics [3, 32], and found to exceed the mobility in the liquid phase by one to two orders of magnitude. It then follows directly that mechanism b) predominates in water. The time required by the proton to travel a given distance (*e.g.* the length of a hydrogen bridge) can be calculated from the rate of drift by applying the Nernst-Einstein relationships. Measurements on ice crystals give values of $0.8\times10^{-13}$ to $1\times10^{-13}$ sec for the lifetime of an $H_3O^+$ ion, while the lifetime of $D_3O^+$ is larger by a factor of 6–8 [33]. On the other hand, the time constant for the liquid phase has a value of about $3\times10^{-12}$ sec, with a "normal" isotope effect ($\tau_{D_2O}/\tau_{H_2O}$) of $\sqrt{2}$. This time constant can, however, be interpreted only as the mean residence time of a proton in a given central position of the hydrate complex. Its order of magnitude is in agreement with the time constant for the structural rearrangement of water, which can be determined directly from ultrasonic absorption measurements [34].

The time constant for the defect proton, which can be derived from the drift mobility in the liquid phase, exceeds that for the excess proton by a factor of 1.75. In ice crystals this difference is probably somewhat great-

[32] *M. Eigen* and *L. de Maeyer*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *60*, 1037 (1956).



[33] *H. Ch. Spatz*, Diploma Thesis, Universität Göttingen, 1962.

[34] *L. Hall*, Physic. Rev. (2) *73*, 775 (1948).

er; the exact numerical value has not yet been determined in this case.

The short lifetime of the "individual" $H_3O^+$ ion should cause the corresponding vibration bands in the infrared and Raman spectra to appear diffuse. In aqueous solution, the $H_3O^+$ bands produced by crystalline monohydrates of strong acids are in fact not very sharp. A band with a very large half-width between 3 and 6 $\mu$ was recently identified in both the infrared [13, 14] and Raman spectra [15]; this corresponds to the continuous increase in absorption in the 2–3 $\mu$ region found previously [35]. However, this band cannot be assigned directly to the $H_3O^+$ ion, since it appears with nearly identical shape in the spectra of concentrated base solutions. Its half-width ($\Delta\lambda \approx 3\ \mu$) corresponds to a lifetime of about $10^{-13}$ seconds (see above [35a]), but it has not yet been shown unequivocally to which normal vibration it should be assigned. Since the lifetime involved here refers to an excited vibrational state, this lifetime can only indirectly be related to that obtained from kinetic measurements.

The high proton mobility in ice crystals – it differs from that of conduction band electrons in metals by only about 2 orders of magnitude, cf. $\sqrt{m_{H^+}/m_{e^-}}$ – and in particular the relatively large isotope effect point to a nonclassical behavior of the proton while overcoming the potential barrier. In the classical sense, the high transfer rate would correspond to practically unlimited mobility of the proton. Similar observations can be made for other hydrogen bridged systems. For example, *Weller* [36] observed a fluorescence transformation [36a] of salicylic acid anions *(1)* which occurs even at the

*(1)*

temperature of liquid hydrogen and which can be attributed to proton transfer between the hydroxyl and carboxyl groups. The time constant involved is $\tau \ll 10^{-8}$ sec. For imidazole crystals, *Zimmermann* [37] observed term splitting which he attributes to delocalization of the protons attached to the ring nitrogen ("protomerism") *(2)*. This delocalization is favored by the resonance of the ionic limiting structures.

*(2)*

## 2. The Kinetics of Recombination and Charge Transfer

The following structural and transport properties of hydrated protons are of particular importance for the kinetics of protolytic reactions:

1. Superposition of the potentials in hydrogen bridges permits practically unhindered proton transfer from the donor to the acceptor, provided the difference [37a] is

$$pK_{acceptor} - pK_{donor}$$

positive. The existence of a hydrogen bridge between the donor and acceptor is a basic prerequisite for this interaction.

2. The rate of proton transfer is determined by the frequency of encounters resulting from molecular thermal motion. We refer to such reactions as diffusion-controlled.

3. Owing to the fact that the proton jumps back and forth between the different $H_2O$ molecules of the complex at a very high rate, the effective cross-section for reactions involving $H_{aq}^+$ is determined by the extent of the entire hydrate complex.

In any mathematical treatment of such processes, it is advantageous (and completely correct in the formal sense) to consider the encounter and its reversal, the diffusion controlled separation of the reactants, as a step preliminary to the actual reaction [38]:

$$\underset{(a)}{H_{aq}^+ + X^{\ominus}} \rightleftharpoons \underset{(b)}{H_{aq}^+ \ldots X^{\ominus}} \rightleftharpoons \underset{(c)}{{}^{\oplus}HX} \qquad (1)$$

$$HO_{aq} + {}^{\oplus}HX \rightleftharpoons HO_{aq} \ldots {}^{\oplus}HX \rightleftharpoons H_2O + X^{\ominus} \qquad (2)$$

Under normal circumstances, the stationary concentration of the encounter complex (b) is invariably very small [compared to (a) and (c)]; on this assumption, the overall rate constants can be expressed as follows:

$$\vec{k} = \frac{k_{ab} \cdot k_{bc}}{k_{ba} + k_{bc}}\ ; \quad \overleftarrow{k} = \frac{k_{cb} \cdot k_{ba}}{k_{ba} + k_{bc}} \qquad (3)$$

The reaction is diffusion-controlled when $k_{bc} \gg k_{ba}$,

$$\vec{k} = k_{ab} \text{ and } \overleftarrow{k} = k_{ba}\frac{k_{cb}}{k_{bc}} \qquad (4)$$

In this case, proton transfer between two systems, HX and HY, can be treated analogously:

$$\underset{(a)}{HX + Y} \rightleftharpoons \underset{(b)}{XH \ldots Y} \rightleftharpoons \underset{(b')}{X \ldots HY} \rightleftharpoons \underset{(a')}{X + HY} \qquad (5)$$

[35] *R. Suhrmann* and *F. Breyer*, Z. physik. Chem. Abt. B *23*, 193 (1933).

[35a] The lifetime of a central $H_3O^+$ in the $H_9O_4^+$ complex should be somewhat greater and that of a peripheral $H_3O^+$ somewhat less than that in ice crystals because of the electrostatic effect of the secondary and tertiary $H_2O$ molecules which are oriented towards the center.

[36] *A. Weller*, Z. Elektrochem. Ber. Bunsenges. physik. Chem. *60*, 1144 (1956), recent data: personal communication.

[36a] Fluorescence transformation is the prototropic or protolytic transformation of a molecule due to a pK change upon excitation. According to *Th. Förster* (Fluoreszenz organischer Verbindungen. Vandenhoeck & Ruprecht, Göttingen 1951) this change can amount to about 5 to 7 pK units. It appears as a pH shift of the point where the fluorescence spectrum changes (from the spectrum of the acid towards the spectrum of the base) relative to the corresponding point where the absorption spectrum changes. The effect is only observable if the reaction takes place within the lifetime of the excited state ($\approx 10^{-8}$ sec).

[37] *H. Zimmermann*, Z. Elektrochem. Ber. Bunsenges. physik. Chem. *65*, 821 (1961).

[37a] pK = the negative logarithm of the acid dissociation constant.

[38] *M. Eigen*, Z. physik. Chem. (N.F.) *1*, 176 (1954).

(Proton transfer in the encounter complex can also take place via water molecules). In this case, the overall rate constants are

$$\vec{k} = \frac{k_{ab}\, k_{bb'}\, k_{b'a'}}{N} \quad \text{and} \quad \overleftarrow{k} = \frac{k_{a'b'}\, k_{b'b}\, k_{ba}}{N} \tag{6}$$

where

$$N = (k_{ba} + k_{bb'})\, k_{b'a'} + k_{ba}\, k_{b'b} = (k_{b'a'} + k_{b'b})\, k_{ba} + k_{b'a'}\, k_{bb'} \tag{7}$$

Here, the intermediate stages b and b′ are again assumed to be in a steady state. Diffusion-controlled reactions result when at least one of the conditions

$$k_{ba} \ll k_{bb'} \qquad k_{b'a'} \ll k_{b'b} \tag{8}$$

is fulfilled. Then, we have

$$\vec{k} = \frac{k_{ab}}{1 + K_b \cdot k_{ba}/k_{b'a'}} \quad \text{and} \quad \overleftarrow{k} = \frac{k_{a'b'}}{1 + k_{b'a'}/(k_{ba} K_b)} \tag{9}$$

The ratio of the rate constants for the two separation processes ($k_{ba}/k_{b'a'}$) for reactants of similar nature equals approximately unity. The factor $K_b$ is the equilibrium constant for proton exchange in the encounter complex. For $k_{ba} \approx k_{b'a'}$, $\log K_b$ is essentially equal to the pK difference of the two acids (HX and HY).

In protolytic reactions, the condition $k_{bc} \gg k_{ba}$ is identical with the assumption that proton transfer takes place immediately after formation of a hydrogen bridge between the reactants (encounter complex), before they again separate as a result of thermal motion. It is of no significance here that this rapid reaction step is followed by another step, *viz.* the breaking of the hydrogen bridge framework of the hydrate complex. This bond-breaking is a multimolecular process involving relatively large entropy and energy increments which partially cancel each other out. This breakdown of the complex structure can take place within $10^{-11}$ sec. For the reverse reaction, this event must be reflected in the equilibrium constants of the partial reaction c $\rightleftharpoons$ b [Equations (1) and (2)] or a′ $\rightleftharpoons$ b′ $\rightleftharpoons$ b [Equation (5)].

The constants $k_{ab}$ and $k_{ba}$ can be calculated from the equations of motion of the reactants (taking electrostatic interactions into account). According to *Debye* [39], one obtains for diffusion-controlled encounters:

$$k_{ab} = 4\pi N_L R_{ij} (D_i + D_j) \frac{\varphi_{ij}}{\exp(\varphi_{ij}) - 1} \tag{10}$$

and for the reverse reaction, *i.e.*, diffusion-controlled separation of the reactants [38]:

$$k_{ba} = (3/R_{ij}^2) \cdot (D_i + D_j) \frac{\varphi_{ij}}{1 - \exp(-\varphi_{ij})} \tag{11}$$

(where $N_L$ = Avogadro's number; $R_{ij}$ = reaction distance; $D_i$ and $D_j$ = diffusion coefficients of the reactants; $\varphi_{ij}$ = ratio of the potential energy of electrostatic interaction and the thermal energy kT).

[39] *P. Debye*, Trans. electrochem. Soc. *82*, 265 (1942).

For dilute solutions, the electrostatic interaction can be represented by a simple coulombic term:

$$\frac{z_i z_j e_o^2}{\varepsilon R_{ij}}$$

(where z = valence; $e_o$ = elementary charge, and ε = effective dielectric constant).

Equation (10) applies to reactants with spherical symmetry. Deviations from this structure must be accounted for by suitable correction factors. (If all quantities are expressed in c.g.s. units, then $k_{ab}$ must be divided by $10^3$ in order to arrive at the usual $M^{-1}$ $sec^{-1}$ dimensions. The quantity $k_{ba}$, being a rate constant of a first-order reaction, has the dimension $sec^{-1}$).

For protolytic reactions, the order of magnitude of $k_{ab}$ is generally $10^{10}$ to $10^{11}$ $M^{-1}$ $sec^{-1}$ (see below); the value of $k_{ba}$ is then between $10^{10}$ and $10^{11}$ $sec^{-1}$. Both constants are essential for the description of the reaction mechanism: $k_{ab}$ represents the maximum value of the overall rate constant for recombination; however, the value of $k_{ba}$ (in relation to $k_{bc}$) determines how closely the actual rate constant can approach this maximum value. For protolytic reactions, $k_{bc}$ is generally of the same order of magnitude as the reciprocal of the lifetime of $H_3O^+$ or $HO^-$ ($>10^{12}$ $sec^{-1}$) so that here the condition $k_{bc} \gg k_{ba}$ is satisfactorily fulfilled, and $k_{ab}$ represents the overall recombination rate constant $k_{H^+}$ or $k_{HO^-}$. The chemical effects, which are reflected in the acidity or basicity of the compound, are then essentially accounted for in the overall rate constant for the dissociation $HX \rightarrow X^\ominus + H^+$ or for the hydrolysis $X^- + H_2O \rightarrow HX + OH^\ominus$ [see Equation (4)]. However, there may be other effects in addition to the individual factors ($D_i + D_j$), $z_i z_j$ and $R_{ij}$ that also influence $k_{ab}$; these will be discussed in greater detail in Section 3.

Experimental study of the kinetics of acid-base reactions was made possible by the development of modern techniques. In

Table 3. Methods for studying fast reactions in solutions.

| Method | Time range [sec] | Method of recording |
|---|---|---|
| Relaxation [40] | | |
| Temperature jump | 1 $10^{-6}$ | Spectrophotometric, polarimetric, fluorimetric, conductometric |
| Pressure jump | $10-5\times10^{-5}$ | Conductimetric |
| Electric field pulse | $10^{-4}-10^{-8}$ | Conductimetric (spectrophotometric) |
| Electric traveling waves | $\approx 10^{-9}$ | impedance measurement |
| Dielectric absorption | $10^{-6}$ $10^{-9}$ | resonance line width (in superimposed, strong d. c. fields) |
| Sound absorption and dispersion [41] | $10^{-5}-5\cdot10^{-10}$ | resonance and reverberation light diffraction (Debye-Sears effect) impulse echo |
| Proton magnetic resonance [42] | $1-10^{-3}$ | line broadening (spin-echo) |
| Fluorescence transformation [43] | $\approx 10^{-8}$ | quantum yield, decay time |

general, the half-lives for attainment of equilibrium are substantially less than one second. For the normal acid and base species defined below, they are even less than 30 μsec. Most of the half-lives reported here were obtained from relaxation spectrometric studies in the time range of $10-10^{-9}$ sec. Some data obtained from nuclear magnetic resonance [44, 45] and of fluorescence transformation [43] studies were also used. Table 3 gives a list of the methods of measurement and their range of application. A detailed description can be found elsewhere [40–43].

## 3. Protolysis and Hydrolysis

### a) Reaction Mechanism

A simple acid-base equilibrium in aqueous solution can be represented by the general reaction diagram shown in Figure 5.

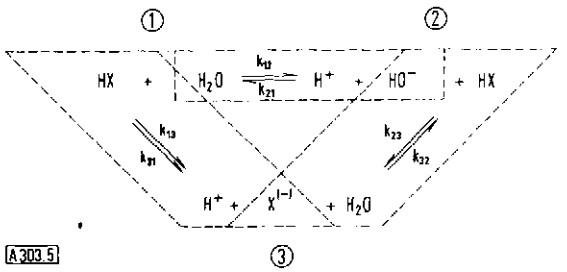

Fig. 5. Reaction scheme for an acid-base equilibrium in aqueous solution.

This diagram shows that the pH value of a solution can be established by means of two mutually indepent processes. We refer to these as protolysis and hydrolysis. In the case of protolysis ($1 \rightleftharpoons 3$), an excess proton ($H^+ \cdot nH_2O$) arises from dissociation of an acid molecule HX or disappears by direct recombination with the base molecule $X^\ominus$. In the case of hydrolysis ($3 \rightleftharpoons 2$), a defect proton ($HO^- \cdot H_2O$) is formed by reaction of the base $X^\ominus$ with an $H_2O$ molecule. The reverse reaction consists of direct recombination of $HO^-$ with the acid HX. The connection between the two reaction paths is brought about by the neutralization ($1 \rightleftharpoons 2$) and its reverse reaction, the dissociation of $H_2O$.

The rate of neutralization can be determined independently of other protolytic and hydrolytic processes only in pure water. Such measurements have been carried out [46] using various relaxation methods (high electric field pulse, temperature jump [47]). The values for the rate constant at 25 °C as determined by the various methods are in good agreement (cf. Table 4a).

Recombination of $H^+$ with $HO^-$ is one of the fastest reactions known. Its rate exceeds that of any other reaction of the same charge type in aqueous solution. Even the reaction of an excess proton with a solvated electron (polaron) in aqueous solution is slower [48] (cf. Table 4a).

In a molecular-kinetic sense, the high rate of reaction of the excess and defect proton is attributable to the special transport mechanism in hydrogen-bridged systems (see above). The orientation of the $H_2O$ molecules during an encounter by structural diffusion favors formation of hydrogen bridges between the two hydrate complexes and thus permits fast proton transfer. The effective reaction distance according to Equation (10) is therefore relatively large. It corresponds to the projection of three to four hydrogen bridges (assuming a bond angle of about 110 °). Both the activation energy [48] and the isotope effect (see Table 4a) are in accordance with the assumption of a diffusion-controlled reaction. The ratio of the recombination rate constants in water and in ice [33] also clearly reflects the influence of the mobilities (see Table 4a). In the hydrogen-bridged lattice of ice crystals, the rate of proton transfer is not restricted by structural diffusion (see above); recombination can therefore occur faster than in the liquid state [2].

### b) Relaxation Spectrum [40]

The kinetics for the establishment of equilibrium can generally be described by two coupled differential equations. By selecting as the variable $x_i(t)$ the deviations of the concentration of the two reactants from their equilibrium values (according to temperature and pressure), *e.g.*, $\delta c_{HX} \equiv x_1$ and $\delta c_{H^+} \equiv x_2$, then the remaining concentration variables are fixed by the secondary conditions:

$$\begin{aligned} \delta c_{X^-} &= -\delta c_{HX} &&= -x_1 \\ \delta c_{H_2O} &= -\delta c_{HX} - \delta c_{H^+} &&= -(x_1 + x_2) \\ \delta c_{HO^-} &= -\delta c_{H_2O} &&= x_1 + x_2 \end{aligned} \qquad (12)$$

At equilibrium ($x_i = 0$), gross change disappears. Hence, for conditions near equilibrium ($x_i \ll c_i$), the rate equations may be linearized. From the original relations ($\dot{x} \equiv dx/dt$), we obtain

$$\begin{aligned} \dot{x}_1 &= a_{11}x_1 + a_{12}x_2 \\ \dot{x}_2 &= a_{21}x_1 + a_{22}x_2 \end{aligned} \qquad (13)$$

where

$$\begin{aligned} a_{11} &= -[k_{13} + k_{31}\, c_{H^+} + k_{32} + k_{23}(c_{HO^-} + c_{HX})] \\ a_{12} &= k_{31}\, c_X - k_{23} c_{HX} \\ a_{21} &= k_{13} + k_{31}\, c_{H^+} - k_{12} - k_{21} c_{H^+} \\ a_{22} &= -[k_{12} + k_{21}\,(c_{H^+} + c_{HO^-}) + k_{31}\, c_X] \end{aligned} \qquad (14)$$

The (reciprocal) time constants $\tau_I$ and $\tau_{II}$, which are characteristic for the kinetics of equilibration, are the roots of the "characteristic equation"

$$\begin{vmatrix} \left(a_{11} + \frac{1}{\tau}\right) & a_{12} \\ a_{21} & \left(a_{22} + \frac{1}{\tau}\right) \end{vmatrix} = 0 \qquad (15)$$

and have the values

$$1/\tau_{I,\,II} = -\frac{S}{2}\left(1 \pm \sqrt{1-4P/S^2}\right) \qquad (16)$$

where

$$S = a_{11} + a_{22} \text{ and } P = a_{11}\,a_{22} - a_{12}\,a_{21} \qquad (17)$$

The coupling of protolysis and hydrolysis becomes evident primarily under neutral conditions. Here, the relaxation times can no longer be ascribed to a single reaction step.

An entirely analogous behavior is observed for coupled vibrations. Here, too, resonance measurements yield only the "normal frequencies," and not the eigenfrequencies of the isolated oscillators. In the case of chemical relaxation, the "normal coordinates" are given by a linear combination of the concentration variables $x_i$. The (reciprocal) relaxation times are assigned, as the negative eigenvalues of the matrix of the rate coefficients $a_{ik}$, to these normal coordinates.

The expression for the relaxation times $\tau_I$ and $\tau_{II}$ describes a relatively simple physical situation: the quantity $(-S)$ contains the sum of all the rate terms, and hence the sum of the reciprocal relaxation times for the three partial equilibria (neutralization, protolysis, and hydrolysis).

$$-S = [k_{12} + k_{21}(\bar{c}_{H^+} + \bar{c}_{HO^-})] + [k_{13} + k_{31}(\bar{c}_{H^+} + \bar{c}_X)]$$
$$+ [k_{32} + k_{23}(\bar{c}_{HO^-} + \bar{c}_{HX})] = 1/\tau_{12} + 1/\tau_{13} + 1/\tau_{23} \qquad (18)$$

Since the square-root term in Equation (16) can only assume values from 0 to 1, $(-S)^{-1}$ determines the order of magnitude of the shortest time constant. Hence, $\tau_I$ is always fixed by the highest rate in the over-all reaction system. Whenever $4P \ll S^2$ (see below), we have

$$\tau_I = -(S^{-1}). \qquad (19)$$

The term P is rather complicated. Using the relaxation times for individual systems defined above ($\tau_{ik}$), it can be represented as follows:

$$P = (1/\tau_{12})(1/\tau_{13}) + (1/\tau_{12})(1/\tau_{23}) + (1/\tau_{13})(1/\tau_{23}) - R \qquad (20)$$

with the remainder (negligible in many cases):

$$R = k_{31}\bar{c}_X k_{21}\bar{c}_{HO^-} + k_{23}\bar{c}_{HX}(k_{12} + k_{21}\bar{c}_{H^+})$$
$$+ (k_{23}\bar{c}_{HO^-} + k_{32})(k_{13} + k_{31}\bar{c}_{H^+}) \qquad (21)$$

Under the above condition, *i.e.*, $4P \ll S^2$, we have

$$\tau_{II} = -(S/P). \qquad (22)$$

It can be shown that this condition applies only if one of the relaxation times $\tau_{ik}$ becomes substantially shorter than the other two, *i.e.* $\tau_{ik} \ll \tau_{il} \lesssim \tau_{kl}$. $\tau_I$ is then given by this shortest relaxation time $\tau_{ik}$, whereas $\tau_{II}$ becomes greater than $\tau_{il}$ but less than $\tau_{kl}$. Whether the value of $\tau_{II}$ is closer to $\tau_{il}$ or to $\tau_{kl}$ depends on the special conditions that determine the magnitude of the remainder in Equation (20). If this term is negligible, we have

$$\tau_{II} \approx \frac{\tau_{il}\,\tau_{kl}}{\tau_{il} + \tau_{kl}} \qquad (23)$$

As an example of the situation described by Equations (19) and (22), let us consider a simple acidic or basic solution of finite concentration. In 0.1 M acetic acid, $c_{HX} \gg \bar{c}_X \approx c_{H^+} \gg \bar{c}_{HO^-}$; in a corresponding ammonia solution $c_X \gg c_{HX} \approx c_{HO^-} \gg \bar{c}_{H^+}$. These conditions are valid as long as the pH is either large or small compared to the pK of the acid, and the degree of dissociation is very much smaller than unity. In such systems, however, only one, *viz.* the longer, relaxation time can be measured. For acetic acid, this is the simple relaxation time $\tau_{13}$ for protolysis, for ammonia, it is that for hydrolysis ($\tau_{23}$). The shorter time constant $\tau_I$, determined by the terms $k_{23}\bar{c}_{HX}$ (acetic acid) and $k_{31}\bar{c}_X$ (ammonia) is not observable. This is because the concentration change (normal variable) associated with this constant, is immeasurably small owing to the extreme differences betwen $c_{HX}$ and $\bar{c}_{HO^-}$ and between $\bar{c}_X$ and $\bar{c}_{H^+}$, respectively. The terms arising from $\tau_{12}$ are also missing; they are cancelled out by the remainder in $\tau_{II}$. In general, two relaxation times can be measured only near neutrality (pH 5–9). The degeneration of the two relaxation times into one time constant in this case is of particular interest. This degeneration occurs when the relaxation times for protolysis ($\tau_{13}$) and hydrolysis ($\tau_{23}$) become equal and large, compared to the relaxation time for neutralization ($\tau_{12}$). In addition, $\bar{c}_{HX}$ and $c_X$ must become large compared to $\bar{c}_{H^+}$ and $\bar{c}_{HO^-}$. For acid-base systems with a pK of about 7, this condition is readily fulfilled in the neutral region. If the recombination of $H^+$ and $HO^-$ is sufficiently fast, then $\frac{1}{\tau_{12}} \ll \frac{1}{\tau_{13}}, \frac{1}{\tau_{23}}$, where $\frac{1}{\tau_{13}} = k_{31}c_X$ and $\frac{1}{\tau_{23}} = k_{23}c_{HX}$. In this case, there is a pH value (close to the pK value) at which $\tau_{13}$ and $\tau_{23}$ become equal

$$k_{31}\bar{c}_X = k_{23}\bar{c}_{HX} \qquad (24)$$

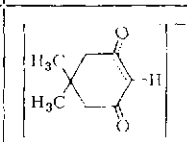
This means that $4P = S^2$, and the square-root term in Equation (16) disappears. Only one time constant is then obtained:

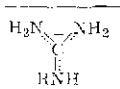
$$\tau = -(S^{-1}) \approx 2[k_{23}\bar{c}_{HX} + k_{31}\bar{c}_X]^{-1} \qquad (25)$$

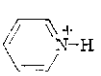
This case is of particular importance in buffering and in acid-base catalysis.

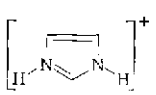
Let us consider imidazole (pK = 6.95) as an example. The rate constants $k_{31}$ and $k_{23}$ are both of the same (maximum) order of magnitude (see Table 4g). Condition (24) is fulfilled at pH 7.2 ($\tau \approx 10^{-10}/C_0$ sec, where $C_0$ = total molar concentration of imidazole). Attainment of the overall equilibrium, which is characterized by a single relaxation time, is fastest at this pH. At pH above or below about 7, one of the relaxation times (the more important one) becomes longer. Correspondingly, under comparable concentration conditions, acid-base systems with pK values $\neq 7$ should also possess larger time constants in the neutral region (pH $\approx$ pK). Hence it

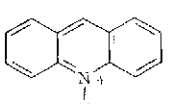
Table 4. Rate constants for the recombination of bases with $H^+$($k_{H^+}$) and of acids with $HO^-$($k_{HO^-}$).

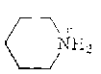


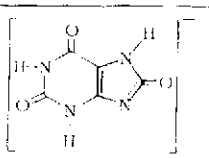


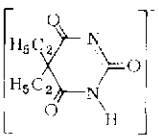


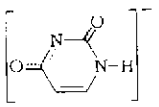


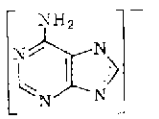


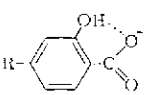


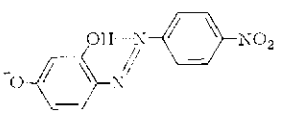


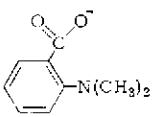


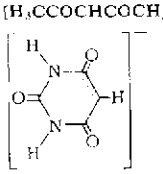


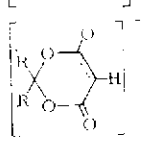


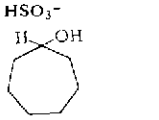












| Acid | Conjugate base | pK | $k_{H^+}$ [$M^{-1}$ sec$^{-1}$] | $k_{HO^-}$ | Ionic strength [mole/liter] | Temp. [°K] | Ref. |

follows that, from a kinetic standpoint, imidazole is an optimum buffer (and catalyst, see below). The same is true for any other acid-base system with a pK near 7 and with a maximum recombination-rate constant in the neutral region. The condition that pH $\approx$ pK for optimum buffering is already known from equilibrium theory. However, it holds in kinetics only if the recombination rate constants $k_{31}$ and $k_{23}$ (and hence, if pK $\approx$ 7, also the dissociation rate constants $k_{13}$ and $k_{23}$) are of the same order of magnitude. For some acids and bases, this is not so (see below). Since at least one of the rate constants is not at a maximum value corresponding to diffusion-controlled reactions, less advantageous kinetic conditions are obtained for buffering and catalysis. This is also true when several acid-base systems are present together and when in addition to the protolysis and hydrolysis reactions under discussion direct proton transfer between the various systems takes place (see Section 4).

### c) Rate Constants

Table 4 gives a list of the rate constants for the most important types of inorganic and organic acids and bases. Only the rate constants for recombination of the base with $H^+$ ($k_{H^+} = k_{31}$) and of the acid with $HO^-$ ($k_{HO^-} = k_{23}$) are given. In the pK range 5–9, both constants are generally important for the process of equilibration. The rate constants for the reverse reactions (acid dissociation and hydrolysis) can be calculated from $k_{31}$ or $k_{23}$ using the pK values:

$$k_{13} = k_{31} \times 10^{-pK}\ sec^{-1}$$

$$k_{32} = k_{23} \times 10^{-(14-pK)}\ sec^{-1}.$$

It should be kept in mind, however, that the pK values cited are referred to zero ionic strength. For the rate constants in Table 4 that are given for finite ionic strengths, the pK values as well as the ion product of water must therefore be corrected, using the (known) activity coefficients, in order to correspond to these ionic strengths before they can be used to compute $k_{13}$ and $k_{23}$.

Apart from a few well-understood exceptions, the order of magnitude of the recombination constants is between $10^9$ and $10^{11}$ liter/mole·sec for all the acids of the OH-, SH- (partly), NH- and $NH^+$-types whose pK values lie in the range −1 to +15. These values are consistent with the expectations discussed in Sections 1 and 2. As will be shown below, the absolute values of the rate constants corresponding to these "normal" acids and bases can be expressed quantitatively. This offers the possibility of evaluating the kinetic constants of all "normal" acid-base systems (including those that have not yet been investigated). This is important for enzyme kinetics, since the exact pK values of acid and basic groups occurring in proteins are not always known. Nearly all the groups that occur in natural amino acids fall into the category of "normal" acids and bases. These groups are (in addition to the carboxyl and α-amino groups) the second carboxyl in aspartic and glutamic acids, the phenolic hydroxyl in tyrosine, the aliphatic hydroxyls in serine and threonine, the sulfhydryl group in cysteine, the ε-amino group in lysine, the imidazole residue in histidine, and the guanidyl group in arginine. Nucleic acid constituents, which are important as substrates, such as phosphate, sugars, and purine and pyrimidine bases (cyclic NH, amino, and enolic hydroxyl groups) also belong in this category. The CH-acids (see below), which are also important as substrates, and some "normal" acids in which special structural relationships (internal hydrogen bridging, *etc.*) prevail form exceptions.

Let us now examine in detail the factors which determine the absolute values of rate constants.

On the basis of the considerations discussed in Section 2, the encounter frequency depends on mobility, reaction distance, possible steric effects, and charge of the two reactants. For the type of reaction under discussion here, the first two quantities do not vary greatly. They depend essentially on the properties of the excess and defect proton discussed above. In agreement with this, all $k_{H^+}$ rate constants generally exceed the $k_{HO^-}$ constants by a factor of 2–3, provided the reactions are diffusion-controlled. The frequency of encounter is rate-determining only if recombination to the acid or base is sufficiently fast, *i.e.*, is complete before the reactants again separate as a result of thermal motion. This requires complete superposition of their potentials and hence a negligibly small activation energy. This requirement is met only if the excess or defect proton has free access to the reaction site via hydrogen bridging (lone electron pair of the base or proton in the acid molecule) and if the reactants are already in a configuration suitable for reaction. Hence, in discussing $k_{H^+}$ and $k_{HO^-}$, we must consider essentially the following four effects:

1. Spatial symmetry and steric factors
2. Electrostatic interactions
3. Hydrogen bond structure
4. Electron distribution (resonance, tautomerism), and molecular structure.

The absolute strength of the acid or base (or the electrophilicity or nucleophilicity) affects the recombination rate only if condition 4 is controlling. In diffusion-controlled reactions, acidity and basicity (depending on pK) are reflected only in the rate constants for acid dissociation ($k_{13}$) or hydrolysis ($k_{32}$).

These effects are evident in the examples given in Table 4 (for more detailed information see [73]).

*1.* The reduced symmetry of $HS^-$ (3 electron pairs) compared to $F^-$ (4 electron pairs) causes a decrease in $k_{H^+}$ by a factor of 0.75. $HO^-$ differs from $HS^-$ in its mechanism of motion (structural diffusion) which in the case of $HO^-$ promotes orientation of the hydrate regions on encounter, so that reaction is favored. For carboxylates, the proton cannot penetrate beyond a hemisphere (factor: 0.5). The symmetry factor, however, is not always as evident as in this case. In the recombination of $HO^-$ with substituted amines, one would expect a decrease in the rate constant relative to the value for $NH_4^+$. Instead, a rate increase is first observed for methylamine followed by a (relatively slight) decrease towards trimethylamine. Here the influence of symmetry is evidently cancelled out by another effect. In water, the hydrophobic methyl groups effect structural aggregation and thus increase the reaction distance (which in reactions between $H^+$ and $HO^-$ is determined by the extension of the hydrogen bridge structure in the vicinity of the reactants). Thus, for example, the rate constant for ethanolamine is less than that for ethylamine or even propylamine [61]. This effect manifests itself particularly in the apparent molar heats of these compounds; it also causes anomalies in acid-base catalysis [74,75].

*2.* Simple electrostatic interactions also have only a relatively small effect on the recombination rates. This is because $H^+$ always adds onto a lone electron pair (*i.e.* to a negative site of the base molecule), whereas $HO^-$ always undergoes recombination with a positively charged reactant, *i.e.* the proton of the acid. Repulsion effects due to excess charge of the same sign are therefore always attributable to more distant groups. As shown by examples b) and c) of Table 4, the rate constant decreases by a factor of 2–3 (for an ionic strength of 0.1) for each charge of equal sign on the other reactant. This applies only to charge centers which are sterically near to each other. More distant groups eventually tend to exert only a very slight effect, *e.g.* heptaphosphate is only negligibly different from triphosphate [54]).

*3.* The effect of the hydrogen bridge structure has already been pointed out in the discussion of amines; it is much more evident from examples i) and k) of Table 4. Here, recombination of $HO^-$ with the acid proton is hindered by disturbance or blockage of the hydrogen bonds between the reactants. In the case of amino polycarboxylic acids, such disturbance is caused by the presence of negatively charged carboxyl groups. These groups disturb the orientation of $H_2O$ molecules in the vicinity of the ammonium proton, thus hindering proton transfer to the hydrated $HO^-$. In hydrogen-bridged chelates of the salicylic acid type or in *o*-hydroxyazo compounds (Table 4 k), approach to the proton is completely blocked. Only after the intramolecular hydrogen bridge is broken (*i.e.* when the molecule rearranges to an isomeric structure by rotation of a group participating in a hydrogen bridge) can a hydrogen bridge arise between the acid proton and the hydrated $HO^-$. Hence, the constant $k_{HO^-}$ is reduced by the value of the stability constant for the internal hydrogen bridge (in $H_2O$ as solvent) compared to the $k_{HO^-}$ values for diffusion-controlled reactions [54]. Whereas the $k_{HO^-}$ values for diffusion-controlled reactions are entirely independent of the basicity of the compound, in the case of hydrogen-bridged chelates the value of the rate constant of recombination reflects the amount of internal hydrogen bridging. The stability of the hydrogen bond depends on the electronegativity of the proton-acceptor group, on any excess charges present, on steric and resonance stabilization of the chelate ring (six-membered rings possess maximum stability), and on other factors.

The chelate effect is of practical interest in relaxation measurements carried out with indicators above pH 11. Many such indicators are of the hydrogen-bridge chelate type mentioned (*e.g.* Tropeolin O, Alizarin Yellow S, *etc.*) and hence are not suitable for use in very fast reactions.

It should be stressed that it is not only the high mobility of the proton as an elementary particle, but primarily the existence of hydrogen bridges that accounts for the high rates of protolytic and hydrolytic reactions relative to electron transfer reactions. Thus, for example, the reaction of the proton with $HO^-_{aq}$ is nearly one order of magnitude faster than the reaction of the proton with a solvated electron (polaron) (Table 4a; the rate of this reaction has been determined only recently with the aid of a pulse radiolysis method [48].) In the case of the neutralization reaction, the proton is led through hydrogen bridges to the electron localized in $HO^-$. On the other hand, the solvated electron (polaron) is delocalized and less likely to undergo recombination. The corresponding hydrolytic reactions of $e^-_{aq}$ are relatively slow, although in aqueous solution, the hydrogen atom is a relatively strong acid. The rate constant for the reaction

$$e^-_{aq} + H_2O \rightarrow HO^- + H$$

lies between $10^3$ $sec^{-1}$ (extrapolated as a lower limit) from measurements on dilute solutions of $H_2O$ in ethylenediamine [76]) and $4\times10^4$ $sec^{-1}$ (obtained as upper limit from pulse radiolysis measurements [48]). The rate constant for the reverse reaction was estimated by *Jortner* and *Rabani* [77] to be $6\times10^5$ $sec^{-1}$. Although the error in these (experimental) values may still be relatively large, it is clear that lack of a hydrogen bridge structure leads to reaction rates which are substantially lower than those of "normal" acids and bases. This is true even for small, highly mobile reactants. As shown by the data under i and k in Table 4, any disturbance of the hydrogen bridge structure in the vicinity of the proton donor and acceptor has a greater effect than simple electrostatic repulsion or steric hindrance.

*4.* If the acid and its conjugate base differ in their electron distribution and molecular structure, *i.e.* if the recombination with $H^+$ or $HO^-$ is associated with a resonance or tautomeric transformation, then the reaction rates may be relatively low, as indicated by the examples under l and m in Table 4. Compounds of the CH- and carbonium type belong to this category.

In general, C–H compounds, *e.g.* simple hydrocarbons, are much too weak acids to be of interest in our considerations. However their acidity can be markedly increased by introducing suitable substituents (*e.g.* halogen). The conjugate base of the CH-acid is a carbanion-type compound. It can be stabilized by delocalization of the negative charge, as in the case of nitroparaffins or the ketones listed in Table 4l. Here, resonance exists between the enolate and carbanion structure of the conjugate base.

Let us consider acetylacetone as an example. The reaction of the negative ion with $H^+$ to give the enol (Table 4d) constitutes a "normal" diffusion-controlled recombination. The reaction with $HO^-$ (Table 4d) is somewhat slower, because the enol is stabilized by an internal hydrogen bridge. The corresponding rate constants for the ketone (Table 4l), on the other hand, are several orders of magnitude smaller. This is due to two interrelated factors:

a) the CH or the $C^-$ group do not readily form hydrogen bridges;

[73] *M. Eigen, W. Kruse, G. Maass,* and *L. de Maeyer* in: Progress in Reaction Kinetics. Pergamon Press, London 1963, Vol. II.

[77] *J. Jortner* and *J. Rabani,* J. physic. Chem. *66,* 2081 (1962).

b) the recombination is associated with a charge displacement and structural modification.

The second factor similarly manifests itself also in the reaction of $CO_2$ with $HO^-$ or of $HCO_3$ with $H^+$ (to give $CO_2 + H_2O$) or in corresponding reactions of carbonium-type compounds.

The widely varying values listed in Table 4 l and m show no obvious general regularities. For example, in the case of acetone, recombination with $H^+$ is practically diffusion-controlled, whereas that with $HO^-$ is very slow. The reaction of $HCO_3^-$ with $H^+$ to give $CO_2$ (linear complex) is slow compared to the analogous formation of $SO_2$ (bent molecule), even though the latter reaction is not diffusion-controlled either. However, regularities do exist within individual groups of compounds; these will become clear from the discussion presented in the following section. The rate of recombination with $H^+$ and $HO^-$ for compounds of this class is associated with the pK difference of the proton donor and acceptor. This is clearly indicated by a plot of log $k_{H^+}$ and log $k_{HO^-}$ *vs.* pK for a few ketones (Fig. 6). In the case of chloroacetone (pK = 16.5), the pK difference with respect to

A 303.6

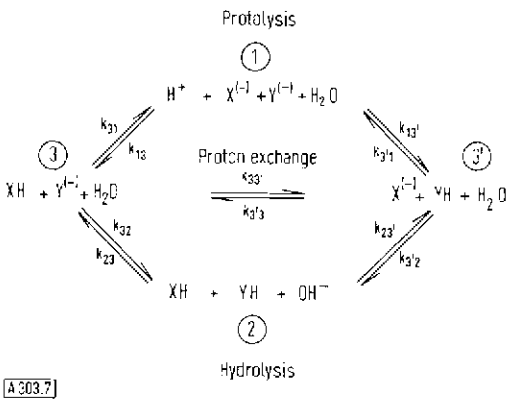
Fig. 6. Dependence of the recombination rate constants $k_{H^+}$ (○—○) and $k_{HO^-}$ (●—●) on their pK in the protolysis of ketonic compounds. Experimental data are from [60, 78, 79]. The broken line denotes the linear extrapolation.

Ordinate: log $k_{H^+}$ and log $k_{OH^-}$.
Abscissa: pK.

the hydrated proton is very large ($\approx 18$) so that recombination of the anion with $H^-$ is very fast. Conversely, the difference with respect to $H_2O$ is small (−0.8): recombination of the ketone with $HO^-$ is therefore slow. In the case of the relatively "strong" barbituric acid (ketone), $k_{H^+}$ is relatively small. It also becomes clear now why the resonance stabilization difference between the acidic and basic forms of the carboxylic acids, phenols, aromatic amines, and other compounds listed under b–g in Table 4 is not reflected in the rates of recombination. As will be shown in the following section, this effect applies to $k_{H^-}$ and $k_{HO^-}$ only when the pK differences between the proton donor and acceptor are relatively small. Qualitatively, however, the behavior is not much different from that of the compounds listed under l and m in Table 4. This problem will be discussed further in the following section, in connection with the question of the definition of "pseudo acids."

Processes of the type just described are decisive for many important reactions of organic chemistry such as the keto-enol rearrangement, halogenation of organic molecules, aldol condensation, *etc.* The fast elementary stages of these reactions can be identified separately using relaxation methods. For example, it is possible to determine separately the rates of protolytic reactions of the keto and enol forms of heterocyclic ring compounds such as barbituric acid, Meldrum's acid [67], *etc.*, even if one of these forms is present in concentrations of $< 0.1$ % of the other. In the relaxation spectrum, the reactions of the keto and enol forms appear in the millisecond and microsecond range, respectively. Until now, relatively little was known about the position of the keto-enol equilibrium for these compounds.

Another class of "anhydro acids" is represented in Table 4 m by $I_2$. Here, the equilibrium is attained relatively slowly, because it is coupled with a further transformation:



$$X_2 + H_2O \rightleftharpoons X_2OH^- + H^+ + XOH \rightleftharpoons X^- + H^+$$

The relaxation times for $Cl_2$, $Br_2$, and $I_2$ are in the millisecond range; equilibration occurs most rapidly for $Br_2$ (see [72]). The first step in this scheme, however, consists of a normal protolytic reaction with $k_{H^+}$ values of the order of $10^{10}$ $M^{-1}$ $sec^{-1}$.

## 4. Proton Transfer between Different Acid-Base Systems

### a) Reaction Mechanism

In the protolysis and hydrolysis treated in Section 3, proton transfer takes place between the conjugated acid-base pair and the solvent. Let us now consider the more general case of proton transfer between two different acid-base pairs in the presence of water as solvent. The general reaction scheme is shown in Figure 7 [*]. Here, the $H_2O$ molecules (present in large

A 303.7

Fig. 7. Reaction scheme for proton transfer between two different acid-base pairs in the presence of water.

excess as the solvent) are not explicitly shown. However, they participate as reactants in the hydrolytic reactions (3 → 2) and (3′ → 2); hence, their dissociation equilibrium $H_2O \rightleftharpoons H^- + HO^-$ must also be considered.

A diagram of this kind describes both the reaction behavior of an acid-base system in the presence of a buffer and the process of pH indication. In these reactions, maintenance of a constant pH value requires the presence of excess buffer, while the indicator, on the other hand, must be present in minute concentration so as not to mask the behavior of the system. In simple cases, the mechanism of acid-base catalysis and of analogous enzymatic processes (to be described in more detail in the second part) can also be represented by such a reaction scheme.

[78] *R. P. Bell* [74], p. 163 et seq.

[79] *R. G. Pearson* and *R. L. Dillon*, J. Amer. chem. Soc. *75*, 2439 (1953).

[*] Owing to the notation chosen to represent this reaction diagram, certain reaction rates are necessarily denoted by symbols different from those used in the protolysis-hydrolysis scheme (Fig. 5). $k_{13}$ and $k_{31}$ have a different meaning: $k_{13}$ in this case refers to the recombination with $H^-$, $k_{31}$ to dissociation of the acid.

b) Relaxation Times

Protolysis-hydrolysis of an acid-base pair in aqueous solution can be completely described by two relaxation times [cf. Equation (16)]. The presence of a second acid-base pair results in a number of additional reactions (protolysis and hydrolysis in the system $HY/Y^{\ominus}$, direct proton exchange with $HX/X^{\ominus}$), but only in one additional normal coordinate. The concentration change for HY always equals that for $Y^{\ominus}$. The reaction diagram (Figure 7) is thus completely described by three relaxation times. Since simultaneous occurrence of three relaxation times is extremely rare, discussion of the complete expression – the solution involves the roots of a cubic equation – can be omitted. Instead, let us consider the following simpler cases.

1. pH $\approx$ 7. The reactants, HX, $X^{\ominus}$, HY, and $Y^{\ominus}$ are all present in finite condentration ($\gg 10^{-7}$ M). The essential transformation consists of a direct proton transfer, described by reaction (3 $\rightleftharpoons$ 3') in Figure 7. This direct transfer is generally so fast that the transformation via states (1) and (2) may be neglected (otherwise cf. case 2). The reciprocal relaxation time for this process is then:

$$\frac{1}{\tau} = k_{33'}(\bar{c}_{HX} + \bar{c}_{Y}) + k_{3'3}(\bar{c}_{X} + \bar{c}_{HY}). \qquad (26)$$

If the systems $HX/X^{\ominus}$ and $HY/Y^{\ominus}$ are present in equimolar amounts, then $1/\tau$ is a linear function of the total (weighed in) concentration in contrast to the $1/\tau$ obtained from Equation (16).

2. pH $\approx$ 4 to 10. The concentrations of HX, $X^{\ominus}$, HY, and $Y^{\ominus}$ are still large compared to $c_{H^+}$ and $c_{HO^-}$; the reactions taking place via the intermediate states (1) and (2), which can be considered to be in a steady state must, however, no longer be neglected. Hence, $k_{33'}$ and $k_{3'3}$ in Equation (26) must be replaced by the following expressions:

$$k^{*}_{33'} = k_{33'} + \frac{k_{31}k_{13'}}{k_{13}\bar{c}_{X} + k_{13'}\bar{c}_{Y}} + \frac{k_{32}k_{23'}}{k_{23}\bar{c}_{HY} + k_{23'}\bar{c}_{HX}}$$
$$k^{*}_{3'3} = k_{3'3} + \frac{k_{3'1}k_{13}}{k_{13}\bar{c}_{X} + k_{13'}\bar{c}_{Y}} + \frac{k_{3'2}k_{23}}{k_{23}\bar{c}_{HY} + k_{23'}\bar{c}_{HX}} \qquad (27)$$

In general, of course, only one of the additional terms appears at a time; for pH $<$ 7, it is the first term (with (1) as intermediate stage), and for pH $>$ 7 the second (with (2) as intermediate stage).

3. The concentration of $H^+$ (pH $\ll$ 7) or $HO^-$ (pH $\gg$ 7) can no longer be neglected compared to the concentration of the two acid-base pairs. In this case, either only the upper (pH $\ll$ 7) or only the lower (pH $\gg$ 7) half of the reaction diagram (Fig. 7), is valid. In either case, two relaxation times are obtained; they can be expressed by relations similar to Equation (16). However, here the coefficients $a_{ik}$ are:

$$a_{11} = [k_{33'}(\bar{c}_{HX} + \bar{c}_{Y}) + k_{3'3}(\bar{c}_{X} + \bar{c}_{HY}) + k_{31} + k_{13}c_{H^+}] \qquad (28)$$

or

$$= -[k_{33'}(\bar{c}_{HX} + \bar{c}_{Y}) + k_{3'3}(\bar{c}_{X} + \bar{c}_{HY}) + k_{32} + k_{23}c_{HO^-}]$$

$$a_{22} = -[k_{13}c_{X} + k_{3'1} + k_{13'}(\bar{c}_{H^+} + \bar{c}_{Y})]$$

or

$$= -[k_{23}\bar{c}_{HY} + k_{3'2} + k_{23'}(\bar{c}_{HO^-} + \bar{c}_{HX})]$$

$$a_{12} = -[k_{33'}\bar{c}_{HX} + k_{3'3}\bar{c}_{X} + k_{13}c_{X}$$

or

$$= -[k_{33'}\bar{c}_{Y} + k_{3'3}\bar{c}_{HY} + k_{23}\bar{c}_{HY}]$$

$$a_{21} = -[k_{3'1} + k_{13'}\bar{c}_{H^+} + k_{31} + k_{13}\bar{c}_{H^+}]$$

or

$$= -[k_{3'2} + k_{23'}\bar{c}_{HO^-} + k_{32} + k_{23}\bar{c}_{HO^-}]$$

The shorter relaxation time is again determined primarily by the sum of all reaction terms, *i.e.*, by the fastest reaction in the overall system.

This section deals primarily with the rate constants for direct proton transfer, $k_{33'}$, and $k_{3'3}$. In determining these constants, conditions should be chosen so that $1/\tau$ is measured directly according to Equation (26) [for pK $\gg$ 7 or $\ll$ 7 according to Equation (27)]; the remaining constants can be determined separately for the isolated systems $HX/X^{\ominus}$ or $HY/Y^{\ominus}$. Such relaxation studies have been carried out on a great number of systems [60,80]. In the following we shall consider again only a selection of typical cases.

c) Rate Constants

As indicated in Section 3, there is a relationship between the rate constant for proton transfer and the pK difference of the donor (*e.g.* HX or HY) and acceptor ($X^{\ominus}$ or $Y^{\ominus}$).

Which behavior may then be expected from the above considerations?

We already know that most of the so-called "normal" bases or acids undergo a diffusion-controlled reaction with the excess or defect proton. The fastest proton transfer, at least at large pK differences, then occurs in the direction of the stronger acceptor ($k_{33'}$, when $pK_{HY}$

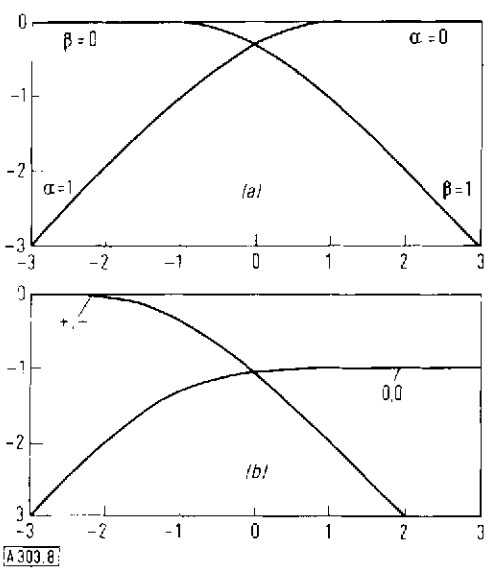


Fig. 8. Idealized log k *vs.* ΔpK dependence for proton transfer in "normal" acid-base systems: (a) for the symmetrical charge type, (b) for charge neutralization.
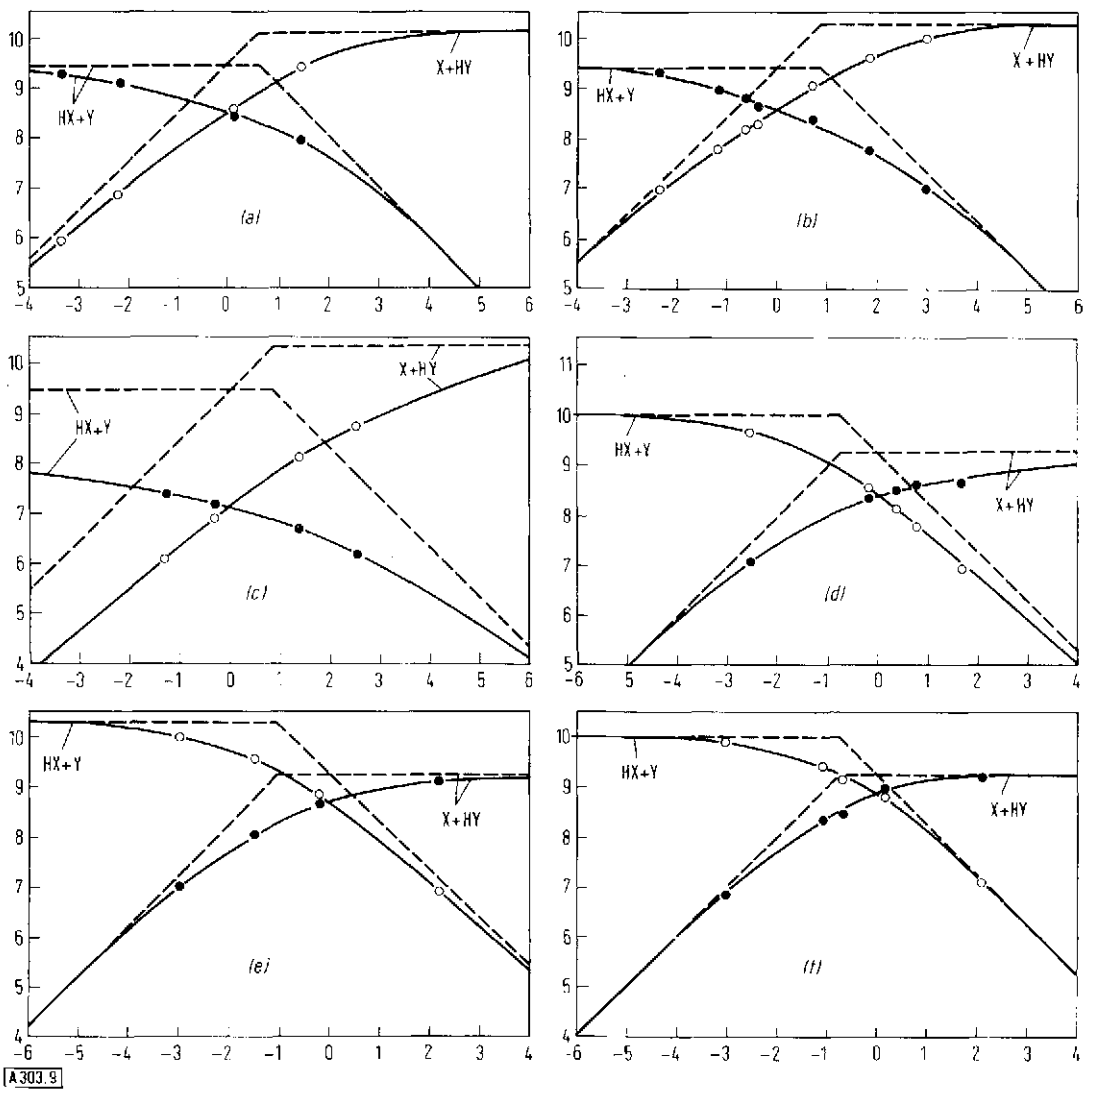
Ordinate: $\log k/k_{max}$.
Abscissa: $pK_{acceptor} - pK_{donor}$.

[80] *M. Eigen* and *G. Maass*, unpublished work.

$> pK_{HX}$), the rate will be independent of the difference in pK. Correspondingly, the logarithm of the rate constant for the reverse reaction ($k_{3'3}$) must be a linear function of the pK difference, since then

$$\log k_{33'} - \log k_{3'3} = pK_{HY} - pK_{HX} = \Delta pK$$
$$\text{or} \qquad \log k_{3'3} = \log k_{3'3} - \Delta pK \tag{29}$$



Moreover, from the considerations presented in Section 1 we know that proton transfer can be very fast even in a symmetrical hydrogen bond (*e.g.* during excess and defect proton conduction in ice, $\Delta pK = 0$), *i.e.* it can take place without any hindrance. In such an "ideal" case, one should expect behavior such as that depicted in Figure 8a. The rate of proton transfer should be independent of the pK difference (diffusion-controlled) as long as the pK value of the acceptor is greater than that of the donor. In the vicinity of $\Delta pK \approx 0$, there is a relatively sharp transition to a linear dependence of log k on $\Delta pK$, since now the reverse reaction becomes diffusion-controlled. For $pK_{HX} = pK_{HY}$, a 50 % probability exists for both directions: $k_{33'}$, ($= k_{3'3}$) is therefore half as large as the maximum value. If we denote the slope d(log k)/d($\Delta pK$) of the curve by $\alpha$ (and that for the reverse reaction by $\beta$), we have

$$\begin{aligned} &\alpha = 0\ (\beta = 1) \text{ for } pK_{HY} \gg pK_{HX} \\ &\alpha = 1\ (\beta = 0) \text{ for } pK_{HY} \ll pK_{HX} \end{aligned} \tag{30}$$

with a relatively sharp transition of $\alpha$ and $\beta$ between 0 and 1 in the vicinity of $pK_{HY} = pK_{HX}$.

Many of the transfer reactions to which these considerations apply present an asymmetry of charge, for example

$$HX + Y \rightleftharpoons X^- + YH^+. \tag{31}$$

A 303.9

Fig. 9. log k *vs.* $\Delta pK$-Dependence for proton transfer reactions. Experimental points [80] refer to the following donors or acceptors in the order from left (negative $\Delta pK$) to right (positive $\Delta pK$):

(a) Donor (HX): acetic acid; acceptors (Y): hydrazine, imidazole, aniline, *m*-chloroaniline.

(b) Donor (HX): phenol; acceptors (Y): phosphate ($PO_4^{3-}$), piperidine, propylamine, carbonate, ammonia, hydrazine, imidazole.

(c) Donor (HX): thioglycol; acceptors (Y): dimethylamine, trimethylamine, hydrazine, imidazole.

(d) Acceptor (X): aniline; donors (HY): *p*-nitrophenol, acetic acid, benzoic acid, formic acid, chloroacetic acid.

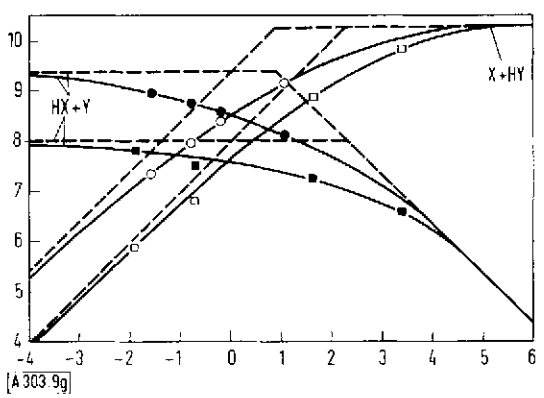
(e) Acceptor (X): imidazole; donors (HY): phenol, $HP_2O_7^{3-}$, *p*-nitrophenol, acetic acid.

(f) Acceptor (X): ammonia; donors (HY): glucose, $HCO_3^-$, phenol, boric acid, *p*-nitrophenol.

The broken lines denote the extrapolated curves with $\alpha$ or $\beta = 0$ or 1 according to Fig. 8.

Ordinates: log k. Abscissae: $pK_{HX} - pK_{HY}$.

In this case, the limiting values for the diffusion-controlled reactions are different for the two directions [$k_3'_3 > k_{33}'$, see Equation (10)], hence, the symmetric behavior with respect to $\Delta pK = 0$ represented in Figure 8a is valid only for reactions of the charge type



$$\begin{aligned} &XH^+ + Y \rightleftharpoons X + YH^+ \\ \text{and}\quad &HX + Y^- \rightleftharpoons X^- + HY \end{aligned} \qquad (32)$$

For the asymmetric charge type described above, one would also expect that the $\alpha$ and $\beta$ curves will become asymmetric with respect to $\Delta pK = 0$ (Fig. 8b). Similarly, any other factor which hinders the reaction and which does not affect $k_{33}'$, and $k_3'_3$ in the same manner (*e.g.*, internal hydrogen bridging) will result in a modification of symmetry.

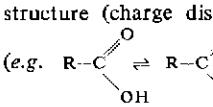
Figures 9a-f show a few (experimental) curves of this type (additional examples are given in [80,81], some values have also been reported by *Weller* [82] and by *Meiboom*, *Grunwald* et al. [44]). It can readily be seen that the acids and bases referred to as "normal" in the preceding section closely approach the ideal behavior illustrated in Figure 8a. However, greater individual deviations are observed in this case than in simple protolytic and hydrolytic reactions. Thus, all the factors discussed in detail in the preceeding section clearly come into play in this case.

As an example Figure 9g shows the different behavior of two geometric isomers, *viz.* fumaric acid and maleic acid. In the case of maleic acid, proton transfer from the mono-protonated form is strongly retarded because this proton is not free to form a hydrogen bridge with the acceptor. The retardation is equivalent to the existence of a pre-equilibrium for forming a hydrogen bond with the acceptor. On the other hand, as an acceptor, maleate ion resembles the fumarate ion and the other carboxylates.

In addition to these effects, which already manifest themselves in simple protolytic and hydrolytic reactions and which primarily affect the limiting values of k (for $\alpha = 0$ and 1), there are deviations from ideal behavior that are restricted to the range in which $pK_{HX} \approx pK_{HY}$ and thus affect only the shape of the $\alpha$- and $\beta$-curves.

[A 303.9g]

Fig. 9g. See legend for Fig. 9a—f.



○—○ and ●—●: Donor (HX): fumaric acid; acceptors (Y): α-picoline, pyridine, aniline, *m*-chloroaniline.

□—□ and ■—■: Donor (HX): maleic acid; acceptors (Y): hydrazine, imidazole, aniline, *m*-chloroaniline.

The log k-$\Delta pK$ relation approximates the ideal behavior depicted in Figure 8 most closely when

a) both the donor and acceptor group belong to the classical hydrogen bond formers (O- or N-type), and b) the electronic and spatial configurations of the acids and their conjugate bases are identical.

With regard to a), Figure 9c (thioglycol) shows that proton transfer in the configuration SH·····N is no longer unhindered when $pK_{HX} \approx pK_{HY}$. Proton transfer between phosphonium ion and phosphines is even slower ($k \approx 10^2$ $M^{-1}$ $sec^{-1}$ [64]). However, the inhibition is greatly reduced at sufficiently large pK differences. Furthermore, as shown in the case of 5,5-diethylbarbituric acid, proton transfer does not occur as readily in hydrogen bridges of the NH···N type as in OH···O-, OH···N-, $O^-$···HN-, or $NH^+$···O-bridge bonds.

With regard to b): Most organic acids differ in electronic structure (charge distribution) from their conjugate bases (*e.g.*  , phenol, aniline, *etc*). At $\Delta pK = 0$, proton transfer can be retarded by the fact that at the instant of transition, the donor and (or) acceptor are not in their final configuration. Hence systems containing conjugated double bonds, such as acetate, phenoxide, aniline, and others, show a less sharp transition from $\alpha = 0$ to $\alpha = 1$ than systems containing only simple bonds [*e.g.*, $NH_3$ in Figure 9f]. A very sharp transition exists also for $H_3O^+$ and $H_2O$ because of their very high transport rates, as reflected in the excess and defect proton conductance in ice. Deviations from the limiting curves shown in Figures 8a and b are restricted to a relatively narrow $\Delta pK$ range for resonance-stabilized OH- and NH-compounds. According to the Franck-Condon principle, as long as protonation is not associated with a marked alteration of the steric structure (bond lengths, bond angle), changes in electron distribution should not significantly affect the reaction rates (cf. the coupling of "protomerism" and "mesomerism" in imidazole [37] described above and acetylacetone [54]). When pK differences between donor and acceptor are large, then proton transfer is associated with an energy gain even for unfavorable limiting structures.

The category of acids and bases, designated as "normal" in Section 3 could thus be subdivided [*]. Systems with conjugated double bonds and resonating structures that are not identical in the protonated and deprotonated state differ in their proton transfer characteristics at $\Delta pK \approx 0$ from simple systems such as $H_2O$, $NH_3$, aliphatic hydroxy compounds, oximes, *etc.*

Phenomena of this kind also determine the kinetic behavior of the ketonic substances listed in Table 4l. Figure 10 shows the log k *vs.* $\Delta pK$ relationship for proton transfer between acetylacetone (keto form) and a few bases, and between its negative ion and conjugate acids [60]. As can be seen, the process is qualitatively the same as that for the other "normal" acids and bases, except that here the transition from $\alpha = 0$ to $\alpha = 1$ occurs over a substantially wider pK range. Also, the individual differences of various acids and bases are more pronounced (see Section 5). However, compounds of a given class have curves of identical shape. For example,

[81] *G. Maass*, Dissertation, Universität Göttingen, 1962.

[82] *A. Weller*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *64*, 55 (1960).

[*] This subdivision corresponds to the differentiation between "hard" and "soft" acids which *R. G. Pearson* (personal communication) proposed in a somewhat different connection.

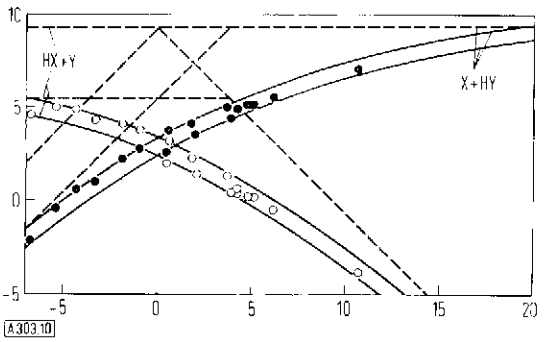


Fig. 10. log k *vs.* ΔpK Dependence for proton transfer between acetylacetone (HX) or its enolate (X) and a series of bases (Y) or acids (HY) [60]. Acetylacetone reacts in its keto form. The acceptors (Y) are (from left to right): $HO^-$, glycerol (anion), mannose (anion), glucose (anion), trimethylphenoxide, phenoxide, pyrophosphate, chlorophenoxide, *p*-nitrophenoxide, $HS^-$, dimedone (enolate), pyridine, acetate, benzoate, hydroxyacetate, chloroacetate, $H_2O$.

all aliphatic and aromatic OH compounds and carboxylic acids fit one curve. Deviations observed for individual compounds can be explained quantitatively, as was shown elsewhere [60].

*Examples:*

Acetylacetone-dimedone: The pK difference can be attributed to the existence of an intramolecular hydrogen bond in acetylacetone. This fraction is kinetically inactive.

Barbituric acid and Meldrum's acid: The activity of CH-acids is very low; only the stronger acidic enol forms are active.

Primary, secondary, and tertiary amines: Like the pK anomalies, these anomalies are associated with the effect of the solvent structure discussed above.

Similar log k *vs.* ΔpK interdependences exist for other CH-acids. Substances of similar molecular structure show almost identical behavior in this respect. This is particularly true for compounds whose protolytic reactions can be represented by a monotonic log k *vs.* $pK_{substrate}$ relation (see Fig. 6). *Bell* [74] has already called attention to a similar relationship between the rate of protolytic reactions and the Brönsted coefficient for acid-base catalysis (see below).

Most of the ketonic compounds cited above are more stable than their enolic tautomers. This shows that the ketone is a weaker acid than the enol: $pK_{ketone} > pK_{enol}$. In spite of this, reaction of the mesomeric anion with proton donors generally yields the enol first; the latter then rearranges to the more stable ketone. This effect can be observed in many systems and led to the formulation of the following rule [83,84]:

When a proton is supplied by acids to the mesomeric anion of weakly ionizing tautomers of markedly unequal stability, then the tautomer which is most quickly formed is the thermodynamically least stable: it is also the tautomer from which the proton is lost most quickly to bases.

However, it follows from the above considerations that this rule cannot have general validity. The reason for the lower rate of reaction of the keto form is not its higher thermodynamic stability, since this would only favor protonation of the anion (and possibly retard deprotonation), but simply the cited structural difference between the CH- and OH-forms. In general, the OH-form is formed faster, especially if it is more stable than the CH-form (cf. dimedone, Table 4d).

### d) Relationships

The nature of the log k *vs.* ΔpK relationship can be characterized empirically by a few parameters. These are:

a) The limiting values of the rate constants (in both directions) at $\alpha$ and $\beta = 0$;

b) The slope of the curves, *i.e.*, the absolute values of $\alpha$ and $\beta$ at $\Delta pK = 0$;

c) The absolute values of the rate-constants at $\Delta pK = 0$ ($k_{33'} = k_{3'3}$).

The factors a) and b) determine the symmetry of the curves with respect to $\Delta pK = 0$. Factor c) characterizes the breadth of the ΔpK range within which the coefficients $\alpha$ and $\beta$ change from 0 to 1 (and from 1 to 0).

If the limiting values of k (at $\alpha$ or $\beta = 0$) are identical, *i.e.*, when the extrapolated straight lines $\alpha = 1$ and $\beta = 1$ intersect at $\Delta pK = 0$, then the slope of the log k curves at $\Delta pK = 0$ is often close to 0.5. However, it is not necessarily equal to 0.5; on the contrary, certain deviations from symmetry with respect to $\Delta pK = 0$ are highly probable for acceptors and donors of different acid or base types (see below). If, however, the limiting values of k differ, then the center of symmetry, defined by the point of intersection of the straight lines $\alpha = 0$ and $\alpha = 1$ (or $\beta = 1$ and $\beta = 0$), is displaced along the ΔpK axis by the difference of the logarithms of these limiting values of k, although the log k curves still intersect at $\Delta pK = 0$, of course (see Fig. 10). If the absolute value of k is much smaller in this ΔpK range than its limiting value, then the transition of the coefficient $\alpha$ from 1 to 0 also extends over a relatively wide ΔpK range. This means that over a narrow interval, the value of $\alpha$ may be approximated by a constant (Brönsted relationship, see below). The closer k is to the limiting value, the narrower is the range over which the approximations can be applied.

From a molecular-kinetic standpoint, the behavior observed can be interpreted as follows.

According to the reaction diagram [Equation (5) of Section 2], one must differentiate between the encounter and separation of the reactants ($k_{ab}$, $k_{a'b'}$, $k_{ba}$, $k_{b'a'}$) on the one hand and proton transfer in the reaction complex ($k_{bb}$, $k_{b'b}$) on the other. The reaction complex is completely defined when a hydrogen bond is formed between the donor proton and the lone electron pair of the acceptor, possibly also with inclusion of an $H_2O$ molecule; otherwise one must assume the existence of a simple encounter complex with a lifetime of 1/k, according to Equation (11). Furthermore, it is thus possible that additional reaction steps occur in the reaction scheme, *e.g.* breaking or formation of an internal hydrogen bond, following the a -> b process or preced-

ing the b′ → a′ step. Evidently, only the rate constants for proton transfer depend on ΔpK, so that, from Equation (6), one obtains:

$$\alpha \equiv \frac{d \log k}{d\,\Delta pK} = \frac{k_{ba}\,k_{b'a'}}{N} \cdot \alpha' + \frac{k_{ba}\,k_{b'b}}{N} \qquad (33)$$

where N is defined as in Equation (7), and

$$\alpha' \equiv \frac{d \log k_{bb'}}{d\,\Delta pK}\;;\left[\frac{d \log k_{b'b}}{d\,\Delta pK} = -(1-\alpha') \cdots -\beta'\right] \qquad (34)$$

If an acid or base molecule exhibits multiple donor or acceptor properties, then the usual statistical corrections [85] must be applied. This relationship fulfills all the requirements arising from the experimental evidence discussed above. Thus:

for $k_{ba} \ll k_{bb'}; k_{bb'} \gg k_{b'b}$ (diffusion-controlled in the forward direction)
$\alpha \to 0$,

for $k_{b'a'} \ll k_{b'b}; k_{b'b} \gg k_{bb'}$ (diffusion-controlled in the reverse direction)
$\alpha \to 1$

and for $k_{ba} \gg k_{bb'}; k_{b'a'} \gg k_{b'b}$ (proton transfer is rate-determining in both directions)
$\alpha \to \alpha'$ $(0 < \alpha' < 1$: transition range).

The ΔpK dependence of α and α′ in the transition range is of particular interest. This is determined by superposition of the potentials of the interaction of the donor and acceptor with the proton in the reaction complex. This superposition is expressed directly neither by the difference of the free reaction energies (≈ΔpK) with their various ΔH and TΔS contributions nor by the enthalpy difference ΔH alone. Thus it is not to be expected theoretically that a given ΔpK dependence will apply to all types of compounds equally well. Nevertheless, the relative pK change should parallel the change in potential for compounds of the same type. A close relation to the electrophilic behavior of the proton donor and the nucleophilic behavior of the proton acceptor should exist (cf. below [91]). Individual deviations from a given log k ΔpK interdependence as shown in Figure 10 thus become understandable.

In the transition region, the coefficient α′ depends on the following properties of the interaction potentials:

1. If the potential curves for donor and acceptor are of the same type, then the variation of α′ will be symmetrical with respect to the state of equal depth of the potential-well characterized (in the simplest case) by $k_{bb'} = k_{b'b}$. This kind of symmetry is not to be expected when the donor and acceptor belong to different categories of acids and bases. On the other hand, the "normal" acids of the OH- and NH-type, which are known to form hydrogen bridges readily, exhibit this symmetry (Fig. 9a-g), although the superposition of potentials is generally so complete here that the α′ transition range becomes very narrow.

2. α′ can be expressed by a constant, if both overlapping branches of the potential function (Figure 11) can be approximated by straight lines. The magnitude of α is determined only by the slope of the straight lines, and not by the distance between the potential minima nor by any deviation from linearity outside the area of intersection.

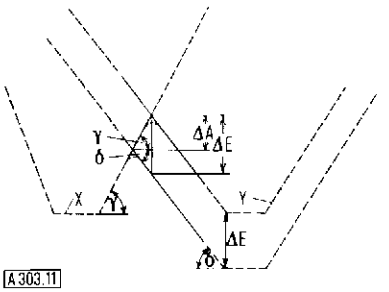

Fig. 11. Geometric illustration of the coefficient α′. The branches of the two potential curves X and Y intersect in a linear range. Displacement of one curve by ΔE causes a shift in the height of the point of intersection by $\Delta A = \frac{1}{1+(\mathrm{tg}\,\delta/\mathrm{tg}\,\gamma)} \cdot \Delta E = \alpha'' \cdot \Delta E$ $(0 < \alpha'' < 1)$. The magnitude of the coefficient α″ (or α′, see below) depends only on the ratio of the slopes of the two branches. On the other hand, the displacement is independent of the distance between the potential minima and of the curvature of the potential functions outside the linear range of intersection. The relationship between ΔA and ΔE therefore also applies to potential curves of realistic (*e.g.* parabolic) shape, provided that in the intersection range they can be approximated by straight lines. For similar compounds, the potential shift ΔE can be assumed to be proportional to ΔpK; the shift in the point of intersection ΔA corresponds to a change in activation energies ($\sim \Delta \log k_{bb'}$). This two-dimensional representation corresponds to a section of the energy surface with three distance coordinates XH, HY, and XY. An explanation of the simple geometric significance of the reaction coordinate as a line connecting the centers X and Y (movement of the "light" proton between the fixed "heavy" donor and acceptor atoms) was given by *Bell* [74].

3. In general, however, the branches of the potential function still possess finite curvature thereby causing continuous variation of α with ΔpK. This variation is particularly pronounced when overlapping is considerable (in the neighborhood of the "bottom of the valley"). This occurs, for example, for all "normal" types of acids and bases (narrow transition range) and generally also in the vicinity of the limiting values $\alpha = 0$ and $\alpha = 1$. On the other hand, linearity is closely approximated [constant $\alpha = 0$ or 1] in the middle of a very wide transition range (small values of k). It should be noted, in particular, that such "linear free-energy relationships" are only approximate relationships derived by expansion of the real function in a Taylor or MacLaurin series:

$$\log k - f(\Delta pK) \approx f(\Delta pK = 0) + \alpha\,\Delta pK + \ldots \qquad (35)$$

### e) Some Remarks on the Characterization of "Pseudo Acids"

The results discussed above also permit an approach to the question of the definition of a "pseudo acid". *Hantzsch* [86] based the differentiation between the "aci" and "pseudo" forms on the difference in their rates of reaction. The disadvantages of such a classification are obvious, even where differentiation between "fast" and "slow" establishment of equilibrium no longer depends on experimental potentialities. The absolute value of the rate constant alone cannot form the basis for a definition

[85] *R. P. Bell:* Acid Base Catalysis. University Press, Oxford 1941.

[86] *A. Hantzsch*, Ber. dtsch. chem. Ges. *32*, 575, 3066 (1899).

(otherwise, according to Table 4l, acetone and acetylacetone, for example, would belong to different categories). The concept of "pseudo"- and "aci"-forms should either be abandoned altogether or used only to characterize limiting structures. One may speak of an "aci"-form when the condition $\alpha$ or $\beta = 0$ in the log k *vs.* $\Delta$pK relation is associated with a diffusion-controlled proton exchange. If, on the other hand, one of the coefficients equals zero, whereas the limiting value is not attained, then a real equilibrium precedes proton exchange. The acid or base is then in a "pseudo"-form. From this it follows that the order of magnitude of the rate constants in the transition range ($\Delta pK \approx 0$) is not sufficient for identification of the limiting forms. In this respect, resonance-stabilized compounds, for example, do not show a well-defined behavior. Most CH-acids are intermediate forms. Thus, at large pK differences, the rate constants for recombination of the carbanion with $H^+$ reach values of the order of $10^{10}$ liter/mole·sec (acetone), whereas the constants for recombination of the CH-acid with $HO^-$ tend to level off already at substantially lower values (Fig. 10 and Fig. 5). The lack of polarity and the small ability to form hydrogen bonds of the CH group account for this effect. If the above classification is used, then even a hydrogen-bridged chelate has the properties of a pseudo-form. Here, rearrangement to an isomer (where the hydrogen bridge is opened) is required before the proton can be released. It is essential for this classification that the preceding reaction step (*e.g.* H-bond opening) be independent of the strength of the acceoptor.

## 5. Remarks Concerning Acid-Base Catalysis

The preceding considerations dealt primarily with the elementary processes of proton transfer in simple acid-base reactions such as protolysis, hydrolysis, pH-indication, and buffering. In the second part of this article [*], the manner in which these elementary processes determine the mechanisms of more complicated reactions catalyzed by (Brönsted) acids or bases will be discussed.

In the simplest case, proton transfer from the catalyst to the substrate is the rate-determining step of the reaction (examples: halogenation of ketones [87], keto-enol rearrangements [88], certain condensation reactions [89]); a more detailed list of prototypes of acid-base catalysis will be given in Part II [*]. Thus, the rules established in Section 4 should also apply to catalysis. Numerous studies of such reactions have been made using classical methods of measurement (for literature see [74,85]). The correlation between the rate constant for the catalysed reaction and the dissociation constant of the catalytically active acid or base was generally established (more or less accurately) using an expression first formulated by *Brönsted* [90]. In its simplest form (statistical corrections are neglected), this equation can be written as:

$$k = G_S \cdot K_S^{\alpha} \quad \text{or} \quad k = G_B \cdot K_B^{\beta} \tag{36}$$

(cf. also Hammett's $\sigma\rho$ relationship [91]).

Here, the coefficients $\alpha$ and $\beta$ are independent of the acid dissociation constant $K_S$ of the catalyst. However, on the basis of considerations presented in Section 4, it can be shown that this (integrated) form of the equation is only an approximation. *Brönsted* and *Pedersen* realized this and expressed it clearly in their fundamental paper on acid-base catalysis [90] (cf. Fig. 3 in [90]). However, the general constancy of $\alpha$ and $\beta$ observed later (disregarding scatter due to individual deviations) explains why relationships of this type have found their way into the literature as "laws of catalysis". The reason for the fact that deviations from constancy of the coefficients $\alpha$ and $\beta$ have been observed in only few cases lies in the relatively limited time range used in classical kinetic experiments. The only reactions studied were those with rate constants sufficiently smaller than the limiting values ($10^9$ to $10^{10}$ liter/mole/sec). The applicability of linear approximations ($\alpha$ or $\beta$ = constant) in this case extends over a relatively wide pK range.

Thus, for example, in the base-catalyzed halogenation of acetylacetone, *Bell* [74,87] found a linear log k – pK relationship with $\alpha = 0.48$ that holds over the limited range accessible by classical methods. Here the rate-determining step is deprotonation of the substrate. His absolute values of the rate constants are in quantitative agreement with the rate constants of proton transfer obtained directly from relaxation measurements (Fig. 10). These measurements show that in a wider pK range $\alpha$ is not a constant. Furthermore, the same catalysts gave other values of $\alpha$ for other ketones, in accordance with the shift in the $\Delta$pK scale. For example, for acetone, pK = 20.0, $\alpha = 0.88$; for bromoacetylacetone, pK = 8.3, $\alpha = 0.42$ [92]. All the curves can be constructed on the basis of the generalized relationship [Equation (33)].

Even the classical example of acid-base catalysis studied by *Brönsted* and *Pedersen* [90], *viz.* the decomposition of nitramide:

$$H_2N{-}NO_2 \rightarrow N_2O + H_2O$$

shows a continuous variation of the coefficient $\alpha$ (Figure 12). On extrapolation of the curve to $\alpha = 0$, it has a limiting value for log k that is about 3 units less than the limiting value for the diffusion-controlled reactions. However, this difference is consistent with the constant (log K) determined by *Brönsted* and *Peder-*

*sen* for the tautomerization equilibrium of nitramide which precedes decomposition. If the rate constant is based on the concentration of the reactive form, then extrapolation to $\alpha - 0$ affords exactly the limiting value for diffusion-controlled reactions.

In other systems, such as mutarotation of glucose [93], dehydration of acetaldehyde hydrate [94], constancy of the values of α is observed over a relatively wide pK range. As expected in these cases, k is relatively small over the entire range. Here, the rate-determining step is not a simple proton transfer but the coupling of several intermediate steps. Such events are particularly important with regard to enzymic processes. They will be the main subject of the discussion presented in Part II.

# The Course of the Willgerodt-Kindler Reaction of Alkyl Aryl Ketones [*]

BY PROF. DR. F. ASINGER, DR. WOLFGANG SCHÄFER, DR. K. HALCOUR, DIPL.-CHEM. A. SAUS, AND DIPL.-CHEM. H. TRIEM

INSTITUT FÜR TECHNISCHE CHEMIE DER TECHNISCHEN HOCHSCHULE AACHEN (GERMANY)

*Respectfully dedicated to Prof. Dr. Karl Ziegler on the occasion of his 65th birthday*

*Ketones react with sulfur and $NH_3$ or amines at room temperature to produce $\Delta^3$-thiazolines, 5-alkylidene-$\Delta^3$-thiazolines, $\Delta^3$-imidazoline-5-thiones, hexathiacycloheptane derivatives, α,α'-dioxodisulfides, bis-(1-aralk-1-yl) disulfides, or thiocarboxamides, depending on the coreactant and on the reaction conditions. It was recognized that the formation of all of these numerous types of compounds can be explained basically by primary thiolations and geminal dithiolations, which in conjunction with their reverse reaction (desulfurization) and the assumption of a thioreductone equilibrium permit a new interpretation of the course of the Willgerodt-Kindler reaction of alkyl aryl ketones.*

## Introduction

The Willgerodt reaction [3–9] proper is the reaction of alkyl aryl ketones with aqueous ammonium polysulfide at 200 °C in a sealed tube. It affords ω-carboxamides and ω-carboxylic acids of the same chain-length without skeletal rearrangement, *i.e.* it involves the reduction of the oxo group to a methylene group, in combination

[*] A review article (a continuation of [1]) is being prepared in which the new compounds discussed in the present paper are treated in greater detail. A paper recently published [2] prompted us to make our concept of the course of the Willgerodt-Kindler reaction known.

with an oxidative modification of the end of the alkyl chain (redox amidation) [10]:

Sulfur acts as the oxidizing agent; the reducing action of $H_2S$ in the reaction was first recognized by *Willgerodt*.

The most important preparative modification of the Willgerodt reaction was introduced by *Kindler* in 1923 [11]. Since then, the Willgerodt-Kindler reaction denotes the reaction of alkyl aryl ketones with sulfur and primary or secondary amines at elevated temperatures. *Fieser* and *Kilmer* [12] were able to reduce the temperature of the Willgerodt reaction to 160 °C by adding dioxan. When morpholine is employed, the Willgerodt-Kindler reaction can be carried out at 130 °C in an open vessel [13].

To date, this reaction has attracted considerable scientific interest; 250 publications have appeared on this subject; nearly 700 compounds have been reacted under Willgerodt and Willgerodt-Kindler conditions. However, the reaction mechanism has not yet been definitely clarified. A comprehensive review of prior work is not indicated here, since several good reviews exist [14–19].

Previous publications concerning the course of the reaction have dealt with the primary attack (at the carbonyl group [20–24] or at the α-position relative to the carbonyl group [16, 25–30]), with the problem of the migration of functional groups along the carbon chain [20–28, 30], and with the irreversible oxidation at the end of the chain [31]. Most frequently, attempts were made to convert hypothetical intermediates into ω-aralkylcarboxylic acids or their derivatives or to throw light on the intermediates of the reaction by using special ketones [3, 22, 25, 27, 32–38].

In 1956, we reported for the first time [39] that the combined action of sulfur and $NH_3$ upon ketones such as cyclohexanone or diethyl ketone, leads to $\Delta^3$-thiazolines [1]. The reaction occurs even at room temperature and often gives excellent yields. Since then, thorough studies have been made of the scope, mechanism, and dependence on the conditions, *etc.* of this reaction and have led to the discovery of several new heterocycles.

With regard to the starting materials (ketone, S, $NH_3$ or amine, possibly $H_2S$), this reaction does not differ from the Willgerodt-Kindler reaction, but the temperature at which it occurs is different. It was to be expected that the reactions would show similarities under these circumstances; hence, a substantial part of our investigations was directed toward uncovering such analogies. The temperatures used were intentionally different from those of the Willgerodt-Kindler reaction. We felt that conducting the reaction at room temperature offered the possibility of obtaining reactive intermediates whose isolation at higher temperature would be impossible. Moreover, we avoided the difficulty of exactly reproducing the Willgerodt-Kindler reaction medium, an aspect that has so far been neglected in reactions where suspected intermediates are used as reactants.

In the primary step of the $\Delta^3$-thiazoline synthesis, α-mercaptoketones (α-mercaptoketimines) are formed [40] [*] in very small concentrations as a result of ketone thiolation. However, these are irreversibly eliminated from the mixture by further reaction with unreacted ketone and $NH_3$ to give $\Delta^3$-thiazolines almost immediately. This technique of capturing reactive intermediates in the form of stable secondary products by systematically varying the reaction conditions and the reactants proved to be very fruitful. The present paper is an attempt to interpret the mechanism of the Willgerodt-Kindler reaction on the basis of results so obtained.

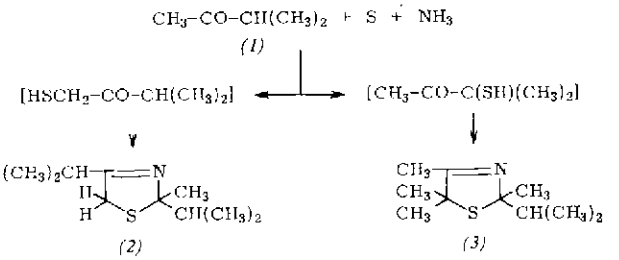
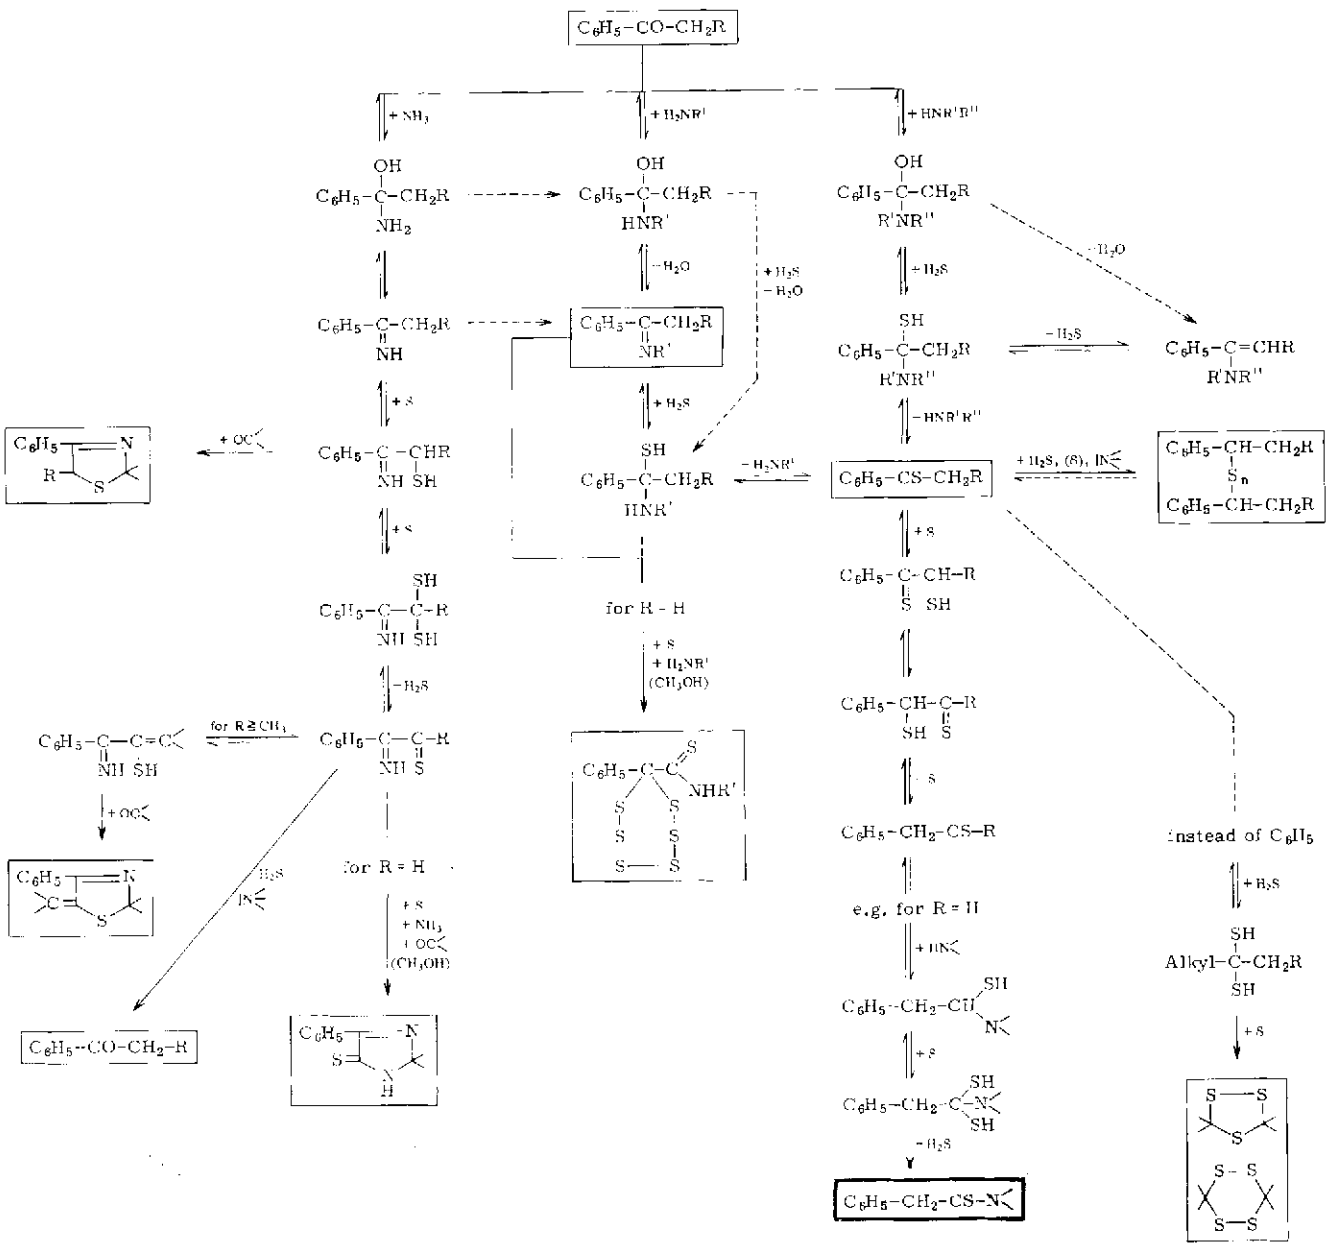
[*] For clarity, the intermediates in Scheme 1 are shown exclusively as ketimines.



For chemical reasons, the subject matter is arranged into three main sections dealing with the products of the reaction of ketones and S with $NH_3$, or primary, or secondary amines, respectively. These correspond to the reaction sequences A, B, and C shown in Scheme 1, where the isolated intermediates and end-products are boxed in.

## 1. The Reaction of Ketones with S and $NH_3$ (Reaction Sequence A)



### a) α-Thiolation of Ketones; $\Delta^3$-Thiazolines

The intermediate α-thiolation of the ketone during $\Delta^3$-thiazoline formation is an amine-catalysed ionic reaction. It can take place only if at least one of the carbon atoms next to the carbonyl group bears at least one hydrogen atom capable of undergoing substitution (thiolation).

Unsymmetric ketones are particularly interesting. They produce as intermediates usually two positionally isomeric α-mercaptoketones or α-mercaptoketimines and hence two $\Delta^3$-thiazolines that are structurally isomeric

with respect to the 4- and 5-positions. For example, isopropyl methyl ketone *(1)* affords the $\Delta^3$-thiazolines *(2)* and *(3)*.

Scheme 1. Review of the reactions carried out to elucidate the mechanism of the Willgerodt-Kindler reaction.

The proportions in which the two $\Delta^3$-thiazolines are formed give some indication of the relative extent of the competing thiolations and permit comparisons of the reactivities of all possible pairs of $CH_3$, $CH_2$, and CH groups. The reactivity generally decreases in the order $CH_2 \gg CH > CH_3$ [41,42]. The isomer ratio remains practically unaltered during the reaction and is unaffected by the overall conversion. In general, the direction of the thiolation can best be influenced by temperature changes. Table 1 shows that thiolation of the $CH_3$ group is always relatively greater at higher temperatures, particularly when a $CH_3$ group is in competition with a CH group.

Solvents and organic bases also affect the isomer ratio, but their effect is generally small. Alcohols tend primarily to increase conversion.

Table 1. Effect of the reaction temperature on the α-thiolation of unsymmetrical ketones with S and $NH_3$.

| Ketone | Thiolated groups | Thiolation [%] at 20 °C | Thiolation [%] at 80 °C |
|---|---|---|---|
| Butanone | $CH_3$ | 3 | 10 |
| | $CH_2$ | 97 | 90 |
| 2-Pentanone | $CH_3$ | 5 | 23 |
| | $CH_2$ | 95 | 77 |
| Methyl isobutyl ketone | $CH_3$ | 20 | 31 |
| | $CH_2$ | 80 | 69 |
| Methyl isopropyl ketone | $CH_3$ | 6 | 72 |
| | CH | 94 | 28 |
| Methyl s-butyl ketone | $CH_3$ | 19 | 87 |
| | CH | 81 | 13 |
| Ethyl isopropyl ketone | $CH_2$ | 94 | 96 |
| | CH | 6 | 4 |

As the first step of the thiolation one might discuss the removal of a proton from the position *alpha* to the carbonyl group. This presupposes that the α-hydrogens are sufficiently acidic to be removed in a nucleophilic reaction with $NH_3$ or an amine. The activity of the α-hydrogens is appreciably increased if the imine is first formed from the ketone.

According to *Haury* [43,44], Schiff bases of acetophenone can be acetylated at the methyl group with ketene. *Moszew* et al. [45] were able to react acetophenone anilide twice with phenyl isocyanate at the methyl group. Neither reaction occurs with acetophenone itself. The *N*-n-butylimine of acetophenone (*N*-butyl-α-phenethylideneimine) is readily thiolated with sulfur in methanol [46, 47]; this will be discussed later. Other, as yet incomplete, experiments [48] show that *N*-substituted ketimines and aldimines undergo thiolation with sulfur, sometimes under very mild conditions. Experiments of this kind have been carried out before, but at markedly higher temperatures [11,16,49–51].

The reverse of thiolation is the desulfurization of α-mercaptoketones to ketones. The latter reaction can generally by accomplished with amines [1] and in certain cases also with $NH_3$ [52]. Secondary amines are less suitable, and tertiary amines are practically unsuitable for this purpose.

The sulfur in polysulfides acts as a thiolating agent; the presence of small amounts of $H_2S$ has a favorable effect on thiolation. Amine/sulfur mixtures (with the exception of pyridine/sulfur) can also give rise to $H_2S$ [53]. This explains the induction period observed in the reaction of S and $NH_3$ with ketones to give $\Delta^3$-thiazolines. This induction period is eliminated when traces of $H_2S$ are added to the system in advance. This is in agreement with the fact that the addition of amines onto ketones or aldehydes is acid-catalysed [54]; $H_2S$ could possibly assume this catalytic role. Naturally, polysulfide formation could also be formulated with carbanions of the system to be thiolated or with free electrons of another catalyst system.

Following the successful extension of the $\Delta^3$-thiazoline synthesis [41,52,55–63] to numerous (including functionally substituted) aliphatic, cycloaliphatic, and heterocyclic ketones, we studied acetophenone, propiophenone, and n-butyrophenone. In these cases, too, the expected $\Delta^3$-thiazolines were formed, but the yields were lower and the products less uniform. Since alkyl aryl ketones are very suitable starting materials for the Willgerodt-Kindler synthesis, we concentrated our attention particularly on the by-products. Thus, we discovered two hitherto unknown types of compounds, *viz.* $\Delta^3$-imidazoline-5-thiones and 5-alkenyl-$\Delta^3$-thiazolines.

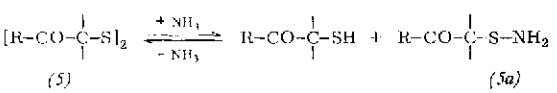
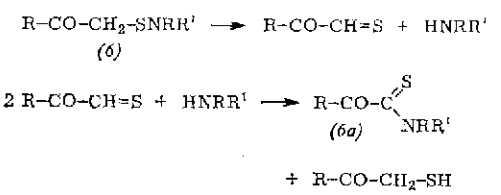
b) $\Delta^3$-Imidazoline-5-thiones

Acetophenone or its ring-substituted derivatives afford yellow, crystalline $\Delta^3$-imidazoline-5-thiones, usually in very good yields, when one mole of the ketone is mixed with 8 gram-atoms of sulfur (theoretically, only 1.5



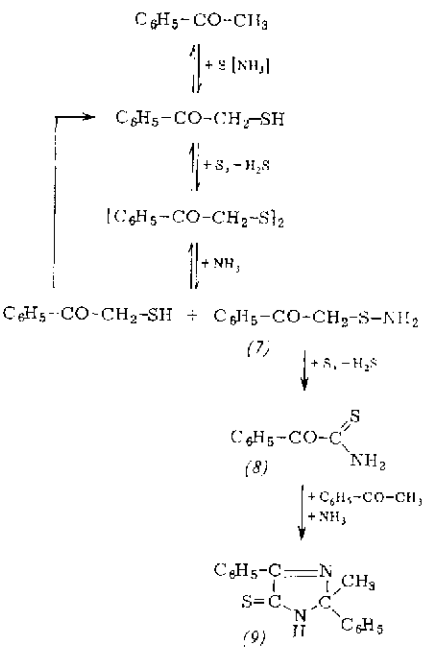
*(4)*

gram-atoms are required) in 250 ml of methanol, and the mixture is treated with $NH_3$ for 24 hours at 20 °C and normal pressure [64, 65]. The structure of these compounds has been unequivocally established [66, 67] and will not be discussed here.



*Course of Reaction*

α-Mercaptoketones react with sulfur in the presence of catalytic amounts of amine or $NH_3$ to produce α,α'-dioxodisulfides. This reaction is more vigorous than the analogous reaction with simple thiols discovered by *McMillan* and *King* [31]. Hence, one would expect the reaction of S and $NH_3$ with ketones to yield α,α'-dioxodisulfides rather than $\Delta^3$-thiazolines. This is not the case, however, because the disulfide formation is an equilibrium reaction [68]. It is therefore possible that α,α'-dioxodisulfides are intermediates in the formation of both $\Delta^3$-thiazolines and $\Delta^3$-imidazoline-5-thiones and that ammonolytic (hydrolytic) cleavage of the dioxodisulfides *(5)* and the reverse reaction also take place [69, 70]. β-Oxosulfenamides *(5a)* are prepared



*(5)* *(5a)*

by treating the β-oxosulfenyl chlorides obtained by chlorolytic cleavage of α,α'-dioxodisulfides with $NH_3$ or primary or secondary amines at −70 °C. The compounds are stable at higher temperatures only in exceptional cases [69]. Phenacylsulfenylmorpholide *(6)*, the primary product of the reaction between phenacylsulfenyl chloride and morpholine, undergoes rearrangement to phenylthioglyoxylmorpholide *(6a)* on heating to room temperature [71]. This novel rearrangement occurs with dehydrogenation and can be formulated as follows [2, 46]:

*(6)* *(6a)*

Addition of sulfur to the mixture before it is heated to room temperature results in appreciably increased yields of the thiomorpholide *(6a)* [72]. Other β-oxosulfenamides also undergo this rearrangement in 20 to 60 % yields [64], but well-defined products are obtained only from *N*-disubstituted sulfenamides [64]. Nevertheless, we wanted to see whether 2-methyl-2,4-diphenyl-$\Delta^3$-imidazoline-5-thione *(9)* could be produced by condensation with acetophenone and $NH_3$ of the phenylthioglyoxylamide *(8)* formed by rearrangement of the unstable phenacylsulfenamide *(7)*.

*(7)* *(8)* *(9)*

We were able to establish that the increase in yield expected on the basis of this scheme from an increase in the amount of sulfur used actually did materialize. We also proved that phenylthioglyoxylamide *(8)* occupies a central position in the reaction scheme. Compound *(9)* is also produced on treating phenylglyoxylonitrile with acetophenone, $NH_3$, and $H_2S$ in a reaction in which phenylthioglyoxylamide is an intermediate [66]. Phenylthioglyoxylamide can be prepared smoothly and in good yields by treating phenylglyoxylonitrile with $H_2S$ in the presence of a tertiary amine and in the absence of solvents having acidic hydrogen [46, 73]; it can be condensed with acetophenone and $NH_3$ to give *(9)* [46].

New informations were gained from the reaction of phenacylsulfenylmorpholide *(10)* with radioactive sulfur [46]. In the resulting mixture of phenylthioglyoxyl-

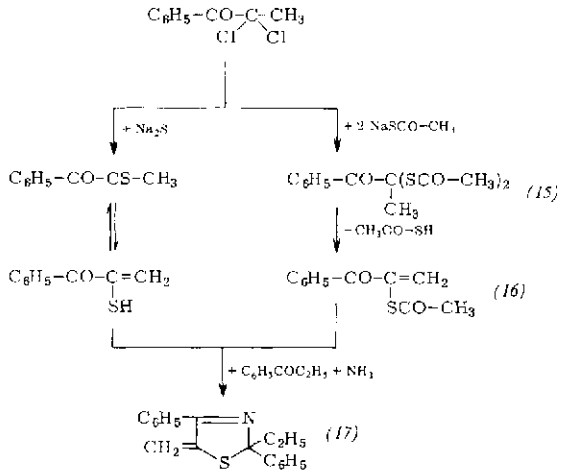
morpholide *(12)* and $H_2S$, the radioactivity was equally divided between these two products. This distribution of the activity exists right from the very beginning of the reaction and remains constant as the reaction proceeds. The possibility of sulfur exchange is thus eliminated. This result can be explained only by postulating the formation of the intermediate *(11)* containing two equally bound sulfur atoms [46].

The sulfenamide *(10)* is cleaved to a thioaldehyde and amine, which immediately react to give the α-amino-α-mercaptoketone. The latter is thiolated further at the methine group whose hydrogen is highly activated by the -I effect of the thiol and amino group. The α-amino-α,α-dimercaptoketone *(11)* becomes stabilized by elimination of $H_2S$ and formation of the α-oxothioamide *(12)*. The probability of elimination is the same for both mercapto groups, and this would account for the observed distribution of radioactivity.

On the basis of these results, the formation of $\Delta^3$-imidazoline-5-thiones can be explained simply and in accordance with all experimental observations by a mechanism involving dithiolation at the same carbon atom, promoted by excess sulfur (Scheme 2).



Scheme 2. Formation of $\Delta^3$-imidazoline-5-thiones *(14)*.

To check this hypothesis, ω,ω-dimercaptoacetophenone (synthetized from the corresponding dichloride and NaSH) was treated with morpholine in the presence of excess sulfur to produce phenylthioglyoxylmorpholide. In the absence of sulfur, lower yields were obtained. The reaction of the ω,ω-dithiol *(13)* with acetophenone and $NH_3$ in the presence of S gave an 84 % yield of *(14)* in a very short time [46]. Without sulfur, lower yields were obtained or the $\Delta^3$-thiazoline was produced [46].

### c) 5-Alkylidene-$\Delta^3$-thiazolines

5-Alkylidene-$\Delta^3$-thiazolines are produced when higher homologues of acetophenone are used, particularly in the presence of excess sulfur. These compounds are also a result of α-dithiolation. For example, treatment of propiophenone or n-butyrophenone with S and $NH_3$ at room temperature affords predominantly the corresponding $\Delta^3$-thiazolines; oils of nearly identical elemental composition are also obtained. The oily fractions were identified as 5-alkylidene-$\Delta^3$-thiazolines *(17)*. The reaction sequence of Scheme 3, which is illustrated with the propiophenone derivatives [74], gives a clue to the structure of these oxidation-sensitive compounds.

Scheme 3. Proof of the structure of the 5-alkylidene-$\Delta^3$-thiazolines *(15)*.

The reaction of α,α-dichloroketones with *S*-sodium thioacetate leads to the unstable diacetylated dithiols *(15)*. These compounds begin to lose thioacetic acid already during their preparation, hence the resulting reaction mixture contains predominantly the α-acetylthio-α-methyleneketone *(16)*. These results agree with those obtained by *Campaigne* and *Edwards* [75] in the acetylation of 1,3-diphenyl-2,2-dimercaptopropane with acetic anhydride.

Our own studies [76] have shown that the condensation of α-acetylthioketones with a variety of oxo derivatives and $NH_3$ generally leads smoothly to $\Delta^3$-thiazolines, sometimes even more readily than that of the α-mercaptoketones themselves. As illustrated in Scheme 3, 1-phenyl-2-acetylthio-2-propene-1-one *(16)* also reacts readily with numerous ketones or aldehydes and $NH_3$ to give 4-phenyl-5-methylene-$\Delta^3$-thiazolines *(17)* [74].

5-Alkylidene-$\Delta^3$-thiazolines are produced by the following reactions (cf. Scheme 1, reaction sequence A). Dithiolation of the carbon atom *alpha* to the oxo (or imino) group produces an α-thioxoketone or an α-thioxoketimine which in its tautomeric α-oxo- (or α-imino) enethiol form, *i.e.* as an α-alkylidene-α-mercaptoketone, undergoes the known condensation with unreacted ketone and $NH_3$ to give the $\Delta^3$-thiazoline. Increasing the amount of sulfur should favor the formation of 5-alkylidene-$\Delta^3$-thiazoline over that of the normal $\Delta^3$-thiazoline. This has been confirmed experimentally [74].

### d) Desulfurization of α-Thioxoketones

The desulfurization of α-thioxoketones with $H_2S$ in the presence of amines, with conversion of the –CO–CS– grouping into $-CO-CH_2-$ [74] (cf. Table 2) is an essential step in the Willgerodt-Kindler reaction.

[74] *F. Asinger, W. Schäfer,* and *H. Triem,* unpublished and partly incomplete work.

[75] *E. Campaigne* and *B. Edwards,* J. org. Chemistry *27*, 4488 (1962).

[76] *F. Asinger, W. Schäfer,* and *N. B. Desai,* unpublished work.

Since α-thioxoketones are very unstable compounds, we used geminal α-oxodichlorides (α,α-dichloroketones) instead. On treatment with $H_2S$ and amine, these undergo desulfurization to the ketone by way of α,α-dimercapto- or α-thioxoketones. Some indication of the course of the reaction is given by the pyridine-catalysed desulfurization with $H_2S$. By this method, α-thioxopropiophenone affords bis-(1-phenylpropane-1-on-2-yl) trisulfide.

Thiones are known to undergo analogous reactions. For example, dichlorodiphenylmethane reacts with NaSH in saturated alcoholic $H_2S$ to produce bis(diphenylmethyl) disulfide [77], from which *Bergmann* et al. [78] obtained disulfides of benzophenone using alcoholic ammonium sulfide.

The exothermic desulfurization of α-thioxoketones discovered by us takes place even at room temperature and can be formulated as the reverse of thiolation:

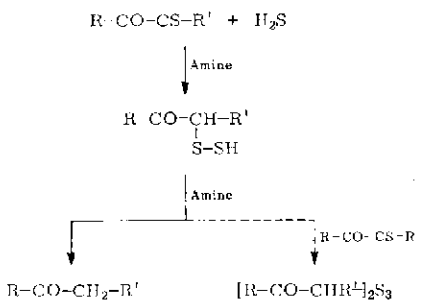


Table 2. Desulfurization of α-thioxoketones with $H_2S$ in the presence of amines in aqueous methanol at room temperature.

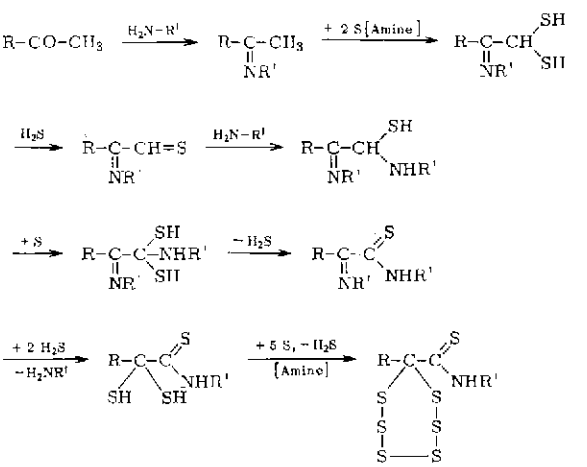
[a] Ac = acetophenone; Pro = propiophenone; But = n-butyrophenone.

## 2. Acetophenone, Sulfur, and Primary Amines (Reaction Sequence B)

Other important indications of the mechanism of the Willgerodt-Kindler reaction are obtained from the reaction of acetophenone [*] with butylamine and sulfur.

[77] *L. Gattermann* and *H. Schulz*, Ber. dtsch. chem. Ges. *29*, 2944 (1896).

[78] *E. Bergmann*, *M. Magat*, and *D. Wagenberg*, Ber. dtsch. chem. Ges. *63B*, 2576 (1930).



[*] A study of higher alkyl aryl ketones is in progress [47,48].

### a) 1-Phenyl-2,3,4,5,6,7-hexathiacycloheptane-1-thiocarboxamide

For all practical purposes, acetophenone and propiophenone do not react with n-butylamine at 20 °C. In the presence of sulfur at room temperature, however, the *N*-n-butylimines of these ketones are obtained in approximately 40 % yields [15]. Thus, for the first time, we succeeded in isolating an intermediate that was formed under mild conditions from the Willgerodt-Kindler reaction mixture (ketone, S, and amine). It was already suspected by *Kindler* [11] and others [49, 79] that ketimines occurred as intermediates.

1-Phenyl-*N*-n-butyliminoethane may be obtained in about 50 % yield by treating butylamine with acetophenone for 20 hours in methanol in the absence of sulfur [46]. Reaction of the ketimine with sulfur and morpholine in methanol for 20 h at 20 °C affords phenylthioacetomorpholide in 65 % yield [46]. To our knowledge, this is the lowest temperature at which a Willgerodt-Kindler reaction has ever been carried out. On treating the ketimine with sulfur and butylamine instead of morpholine at 20 °C, unexpectedly a 40 % yield of 1-phenyl-2,3,4,5,6,7-hexathiacycloheptane-1-n-butylthiocarboxamide was obtained. With acetophenone as starting material, the yields are somewhat lower.

The structure of the compound can be considered as established, although our studies on the mode of formation, the degradation reactions, *etc.* are not yet complete [80]. Preliminary results obtained to date indicate that this reaction can also be used to prepare other hexathiacycloheptanes and that it, too, involves dithiolation at the methyl group with formation of 2 moles of $H_2S$. In analogy to the formation of geminal dithiols from the Schiff bases of some aliphatic ketones observed by *Magnusson* [81,82], $H_2S$ adds onto the azomethine linkage. The resulting dithiol undergoes an intramolecular McMillan-King reaction leading to the formation of the hexathiacycloheptane ring (Scheme 4).

| R | R' | M.p. [°C] |
|---|---|---|
| $C_6H_5$ | n-$C_3H_7$ | 139 |
| $C_6H_5$ | $CH(CH_3)_2$ | 138 |
| $C_6H_5$ | n-$C_4H_9$ | 109 |

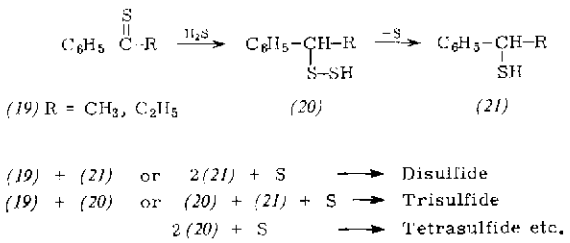
### 3. Reaction of Alkyl Aryl Ketones with Sulfur and Secondary Amines (Reaction Sequence C)

#### a) Di-(α-aralkyl) Polysulfides



The formation of hexathiacycloheptane derivatives from α-phenethylideneimines in the presence of excess sulfur poses the question whether the reaction mechanism in addition can be altered by an excess of $H_2S$. This was found to be the case.

This study was based on the observation that $\Delta^3$-thiazoline formation can be inhibited by introducing excess $H_2S$ during the reaction (cf. [1]). While studying this phenomenon, we found a new synthesis for 1,2,4-trithiolanes and 1,2,4,5-tetrathianes [83,84]. It involves treatment of $H_2S$ and S with ketones (aldehydes are less suitable) in the presence of $NH_3$ or primary or secondary amines at 0 °C. In the absence of S, geminal dithiols are obtained [85]. Since these dithiols can also be synthetized from ketimines (aldimines are less suitable) and $H_2S$ [81,82], the reaction mechanism represented in Scheme 5 is probably correct.

Scheme 5. Formation of 1,2,4-trithiolanes and 1,2,4,5-tetrathianes.

The central intermediate is the thione *(18)*. Its formation is readily explained when either primary or secondary amines (or $NH_3$) are used, and no differentiation between the amines is necessary for the following discussion. It is significant that especially the alkyl aryl ketones which are predestinated for the Willgerodt-Kindler reaction, when treated with $H_2S$ and amine, do not afford trithiolanes or tetrathianes, and that the reaction of the corresponding ketimines with $H_2S$ does not give dithiols [83,87]. Instead, open-chain di-(α-aralkyl) di- and polysulfides are obtained [86]:

Because of the proximity of the phenyl group, the addition of $H_2S$ onto the thione *(19)*, leads to the monoarylalkylsulfane *(20)* rather than to the geminal dithiol. In the presence of amine or $NH_3$, the sulfane undergoes partial desulfurization to the thiol *(21)* [87,88]. Further desulfurization is precluded by the lack of activating groups in the α-position.

Combinations between *(19)*, *(20)*, or *(21)* lead to polysulfides, and McMillan-King reactions are rendered possible by the presence of sulfur (from the partial desulfurization). It is known that disulfides can be produced in the reaction of thiones or thioaldehydes with thiols containing an adjacent phenyl group [22,23,34,87–92]; sulfurization of disulfides in the presence of base is also known [93]. Di-(α-phenethyl) disulfide was first obtained, along with an unidentified oil, by *Baumann* and *Fromm* on treating acetophenone with $NH_4SH$ for 7 days in methanol [94]. The oily product was identified as a mixture of di-(α-phenethyl) di- and polysulfide [86]. Under identical conditions, propiophenone gives analogous products [86].

On passing $H_2S$ into the *N*-n-butylimine of acetophenone or propiophenone a deep dark-blue solution (thioacetophenone formation) is first obtained, followed by polysulfide formation, which is indicated by brightening of the solution [86]. Secondary amines form the geminal aminohydroxy compound first. On treatment with $H_2S$, the latter undergoes replacement of a hydroxyl by a mercapto group to give the geminal aminomercapto compound, which is then converted into the thione by elimination of amine. Enamine formation by dehydration of the geminal aminohydroxy compound is less probable in view of the mild reaction conditions.

Thus, di-(α-aralkyl) polysulfides are not the real intermediates in the Willgerodt-Kindler reaction. Although they undergo conversion into ω-aralkylcarboxylic acids under Willgerodt-Kindler conditions, the yields are markedly lower than those obtained when, for example, acetophenone or propiophenone are treated directly with amine and sulfur under identical conditions [86]. Moreover, these polysulfides are not formed to an appreciable extent in the Willgerodt-Kindler reaction

of alkyl aryl ketones, probably because of their low reactivity. *Naylor* [24] suggested that the di- and polysulfides are intermediates.

However, the study of these compounds has produced further support for the contention that ketimines and thiones are the intermediates in the Willgerodt-Kindler reaction and that they enter into the "polysulfide side-branch" only in the presence of excess $H_2S$. Moreover, regardless of whether the reaction is carried out in the presence of $NH_3$ or a primary or secondary amine, their existence indicates that geminal aminohydroxy compounds, imines and thiones are central intermediates that do not depend on the type of amine used. Intermediates containing thioxo groups have also been suggested by other workers [21,25,34,35].

### b) Migration of Functional Groups along the Alkyl Chain

So far, this discussion has dealt with reactions which, on the basis of our current knowledge, could take place at room temperature, depending on the combination and concentration of the reactants, *i.e.* ketone, S, $NH_3$ or a primary or secondary amine, and $H_2S$, and might be important for the Willgerodt-Kindler reaction. The problem of the migration of any particular functional group along the hydrocarbon chain was not considered. The assumption that the thiolation and desulfurization reactions are associated with a thioreductone equilibrium [*] [95], seems to us at present to offer the best possibility of bringing this phenomenon into harmony with the established facts (see Scheme 1, reaction sequence C). Thus, the Willgerodt-Kindler reaction involves the following steps:

$\alpha$) *Oxidation Steps.* Methylene and, at slower rates, methine and methyl groups undergo thiolation to give $\alpha$-mercaptoketones, whereas $CH_2$ and $CH_3$ groups are also dithiolated to give $\alpha$-thioxoketones when the $\alpha$-position is occupied by unsaturated groups ($\rangle C{=}N$ ; $\rangle C{-}S$; $\rangle C{-}O$) which can be modified (*e.g.* $\rangle N\text{-}C\text{-}OH$, OR, SH, SR) tending to increase the mobility of the hydrogen atoms [**].

$\beta$) *Reduction Steps.* In the presence of amine alone or amine + $H_2S$, reversal of the formation of mercapto and thioxo compounds according to $\alpha$) leads to desulfurization.

$\gamma$) *Migration and Capture Steps.* The oxidations (thiolations) and reductions (desulfurizations) as reversible reactions proceed in both directions along the carbon chain, with migration of the – possibly modified – functional groups, until the irreversible oxidation (thiocarboxamide formation) of the thiolatable chain ends occurs. The resulting increase in the amount of $H_2S$ formed ensures continuation of the reaction (ketimine → thione).

The fact that primary amines are less suitable for the Willgerodt-Kindler reaction than secondary amines is probably due to the higher desulfurization activity of the former. If the chain contains a quaternary carbon atom, then only reduction of the carbonyl to the methylene group takes place [21]; when a tertiary carbon atom is present, the Willgerodt reaction still takes place, but the yields are only 0.5–3 % [5,7,8,21,31, 96–98]; higher yields were obtained only in a few cases (maximum: 19 %) [6,20,21]. Since, in the case of branched chains, the thioreductone phase of the reaction is not so easy to interpret, we see in these results a confirmation of our proposed mechanism. In agreement with this concept, the Willgerodt-Kindler reaction of unbranched alkyl aryl ketones gives far higher yields.

The use of $C_6H_5COCH_2CD_2CH_2CH_3$ in the Willgerodt reaction leads to 95 % loss of $D_2$ [99]; this is readily explained by intermediate formation of C=S.

The fact that migration does not proceed via acetylenic and olefinic bonds (cf. [20,21]) is supported by the results of *Nightingale* et al. [100]. On using $C_6H_5\text{-}C{\equiv}CCOCH_3$ and $C_6H_5{-}CH{=}CHCOCH_3$ in the Willgerodt-Kindler reaction, these workers obtained the corresponding unsaturated carboxylic acids containing the triple and double bond in their original positions [101].

The migration of a thioxo group is supported not only by the increased yield resulting when trithioacetophenone is used in place of acetophenone (72 → 83 %) [102], but also by the results of a Willgerodt reaction with compounds that already contain a carbonyl group at the end of the side chain. In this case, the migrating thioxo group eventually reaches the carboxyl group, *i.e.* a configuration favorable for $NH_3$- or amine-catalysed decarboxylation is attained. In fact, aralkylcarboxylic acids with one less carbon atom and with a terminal carboxyl group are obtained [23,38,103,104].

Additional interpretations of special cases (retention of the oxo group, reaction of compounds such as cyclohexanone or tetralone) are now also possible; however, because of lack of space, these cases will not be considered here.

[*] The possibility that thioreductones play an important role in the Willgerodt-Kindler reaction was first suspected by my (F. A.) former close collaborator Dr. *Max Thiel*. On the basis of our findings concerning $\alpha$-thiolation, *Berchtold* [25] considered thioreductone reactions as one of three possible explanations for functional group migrations.

[95] For information concerning thioreductones, see *H. v. Euler* and *B. Eistert:* Chemie und Biochemie der Reduktone und Reduktonate. Enke, Stuttgart 1957.

[**] For clarity, only $\rangle N\text{-}C\text{-}OH$ and $\rangle C{=}N$ are shown in Scheme 1.

## 4. Future Prospects

Because of the large number of steps which can occur in the Willgerodt-Kindler reaction, especially when one considers in a broader sense the different classes of compounds that have already been reacted with sulfur and amine, no single reaction mechanism can possibly account for all the observed facts. It is possible, however, that a thione is a central intermediate in any case. We believe that the Willgerodt-Kindler reaction also takes place with starting materials other than ketones, for example, in the presence of suitable solvents, at markedly lower temperatures than those used previously. This gives us a chance to extend our knowledge of the Willgerodt-Kindler reaction with new viewpoints and possibly provides a means for reducing the number of reactions and side reactions.

*We wish to thank the Landesamt für Forschung Nordrhein-Westfalen and the Bundesministerium für wissenschaftliche Forschung for supporting our work.*

# Recent Developments in the Study of Lysozymes [*]

BY DR. P. JOLLÈS

LABORATOIRE DE CHIMIE BIOLOGIQUE, FACULTÉ DES SCIENCES DE L'UNIVERSITÉ DE PARIS (FRANCE)

*Lysozymes are widely distributed enzymes. They split the chemical skeleton of bacterial cell walls by hydrolysing the β(1 → 4) linkages between N-acetylmuramic acid and N-acetylglucosamine. The amino acid sequence of lysozyme from hen's egg-white is known (129 amino acid residues). Lysozymes of different origins frequently differ in their primary structures although they exhibit qualitatively the same biological activity. The results obtained from investigations with lysozymes allow conclusions to be drawn regarding the chemical structure of the "backbone" of bacterial cell walls.*

## Introduction

The name of *Fleming* is not only associated with the discovery of penicillin but also with that of an enzyme which was called lysozyme and which has "the power of rapidly dissolving certain bacteria, which is possessed by many animal and vegetable tissues and secretions, and to a very marked degree by egg-white" [1]. About the same time, *Fleming* also discovered a coccus which was very sensitive to the action of lysozyme, *viz. Micrococcus lysodeikticus*. His first observations were rapidly confirmed by many research workers. Lysozymes were found in a great number of human organs, tissues, and secretions (spleen, kidney, tears, saliva, etc.). Similar lytic enzymes were characterized in organs and secretions of many vertebrates; invertebrates, bacteria, and even plants (*e.g. Papaya* latex) also contain lysozymes, which therefore appear to be widely distributed substances [2]. The most important source for lysozyme is the white from the eggs of different birds, especially hens. For this reason, the knowledge of egg-white lysozyme is the most extensive.

This paper will deal in a first section with recent results concerning the physico-chemical properties, the structure, and the relationship between the biological activity and structure of hen's egg-white lysozyme. In the second part, a short comparative study is given of lysozymes of various origins recently obtained chromatographically pure. Finally, some recent experiments concerning the lysozyme substrate and some aspects of the action of lysozyme on the latter will be discussed. However, first the definition of a lysozyme and a quantitative assay method will be given.

### a) Definition of a Lysozyme [3,4]

A lytic enzyme can becalled a lysozyme when it possesses the following properties: it must be a basic protein of low molecular weight (near 15000), which is stable at acidic pH (even at 100 °C and pH 4.5 for 1–2 minutes) without significant loss of activity and unstable at alkaline pH; it must be active against suspensions of *Micrococcus lysodeikticus* and liberate by its action on an appropriate substrate compounds which can be detected by reagents for reducing sugars and for *N*-acetylhexosamines and which are derived from glucosamine and muramic acid. For this reason, lysozyme is also called β-glucosaminidase or muramidase or *N*-acetylmuramide glycanohydrolase.

[*] The survey of literature pertaining to this review was completed on January 28th, 1963.

b) Determination of Lytic Activity

The lytic activity of a preparation containing a lysozyme is usually determined by observing spectrophotometrically the extent of lysis of a suspension of dead cells of *M. lysodeikticus*. Beside the classical methods of *Smolelis* and *Hartsell* [5] and *Fraenkel-Conrat* [6], some recent modifications introduced by *Shahani* [7] and *Léonis* [8] are worthy of mention.

## II. Hen's Egg-White Lysozyme

### 1. Purification

Lysozyme can be crystallized directly from hen's egg-white as described by *Alderton* and *Fevold* [9]. The method was modified by *Sophianopoulos* et al. [10] by introducing fractionation with ammonium sulfate as a final step in order to obtain chromatographically pure lysozyme. Purification of crystallized or commercial preparations can be achieved by chromatography on carboxymethylcellulose or Amberlite CG-50 [11]. Beside the principal peak (90 + 10 %), it is possible to detect two other fractions. However, since the amounts of these fractions vary with the method of preparation and the time of storage, their slightly different chromatographic behavior may reflect only different contents of amide groups: this point of view seems to be confirmed by quantitative amino-acid analyses.

### 2. Physico-Chemical Studies

Physical data on lysozyme are surprisingly scant, especially in comparison with the progress made in elucidating its sequence of amino acids. In addition, many of the physical measurements were made before the advent of purification by ion-exchange and cellulose chromatography, which have shown, as noted above, that the enzyme can contain varying amounts of minor components.

Its isoelectric point lies between 10.5 and 11.

The molecular weight obtained for lysozyme by different physical methods have recently be reviewed by *Jollès* [12]. The value nearest to that based on analytical data is 14500 ± 200. Some recent experiments by *Sophianopoulos* et al. [10] on chromatographically pure lysozyme indicate a molecular weight of 14400 ± 100 at pH 5.4. These authors re-determined the sedimentation coefficient; after extrapolation to infinite dilution, $S_{20w} = 1.91\times10^{-13}$ sec (previous values: $1.8\times10^{-13}$ $1.87\times10^{-13}$, $1.9\times10^{-13}$, and $2.11\times10^{-13}$ sec); they also gave an average value for the partial specific volume of 0.703 ml/g at 20 °C which is lower than values quoted by *Charlwood* [13] (0.714 at 15 °C) and *McMeekin* et al. [14] (0.722 at 20 °C) but higher than that given by *Colvin* [15] (0.688 at 25 °C).

Recently published values for the optical rotation and optical rotatory dispersion of lysozyme are given in Table 1 [16–18]. These values are important as the partial helical content of lysozyme has been estimated from optical rotatory dispersion and its degree of folding from the change in optical rotation with denaturation [22]. These results suggest that the peptide chain of lysozyme contains about 35 % of its residues in a helical conformation [16, 23].

Table 1. Optical rotation $[\alpha]_D$ and optical rotatory dispersion constant $\lambda_c$ of hen's egg-white lysozyme.

| Solvent | $[\alpha]_D$ | $\lambda_c$ [mμ] | Ref. |
|---|---|---|---|
| 2 M NaCl | −47.1 | 254 | [19] |
| $H_2O$ | −44 | | [16] |
| 8 M urea | −85 | | [16] |
| 0.25 M NaBr, pH 5.6 | −47 | 254 | [17] |
| 4 M guanidine thiocyanate | −83 | 215 | [20] |
| 0.1 M NaCl, pH 3.1 | −51.3 | | [21] |
| 1.9 % aqueous solution, pH 5.5 | | 251 | [18] |

Hydrogen-deuterium exchange was used by *Blout* [24] as an index of the partial helical content in native lysozyme; he found that only 45 % of the amide hydrogen was readily exchanged. *Kanarek* et al. [25] stated that this exchange is a function of pH and is high in acidic solutions. The minimum helical content calculated here is again 35 %.

The intrinsic viscosity and sedimentation coefficient are consistent with either a nearly spherical molecule with a hydration of 0.6 g of water per g of protein or an oblate ellipsoid of lower hydration [10]. *Donovan* et al. [18] used titration curves and ultraviolet difference spectra to obtain information about interactions which make some of the carboxyl groups of lysozyme behave abnormally.

Crystallographic investigations by *Alderton* [26], *Corey* [27], *Steinrauf* [28], and *King* [29] showed that lysozyme can be crystallized in several crystal forms as salts of mineral acids.

Crystals of lysozyme chloride grown at pH 4.7 [26] are tetragonal; each unit contains eight lysozyme molecules [28] together with 1 M NaCl solution (the buffer used contained $Na^+$-ions) which is occluded and contributes about 33.5 % of the weight of the crystal.

Recently a detailed X-ray crystallographic investigation was begun by *Blake* et al. [30], which ought to lead to a knowledge of the molecular configuration. Their first result was a three-dimensional electron-density map at 6 Å resolution of lysozyme in the tetragonal crystal form. Three heavy-atom derivatives have been used, containing mercuric iodide, hexachloropalladate(IV) and 2-hydroxymercury(II)-toluene-4-sulfonic acid. Similar studies are being made by *Stanford* et al. [31] using tetragonal lysozyme chloride crystals containing complex ions of niobium and tantalum and by *Dickerson* et al. [32] with triclinic lysozyme nitrate.

## 3. Chemical Structure

### a) Analysis

Hen's egg-white lysozyme contains 129 amino acid residues (molecular weight: 14388): $Gly_{12}$, $Ala_{12}$, $Ser_{10}$, $(Cys)_8$, $Met_2$, $Thr_7$, $Pro_2$, $Val_6$, $Leu_8$, $Ileu_6$, $Phe_3$, $Tyr_3$, $Try_6$, $Asp_{21}$, $Glu_5$, $Lys_6$, $Arg_{11}$, $His_1$, $(NH_2-)_{18}$. It is the first protein containing all the common amino acids, especially Met, Try, and Cys together, whose chemical structure has been determined [12].

### b) Primary Structure

*Jollès* and *Jollès* [33] determined the chemical structure of egg-white lysozyme in 1961. The protein consists of a single polypeptide chain folded by the four –S–S– bridges of the cystine residues. Cleavage of the –S–S- bridges does not split the molecule into several polypeptide chains.

Table 2. Separation of the products of digestion with trypsin of hen's egg-white lysozyme by ion-exchange column chromatography. Behavior of the amino acids tryptophan (Try), cystine (Cys), and methionine (Met) [34].

| Resin | Lysozyme | Try | Cys | Met | Observations |
|---|---|---|---|---|---|
| | | appears in eluate as | | | |
| Dowex 50X2 | Native | Try | Cys | Met | Very slight digestion by trypsin |
| | Heat-denatured | Try | Cys | Met | Cys-containing peptides remain adsorbed |
| | Oxidized | Kynurenine | Cysteic acid | Methionine-sulfone | Try-containing peptides remain adsorbed |
| | Reduced and treated with $ICH_2COOH$ | Try | *S*-Carboxy-methyl-cysteine | Homoserine | Peptides with high content of aromatic amino acids remain adsorbed |
| Dowex 1X2 | Reduced and treated with $ICH_2COOH$ | Try | *S*-Carboxy-methyl-cysteine | Homoserine | Separation of all the products |

To establish the primary structure, the lysozyme was denatured (heat, oxidation, reduction) and digested with trypsin; the native enzyme cannot be split by trypsin. The products of this hydrolysis were separated by chromatography on Dowex 50X2 or Dowex 1X2 columns. Table 2 points out the differences encountered in this study [34]. It was possible to join the units from the digestion with trypsin together in the right order after hydrolysis with chymotrypsin yielded units containing basic amino acids which gave information about the sequence of the tryptic cleavage products. Figure 1 indicates the primary structure [33–35].

### c) Secondary and Tertiary Structure; Disposition of the –S–S-Bridges

Some results concerning the secondary and tertiary structure have already been mentioned in the part devoted to the physico-chemical properties. *Léonis* [36] investigated the secondary structure, *i.e.* the hydrogen-bonds between the peptide groups, by dissolving the enzyme in urea and by measuring the absorption spectrum in the far ultraviolet and the variations of the optical rotatory dispersion.

The tertiary structure (arrangement of the side chains, etc.) was also studied by *Léonis* [36]. The results of his experiments suggest the importance of the hydrophobic linkage in the stability of the molecular configuration of lysozyme. The configuration of native lysozyme is not necessarily the most organized structure. Following treatment of lysozyme with urea, column chromatography on Amberlite CG-50 yielded a whole family of

[36] *J. Léonis* [8a], Vol. 1, p. 125.

very closely related lysozymes which seem to differ mainly by their tertiary structure [8]. *Jauregui* and *Jollès* [37] also obtained similar results after treatment of lysozyme with iodoacetic acid at pH 5.5.

peptide was then oxidized with performic acid with a view to determining which of the half-cystine residues were joined together in native lysozyme. Figure 1 indicates a first disulfide bond characterized in this way.

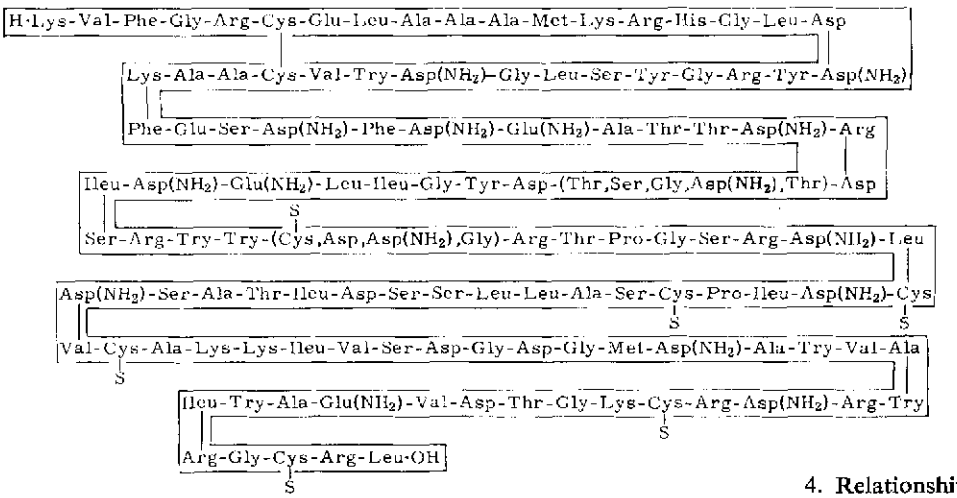

Fig. 1. The chemical structure of hen's egg-white lysozyme.

## 4. Relationships between Structure and Biological Activity

In order to identify the positions of the disulfide bonds, *Jollès* et al. [38] digested the native enzyme with pepsin and chymotrypsin and were then able to isolate the peptides containing cystine by chromatography on Dowex 50X2 (Figure 2). Each peak containing a cystine

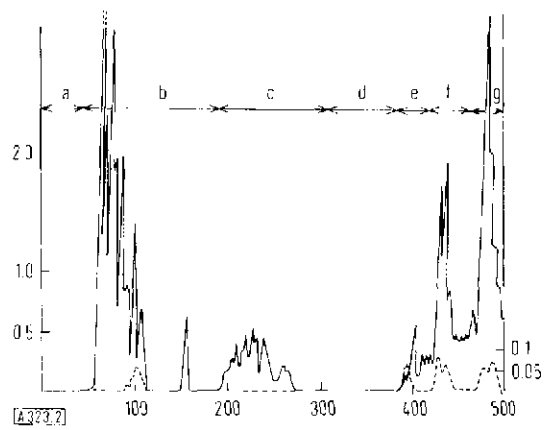

Fig. 2. Chromatogram of the peptides obtained by hydrolysis of hen's egg-white lysozyme with pepsin and chymotrypsin on a Dowex 50 X 2 column (length: 100 cm, diameter: 2 cm) [38]. Eluting buffer:

(a) 0.2 M sodium citrate, pH 3.1
(b) 0.2 M sodium citrate, pH 3.1 → 1.0 M sodium citrate, pH 5.1
(c) 1.0 M sodium citrate, pH 5.1 → 2.0 M sodium citrate, pH 5.1
(d) 2.0 M sodium acetate, pH 6.4
(e) 0.5 M sodium phosphate, pH 7.2
(f) 0.75 M sodium borate, pH 9.5
(g) 0.5 M sodium borate, pH 12.3.

Volume of the mixing chamber for (b) and (c): 500 ml.
Volume of fractions: 10 ml.

Ordinate on the left and full curve: Intensity of the ninhydrin reaction after alkaline hydrolysis (leucine equivalents [mmole/l]).

Ordinate on the right and dashed curve: Peptides containing cystine; intensity of the coloration with phosphotungstic acid (absorption at 700 mμ).

Abscissa: Number of fractions.

The biological activity of lysozyme cannot, of course, be related to any single amino acid, but the maintainance of different groups of amino-acid residues seems necessary for the enzymatic properties; these include:

a) the tryptophan residues; the activity is lost if these residues are altered by treatment with *N*-bromosuccinimide [39];

b) the cystine residues; maintainance of at least two –S–S– bridges appears to be necessary for the biological activity, judging from partial reduction experiments by *Jollès* et al. [34]. *Churchich* [40] observed that oxidation in air of the partially reduced lysozyme resulted in 80% recovery of the protein, yielding a water-soluble compound with 60% of the specific activity of the native enzyme. Lysozyme oxidized with performic acid is inactive;

c) the single histidine residue; it is inaccessible to iodoacetic acid at pH 5.5; if the native enzyme is treated with iodoacetic acid for 20 minutes, a group of active lysozymes can be separated by column chromatography, which seem to be very closely related substances (Figure 3) [37]. They all contain histidine and probably differ slightly in their tertiary structure.

The C-terminal Arg-Leu sequence of the protein can be split off without loss of activity; however, it has not yet been possible to isolate a short active sequence from lysozyme.

The relationships between treatment with various reagents and the biological activity of lysozyme are indicated in Table 3. The following points are noteworthy:

a) Radioactive lysozyme remains active up to a specific activity of 0.20 mC/mmole [41].

Table 3. Enzymatic activity of hen's egg-white lysozyme after various treatments

| Treatment | Amino acids or groups altered by treatment | Activity | Ref. |
|---|---|---|---|
| Oxidation | Cys [*], Met, Try | Inactivation | [6] |
| Photooxidation | His, aromatic amino acids | Reduced activity | [44] |
| Reduction | Cys | Reversible inactivation | [40,44a] |
| Anhydrous formic acid | $N \rightarrow O$-Acyl shift; hydroxyamino acids | Reversible inactivation | [45] |
| Esterification | Free COOH groups | Depends on the reagent | [6] |
| Acetylation | Free $NH_2$ groups | Progressive inactivation | [6,42] |
| Guanidination | Lys | Active | [42] |
| Xanthination | Try | Inactivation | [43] |
| Iodination | His, aromatic amino acids | Inactivation; reactivation possible | [6] |
| Iodoacetic acid (pH 5.5) | Partially Met, Lys | Formation of active closely related substances | [37] |
| Urea | | Formation of active closely related substances | [8] |
| *N*-Bromo-succinimide | Mainly Try | Progressive inactivation | [39] |
| Incorporation of radioisotopes | | Active up to 20 mC/mmole | [41] |

[*] Cys = cystine.

[43] *S. R. Dickman, R. B. Kropf*, and *C. M. Proctor*, J. biol. Chemistry *210*, 491 (1954).

b) Urea has two modes of action: an instantaneous but completely reversible inhibition, and a slow but irreversible action, whereby native lysozyme is transformed into closely related active substances [8].

c) Any treatment of the enzyme which increases its (relative) content of acidic groups (acetylation) inactivates it, any treatment increasing its basicity (guanidination) leaves the protein active [42].

It will be interesting to search for the structural basis of the bacteriolytic activity at the level of the tertiary structure, especially in the stabilizing action of the hydrophobic linkages, as it is possible to obtain inactive fractions without modification of the secondary structure [36].

## III. Lysozymes of Different Origins

The purification and analysis of different lysozymes has been undertaken in the author's laboratory with a view to comparing the enzymes and establishing whether the same qualitative biological activity can be related to some common points.

### 1. Choice of the Lysozymes

Two groups of lysozymes were investigated: 1. Lysozymes extracted from the same organ of two different animal species (hen's and duck's egg-white [46], rabbit [47] and dog spleen [48]). 2. Lysozymes extracted from different organs or body fluids of the same animal (hen's egg-white and lung [49]; dog spleen [48] and kidney; human milk [50], placenta [51], saliva [51a], leucocytes [52], and spleen). All these lysozymes have been obtained in a chromatographically pure state by the procedure described below.

### 2. Purification Procedure

The purification procedure described by *Jollès* et al. [53] includes five main steps:

1. Heating of the ground organ or fluid at 100 °C for 1–2 minutes at pH 4–4.5.

2. Adsorption on Amberlite CG-50 and elution of basic substances.

3. Chromatography on carboxymethylcellulose.

4. Desalting on Sephadex G-25 or G-50.

5. Ion-exchange chromatography on Amberlite CG-50 columns, without change of the temperature, the pH, and the molarity of the buffer. The enzyme obtained is chromatographically pure. Table 4 indicates the pH at which the various lysozymes were chromatographed.

Table 4. Optimum conditions for quantitative elution of lysozymes of various origins from ion-exchange chromatography columns; 1 mg of enzyme on Amberlite CG-50 columns (length: 20 cm, diameter: 1 cm) with a phosphate buffer at 20 °C [12,46–52].

| Lysozyme | pH (± 0.02) | Molarity of buffer | Volume of eluate [ml] |
|---|---|---|---|
| Hen's egg-white | 7.18 | 0.2 | 90 |
| Hen lung I | 6.40 | 0.325 | 70 |
| Hen lung II | 6.40 | 0.412 | 70 |
| Duck egg-white I | 7.58 | 0.2 | 20 |
| Dog spleen | 6.50 | 0.2 | 120 |
| Dog kidney | 6.40 | 0.2 | 20 |
| Rabbit spleen I | 6.55 | 0.2 | 20 |
| Rabbit spleen II | 6.55 | 0.2 | 60 |
| Human milk I | 6.82 | 0.2 | 40 |
| Human milk II | 6.98 | 0.2 | 70 |
| Human saliva | 6.98 | 0.2 | 30 |
| Human leucocytes | 6.98 | 0.2 | 40 |
| Human placenta | 6.98 | 0.2 | 30 |
| *Nephthys hombergi* (annelid) | 6.60 | 0.2 | 1000 |

All the lytic enzymes studied except for the lysozymes from human saliva and human placenta have different chromatographic behaviors.

### 3. Analysis and Molecular Weight

The various lysozymes summarized in Table 4 have been analyzed. With the exception of the two enzymes isolated from rabbit spleen [47], which differ only in the number of their amide groups [12] and the lysozymes from human saliva and placenta, all the lysozymes studied have different amino-acid compositions [12]. These differences affect mainly the Glu, Pro, and Arg residues and the aromatic amino acids (Table 5). The molecular weight of all these enzymes is approximately 15000, judging from estimations with calibrated cellophane membranes.

Table 5. Main differences in the amino-acid compositions of some lysozymes [12,46–49,51,54,56].

| Lysozyme | Residues/molecule | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | Cys [a] | Glu | Pro | Tyr | Phe | Try | His | Arg |
| Hen's egg white | 4 | 5 | 2 | 3 | 3 | 6 | 1 | 11 |
| Hen lung I | | 9–10 | 8 | 3 | 3 | | 3 | 6 |
| Dog spleen | 4 | 10±1 | 8 | 3 | 3 | 6 | 1 | 8 |
| Dog kidney I | | 6±1 | 7±1 | 3 | 3 | | 1 | 11±1 |
| Rabbit spleen I [b] | 4–5 | 11 | 5 | 3 | 3 | 2 | 1 | 6 |
| Rabbit spleen II [b] | 4–5 | 11 | 5 | 3 | 3 | 2 | 1 | 6 |
| Human placenta [c] | 3 | 9±1 | 3 | 5 | 2 | 3±1 | 1 | 11±1 |
| Human saliva [c] | 3 | 9±1 | 3 | 5 | 2 | 3±1 | 1 | 11±1 |
| Human milk I | | | 5–6 | 3 | 3 | | | 11±1 |
| Human milk II | | | 3 | 5 | 2 | | | 11±1 |
| *Nephthys hombergi* | | 8–9 | 12 | 3 | 3 | 1–2 | | 7 |
| *Papaya* latex | 8 | 11 | 18 | 13 | 12 | 7 | 3 | 13 |

[a] Cys = cystine.
[b] Differ in their amide-group content.
[c] Do not differ even in the content of other amino acids.

### 4. Biological Activity

The lysozymes listed in Table 4 have qualitatively the same biological activity toward the same bacteria. Under the same conditions of assay at the optimum pH, hen's egg-white lysozyme is as active as rabbit spleen lysozyme [47] or hen lung lysozyme [49], but only one-half to one-third as active as dog spleen lysozyme [48], human placenta lysozyme [51], or *Nephthys hombergi* (annelid) lysozyme [49]. Lysozymes from *Papaya* latex [54] and from *B. subtilis* [55] are only one-fifth as active as egg-white lysozyme.

### 5. Comparison of the Structures and Activities of Different Lysozymes (Heteroenzymes)

Lysozymes isolated from different animal species (even from the same organ) have different chromatographic behaviors, and different amino-acid compositions. The units from digestion with trypsin of oxidized dog spleen lysozyme have been isolated, analyzed, and compared with those of hen's egg-white lysozyme [57]; it was not possible to find any common sequences between the two, the primary structures of these two enzymes must therefore be different. The same applies to human milk lysozyme I and hen's egg-white lysozyme [56]. On partial reduction, dog spleen lysozyme loses its activity but can be reactivated.

If two lysozymes extracted from the same organ exhibit different chromatographic behaviors, this may be due to differences in the number of their amide groups (*e.g.* with rabbit spleen lysozymes I and II) or amino-acid residues (*e.g.* with human milk lysozymes I and II).

Lysozymes from different organs or fluids of the same animal may have the same chromatographic behavior and the same amino-acid composition (*e.g.* human placenta and human saliva lysozymes) [51]; it is rea-

[54] *E. L. Smith, J. R. Kimmel, D. M. Brown,* and *E. O. P. Thompson,* J. biol. Chemistry *215,* 67 (1955).

[55] *Y. Satomura, S. Okada,* and *J. Fukumoto,* J. agric. chem. Soc. Japan *31,* 281 (1957).

[56] *P. Jollès* and *J. Jollès,* unpublished results.

[57] *P. Jollès* and *M. Ledieu,* Biochim. biophysica Acta *36,* 284 (1959).

sonable to consider that they then have the same structure. However, such lysozymes can also be quite different chromatographically and in composition; this applies, for example, to human placenta (or human saliva) lysozyme [51] and human milk lysozyme I [56]. A first comparison of the products of hydrolysis with trypsin by paper chromatography and electrophoresis indicated that the structures of these lysozymes seem to be different. Another example is the lysozymes from dog spleen and kidney, the first instance of the occurrence of heteroenzymes [*] in different organs of the same animal [3, 48].

It is actually possible to relate the common biological activity of lysozymes to their basicity and to some common aspects of their tertiary structure (some hydrogen and hydrophobic bonds, and presence of at least two –S–S– bonds). The single histidine residue contained in a great number of these enzymes and some aromatic amino acids may be of importance. Sequences that are common to two or more lysozymes with different amino-acid contents have not been isolated until now. In one case, such sequences were definitely excluded [57].

### 6. Lysozymes from Plants and Bacteria

Beside the lysozymes described above, only few others have been obtained in sufficient purity. The only pure lysozyme obtained from plants until now is the enzyme from *Papaya* latex [54] (molecular weight: 25000).

Lysozymes from bacteria include those from strains of *B. subtilis* studied by *Richmond* [59] and *Satomura* [55]. One of the enzymes from *Streptomyces* studied by *Ghuysen* [60] is essentially an *N*-acetylhexosaminidase and therefore similar to egg-white lysozyme.

*Koch* and *Dreyer* characterized an enzyme of phage $T_2$ as a lysozyme [61]. $T_2$-infected cells of *Escherichia coli* B synthetize an enzyme which lyses the cell from within: it is also a lysozyme with a molecular weight of 15000 and was studied by *Weidel* et al. [62]. A particle-bound $T_2$-phage lysozyme which appears to have a higher molecular weight (21000) was isolated by the same authors [63].

## IV. The Substrate and Enzymatic Action of Lysozyme

As already mentioned, *Fleming* discovered simultaneously lysozyme and a Gram-positive coccus which he named *Micrococcus lysodeikticus* because of its great susceptibility to the enzyme. The first substrate of lysozyme used was a suspension of *Micrococcus lysodeikticus*. After various attempts to isolate the substrate directly from whole cells, *Salton* [64] reported that the substrate occurred entirely in the cell wall, and thanks to his efforts, purified cell wall preparations were then obtained [65]. *Salton* and *Pavlik* [66] observed that the isolated walls of 23 different Gram-positive bacteria investigated showed some degree of susceptibility to digestion with lysozyme; the percentage reduction in turbidity varied from 9 % for *Staphylococcus aureus* walls to 98 % for the walls of *M. lysodeikticus*. Although all of the cell walls contained muramic acid and glucosamine, the sensitivity to lysozyme could not be correlated to the total amino sugar content.

Over the past few years, attempts to isolate the bacterial substrate from *M. lysodeikticus* have been made by *Schütte* and *Krisch* [67]. Their substrate was highly purified, entirely soluble in water, but not homogeneous. *Colobert* et al. [68] purified a similar preparation by chromatography on DEAE-cellulose. It appeared to be a mucopeptide. *Jollès* [69] has shown that after chromatography on DEAE-cellulose it was possible to obtain two different soluble substrates containing equal quantities of glucosamine and muramic acid, glucose, and a peptide consisting of Gly, Ala, Glu, and Lys. Lysozymes from hen's egg-white, duck's egg-white (I) and human milk (II) hydrolyse these substrates. This fact seems to confirm that the three lysozymes which are analogous but not identical substances are β-glucosaminidases. However, the kinetics of their action are different. At pH 5.8, duck's egg-white lysozyme is the most basic and is also the most active (Figure 4).

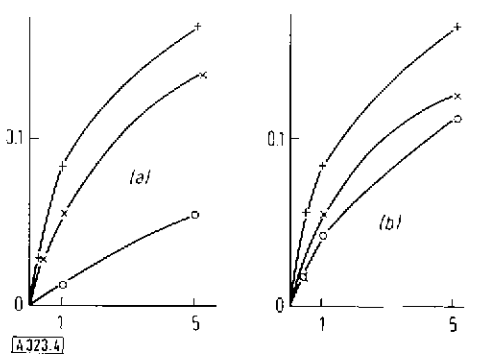

Fig. 4. Kinetics of the hydrolysis of two substrates by three lysozymes at pH 5.8 [69].

(a) Substrate: eluted from DEAE-cellulose at pH 7.2 [69]
(b) Substrate: eluted from DEAE-cellulose at pH 2.8 [69]
+–+–+ Lysozyme I from duck's egg-white

[69] *P. Jollès*, Biochim. biophysica Acta *69*, 505 (1963).

The substrate of hen's egg-white lysozyme is now known to be distributed not only in Gram-positive but also in Gram-negative bacteria following investigations of *Weidel* et al. [70,71] on the occurrence of both diaminopimelic acid and muramic acid in the walls of *Escherichia coli* and of *Salton* [72,73] on a variety of Gram-negative bacteria. *Mandelstam* [74] also noted that the cell walls of the Gram-negative *E. coli* contain lysozyme-sensitive mucopeptides made up of muramic acid, glucosamine, Gly, Glu, Ala, diaminopimelic acid and Lys. *Martin* and *Franck* [75] recently identified a rigid layer in the cell wall of *E. coli* B which contains a mucopolymer and which can be digested by lysozyme. *Colobert* et al. [76] succeeded in obtaining another highly purified substrate from the Gram-negative organism *Salmonella typhosa*. It is interesting that blue-green algae contain a mucopolymer cell-wall component closely resembling that found in the cell walls of bacteria [77].

Although it was known that lysozyme splits glycosidic bonds with liberation of *N*-acetylamino sugars, direct evidence establishing the nature of the linkages broken became available only when isolated cell walls were used as a substrate. This question has been discussed recently by *Salton* [78]. He observed that enzymatic lysis of cell walls from *M. lysodeikticus*, *Bacillus megatherium*, and *Sarcina lutea* resulted in dialysable and non-dialysable products; the former consisted in part of a disaccharide of *N*-acetylglucosamine and *N*-acetylmuramic acid and the latter of compounds with molecular weights of 10000 to 20000 [79]. The structure of the disaccharide was determined by *Salton* and *Ghuysen* [80]: it is an *N*-acetylglucosaminyl-$\beta(1 \rightarrow 6)$-*N*-acetylmuramic acid. Quite recently, *Jeanloz* et al. [80a] proposed a different structure with a $\beta(1 \rightarrow 4)$ linkage instead of *Salton*'s $\beta(1 \rightarrow 6)$ linkage. In addition to the disaccharide, a tetrasaccharide was detected [80] which is a dimer of the disaccharide joined by a $\beta(1 \rightarrow 4)$ linkage. This tetrasaccharide (Figure 5) is split by egg-white lysozyme which possesses $\beta(1 \rightarrow 4)$-*N*-acetylglucosaminidase or $\beta(1 \rightarrow 4)$-muramidase action, and may be considered to be a characteristic substrate of lysozyme.

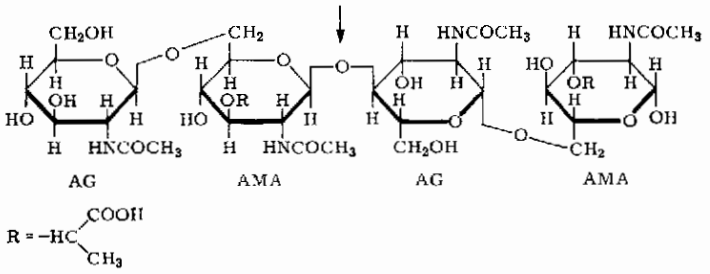

Fig. 5. Tetrasaccharide released by lysozyme from the cell walls of *M. lysodeikticus* and used as a lysozyme substrate [80].
AG = acetylglucosamine; AMA = acetylmuramic acid; the arrow indicates the bond split by lysozyme.

These studies confirm and extend the observations of *Berger* and *Weiser* [81] and of *Perkins* [82]. *Jollès* [83] detected the same disaccharide not only when egg-white lysozyme but also when lysozymes from dog spleen and *Nephthys hombergi* degraded the cell walls of *M. lysodeikticus*. *Ghuysen* found that an enzyme secreted by a *Streptomyces* has the same effect [60].

From these results it was possible to obtain an idea of the structure of the cell-wall mucopeptide. The wall probably has a basic skeleton [84] of alternating *N*-acetylmuramic acid (AMA) and *N*-acetylglucosamine

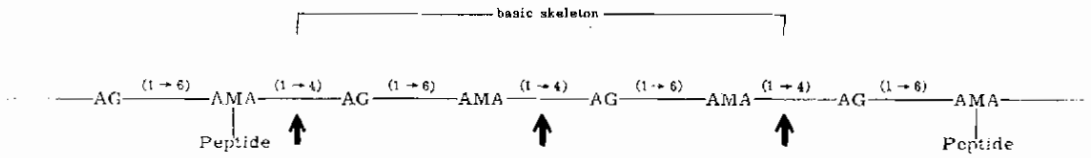

Fig. 6. Schematic representation of the structure proposed for the basic skeleton of the cell walls of *M. lysodeikticus* [80].
AG = acetylglucosamine; AMA = acetylmuramic acid; the bonds marked with arrows are split by lysozyme.

(AG) residues with alternating $\beta(1 \rightarrow 4)$ and $\beta(1 \rightarrow 6)$ linkages. Some of the muramic acid residues have peptide substituents: AMA-Ala-($Glu_1$, $Gly_1$, $Lys_1$, $Ala_1$) [85]. Figure 6 shows the structure proposed by *Salton* for the skeleton of *Micrococcus lysodeikticus* walls.

It is now possible to understand the manner in which lysozyme degrades bacterial walls but many problems concerning lysozyme sensitivity remain to be solved. Lysozyme can act on a naturally resistant cell wall if the substrate is present and exposed by the synergistic action of certain agents, *e.g.* trypsin [86], antibiotica, solvents, or metal complexing reagents [87]. The development of resistance to lysozyme by *M. lysodeikticus*

was described by *Brumfitt* [88,89], who associated this phenomenon with an increase in the content of *O*-acetyl groups in the cell wall, and by *Litwack* [90–92], who reported that resistant cells were white in color and devoid of carotenoids. *Salton* and *Pavlik* [66] established that only walls of *M. lysodeikticus* and *Lactobacillus arabinosus* were more sensitive to lysozyme after removal of *O*-ester groups or teichoic acid. Other explanations of differences in sensitivity to lysozyme include the possibility of different linkages between the amino sugars of the skeleton, differences in the ratios of amino sugars, relatively few disaccharide units, branching points, single amino-acid substituents attached to muramic acid, and a high frequency of cross-linked peptides between muramic acid residues [66].

Finally it is of interest to note that a lysozyme can carry out a transglycosylation reaction: *Salton* [93] observed that on incubation of *Papaya* latex-lysozyme with the disaccharide AG–AMA an appreciable amount of tetrasaccharide is formed.

## V. Conclusion

Thanks to their stability, the lysozymes of different origins are excellent for comparative studies of structure, enzymatic action, speed of action, and specificity. These enzymes also helped to increase our knowledge of the structure of the cell walls of Gram-positive and Gram-negative bacteria. The fact that numerous species of both groups contain a lysozyme substrate lends new interest to *Fleming*'s original hypothesis that lysozyme plays a part in the body's fight against infection. Antibiotic action is certainly one of the functions of the enzyme and will find practical applications; hen's egg-white lysozyme is already used together with other antibiotics. However, distinction must be made between enzymatic and non-enzymatic activity of lysozymes [94]: *e.g.* the role of lysozyme in blood coagulation is due to its basicity; however, when added to cow's milk for feeding sucklings, its action seems to be an enzymatic one. *Runti* [95] has recently published a review on the pharmacological applications of lysozyme. Finally, the production of lysozyme-like substances by a broad variety of living systems seems to indicate a fundamental metabolic role for these enzymes.

# Theories of the Glass Electrode

BY PROF. DR.-ING. K. SCHWABE AND DR. H. D. SUSCHKE

INSTITUT FÜR ELEKTROCHEMIE UND PHYSIKALISCHE CHEMIE DER TECHNISCHEN UNIVERSITÄT DRESDEN (GERMANY)

*A review of the various theories of potential formation on the glass-electrode is followed by a discussion of the deviations from the ideal hydrogen (H) electrode function in the acidic and alkaline ranges from the viewpoint of the phase-boundary-potential theory. The effect of the composition and solubility of the glasses on the electromotive behavior is interpreted as a "medium effect" in the gel layer.*

## I. Introduction

Glass electrodes are used today not only in almost every laboratory and in the most diverse industrial undertakings for measuring and regulating pH [1,2], they are also finding increasing use in the determination of alkali ion content [3]. Although the formation of potentials on glass membranes has been studied for some sixty years, theoretical treatment of the phenomenon is difficult and has only in recent years yielded a certain modicum of clarity. It is thus understandable that numerous attempts have been made at interpretation of the electromotive behavior of glass electrodes, starting from a variety of points of view.

The *adsorption-potential theory* starts from the concept that an adsorbed layer of cations, especially $H^+$-ions, exists at the glass surface in equilibrium with the corresponding ions in solution. A potential drop occurs at the adsorption layer/solution boundary and corresponds to the chemical potential difference between adsorbed and free ions.

[1] *R. G. Bates:* Electrometric pH-Determinations. Wiley, New York 1954.

[2] *K. Schwabe:* Fortschritte der pH-Meßtechnik. Verlag Technik, Berlin 1958.

[3] *H. D. Suschke* and *J. Lüdenbach,* Z. Chem., in the press.

The *membrane-potential theory* considers the glass membrane to be permeable to cations, in particular to $H^+$-ions, and regards the potential drop as a diffusion potential caused by the difference in mobility of the cations and anions in the glass.

The *statistical-mechanical theory* attempts to interpret the behavior of the glass-electrode by considering the bond relations between the cations, especially $Na^+$- and $H^+$-ions, in the glass and in the solution. The passage of the $H^+$- and $Na^+$-ions from one phase into the other is computed statistically. The potential difference arises from the difference in the chemical potentials of the ions, which tend to attain an exchange equilibrium.

The *phase-boundary-potential theory* also traces the cause of the glass-electrode potential to the formation of a thermodynamic equilibrium between the glass phase and the electrolyte solution. Because the ions participating in the establishment of the equilibrium, especially the $H^+$-ions, must be present in both phases (hence also in the glass phase), and furthermore because the establishment of the potential at the glass electrode occurs much faster than would be expected from a true phase equilibrium, it is assumed that only the gel layer of the glass participates directly in the establishment of equilibrium. According to recent measurements [4], it is even certain that only that part of the gel layer which is directly adjacent to the solution is responsible for the establishment of the potential, whereas the deeper regions of the gel layer have essentially no effect upon potential formation. The external part of the gel layer exchanges ions with both the glass phase and the solution and acts as an intermediary in the establishment of equilibrium between the deeper regions of the gel layer and the electrolyte solution.

The preceding classification is actually more or less arbitrary, because the views of the various authors approach and overlap one another in many respects. In the following, a review is presented of the development and status of the theory of the glass electrode.

## I. Adsorption-Potential Theory

During investigations of the electromotive behavior of quartz membranes, *von Lengyel* alone and in collaboration with *Matrai* [5] found that even though the potential of quartz glass electrodes depends on the pH of the solution, it does not obey the Nernst relationship. Since quartz is a nearly ideal dielectric, it prevents establishment of the electrical equilibrium in the solid phase which is necessary for the existence of a quartz-solution phase-boundary potential. Thus the electrical behavior of the quartz membrane is attributed to an adsorption potential, *i.e.* the potential drop is caused by a difference in the concentration of charge carriers in the adsorption layer relative to that in the solution. Although these considerations cannot be applied without reservation to electrode glasses, which have relatively high electrical conductivity and current carrying capacity, *Yevstrop'yev* and *Suikovskaya* [6] also assumed such an adsorption mechanism for glass electrodes. Assuming that the Freundlich adsorption relationship also holds for $H^+$-ions on glass, they found that

$$\frac{\Delta E}{\Delta \ln c_{H^+}} = \left(1 - \frac{1}{n}\right) \frac{RT}{F} \qquad (1)$$

where E = electrode potential; R = gas constant; $c_{H^+}$ = proton concentration in solution; T = absolute temperature; n = constant in the Freundlich equation; F = Faraday constant

A linear dependence of the electrode potential on the hydrogen ion concentration in the electrolyte is thus obtained, although the slope is smaller than that for the hydrogen electrode.

Moreover, the behavior of the glass electrode in acidic and alkaline ranges cannot be interpreted by means of this theory.

## II. Membrane-Potential Theory

### 1. The Glass Foil as a Membrane

*Cremer* [7] and *Michaelis* [8] investigated electrical phenomena at membranes and observed characteristics similar to those shown by the glass electrode, and thus arrived at a basically different concept. They therefore interpreted the electromotive behavior of the glass electrode in terms of the specific permeability characteristics of the glass. *Michaelis* observed that the ratios of anion to cation mobility in various membranes are much lower in the membrane than in the solution. He therefore assumed by analogy that only $H^+$-ions can pass through the glass membrane in the acidic and neutral range.

The glass-electrode potential can then be computed from the Donnan equations for semipermeable membranes or from diffusion potentials, setting the anion mobility at zero. On this assumption, *Cremer* derived a hydrogen-electrode function [$E = f(H^+)$] for the potential at the glass membrane:

$$E = \frac{l_K - l_A}{l_K + l_A} \cdot \frac{RT}{F} \ln \frac{a_{H^+(b)}}{a'_{H^+}} + \frac{l_K - l_A}{l_K + l_A} \cdot \frac{RT}{F} \ln \frac{a'_{H^+}}{a_{H^+(a)}} \qquad (2)$$

where $l_K$ = mobility of the cation; $l_A$ = mobility of the anion; $a'_{H^+}$ = $H^+$-activity in the glass; $a_{H^+}$ (a) and $a_{H^+}$ (b) = $H^+$ activity on sides (a) and (b) of the glass electrode, respectively

[4] *K. Schwabe* and *H. Dahms*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *65*, 518 (1961).

[5] *B. v. Lengyel*, Z. physik. Chem., Abt. A *153*, 425 (1931); *159*, 145 (1932); *159*, 393 (1932).

[6] *Yu. Yevstrop'yev* and *Suikovskaya*, cited in *B. P. Nikolskiy*, Zh. Fiz. Khim. *10*, 495 (1937).

[7] *M. Cremer*, Beitr. Physiol. *2*, 229 (1924); in *A. Bethe* and *G. Bergmann:* Handbuch der normalen und pathologischen Physiologie. Springer, Berlin, Vol. 8, p. 999.

[8] *L. Michaelis*, Naturwissenschaften *14*, 33 (1926).

Assuming that the hydrogen-ion activity in the glass $a'_{H^+}$ is constant and setting $l_A = 0$ (*i.e.* the anion makes no contribution to the diffusion potential since it does not cross the phase boundary), Equation (2) becomes:

$$E_H = \frac{RT}{F} \ln \frac{a_{H^+(b)}}{a_{H^+(a)}} \tag{3}$$

This equation is still valid even when the solution contains other ions, provided their mobilities in the glass membrane are negligible compared to that of the $H^+$-ions.

To interpret the deviations of the glass electrode from the function given in (3), *Michaelis* assumed that other ions, especially alkali metal ions, can also diffuse through the glass at higher pH values, but he gave no quantitative relationships.

### 2. Comparison of the Glass-Electrode Potential to a Liquid Potential

A quantitative explanation of the electrode error was first given by *Dole*, who rejected the view of the glass membrane as a semipermeable membrane but retained the concept of the glass-electrode potential as a liquid potential.

a) *Acid Error*

*Dole* [9] regarded the altered activity of the water in the solution under examination as the source of the acid error in the glass electrode. By assuming that $H_2O$ is transferred concurrently with the $H^+$-ion, he determined the acid error quantitatively as

$$\Delta E_{acid} = \frac{RT}{F} \ln a_{H_2O(b)} \tag{4}$$

b) *Alkali Error*

To interpret the alkali error, *Dole* also took the activity of the $Na^+$-ion in the solution and in the glass into account and considered the cell:

$$\begin{array}{c|c|c} \text{Reference Solution (a)} & \text{Glass} & \text{Test Solution (b)} \\ a_{H^+(a)} & a'_{H^+};\ a'_{Na^+} & a_{H^+(b)};\ a_{Na^+(b)} \end{array} \tag{5}$$

which yields an electromotive force

$$E_g = \varepsilon_a + \varepsilon_b = \frac{RT}{F} \ln \frac{l_{H^+}\, a_{H^+(b)} + l_{Na^+}\, a_{Na^+(b)}}{l_{H^+}\, a_{H^+(a)}} \tag{6}$$

$$= \frac{RT}{F} \ln \frac{a_{H^+(b)} + a_{Na^+(b)}\, l_{Na^+}/l_{H^+}}{a_{H^+(a)}}$$

(where $\varepsilon_a$ and $\varepsilon_b$ = phase-boundary potentials)

under conditions at which the Planck-Henderson relationsbip is valid (*i.e.* at constant mobility of the ions in both phases) and hence the mobility of the anions in the glass can be taken as zero.

Since Equation (3) is valid for ideal behavior, the alkali error of the glass electrode becomes

$$\Delta E_{alkali} = E_g - E_H = \frac{RT}{F} \ln \frac{a_{H^+(b)} + a_{Na^+(b)}\, l_{Na^+}/l_{H^+}}{a_{H^+(b)}}$$

$$= \frac{RT}{F} \ln \left[ 1 + \frac{l_{Na^+}}{l_{H^+}} \cdot \frac{a_{Na^+(b)}}{a_{H^+(b)}} \right] \tag{7}$$

This relation predicts an increasing alkali error with decreasing hydrogen-ion activity and with increasing $Na^+$-activity. It shows furthermore that for low $H^+$-activity, as long as $l_{Na^+} \ll l_{H^+}$, the error increases with $\ln a_{Na^+(b)}$ and that thus the glass electrode functions as a sodium electrode.

Because the ratio $l_{Na^+}/l_{H^+}$ is itself found to be dependent on the pH, *Dole* provides the $a_{H^+(b)}$ term with an exponent $n < 1$ to effect agreement with the experimental values:

$$\Delta E_{alkali} = \frac{RT}{F} \ln \left[ 1 + \frac{B}{\left(a_{H^+}\right)^n_{(b)}} \right] \tag{8}$$

$$B = \frac{l_{Na^+}}{l_{H^+}} \cdot a_{Na^+(b)}$$

The constant B must be determined here for every ion which disturbs the H function (hydrogen-electrode function) and for every activity.

According to electrolytic experiments by *Haugaard* [10], the glass electrode cannot be regarded as a selectively permeable ion sieve in the sense of *Michaelis*. *Haugaard* established that only $Na^+$-ions can pass through the glass membrane. However, since his measurements were rendered inaccurate by the release of alkali from the glass and by the small amount of material involved in the reactions, they were repeated by *Schwabe* and *Dahms* [11], who were able to show by using tritium as a tracer that the glass electrode does not act as a membrane providing direct passage of $H^+$-ions.

## III. The Statistical-Mechanical Theory

Equation (7) agrees quantitatively with the experimental results only if it is assumed that the mobility of the $H^+$-ion exceeds that of the $Na^+$-ion by a factor of approximately $10^{11}$. *Dole* [12] was able to explain the value $l_{Na^+}/l_{H^+} = 10^{-11}$ by means of a statistical-mechanical interpretation. Starting from the theory of *Gurney* [13], he assumes that the positive ions assume equilibrium positions and that the distribution of the ions among diffe-

[9] *M. Dole*, J. Amer. chem. Soc. *54*, 2120, 3095 (1932).

[10] *G. Haugaard*, C. R. Trav. Lab. Carlsberg, Sér. chim. *22*, 199 (1938).

[11] *K. Schwabe* and *H. Dahms*, Mber. dtsch. Akad. Wiss. Berlin *1*, 279 [1959].

[12] *M. Dole*, J. chem. Physics *2*, 862 (1934).

[13] *R. W. Gurney*, Proc. Roy. Soc. (London), Ser. A *136*, 378 (1932).

rent energy levels obeys Boltzmann statistics. The H function for the potential of the glass electrode is then attributed to the ability of $H^+$-ions to pass from their equilibrium state close to a water molecule in solution to an equilibrium state at the glass surface.

By computing the number of s- and d-states, *i.e.* the number of ions with sufficient energy to pass from the glass into the solution (s) and from the solution to the glass surface (d), he arrives at the relationship:

$$\Delta E_{alkali} = E_g - E_H \qquad (9)$$

$$= \frac{RT}{F} \ln \left[ 1 + \frac{\beta_{Na^+}}{\beta_{H^+}} \cdot \exp \left( \frac{Q_{Na^+} - Q_{H^+}}{RT} \right) \cdot \frac{a_{Na^+(b)}}{a_{H^+(b)}} \right]$$

where $Q_{Na^+}$ = difference in the bonding energy of the cation $_{Na}{}^+$ in solution and at the glass surface and $\beta$ is the quotient of the probabilities of d and s transitions for any ion.

When the ratio $\beta_{Na^+}/\beta_{H^+}$ is set equal to 1 and $Q_{H^+}$ is larger than $Q_{Na^+}$ by about 15 kcal/mole, one obtains

$$\frac{\beta_{Na^+}}{\beta_{H^+}} \exp \left( \frac{Q_{Na^+} - Q_{H^+}}{RT} \right) = 10^{-11}.$$

## IV. Phase-Boundary-Potential Theory

### 1. Development of the Phase-Boundary-Potential Theory

*Nernst* [14] already predicted the existence of potential differences at solid electrolyte/liquid electrolyte phase boundaries when both phases contain the same ions. Even though it would then be expected that soda glass would show sodium-dependent behavior, *Cremer* [15] established that the potential at the glass/electrolyte phase boundary depends on the acidity of the solution. However, previous work by *Schott* [16] and *Förster* [17] had shown that the glass surface is able to take up water. *Haber* and *Klemensiewicz* [18] considered this hydrated glass as an "electrolytically conductive water phase", in which both the $H^+$ and $OH^-$ activities are constant. They subjected the system

| $H_2O$ | $H_2O$ | $H_2O$ | (10) |
|---|---|---|---|
| I(a) | II | I(b) | |
| $a_{H^+} \cdot a_{OH^-} = \text{const.}$ | $a_{H^+} = \text{const.}$ $a_{OH^-} = \text{const.}$ | $a_{H^+} \cdot a_{OH^-} = \text{const.}$ | |

in which the "solid" water phase II is surrounded on both sides by an aqueous phase I, to a thorough thermodynamic analysis, and obtained for the electromotive force

$$E = \frac{RT}{F} \ln \frac{a_{H^+(b)}}{a_{H^+(a)}} \qquad (11)$$

This relation is used to compute the unknown $H^+$-activity $a_{H^+(b)}$ in practical pH measurements when $a_{H^+(a)}$ is known and kept constant.

However, according to *von Lengyel* and *Blum* [19], this relation is only valid in the pH range from 2 to 9, when a MacInnes glass (72 % $SiO_2$, 22 % $Na_2O$, 6 % CaO) is used. The limited validity of Equation (11) must have remained unknown to *Haber* and *Klemensiewicz*, since they used the glass electrode only for potentiometric titrations. Thus, they neglected to apply their equation to the computation of pH values in the strongly alkaline or strongly acidic regions.

The "solid" water phase with constant $H^+$-activity assumed by *Haber* and *Klemensiewicz* was interpreted by *Watson* [20] in terms of a buffer action exerted on silicic acid by the sodium and calcium silicates present in the glass. With this concept, *Hughes* [21] was able to interpret qualitatively the disturbance of the hydrogen electrode function of the glass electrode in the alkaline region. In the pH region from 2 to 9, the buffer action prevents the ion exchange at the glass/electrolyte boundary – which determines the phase-boundary potential – from altering the $H^+$-activity in the glass phase. However, at pH > 9, the buffer action of sodium silicate is no longer sufficient to stop the decrease of the $H^+$-activity in the glass phase resulting from an exchange with alkali metal ions.

*Hughes* professed to see a confirmation of his theory in the facts that the deviations from the hydrogen-electrode function start at an $H^+$-activity in the solution of $10^{-9}$ and that the first dissociation constant of silicic acid is approximately $10^{-9}$.

However, it is known from studies by *Gardiner* and *Sanders* [22] and by *Powney* and *Jordan* [23] that the higher the $Na^+$-ion concentration in the solution, the higher is the $H^+$-activity at which the glass electrode begins to deviate from the hydrogen-electrode function. This phenomenon and its dependence on the nature of the cation could not be explained by *Hughes*' theory.

*Gross* and *Halpern* [24] interpreted that the deviations in the behavior of the glass electrode at extreme pH values result from the appearance of mixed potentials but were also unable to provide quantitative relationships. They considered not only the solubility of water in the glass phase but also that of the glass in water. An electrolyte $M^+A^-$ dissolved in the aqueous phase should also tend towards an equilibrium distribution between both phases. This assumption leads to a phase-boundary potential:

$$\varepsilon = \frac{RT}{F} \ln \frac{a'_{M^+}}{a_{M^+}} \qquad (12)$$

where $a'_{M^+}$ = the activity of the metal ion in the solid phase
$a_{M^+}$ = the activity of the metalion in the solution

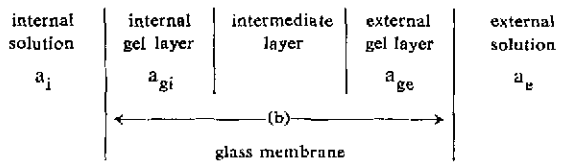
[15] *M. Cremer*, Z. Biol. *47*, 562 (1906).
[16] *O. Schott*, Z. Instrumentenkunde *9*, 86 (1889).
[17] *F. Förster*, Ber. dtsch. chem. Ges. *25*, 2494 (1892); *26*, 2915 (1893).
[18] *F. Haber* and *Z. Klemensiewicz*, Z. physik. Chem. *67*, 385 (1909).
[19] *B. v. Lengyel* and *E. Blum*, Trans. Faraday Soc. *30*, 461 (1934).
[20] *F. J. Watson*, Chem. Engng. Mining Rev. *20*, 59 (1927).
[21] *W. S. Hughes*, J. chem. Soc. (London) *1928*, 491.
[22] *W. C. Gardiner* and *H. L. Sanders*, Ind. Engng. Chem., analyt. Edit. *9*, 274 (1937).
[23] *J. Powney* and *D. O. Jordan*, J. Soc. chem. Ind., Chem. and Ind. *56*, 133 (1937).
[24] *P. Gross* and *O. Halpern*, Z. physik. Chem. *115*, 54 (1925).

The dissociation constants of $M^+ A^-$ in both phases and the distribution coefficient are all involved in this relationship.



If it is assumed that the activity of $M^+$ in the solid phase is negligible in comparison with the $H^+$-activity $a'_{H^+}$ and that (except for the solid electrolyte anion) only $H^+$- or $OH^-$-ions occur in the solid phase, then the ratio $a'_{M^+}/a_{M^+}$ becomes proportional to the $H^+$-activity of the solution.

On the other hand, when there are practically no $H^+$- or $OH^-$-ions present in the glass, and the ionic content of the solid phase is thus determined solely by the ions of the glass itself, then the potential becomes a function of the activity of the $M^+$-ion in the solution. Such an electrode then behaves like a metal electrode and its potential varies according to the Nernst equation.

However, because of numerous simplifying assumptions, some of which appear to be poorly founded, this theory does not lead to quantitative predictions.

## 2. Status of the Phase-Boundary-Potential Theory

The fact that a new glass electrode gives up $Na^+$-ions to the solution and takes up $H^+$-ions in return with formation of a hydrated silica-gel layer led *Haugaard* [25] to the concept of a three-layer membrane in which an intermediate conductor consisting of unaltered glass is covered on both sides with a layer which strongly protects the glass from further attack (Scheme 1).

Scheme 1. Glass-electrode layers according to the phase-boundary-potential theory

This view led to the assumption that a thermodynamic equilibrium is established only between gel layer and solution without direct participation of the intermediate conductor.

*Schwabe* and *Glöckner* [26] thus subjected the transport of electrical charges by $H^+$-ions across the a/b and b/c phase boundaries to thermodynamic analysis. The change in chemical potential on passage of one mole of $H^+$-ions from the internal solution into the internal gel layer is

$$\Delta\mu_{(b)/(a)} = \mu_{gi} - \mu_i \qquad (13)$$
$$= \left(\mu^\circ_{gi} - \mu^\circ_i\right) + RT \ln \frac{a_{gi}}{a_i} = + F \cdot \varepsilon_{(a)/(b)}$$

Similarly, for the passage of $H^+$-ions from the external solution into the external gel layer:

$$\Delta\mu_{(b)/(c)} = \left(\mu^\circ_{ge} - \mu^\circ_e\right) + RT \ln \frac{a_{ge}}{a_e} = + F \cdot \varepsilon_{(c)/(b)} \qquad (14)$$

If the same reference state is always choosen for the chemical potential of the $H^+$-ions in the gel layer, then $\mu^\circ_{ge} - \mu^\circ_{gi}$. Since $\mu^\circ_e$ also equals $\mu^\circ_i$, the potential difference between the internal and external solutions is:

$$E_{(a(/(c)} = \varepsilon_{(a)/(b)} + \varepsilon_{(b)/(c)} = \frac{RT}{F} \ln \frac{a_e}{a_i} + \frac{RT}{F} \ln \frac{a_{gi}}{a_{ge}} \qquad (15)$$

When the $H^+$-activity is the same in both gel layers, the electromotive force of the glass cell becomes

$$E = \frac{RT}{F} \ln \frac{a_e}{a_i} . \qquad (16)$$

The deviation from ideal behavior is then given by

$$\Delta E = \frac{RT}{F} \ln \frac{a_{gi}}{a_{ge}} . \qquad (17)$$

Consequently, the phase-boundary-potential theory is able to explain both the acid and alkali errors by changes in the $H^+$-activity in the gel layer. However, supplementary assumptions are necessary to account for the mechanism of this activity change.

### a) *Interpretation of the Acid Error*

Some time ago, *MacInnes* and *Belcher* [27] discovered that the glass electrode shows deviations from the H function in the strongly acidic range. They attributed these poorly reproducible potential shifts to the effect of anions in the solution. *Dole* [9] did not accept this view, since he was unable to observe any effect of the anion species in solution in the neutral range even at high electrolyte concentrations; this was confirmed by *Schwabe* [28] in a series of careful measurements. *Dole* saw the cause of the acid error in the altered activity of the water in the test solution and determined the acid error from Equation (4). However, *Hubbard*, *Hamilton*, and *Finn* [29] discovered that the behavior of the electrode glass differed in strong HCl and in $H_2SO_4$. The acid error of a MacInnes-glass electrode in 5 N HCl observed by *Sinclair* and *Martell* [30] exceeded the error computed by *Dole*, whereas measurements in 5 N and 10 N $H_2SO_4$, even on prolonged exposure, yielded smaller errors than would be expected from *Dole*'s relationship. On the other hand, *Ismailov* and *Aleksandrova* [31] were able to demonstrate a pure anion function with certain electrode glasses in strongly acidic solutions. *Ismailov* and *Vassil'yev* [32] sought the cause

of this phenomenon in the replacement of the hydroxyl group in the Si–OH of the gel layer by an anion from the acid. Finally, *Beck* and *Wynne-Jones* [33] ascribe the deviation of the glass electrode in the acid range solely to a change of the asymmetry potential.

*Schwabe* and *Glöckner* [26] also investigated the behavior of the glass electrode in HCl, $H_2SO_4$, and $H_3PO_4$. For the acid-error range, they assumed a rise in $H^+$-activity in the external gel layer, leading to a negative value of $\Delta E$ [see Equation (17)] in agreement with experiment. Furthermore, since the electroneutrality of the gel layer must be preserved, the following processes are conceivable:

α) The transfer of $H^+$-ions from the solution to the gel layer is associated with a simultaneous transfer of anions.

β) In accordance with the ion-exchange equilibrium

$$Na^+_{glass} + H^+_{soln} \rightleftharpoons Na^+_{soln} + H^+_{glass}$$

a $Na^+$-ion is given up to the solution for each $H^+$-ion penetrating into the gel layer.

γ) Although their volumetric concentration remains constant, the activity of the $H^+$-ions can be increased by dehydration of the gel layer.

The change in the acid error of a MacInnes-glass electrode with time can be described by the relation

$$-\Delta E_{acid} = A + B \log (C + t) \qquad (18)$$

Since at time $t = 0$, the acid error is zero, one obtains

$$q = 10^{-\Delta E_{acid}/B} = \frac{C + t}{C} \qquad (19)$$

A similar relationship is obtained when $a_{gi}$ in Equation (17) is made equal to C and the increment of the $H^+$-activity in the outer gel layer caused by the acid is denoted by x

$$-\Delta E_{acid} = \frac{RT}{F} \ln \frac{C + x}{C} \qquad (20)$$

$$q = 10^{-\Delta E_{acid} \cdot F/2.303 \cdot RT} = \frac{C + x}{C}$$

The increment x of the $H^+$-activity in the external gel layer can thus be deduced from the variation of q with time.

When $\frac{dq}{dt} = \frac{t}{C}\left(\frac{dx}{dt}\right)$ is constant – as is the case with HCl – then the acid uptake is uniform. Case α) can then be assumed to apply, for the rate of penetration of the acid will be proportional to its concentration, which is not appreciably decreased.

On the other hand, the reverse reaction will set in to a noticeable extent in cases β) and γ), after a unidirectional process has gone on for a time. Thus, a constant value for dq/dt cannot be expected. This is in fact observed with $H_2SO_4$ and $H_3PO_4$.

These results were checked and confirmed by *Schwabe*, *Dahms*, *Nguyen*, and *Hoffmann* [34] by means of radioactive tracer experiments. It turned out that the uptake of acid by the gel layer, u, was about an order of magnitude higher in 4 N HCl than in equal concentrations of HBr or HI, the immersion times being equal in all cases. Since the acid error q exhibits the same behavior and the ratio u/q for these acids has practically the same value for any given time, the acid error can be unequivocally attributed in these cases to the uptake of acid by the gel layer.

The variation with time of the acid error $dq/dt = \dot{q}$ varies with the acid concentration and also assumes consistently much higher values for HCl than for HBr or HI.

If it is assumed that only ion pairs penetrate into the gel layer, it would be expected that the acid error would increase with activity, *i.e.* with the vapor pressure of the acid over the solution. However, at equal acid concentrations, the vapor pressures of hydrogen halides decrease rapidly in the sequence $HCl \gg HBr \gg HI$; it is thus understandable that the acid error also decreases in the same order.

However, $\dot{q}$ will also increase with the vapor pressure of the acid. *Boksay*, *Csákvári*, and *von Lengyel* [35] had already found that for HCl, the variation of the acid error with time can be expressed by the relationship

$$\log \dot{q} = K_1 \log p_{HCl} + K_2 \qquad (21)$$

The fact that the quotients

$$\frac{\log \dot{q}_{HCl}/\dot{q}_{HBr}}{\log p_{HCl}/p_{HBr}}, \quad \frac{\log \dot{q}_{HCl}/\dot{q}_{HI}}{\log p_{HCl}/p_{HI}} \quad \text{and} \quad \frac{\log \dot{q}_{HBr}/\dot{q}_{HI}}{\log p_{HBr}/p_{HI}}$$

yield similar values confirms the hypothesis that the abilities of the halogen acids to penetrate into the glass depends significantly on their fugacities.

In contrast there was no observable uptake of sulfate or phosphate ions by the gel layer. The acid error can be ascribed here to the reduced activity of the water in these acids. The acid error calculated from Equation (4) is in satisfactory agreement with the values obtained experimentally for $H_2SO_4$ and $H_3PO_4$.

While the acid error can thus be explained successfully by assuming that the acid molecules migrate into the gel layer (case α) or that the activity of water in the gel layer is altered (case γ), the alkali error can be derived quantitatively by assumption of ion exchange at the glass surface (case β).

### b) *Interpretation of the Alkali Error*

In his treatment of the alkali error of the glass electrode, *Nikolskiy* [36,37] considered the ion exchange that occurs at the glass surface and linked it with certain ideas of *Horovitz* [38], who had previously assumed that

[33] *W. H. Beck* and *W. F. K. Wynne-Jones*, J. Chim. physique *49*, 97 (1953).

[34] *K. Schwabe*, *H. Dahms*, *O. Nguyen*, and *G. Hoffmann*, Z. Elektrochem., Ber. Bunsenges. physik. Chem. *66*, 304 (1962).

[35] *Z. Boksay*, *B. Csákvári*, and *B. v. Lengyel*, Z. physik. Chem. *207*, 223 (1957).

[36] *B. P. Nikolskiy*, Zh. Fiz. Khim. SSSR *10*, 495 (1937).

[37] *B. P. Nikolskiy* and *T. A. Tolmatsheva*, Zh. Fiz. Khim. SSSR *10*, 513 (1937).

[38] *K. Horovitz*, Z. Physik *15*, 369 (1923).

cations in the glass can be replaced by cations from the solution via an "exchange" adsorption (he later corrected this to "ion exchange" [39]). According to his view, in acid solutions, $H^+$-ions are taken up and impart a $H^+$-solution pressure to the glass electrode. According to this concept, the glass electrode can take up other positive ions in neutral and alkaline solution in lieu of $H^+$ and can then act as an Na, K, or Li electrode, depending on the cation in the solution.

According to this picture, $Na^+$- and $H^+$-ions are exchanged between the glass and the solution until an equilibrium is established between the nascent gel layer Q and the solution:

$$H^+_{soln} + Na^+_Q \rightleftharpoons H^+_Q + Na^+_{soln} \qquad (22)$$

The position of this equilibrium depends on the activity of the ions in the solution and on their bonding strength in the gel layer and in the solution.

Using the equilibrium constant for this ion exchange

$$K = \frac{a_{H^+} \cdot N_{Na^+} \cdot f'_{Na^+}}{a_{Na^+} \cdot N_{H^+} \cdot f'_{H^+}}, \qquad (23)$$

where $f'_{Na^+}$ and $f'_{H^+}$ = the activity coefficients in the gel layer, and $N_{Na^+}$ and $N_{H^+}$ = the mole fractions of the ions in the gel layer,

and from thermodynamic considerations, *Nikolskiy* arrived at the relationship

$$E_G = E^\circ + \frac{RT}{F} \ln \frac{a_{H^+} \cdot (f'_{Na^+}/f'_{H^+}) + K \cdot a_{Na^+}}{f'_{Na^+}}, \qquad (24)$$

where $N_{Na^+} + N_{H^+} = N_0$ is assumed to be constant.

*Nikolskiy* first assumed that the interaction of the $H^+$- and $Na^+$-ions with the neighboring positive and negative ions is constant for a given glass and is independent of the degree to which the $Na^+$-ions have been replaced by $H^+$-ions. He considered these interactions to be weak because of the relatively large distances between the ions and because the intervening medium (silicic acid) has a relatively high dielectric constant (5–7). He therefore assumed $f'_{Na^+} = f'_{H^+} = 1$ and obtained from (24):

$$E_G = E^\circ + \frac{RT}{F} \ln (a_{H^+} + K \cdot a_{Na^+}). \qquad (25)$$

The alkali error $\Delta E_{alkali}$ then becomes

$$\Delta E_{alkali} = E_G - E_H = -\frac{RT}{F} \ln \left(1 + K \frac{a_{Na^+}}{a_{H^+}}\right) \qquad (26)$$

which is identical with the relationship derived by *Dole* by statistical analysis.

The exchange constant K can be determined by measurement of the electromotive force of the glass cell at varying $Na^+$-activities and constant pH values [39]. Thus, at 20 °C one obtains from Equation (25)

$$\left(\frac{\partial E}{\partial \log a_{Na^+}}\right)_{pH} = \alpha = 58 \frac{K \cdot a_{Na^+}}{a_{H^+} + K \cdot a_{Na^+}} \qquad (27)$$

or

$$K = \frac{\alpha \cdot a_{H^+}}{(58 - \alpha) \cdot a_{Na^+}}. \qquad (28)$$

[39] *K. Horovitz*, Z. physik. Chem. *115*, 424 (1925).

However, the value of K can also be computed from measurements of the EMF of the glass cell at constant $Na^+$-activity and variable pH when $E^\circ$ is known from measurements within the range of applicability of the hydrogen-electrode function. In the high pH range, where the glass electrode behaves like a sodium electrode, one obtains:

$$E_{Na} = E^\circ + \frac{RT}{F} \ln K + \frac{RT}{F} \ln a_{Na^+} \qquad (29)$$

$$\text{or} \quad -\log K = \frac{E^\circ - E_{Na}}{58} + \log a_{Na^+}. \qquad (30)$$

However, later investigations showed that even though Equation (25) holds well in the region of applicability of the pure hydrogen-electrode function ($a_{H^+} \gg K a_{Na^+}$) and of the pure sodium-electrode function ($a_{H^+} \ll K a_{Na^+}$), it shows large deviations (up to 20 mv) from data obtained experimentally in the transition region.

In a generalized theory, *Nikolskiy* [40] accounts for this phenomenon by assuming that because of the differences in composition, structure, and relative arrangement of the anions, the $H^+$-ions may form z species of bonds with the anions in the gel layer. Thus the activity coefficients of the $H^+$-ions remain constant, independent of their concentration in the gel layer, but vary for the various anion species. Furthermore, the $Na^+$-activity in the gel layer is assumed to be equal to the $Na^+$-concentration regardless of which sites the $Na^+$-ions occupy. *Nikolskiy* thus arrived at the relationship.

$$E = E^\circ - \frac{RT}{F} \ln \sum_{i=1}^{z} \frac{\alpha_i \cdot \beta_i}{a_{H^+} + \alpha_i \cdot K \cdot a_{Na^+}}. \qquad (31)$$

It is assumed that the stability of a bond between an $H^+$-ion and an anion species $A_1^-$, $A_2^-$, ····· $A_z^-$ in the glass phase increases from 1 to z. Furthermore, an equilibrium is assumed to be set up in the gel layer between free $H^+$- and $Na^+$-ions and the $H^+$- and $Na^+$-ions bound to anions of species i ($A_i^-$)

$$H^+A_i^- + Na^+_{free} \rightleftharpoons Na^+A_i^- + H^+_{free} \qquad (32)$$

The equilibrium constant for this reaction is $\alpha_i$. Its value decreases as the strength of the bonds between the $H^+$-ions and the $A_i^-$-anions increases.

Let us denote the number of anion sites per unit volume of the glass at which $H^+$-ions can form the bond i by $N_i^\circ$; $N_i^\circ$ then consists of sites occupied by $H^+$-ions ($N_i$) and sites occupied by $Na^+$-ions ($N_i^\circ - N_i$). We thus obtain

$$\alpha_i = \frac{N_i^\circ - N_i}{N_i} \cdot \frac{a''_{H^+}}{a''_{Na^+}}. \qquad (33)$$

where a'' = the activity of the "free" ions in the glass phase.

Assuming the activity coefficient of the $Na^+$-ions to be constant ($f_{Na^+} = 1$) and considering all the bonds of the $H^+$-ions from 1 to z, it follows that

$$a''_{H^+} = \sum_{i=1}^{z} \alpha_i \cdot N_i. \qquad (34)$$

[40] *B. P. Nikolskiy*, Zh. Fiz. Khim. *27*, 724 (1953).

Hence, the $H^+$-activity in the glass phase is seen to be the sum of partial activities, each representing the product of the individual equilibrium constant $\alpha_i$ and the concentration of the $HA_i$ molecules. Thus, $\alpha_i$ can be regarded formally as the activity coefficient of the $H^+$-ions that enter into bonds of type i. The state of the $H^+$-ions that form the weakest type of bond, *i.e.* bonds of type 1 representing the state of the $H^+$-ions in $HA_1$ molecules, is taken as the standard state with $\alpha_1 = 1$. We can then designate $\beta_i = N_i^0/N_1^0$ as the ratio of sites with bonds of type i to those with bonds of the weakest type 1 ($\beta_1 = 1$).

1. In the case of the same kind of bonding of all the $H^+$-ions in the gel layer ($\beta_2 = \beta_3 = 0; \alpha_1 = 1$), Equation (31) reverts to the relationship obtained from the simple ion-exchange theory

$$E = E^0 + \frac{RT}{F} \ln \left(a_{H^+} + K \cdot a_{Na^+}\right). \tag{35}$$

2. Limiting Cases

*a)* $a_{H^+} \gg K \cdot a_{Na^+}$

$$E = E^0 - \frac{RT}{F} \ln \sum_{i=1}^{z} \frac{\alpha_i \beta_i}{a_{H^+}} \tag{36}$$

$$= E^0 - \frac{RT}{F} \ln \sum_{i=1}^{z} \alpha_i \beta_i + \frac{RT}{F} \ln a_{H^+},$$

$$= E^{0'} + \frac{RT}{F} \ln a_{H^+}.$$

The glass electrode behaves like a hydrogen electrode.

*b)* $a_{H^+} \ll K \cdot a_{Na^+}$

$$E = E^0 - \frac{RT}{F} \ln \sum_{i=1}^{z} \frac{\beta_i}{K \cdot a_{Na^+}} \tag{37}$$

$$= E^0 + \frac{RT}{F} \ln K - \frac{RT}{F} \ln \sum_{i=1}^{z} \beta_i + \frac{RT}{F} \ln a_{Na^+},$$

$$= E^{0''} + \frac{RT}{F} \ln a_{Na^+}.$$

The glass electrode behaves like a sodium electrode.

By assuming three types of bonds (z = 3), it is generally possible to choose such values of the constants $\alpha_i$ and $\beta_i$ that their substitution in Equation (31) will give good agreement with experiments.

Whereas Equation (31) is based on the assumption that the activity coefficient of the $Na^+$-ions in the gel layer is constant and that only $f'_{H^+}$ can assume a range of values, exactly the opposite conclusion was reached by *von Lengyel, Czákvári,* and *Boksay* [41]. They assumed that the $H^+$-ions in the gel layer are predominantly bound to $H_2O$ molecules, so that deep penetration of the protons into the electron cloud of the oxygens in the silicate framework can hardly be expected; however, their polarizing action via hydrogen bridges remains more strongly marked than that of the metal cations.

[41] *B. v. Lengyel, B. Csákvári,* and *Z. Boksay,* Acta chim. Acad. Sci. hung. *25*, 225 (1960).

Incorporation of an $H^+$-ion in the gel layer shifts the distribution of the electrons surrounding the oxygen atom in such a way that the bonding between the oxygen and the more distant ions is weakened. Thus, the activity coefficient of the $H^+$-ions should be regarded as constant, while $f'_{Na^+}$ should vary with the composition of the gel layer. On the basis of this picture, an equation describing the alkali error is developed which contains three empirical constants.

These assumptions of *Nikolskiy* and *von Lengyel* serve only to simplify the process of the computation. However, radioactive tracer measurements of the concentration of ions in the gel layer, combined with simultaneous observation of the electromotive forces [4], gave some information concerning the variation of the activity of $H^+$- and $Na^+$-ions with their concentration in the gel layer. Since the activity $a'_{H^+}$ of the $H^+$-ions in the gel layer may be considered constant in the range of the H function of the glass electrode, and the same is true for $a'_{Na^+}$ in the range of pure Na function, it is advantageous to define these activities as reference states with $a'_{H^+} = 1$ for the H function and $a'_{Na^+} = 1$ for the Na function, respectively.

With this assumption it is easy to determine the activity of the $H^+$-ions in the gel layer in the range of the alkali error of the glass electrode by means of the cell

$$(Pt)H_2/a_{H^+(b)}, a_{Na^+}/glass/a_{H^+(a)}, KCl, Hg_2Cl_2/Hg \tag{38}$$

In the range of pure H function of the glass electrode and with a constant internal content, this cell has a constant EMF at varying $a_{H^+(b)}$. The deviations $\Delta E$ in the alkali-error range can then be attributed solely to a change in the $H^+$-activity in the gel layer:

$$\Delta E_{alkali} = -\frac{RT}{F} \ln a'_{H^+} \tag{39}$$

or, when the EMF is expressed in pH units:

$$\Delta pH = -\log a'_{H^+} \tag{40}$$

The concentration of $H^+$ in the gel layer, corresponding to the activity $a'_{H^+}$ computed from Equation (40), is obtained from measurements of the uptake of $Na^+$ by the gel layer.

If the total number $N_0$ of exchangeable sites per unit area of the gel layer is divided among the $H^+$- and $Na^+$-ions, then the share x falling to each of these ions is

$$x_{Na^+} = \frac{N_{Na^+}}{N_0} \quad \text{and} \quad x_{H^+} = 1 - x_{Na^+}. \tag{41}$$

$N_0$ can be determined radiochemically with $^{24}Na$, from the saturation value for uptake of $Na^+$ by the gel layer from a solution of low $H^+$- and high $Na^+$-activity. The number $N_{Na^+}$ of $Na^+$-ions exchanged per $cm^2$ may also be obtained from radiochemical measurements.

Employing the equilibrium constant for the ion exchange, which can be obtained from a single EMF measurement in the range of the Na function of the glass electrode,

$$K = \frac{10^{-pH}}{10^{-\Delta pH} \cdot a_{Na^+}} = \frac{a_{H^+} \cdot a'_{Na^+}}{a'_{H^+} \cdot a_{Na^+}} \quad (42)$$

$a'_{Na^+}$, the activity of the $Na^+$ in the gel layer can then be calculated. This value corresponds to that of $a'_{H^+}$ in Equation (40).

Figure 1 shows a plot of the $H^+$-activity obtained from Equation (40) *vs.* the mole fraction $x_{H^+}$ derived from (41), and of $a'_{Na^+}$ computed from (40) and (42) *vs.* $x_{Na^+}$. It is seen that both $f'_{Na^+}$ and $f'_{H^+}$ vary with the composition of the gel layer.

A simple relationship exists between the activities of the $H^+$- and $Na^+$-ions in the gel layer:

$$a'_{Na^+} = \left(1 - a'_{H^+}\right)^n \quad (43)$$

With the aid of Equations (40), (42), and (43), it is possible to set up a simple function describing the dependence of the alkali error of the glass electrode on the activities of the $H^+$- and $Na^+$-ions in the solution.

$$\Delta pH + n \log \left(1 - 10^{-\Delta pH}\right) = pH + \log a_{Na^+} + \log K . \quad (44)$$

The factor n can be found from a single EMF measurement in the region of transition from the H to the Na function.

*Nikolskiy* tested his theory primarily on glasses containing $Al_2O_3$ and $B_2O_3$, which were already known from *Hughes*' experiments to show deviations from hydrogen-electrode function even in the neutral range.

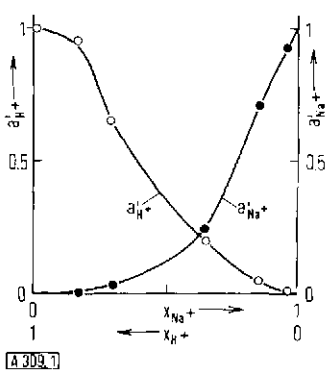

Fig. 1. Relationship between the activity (a') and the mole fraction (x) of the $H^+$- and $Na^+$-ions in the gel layer of a titanium glass.

The replacement of $H^+$ in the gel layer by $Na^+$ from the solution occurs readily in these glasses because borates and aluminosilicates bind $Na^+$-ions more firmly than silicates. It can also be assumed that the gel layer contains complex silicic acids, in which the proton bond to the anion is weakened.

The stronger the bonding of the alkali metal ions to the glass and the weaker the corresponding $H^+$-ion bonding, the more readily the electrode function changes. While MacInnes glass (exchange constant $K = 2 \times 10^{-12}$) shows pure hydrogen-electrode function up to pH 11 in solutions of low $Na^+$ content, marked deviations from ideal behavior can be observed in sodium glass containing approximately 9 % $B_2O_3$ even at pH 7 ($K = 6 \times 10^{-9}$). In sodium glasses containing approximately 7 % $Al_2O_3$ ($K = 2 \times 10^{-6}$), these disturbances of the H function start already in the strongly acid region [36, 37]. Furthermore, the pH values at which the deviations of the glass electrode from the H function start decrease with increasing $Na^+$ concentration in the solution.

However, it is not only transitions from H to Na function that are obtained with glass electrodes, transitions from one metal-electrode function to another are also observed. *Nikolskiy* et al. [42] made a quantitative study of the effect of various ions on the Na function of a sodium glass by comparing the cell without transport

$$Ag/AgCl,NaCl(a)/glass/NaCl(a'),AgCl/Ag \quad (45)$$

which has the equilibrium EMF

$$E_{eq} = \frac{RT}{F} \ln \frac{a_{NaCl}}{a'_{NaCl}} + \varepsilon_{As} \quad (46)$$

where $\varepsilon_{As}$ is the asymmetry potential, with the hypothetical Helmholtz double cell

$$Ag/AgCl,NaCl(a')/Na/NaCl(a''),AgCl/Ag , \quad (47)$$

which has a theoretical EMF

$$E = \frac{2\,RT}{F} \ln \frac{m'_{NaCl} \cdot f'_{\pm NaCl}}{m''_{NaCl} \cdot f''_{\pm NaCl}} \quad (48)$$

When the glass electrode in cell (45) behaves like an ideal Na electrode and the EMF of this cell is measured with a constant internal content using both an NaCl solution of activity $a'_{NaCl}$ ($E'_{eq}$) and an NaCl solution of activity $a''_{NaCl}$ ($E''_{eq}$), then the EMF must be:

$$\Delta E_{eq} = E'_{eq} - E''_{eq} = E$$

If another chloride (MCl), whose concentration is kept constant during a test series, is then added to the NaCl solution then the EMF of cell (47) will be

$$E = \frac{RT}{F} \ln \frac{m'_{NaCl}\,(m'_{NaCl} + m_{MCl})}{m''_{NaCl}\,(m''_{NaCl} + m_{MCl})} + 2\frac{RT}{F} \ln \frac{f'_{\pm NaCl(MCl)}}{f''_{\pm NaCl(MCl)}} \quad (49)$$

where m = concentration in moles/kg of solvent.

As long as the $M^+$-ion added does not affect the Na function of the glass electrode, the relationship $\Delta E_{eq} = E$ still holds.

Mixtures of NaCl with HCl, LiCl, KCl, RbCl, $NH_4Cl$, $MgCl_2$, and $CaCl_2$ were studied in this way at 20, 35, 60, and 65 °C. The MCl concentration was constant and the NaCl concentration ranged from $10^{-3}$ to 2 M.

The effect of cations on the Na function of a soda-glass (71 % $SiO_2$, 3 % $Al_2O_3$, 11 % $B_2O_3$, 15 % $Na_2O$) electrode decreases in the order $H^+ > K^+ > Li^+ > Rb^+ > NH_4^+ > Mg^{++} > Ca^{++}$.

The effect of these cations on the K function of an electrode of potassium glass (71 % $SiO_2$, 3 % $Al_2O_3$, 11 % $B_2O_3$, 15 % $K_2O$) decreases in the order $H^+ > Na^+ > Li^+ > Ba^{++} > Mg^{++} > Ca^{++}$.

[42] *B. P. Nikolskiy, M. M. Schulz,* and *N. V. Peschechonova*, Zh. Fiz. Khim. SSSR *32*, 19 (1958).

The $Li^+$-ion has a relatively small effect on the Na or K function of a glass electrode.

Potassium glasses do not appear suitable for practical application, since they have high melting points and narrow transformation ranges [*] – serious disadvantages in the preparation of glass electrodes. Furthermore, potassium-glass electrodes have very high resistance and display high and variable asymmetry potentials.

However, a K function can be induced to a marked extent in Na glass electrodes by subjecting the latter to prolonged electrolysis in a solution of a potassium salt [43].

In order to test whether the simple ion-exchange theory can give a quantitative explanation of the transition of boron aluminosilicate glasses from the Na function to H, K, and Li functions, *Nikolskiy* et al. [44] considered the cell

$$Ag/AgCl,NaCl(a)/glass/NaCl(a') + MCl,AgCl/Ag \qquad (50)$$

Using a soda glass and applying the ion-exchange theory, they calculated the equilibrium EMF of the cell to be

$$E_{eq} = \frac{RT}{F} \ln \frac{K \cdot a_{NaCl}}{a'_{MCl} + K\, a'_{NaCl}} - + \varepsilon_{As} . \qquad (51)$$

The difference in EMF of two mixed solutions with MCl and NaCl activities a′ and a″, respectively, is:

$$\Delta E_{eq} = \frac{RT}{F} \ln \frac{a'_{MCl} + K\, a'_{NaCl}}{a''_{MCl} + K\, a''_{NaCl}} . \qquad (52)$$

From this, the change in EMF to be expected theoretically can be computed if the exchange constant and the average activity coefficients of MCl in the presence of NaCl ($f_{\pm\,MCl(NaCl)}$) and of NaCl in the presence of MCl ($f_{\pm\,NaCl(MCl)}$) are known for the given case. A comparison can then be made with the experimental values determined with cell (50). Every deviation from the simple ion-exchange theory must then show up as a difference between the calculated and observed values. It was thus established at room temperature that there are deviations in the region of transition from the Na- to the H-electrode function which can only be explained with the aid of the generalized theory. Since these deviations do not occur at higher temperature (65 °C), it can be assumed that the exchange constants of the variously bonded $H^+$-ions become identical at higher temperatures. On the other hand, since the transition of the glass electrode from the Na function to the K or Li function also follows the "simple" ion-exchange theory in the transition region, all the bonds of the $Na^+$-, $K^+$-, or $Li^+$-ions to the silicate anion in the gel layer can be regarded as being energetically equivalent.

When small amounts of $Al_2O_3$ and $B_2O_3$ are added to the glass, the behavior of the glass electrode can be described by Curve I (Fig. 2) and can be explained by the generalized theory; however, higher concentrations (3–9 %) of $Al_2O_3$, $B_2O_3$, $Fe_2O_3$, or $ZrO_2$ (Curve II) cause the disappearance of the second region (d-e) of the hydrogen-electrode function [45].

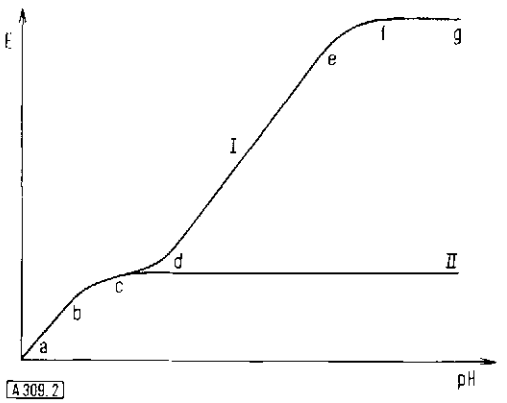

Fig. 2. Dependence on pH of the glass-electrode potential E for various glass compositions.
Curve I: Low $Al_2O_3$ and $B_2O_3$ content.
Curve II: A total content of 3–9 % $Al_2O_3$, $B_2O_3$, $Fe_2O_3$, $ZrO_2$.

The region a-b corresponds to the pure H function; b-c-d is the region of transition from the H to the metal function. This region corresponds to the replacement of the $H^+$-ions which are weakly bound to the anions of the gel layer by alkali metal ions from the solution. In the segment d-e, the electrode has a partial H function owing to firmly bonded $H^+$-ions in the gel layer. These are also displaced from the gel layer at high pH values so that the pure metal function (f-g) results after a new transition region e-f. Curve I is gradually transformed into curve II with increasing content of $B_2O_3$ or $Al_2O_3$; thus, addition of sufficient amounts of these oxides can produce glass electrodes which display pure metal functions over wide ranges of pH [19,46].

Although interpretation of the electromotive behavior of the glass membrane in terms of adsorption potentials does not lead to quantitative relationships, it is possible to give a satisfactory explanation of the behavior of the glass electrode not only in the neutral region but also in alkaline and acid media by means of either the membrane theory or diffusion potentials. However, since it has been definitely established that the glass electrode is not a semipermeable membrane, preference must be given to the phase-boundary-potential theory. With its help, the behavior of the glass electrode in both the acid and alkaline regions can be explained, but only after the determination of two or three empirical constants.

### c) *Interdependence of Electrode Function and Glass Composition*

The relationship between the composition of the electrode glass and the electromotive behavior can also be interpreted, in principle, on the basis of the phase-boundary-potential theory. The first empirical attempt to explain the differing electromotive behavior of glasses of different composition was undertaken by *Horovitz*

[*] Transformation range denotes the range of temperature, where the glass is plastic.

[43] *B. P. Nikolskiy*, Zh. Fiz. Khim. SSSR *10*, 504 (1937).

[38,39]. According to his studies, the H function of a glass is related to its solubility. He established nearly pure H functions for easily attacked glasses but found a sodium functional behavior in glasses that were resistant to attack. *Horovitz* hypothesized that the adsorption of $H^+$-ions reaches a saturation value relatively fast with readily attacked glasses, whereas with resistant glasses this state occurs only at very high $H^+$-activities in the solution, so that a hydrogen function can be expected here only in the acid region.

*Hubbard, Hamilton,* and *Finn* [29] also found a relationship between the H function and the solubility of the glass. Systematic investigations [47] of Na and K glasses of various compositions revealed that glasses of very high chemical stability and low water uptake and glasses with high solubility and high water uptake yield H functions that do not obey the Nernst relationship: $\Delta E/\Delta pH = 58$ mv at 20 °C (cf. Fig. 3). Optimum electrode behavior is shown by glasses of intermediate solubility, containing 84–86 % $SiO_2$ and 14–16 % $Na_2O$.

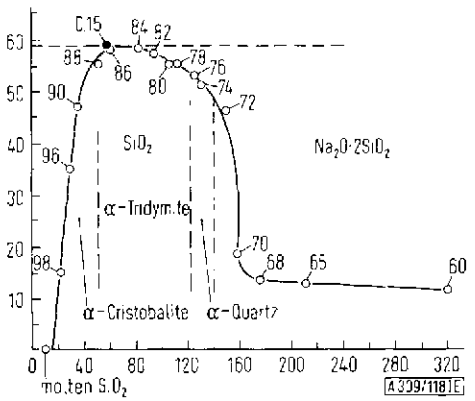

Fig. 3. Average $\Delta E/\Delta pH$ values for various $Na_2O$–$SiO_2$ glasses and for Corning-0.15-glass as a function of their hygroscopicity.

(The numbers at the plotted points give the percentage of $SiO_2$ in the glass.)

Ordinate: $\Delta E/\Delta pH$ [mv].

Abscissa: Water uptake at saturation [mg/ml].

As emphasized by *Nikolskiy* [36,37,40,42–45], the difference in bonding energies of the $H^+$- and $Na^+$-ions in the glass phase and those in the solution plays a decisive role in the formation of the gel layer. These factors determine the magnitude of the exchange constant K, which evidently assumes higher values for Na-functional electrode glasses, because the bond energy of the $H^+$-ions in the glass phase of these glasses is of the same order of magnitude as that of the $Na^+$-ions. However, high solubility of the glass implies high hydration energy of the ions in the glass, since otherwise the bond energies in the solid could not be overcome. Dissolution of the glass is thus preceded by solvation of the ions, leading to the water uptake observed. However, the more the solid swells, the more waterlike the solid phase becomes. This is associated with weakening of the bond between the $H^+$-ions and the anions in the glass; the standard state of the $H^+$-ions in the glass phase thus approaches that of the $H^+$-ions in the aqueous solution. The phase-boundary potential must then decrease, since it depends on the existence of two different phases with different standard states of the same ion.

When the pure H function is chosen as the reference state for the $H^+$-ions in the gel layer, and the chemical potential of the $H^+$-ions in the gel layer is written as

$$\mu = \mu^0 + RT \ln a'_{H^+} \qquad (53)$$

then, for a pure H function, $\mu^0$ refers to the $H^+$-activity ($a'_{H^+} = 1$) in the gel layer. It also seems appropriate to assume a "medium effect" in the glass phase, analogous to the change in $H^+$-activity observed at constant $H^+$-concentration in aqueous solutions upon addition of organic solutes, *i.e.* a decisive effect on the form of the electrode function can be ascribed to the water content of the gel layer. Thus, in the formation of an ideal H function, the equilibrium constant for the exchange between $H^+$-ions and the cations of the glass is not the only important factor, since the water content of the gel layer is also of great significance.

It is only when this content is low compared with that in the solution, *i.e.* when there is a sharp phase boundary, that there can be a phase-boundary potential that rigorously satisfies the Nernst equation in the form of Equation (25). It also follows from studies of the kinetics of the variation of the potential and of the rate of uptake of labelled cations by the gel layer [4] that the condition of the phase boundary does in fact determine the potential. In practice, the very slow uptake of alkali metal ions by the interior of the gel layer ceases to influence the potential. On the other hand, in the acid region, where the $K \cdot a_{Na^+}$ term of Equation (35) is negligible, MacInnes glasses show as exact a dependence on the $H^+$-activity, *i.e.* on the average activity of the acid, as the hydrogen electrode does (deviations $\leqq 10$ μv) [48]. From this it may be concluded that a genuine thermodynamic equilibrium is the sole factor determining the potential under these conditions. According to the present state of our knowledge, an ion-exchange equilibrium is involved here at the glass/solution phase boundary. This equilibrium cannot be formed when the glass phase is either a waterlike gel or is only capable of adsorbing ions without formation of an ion-exchanging solid phase (quartz).

# The Reaction of Oxides with Water at High Pressures and Temperatures

BY DR. H. G. WENDLANDT AND PROF. DR. O. GLEMSER

ANORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT GÖTTINGEN (GERMANY)

*Dedicated to Prof. Dr. H. Brockmann on the occasion of his 60th birthday*

*The reactions of the oxides $SiO_2$, $MoO_3$, and $WO_3$ with steam at temperatures between 400 and 700 °C and pressures of 5 to 500 atm were studied by means of the transfer method. The results were evaluated by a new method. In the system $SiO_2/H_2O$, the formation of gaseous $Si(OH)_4$, $Si_2O(OH)_6$, and $[SiO(OH)_2]_\lambda$ was found to occur in three different water-density ranges. In the systems $MoO_3/H_2O$ and $WO_3/H_2O$, the gaseous compounds $MoO_2(OH)_2$ and $WO_2(OH)_2$, which were already known, exist up to densities of approximately 0.05 g/cm³. At higher densities, at which the supercritical phase begins to show the properties of a liquid to an ever increasing extent, isopolymolybdic or isopolytungstic acids appear.*

## 1. Introduction

When various oxides are treated with steam at elevated temperatures and at pressures of up to 1 atm, gaseous hydroxides are formed [1]. Gaseous hydroxides are also formed by evaporation or sublimation of solid and liquid hydroxides. Thus, there are two classes of gaseous hydroxides, which are distinguished by their formation equilibria, as follows:

(1) Evaporation or sublimation equilibrium:
$\text{Hydroxide}_{(\text{solid, liquid})} \rightleftharpoons \text{Hydroxide}_{(\text{gas})}$

(2) Reaction equilibrium:
$\text{Oxide}_{(\text{solid, liquid})} + \text{H}_2\text{O}_{(\text{gas})} \rightleftharpoons \text{Hydroxide}_{(\text{gas})}$

Most of the hydroxides formed according to Equation (2) are stable only at elevated temperatures and in the gaseous state; at lower temperatures, they redecompose into the oxide and water. Several suboxides and subhalides, *e.g.* SiO, AlCl, behave in a similar manner. This reversibility of the equilibrium (2) permits transport of the oxides via the gas phase. Since reactions of this type may also occur in nature, their study can provide the mineralogist and the petrologist with a better understanding of geological transport phenomena which lead to the formation of mineral deposits.

The existence of gaseous hydroxides is also of technical interest. For example, beryllium oxide may be purified by its reaction with steam, *i.e.* via the gaseous beryllium hydroxide [2]. Corrosion phenomena in iron and alloy steel can be better understood; thus the scaling of certain alloy steels takes place more rapidly in the presence of steam, because the alloying elements vanadium, chromium, molybdenum, and tungsten form gaseous hydroxides [1]. Indeed, even the well-known reaction between steam and iron proceeds above 1300 °C according to:

(3) $\text{Fe}_{(\text{solid})} + 2\,\text{H}_2\text{O}_{(\text{gas})} \rightleftharpoons \text{Fe(OH)}_{2(\text{gas})} + \text{H}_{2(\text{gas})}$

*i.e.* via the formation of gaseous $Fe(OH)_2$ [3].

However, neither in nature nor in technical applications are the reactions of oxides with steam limited to pressures below 1 atm. Therefore, it was the purpose of the present investigations to study oxide reactions with steam at pressures ranging from 1 atm to supercritical pressures [4]. It might be pointed out already now that, at low steam pressures, the reactions can be described to a good approximation by assuming ideal behavior in the gas phase. However, at higher pressures or densities a range is attained in which the supercritical phase gradually acquires the properties of a liquid. Thus, the gas phase changes into a system in which, as *Franck* [5] has shown, solvation and electrolytic dissociation can occur in the same fashion as in liquid water.

The question is whether definite compounds can be expected under such conditions. Several authors [6] answer in the affirmative as far as the reaction of $SiO_2$ with water is concerned; however, they differ greatly in their opinions as to what possible compounds actually do exist.

In the following, the reactions of $SiO_2$, $MoO_3$, and $WO_3$ with water at elevated temperatures and pressures will be discussed.

## II. Experimental Technique

### 1. General Description of the Apparatus and Method

Equilibrium reactions between an oxide and steam can be investigated by the transfer method. In this process, steam (diluted, if necessary, with an inert gas) is passed through the reaction zone in such a way that it is satu-

[3] *G. R. Belton* and *F. D. Richardson*, Trans. Faraday Soc. *85*, 1562 (1962).

[4] The term "supercritical water" or "supercritical phase" was applied by *E. U. Franck* [5] to water at supercritical temperatures with densities $\geq$ 0.2–0.3 g/cc.

[5] *E. U. Franck*, Angew. Chem. *73*, 309 (1961).

[6] Literature references see Section IV. 1 (The System $SiO_2/H_2O$).

rated with the reaction products under equilibrium conditions. The reaction products are carried along by the gas stream and are condensed in the receiver as oxides which are then determined quantitatively.

The apparatus for measurements at pressures below 1 atm is shown schematically in Figure 1. Its basic features have been

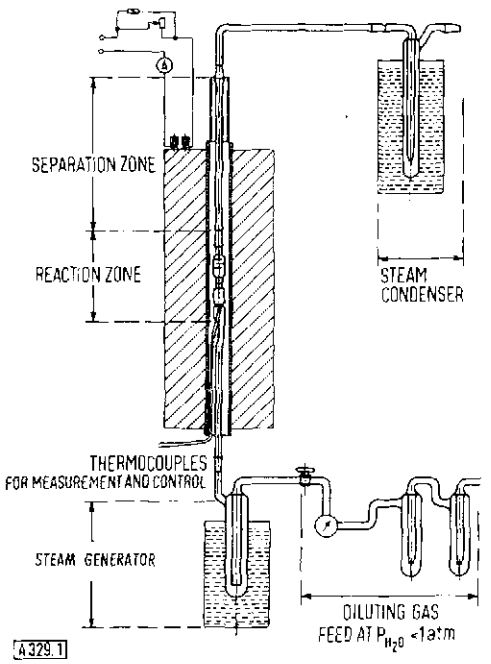

Fig. 1. Diagram of a transfer-method apparatus for pressures of up to 1 atm.
A = ammeter.

adapted for application to the high-pressure equipment (Fig. 2). In the latter, water from the feed vessel W is passed at a given temperature over the oxide contained in the reaction cell R. Below the critical point, the total pressure in the reaction cell is given by the pressure of the saturated water vapor. Above the critical point, the pressure is determined by the total volume of the apparatus and by the quantity of

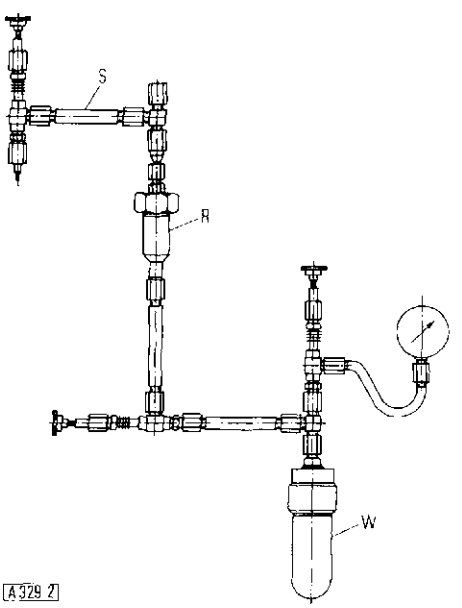

Fig. 2. Diagram of a transfer method apparatus for measuring reactions at higher pressures.
S = separator
R = reaction cell (cf. Fig. 3)
W = water reservoir.

water present in it at that time. The steam containing the dissolved reaction products is cooled in the separator S to a temperature of 60–70 °C. It is then discharged from the apparatus through a pressure relief valve attached to S. The transported sample, which is mostly dissolved in the liquid water, is determined by analysis of the water collected. When the substance has no solubility in water at the separation temperature, the separator S is unscrewed after the end of the experiment, and the substance precipitated on the walls of this receiver is removed with solvents and analysed.

## 2. Structural Elements of the Apparatus

The various parts of the apparatus [7] are designed to withstand a maximum temperature of 700 °C and pressures of up to 500 atm in the reaction cell. All internal parts of the apparatus are protected by a noble metal lining; the reaction cell (including the feed and drain pipes) is lined with gold foil and the other parts of the apparatus with silver foil.

The water feed vessel W has a volume of approximately 220 $cm^3$ and is provided with a Bridgman seal [8]. The two holes in its cover carry, respectively, a thermowell and a screw fitting. The latter carries adapters for the removal of the water and for attaching the armatures of the pressure gauges.

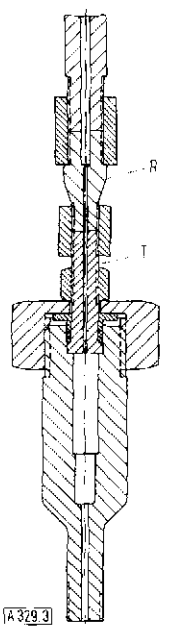

Fig. 3. Reaction cell.
T = transition adapter.
R = reducing adapter.

The reaction cell (Fig. 3) has a volume of approximately 15 $cm^3$ and is sealed with a Bridgman-type seal. The transition adapter T has an axial 1 mm⌀ capillary boring. It is connected to a $^3/_8 \times {}^1/_2$ inch reducing adapter R, which in turn is coupled to the outlet pipe. The 1 mm internal diameter helps to reduce diffusion effects. The total volume of the cell is available for the test material. A platinum wool plug is inserted into the bottom feed pipe to support the test substance. The test substance in the cell is loosely packed to allow good exchange with the passing gas. The topmost layer of the test

[7] Constructed with Remanit 1880 SST, Product No. 4571, from Deutsche Edelstahlwerke. The reaction vessel was made of Thermax 1636, Product No. 6864, from Deutsche Edelstahlwerke.

[8] *P. W. Bridgeman:* The Physics of High Pressure. McMillan, New York 1950.

substance is compressed and sintered, in order to prevent elutriation of fine particles. Depending on the nature of the test material, 20–40 g of it can be placed in the reactor.

The reactor cell and the feed vessel are connected by means of pipes with 22 mm outer diameter and 6 mm internal diameter. The separator is of the same dimensions as the connecting pipes. Self-sealing flanges without gaskets are used throughout. The flange bolts carry double locking nuts. The 4 mm internal diameter valves [9] serve both for cutoff of the flow and for regulation of the flow rate.

The water feed vessel and the reaction cell are heated by resistance furnaces. Each of these furnaces has two coils, which can be controlled separately. In addition, each furnace has an auxiliary heating coil, so that better control over the preset temperature gradients can be achieved. The exposed parts of the apparatus and the ends of the furnaces are insulated with asbestos wool in order to minimize heat losses. The separation zone S is wound with a lead coil through which cold water flows.

The temperature over the entire length of the reaction cell is measured by means of miniature-thermocouples (Chromel-Alumel), which are placed in thermowells. The e.m.f. produced is measured in a potentiometer circuit. Compensating wires lead from the thermocouples to a constant-temperature junction. Several calibrated platinum/platinum-rhodium thermocouples are used as controls.

Two resistance thermometers with appropriate controllers are available for regulating the temperature of the reactor furnace. All other controllers are activated by means of thermocouples. The water temperature in the feed vessel is controlled by means of a thermocouple placed in a thermowell immersed in the water. This thermocouple activates a controller connected to an auxiliary resistance heater, wrapped around the feed vessel. The feed vessel is placed in a furnace the temperature of which is kept 5 °C below the desired water temperature. When working in the supercritical range, the temperature of the water is controlled manually from the manometer readings, using the auxiliary heating coil.

Pressure measurements are made with a Class 1.0 set of manometers, which were checked against PTB-calibrated [*] manometers. In the subcritical range good agreement is reached between the manometer pressure and the saturated-steam temperature and pressure as given by the steam tables of the Verein Deutscher Ingenieure [10]. The density of the supercritical phase was calculated from the data of *Holser* and *Kennedy* [11].

## 3. Evaluation of Results

Let us consider the general reaction equation

(4) $r\,(\mathrm{Oxide})_{solid} + m\,(H_2O)_{gas} \rightleftharpoons [(\mathrm{Oxide})_r \cdot m\,(H_2O)]_{gas}$

Experimentally, the moles of oxide $n^*_{ox}$ dissolved per mole of $H_2O$ ($n_{H_2O}$) at equilibrium are determined. However, $n_{H_2O} \gg n^*_{ox}$ and $P_{total} \approx P_{H_2O}$. Therefore, the mole fraction $X^*_{ox}$ of the transported oxide is

$$X^*_{ox} = n^*_{ox}/n_{H_2O}$$

Since the effect of the saturated oxide vapor pressure can be disregarded, it follows that $X_{hyd} = n_{hyd}/n_{H_2O}$, where $n_{hyd}$ = the number of moles of hydroxide formed in the reaction and $X_{hyd}$ = the mole fraction of the hydroxide with the empirical formula $[(\mathrm{Oxide})_r \cdot m\,H_2O]$ formed in the reaction.

In order to clarify the stoichiometry of Equation (4), the coefficient m, which we designate as the association number, is determined first. To do this, $X_{hyd}$ has to be expressed as a function of the concentration of the water in the gas-filled space. In this way, we account for the real behavior of the gas or supercritical phase, as well as for the pressure dependence of the chemical potential of the solid phase. Thus the measurements are described as a function of the pressure-volume-temperature data of water, known experimentally and represented by the density. It will be assumed that interactions between the molecules of the nascent compound, as well as interactions between these molecules and those of the water, have no perceptible influence. The equilibrium constant of Equation (4) is:

$$K_c = C_{hyd}/(C_{H_2O})^m \qquad (5)$$

where $C_{hyd} = C_{[(\mathrm{Oxide}) \cdot m\,H_2O]}$

Moreover, $C_{hyd} = n_{hyd}/V$ and $C_{H_2O} = n_{H_2O}/V$.

$V \approx V_{H_2O} = n_{H_2O}/\rho_{H_2O}$; $V_{hyd} \ll V_{H_2O}$; $\rho_{H_2O}$ = density of the water; V = total volume.

Using Equation (5), one obtains

$$(6)\quad K_c = \frac{n_{hyd}}{n_{H_2O}} \cdot \frac{\rho_{H_2O}}{(\rho_{H_2O})^m} = X_{hyd}\,\frac{1}{(\rho_{H_2O})^{m-1}}$$

The pressure dependence of the chemical potential $\mu_{oxide}$ of the solid phase may be expressed as

$$\left(\frac{\delta \mu_{oxide}}{\delta p}\right)_T = V_{oxide}$$

where $V_{oxide}$ = molar volume of the oxide.

By integrating the pressure from $p^1 = 1$ atm to the reaction pressure P and by assuming pressure independence of the molar volume we obtain

$$\mu^P_{Oxide} - \mu^o_{Oxide} = P \cdot V_{Oxide}$$

and, therefore,

$$(6a)\quad \log a = \frac{V_{Oxide} \cdot P}{4{,}574 \cdot T}$$

where a = activity of the solid phase. Accordingly, the experimental data can be represented by the equation

$$(7)\quad K^a_c = \frac{X_{hyd}}{(\alpha_{Oxide})^r \cdot (\rho_{H_2O})^{m-1}}$$

where $K^a_c$ = equilibrium constant

or

$$(8)\quad \log [X_{hyd}/(a_{Oxide})^r] = (m-1) \log \rho_{H_2O} + \log K^a_c$$

Equation (8) can be evaluated, if the reaction follows Equation (4). However, since the present investigation covers a wide range of densities, *viz.* from 0.003 to 0.8 g/cm³, the possibility of the occurrence of several reactions must be considered. Certain density ranges might be reserved to a certain kind of molecules, others might be transition ranges, in which more than one species may occur. On the basis of these assumptions, Equation (8) becomes the equation of the tangent of the curve that limits the range of existence of the i-th species. It therefore permits determination of the i-th association number and the i-th equilibrium constant. If the experimental conditions are favorable, then the curves for the range of existence can be approximated with straight lines.

[9] Supplied by: A. Hofer, Hochdruckapparatebau GmbH, Mülheim/Ruhr (Germany).

[*] PTB = Physikalisch-Technische Bundesanstalt (The German Bureau of Standards).

[10] *E. Schmidt:* VDI-Wasserdampftafeln. Springer, Heidelberg 1956.

[11] *W. T. Holser* and *G. C. Kennedy*, Amer. J. Sci. *256*, 744 (1958); *257*, 71 (1959).

The evaluation is first carried out with an estimated value of r. The determination of the association number m is not adversely affected by this, but the value of the equilibrium constant becomes uncertain by a factor of r. This first evaluation yields an indication whether several species, *i.e.* several reactions, occur in the density range considered. If this is the case, the evaluation is repeated with the most probable r values.

## III. Experimental Procedure

The powdered sample is made into a paste using a small amount of water and then dried at 300 °C. The resulting hard material is crushed into particles of 2–3 mm diameter. The reaction cell is filled with the sample. Material of a somewhat larger particle size (5–6 mm diameter) is placed at the bottom of the cell. A total of 20–40 g of substance is normally needed. The cell is then closed and connected to the apparatus. Screw joints, which will be subjected to high temperatures, are lightly greased with molybdenum disulfide paste. At this stage the movable furnace attached to a mounting frame is still in its upper position to allow free access to the cell and the thermocouples. The auxiliary heaters are installed. The furnace is then lowered and turned on. The preselected temperature program is regulated by means of a controller and checked on recorder charts. While the furnace is heating up, the feed vessel W is filled with doubly distilled water, and also heated to the temperature required for the desired pressure.

The actual experiment starts after the preselected temperatures have become stabilized. The pressure relief valve is then opened and adjusted to a flow rate of 10–20 g of water/hour. It has been ascertained by preliminary tests that, other conditions being equal, the quantity $A_{(Oxide)}$ of substance transported is independent of the rate of flow in this flow range.

The condensed water, in which the entrained substance is dissolved, is removed through the pressure relief valve. A graduated tube, provided with Schellbach strips, serves as receiver; using this tube and a stop watch, the flow rate can be rapidly checked and regulated as necessary. Five to 10 ml of water are collected for one determination. Since the apparatus has a dead volume [12] of approximately 5 ml (based on a water density of 1.0), each run was preceded by a forerun in which 5–10 ml of condensate was removed and discarded. In this way, the effect of the dead volume is eliminated; in addition, the forerun also allowed careful adjustment of the flow rate. Below the critical point, the pressure in the entire apparatus is, of course, a well-defined function of the water temperature in the feed tank. In the supercritical range, the total pressure can be kept constant to a good approximation by increasing the temperature of the water in the feed vessel.

### Error Analysis

Assuming that the solid phase is well defined and remains unaltered during the measurement, systematic errors can occur owing to supersaturation or incomplete saturation in the reaction cell. Supersaturation can occur as a result of diffusion. Incomplete saturation is caused by too high a flow rate, which would exceed the reaction rate [13]. Both errors can be reduced by taking suitable precautions in the construction of the apparatus. When proper experimental conditions are selected, such errors can be eliminated for all practical purposes. The analytical methods used for determining the transferred substance were checked with standard solutions. The accuracy of the temperature and pressure measurements was tested by control runs and was checked against calibrated thermocouples and gauges. They were thus eliminated as a source of systematic errors. The individual measurements may vary within the following limits:

| | |
|---|---|
| Reaction temperature: | ± 2 °C |
| Pressure: | ± 3 atm (for pressures below 100 atm ± 2 atm) |
| The quantity of entrained substance: | ± 3 % |

## IV. Examples

### 1. The System $SiO_2/H_2O$

Data on the reaction between $SiO_2$ and water can be obtained from the solubility of the oxide, determined at various pressures and temperatures. The experimental breakthrough goes back to the work of *Morey* and *Hesselgesser* [14] and *Kennedy* [15]. These authors found that the solubility of $SiO_2$ in steam increases with pressure. According to *Jasmund* [16] and *Mosebach* [17], the data obtained by the above authors can be correlated by the empirical equation [18, 19],

$$\log L = (m \cdot \log D) + b$$

which led to the conclusion that the association number is m = 2, hence the reaction was formualted as $SiO_2 + 2\,H_2O = Si(OH)_4$. In agreement with this finding, *Franck* [20] and *Wasserburg* [21] have also adopted the association number of m = 2 for the entire pressure range up to 2000 bars. *Wood* [22] believes that m = 2

[12] The dead space is the volume between the reaction cell and the pressure release valve.

[13] *H. K. Hofmeister, R. von Haeseler,* and *O. Glemser,* Z. Elektrochem., Ber. Bunsenges. physik. Chem. *64,* 513 (1960).

[14] *G. W. Morey* and *J. M. Hesselgesser,* Trans. Amer. Soc. mech. Engrs. (ASME) *1951,* 865; Econ. Geol. *46,* 821 (1951).

[17] *R. Mosebach,* Neues Jb. Mineralog. Mh. *87,* 351 (1955); J. Geology *65,* 347 (1957).

[18] L = the solubility of $SiO_2$ in water [g of $SiO_2$ per kg of water]; D = density of the vapor phase; m = association number; b = a constant dependent upon the temperature.

[19] This empirical relationship can be derived from an expression given by *Franck* [20]. For the limiting case of high densities and strong interaction *Franck* obtains the formula

$$\ln \frac{X_2}{x_2^0} = \frac{V_{2f} \cdot P}{RT} + m \ln \frac{K_m}{V}$$

where $X_2$ = the mole fraction of solute, $x_2^0$ = the mole fraction of oxide dissolved under its own vapor pressure, $V_{2f}$ = the molar volume of the solid, P = total pressure, m = association number, 1/V = overall density, and $K_m$ = constant.

[20] *E. U. Franck,* Z. physik. Chem. N. F. *6,* 345 (1956); Angew. Chem. *73,* 309 (1961).

[21] *G. J. Wasserburg,* J. Geology *66,* 559 (1958).

[22] *J. A. Wood,* Amer. J. Sci. *256,* 40 (1958); see, however, *G. J. Wasserburg* and *J. A. Wood,* Amer. J. Sci. *256,* 438 (1958).

probably holds to a pressure of 500 bars; he assumes that the association numbers are greater at higher pressures. On the other hand, *Brady* [23] believes that m = 3 holds for lower pressures and m = 2 for higher pressures.

We have studied the effect of water on $SiO_2$ (quartz) [24] at 400 and 500 °C, between 10 and 500 atm. The quantity of $SiO_2$ transported was determined as silicomolybdenum blue by photometric analysis of the silicic acid dissolved in the condensed water [25,26]. Concentrations of as low as 0.001 mg of $SiO_2$ per g of water could be detected by this method.

*Results*

The results of measurements made at 400 and 500 °C are plotted in Figure 4 in the form $\log X_{hyd} = f(\log \rho_{H_2O})$, corresponding to Equation (6). For orientation purposes, the pressures (in atm) corresponding to the various temperatures are printed above the abscissa for several density values. The figure also shows the experimental data of *Morey* and *Hesselgesser* and of *Kennedy*. The agreement of our values with those given by

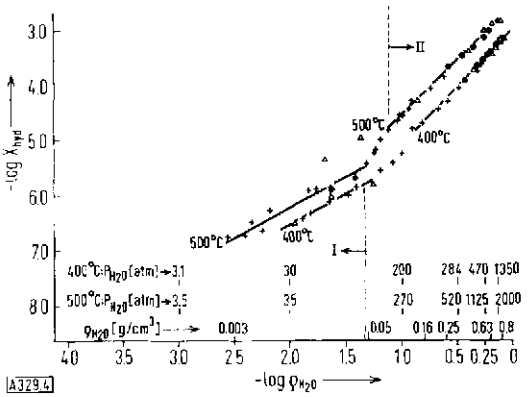

Fig. 4. Solubility of $SiO_2$ (quartz) in $H_2O_{(gas/liquid)}$ at 400 and 500 °C in relation to the density of the water.

● Values of *Kennedy*

+ Our values.

these authors is good, so that all the experimental data can be discussed together. Two density ranges (I, II) appear. To a good approximation the points in each range fall on a straight line (isotherm). In range II, the increase in the solubility with the density is greater, but it is assumed that this is not caused by changes in the solid phase.

For higher pressures the pressure dependence of the chemical potential of the solid phase has to be taken into account, according to Equation (4). The recalculated data are given in Figure 5. Let us assume r = 1 for the density range I and r = 2 for range II. Up to pressures of approximately 350 atm, the curves in Figure 5 are in practically complete agreement with those in Figure 4. With in-

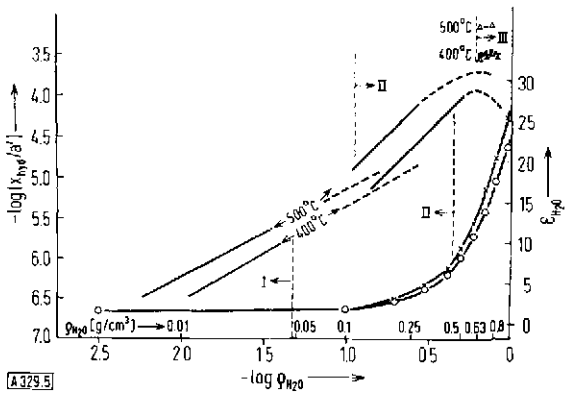

Fig. 5. Solubility of $SiO_2$ (quartz) in $H_2O_{(gas/liquid)}$ at 400 and 500 °C in relation to the density of the water. The values measured were evaluated with due consideration of the pressure dependence of the chemical potential and on the assumption of different possible reactions.

o Dielectric constant $\varepsilon_{H_2O}$ at 500 °C.

creasing pressure, however, a sharp curvature becomes apparent. From this, one would infer a negative solubility gradient, which seems impossible. The downward curvature actually results from the fact that the assumption of r = 2 does not hold any more at high pressures. Thus, a transition region appears between the density range II and another range III. Assuming that r = 1, we find that, within the limits of error, the isotherms in range III run parallel to the abscissa. In order to get a first orientation the limits of the various density ranges might be drawn, irrespective of different temperatures, as follows:

| | |
|---|---|
| Density range I | up to approximately 0.05 g/cm³ |
| Density range II | from 0.1 to 0.45 g/cm³ |
| Density range III | from 0.65 g/cm³ upwards |

The transition region between I and II coincides with the sharp increase of the dielectric constant (DC) with density, as is clearly evident from the shape of the curve in Figure 5 [27]. The increase in solubility observed in range II might be correlated with this increase of the DC. It is important to note that the solubility starts increasing below a density of 0.2–0.3 g/cm³, which served as a basis for the definition of the "supercritical water" [4].

The values of aggregation number r have been surmised. Their postulation can be reconciled with the following considerations. *Morey* et al. [28] have shown that in the range 65–300 °C and at 1000 atm, the heat of solution of quartz is 5.4 kcal/mole. From the temperature function of the isotherms of density range II, we found a heat of solution of quartz of 10.6 kcal per unit formula. This estimate was made with only two $K_c$ values, but the result is representative since each $K_c$ value is based on approximately 20 determinations.

By this, one avoids the use of the term kcal/mole, since it is not known from our experiments how many moles of the solid phase participate in the reaction. This limitation also

[26] *J. Bochem*, Mitt. Vereinig. Großkesselbesitzer *27*, 150 (1952).

[27] The dielectric constants are taken from a publication by *Franck* [20].

[28] *G. W. Morey, R. O. Fournier*, and *J. J. Rowe*, Geochim. cosmochim. Acta *26*, 1029 (1962).

holds for the value given by *Morey* et al. It can be seen that the values are related by a ratio of approximately 1:2. The conditions of *Morey*'s experiment correspond roughly, as far as the density and the pressure are concerned, to those of our density range III. Assuming that the heat of solution of quartz in kcal/mole has the same value in ranges II and III, and that one mole of $SiO_2$ per unit formula enters into the reaction in range III, it follows that in range II 2 moles of $SiO_2$ per unit formula are dissolved. Accordingly, if $r_{III} = 1$, we would have to assume that $r_{II} = 2$. With these values for r we have plotted log $(X_{hyd}/a^r)$ versus log $\rho_{H_2O}$ (Fig. 5); $X_{hyd}$ is the mole fraction that was determined with the given value of r; $r_I$ was likewise made equal to 1.

In Figure 5, there are three prominent density ranges, I, II, and III, with the corresponding association numbers $m \approx 2$, $m \approx 3$, and $m \approx 1$ [29]. Using the tentative aggregation numbers $r_I \approx 1$, $r_{II} \approx 2$, $r_{III} \approx 1$, the experimental results can be represented by the following equations:

| | | Density range |
|---|---|---|
| (9) | $SiO_{2(quartz)} + 2\,H_2O_{(gas)} \rightleftharpoons Si(OH)_{4(gas)}$ | I |
| (10) | $2\,SiO_{2(quartz)} + 3\,H_2O_{(gas)} \rightleftharpoons Si_2O(OH)_{6(gas)}$ | II |
| (11) | $SiO_{2(quartz)} + H_2O_{(gas)} \rightleftharpoons SiO(OH)_{2(gas)}$ | III |

$Si(OH)_{4(gas)}$ appears under reaction conditions which correspond approximately to ideal behavior in the gas phase. The other compounds are present as solutes in the supercritical phase only. Their designation by the subscript (gas) holds true only when the supercritical phase is defined as a gaseous phase. This, however, is not quite justified, since in range III (Equation 11) the density approaches a value of 0.6 g/cm³. Therefore, this reaction should be regarded as a reaction in solution. Furthermore, the nascent "$SiO(OH)_{2(gas)}$" will possibly polymerize yielding oligosilicic acids [30] of the type $(H_2SiO_3)_x$, with x = 5 or 6 [31].

## 2. The System $MoO_3/H_2O$

The reaction of $MoO_{3(solid)}$ with $H_2O_{(gas)}$ has been investigated at steam pressures below 1 atm and temperatures of 400–630 °C [32, 33]. Gaseous molybdenum hydroxide is formed according to the equation:

$$MoO_{3(solid)} + H_2O_{(gas)} \rightleftharpoons MoO_2(OH)_{2(gas)}$$

The effect of $H_2O$ on $MoO_3$ at higher pressures had not yet been studied systematically. The first paper about this problem was published by *van Nieuwenberg* and *Blumendal* [34]. *Elliott* [35] later attempted to determine what association number should be assigned to the reaction of steam with $MoO_3$ at higher pressures. He gives an association number of m = 1, but does not specify to what pressure this number applies. Scrutiny of his experimental results does not allow any conclusions on this matter either.

We studied the action of water on $MoO_3$ between 380 and 500 °C in the pressure range 10–500 atm. As solid phase, we used chemically pure, analytical grade $MoO_3$ from E. Merck, Darmstadt. The amount of $MoO_3$ transported was determined by two analytical methods. In the first, the molybdenum compound is titrated with a 0.005 M lead nitrate solution, which gives lead molybdate [36]. Pyridyl-2-azoresorcinol is used as an indicator. The other method uses the fact that molybdenum(VI) solutions form a yellow complex with thioglycolic acid in weakly acidic solutions (pH 3.5 to 4.5). This complex is well suited to the photometric determination of molybdenum. The extinction is measured at 365 mμ [37]. The titrimetric method allows determination of concentrations of 0.2 mg of $MoO_3$ per g of water, provided a lead nitrate solution of known concentration is added prior to titration. With the photometric method, as little as 0.01 mg of $MoO_3$ per g of water can be determined.

### *Results*

Figure 6 shows the results of the measurements at 500 °C. From a density of 0.05 g/cm³ onwards, the solubility starts to increase. After a transition interval, the solubility curve assumes a constant slope. This curve of

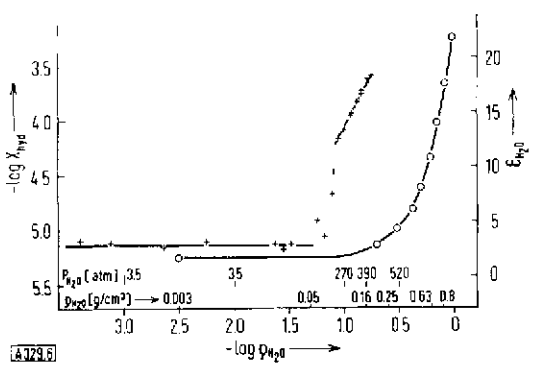

Fig. 6. Solubility of $MoO_{3(solid)}$ in $H_2O_{(gas/liquid)}$ at 500 °C in relation to the density of the water.
o Dielectric constant $\varepsilon_{H_2O}$.

constant slope starts at a density of approximately 0.08 g/cm³ which corresponds to the relationships observed in the case of $SiO_2$. Again there is a possible correlation between the solubility and the rise in the DC with density. Another isotherm was determined at 440 °C. Its slope corresponds to that of the isotherm shown in Figure 6.

Appraisal of Figure 6 yields the association number $m \approx 1$ for densities up to 0.05 g/cm³, and $m \approx 3$ for densities of the order of 0.1 g/cm³. These relationships may be described by the following equations:

(12) $MoO_{3(solid)} + H_2O_{(gas)} \rightleftharpoons MoO_2(OH)_{2(gas)}$

(13) $7\,MoO_{3(solid)} + 3\,H_2O_{(gas)} \rightleftharpoons Mo_7O_{18}(OH)_{6(gas)}$, *i.e.* $H_6Mo_7O_{24}$

[29] Like *Franck* [20], we also select whole numbers for our association numbers.

[30] *R. Schwarz* and *K. G. Knauff*, Z. anorg. allg. Chem. *275*, 190 (1954).

[31] An example of a derivative of cyclic hexasilicic acid $(H_2SiO_3)_6$ or $H_{16}(Si_6O_{18})$ is the mineral beryl $Be_3Al_2(Si_6O_{18})$.

[37] *F. Will* and *J. H. Yoe*, Analytic. Chem. *25*, 1363 (1953).

Since mass-spectrometric studies on the system $WO_3/H_2O$ gave the aggregation number r = 1 and hence the formula $WO_2(OH)_2$ for gaseous tungsten hydroxide [32], a similar formula is very probable for the corresponding compound in the system $MoO_3/H_2O$. However, this formula holds only for the low-density range. The aggregation number r = 7 selected for the higher density range is stoichiometrically plausible, since it explains the increase in solubility observed for the compound with the experimental association number m = 3, in contrast to the reaction with the association number m = 1. Using the aggregation number r = 7, we can formulate the reaction product. The resulting formula is analogous to that of the isopolymolybdates $[Mo_7O_{24}]^{6-}$, which are formed by acidification of molybdate solutions. The ultraviolet absorption curves of our aqueous solutions, obtained by quenching the reaction products, do in fact show a displacement of the absorption peaks toward longer wavelengths as compared to a monomolybdate solution. This can be taken as an indication that heptamolybdate ions are present [38].

However, it should be noted that the experimental results are also compatible with values of r = 6 or r = 8. Moreover, even though heptamolybdate seems to occur in the quenched reaction solution, it still remains to be proved that this ion is present during the actual high-temperature reaction. Definite proof of this can only be obtained from experiments in which the activity of the solid phase is varied. Studies along this line are in progress.

### 3. The System $WO_3/H_2O$ [39]

The reaction of $WO_3$ with $H_2O_{(gas)}$ had previously been studied between 400 and 1100 °C at steam pressures below 1 atm [32,40]. Gaseous $WO_2(OH)_2$ is formed according to the equation:

(14) $WO_{3(solid)} + H_2O_{(gas)} \rightleftarrows WO_2(OH)_{2(gas)}$

As mentioned above, the aggregation number r = 1 was demonstrated by mass spectrometric experiments.

The starting material for our pressure experiments was $WO_3$ obtained from E. Merck, Darmstadt. The quantity of $WO_3$ transported can be determined photometrically with sodium alizarin-3-sulfonate [41]. It can also be determined titrimetrically in a procedure similar to that used for $MoO_3$ [42].

The experimental data obtained at 500 °C and in the pressure range 40–400 atm are plotted in Figure 7. Two density ranges can be distinguished. The upper limit of range I, with m = 1 and r = 1, has been found by extrapolation at a density of 0.01 g/cm³. Range II gives m = 3. This system also shows some correlation between the solubility and the increase in the DC with the

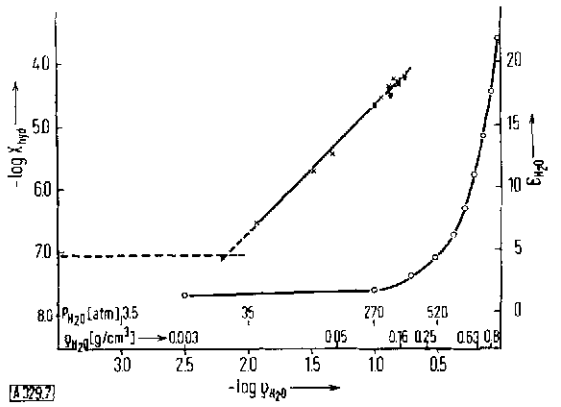

Fig. 7. Solubility of $WO_{3(solid)}$ in $H_2O_{(gas/liquid)}$ at 500 °C in relation to the density of the water.
o Dielectric constant $\varepsilon_{H_2O}$.

density. To account for the greatly increased solubility in range II, we selected the value r = 6 and formulated the reaction as

(15) $6\ WO_{3(solid)} + 3\ H_2O_{(gas)} \rightleftarrows W_6O_{15}(OH)_{6(gas)}$, *i.e.* $H_6W_6O_{21}$

The aggregation number r = 6 indicates a relationship between the product of the vapor reaction and the ion $[HW_6O_{21}]^{5-}$, which is produced on acidification of tungstate solutions [43,44]. As we know [45], this ion polymerizes relatively rapidly to a dodecatungstate ion, thus a polymerization can follow the primary reaction, as was assumed above for "$SiO(OH)_2$".

The experimental results are also compatible with a value of r = 4 yielding the equation:

(16) $4\ WO_{3(solid)} + 3\ H_2O_{(gas)} \rightleftarrows W_4O_9(OH)_{6(gas)}$, *i.e.* $H_6W_4O_{15}$

On acidifying tungstate solutions, *Schwarzenbach* et al. [46] found an initial short-lived intermediate product which proved to be a tetratungstate ion $[H_5W_4O_{16}]^{3-}$ with a degree of acidity of Z = 1.25 [47]. It converts further into $[HW_6O_{21}]^{5-}$ via an as yet unexplained sequence of reactions. However, instead of an $[H_5W_4O_{16}]^{3-}$ ion, the above value of Z also permits a formulation such as

$$4\ WO_4^{2-} + 5\ H^+ \rightleftarrows H_3W_4O_{15}^{3-} + H_2O$$

which bears a relationship to Equation (16). The question remains whether it is Equation (15) or Equation (16) which is correct. An answer will be given by experiments that will yield some information on the aggregation number r. In both cases, the primary reaction is expected to be followed by condensation or polymerization reactions.

## V. Concluding Remarks

The experiments have shown that the action of water on $SiO_2$, $MoO_3$, and $WO_3$ at high temperatures results in different reactions, depending on the density of the gas

or the supercritical phase. It has been shown that the quantity of oxide transported per unit volume of the transport medium is more than two orders of magnitude greater at high densities of the transport media than at low densities. This finding is pertinent to the study of the corrosion of industrial materials. It also helps to explain transport phenomena in nature, which are of great importance, for example, in the formation of mineral deposits. Last but not least, it also opens up new preparative possibilities.

The present results are in good agreement with the recently developed concept regarding the supercritical water as an electrolytic solvent. The magnitude of the effects observed is certainly a function of the specific interaction between the appropriate oxide and water. However, the prerequisite for a solubility effect is polarity of the water molecules in the supercritical state. With increasing density, the electrolytic properties of this supercritical phase will become similar to those of a liquid. This might explain why, at higher pressures, the concentration of the solute tends towards a limit. It might also explain the fact that at high temperatures and pressures compounds will appear in the supercritical phase which are already known from aqueous solutions. It might in future be possible to use pressure methods for the study of polyanions. By the determination of the heat of reaction one has the possibility to determine the enthalpies of formation of these compounds. It will be necessary to clarify whether, under the prevailing reaction conditions, these compounds exist as hydrated undissociated molecules or whether they dissociate into ions. Conductivity measurements might offer further insight into this problem.

# Reversibility of Energy Transformations in the Respiratory Chain [*]

BY DOZ. DR. M. KLINGENBERG

PHYSIOLOGISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT MARBURG (GERMANY)

*Dedicated to Otto Warburg on the occasion of his 80th birthday*

*In oxidative phosphorylation, the energy from the combustion of substrate hydrogen can be reversibly transformed into phosphate-bond energy. This is the reason that oxidation-reduction reactions in the respiratory chain can take place against the redox potential gradient if energy is supplied. The latter can come from ATP or directly from energy-rich intermediates arising in the course of oxidative phosphorylation. – At the center of the present considerations is the postulate that there is an equilibrium prevailing in the respiratory chain that results from the reversibility of the reactions. At the same time this postulate provides a unifying approach to various phenomena related to the process of oxidative phosphorylation. Such an equilibrium may involve several components of the respiratory chain. Respiration thus corresponds to a dynamic equilibrium in the respiratory chain which deviates increasingly from the static equilibrium the greater the rate of respiration. Consequently, respiration can be considered as being regulated by the phosphorylation potential. – The stationary redox state of the components of the respiratory chain can be viewed as a simultaneous function of the phosphorylation potential and of the redox potential that effects both ends of the respiratory chain. The latter reacts to either extreme, i.e. to minimum or maximum differences in the redox potential, by forming characteristic patterns of the state of reduction of its components. Differences in redox potential amounting to as much as 280 mV can be overcome by the phosphorylation potential for a single phosphorylative step. – The conditions for an equilibrium in the respiratory chain are also fulfilled from a kinetic viewpoint as the rates of the reverse reactions involving either electron or proton transfer are of the same order of magnitude as those of the forward reactions.*

## 1. Introduction

The combination of hydrogen from an appropriate substrate with oxygen via the respiratory chain – reactions studied many years ago by *Otto Warburg* – is the reaction sequence in animal metabolism with the highest energy gradient. It is not surprising therefore that it has generally been considered to be irreversible. This view presumably rested on the analogy of the overall process of cellular "combustion" to that of the combustion of hydrogen with oxygen. Because the energy of oxidation in the respiratory chain is transformed into the energy of the phosphoric anhydride

[*] Based on lectures given in April, 1962 at the Enzyme Research Institute, University of Wisconsin, Madison, and the Johnson Foundation, University of Pennsylvania, Pa. (U.S.A.).

bond of adenosine triphosphate (ATP) [*], it must be possible in principle to reverse the substrate-combustion reaction, provided the energy supply is also reversed. Such an eventuality presupposes a firm coupling between the oxidation-reduction reactions and those involving the transfer of energy to ATP. On the basis of this prerequisit it has in fact proved possible to demonstrate the reversibility of the major portion of the respiratory chain.

The reversibility of oxidative phosphorylation should not be considered simply as an extreme reversal of physiological events, possible only *in vitro*. Rather, it makes possible a static equilibrium within the respiratory chain with important consequences for energy transfer *in vivo*. The most important application is probably the regulation of respiration. Here the static equilibrium represents the limiting situation from which the actual dynamic equilibrium deviates increasingly as the rate of respiration increases. In this review, we shall lay particular emphasis on the aspect of the energy-dependent redox equilibrium in the respiratory chain as we interpret the various phenomena of reversibility.

## 2. Survey

In principle, the reverse reaction of oxidative phosphorylation consists of an ATP-dependent oxidation-reduction reaction between two components $C_1$ and $C_2$ of the respiratory chain:

$$C_{2\,red} + C_{1\,ox} + ATP \rightleftharpoons C_{2\,ox} + C_{1\,red} + ADP + P \qquad (1)$$

Here it is assumed that the ATP-consuming reaction corresponds inversely to the pathway of ATP synthesis during the course of oxidative phosphorylation. Reaction (1) can be written in two steps, one involving energy transfer, *i.e.*

$$X + ATP \rightleftharpoons {\sim}X + ADP + P \qquad (2)$$

and the oxidation-reduction reaction that is coupled to the energy transfer:

$$C_{2\,red} + {\sim}X + C_{1\,ox} \rightleftharpoons C_{2\,ox} + C_{1\,red} + X \qquad (3)$$

In the above notation, $\sim$X designates the chemical bond energy which may occur in an as yet unknown form lying between the redox energy and that of phosphate bonds. It may be localized either in the components of the respiratory chain or in another unknown compound. This intermediate form of energy does not contain phosphate; its existence is a necessary postulate as a result of investigations on the reversibility of oxidative phosphorylation.

The reversibility of the phosphorylation reaction (2) has long been known from the exchange between $^{32}PO_4^{3-}$ and ATP, that is catalysed by mitochondria, and the exchange among $H_2{}^{18}O$, ATP, and $PO_4^{3-}$ [1–5]. Doubts have been repeatedly expressed concerning the significance of this reaction for oxidative phosphorylation, in spite of strong arguments in its favor. It appears that this reaction is involved in only one of the three phosphorylation steps of the respiratory chain, *i.e.* in the step concerned with flavin. The reversibility of Reaction (3) was also discovered before the reversibility of Reaction (1) was known: mitochondrial DPN is reduced in respiring mitochondria by substrates which are dehydrogenated primarily by flavoproteins [6–9].

However, today a large amount of experimental evidence is available to demonstrate the reversibility of oxidative phosphorylation. The intimate coupling required between the oxidation and the energy transfer is accomplished in physiologically intact preparations of the respiratory chain, *viz.* in mitochondria, which consequently have become the favorite preparation for these investigations. The short list that follows includes only completely reversible reaction sequences, *i.e.* those that were achieved with ATP. Figure 1 shows a diagram that illustrates the interrelationships.

1. Control of respiration by ATP [10, 11].

2. Influence of ATP on the pattern of stationary oxidation-reduction reactions in the respiratory chain and reversal of the transfer of electrons and protons by ATP:

a) in respiring mitrochondria [10–12].

b) in mitochondria with inhibited respiration [13–16].

3. ATP-induced transfer of hydrogen between exogenous hydrogen donors and acceptors [11, 17–26].

4. ATP-dependent redox reactions occurring outside the respiratory chain:

a) stimulation of succinate oxidation [27–29].

b) hydrogen transfer between the DPN and TPN system in mitochondria [30, 31].

c) energy-dependent hydrogen transfer between substrates which are dehydrogenated primarily by pyridine nucleotides [21, 32, 33].

The reversal of electron or hydrogen transport processes within the respiratory chain was first observed in respiring mitochondria to which no ATP had been added. Here the chemical bond energy produced in the course of respiration is apparently in an intermediate form, *i.e.* it does not first form ATP, and is used up in the reverse reaction of hydrogen transfer. The effectiveness of this intermediate form of energy becomes particularly clear when respiring mitochondria are allowed to pump fairly large quantities of hydrogen from one substrate to the other against a redox potential [19, 20]. An example of such a situation is the transfer of hydrogen from succinate (standard potential $E'_0$ = + 50 mV at pH 7) to acetoacetate (standard potential $E'_0$ = −260 mV at pH 7).

### 3. Energy-Dependent Oxidation-Reduction Equilibrium

To understand these phenomena the occurrence of an energy-dependent redox equilibrium in the respiratory chain has been postulated [16, 34, 35]. The components of the respiratory chain may be involved in an oxidation-reduction equilibrium provided that the redox potential of one of the components has been shifted so far, *e.g.* towards negative values, owing to the formation of an energy-rich intermediate, that it equals the potential of its neighbor (Fig. 2). This intermediate would then be involved in a phosphorylation equilibrium with the ATP/ADP system. These alternating redox and phosphorylation equilibria constitute a system of equilibria throughout the entire respiratory chain. This aspect proved to be particularly fruitful for analysis of the effects of ATP in the case of total reversal of oxidative phosphorylation. It permits both a qualitative and a quantitative interpretation of these effects [36].

At equilibrium, the redox state of the respiratory-chain components involved in oxidative phosphorylation is a function of the phosphorylation potential of ATP, *i.e.* of the quotient (ATP)/(ADP)·(P). Moreover, the reversibility of oxidative phosphorylation should always be a function of this ratio. The assumption of an energy-dependent redox equilibrium also has kinetic implications.

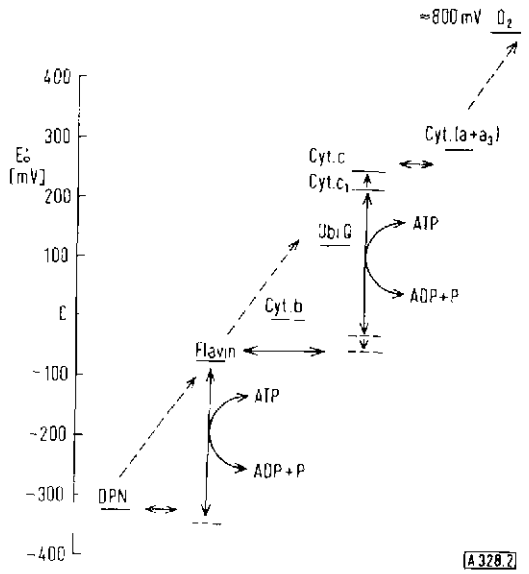

Fig. 2. The equilibrium in the respiratory chain. The components of the chain have been arranged in the order of their standard potentials at pH 7. Their redox potentials are shifted in a negative direction by virtue of the formation of an energy-rich intermediate in the phosphorylation equilibrium involving ATP. The shift of 280 mV indicated was observed under anaerobic conditions [36]. Solid arrows indicate equilibria, broken arrows states of nonequilibrium. The overall equilibrium in the respiratory chain results from the alternating sequence of redox(↔) and phosphorylation (↕) equilibria.

Ordinate: Standard potential $E'_0$ at pH 7 [mV].

For example, it implies that, close to equilibrium, the rate of the reverse reaction involving electron transport is of the same order of magnitude as the forward reaction, *i.e.* respiration. Thus, in the case of respiration coupled to oxidative phosphorylation, a dynamic equilibrium develops which must be considered to lie in general close to the static equilibrium. Consequently, it becomes possible to analyse dynamic equilibria in the respiratory chain with the relatively simple methods which have been developed for the analysis of relaxation spectra of chemical reactions [37] and which have also been applied to the analysis of reactions with isolated enzymes [38, 39].

## 4. Respiration

In physiologically intact preparations, the rates of respiration and phosphorylation are interdependent. The rate of respiration can be limited by the rate of phosphorylation. If the latter is inhibited by the lack of suitable substrates (ADP or phosphate) respiration is also inhibited. Both *Lardy* [40] and *Chance* [41, 42] have designated the lack of ADP or of phosphate as the controlling factor in their analysis of the regulation of respiration which they have termed "respiratory control". In this connection an effect of ATP opposite to that of ADP or phosphate has not been reported. Therefore, an ADP-trigger mechanism for the regulation of respiration was postulated [43]. Since this hypothesis of the regulation of respiration is considered to involve inhibition and activation, it implies a kinetic control mechanism.

The mechanism of the control of respiration based on the phosphorylation equlibrium differs in principle from the preceding hypothesis. Here respiration is thought to be controlled by the concentration of phosphate and ADP on the one hand, and by ATP on the other. This constitutes a thermodynamic mechanism for respiration control.

The first piece of evidence for the existence of this thermodynamic mechanism came from observations on mitochondria from skeletal muscles, whose respiration was inhibited by the addition of ATP [10, 11]. In subsequent studies, it proved possible to demonstrate that the respiration of liver mitochondria was dependent on the ratio of the concentrations of ADP and ATP [44]. Figure 3 illustrates by means of a simultaneous recording of respiratory activity and pyridine nucleotide absorption that the addition of ATP can partially inhibit respiration that has been fully stimulated by prior addition of ADP. At the same time, the pyridine nucleotides

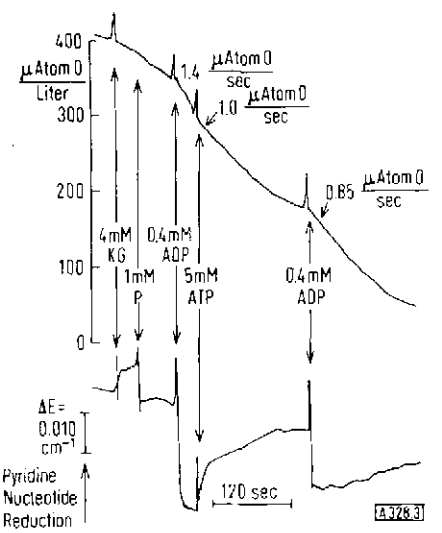

Fig. 3. The opposing influence of ADP and ATP on the respiratory activity and the redox state of the pyridine nucleotides in mitochondria. Simultaneous recording of respiration and absorption of pyridine nucleotides in a suspension of liver mitochondria: 2 mg of protein in 0.5 ml of sucrose-EDTA medium at pH 7 and 25 °C.

The respiration with α-ketoglutarate (KG) as substrate was speeded up by the addition of ADP and slowed down by the addition of ATP before all of the ADP had been used up. The pyridine nucleotides were oxidized by the addition of ADP and reduced even more strongly after the addition of ATP. After the first addition of ADP had been used up, new DAP was added, but the respiration was then stimulated less and the pyridine nucleotides were oxidized less than they were before the addition of ATP.

Spectrophotometrically the difference between absorption at 340 mμ (the maximum of the DPNH band) and at 405 mμ (reference wavelength) was measured.

[44] *M. Klingenberg,* unpublished results.

change to a more reduced state. This reduction of the pyridine nucleotides, which occurs parallel with the inhibition of respiration, shows that ATP, by reversing oxidative phosphorylation, exerts an effect that opposes that of ADP. In this ATP-induced state of the respiratory chain, the pyridine nucleotides attain a situation similar to that which occurs during ADP deficiency (the "controlled state"), for they are more reduced than they are when there is a sufficient supply of ADP (the "active state") [*].

It can thus be seen that the activity of respiration depends on the ratio (ATP)/(ADP) (cf. Fig. 4). In the absence of ATP, respiration is approximately at half of its maximum if approximately 0.05 mM ADP is present. This is in agreement with the data of *Chance* and *Williams* [42]. However, in the presence of ATP, appreciably higher concentrations of ADP are required for respiration to attain the half-maximum value, *e.g.* 0.1 mM ADP for 2.5 mM ATP, and 0.25 mM ADP for 5 mM ATP. If 5 mM ATP has been added, maximum respiration requires 1 mM ADP instead of the 0.1 mM ADP needed in the absence of ATP. The correlation between respiratory activity and the ratio (ATP)/(ADP) is in accord with the suggestion that respiration is controlled by an equilibrium between the ATP/ADP system and the respiratory chain. Hence, control of respiration is a function of the reversibility of oxidative phosphorylation.

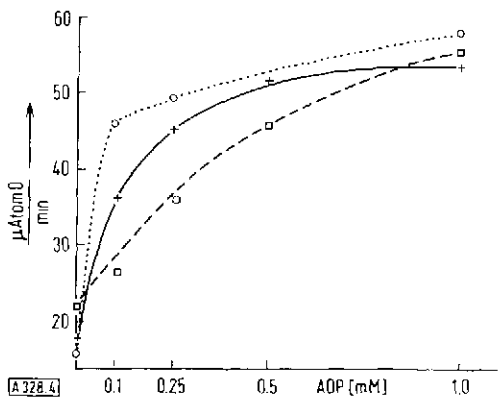

Fig. 4. Respiratory activity of mitochondria shown as a function of the phosphorylation potential, which was varied by changing the ratio (ATP)/(ADP). Liver mitochondria were incubated in sucrose-EDTA media at pH 7 and 25 °C.

o = no ATP; + = 2.5 mM ATP; □ = 5 mM ATP.

The above relationships observed in isolated mitochondria are of special significance for the physiological control of respiration, because ATP occurs in most cells *in vivo* in relatively large concentrations. The respiratory activity of a cell can therefore be supposed to show a dependence on the (ATP)/(ADP) ratio similar to that depicted in Figure 4. This implies that respiration would increase only relatively sluggishly with an increase in the concentration of ADP, and would be fully activated only at a relatively high ADP level. It can therefore be regulated over a fairly wide range by changes in the ADP level and is hence a subtle function of the differential utilization of ATP by the organism. In contrast, the "kinetic mechanism" would provide a more abrupt regulation of respiration because of its narrower range of regulation. The new theory demands reinterpretation of a variety of experiments which were previously interpreted along the lines of the kinetic theory of respiratory control; an example is the question of the amount of ADP liberated in a single contraction when a muscle performs work [45,46].

[*] The terms "controlled" and "active" state refer to the respiratory and oxidative phosphorylation activities of mitochondria and constitute extreme cases. The "controlled" state exists when phosphorylation and the respiration coupled to it are inhibited owing to lack of substrates of the oxidative phosphorylation, *e.g.* inorganic phosphate or ADP, but not of oxidizable substrates. In the "active" state both oxidative phosphorylation and, hence, respiration are fully activated, as phosphate and ADP are in sufficient supply.

## 5. The Redox Patterns of the Respiratory Chain

The first indications of the reversibility of oxidative phosphorylation were provided by changes in the redox state of respiratory-chain components. These observations implied a reversal of the direction of flow of protons and electrons. After the observation in isolated instances of the reduction of pyridine nucleotides in mitochondria [6,9], the general significance of this phenomenon for mitochondria of varying origin was recognized [7]. In addition, the reduction of the iron-flavoprotein complex in the respiratory chain was shown to be energy-dependent [35]. Until then, reversibility had been demonstrated only for the phosphorylation step in the DPN-flavin region of the respiratory chain. By changing the experimental conditions, it then also proved possible to demonstrate the reversibility of the electron transport in the cytochrome region [13–16].

For better comprehension, it may be best at first to neglect the reverse transport of hydrogen and electrons and instead to concentrate on the static picture of the redox pattern, on the basis of which the redox state of the components can be compared in a variety of functional states of the repiration chain. The concept of an energy-dependent equilibrium appears to be particularly fruitful in this connection.

Frequently the redox patterns can be arranged according to a surprisingly simple scheme. The influence of the respiratory control on the redox pattern – which we had demonstrated previously on mitochondria from insect flight muscle [46a] – may be shown here again on another example (liver mitochondria) in Fig. 5a. In the presence of phosphate (controlled state) and of succinate as substrate, the percentage degree of reduction of the components of the respiratory chain decreases progressively from the substrate side, *i.e.* from DPN, towards cytochrome a. However, in the presence of ADP, the degree of reduction is more balanced. This behavior was already observed in principle by *Chance* and *Williams*

[45] *B. Chance* and *C. M. Conelly*, Nature (London) *179*, 1235 (1957).

[46] *B. Chance*, Ann. N. Y. Acad. Sci. *81*, 477 (1959).

[46a] See Figures 18 and 19 in [6].

[47] in their fundamental studies of the redox states of the respiratory chain. In the presence of ATP, the drop in the degree of reduction is preserved even upon addition of ADP (Fig. 5b). The relatively small shifts ob-

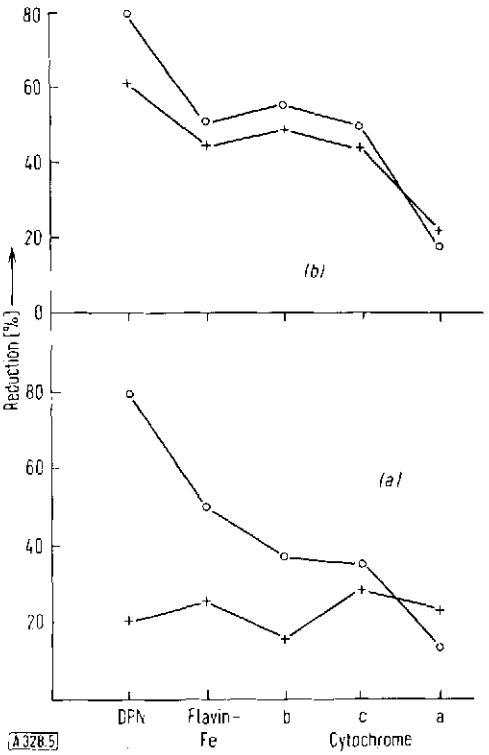

Fig. 5. Redox patterns of the respiratory chain of respiring mitochondria. Stationary redox states before (o—o) and after (+ +) addition of 0.25 mM ADP. Liver mitochondria were incubated in air-saturated sucrose-EDTA media at pH 7.2 and 25 °C; 4 mM succinate; 1 mM $PO_4^{3-}$.

a) Mitochondria without ATP b) Mitochondria with 5 mM ATP.

served upon addition of ADP reflect the partial transition of the controlled to the active state. As shown above, in this case, respiration is also only partially activated (cf. Fig. 2). The redox patterns of the respiratory chain are therefore subject to the opposing in-

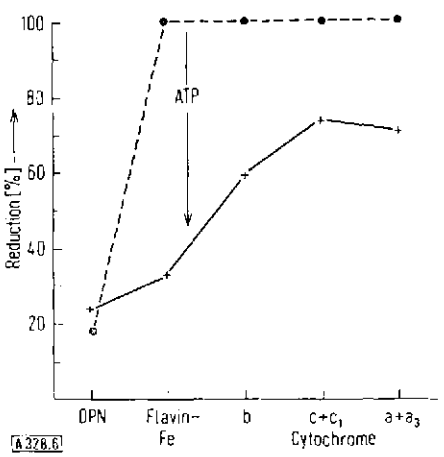

Fig. 6. Redox patterns of the respiratory chain of mitochondria with inhibited respiration. State of the respiratory-chain components before and after addition of 1 mM ATP. 1 mM KCN served as respiration inhibitor and 1 mM oxaloacetate as hydrogen acceptor on the DPN side.

[47] *B. Chance* and *G. R. Williams*, J. biol. Chemistry *217*, 409 (1955).

fluences of ADP and ATP between the extremes of the "active" and "controlled" states.

If respiration and hence the electron flux in the respiratory chain are prevented either by elimination of oxygen or by inhibition with cyanide, the resulting redox patterns are of a different type (Fig. 6). In the absence of ATP, the components of the respiratory chain are then either totally or largely reduced and become partially reoxidized only on addition of ATP. This occurs because the reduction equivalents of the cytochromes and flavoproteins are shifted towards the substrate side by reversal of the electron flux. There they can be taken up by mitochondrial DPN and by DPNH-oxidizing substrates. These experiments thus demonstrate the reversal of electron transport in the cytochrome region, including cytochrome a [13–16].

Under these conditions, the stationary redox patterns may exhibit a rise in the degree of reduction from the substrate side in the direction towards the oxygen. This rise is particularly noticeable in the presence of small concentrations of ATP and of substrates that oxidize DPNH (cf. Fig. 6). The rise can be explained by an energy-dependent redox equilibrium in the following manner. On the substrate side, the redox potentials are relatively positive in the presence of an excess of hydrogen acceptor, whereas they are relatively negative on the side of cytochrome oxidase without oxygen. In the case of the effect of ATP on respiring mitochondria, as shown in Figure 4, the supply of the respiratory chain is exactly the reverse: there is an excess of reducing substrate and of oxygen, with the result that the difference between the redox potential at the two ends of the chain is relatively small [30]. Hence, the state of reduction of the respiratory-chain components can be under the control of the terminal redox potentials as the equilibrium embraces the entire respiratory chain.

## 6. Kinetics

Any shift in the respiratory chain from nonequilibrium to equilibrium can lead to a net forward or backward flux of reduction equivalents. It is to be assumed that the rate of the reverse reaction near the equilibrium equals that of the forward reaction. Two methods are available to measure the forward and reverse reactions of electron transport, *viz.* either measurement of the changes in the redox state of the respiratory-chain components themselves, or measurement of the entire electron transport in the reaction substrate → oxygen (respiration) and in the reaction substrate → substrate, where turnover is higher by several orders of magnitude, because here the components of the respiratory chain act as catalysts for the overall reaction.

The rate of the reverse reaction in electron transport can be determined for the ATP-dependent oxidation of cytochromes in mitochondria with inhibited respiration [44]. In order to do this it is necessary to ensure that the rate is in fact limited by electron transport and not, for example, by limited permeability of ATP into the mitochondria. As shown in Figure 7a, the oxidation of

cytochrome c initiated by ATP proceeds relatively slowly. The reverse reaction assumes a much higher rate if ATP in the presence of excess Mg, *i.e.* in the form of an ATP-Mg complex, is first allowed to act on the mitochondria for a few seconds (Fig. 7b). ATP-Mg has a lower phosphorylation potential than free ATP. On

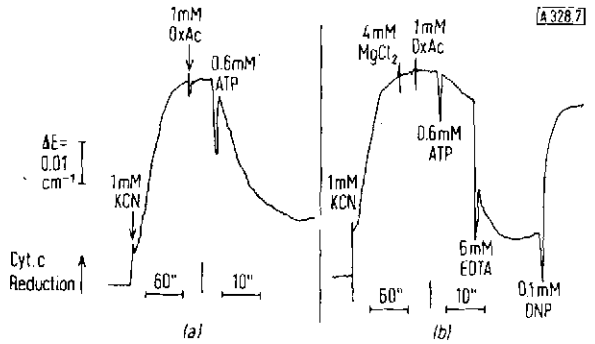

Fig. 7. Kinetics of the reversed electron transport: ATP-induced oxidation of cytochrome c in mitochondria with inhibited respiration. A double-beam spectrophotometer was used to record the absorption of a suspension of liver mitochondria (2 mg of protein in sucrose-EDTA medium at 9.5 °C). Following the addition of KCN, cytochrome c was first reduced by endogenous proton donors of the mitochondria.

(a) On addition of ATP, the cytochrome c became oxidized, oxaloacetate having been added as hydrogen acceptor for the hydrogen from DPNH. The rate of oxidation was relatively small.

(b) After prior addition of $Mg^{2+}$, the rate of oxidation of cytochrome c was still smaller than in case (a). When EDTA was added 10 sec after the addition of ATP, cytochrome c was oxidized quite rapidly. Subsequent addition of an agent such as dinitrophenol (DNP) that uncouples oxidative phosphorylation induces a rapid reduction. The spectrophotometric measurements were made of the difference in absorption at 550 mμ, the maximum of the α-band of cytochrome c, and at 540 mμ, the reference wavelength.

addition of EDTA, cytochrome c undergoes oxidation more rapidly than can be measured with the apparatus used. It can be assumed that ATP can diffuse into the mitochondria in the form of a relatively inactive ATP-Mg complex and then be released at the site of reaction by the action of EDTA. This may be the reason that the rates, which may conceivably be the true rates of the reverse reaction of electron transport, are much higher than those observed at the start of ATP addition.

It is also possible to measure the rate of the reverse reaction with the aid of the energy-dependent hydrogen transport between two substrates; this transport is catalysed by mitochondria and hence by enzymes of the respiratory chain. In practice, succinate is used as the reducing and either acetoacetate or ketoglutarate + $NH_3$ as the oxidizing substrate [11, 17–21]. The reverse reaction then occurs only in the DPN-flavin region of the respiratory chain. The kinetics of this reaction can be followed by determining the substrate disappearing and the substrate being formed. These "overall" experiments involve minutes rather than the seconds required for the study of cytochrome oxidation.

Table 1 gives a comparison of both methods based upon the cytochrome-c-content as a common reference point for the concentration of the respiratory chain components. The rates of the ATP-induced cytochrome-c-oxidation can only be estimated approximately from the recordings. The values should be multiplied by a factor of 5 if they are to be compared with the data of the substrate reaction, in order to compensate for the temperature difference of 18 °C between the two experiments. This shows that the rate of electron transport in the reaction cytochrome → substrate, given here as cytochrome-turnover rate (approx. 100 $min^{-1}$), is approximately equal to the rate of hydrogen transport in the reaction succinate → acetoacetate; consequently it is also approximately equal to the reverse reaction in the DPN-flavin region. The value is also equal to the rate of the forward reaction which can be determined from the activity of respiration: the cytochrome-c-turnover rate for oxidation of hydroxybutyrate is 110 $min^{-1}$, and that of succinate is 440 $min^{-1}$.

Table 1. Rates of the reverse reaction in the electron transport of the respiratory chain. Liver mitochondria in sucrose-EDTA medium.

| Conditions | Temp. [°C] | Rate expressed as cytochrome-c-turnover rate [$min^{-1}$] |
|---|---|---|
| Cytochrome c | | |
| ↓ | | |
| Oxaloacetate | | |
| Inhibited with KCN | 9,5 | |
| + ATP | | 4 |
| + ATP + $Mg^{2+}$ | | 0,8 |
| + ATP + $Mg^{2+}$ + EDTA | | 20 |
| Succinate | | |
| ↓ | | |
| Acetoacetate | | |
| aerobic | 28 | 110 |
| anaerobic ($N_2$) | | 70 |

The preceding considerations show that the kinetic requirements for the existence of an energy-dependent redox equilibrium in the repiratory chain have been met. On the basis of experiments with ATP-induced oxidation of cytochrome c, *Chance* and *Hagihara* [48] reported a ratio of 25:1 for the rates of the forward and reverse reactions. They had previously interpreted the reverse reaction as excluding an energy-dependent redox equilibrium in the respiratory chain [49]. In the light of the experiments described above, the low rate of the reverse reaction reported by *Chance* and *Hagihara* can probably be attributed to inhibition of the diffusion of the ATP to the respiratory chain.

## 7. Thermodynamic Considerations

Thermodynamic considerations provide the framework for an energy-dependent oxidation-reduction equilibrium: The free energy of the ATP-ADP system must be equivalent to the free energy resulting from the difference in redox potentials of components $C_2$ and $C_1$ [Equation (1)]. Quantitative studies of mitochondria with inhibited respiration did in fact result in the ex-

[48] *B. Chance* and *B. Hagihara:* Proceedings of the Fifth International Congress of Biochemistry, Moscow 1961. Pergamon Press, Oxford 1963, Vol. 5, p. 3.

[49] *B. Chance*, J. biol. Chemistry *236*, 1577 (1961).

pected relationship between the redox ratio of cytochrome c ($c_{red}/c_{ox}$) and the phosphorylation potential, (ATP)/(ADP) · (P) [36]. For a ratio of $c_{red}/c_{ox} = 1$, a "normal" phosphorylation potential of $\Delta F = -12.8$ kcal/mole was found. This corresponds to a difference in redox potential of $\Delta E = 260$ mV. Consequently, it appears possible to overcome the potential difference between cytochrome c and DPN ($\Delta E = 520$ mV) by means of two successive phosphorylation steps.

Respiring mitochondria apparently require a higher phosphorylation potential for equilibrium to occur. On the basis of the relationship between respiratory activity and the ratio (ATP)/(ADP) (see Fig. 3), it can be estimated that the normal phosphorylation potential (ATP)/(ADP)·(P) is 15 l/mmole at half-maximum respiration. This would correspond to $\Delta F = -14.5$ kcal/mole and to a redox potential of $\Delta E = 320$ mV.

The differences in phosphorylation potential observed under aerobic and anaerobic conditions can be explained by differences in the terminal redox potentials in the respiratory chain. Thus, in respiring mitochondria, the redox potentials of the two ends of the respiratory chain appear to differ fairly widely, as discussed above. Hence a higher phosphorylation potential is also required in order to overcome this relatively large potential difference. In mitochondria with inhibited respiration on the other hand, the redox potentials approach one another in value, owing to the exclusion of oxygen and the excess of oxidizing substrates, with the result that the entire respiratory chain can be bridged with a smaller potential.

### 8. Conclusions

In principle, the efficiency of oxidative phosphorylation can approach 100 % on the basis of reversibility. From the present state of our knowledge, this applies only to the potential difference between the substrate and cytochrome c; this difference amounts to between 520 and 600 mV and can thus theoretically be overcome by two successive phosphorylation steps. The reversibility of the third step of phosphorylation, which is presumed to involve the activation of oxygen by cytochrome oxidase, has not yet been demonstrated. It is conceivable that this step is not reversible even with an extremely large phosphorylation potential, as there are particularly large redox-potential differences to be overcome ($\Delta E \approx 420$–$520$ mV). If this is true, then the effects of the reversibility of oxidative phosphorylation, *e.g.* the regulation of respiration, involve only the first two phosphorylation steps.

This reversibility has significance not only for cellular function and the energy yield of oxidative phosphorylation. Its study also provides a new approach for the exploration of the mechanism of energy transfer and the associated oxidation-reduction reactions in the respiratory chain. The as yet unidentified energy intermediate which is bound to be involved in the transformation of redox energy into phosphate-bond energy can be generated from ATP rather than from electron transport. Moreover, a study of the reversibility will lead to knowledge of the conditions under which this intermediate is likely to accumulate. Hence, such a study can also serve as a means – which has already found frequent application – for elucidating the mechanism of oxidative phosphorylation.

The reversibility of these reactions may also have significance for a phenomenon that has not been discussed here in detail, *viz.* "active" transport; the latter may well be driven with the aid of "redox pumps" which in turn generate a cyclic, ATP-dependent electron transport, as a result of which charge displacement effecting "active" transport may occur [50]. The reversibility of oxygen uptake may also be of significance in photosynthetic oxygen formation [51].

### Preparation of Pure Disulfur Monoxide

By Prof. Dr. P. W. Schenk and Dipl.-Chem. R. Steudel

Anorganisch-Chemisches Institut der Technischen Universität Berlin (Germany)

Disulfur monoxide is formed by disproportionation of sulfur monoxide, which is stable only at high temperatures.

$$3\,SO = S_2O + SO_2$$

The mixture has hitherto not been separated. Up to 85 % $S_2O$ is also obtained [1] when SO is prepared by a glow discharge and allowed to react with sulfur vapor.

$$2\,SO + S_2 = 2\,S_2O$$

By modification of a procedure for the preparation of sulfur monoxide by the reaction of thionyl chloride vapor and dehalogenating reagents, *e.g.* Ag or Sn [2],

$$SOCl_2 + 2\,M = 2\,MCl + SO$$

we have prepared disulfur monoxide directly by using metal sulfides, *e.g.* CuS, PbS, $Sb_2S_3$, CdS, or $Ag_2S$, in place of the metals. For $Ag_2S$, the reaction with thionyl chloride

$$SOCl_2 + Ag_2S = S_2O + 2\,AgCl$$

proceeds quantitatively at 160 °C and 0.5 mm Hg, $S_2O$ resulting in over 96 % purity, accompanied by some $SO_2$. The purity depends largely on the experimental conditions. Elevated temperatures promote $Ag_2S$-catalysed decomposition [3] of the $S_2O$ into sulfur and sulfur dioxide.

## Preparation of 1,6-Dithio-D-glucose

By Dr. J. Kocourek, Dipl.-Chem. Marie Tichá, and Dr. V. Jiráček

Biochemistry Department, Faculty of Science, University of Prague (Czechoslovakia)

We have found that the sequence of reactions given in Scheme 1 is especially favorable for the preparation of 1,6-dithio-D-glucose [1].

(1) (2) (3) (4)

1,2-Isopropylidene-3,5-di-*O*-acetyl-6-deoxy-6-iodo-α-D-glucofuranose *(1)* [2] was subjected to acidic hydrolysis in acetone plus aqueous $H_2SO_4$ and subsequent acetylation with sodium acetate and acetic anhydride to give a mixture of the α- and β-anomers of 1,2,3,4-tetra-*O*-acetyl-6-deoxy-6-iodo-D-glucopyranose *(2)* [3] in 56 % yield. Acetobromination of the latter yielded 84 % of compound *(3)* [4]. This derivative, which can also be obtained in lower yields by direct acetobromination of the hydrolysate obtained from *(1)* after removal of the water, is readily converted with potassium thiobenzoate [5] in dimethylformamide at room temperature into *(4)*, m.p. 130–131 °C, $[\alpha]_D^{20} = -9.0°$ (c = 4 in $CHCl_3$), in 65 % yield. Compound *(4)* can easily be converted into the free sugar (61 %) by the usual methods.

## 1-Methylene-2,5-cyclohexadiene

By Prof. Dr. H. Plieninger and Dipl.-Chem. W. Maier-Borst

Organisch-Chemisches Institut der Universität Heidelberg (Germany)

The existence of the two toluene isomers *(1)* and *(2)* has long seemed to be unlikely [1]. Recently, however, 5-methylene-1,3-cyclohexadiene *(1)* was identified by *Bailey* and *Baylouny* [2] as a chemical entity which is quite stable at low temperature in dilute solution.

We have now managed to prepare 1-methylene-2,5-cyclohexadiene *(2)* from 1,4-dihydrobenzoic acid by conversion via the acid chloride to the dimethylamide, reduction of the latter to *N*-dimethyl-1,4-dihydrobenzylamine, and methylation of the amine to give the quaternary salt *(3)*; the latter is heated with powdered KOH and the resultant vapors are passed into cooled ether.

(1) (2) (3)

An ether solution is obtained which has an ultraviolet absorption maximum at 242 mμ with a shoulder at 247 mμ, log ε = 4.4 (concentration determined by rearrangement to toluene); toluene is also produced. Traces of mineral acid destroy the absorption at 242 mμ and increase the yield of toluene. Sufficient *(2)* was obtained by preparative gas chromatography to enable its NMR spectrum to be determined. The required proton ratio of 4:2:2 is observed. The four vinyl protons attached to the ring give signals between 3.7 and 4.5 τ; the *exo*-methylene-group protons resonate at 5.35 τ and the protons on the saturated carbon atom at 7.06 τ. Confusion with *(1)* is not possible as the latter exhibits an absorption maximum at 303 mμ.

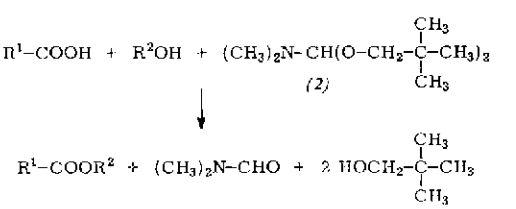
## N,N-Dimethylformamide Dineopentylacetal: a Reagent for Esterifying Carboxylic Acids with Benzyl Alcohols

By H. Büchi, Katharina Steen, and Prof. Dr. A. Eschenmoser



Organisch-chemisches Laboratorium der Eidgenössischen Technischen Hochschule Zürich (Switzerland)

The results of stereochemical [1] and kinetic [2] investigations support the view that the rate-determining step of the esterification [1,3] of carboxylic acids with *Meerwein*'s acetals of dimethylformamide [4] is the alkylation of the carboxylate anion with an alkoxyimmonium ion of type *(1)* [5]; both of these ions and the alcohol $R^2OH$ are in eqilibrium with the reagents.

(1)

This reaction scheme predicts that, because of the low reactivity of the immonium ion *(1)*, $R^2$ = neopentyl] in the $S_N2$ alkylation step, dimethylformamide dineopentylacetal *(2)* will mediate esterification according to Scheme 1 of carboxylic acids with alcohols the alkoxyimmonium ions *(1)* of which are highly reactive. We have tested this hypothesis with a number of amino-acid derivatives using *p*-dodecylbenzyl alcohol *(3)* and *p*-methoxybenzyl alcohol *(4)*; the results are given in Table 1.

Scheme 1

Table 1. Esterification of carboxylic acids with 1.1 equivalents of *(3)* or *(4)* using 1.3 equivalents of *(2)* at room temperature.

| $R^1$ COOH [mole/l] | $R^2OH$ | Solvent | Time [h] | $R^1$-COOR$^2$ M.p. [°C] | $[\alpha]_D$ [°] | Yield [a] [%] |

| $C_6H_5COOH$ [0.19] | — | $CH_2Cl_2$ | 46 | | | 96 [d] |

[a] Recrystallized, thin-layer-chromatographically homogeneous material.

[b] DoBC = $CH_3-(CH_2)_9-O-C_6H_4-CH_2-O-CO-$; Cbo = $C_6H_5-CH_2-O-CO-$.

[c] Because of low solubility, reacted for 48 h at 80 °C and subsequently for 72 h at room temperature.

[d] Unchanged benzoic acid.

The advantages of this procedure over the use of the dimethylformamide acetals derived from *(3)* and *(4)* are that only one equivalent of the alcohol is required and that, in the optimum case, only volatile by-products are formed.

## α,δ-Dibromovaleryl Bromide and Methyl α,δ-Dibromovalerate

By Prof. Dr. N. Isenberg, I. Barkocy, and S. R. Parker [*]

Chemistry Department, Skidmore College, Saratoga Springs, N.Y. (U.S.A.)

Acyl halides are useful intermediates in the synthesis of peptides. We wish to report a convenient synthesis of α,δ-dibromovaleryl bromide *(2)* which gives reasonably good yields; *(2)* has not been described in the literature before.

1,5-Pentanediol was converted into δ-valerolactone *(1)* with copper chromite in 61 % yield [1]. The lactone (22.6 g) was mixed with 2.64 g of red phosphorus, and 43.51 g of bromine were added with cooling and stirring at 20–30 °C [2]. The mixture was heated to 70 °C, and additional 43.5 g of bromine were added. The mixture was allowed to stand for 3 hours at 70 °C and was then distilled to yield 62.8 g (86 %) of α,δ-dibromovaleryl bromide *(2)*, b.p. 106°/1.6 mm, $n_D^{25} = 1.5604$. The position of the carbonyl absorption peak in the infrared spectrum was 1770 cm$^{-1}$.

*(1)* *(2)*

Methyl alcohol (0.5 ml) was added dropwise with stirring to 4.0 g of *(2)* to yield 2.5 g (73 %) of methyl α,δ-dibromovalerate, b.p. 93–95 °C/1.5 mm, $n_D^{25} = 1.5099$. The position of its carbonyl absorption peak in the infrared spectrum was 1725 cm$^{-1}$.

## Dimeric Aldehyde Hydrazones

By Doz. Dr. Th. Kauffmann, cand. chem. G. Ruckelshauss, and Jutta Schulz

Institut für Organische Chemie
der Technischen Hochschule Darmstadt (Germany)

The apparently unknown oily hydrazones (Table 1) of acetaldehyde, propionaldehyde, butyraldehyde, valeraldehyde, and capronaldehyde, which are produced by cleavage of the corresponding styrene derivatives with sodium hydrazide [1] or, more simply, by reaction of the aldehydes with hydrazine hydrate below 5 °C [2] and distillation of the reaction products extracted with ether, dimerize at room temperature to give the crystalline 3,6-dialkylhexahydro-*s*-tetrazines *(1)–(5)* [3].

Table 1. Monomeric and dimeric aldehyde hydrazones.

| R | $R-CH=N-NH_2$ B.p. [°C/mm] | Yield [%] |  M.p. [°C] | Yield [%] |
|---|---|---|---|---|
| $H_3C$ | 100–102/755 | 68 | *(1)* 163–164 | 45 |
| $H_3C-CH_2$ | 108–110/755 | 60 | *(2)* 193–194 | 52 |
| $H_3C-(CH_2)_2$ | 149–151/750 | 51 | *(3)* 153–154 | 44 |
| $H_3C-(CH_2)_3$ | 65–66/20 | 50 | *(4)* 168–170 | 46 |
| $H_3C-(CH_2)_4$ | 83–85/15 | 46 | *(5)* 150–152 | 43 |
| $H_3C-(CH_2)_5$ | | | *(6)* 154–155 | 52 |
| $H_3C-(CH_2)_6$ | | | *(7)* 147–149 | 71 |
| $H_3C-(CH_2)_8$ | | | *(8)* 143–144 | 75 |

The dimers *(1)–(5)* and their higher homologues *(6)–(8)* [4] are formed directly by addition of the aldehyde to hydrazine hydrate below 5 °C; the solution is allowed to stand for several days in a refrigerator and the hydrated crystals which separate out are dried and recrystallized from absolute ethanol.

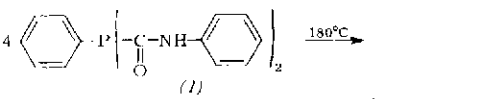
At 20 °C in 0.05 M aqueous solution, *(3)* is 77 % dissociated, as is indicated by cryoscopic molecular-weight determinations on a solution that was rapidly chilled after attainment of equilibrium; at 60 °C, *(3)* is almost completely dissociated. The dry solid also dissociates into the monomer when heated above its melting point. Like the other dimeric hydrazones described in Table 1, it is stable when kept in a sealed tube at 20 °C.

Received, October 28th, 1963 [Z 610/437 IE]
German version: Angew. Chem. 75, 1204 (1963)

[1] Cf. *Th. Kauffmann* et al., Angew. Chem. *74*, 650 (1962); Angew. Chem. internat. Edit. *1*, 456 (1962).

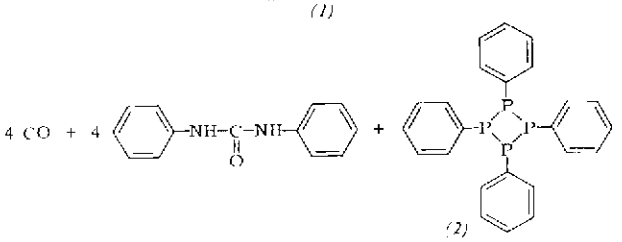
[2] The following statement in *C. C. Clark:* Hydrazine, Mathieson Chemical Corporation, Baltimore 1953, p. 38, is misleading: "Most aldehydes condense very readily with hydrazine in the cold. The aldehydrazone first formed reacts with aldehydes with greater speed than does hydrazine itself so that the azine is the normal end-product".

[3] Hexahydro-*s*-tetrazines with substituents on the nitrogen atoms are known: cf. *E. Schmitz* and *R. Ohme*, Liebigs Ann. Chem. *635*, 82 (1960).



[4] The compounds alleged to be enanthaldehyde hydrazone described by *A. Darapsky*, J. prakt. Chem. [2] *97*, 214 (1918), and by *W. Seibert*, Chem. Ber. *80*, 499 (1947), melting at respectively 132 °C and 148–155 °C were probably incompletely dried samples of the base *(6)*.

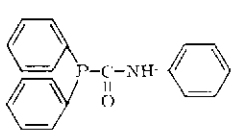
## A New Method for the Formation of P-P Bonds



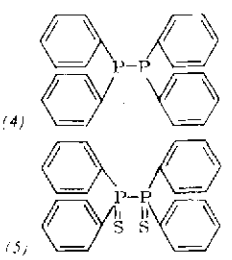
By Dr. H. Fritzsche, Dr. U. Hasserodt, and Prof. Dr. F. Korte

Shell Grundlagenforschung-GmbH.,
Schloß Birlinghoven (Germany)

When phenylbis(phenylcarbamoyl)phosphine *(1)* was heated for 2 hours at 180 °C under nitrogen, it gave tetraphenylcyclotetraphosphine *(2)* in 40 % yield, together with CO and diphenylurea.

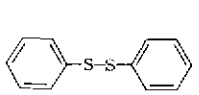


*(1)*

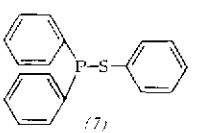


*(2)*

Under the same conditions, diphenylphenylcarbamoylphosphine *(3)* gave tetraphenyldiphosphine *(4)*, CO, and diphenyl urea; *(4)* was characterized by its reaction with sulfur to give a 32 % yield of tetraphenyldiphosphine-*P*,*P'*-disulfide *(5)*.



*(3)*



*(4)* *(5)*

As diphenylphosphorus radicals [1] were thought to be formed during the decomposition of *(3)* at elevated temperatures, we tried to trap them with phenylsulfur radicals [2].

*(6)*

*(7)*

The mixed dimer, *viz.* phenyl diphenylthiophosphinate *(7)*, m. p. 46–48 °C, was successfully isolated in 80 % yield from the decomposition under nitrogen of a mixture of *(3)* and *(6)*.

## Dimerization during the Cyclization of Proline Peptides [1]

By Priv.-Doz. Dr. M. Rothe, cand. chem. K.-D. Steffen, and Dr. I. Rothe

Organisch-Chemisches Institut
der Universität Mainz (Germany)

For steric and energetic reasons, cyclohexapeptides arise on cyclization of tripeptides, rather than the expected 9-membered rings of cyclotripeptides [2]. Tripeptides of proline seemed to form an exception [2a].

Our experiments on the cyclization of varying concentrations of tripeptides containing different sequences of L-proline and glycine always yielded the crystalline 18-membered cyclohexapeptide c-diglycyl-L-prolyl-diglycyl-L-prolyl as sole product [m.p. > 350 °C (decomp.); $[\alpha]_D^{25}$ – + 48.3 ° (c = 0.6 in $H_2O$)] contrary to results described in the literature [2a]. Ring closure was effected with the *p*-nitrophenyl ester of glycyl-L-prolyl-glycine (yield: 88 %) and the 2,4-dinitrophenyl ester of diglycyl-L-proline (73 %) in dimethylformamide at 100 °C and 50 °C, respectively, and also with the two linear free tripeptides by the phosphite method [3] in diethyl phosphite at 100 °C (55 % and 48 % yield, respectively), making use of the dilution principle. The identity of all these cyclic peptides with the product obtained from glycyl-L-prolyl-glycine ethyl ester and tert. amine according to [2a.] was shown by infrared spectroscopy and by paper and thin-layer chromatography in four different solvent systems [4]. The ring size was elucidated by molecular-weight determinations in the vapor pressure osmometer, by cryoscopy according to *Rast* in the lactam of 4-aminocyclohexane-1-carboxylic acid (found 430), and by partial hydrolysis with 0.1 N $Ba(OH)_2$ followed by thin-layer chromatographic identification of the resulting linear peptides. Further indications are provided by the infrared spectrum; the appearance of the amide II band at 1535 $cm^{-1}$ indicates the *trans*-amide bonds of the 18-membered ring [4a]. Our results show that the association brought about by hydrogen bonding of two peptide molecules that are lying antiparallel to each other cannot be the deciding factor in the cyclodimerization.

The chlorination method using t-butyl hypochlorite [5] is particularly suitable for rendering the cyclopeptides (and *N*-masked peptides) visible on thin-layer chromatograms.

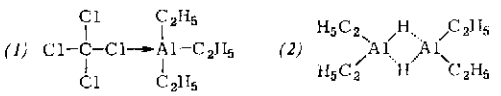
## Explosion of a Mixture of Triethylaluminum and Carbon Tetrachloride

By Dr. H. Reinheckel



Institut für Fettchemie der Deutschen Akademie der Wissenschaften, Berlin-Adlershof (Germany)

References to the action of halogenated hydrocarbons on aluminum alkyls [1] are sparse and occasionally contradictory. In the course of our investigations into the suitability of the lower halogenated hydrocarbons as solvents for reactions involving organoaluminum compounds, a violent explosion occurred with a mixture of triethylaluminum and $CCl_4$.

When mixtures of $Al_2Cl_3(C_2H_5)_3$ with $CCl_4$ that had been prepared with ice-cooling reached room temperature, they first darkened, then exploded violently. No reaction was evident when a mixture of triethylaluminum and $CCl_4$ in a molar ratio of 1:3 was kept cold in ice, and unchanged $CCl_4$ was recovered after working up.

When the experiment was repeated with a mixture of identical composition, and the ice was then removed, the violent explosion occured even before the mixture reached room temperature, and without previous darkening. The hood was destroyed; the reaction flask and stirrer were so completely shattered that it was impossible to find a single splinter.

The explosion must be due to the formation of an adduct *(1)*.

*(1)* *(2)*

Diethylaluminum hydride *(2)*, which does not form adducts of the type *(1)* owing to its tendency to associate, has a weakly dehalogenating action on $CCl_4$; exothermic reaction only occurs after long boiling under reflux (molecular ratio 1:3 or more concentrated) and without damage to the apparatus.

## The Reducing Action of Triethylaluminum

By Dr. H. Reinheckel

Institut für Fettchemie der Deutschen Akademie der Wissenschaften, Berlin-Adlershof (Germany)

The action of triethylaluminum on halogenated hydrocarbons is not substitutive, as might be expected, but reductive. $CH_2Cl_2$ is converted into $CH_3Cl$, $CHCl_3$ into $CH_2Cl_2$ plus $CH_3Cl$, and $CCl_4$ under suitable conditions (*e.g.* high dilution to avoid explosions [1]) into the three lower halogenated methanes. This is not due to initial dissociation of the triethylaluminum into ethylene and diethylaluminum hydride, with the latter as the actual reducing agent. Indeed, the above halogenomethanes react differently with pure diethylaluminum hydride: $CH_2Cl_2$ is not dehalogenated, $CHCl_3$ only very slightly, and $CCl_4$ only reacts on refluxing. Reaction of $CCl_4$ evidently proceeds differently, as is shown, for example, by the formation of ethyl chloride.

We attribute the reducing action to the formation of a cyclic transition complex *(1)* from the initial adduct. Because of its marked tendency towards association [1], the pure hydride does not form any such adducts.

*(1)*

The ethylene cannot be isolated. It apparently adds onto Al-ethyl bonds, as in the *Ziegler* synthesis, to give butyl and hexyl residues, since these can be detected as butane and hexane after hydrolysis.

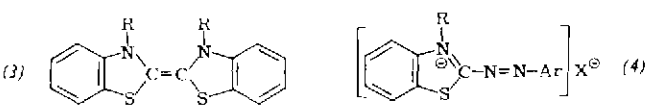
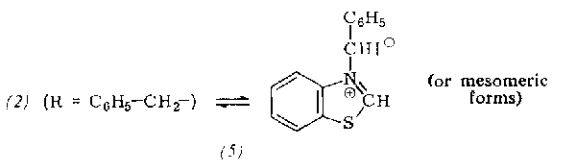
## Low-Energy "Carbenes" [1]

By Prof. Dr. H.-W. Wanzlick and Dr. H.-J. Kleiner



Organisch-Chemisches Institut der Technischen Universität Berlin (Germany)

Some initial results have been obtained in our search for "carbenes possessing quasi-aromatic resonance stabilization" [2]. *N*-Alkylbenzthiazolium halides *(1)* lose hydrogen halide even on mild treatment with certain tertiary amines, *e.g.* triethylamine. Yellow crystalline products are formed which behave chemically like the resonance hybrids *(2)*.



*(1)* *(2)*

Dimerization occurs more or less readily, according to the nature of R, to yield colorless, sometimes stereoisomeric ethylene derivatives *(3)*. However, before dimerization occurs, some typical reactions can be carried out. The salts *(1)* are reformed on reaction with acids, *N*-alkyl-2-thionobenzthiazolines are formed with sulfur, and azo dyes *(4)* are formed with diazonium salts.

*(3)* *(4)*

The new compounds possess intact alkyl groups (NMR spectra). The benzyl derivative, on the other hand, shows indications of tautomerism, cf. *(5)*.

*(2)* (R = $C_6H_5$–$CH_2$–) *(5)* (for mesomeric forms)

## Detection of a Nitrogen-Free Precursor of Anthranilic Acid in the Biosynthesis of Tryptophan by Saccharomyces cerevisiae

By Doz. Dr. F. Lingens and Dipl.-Chem. W. Lück

Chemisches Institut der Universität Tübingen, Biochemische Abteilung (Germany)

The biosynthesis of tryptophan in microorganisms has been well worked out from the stage of anthranilic acid *(1)* onward. Precursors of *(1)* in tryptophan-deficient mutants have not yet been described. Recently we succeeded in obtaining proof of the accumulation of a nitrogenous product in the medium of a tryptophan-deficient mutant of *S. cerevisiae* with a genetic block before the stage of *(1)* [1]. A second labile, crystalline accumulation product, m.p. 178–182 °C (decomp.) has now been isolated from the medium of another mutant, which also grows selectively with tryptophan, indole, or *(1)*. Its properties are in accordance with the structure of a 3-enolpyruvic acid ether of *trans*-3,4-dihydroprotocatechuic acid *(2)*. Ether *(2)* has maxima in the ultraviolet at $\lambda = 274$ and 224 mμ in water, reacts in the cold with alkaline triphenyltetrazolium chloride, and gives no reaction with 2,6-dichloroindophenol. On heating *in vacuo*, *(2)* yields pyruvic acid *(3)* and phenol. Disproportionation of neutralized *(2)* with Pd/C gives an aromatic compound, which on ether cleavage yields

*(2)*

*(3)* and protocatechuic acid; identical treatment of unneutralized material leads to preferential production of *p*-hydroxybenzoic acid and *(3)*. Compound *(2)* can be split with periodate. In addition to the 2,4-dinitrophenylhydrazone of *(3)*, a second acidic 2,4-dinitrophenylhydrazone *(4)* is also obtained. The ultraviolet spectrum of *(4)* is in agreement with that of the 2,4-dinitrophenylhydrazone of mucondialdehyde. A crystalline compound is obtained by hydrogenation of *(4)* with $Pt/H_2$. On ether cleavage under mild conditions [2], this yields lactic acid and a substance which behaves on paper chromatograms like *trans*-3,4-dihydroxycyclohexane-1-carboxylic acid [3]. Compound *(2)* can be converted into *(1)* enzymatically [4]. *Gibson* has demonstrated that *(2)* occurs as a by-product of aromatic biosynthesis in bacteria [4]. His proof of the constitution of *(2)*, which was isolated as the labile Ba salt, was derived from ultraviolet, infrared, and NMR spectroscopic data.

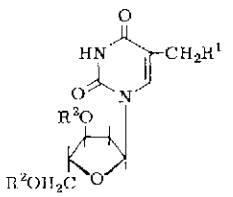
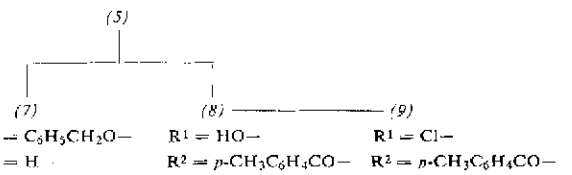
## A Simple Synthesis of Natural and Artificial 5-Hydroxymethyluracil Nucleosides



By Dr. R. Brossmer and E. Röhm

Max-Planck-Institut für Medizinische Forschung, Institut für Chemie, Heidelberg (Germany)

We have managed [1] to synthetize 5-hydroxymethyl-2′-deoxyuridine *(1)* in good yield. The 5′-phosphate of *(1)* is known to replace the entire thymidylic acid in the DNA of the *Bacillus subtilis* phage SP 8. Benzylation of 5-hydroxymethyluracil with benzyl alcohol and hydrochloric acid gives a 91 % yield of 5-benzyloxymethyluracil *(2)*, m.p. 202–203 °C [2], which is especially suitable for nucleoside syntheses. Compound *(2)* reacts either via its 1-acetyl derivative *(3)*, m.p. 131–132 °C, 80–90 %, or more simply directly with mercuric acetate to yield a mercury salt *(4)*. The latter condenses almost quantitively with 3,5-di-*p*-toluyl-2-deoxy-D-ribofuranosyl chloride in toluene to give a mixture of the anomers of the nucleoside: β-anomer *(5)*, m.p. 141–142 °C, $[\alpha]_D^{20} = -60°$ in chloroform, 49 %; α-anomer *(6)*, m.p. 99–101 °C, $[\alpha]_D^{19} = +10°$ in chloroform, 25–35 %. Proof of the constitution of *(5)* is afforded by its conversion into β-thymidine.



*(5)* $R^1$ = O-Benzyl, $R^2$ = p-Toluyl

*(6)* $R^1$ = O-Benzyl, $R^2$ = p-Toluyl

Selective removal of the protective groups yields partially substituted nucleosides. For example, 90 % *(7)*, m.p. 117 to 118 °C, arises on alkaline treatment of *(5)*, while catalytic hydrogenation of *(5)* yields 98 % *(8)*, m.p. 167–169 °C. The allylic hydroxyl group of *(8)* is readily etherified, *e.g.* to the butyl ether, m.p. 162–163 °C. The reaction of *(8)* with thionyl chloride gives a quantitative yield of *(9)*, m.p. 201–203 °C, and alkaline hydrolysis of the acyl groups produces 90 % free *(1)*, m.p. 180–182 °C, $[\alpha]_D^{20} = +19°$ in water [3].

*(7)* $R^1 = C_6H_5CH_2O-$, $R^2 = H$ — *(8)* $R^1 = HO-$, $R^2 = p\text{-}CH_3C_6H_4CO-$ — *(9)* $R^1 = Cl-$, $R^2 = p\text{-}CH_3C_6H_4CO-$

The previously unknown compounds of the α-series, including the free α-nucleoside, m.p. 169–170 °C, $[\alpha]_D^{20} = 0°$ in water, are derived analogously from *(6)*.

The chloride *(9)* reacts with nucleophilic substances to give biologically interesting compounds. Condensation of *(4)* with 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide affords the protected β-nucleoside *(10)*, m.p. 124–126 °C in 80 % yield. A 61 % yield of the free *N*-glucosidic analogue of *(1)*, m.p. 230–231 °C, $[\alpha]_D^{21} = +15°$ in $H_2O$, is obtained from *(10)* via the 5-hydroxymethyl compound, but it is not as yet known to occur naturally.

## A New Method for Preparing Trialkylarsines and Trialkylstibines

By Dr. W. Stamm and A. Breindel, M.S.

Research Center, Stauffer Chemical Company, Chauncey, N.Y. (U.S.A.)

Alkylations of arsenic and antimony halides with Grignard reagents, zinc alkyls [1], or aluminum alkyls [2] are known methods for the preparation of trialkylarsines and -stibines. We have succeeded in alkylating the oxides $As_2O_3$ and $Sb_2O_3$

with aluminum alkyls to form $AsR_3$ and $SbR_3$, respectively, in acceptable yields [3].

Finely powdered $As_2O_3$ (or $Sb_2O_3$) is dispersed in hexane, and the trialkylaluminum is added slowly, the mixture then being kept at 60 °C for 1–2 h. The trialkylarsines (or trialkylstibines) formed are then removed from the equilibrium mixture at highly reduced pressure:

$$2\ AlR_3 + M_2O_3 \rightleftharpoons (R_2M)_2O + 2\ RAlO \xleftarrow{AlR_3} 2\ MR_3 + 3\ RAlO$$

In order to obtain fully alkylated arsines and stibines in satisfactory yields, excess trialkylaluminum has to be employed. The yields of $MR_3$ decrease in the following order:

$M = Sb > As > Bi$ and

$R = C_2H_5- > n\text{-}C_4H_9- > i\text{-}C_4H_9- > i\text{-}C_6H_{13}-$

as can be seen from the following examples, where a molar ratio $AlR_3 : M_2O_3 = 3:1$ was employed:

$(C_2H_5)_3Sb$ — 89 %; $(n\text{-}C_4H_9)_3Sb$ — 87 %; $(i\text{-}C_4H_9)_3Sb$ — 71 %; $(i\text{-}C_6H_{13})_3Sb$ — 62 %; $(C_2H_5)_3As$ — 72 %; $(i\text{-}C_4H_9)_3As$ — 32 %, and $(n\text{-}C_4H_9)_3Bi$ — 6 %.

Alkylation of $As_2O_3$ with higher aluminum alkyls ($R \geq C_4$) resulted mainly in dialkylarsine oxides. Some of these were hitherto unknown, *e.g.* $[(i\text{-}C_4H_9)_2As]_2O$ (62 %, b.p. 68 to 70 °C/0.05 mm).

Diisobutylarsine oxide was oxidized to the new compound diisobutylarsinic acid $(i\text{-}C_4H_9)_2AsOOH$, m.p. 135 °C.

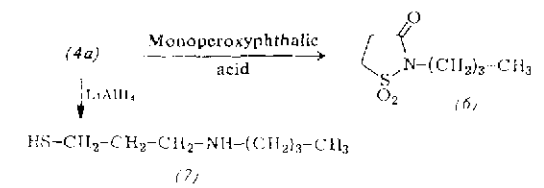
## ω-Chlorosulfenylalkylcarbonyl Chlorides

By Prof. Dr. A. Lüttringhaus and Dr. Rupert Schneider

Chemisches Laboratorium der Universität Freiburg/Breisgau (Germany)

We were able to convert dithiaalkane-α,ω-dicarboxylic acids into the corresponding α,ω-dicarbonyl chlorides *(1a)*, *(1b)*, and *(1c)* by treatment with thionyl chloride [1]. Chlorolysis of these at −25 °C in $CCl_4$ according to the method of *Brintzinger* [2] produced the ω-chlorosulfenylalkylcarbonyl chlorides *(2a)*, *(2b)*, and *(2c)* [3]. The yields were so good (up to 90 %) that the $CCl_4$ solutions could be used directly for further reactions, *e.g.* for the addition onto olefins to give β-chloroalkyl thioethers which serve as evidence for the structures of *(2)*. Thus, *(2a)* and ethylene formed 4-thia-6-chlorocaproyl chloride *(3)*, b.p. 80–81 °C/0.1 mm. Reaction of *(2a)* in $CCl_4$ with primary amines in the presence of pyridine and with strict exclusion of moisture gave rise to the new *N*-alkylisothiazolidin-3-ones *(4a)*, *(4b)*, and *(4c)*. Correspondingly, *(2b)* formed *(4d)*, and *(2c)* gave the new *N*-alkyltetrahydro-1,2-thiazin-3-ones *(5a)* and *(5b)*.

The heterocyclic compounds *(4a)*, *(4b)*, *(4c)*, *(5a)*, and *(5b)* are colorless oils which decompose fairly rapidly on exposure to moist air. Aqueous bases and acids hydrolyse the S–N bond almost instantaneously. They presumably [4] give rise to intermediate carboxamides with an ω-sulfenic acid group, for we always found disulfide-type products of disproportionation of the latter, namely the diamides corresponding to *(1)*, among the subsequent products. Compound *(4d)*, which is also a colorless oil, has its sulfur atom bonded to a tertiary carbon atom and is thus considerably more stable.



| | R¹ | n | b.p. [°C/mm] | | R² | b.p. [°C/mm] |
|---|---|---|---|---|---|---|
| *(1a)* | H | 1 | 130–150/$10^{-3}$ [a] | *(4a)* | $C_4H_9$ | 62–62/0.05 |
| *(1b)* | $CH_3$ | 1 | 120–130/$10^{-3}$ [a] | *(4b)* | $CH_3$ | 46–47/0.05 |
| *(1c)* | H | 2 | 150–$10^{-3}$ [a,b] | *(4c)* | $C_6H_5$ | [c] |
| *(2a)* | H | 1 | | *(4d)* | $C_4H_9$ | 55/0.01 |
| *(2b)* | $CH_3$ | 1 | | *(5a)* | $C_4H_9$ | 62–63/0.01 |
| *(2c)* | H | 2 | | *(5b)* | $CH_3$ | 46/0.4 |

[a] Oil-bath temperature.
[b] Unstable.
[c] Decomposes on distillation.

Oxidation with excess monoperoxyphthalic acid in ether/chloroform converts *(4a)* into *N*-butylpropanesultam-3-one *(6)* [5], whereas reduction with lithium aluminohydride in ether causes ring fissure to give 3-(butylamino)propane-1-thiol *(7)*, b.p. 82–84 °C/0.2 mm.

## Capture of Benzynes by Acyldiazoalkanes

By Prof. Dr. W. Ried and Dipl.-Chem. M. Schön

Institut für Organische Chemie der Universität Frankfurt am Main (Germany)

Benzynes (dehydrobenzenes) are readily accessible [1], and are trapped in the presence of acyldiazoalkanes to give substituted indazoles as their conversion products. The reaction is essentially a 1,3-dipolar addition [2]. A solution of anthranilic

$R^1$ = acyl
$R^2$ = H or $C_6H_5$

Scheme 1.

acid in acetone was added dropwise to a boiling solution in methylene chloride of a mixture of the diazo compound and isoamyl nitrite. The indazoles thus prepared are listed in Table 1.

Table 1. Indazoles obtained according to Scheme 1.

| Diazo compound | Dehydrobenzene | Reaction product | M.p. [°C] | Yield [%] |
|---|---|---|---|---|
| Benzoyldiazomethane | $C_6H_4$ | 3-benzoylindazole [3] | 189 | 88 |
| *m*-Methylbenzoyldiazomethane | $C_6H_4$ | 3-(*m*-methylbenzoyl)-indazole | 157 | 81 |
| *p*-Chlorobenzoyldiazomethane | $C_6H_4$ | 3-(*p*-chlorobenzoyl)-indazole | 202 | 79 |
| β-Naphthoyldiazomethane | $C_6H_4$ | 3-(β-naphthoyl)-indazole | 208 | 82 |
| Benzoyldiazomethane | $C_6H_3Br$ | 3-benzoyl-5(6)-bromoindazole | 258–259 | 71 |

The structure of the new indazoles follows from their analyses, infrared spectra, and derivatives (*e.g.* 2,4-dinitrophenylhydrazones). Furthermore, some of the reaction products have already been prepared by another route [3]. These experiments, which have so far produced yields of over 70 %, are being continued.

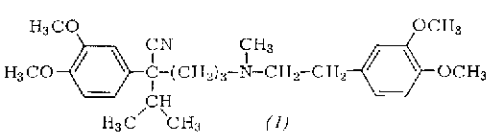
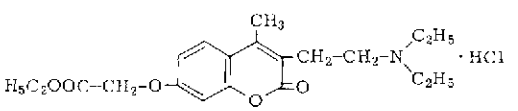
# CONFERENCE REPORTS



## Therapy Congress and Pharmaceutical Exhibition

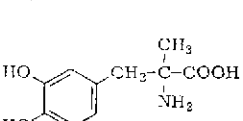
### Karlsruhe (Germany), August 31st to September 7th, 1963

Nearly 8000 physicians, pharmacologists, and representatives of the pharmaceutical chemical industry from Germany and elsewhere assembled at the 15th German Therapy Week in Karlsruhe. The program of lectures dealt with treatment of the peripheral circulation and disturbances of the blood supply to organs, with the therapy of bronchitis, bronchial asthma, and emphysema of the lungs, with the early detection and treatment of malignant tumors, with the clinical use of steroids, with the therapeutic problems of geriatry, with the importance in therapy of the water-electrolyte balance, and with the treatment of diseases of the abdomen and the maxillary sinus, *etc.* In his plenary lecture on "Scientifically Based Therapy", Prof. Dr. *H. Schäfer*, Heidelberg (Germany), pointed out *inter alia* that although the pathogenesis of diseases was often known nowadays, the etiology, *i.e.* the actual cause of illness, was usually still unknown, especially in the case of internal disorders. Therapy of such diseases must, therefore, still be confined largely to the treatment of the symptoms.



Almost 250 firms took part in the exhibition of pharmaceuticals. Of the many new preparations on show, only those in which new chemical compounds are being put on the market receive mention below. No reference is made to new presentations that are merely mixtures of known substances.

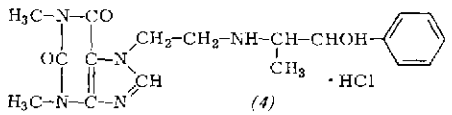
Knoll AG., Ludwigshafen (Germany), exhibited a new coronary dilator, Isoptin®. This greatly increases the supply of blood to the coronary vessels for a long time, and in particular ensures increased oxygenation of the heart muscle without greater effort from the heart. Therapeutic doses of Isoptin do not influence any other blood vessels. The active compound is 2-(3,4-dimethoxyphenyl)-5-(*N*-homoveratryl-*N*-methylamino)-2-isopropylvaleronitrile *(1)*, mol. wt. 454.62, a pale yellow oil of b.p. 243–246 °C/0.01 mm, $n_D^{25} = 1.5448$. It is used in the form of its hydrochloride, a white crystalline powder, m.p. 138.5–140.5 °C (corr.), which is sparingly soluble in chloroform, readily soluble in methanol and dimethylformamide, soluble in ethanol, isopropanol, acetone, ethyl acetate, *etc.*, and 7.2 % soluble in water at 21 °C.



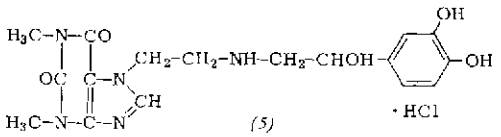
*(1)*

Another preparation for increasing coronary circulation is Intensain®, introduced by Cassella-Riedel Pharma GmbH. Intensain is 3-(β-diethylaminoethyl)-7-ethoxycarbonylmethoxy-4-methyl-2-oxo-1,2-chromene hydrochloride *(2)*, mol. wt. 397.66, a white crystalline powder, m.p. 159–160 °C, with a slightly bitter taste. It is readily soluble in water, alcohol, methylene dichloride, and chloroform. The free base is insoluble in water. Oral or parenteral administration of Intensain gives a degree of dilation of the coronary heart vessels not previously attained, and this is maintained for some hours. It has no effect on the blood pressure and causes no vasodilation in the peripheral circulation.

*(2)*



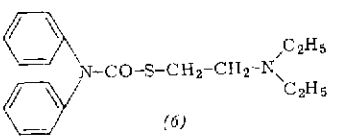
Presinol® from Farbenfabriken Bayer is a new hypotensive agent with the structure of (−)-3-(3,4-dihydroxyphenyl)-2-methylalanine *(3)*, (generic name: α-methyldopa). It melts at 292–293 °C and is soluble in water and in aqueous acids and alkalis. Although Presinol causes a large drop in the blood pressure, it ensures sufficient circulation in the peripheral system and vital organs. It is well tolerated and can be used for extended treatments. α-Methyldopa is a structural analogue of the natural amino acid dihydroxyphenylalanine (dopa), a precursor in the biosynthesis of noradrenaline. Administration of α-methyldopa probably blocks the synthesis of noradrenaline by inhibiting dopa decarboxylase.



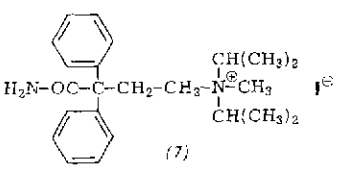
*(3)*

Chemiewerk Homburg have brought out a circulation analeptic, Akrinor®, containing two new derivatives of theophylline, *viz.* (−)-7-[2-(β-hydroxy-α-methyl-β-phenethylamino)ethyl]-theophylline hydrochloride *(4)*, mol. wt. 393.9, m.p. 244 to 246 °C, and 7-{2-[2-(3,4-dihydroxyphenyl)-2-hydroxyethylamino]ethyl}theophylline hydrochloride *(5)*, mol. wt. 411.9,

m.p. 186–188 °C; both are white crystalline powders. Akrinor is indicated in all cases of circulatory failure or poor circulation, of hypertonia, and of defective orthostatic regulation of the circulation.

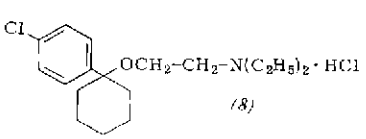


(4)



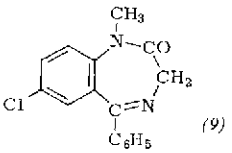
(5)

Farbenfabriken Bayer introduced a newly developed spasmolytic for use in parturition, Escorpal®. This reduces the abdominal tension of the natal canal, dilates the external orifice of the uterus, and thus shortens and eases childbirth. Escorpal is diethylaminoethyl diphenylthiocarbamate *(6)*, (generic name: phencarbamide), a white crystalline material, mol. wt. 328.5, m.p. 48–49 °C; it is very readily soluble in methanol, ether, and chloroform, readily soluble in light petroleum, and practically insoluble in water. It is administered either as the free base in suppositories, or intramuscularly or intravenously as a solution of the hydrochloride, mol. wt. 364.9, m.p. 180–182 °C.



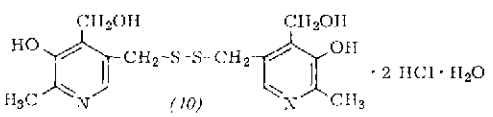
(6)

Stelabid®, an anticholinergic and neuroleptic from Röhm and Haas, Darmstadt (Germany), contains the known neuroleptic phenothiazine derivative Jatroneural® (generic name: trifluoperazine) together with the anticholinergic Tyrimide®, 4-(*N*,*N*-diisopropyl-*N*-methylammonium)-2,2-diphenylbutyramide iodide *(7)*, (generic name: isopropamide), which has been known for some time in the U.S.A. but which is new to the German market. Isopropamide is a crystalline compound, m.p. 198–201 °C (decomp.); the free base melts at 84–86 °C. Stelabid is suitable for stress-conditioned disorders of the digestive tract; it prevents hypermotility and spasm, reduces gastric secretion, and protects against nausea and vomiting.



(7)

Tonoquil®, from C. H. Boehringer & Co., Mannheim (Germany), is a psychotherapeutic combination of a new parasympatholytic drug, Chlorphencyclan, with the known phenothiazine derivative thiopropazate. Chlorphencyclan is 1-*p*-chlorophenyl-1-(β-diethylaminoethoxy)cyclohexane hydrochloride *(8)*, m.p. 143–145 °C, and has predominantly central with a little peripheral sympatholytic activity, combined with an antidepressant and stimulant action. Thiopropazate mainly suppresses the sympathetic system and thus relieves anxiety and emotional tension.

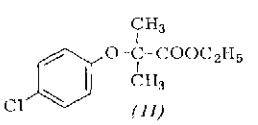


(8)

A new tranquillizer, Valium®, was introduced by Hoffmann-La Roche. The active constituent is 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one *(9)*, which is closely related structurally to the known tranquillizer Librium®. Valium has marked relaxant, sedative, hypnotic, and muscle relaxant properties. It is usually well tolerated; serious side-effects are not encountered at therapeutic doses.

(9)

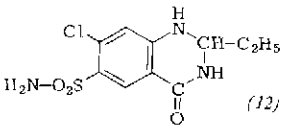
Encephabol® is a new dynamizing neurotrophic agent produced by E. Merck, Darmstadt (Germany). It contains Pyrithioxin® (generic name: pyritinol), bis-(3-hydroxy-4-hydroxymethyl-2-methylpyrid-5-ylmethyl) disulfide dihydrochloride monohydrate *(10)*, which is a crystalline solid that is readily soluble in water. Encephabol increases vigilance tone and thus relieves many clinical symptoms associated with cerebral insufficiency. It is indicated, for example, in organic psychosyndromes resulting from damage to cerebral blood vessels, nervous exhaustion and failure in senile involution, in secondary conditions arising from skull and brain traumas, intoxications, apoplectic attacks, encephalitis, *etc.* In spite of its structural resemblance to pyridoxin, Pyrithioxin has no vitamin $B_6$ activity.



(10)

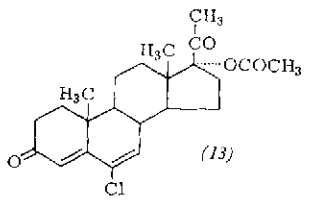
Pergalen®, a new and completely synthetic anticoagulent, produced by Farbwerke Hoechst, is presented in the form of an ointment that causes thrombolysis and resorption. The active substance is the sodium salt of a polyethylenesulfonic acid with a mean molecular weight of 7000, is highly effective, and has low toxicity. It is a white, non-crystalline powder which is stable at room temperature and readily soluble in water. Pergalen can be used for treating thrombosis, thrombophlebitis, ulcus cruris, hematomas, and contusions and for the dispersal of scar tissue, *etc.*

Epsilon-aminocaproic acid "Behringwerke" is a new blood-clotting agent marketed by Farbwerke Hoechst. It is suitable for stopping haemorrhages caused by excessive fibrinolysis and fibrinogenolysis, and can be used to prevent bleeding in gynecology, surgery, and especially in cases of overdosing with streptase or other fibrinolytic agents. Epsilon-aminocaproic acid blocks the activation of the proactivator-plasminogen complex leading to plasmin, and large doses will inhibit active plasmin itself. The drug is supplied as ampoules of sterile pyrogen-free solution, containing 10 g of the amino acid per 100 ml.



Atromid is an orally administered drug for arteriosclerosis and diseases of the blood vessels that was developed by I.C.I. and is marketed in Germany by Rhein-Pharma GmbH., Heidelberg. It is a mixture of androsterone and ethyl α-(*p*-chlorophenoxy)isobutyrate *(11)*, (generic name: clofibrate), a colorless liquid with a faint odor, $d_{20}$ = 1.140, b.p. 158–160 °C/25 mm, that is soluble in the usual solvents but not in water. Atromid causes rapid lowering of the serum triglyceride and cholesterol levels. It also reduces the uric acid level when this is raised by disease of the coronary arteries.

(11)



7-Chloro-2-ethyl-4-oxo-1,2,3,4-tetrahydroquinazoline-6-sulfonamide, *(12)*, (generic name: quinethazone), is a new mercury-free diuretic that was introduced in the U.S.A. a few

months ago by Lederle under the name Hydromox and is now marketed in Germany as Aquamox. It may be classified as a saluretic, since it promotes excretion of sodium chloride by inhibition of resorption in the renal tubules. Aquamox lowers pathologically high blood pressures without affecting the normal blood pressure. It differs from the benzothiadiazine dioxide series of sulfonamide diuretics by the formal replacement of the $SO_2$ group with a CO group.

*(12)*

E. Merck, Darmstadt (Germany), have marketed a new, highly active, and well tolerated oral progesterone derivative, *viz.* Gestafortin®, 17α-acetoxy-6-chloro-6-dehydroprogesterone *(13)* (generic name: chloromadinone acetate), m.p. 212–214 °C. The indications for Gestafortin are in general the same as for other gestagens. It causes a secretory change of the mucous membrane of the uterus producing a transformation of the endometrium that is histologically almost identical with that of a normal secretory change.

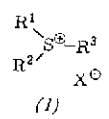
## Recent Investigations on the Structure of Heavy Metal Compounds

*K. Brodersen*, Aachen (Germany)

The reaction between mercuric chloride or bromide and tertiary enamines (*e.g.* 1-pyrrolidino-1-cyclohexene, 1-pyrrolidino-1-cyclooctene, 1-pyrrolidinoisobutene, 1-morpholino-1-cycloheptene, and α-morpholinostyrene) in ether gives *N*-mercurated α,β-unsaturated ammonium salts. 1-Pyrrolidino-1-cyclopentene and $HgCl_2$ or $HgBr_2$ react in ether, however, to yield *C*-mercurated immonium salts.



Reduction at −70 °C with lithium aluminohydride or metallic sodium or potassium formate in the presence of potassium t-butoxide as proton acceptor at room temperature gives the saturated tertiary amine (pyrrolidinocyclopentane), metallic mercury, and the halides from the *C*-mercurated immonium salts. When the *N*-mercurated enammonium salts are reduced, the enamines are recovered, and their hydrolysis products can be characterized. The conversion of enamines into *N*-mercurated enammonium salts is accompanied by a bathochromic shift whereas conversion into *C*-mercurated immonium salts results in a hypsochromic shift of the double-bond band in the infrared spectrum.

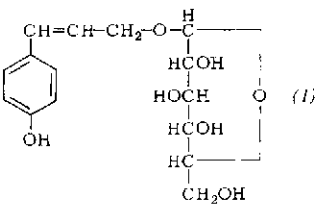
# SELECTED ABSTRACTS

**Sulfonium salts with alkyl and β-halogenoethyl ligands** have been prepared by *A. Lüttringhaus* and *A. Machatzke*. Their cytostatic activity was examined. These compounds are analogous to the previously known tri-(β-halogenoethyl)- and di-(β-halogenoethyl)vinylsulfonium salts *(1a)* and *(1b)*. The di-(β-chloroethyl)alkylsulfonium salts *(1c)* could be prepared by careful treatment of the β-hydroxyethylsulfonium compounds with thionyl chloride, but not by direct alkylation of mustard gas. The mono-(β-halogenoethyl)dialkylsulfonium



*(1)*

*(1a)* $R^1 = R^2 = R^3 = -CH_2CH_2Cl$
*(1b)* $R^1 = R^2 = -CH_2CH_2Cl$; $R^3 = -CH{=}CH_2$
*(1c)* $R^1 = R^2 = -CH_2CH_2Cl$; $R^3$ = alkyl
*(1d)* $R^1 = -CH_2CH_2Cl$; $R^2 = R^3$ = alkyl

salts *(1d)* could be prepared both by direct alkylation of hemi-mustard compounds [mono-(β-chloroethyl)mustards] and by chlorination of the β-hydroxyethylsulfonium salts with thionyl chloride. The sulfonium salts *(1c)* had a good cytostatic effect on tumors in experimental animals. On account of their improved effect on the Ehrlich carcinoma and of the possibility of varying the alkyl ligands, these compounds were found to be superior to the tri-(β-chloroethyl)sulfonium salts. The salts *(1d)* have no cytostatic activity. / Arzneimittel-Forsch. *13*, 366 (1963) / –R. [Rd 684/188 IE]

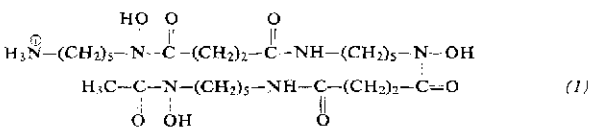
**The electron configuration of tetravalent and trivalent uranium** was examined by *B. Jezowska-Trzebiatowska*. It has so far not been possible to ascertain whether the elements with atomic numbers over 89 incorporate their additional electrons as d- or as f-electrons. The spectra of uranium(III) and uranium(IV) compounds can be interpreted by the ligand field theory, on the basis of an electron configuration $5f^2$ for U(IV) and $5f^26d^1$ for U(III). This view gained support from the magnetic properties of U(IV). / J. Chimie Physique *60*, 843 (1963) / –Hz. [Rd 776/200 IE]

**Triandrin, a new phenolic glycoside,** was isolated by *H. Thieme* from the bark of the almond willow (*Salix triandra* L.) by means of polyamide chromatography and was shown to be 3-(*p*-hydroxyphenyl)-2-propen-1-yl-1-β-D-glucopyranoside. Triandrin *(1)*, $C_{15}H_{20}O_7$, forms colorless needles from ethyl acetate, m.p. 177–179 °C, $[\alpha]_D^{20} = -60.5°$ (water). Emulsin splits *(1)* into glucose and *p*-coumaryl alcohol, m.p. 115 to 117 °C. Treatment with acetic anhydride/pyridine converts *(1)* into the pentaacetyl derivative, m.p. 108 °C, $[\alpha]_D^{20} = -37.2°$.

*(1)*

Triandrin was also detected in several other species of willow. / Naturwissenschaften *50*, 571 (1963) / –De. [Rd 780/195 IE]

**A method for the micro-determination of $Mg^{2+}$ and $Ca^{2+}$ in tissues** has been developed by *M. Höfer*. Phosphates and heavy-metal ions, such as $Fe^{2+}$, $Zn^{2+}$, $Cu^{2+}$, and $Mn^{2+}$, do not interfere. The test solution is passed through an ion-exchange column (Dowex 50-X8, $H^+$ form) and $Mg^{2+}$ and heavy metals are eluted with 2 N HCl. The heavy metals are complexed with 8-hydroxyquinoline and extracted with chloroform. $Mg^{2+}$ is titrated with EDTA in the presence of Eriochrome Black T, the end-point being detected by extinction measurements at 650 mμ. $Ca^{2+}$ is eluted with 3 N HCl and determined photometrically at 390 mμ as calcium naphthylhydroxamate. Sensitivity limits for the simultaneous determinations are: 15 μg $Mg^{2+}$, 5 μg $Ca^{2+}$. / Experientia (Basel) *19*, 367 (1963) / –Re. [Rd 787/206 IE]



**Optically excited electron states of mono- and disubstituted benzene derivatives** (nitro- and nitrosobenzene, dimethyl- and *p*-nitrodimethylaniline, *p*-dimethylaminobenzaldehyde) were measured and calculated by *H. Labhart* and *G. Wagnière* with regard to the position and intensity of the bands, the charge distribution, and the magnitude and direction of transition moments. The experiments are based on measurements of the dipole moments of the excited singlet states according to three methods, *viz.* electrical fluorescent polarization, electrical dichroism, and the influence of solvents on the spectra. The calculation is carried out according to the Pariser-Parr and Pople method, the single electron functions being taken as self-consistent for the ground state. The $\pi-\pi^*$ transitions are calculated from the basic functions, the configurational interaction being taken into account. The free parameters are adjusted so that the $\pi$-dipole moments, $\pi-\pi^*$ transitions, and $\pi$-ionisation energies for simple molecular fragments agree as closely as possible with the experimental values. / Helv. chim. Acta *46*, 1314 (1963) / –Jg.

[Rd 694/192 IE]

**The stability constants of 1:1, 1:2 and 1:3 complexes of Fe(III) with hezhydroxamic acid and acethydroxamic acid (CHA)** were determined by *G. Schwarzenbach* et al. by combination of optical ($FeA^{2+}$), redox potentiometric ($Fe^{3+}$), and pH measurements, the acidity constant of free hydroxamic acid being known.

$$Fe^{3+} + HA \rightleftharpoons FeA^{2+} + H^+;\ \log K_I = 11.42$$
$$FeA^{2+} + HA \rightleftharpoons FeA_2^{+} + H^+;\ \log K_{II} = 9.68$$
$$FeA^{+} + HA \rightleftharpoons FeA_3 + H^+;\ \log K_{III} = 7.2$$

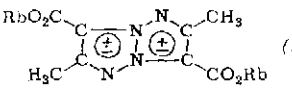
The equilibrium constants of the Fe(III) complexes of deferri-ferrioxamine B ($H_4$-DFO$^+$) *(1)* and similar polybasic hydroxamic acids can be obtained only by optical methods

*(1)*

(on account of their marked complex formation) from the equilibria with aminopolycarbonic acid (Trilon) complexes.

$$Fe^{3+} + H_2\text{–DFO}^- \rightleftharpoons Fe(H_2\text{–DO})^{2+};\ \log K_{II} = 21.7$$
$$Fe^{3+} + H\text{–DFO}^{2-} \rightleftharpoons Fe(H\text{–DFO})^{+};\ \log K_{III} = 30.5$$

Hydroxamic acid complexes are formed by many heavy metals as well as by $Ca^{2+}$, $Al^{3+}$, $Th^{3+}$, $La^{3+}$, and the rare earths. As these complexes are considerably less stable than those of Fe(III), the complex constants can be obtained from the NaOH titration curves of the free acids and the chelates. Hydroxamate (hydroxamic acid) complexes of Fe(III) occur in micro-organisms. / Helv. chim. Acta *46*, 1390, 1400, 1409 (1963) / –Jg. [Rd 693/191 IE]



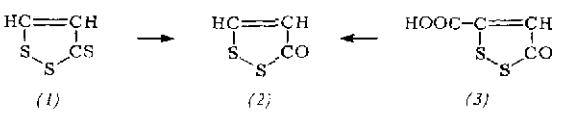
***S*-Phosphorylated thiols, a new class of energy-rich compounds,** can be obtained in high yield according to *S. Åkerfeldt* by a new synthetic pathway, *viz.* alkylation of the $SPO_3^{3-}$ ion by substituted alkyl halides. The *S*-phosphorylated thiols are obtained in up to 95 % yield and are separated as their Li or Li/Na salts; on hydrolysis, the S–P-bond is split only on warming in mineral acid (*e.g.* 1 N HCl at 100 °C) or enzymatically, *e.g.* by enzymes from human erythrocytes. For example, these split cysteamine-*S*-phosphate into cysteamine and orthophosphate. Some of the compounds synthetized, *viz.* *S*-(2-dimethylaminoisopropyl)-, *S*-(2-guanidinoethyl)-, and *S*-(3-guanidinopropyl)-phosphorothioxide possess radiation protective action. *S*-Phosphorylated thiols can serve as phosphorylating reagents as well as intermediate products for thiols (high yields); the compounds are of biochemical interest. / Svensk kem. Tidskr. *75*, 4 (1963) / –De.

[Rd 691/193 IE]

*ortho*-**Substituted phenols** were examined by *R. A. Nyquist*. They show an intense and remarkably wide infrared absorption band in the range 300–860 cm$^{-1}$, which can be ascribed to a non-planar deformation vibration of the hydroxyl group. The wide frequency range in which the band occurs is explained by the marked influence of intramolecular hydrogen bonds on this vibration. Relationships were found between the frequency of this vibration and both the valence frequency of the hydroxyl group and the Taft resonance parameters; accordingly, this vibration appears useful as a "characteristic" vibration. / Spectrochim. Acta *19*, 1655 (1963) / –Hz.

[Rd 774/198 IE]

**Identification of an aromatic non-benzenoid ring system by X-ray analysis** has been achieved by *M. Brufani*, *W. Fedeli*, *G. Giacomello* and *A. Vaciago*. The structure of derivatives of 1,3a,4,6a-tetra-azapentalene was elucidated by Patterson synthesis, with successive refinement by two-dimensional Fourier and Fourier-difference synthesis.



*(1)*

Derivatives of *(1)* are approximately planar; the stability of these compounds containing a ten-$\pi$-electron system confirms the "(4n + 2) rule". / Chem. Ber. *96*, 1840 (1963) / –Kr.

[Rd 777/194 IE]

**Dithione,** *i.e.* **1,2-dithiacyclopenten-3-one** *(2)*, has been synthetized for the first time by *R. Mayer* and *J. Faust*. Compound *(2)*, $C_3H_2OS_2$, m.p. 3 °C, b.p. 47 °C/0.1 mm, is obtained in 70 % yield by desulfurization of trithione *(1)* with mercurous acetate in chloroform/glacial acetic acid at room temperature. Decarboxylation of dithione-5-carboxylic acid

*(1)* *(2)* *(3)*

*(3)* by pyrolysis at 230–240 °C/10 mm affords 2–7 % *(2)*. Dithione is a colorless oily liquid, which is very stable, and is smoothly converted into *(1)* on treatment with $P_4S_{10}$ in $CS_2$. / Chem. Ber. *96*, 2702 (1963) / –Ma. [Rd 784/197 IE]

**Photocyanation of saturated ethers,** such as diethyl ether, glycol dimethyl ether, dioxan, tetrahydrofuran, and tetrahydropyran, gives yields of over 90 % according to *Eugen Müller* and *H. Huber*. Anhydrous ether/cyanogen chloride solutions (1:1) are irradiated with ultraviolet light from a high-pressure mercury lamp at 10–20 °C. Equivalent amounts of suspended $NaHCO_3$ absorb the HCl formed. Even small amounts of acetone increase the rate of photocyanation appreciably, probably by supplying additional radicals to initiate the reaction, which is thought to have a free radical mechanism. Open chain ethers are substituted exclusively in the $\alpha$-position, and cyclic ethers predominantly so. The amount of other isomers decreases with increasing distance from the oxygen atom. Saturated hydrocarbons can be cyanated in a similar manner. / Chem. Ber. *96*, 2319 (1963) / –Jg.

[Rd 782/196 IE]

**The mechanism of the protection by 1-hydrazinophthalazine against radiation** has been investigated by *S. Fallab* and *H. Erlenmeyer*. The reaction between *o*-phenylenediamine *(1)* and $H_2O_2$, which is catalysed by copper phthalocyaninetetrasulfonate, was taken as a model. In this reaction, H and OH radicals, which are produced in the material by hard radiation, are involved as well as $H^+$ and $OH^-$ ions. Oxidation of *(1)* with $H_2O_2$ was completely suppressed by stoichiometric quantities of 1-hydrazinophthalazine. It is concluded that oxidation-kinetic factors are decisive in the protective action observed *in vivo*. These experiments support the mechanism proposed for the protection by thiols. / Experientia (Basel) *19*, 374 (1963) / Re. [Rd 786/205 IE]

**Fresh Water from the Sea** (Dechema Monographs Nos. 781—834, Vol. 47) in two parts, 54 lectures presented at the European symposium "Fresh Water from the Sea" in Athens (Greece), May 28th to June 2nd, 1962. Verlag Chemie GmbH., Weinheim/Bergstr. 1962. 1st Edit., xii + 875 pp., numerous illustrations and tables. Clothbound, DM 100.– (about $25.00).

At the present time, it costs about $1 to produce 1000 gallons of fresh water from sea water; in favorable cases, this figure may be reduced to about $0.40 per 1000 gal. Of the most important methods, *viz.* evaporation, freezing, electrodialysis, hydrate formation, and ion-exchange techniques, the first two have the best prospects technically. In the distillation process, it is possible to conserve heat by evaporation in several successive stages and to prevent boiler scale formation by flash distillation; in the freezing process, the main difficulties are finding cheap methods of producing low temperatures and freeing the ice crystals from brine. The sharp increase in demand for domestic water supplies due to rises in population, industrial development, and the raising of the standard of living (present annual demand in the U.S.A. is 1000 $m^3$ per person; estimated demand for the year 2000 is 2000 $m^3$ per person) makes desalination of sea water one of the most important technical problems of our time.

The Greek Chemical Society and Greek Chamber of Technology invited specialists from all over the world to the 39th Congress of the European Federation of Chemical Engineering at Athens in order to discuss these problems. The 54 lectures of this symposium have now been printed in Dechema monographs in the lecturers' own languages (German, English, or French). Twenty-three articles deal with the evaporation process and 9 with the freezing process, while 20 contributions are devoted to the electrodialysis and related processes. Each paper has a summary in three languages, and each section is prefaced with an introductory article which indicates the present state of the appropriate technique and outlines its problems and possible developments.

Thus, this volume of Dechema monographs does not only give a comprehensive review of this technically and economically very important field, but also reveals the very special problems involved and makes it obvious that considerable development work will have to be undertaken before deserts can be irrigated and made useful. *D. Moegling* [NB 00685/62 IE]

**Analyse der Metalle** (Analysis of Metals), published by the Chemikerausschuß der Ges. Deutscher Metallhütten- und Bergleute (Chemical Committee of the German Society of Mining and Metallurgy), Vol. 2: Routine Analysis. 2nd Edit. Part 1. Aluminum-Sulfur, XVI + 726 pp., Part 2: Selenium-Zirconium, Physico-chemical Procedures, IV + 842 pp., Springer-Verlag, Berlin-Göttingen-Heidelberg, 1961, cloth. Price for both volumes: DM 158.-(about $40.-)

The fact that Vol. 2 of the "Analysis of Metals", covering "Routine Analysis", was sold out within six years of its first appearance indicates clearly the high regard and wide circulation that this detailed collection of analytical methods for routine work enjoys in the laboratories of the mining and metallurgical industries. The appearance of this second revised edition within eight years of the first publication is greatly to be welcomed. The established reliable arrangement of the extensive material has been retained unaltered. Some chapters are greatly extended, many old procedures have been discarded, others improved, and many new methods, particularly those employing complexometric titration and photometry, have been included. Chapters on conductometric and high-frequency titration have been added; the chapter on "Standard Samples" has been omitted and a chapter on "Buffer Solutions" is taken up, which contains an extensive collection of commonly used buffer solutions, with details of their pH values and adjustable pH ranges. The progress and development of analytical methods since the publication of the first edition has been taken into account in a pleasing and completely satisfactory manner. The size of the complete volume has only increased by about 10% despite these considerable additions and extensions. It is certain that this second edition will quickly gain the wide circulation it undoubtedly deserves and that its use will not be confined to the laboratories of the branches of industry that are immediately interested.

This positive overall evaluation, far from being undermined by some critical remarks, should be complemented by some suggestions for a new edition which is sure to be required before very long. It is noticeable that in only some of the chapters have the old methods for the determination of iron – titration with titanium(III) chloride, or colorimetric determination with potassium thiocyanate – given way to the new photometric methods of analysis. In various chapters different temperatures are recommended for the ignition of silicon dioxide (between 800 and 1200 °C) and of alumina and sesquioxides (between 900 and 1200 ± 50 °C). The reviewer is well aware of the time and trouble involved in securing the desirable improvements in the co-ordination of the chapters as mentioned in these examples. The terms "analytical moisture" and "analytically moist samples for analyses" (chapter on "Solid Fuels", p. 1144) are most unhappily chosen; they imply respectively the actual moisture content of the air-dried sample, and the air-dried sample in contrast to the sample dried to constant weight by heating (mostly at 110 °C).

The need for better accordance is also apparent in the chapters on "Physico-chemical Procedures". The principle adopted in the chapter on "Spectrophotometric Analysis" (see preamble, p. 1350) of extensively restricting the description of commercial instruments and of working out in exchange the user's requirements on these instruments to form a clear judgement ought to have been applied also in the following chapters, including the chapter on photometry. The user of the book is little served by mere enumeration of instrument types, some of which are already completely out-of-date and almost commercially unobtainable.

The chapter on "Potentiometry" should be expanded by inclusion of the techniques of amperometric and voltametric titrations and entitled "Analytical Measurements Employing Electrical End-Point Detection", as is fittingly required by the increasing use of these analytical methods derived from potentiometry.

The new chapter on "High-Frequency Titration" certainly gives an excellent survey of the literature of its applications, with 180 references, but it goes far beyond the strict field of metal analysis.

The reviewer, who is himself a long-standing user of the "Analysis of Metals" manuals, hopes that the defects pointed out can be rectified in the next edition and wishes the editor and authors all success. *K. E. Stumpf* [NB 72/60 IE]

# Defensive Substances of the Arthropods, Their Isolation and Identification

BY PROF. DR. H. SCHILDKNECHT [*]
IN COLLABORATION WITH DR. K. HOLOUBEK, DR. K. H. WEIS, AND DIPL.-CHEM. H. KRÄMER
INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT ERLANGEN-NÜRNBERG (GERMANY)

*Numerous orders of arthropods have organs which produce and store defensive substances. The purpose of our studies was to learn more about the chemical composition of these defensive secretions. In this work, we had to forego a priori many of the possibilities of classical organic-chemical analysis, since some of the insects were difficult to obtain and operation with substantial amounts of material was precluded. However, the defensive substances of various families of Arthropoda were characterized by using modern chemical and physical analytical procedures and our own methods of separation, purification, and enrichment which we developed specifically for this purpose.*

## 1. Introduction

On a winter's afternoon, on January 10th, 1789, *Pierre Lyonet* died in the Hague (Holland). Like *Swamerdam* [1], as an ingenious master of the lens and with homemade microscopes, he had investigated the internal fine morphology of insects [2]. Less than a decade after his death, the entomologist *Wilhelm* demanded a "new Lyonet", from whom he hoped to obtain a "micrographia" of the *Brachynidae*, by which the riddle of the bombardier beetle was to be solved [3]; however, he did not live to see the most important anatomical studies on the abdominal organs of carabid beetles [4–8]. He would perhaps have been disappointed; for, after outstanding work on the pygidial bladders of the great water beetle [9], *Dierckx* came to the conclusion that only with a knowledge of the chemistry of these organs could their significance and function be explained. What was lacking, therefore, was a "chemical anatomy", *i.e.* the correlation of the substances contained in the secretions and the chemical mechanisms involved in their formation to the types of organ already defined anatomically.

*Lyonet* extended and deepened the knowledge of insect anatomy with new means; the insect chemistry desired as a parallel to it likewise needed new methods to help identify the secretions of the defense bladders (Figs. 1 and 2) of different beetle species.

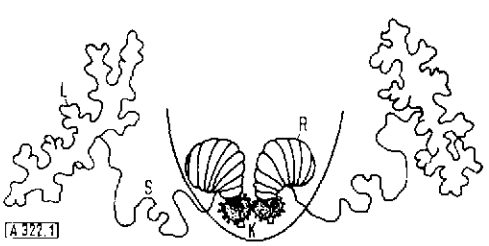

Fig. 1. Pygidial bladders of the bombardier beetle with reservoir R, explosion chamber K, lobes L, and collecting channel S (S and L have been drawn outside the abdomen). After [10].

## 2. Methods

Because of the small size of the organs and the often very small number of experimental animals that are available, the classical methods for the enrichment, separation and identification of mixtures of substances usually have to be dispensed with and modern microprocedures applied or developed [11].

Gases can be identified [12] accurately and elegantly with the mass spectrometer, and volatile compounds may be isolated with the simple suction apparatus [13] illustrated in Fig. 3.

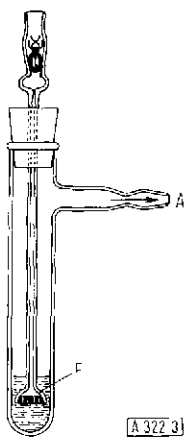

Fig. 3. Suction apparatus for isolating insects' defensive substances. F = porous glass plate.

If the beetle is irritated by pressing, pinching, or heat and air is slowly sucked past it and bubbled through a solvent in a trap, then only the substances discharged for defense are obtained. The beetle should remain alive so that, when it has regenerated its defensive material, it can be "milked" afresh. Naturally the extracts obtained in this way are still very dilute, so that the compounds sought can often not be determined unequivocally. The solutions, however, can be concentrated – without loss by decomposition and solvent volatility – by freezing out the solvent, *i. e.* by "normal freezing" [14, 15] and ice zone melting [16].

Using zone melting, traces of substances may also be isolated from solid solutions on a micropreparative scale [17], and mixtures of substances can even be separated, *e.g.* insect waxes [18] and fatty alcohols [19]. The most important supplement to these procedures for enrichment and separation are chromatographic methods, which also facilitate identification; however, successful identification usually requires spectroscopy.

We began our experiments in this way with carabid beetles, 6 to 8 mm in size, which possessed the best-developed defensive mechanism, *viz.* with the bombardier beetles [12, 20] (cf. Fig. 4).

Fig. 4. *Brachynus crepitans*, a carabid beetle 8 mm long with rust-red prothorax and blue-green elytra (wing cases); cf. [21]. Magnification: 2.5-times.

## 3. Bombardier Beetle (Brachynidae)

It was only many years after the old master of entomology, *De Geer* [22], had reported in his natural history of insects on the bombardier beetles that *Bergsträsser* [23] in 1778 ventured an explanation of the discharge, which he took to be a "Windschuss", *i.e.* an effect of compressed air. After this rather physical consideration, a doctor in the medical corps of the third French army corps of Napoleon gave the first details of the chemical nature of the substances expelled. During the Spanish campaign of 1808 in the Pyrenees, he had enough time to investigate the bombardier beetles *Brachinus* and *Aptinus* [4, 24, 25]. Inspired by the familiar chemistry of defense

of that time, he explained the red to brown spots on the skin caused by the discharge as being due to the action of nitric acid or of nitrous gases.

Without knowing of the results of this investigation, naturalists continued to interpret the bombardier beetle's discharge either from a physical or from a chemical point of view (Table 1). The final decision occurred only in 1957 when we were able to detect benzoquinone and toluquinone [12] in the "powder smoke" from living

Table 1. History of research on the bombardier beetle.

| Suggested bladder contents | Suggested expulsion mechanism | Year | Reference |
|---|---|---|---|
| Compressed air | "Windschuß" | 1778 | [23] |
| $HNO_3$ | Liquid spray | 1808 | [4, 24, 25] |
| Transparent liquid; reacts with $O_2$ of the air to give $HNO_2$ and $N_2O$ | Vapor spray | 1848 | [7] |
| Low boiling liquid | Vapor spray | 1860 | [27] |
| Compressed air (in the "condensateur") | "Air gun" with a "shot of an organic chemical nature" | 1884 | [28] |
| Iodine from an iodine-nitrogenous compound | Liquid spray | 1885 | [29] |
| Low boiling liquid with b.p. 8 and 15 °C | Vapor spray | 1899 | [9] |
| Nitrites, nitrous acid | Liquid spray | 1939 | [30] |

bombardier beetles by "bombardment" of chromatography paper impregnated with 2,4-dinitrophenylhydrazine (2,4-DNP) and by ultraviolet spectroscopy of the *Brachynus* extract together with 95–98 % oxygen, which was identified by mass spectroscopy and by micro gas analysis according to *Berg* [26]. However, in the storage bladders, which on the average weigh 0.8 mg, the appropriate "ammunition" must have occurred as a liquid or as a dissolved, colorless mixture of substances, for this is all that can be recognized by examination of the defense organs (Fig. 5).

Fig. 5. Bombardier beetle with pygidial bladders exposed.

However, if the secretion reservoir is pierced, its contents bubble out, and become colored more and more red-brown and finally violet (Fig. 6a–d).

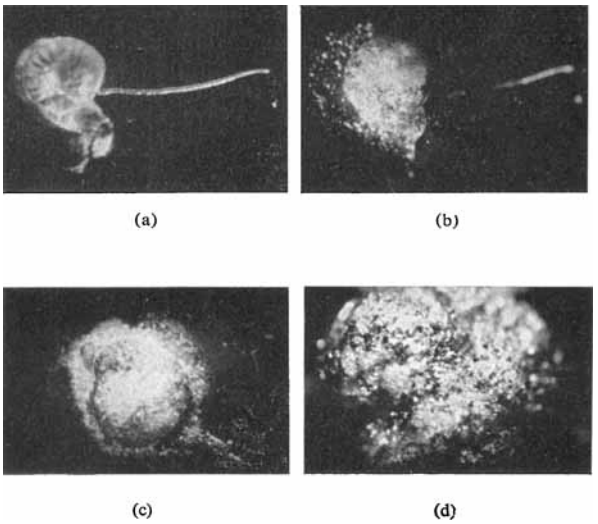

Fig. 6.
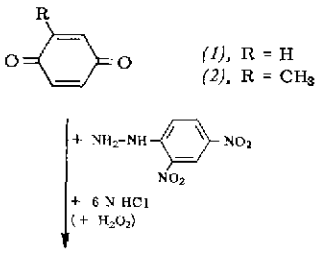
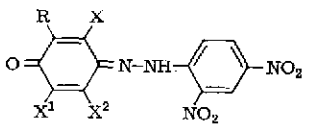
(a) An undamaged bladder from a bombardier beetle, entirely filled with a colorless liquid, dissected out with its collecting channel.
(b) Injured bladder. Start of the reaction: effervescence and bubble formation.
(c) End of the bladder reaction.
(d) The bladder reaction has stopped and crystalline quinhydrone (black dots) can be recognized.



The air around the destroyed bladder has a pungent smell like that of the discharge of the beetle. The smell is caused by enzymatically catalysed development of quinones. The coloration is sometimes very intense blue to violet and can be understood as being due to quinhydrone formation. That was a first indication that the quinones arose from hydroquinones. These were in fact detected in the colorless bladder contents in substance, by paper chromatography, and also by ultraviolet and infrared spectroscopy. They occur in the bladder as an approximately 10 % solution in about 25 % hydrogen peroxide, which was identified both qualitatively and quantitatively.



The hydrogen peroxide was detected in bladder extract obtained at −50 °C by oxidation of potassium iodide and reduction of potassium permanganate as well as colorimetrically with titaneous sulfate. The final decision as to whether $H_2O_2$ alone was really present was provided by paper chromatography with the solvent system ethyl acetate/dioxan/water (20:45:46) recommended by *Rieche* [31] for the separation of hydrogen peroxide and peroxides.

Also the 2,4-dinitrophenylhydrazones formed from the bladder substances indicated highly concentrated $H_2O_2$. As a study of the reaction of benzoquinones with 2,4-DNP showed, chlorinated hydroquinones are formed in presence of 6 N HCl before hydrazone formation occurs. These react either as such or after oxidation with still unreacted quinone to yield chlorinated 2,4-dinitrophenylhydrazones. In presence of $H_2O_2$, a further chlorobenzoquinone is generally formed. Thus, *p*-benzoquinone *(1)* reacts with 2,4-DNP in 6 N HCl to give the hydrazones of benzoquinone *(3)* and 3-chlorobenzoquinone *(4)*. In presence of $H_2O_2$, the 2,4-dinitrophenylhydrazone of 2,3-dichlorobenzoquinone

[31] *A. Rieche*, Angew. Chem. *70*, 263 (1958).

*(5)* was also formed. Toluquinone, 2,4-DNP, and 6 N HCl yield the hydrazones of toluquinone *(6)* and

| | R | X | $X^1$ | $X^2$ |
|---|---|---|---|---|
| *(3)* | H | H | H | H |
| *(4)* | H | H | H | Cl |
| *(5)* | H | H | Cl | Cl |
| *(6)* | $CH_3$ | H | H | H |
| *(7)* | $CH_3$ | Cl | H | H |
| *(8)* | $CH_3$ | H | Cl | H |

6-chlorotoluquinone *(8)*; if $H_2O_2$ is present, the hydrazone of 3-chlorotoluquinone *(7)* is obtained as well. In contrast to all the other hydrazones investigated, the 2,4-dinitrophenylhydrazones of 3- and 6-chlorotoluquinone dissolve in ethanol with a blue-green to violet color. Table 2 shows the $R_F$-values of the hydrazones *(3)* to *(8)*.

Table 2. Paper chromatography (descending) of the 2,4-dinitrophenylhydrazones of benzoquinones. The colors appear usually only after gassing the chromatograms with ammonia or spraying with caustic alkali. They remain after the evaporation of the ammonia.

| Compound | $R_F$-value[a] in; Color after treatment with | | |
|---|---|---|---|
| | Benzene/$CHCl_3$ (1:1); $NH_3$ | Diisopropyl ether/cyclohexane (1:1); 0.1 N NaOH | Diisoamyl ether/cyclohexane (4:1); 0.1 N NaOH |
| *(3)* | 1.0; red-violet | 1.0; red-violet | 1.0; red-violet |
| *(4)* | 0.08; red-violet | 1.20; red-violet | 1.39; red-violet |
| *(5)* | 0.00 | 0.42; red-violet | 0.44; red-violet |
| *(6)* | eluted | 1.10; blue | 1.15; blue |
| *(7)* | 0.47; red-violet | 0.21; red-violet | 0.11; red-violet |
| *(8)* | 1.0; violet | 1; blue-violet | 1; blue-violet |

[a] Relative to $R_F$ of *(3)* = 1.0.

The change in color of the hydrazones mentioned with alkalies is of the greatest value, especially if it is measured spectrophotometrically, for the rapid and reliable characterization of very small amounts of quinones (Figs. 7–9).

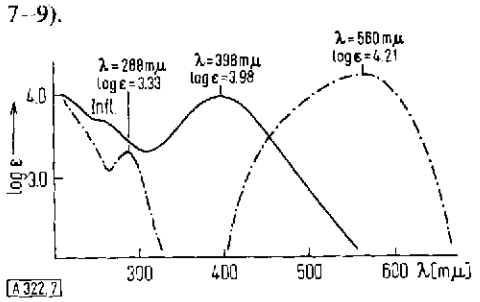

Fig. 7. Ultraviolet absorption curves of benzoquinone-2,4-dinitrophenylhydrazone *(3)*:
—— in 95 % ethanol; — · — · — in 0.1 N ethanolic NaOH.

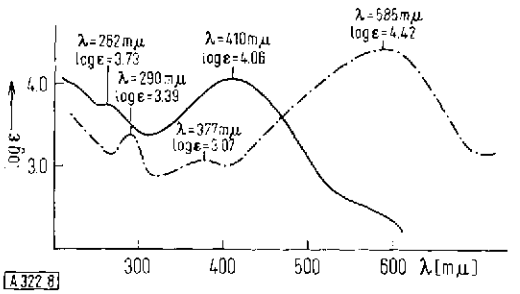

Fig. 8. Ultraviolet absorption curves of toluquinone-2,4-dinitrophenylhydrazone *(4)*:
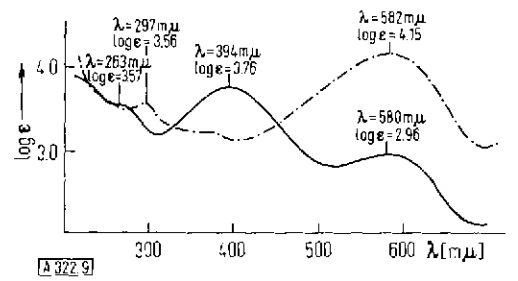
—— in 95 % ethanol; — · — · — in ethanolic 0.1 N NaOH.



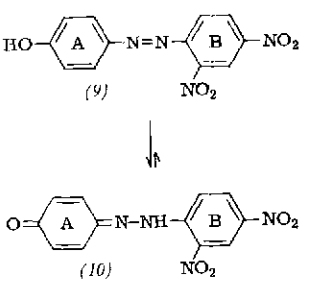


Fig. 9. Ultraviolet absorption curves of 6-chlorotoluquinone-2,4-dinitrophenylhydrazone *(8)*:
—— in 95 % ethanol; — · — · — in 0.1 N ethanolic NaOH.

This bathochromic shift is understandable when one realizes that 2,4-dinitro-4'-hydroxyazobenzene *(9)*, for example, exists entirely in the quinonoid form *(10)* [34] (in contrast to 4-hydroxyazobenzene [32, 33]).

In alcoholic solution, the 2,4-dinitrophenylhydrazones of quinones or even those of aldehydes and ketones [35–38] can therefore be regarded as weak acids, with the proton on the basic azo nitrogen [39]. The dissociation of these very weak acids is stronger if ring A is substituted with a methyl group. It is strenghtened even further by halogeno substituents.

The resonance-stabilized cation can be recognized in the ultraviolet absorption spectra by an inflexion of the absorption curve between 580 and 585 mμ for toluquinone-2,4-dinitrophenylhydrazone (Fig. 8, continuous curve) and by a maxi-

mum at 580 mμ for 6-chlorotoluquinone-2,4-dinitrophenylhydrazone (Fig. 9, continuous curve). It corresponds to the chief maximum of benzoquinone-2,4-dinitrophenylhydrazone in alkaline solution (Fig. 7, broken curve).

## 4. Darkling Ground Beetles (Tenebrionidae)

The members of this family of beetles are often termed "black beetles", although not all of them are black; a better designation would be "quinone beetles", for neither a study of the literature [40,41] nor our own investigations [13,42,43] have disclosed a tenebrionid without benzoquinone. Even 100 year old black beetles we obtained from museums contained quinones in the abdomen [43]. Since the tenebrionids do not always possess a well-filled storage organ for their defensive substances and as their defensive reaction often simply involves exposure of folds in the skin that contain glands [44], the secretion must be collected and concentrated by frequent "milking" of the beetles with the arrangement shown in Fig. 3. Frequently, however, when certain species – especially the death-watch beetle – are threatened, they give off a liquid, highly volatile yellow secretion from two cylindrical vessels [45], which can be analyzed without previous enrichment, *e.g.* by zone melting techniques.

In each case, the defensive fluid gave the typical ultraviolet absorption spectrum of *p*-benzoquinone, formed a quinhydrone, and gave a precipitate with 2,4-dinitrophenylhydrazine which was easy to purify by chromatography on a column of silica gel with chloroform as eluant. This enabled us to carry out a semiquantitative determination of the amounts of quinone stored by the beetles (Table 3).

Table 3. Amounts of quinone secreted by black beetles.

| Number of animals "milked" | Beetle species | Total amount of mono-hydrazones obtained [μg] | Calculated amount of quinone/beetle [μg] |
|---|---|---|---|
| 5 | *Blaps mortisaga* | 270 | 20 |
| 5 | *Bl. lethifera* | 360 | 27 |
| 10 | *Bl. mucronata* | 580 | 22 |
| 10 | *Bl. requienii* | 2430 | 91 |
| 20 | *Diaperis boleti* | 950 | 17 |
| 10 | *Helops quisquilius* | 160 | 6 |
| 5 | *Opatrum sabulosum* | 180 | 13 |
| 5 | *Scaurus uncinus* | 130 | 10 |

The monohydrazones of quinones may be identified rapidly and without much effort using our chromatographic procedure. When working with unknown mixtures, it is recommended to select the solvent after preliminary tests with a drop of secretion. As markers, the mono-2,4-dinitrophenylhydrazone of benzoquinone is used for the solvent mixture chloroform/benzene (2:1), that of 2-ethylquinone for cyclohexane/benzene (1:2), and that of 2-butylquinone for cyclohexane/benzene (2:1). The most suitable mixture for the 2,4-dinitrophenylhydrazones of the quinones from *Tenebrionidae* was chloroform/benzene (1:1). Fig. 10 shows a typical chromatogram.

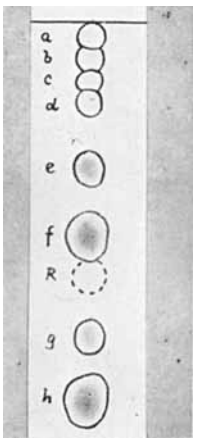

Fig. 10. Chromatogram of the bladders of different *Blaps* species, after treatment with 2,4-dinitrophenylhydrazine hydrochloride.

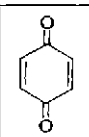

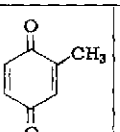

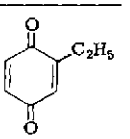

The red-violet spots a–d are the 2,4-dinitrophenylhydrazones of chlorinated quinones, which are formed in 6N HCl and facilitate interpretation of the chromatogram. The blue-violet spot f and the greyish, dark violet spot h are due to the 1-mono-2,4-dinitrophenylhydrazones of 2-methyl- and 2-ethyl-*p*-benzoquinone, respectively. The blue-violet spots e and g are derived from the 1-mono-2,4-dinitrophenylhydrazones of 3-methyl- and 3-ethyl-*p*-benzoquinone.

We have confirmed this allocation of the spots by paper chromatographic comparison with monohydrazones which we synthetized by coupling the corresponding phenols with 2,4-dinitroaniline according to the procedure of *Lauer* and *Miller* [34].

The secretions of all the black beetles investigated contain – with exception of the flour beetle *T. molitor* [13] – ethylbenzoquinone and toluquinone. In the case of two species of death-watch beetles and a *Scaurus* from Italy, benzoquinone is also found (Table 4).

In addition, the male of *Blaps requienii* possesses a brown bristly spot between the first and second ventral sternites that has been designated as its "Duftapparat"

Table 4. Substances contained in the pygidial bladders of 12 *Tenebrionidae* and one *Alleculidae* species.

[46] We thank Prof. Dr. *Pavan* (Pavia, Italy) for sending us this beetle.

or "perfume gland" [47]. In it we found a very small amount of *p*-benzoquinone, which is absent in the pygidial bladders of this species.

### 5. Earwigs (Forficulidae)

Our attempts to find secretions in the vast and multifarious insect family of the *Hymenoptera* had to be limited to earwigs, because our native grass-hopper species have no sign of the presence of defensive substances. There are five species of earwig in Germany, but we were only able to secure the common earwig *Forficula auricularia* (Fig. 11).

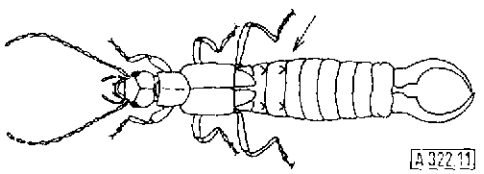

Fig. 11. *Forficula auricularia* Linn. (after [48]) with the 4 glandular orifices (arrow), from which the insects can spray their defensive substances distances of up to 10 cm.

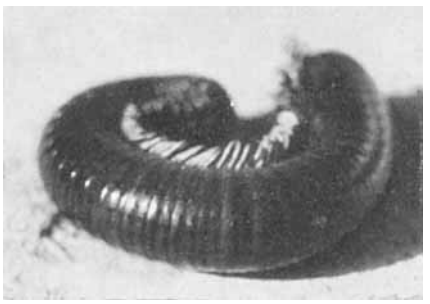
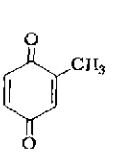
Its stink bladders contain a yellow to brownish, often violet-tinged liquid, in which quinones can be detected even in preliminary tests, *e.g.* by its absorption at 246 mμ. The secretion was worked up micropreparatively as for the death-watch beetles, *viz.* by "milking" the secretion into a trap with 2,4-DNP solution, extraction of the hydrazones with chloroform and purification on a silica gel column. The hydrazones obtained were those of toluquinone and ethylbenzoquinone; one earwig even yielded 20 μg of the quinone mixture per ejaculation [49]. Besides the quinones, the defensive bladders contain the hydroquinones, as can be shown by thin-layer chromatography [50].

### 6. Millipedes (Diplopoda)

When attacked, millipedes at once roll themselves together (Fig. 12) and extrude a yellow liquid from nearly every segment of their extremely hard chitinous shell.

This appeared at first to have a composition similar to that of the secretion of the *Tenebrionidae* and *Forficulidae*, but there were in fact two distinct differences. The ultraviolet absorption curve showed maxima between 250 and 254 mμ and between 370 and 375 mμ, and a micropreparation of a quinone fraction, obtained by column chromatography, dissolved in alkali very slowly with decompositon. The position of the ultraviolet absorption maxima suggested a methoxyquinone





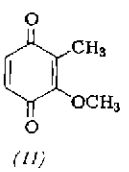


Fig. 12. Millipede (a *Spirostreptus* species from Peru) in alarmed condition [51].

[52], which, being a vinologous ester, ought to be saponifiable. We were able to characterize the quinone [54] as 2-methyl-3-methoxy-*p*-benzoquinone *(11)* in good agreement with the analytical results which *Pavan* [53] obtained with *Archiolus sabulosus*.

Table 5. Composition of the secretion of different diplopod species.

| Diplopod species | Relative amounts [%] of  |  *(11)* |
|---|---|---|
| Diplopod from Belgian Congo | 21 | 79 |
| Diplopod from New Guinea | 17 | 83 |
| Diplopod from Madagascar | 36 | 64 |
| *Rhinocricus* species from Peru | 48 | 52 |
| *Brachyiulus unilineatus* | 49 | 51 |
| *Cylindroiulus teutonicus* | 58 | 42 |

All six species of diplopods investigated secreted toluquinone and 3-methoxytoluquinone *(11)*, although the origins of the animals were quite different. Only the proportions vary. We isolated 0.5–1.5 mg of quinones per specimen in the form of their hydrazones from the indigenous species and more than 3.0 mg of quinones from the foreign species.

### 7. Bugs (Pentatomidae)

Very few readers will know the stink bladders of leaf beetle, but most may well have tasted their contents. From this detestable taste it may be concluded that the substances of the stink bladders of *Dolycoris baccarum*, for example, are not quinones but rather carbonyl compounds, as preliminary chemical and spectroscopical

[51] We wish to thank Dr. *O. Kraus* (Senckenbergische Naturforschende Gesellschaft), Prof. Dr. *H. J. Stammer* and Priv.-Doz. Dr. *G. Osche* (Institut für Zoologie der Universität Erlangen) for supplying us with foreign millipedes.

[52] *W. Flaig* and *J. Ch. Salfeld*, Liebigs Ann. Chem. *618*, 117 (1958).

[53] *R. Trave*, *L. Garanti*, and *M. Pavan*, Chim. et Ind. *41*, 19 (1959).

[54] *H. Schildknecht* and *K. H. Weis*, Z. Naturforsch. *16b*, 810 (1961).

tests did in fact show. Hence in this case, too, a red precipitate is obtained with 2,4-DNP; this we investigated with reference to our work on the phytoncides of angiosperms [55]. After preliminary purification on a silica gel column, we separated the mixture of hydrazones by thin-layer chromatography on silica gel G and analysed the fractions by paper chromatography. Table 6 gives the melting points and absorption maxima of the 2,4-dinitrophenylhydrazones found and synthetized for comparison.

Table 6. Ultraviolet absorption maxima and melting points of the 2,4-dinitrophenylhydrazones of three α,β-unsaturated carbonyl compounds and of three substances (A, B, and C) isolated from bugs.

| Substance | M.p. [°C] | $\lambda_{max}$ in ethanol [mμ] | $\lambda_{max}$ in ethanol/ 0.25 % NaOH [mμ] |
|---|---|---|---|
| A | 142 | 374 | 455 |
| $\Delta^2$-n-Hexenal-DNPH | 144 | 374 | 455 |
| B | 126 | 374 | 460 |
| $\Delta^2$-n-Octenal-DNPH | 126 | 372 | 455 |
| C | 120 | 372 | 455 |
| $\Delta^2$-n-Decenal-DNPH | 124 | 374 | 455 |

In agreement with the findings of *Waterhouse* [56], who investigated Australian leaf beetles, all our analytical data pointed to the result that the bug species listed in Table 7 give off $\Delta^2$-n-hexenal *(12)*, $\Delta^2$-n-octenal *(13)*, $\Delta^2$-n-decenal *(14)*, and a still unknown carbonyl compound for their defense [57].

Table 7. Proportions of the contents of bug bladders.

$H_3C-(CH_2)_n-CH=CH-CHO$ *(12)*, n = 2; *(13)*, n = 4; *(18)*, n = 6

| Bug species | Relative proportions [%] of | | | |
|---|---|---|---|---|
| | *(12)* | *(13)* | *(14)* | unknown carbonyl compound |
| *Dolycoris baccarum* L. | 50 | 20 | 5 | 25 |
| *Eurogaster* species | 60 | 20 | 0 | 20 |
| *Palomena viridissima* P. | 30 | 5 | 25 | 40 |
| *Cimex lactularius* P. (bed bug) | 70 | 30 | 0 | 0 |

Since hexenal is not lacking in the stink bladders of the bed bug, this is a good indication that leaf bugs very probably also synthetize hexenal in their own metabolism and do not merely take it up with their food from leaves, in which unsaturated aldehydes invariably occur [55, 58, 59].

*Scherny* reported the occurrence of about 20000 known carabid beetle species [60], of which about 900 are found in Germany. When excited, all of these beetles release colorless, liquid, highly volatile secretions from paired defense organs [61]. In this way, two groups of carabids can be distinguished simply by their smell.

One group, including all members of the subfamily *Carabinae*, but also some *Harpalinae*, secrete, as *Scherney* himself put it, "a sharp, peculiarly aromatic smelling liquid", which causes a transient but nonetheless painful burning sensation in the eye. *Horion* [62] speaks of an intense musky smell, that clings to the fingers.

The other group, exclusively beetles of the subfamily *Harpalinae*, also excrete a liquid secretion, but this has a pungent smell.

### a) The "Aromatic" Carabid Beetle Secretion

As early as more than a hundred years ago, a notable publication by *Pelouze* [63] appeared which has not been questioned till today. In his article "Sur la nature du liquide sécreté par la glande abdominale des insectes du genre Carabe" he advanced the view that the secretion of *Carabus niger* and of *C. auratus* consisted of mainly butyric acid. In our experience, butyric acid smells differently. In agreement with *Pelouze*, however, we found that the carabid beetle's secretion reacts acidic, corrodes the skin, and that its alkali salts are strongly surface active.

The observation that the secretion evaporated easily but often formed spontaneously a plastic film were hard to explain. The question of the state of aggregation of the acid we were seeking could not be elucidated at first by repeated observation of the crude secretion. The possibility of a gaseous or solid substance in solution existed just as much as that of a liquid compound. We were extremely fortunate, therefore, when a gold beetle *Carabus auratus* (Fig. 13) sprayed the lens of my companion's

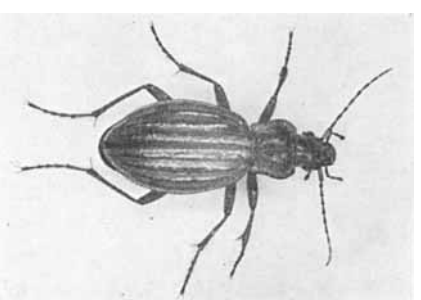

Fig. 13. *Carabus auratus* L., the gold beetle, a carabid beetle 20–27 mm long, with a metallic green colored prothorax and yellowish, gold-green elytra. Magnification ca. 1.1-times.

[63] *M. J. Peloaze*, C. r. hebd. Séances. Acad. Sci. *43*, 122 (1856).

spectacles and its defensive secretion immediately solidified, at least partially. From its melting point of 62 °C preliminary spectrophotometrical tests, preliminary chemical tests with $KMnO_4$, bromine water, and tetranitromethane, and by chromatographic comparison with different organic acids, we were also led to suspect a carboxylic acid of moderate molecular weight, but an unsaturated one.

Further characterization of the acid was only possible when we happened to observe how a beetle's discharge gave a persistent mist of an ammonium salt when held near to an open bottle filled with aqueous ammonia.

Afterwards by collecting the secretion spray on a microscope slide and treating it with ammonia gas, we succeeded in obtaining a colorless, crystalline, easily sublimable ammonium salt. This was particularly suitable for establishing a small store of secretion. Nevertheless, we had only a few milligrams from which to remove always only a minute fraction for infrared spectroscopical comparison with other branched and unsaturated carboxylic acids. We finally found the best agreement between the secretion and tiglic acid. In spite of the similarity of the infrared spectra of the ammonium salts of the two acids, two absorption bands that were especially characteristic for each of the spectra lay at different wave numbers. The spectrum of tiglic acid contains bands at 798 and 748 $cm^{-1}$, that of the beetle secretion at 924 and 823 $cm^{-1}$ (Fig. 14). From the differing positions of these skeletal vibrational bands, the spectroscopist can interpret differing chain lengths. Elementary analysis [64] and a quantitative microhydrogenation were also indicative of a shorter chain, thus suggesting methacrylic acid *(15)*. In addition, we examined the hydrogenation product by paper chromatography. Surprisingly, we established thereby that instead of the one acid expected, there were actually two, one of which, of course, greatly predominated. This not only showed the same $R_F$-value in the chromatogram as isobutyric acid, but also gave the same infrared spectrum. This was the second important indication of methacrylic acid in the beetle secretion; examination of the secretion in the crude state then gave the infrared spectrum of this acid (Fig. 15).

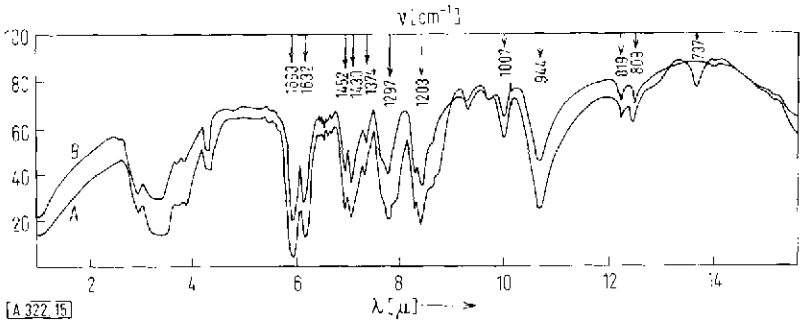

Fig. 15. Infrared spectra of the crude beetle secretion (A) and of methacrylic acid (B).
Ordinate: Transparency [%].

Here, a broadening of the band at 1297 $cm^{-1}$ and an only moderately pronounced band at 737 $cm^{-1}$ also indicate a second substance, which was later identified as tiglic acid. On comparing the spectra of the ammonium salts of the secretion, of methacrylic acid *(15)*, and of tiglic acid *(16)* (Fig. 14), the inflexion at 798 $cm^{-1}$ and the band at 748 $cm^{-1}$ may equally be ascribed to tiglic acid. Finally tiglic acid itself was successfully isolated in the crystalline state from the secretion and characterized [66] like the methacrylic acid by its infrared and mass spectra and as its tetraphenylstibonium salt [65].

The similar appearance of all the infrared absorption spectra of the crude ammonium salts served as particular evidence that methacrylic acid and tiglic acid also occur in the secretions of numerous other carabids. At the same time, the relative proportions of the acids may be determined from these spectra (Table 8).

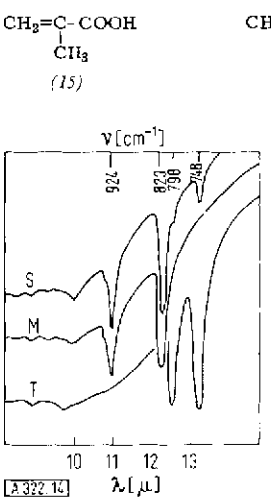

Fig. 14. Sections from the infrared spectra of the ammonium salts of carabid beetle secretion (S), methacrylic acid (M) *(15)*, and tiglic acid (T) *(16)*, superposed for comparison.

Table 8. Carabid beetles with methacrylic acid and tiglic acid as defensive substances.

| Beetle | Methacrylic acid [%] | Tiglic acid [%] |

[64] We wish to thank Dr. *H. Gysel* (CIBA AG., Basel) for his great kindness in carrying out the relevant elementary analyses.

[65] *H.E. Affsprung* and *H.E. May*, Analytic. Chem. *32*, 1164 (1960).
[66] *H. Schildknecht* and *K. H. Weis*, Z. Naturforsch. *17b*, 439 (1962).

In the manner described, we have also found a methacrylic-tiglic acid mixture qualitatively in the following carabid beetles:

*Carabus coriaceus* L.
*C. cyaneus* F.
*C. violaceus* L.
*C. irregularis* Fbr.
*C. Ullrichi* Germ.
*Pterostichus metallicus* Fbr.

We found only methacrylic acid in the Japanese carabid beetles *C. procerulus*, *Damaster oxuroides*, and in the indigenous *Cychrus rostaratus*.

b) The "Pungent" Carabid Beetle Secretion

In contrast to the *Pterostichini* on the one hand and the *Brachynini* on the other, *Pseudophonus pubescens* and *Ps. griseus* excrete a quickly evaporating, sharp and pungent smelling liquid in self-defense. Its reaction with pH indicators, its ultraviolet spectrum, and its irritant properties suggest a strong acid. Chromatography according to *Long* [67] gave only one spot for the bladder contents of these three *Harpalinae* species. Paper chromatography was also the only method that could be used for investigating the secretion of *Harpalus dimidiatus* Rossi, since we had only two specimens of this species available. Chromatography afforded formic acid, which was also determined quantitatively by the method of *Frehden* and *Fürst* [68] and by titration. It was calculated that 1.5–2.0 mg of 75 % formic acid must be present in the beetle's bladder [69].

Using paper chromatography with the system ethanol/water/ammonia (80:16:4) (Schleicher and Schüll paper 2043b), we also detected formic acid ($R_F = 0.50$) as the defensive substance in members of the genera *Calathus*, *Acinopus*, and *Carterus* (Sicilian carabid beetles) which were not identified more closely.

## 9. Water Beetles (Dytiscidae)

The true water beetles became aquatic only late in the process of evolution. They have then very probably lost the ability of the carabid beetles of suddenly discharging the contents of the pygidial bladder. Thus one finds – especially with freshly caught water beetles – that the glistening yellow bladders are usually tightly filled. On extrusion into ethanol, one obtains a yellow solution and a colorless precipitate, which was at first recognized only as a glycoprotein by infrared spectroscopy and electrophoresis [70].

Chromatography on silica gel of the solution from one beetle yields about 3 mg of colorless crystals, which can be readily sublimed (m.p. 110 °C) [71]. These crystals have a low molecular weight *(115)*, but a very complex infrared absorption spectrum, and are not made up of a homogeneous substance. That was to be expected, for, in accordance with the thin-layer and paper chromatograms, which contain at least three spots, different types of gland cells can be clearly distinguished in the secretion-producing cell complexes [72].

Since we did not obtain a reliable analytical result simply by chromatography, and since the mixture of substances could be separated by micropreparative zone melting, we subjected the pygidial bladder secretion of the great water beetle to micro-zone melting [73]. After the passage of 20 zones through a micro-ingot [74], we obtained at first two fractions. A eutectic was separated from the low melting fraction by renewed zone melting [75] (Fig. 16).

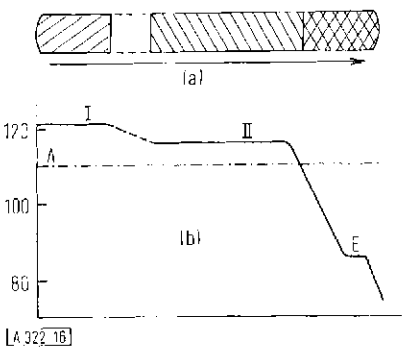

Fig. 16. Zone-melted ingot (a) and melt diagram (b) of the soluble portion from the crude secretion of *Dytiscus marginalis*. The data leading to characterization of the fractions I (m.p. 121 °C) and II (m.p. 116 °C) as well as one of the substances isolated from the eutectic E (m.p. 86 °C) are shown in Table 9.

A = Starting mixture (m.p. 110 °C).

The arrow under the ingot indicates the direction of movement of the zones.

Ordinate: Melting point [°C].

Table 9 shows how chemical characterization of the components of the secretion became possible by comprehensive analysis of the fractions obtained by zone melting. The eutectic mixture which was not further separable by fractional melting, was subjected to thin-layer chromatography and yielded a substance, which after repeated zone melting, was pure enough to be identified as methyl *p*-hydroxybenzoate. All the species of the genus *Dytiscus* investigated by us defend themselves – presumably only against attack by micro-organisms – with a mixture of benzoic acid *(17)*, methyl *p*-hydroxyhenzoate *(19)*, and *p*-hydroxybenzaldehyde *(18)* (Table 10); the first two compounds may also be used, according to German food laws, for stabilizing foodstuffs, especially canned fish. ## 10. Summary

We have identified homologues of *p*-benzoquinone in all darkling ground beetles (*Tenebrionidae*). The quinones are sometimes stored in bladders and are always accompanied by the corresponding hydroquinones, which, in the bombardier beetles (*Brachynidae*), are present alone and undecomposed besides hydrogen peroxide. It was surprising that earwigs, too, which taxonomically belong to the *Hymenoptera*, squirt out toluquinone and ethylbenzoquinone for self-defense and even lower animals like the millipedes can give off toluquinone and methoxytoluquinone dropwise in the form of a yellow solution or suspension. The stink bladders of bugs contain α,β-unsaturated carbonyl compounds, too, *viz.* hexenal, octenal, and decenal.

The bladder contents of most carabid beetles (*Carabinae*, *Harpalinae*) are either nearly 75 % formic acid or a mixture of 95 % methacrylic acid and 5 % tiglic acid. Here, too, it is not yet explained how this mixture can be stored without decomposition and without attacking the very thin walls of the bladder. Although the water beetles (*Dytiscidae*) are closely related to the carabid beetles, their pygidial bladders contain only one carboxylic acid, *viz.* benzoic acid. The major amount of the contents is formed by *p*-hydroxybenzaldehyde, which is accompanied by methyl *p*-hydroxybenzoate.

Who ever watched one of the insects described aiming and shooting at an intruder, is convinced that they cannot only fight their like but also larger animals. The amounts of defensive substances are small, but so are most of the aggressors, who frequently can only rescue themselves by fleeing hastily from the biting and ill-smelling cloud of poison gas. An insect kept in a closed jar is perished by its own defensive substances. From the type of compounds found and particularly from the chemical composition of the bladder contents of water beetles it follows that the defensive substances produced can also be directed against micro-organisms. Hence these substances might also be termed antibiotics of the insect kingdom. They make it possible for the animals to live in most awful surroundings without being troubled by parasites.

*We are very grateful to the Deutsche Forschungsgemeinschaft and to the Fonds der Chemischen Industrie for supporting our work on insect compounds by financial and material aids. We also thank our colleagues who, with much idealism, helped us to catch and to determine the insects and millipedes.*

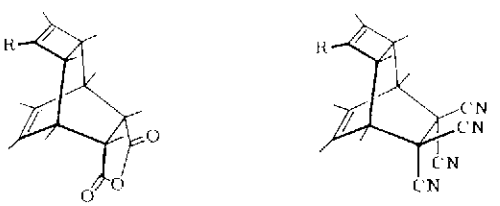
# The Valence Tautomerism of Cyclooctatetraene

BY PROF. DR. R. HUISGEN AND DIPL.-CHEM. F. MIETZSCH

INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT MÜNCHEN (GERMANY)

*The Diels-Alder adducts of cyclooctatetraene and its derivatives are derived from the bicyclo[4,2,0]octane structure. A kinetic investigation shows that the Diels-Alder addition of dienophiles to cyclooctatetraene and phenylcyclooctatetraene is preceded by a valence tautomerism equilibrium with bicyclo[4,2,0]octa-2,4,7-triene or its 7-phenyl derivative.*



The reactions of cyclooctatetraene have repeatedly claimed the attention of theoretical chemists. *Willstätter* and *Waser* [1], whose outstanding work first made the tetra-unsaturated hydrocarbon available, expressed some disappointment at the establishment of its non-aromatic character. A thorough study of the chemistry of cyclooctatetraene was made possible by *Reppe*'s discovery of a convenient synthesis [1a] for this compound. The variety of its reactions required an interpretation which involved the structures *(1)* to *(3)* [2].

*(1)* *(2)* *(3)*

However, it was not known whether the eight-membered ring structure *(1)* first isomerized to form *(2)* or *(3)*, or whether rearrangement occurred in a collision complex formed with the reagent, thus giving products which are formal derivatives of *(2)* or *(3)*. Both the first [3] and the second [4,5] interpretation have been suggested. The following kinetic studies of the Diels-Alder reaction indicate a true valence tautomerism between cyclooctatetraene *(1)* and bicyclo[4,2,0]octa-2,4,7-triene *(2)*.

It has been firmly established [2,6] that the maleic anhydride adduct of cyclooctatetraene is represented by structure *(4)*. The analogous adduct *(5)* of phenylcyclooctatetraene [7], which was isolated in 92 % yield, exhibits the ultraviolet absorption characteristic of styrene derivatives. Addition of one mole equivalent of hydrogen to the cyclobutene ring changes the light absorption to that of an alkylbenzene, and indicates that the phenyl group is situated as shown in *(5)*. Nuclear magnetic resonance spectra confirm this constitution. The number of vinyl hydrogen atoms in the cyclobutene ring is shown to be two for *(4)* but only one for *(5)*. Sharp singlets occur at 4.03 $\tau$ for *(4)* and 3.80 $\tau$ [7a] for *(5)*. Formulae *(6)* and *(7)* for the Diels-Alder adducts of tetracyanoethylene with *(1)* [8] and *(8)* respectively, which we obtained in yields of 92 % and 96 %, are also supported by NMR spectra and hydrogenation. The adduct of fumaryl chloride with *(8)*, which was analyzed and investigated by NMR spectroscopy after methanolysis (two diastereoisomers), was shown to contain the same ring structure. These Diels-Alder adducts are therefore, at least formally, derived from the bicyclic structures *(2)* and *(9)*.

*(4)* R = H
*(5)* R = $C_6H_5$

*(6)* R = H
*(7)* R = $C_6H_5$

The boat conformation of cyclooctatetraene *(1)*, proven by physical methods, contains no 1,3-diene system providing the approximately planar configuration essential for a Diels-Alder reaction. On the other hand, the bicyclic structure *(2)* does offer a planar diene system, particularly since the incorporation of the cyclobutene ring causes further flattening of the 1,3-cyclohexadiene system. At 140 °C, 1,3-cyclohexadiene adds maleic anhydride [9] 120 times more rapidly than does *(1)*. This suggests that a moderate equilibrium concentration of *(2)*, rather than *(1)*, may enter into the Diels-Alder reaction. Neither 1,3-cyclooctadiene [3] nor 1,3,5-cyclooctatriene can take up maleic anhydride, but bicyclo-[4,2,0]octa-2,4-diene [10], which is also a derivative of cyclohexadiene, is able to do so. This behavior, like the configuration of the adducts, confirms the above hypothesis.

C B A

*(1)* R = H *(2)* R = H

*(8)* R = $C_6H_5$ *(9)* R = $C_6H_5$

The reaction of cyclooctatetraene *(1)* with an excess of dienophiles was followed dilatometrically [11] (any union of two molecules to form one molecule is accompanied by a contraction in volume) and the pseudo-first-order rate constants $k_d$ were determined.

$$\frac{d[A]}{dt} = k_d [C].$$

As long as the valence tautomerism is mobile and the rate is dependent only on the reaction of *(2)* with the dienophile D ($k_2 \ll k_1, k_{-1}$), the following relationship holds (with the symbols as above):

$$k_d = \frac{k_1}{k_{-1}} k_2 [D].$$

The required linear relationship between $k_d$ and [D] may be illustrated by the reaction of cyclooctatetraene with maleic anhydride in chlorobenzene at 140 °C (I in Fig. 1).

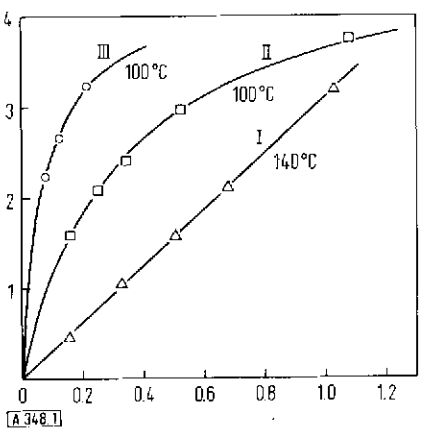

Fig. 1. Pseudo-first-order rate constants for the reactions of cyclooctatetraene with maleic anhydride in chlorobenzene (I), and with tetracyanoethylene (II), and dicyanomaleic imide (III) in dioxane.
Ordinate: $10^4 k_d$ [sec$^{-1}$].
Abscissa: dienophile concentration [mole/l].

The use of an extremely reactive dienophile which immediately traps every molecule of the bicyclic tautomer *(2)* formed from *(1)* (*i.e.* $k_2 \gg k_1, k_{-1}$), would give dilatometrically measured rate constants which are independent of the concentration of excess dienophile, *i.e.* $k_d = k_1$. We would then expect a straight line, parallel to the abscissa in Fig. 1.

Between these two extremes, *i.e.* where $k_2$ is of the same order of magnitude as $k_1$ and $k_{-1}$, a more complicated rate equation is obtained, which gives rise to a concave curve, bent towards the abscissa, when $k_d$ is plotted against increasing dienophile concentrations. Since the concentration of the intermediate *(2)* is small, the concentration change will also be small, and the Bodenstein theorem can be applied.

$$\frac{d[B]}{dt} = 0; \; k_1 [C] = k_{-1} [B] + k_2 [B] [D].$$

$$\frac{d[A]}{dt} = k_d [C] = \frac{k_1 k_2 [C] [D]}{k_{-1} + k_2 [D]}.$$

By a simple transformation one arrives at the equation for a straight line for the plot of $k_d$ against $k_d/[D]$.

$$k_d = k_1 - \frac{k_{-1}}{k_2} \frac{k_d}{[D]}.$$

At 20 °C, tetracyanoethylene adds onto 1,3-cyclohexadiene 1150 times more rapidly than does maleic anhydride [9]. The reaction of tetracyanoethylene with *(1)* can be followed at 100 °C in dioxane. The $k_d$ values measured for increasing concentrations of tetracyanoethylene indicate that the order of magnitude of $k_2$ becomes comparable to that of $k_{-1}$ (II in Fig. 1). The plot of $k_d$ against $k_d/[D]$ is indeed a straight line (I in Fig. 2) with $10^4 k_1 = 4.85$/sec and $k_{-1}/k_2 = 0.34$ mole/l.

The constant $k_1$ of the preliminary valence isomerization, measured via $k_d$, should be independent of the nature of the dienophile, provided that the latter is sufficiently active. In confirmation, dicyanomaleic imide, which adds to butadiene at 20 °C five times more rapidly than does tetracyanoethylene [9], gives the following values with cyclooctatetraene: $10^4 k_1 = 4.4$/sec and $k_{-1}/k_2 = 0.078$ mole/l (III in Fig. 1 and II in Fig. 2).

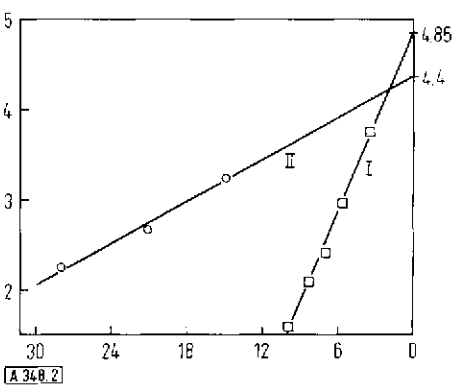

Fig. 2. Dilatometrically determined rate constants from Fig. 1, plotted against $k_d/[D]$ (dioxane, 100 °C).
I: Reaction with tetracyanoethylene
II: Reaction with dicyanomaleic imide
Ordinate: $10^4 k_d$ [sec$^{-1}$].
Abscissa: $10^4 k_d/[D]$ [l·mole$^{-1}$, sec$^{-1}$]

Surprisingly, it is found that the dilatometrically determined rate constants for the reaction of phenylcyclooctatetraene *(8)* with tetracyanoethylene at 70 °C and concentrations greater than 0.2 M depend only slightly on the excess concentration of the dienophile (I in Fig. 3). The small slope of the straight line I in Fig. 4 corresponds to $k_{-1}/k_2 = 0.022$ mole/l and shows that in this case the reverse reaction, *i.e.* *(9)* → *(8)*, has already been largely suppressed. Even more striking is the "plateau phenomenon" observed with dicyanomaleic imide (III in Fig. 3). The curved path followed by the $k_d$ values for the addition of fumaryl chloride to phenylcyclooctatetraene (II in Fig. 3) gives $k_{-1}/k_2 = 0.49$ mole/l,

[11] We thank Dr. *W. D. Wirth*, Universität München 1960, for the development of the dilatometric technique used in these experiments.

when plotted against $k_d/[D]$ in Fig. 4. Kinetic studies with the three dienophiles furnish the respective values of 2.28, 2.28 and 2.21 for $10^4 k_1$ [$sec^{-1}$], and confirm the required independence of the nature of the dienophile.

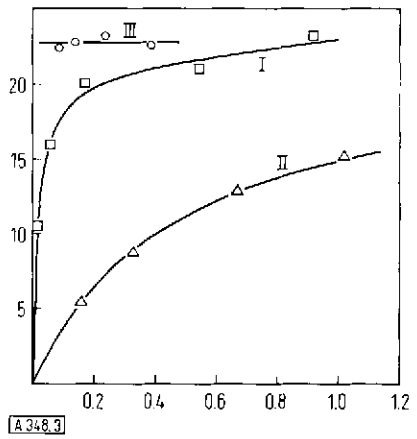

Fig. 3. Dilatometrically determined rate constants ($k_d$) for the reactions of phenylcyclooctatetraene *(8)* at 70 °C with tetracyanoethylene (I) and fumaryl chloride (II) in ethyl acetate, and with dicyanomaleic imide (III) in tetrahydrofuran.
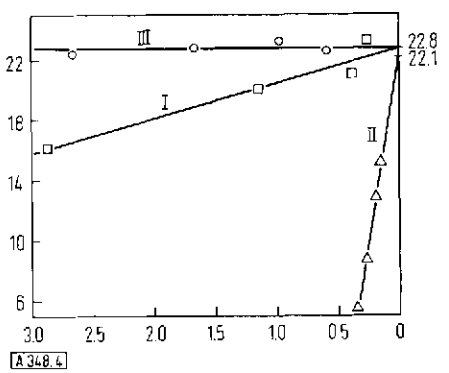
Ordinate: $10^5 k_d$ [$sec^{-1}$].
Abscissa: Dienophile concentration [mole/l].



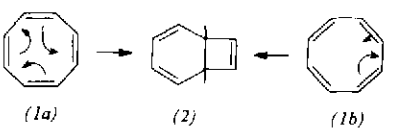


Fig. 4. Rate constants of the Diels-Alder reactions shown in Fig. 3, plotted against $k_d/[D]$.
I: Tetracyanoethylene
II: Fumaryl chloride
III: Dicyanomaleic imide
Ordinate: $10^5 k_d$ [$sec^{-1}$].
Abscissa: $10^5 k_d/[D]$ [$l \cdot mole^{-1} \cdot sec^{-1}$].

It appears almost certain that the equilibrium which consists of first-order forward and reverse reactions and precedes the Diels-Alder addition is the valence tautomerism *(1)* $\rightleftharpoons$ *(2)* or *(8)* $\rightleftharpoons$ *(9)*. An alternative explanation of the "plateau phenomenon" of Figures 1 and 3 (without valence tautomerism) which suggests a practically complete combination of diene and dienophile to form a charge-transfer complex has been refuted. At room temperature, the association constants of the charge-transfer complexes which are found in the systems studied kinetically are so small that they cannot be determined spectrophotometrically [12] ($K \leqslant 0.2$).

The activation parameters for the valence tautomerism of phenylcyclooctatetraene and *(9)* in ethyl acetate can be determined from the plateau values ($k_1$) at 60, 70, and 78 °C: $\Delta H^{\neq} = 25.0$ kcal/mole; $\Delta S^{\neq} = -3$ e.u.

The activation energy is therefore considerably higher than the value of 13.7 kcal/mole found for the isomerization of cyclooctatetraene, which involves the interchange of double and single bonds, probably through a strained planar configuration [13]. Of the two possible modes of electron displacement [14,15], *(1a)* (3 $\pi$-bonds $\rightarrow$ 2 $\pi$-bonds and 1 $\sigma$-bond) appears to be sterically more favorable than *(1b)* (2 $\pi$-bonds $\rightarrow$ 1 $\pi$- and 1 $\sigma$-bond).

The above data do not as yet give the thermal equilibrium concentration of *(2)* or *(9)*, which we are attempting to determine. An estimate can be made by equating the rate constants of the addition of tetracyanoethylene onto *(2)* with that onto bicyclo[4,2,0]octa-2,4-diene, the valence tautomer of 1,3,5-cyclooctatriene [10]. Preliminary measurements [16] give a value of $k_2 = 16$ $l \cdot mole^{-1} \cdot sec^{-1}$ in dioxane at 100 °C. Under these conditions, the equilibrium concentration of the bicylic tautomer *(2)* is found to be 0.01 %.

Compound *(2)* has recently been postulated as a product of the photorearrangement of *(1)* [17].

*The authors wish to thank the Deutsche Forschungsgemeinschaft and Fonds der Chemischen Industrie for their support of the research program. We are also indebted to Prof. C. F. Wilcox of Cornell University, for his advice with regard to the steady state evaluation. Dr. B. C. McKusick of Du Pont de Nemours & Co., Wilmington (U.S.A.), kindly supplied a sample of dicyanomaleic imide. For a generous gift of cyclooctatetraene we owe thanks to Dr. A. Steinhofer and Dr. G. Hummel, BASF, Ludwigshafen (Germany).*

# Recent Developments in the Chemistry of Aminoboranes

BY DR. K. NIEDENZU

U.S. ARMY RESEARCH OFFICE
AND DEPARTMENT OF CHEMISTRY, DUKE UNIVERSITY, DURHAM, NORTH CAROLINA (U.S.A.)

*The isosterism of BN and CC groupings invites comparisons. Recent investigations on substituted aminoboranes $R^1R^2N-BR^3R^4$ have been attempted in order to evaluate this concept of isosterism. Some of the latest results include evidence for geometric isomerism due to hindered rotation about the B–N bond, isolation of isomeric compounds which can be considered as formal analogues of cyclohexanes, and the incorporation of BN groups into aromatic systems.*

## A. Introduction

The chemistry of boron hydrides has had great appeal for some time in the search for high-energy solid propellants. As a result, other aspects of boron chemistry have been neglected. Within the last five to eight years, however, interest in the chemistry of boron-nitrogen compounds has been rejuvenated. This resulted primarily from the recognition of isosterism of the BN group with a CC grouping, a phenomenon which invited stimulating comparisons of both systems. Earlier basic investigations in this area, such as the work of *Wiberg* [1] from 1930 to 1940, were already founded on this concept. New interest in boron-nitrogen chemistry was also aroused by the synthesis of *B*-trichloroborazine [1a], which resulted in partial supplantation of high vacuum techniques, and by the utilization of spectroscopy as a tool for explaining both structures and mechanisms.

Some results of recent investigations in the field of aminoborane chemistry are reported in this article [*], the scope of which is necessarily rather limited [**]. Those compounds will be considered as aminoboranes which have a normal covalent bond between boron and nitrogen atoms and in which the free electron pair of the nitrogen can participate in the N–B bond [1b]. The chemistry of borazines (= borazoles) will not be discussed, as a detailed review can be found elsewhere [2].

Three major areas of research have developed in the chemistry of aminoboranes:

1. The investigation of open-chain aminoboranes, with special interest in the interpretation of BN bonding.
2. The chemistry of trimeric aminoboranes, which can be considered as formal analogues of cyclohexane.
3. The synthesis and characterization of heteroaromatic compounds, in which a CC group of an aromatic ring system has been substituted by an isosteric BN group.

## B. The Nature of the B-N Bond in Aminoboranes

*Wiberg* [1] already postulated a B–N double bond in aminoboranes due to participation of the free electron pair from the nitrogen atom in the linkage, possible because of the electron deficiency on the boron atom. The planarity of the three bonds of boron, which was demonstrated by *Goubeau* and *Becher* [3], is a prerequisite for this interaction ($sp^2$ hybridization). Calculation of the force constants [4a] indicated a bond order of 1.8 for the B–N bond of aminoboranes at room temperature.

[4a] Cf. review article by *J. Goubeau* in [4].

The BN group is the only combination of boron with another element which can reach such a high bond order at room temperature. Dipole measurements by *Becher* [5] indicated, however, that three structures *(1a)–(1c)* are necessary to illustrate the BN bond according to *Pauling*'s electronic theory. Since the bond moments

*(1a)* *(1b)* *(1c)*

of some methylated aminoboranes have been found to be practically zero, it can be assumed that resonance between the forms *(1a)*, *(1b)*, and *(1c)* occurs. In agreement with this, calculations of the charge distribution between the boron and nitrogen by the LCAO-molecular orbital method [6] indicated that in simple aminoboranes, charge transfer occurs from the boron to the nitrogen; the nitrogen is the more negative partner of the bond by a value of about 0.28 electrons.

Another result of the molecular orbital calculations was that hindered rotation about the BN linkage of about 10 kcal/mole should exist. The possibility of hindered rotation, and thus of the occurrence of geometric isomers in the aminoborane system, was discussed in 1960 by *Niedenzu* and *Dawson* [7]. Nuclear magnetic resonance investigations later confirmed this concept [8]. Therefore the double bond character of the boron-nitrogen linkage in aminoboranes can be accepted.

The NMR investigations are based on the following considerations. In an unsymmetrically substituted aminoborane, *e.g.* of the type $Me_2B-NR'R''$ [8a], the two methyl groups are magnetically non-equivalent if hindered rotation about the BN linkage exists. The $^1H$ resonance spectrum will therefore indicate two methyl signals with different chemical shifts. At higher temperatures the rotation about the BN bond increases, so that the two groups will become magnetically equivalent, and their NMR signals will merge. The energy of activation of rotation can be calculated from the temperature dependence of the chemical shift. Thus far, experimental values in the order of 10–15 kcal/mole have been found; these are in good agreement with the theoretical value.

The B–N distance in aminoboranes has not been determined experimentally. However, an estimate of about 1.44 Å should be fairly close to the actual value. By the use of empirical formulae, such as *Gordy*'s rule [9], the BN bond order can then be calculated from the position of the BN absorption in the infrared and Raman spectrum of any aminoborane. Decreases in bond order are indicated by shifts of the asymmetrical BN stretching frequency to lower values. Generally this vibration has been found in the range 1500–1350 $cm^{-1}$ for aminoboranes. Detailed investigations resulted in the following picture. Substitution at the nitrogen by aryl groups causes a decrease in the BN bond order as compared with *N*-alkyl compounds, due to resonance of the free electron pair on the nitrogen with the aromatic ring. The N-$C_{aryl}$ bond assumes partial double-bond character, and the electron density at the boron atom is correspondingly decreased. Aryl groups at the boron show a lesser effect, although here too resonance of the π-electrons of the aromatic system with the electron deficiency of the boron is possible. Thus, the electron density of the boron is not diminished, although the BN bond order is.

The results of such a spectroscopic investigation [10] have been checked by LCAO-MO-calculation according to *Hückel* [11] and were completely confirmed. A detailed review of such a spectroscopic investigation is reported elsewhere [12].

## C. Acyclic Aminoboranes

### 1. Monoaminoboranes

The basic compound of this group, $H_2N-BH_2$, is not known in monomeric form (see below). Monoaminoboranes with the following substituents are known:

at the boron atom: hydrogen, deuterium, alkyl, aryl, silyl, halogen, alkoxyl, and aroxyl;

at the nitrogen atom: hydrogen, deuterium, alkyl, aryl, and silyl.

In addition, either the nitrogen or the boron can be incorporated in a ring system. Examples of relatively unusual compounds with aminoborane linkages include dimethylisocyanatoborane, $(CH_3)_2B-NCO$ [13], and the compounds $S_7N-BX_2$, where X = Cl or Br [14].

Aminoboranes $R_2N-BX_2$, that are halogenated at the boron atom, were obtained more than sixty years ago by *Michaelis* on interaction of boron halides and secondary amines [15]. *Wiberg* [1] reported a number of substituted aminoboranes in his investigations on the thermal decomposition of amineboranes (→ aminoboranes → borazines). *Schaeffer* and *Anderson* reported the preparation of aminoboranes by the reaction of metal borohydrides with amine salts [16]:

$$R_2NH_2Cl + LiBH_4 \rightarrow 2H_2 + LiCl + R_2N-BH_2$$

Some recent investigations [7, 17] dealt with the Grignard reaction of aminohalogenoboranes, which can readily be obtained from amine-halogenoboranes by dehydrohalogenation with tertiary amines [18]:

$$R_2NH\cdot BX_3 + NR'_3 \rightarrow R_2N-BX_2 + R'_3NHX$$
$$R_2N-BX_2 + 2\,R'MgX \rightarrow R_2N-BR'_2 + 2\,MgX_2$$

Unsymmetrically substituted aminoboranes of the type $R^1R^2N{-}BR^3R^4$ have been obtained from the appropriate starting materials via the intermediates $R^1R^2N{-}BR^3X$ *(2)* [7]. Analogous compounds *(2)* are formed by dismutation of $R_2N{-}BX_2$ with $R_2N{-}BR_2$ [19].

*Nöth* described the reaction of bis(dialkylamino)boranes with HCl, which resulted in the formation of dialkylamine hydrochloride and (dialkylamino)chloroborane, $R_2N{-}BHCl$ [20]. *Comproportionation of trisdialkylaminoboranes* with trialkylboranes according to the

$$B(NR_2)_3 + 2\,BR'_3 \rightarrow 3\,R_2N{-}BR'_2$$

equation has also been investigated [21]. Transamination, however, seems to be especially important for preparative purposes. Within the last three years, the equilibrium reaction

$$R_2N{-}BR_2 + HNR'_2 \rightleftharpoons R'_2N{-}BR_2 + HNR_2$$

has been studied in various laboratories [22a-d]; its application to boron chemistry is based on work by *Gerrard* and co-workers [23]. The action of $Al(NMe_2)_3$ on various boron compounds (trialkylboranes, boroxines, *etc.*) has also been investigated [24] and found advantageous for the preparation of *N,N*-dimethylaminoboranes. Some typical aminoboranes which have become available in recent years are listed in Table 1:

Table 1. Aminoboranes $R^1R^2N{-}BR^3R^4$.

| $R^1$ | $R^2$ | $R^3$ | $R^4$ | Constants [°C] | Ref. |
|---|---|---|---|---|---|
| H | H | $C_6H_5$ | $C_6H_5$ | m.p. 129–130 | [25] |

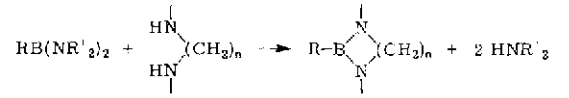
Aminoboranes are usually monomeric. However, dimeric compounds and more highly aggregated species are known; association occurs most readily if one or more of the substituents is hydrogen or halogen. The monomeric aminoboranes are sensitive towards hydrolysis. Steric effects are important for the stability of these compounds; however, *N*-phenyl compounds are extraordinarily unstable and it is noteworthy that, in general, with decreasing double-bond character of the B–N linkage, the stability toward water, alcohols, *etc.*, decreases. Although no detailed investigations of this problem have been made, it can be assumed that by decreasing the BN bond order, the possibility for Lewis acid-Lewis base interaction is increased. It has been shown [32,33] that the addition of acceptor molecules is directly related to their strength as acceptors. Trimethylborane and dimethylfluoroborane do not react with aminoboranes at low temperatures. Trichloroborane, however, forms an addition compound, which decomposes near −60 °C.

$$Me_2N{-}BMe_2{\cdot}BCl_3 \rightarrow Me_2BCl + Me_2N{-}BCl_2$$

Trifluoroborane reacts analogously.



## 2. Bis- and Trisaminoboranes

Bisaminoboranes $R'B(NR_2)_2$ are readily obtained by aminolysis of organodichloroborane or by comproportionation of trisaminoboranes with triorganoboranes. *Mikhailov* [34] described the aminolysis of the S–B bond in alkylthioboranes, which can be utilized especially for the preparation of bisaminoboranes with $R' = H$.

$$(Et_2N)(RS)BH + Et_2NH \rightleftharpoons (Et_2N)_2BH + RSH$$

This latter type has also been obtained by hydrogenation of bisdialkylaminochloroboranes with lithium hydride in ether or by transamination of the readily available compound $HB(NMe_2)_2$ [20]. Pyrolysis of dialkylamine boranes, $R_2NH{\cdot}BH_3$, in the presence of dialkylamine has been investigated by *Burg* [35]. In the presence of catalytic amounts of $(R_2NH_2)^+$, the corresponding bis(dialkylamino)alkylboranes [36] are formed from dialkylamine and trimethylamine alkylborane at 100–150 °C. Analogous compounds have been obtained on interaction of boron compounds with $Al(NR_2)_3$ [24].

Transamination of bisaminoboranes with aliphatic diamines affords access to cyclic aminoboranes [22c,22d].

This reaction proceeds more smoothly than the thermal decomposition of the corresponding amine-$BR_3$ adducts [37]. This procedure offers future possibilities, since even more complicated compounds, for example *(4)*, are obtained via transaminations [38].

*(4)*

Bisaminoboranes do not dimerize. Correspondingly, the chemical shift of the $^{11}B$ resonance is found at about 20 ($\delta \times 10^{-6}$) [36,39]. They are readily hydrolysed, but the rate of hydrolysis decreases with increasing chain length of the alkyl substituents. An interesting salt-like compound *(5)* was obtained by *Nöth* [40] on treating HCl with $ClB(NMe_2)_2$.

*(5)*

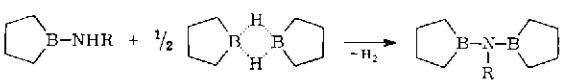
Such compounds are encountered relatively seldom in boron chemistry [41].

The preparation of trisaminoboranes $B(NR_2)_3$ has been investigated in detail. In addition to aminolysis of boron trichloride, the reaction of boron trifluoride with primary or secondary amines in the presence of either a Grignard reagent [42] or metallic lithium [43] is suitable. Transamination also proceeds smoothly [22a,22c,44] and can also be utilized for the preparation of unsymmetrical trisaminoboranes [45].

Physicochemical investigations of trisaminoboranes are not as advanced. Studies of trisdimethylaminoborane [46] disclosed a valence force constant of the boron-nitrogen linkage of about $5.5 \times 10^5$ dyne/cm. This value is below those reported for borazines (6.3) and monoaminoboranes (7.0 7.5) but above the value calculated for amine boranes (ca. $3.5 \times 10^{-5}$ dyne/cm). The infrared spectra of various trisaminoboranes were recorded by *Lappert* [47]. A considerable double-bond character can be deduced for the BN linkage. The bond order, however, decreases in the series

$B(NHAr)_3 > B(NHR)_3 > B(NR_2)_3 > B(NRAr)_2$

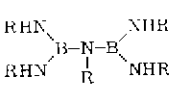
The heat of formation of trisdimethylaminoborane was determined by *Skinner* and *Smith* [48] to be 77.1 kcal/mole, resulting in an energy of dissociation of the BN bond of 89.7 kcal/mole. This value is in the order of that of the BN bond in borazines.



Hydrochlorides of the type $B(NR_2)_3 \cdot nHCl$ are not stable [40]. The action of HCl on trisaminoboranes causes them to rearrange to amine boranes.

### 3. Bisborylamines

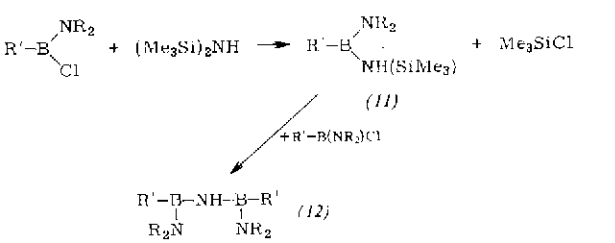
Bisborylamines $(R_2B)_2NH$ in which two boron atoms are bonded to a central nitrogen atom were first mentioned by *Nöth* [49], who obtained such compounds by the reaction of dialkylchloroboranes with bistrimethylsilylamine.



$$2\ R_2BCl + (Me_3Si)_2NH \rightarrow R_2B{-}NH{-}BR_2 + 2\ Me_3SiCl \qquad (6)$$

*Köster* [50] obtained analogous compounds with a B–N–B grouping in which the boron is incorporated in an aliphatic ring on thermal decomposition of bisborolanes *(7b)* with aminoborolanes *(7a)*.

*(7a)* *(7b)* *(8)*



*Lappert* [51] reported the preparation of *(9)* by aminolysis of bis-t-butylaminochloroborane with t-butylamine.

*(9)*, R = t.Butyl

In the first step of the reaction of dialkylchloroborane with bistrimethylsilylamine, *Niedenzu* [52] obtained an *N*-silylated aminoborane *(10)*. With excess diorganochloroborane, the bisborylamine *(6)* is obtained with elimination of additional trimethylchlorosilane. In the corresponding reaction of aminochloroboranes, primar-

$$R_2BCl + (Me_3Si)_2NH \rightarrow R_2B{-}NH(SiMe_3) + Me_3SiCl \qquad (10)$$

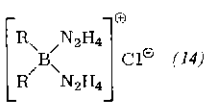
ily a monosilylated bisaminoborane *(11)* is formed which reacts with excess aminochloroborane to yield the bisborylamine *(12)*.

Bisborylamines of type *(6)* are relatively unstable and decompose to form borazoles.

$$3\,(R_2B)_2NH \rightarrow 3\,BR_3 + (-BR-NH-)_3$$
*(6)*

This decomposition is catalysed by acids and also occurs during exchange reactions of *(8)*, *e.g.* during attempts to convert *(8)* into *(6)* with tetraalkyldiboranes.

Trisborylamines in which three boron atoms are bonded to a central nitrogen atom have not yet been recorded.



### 4. Hydrazino- and Azidoboranes

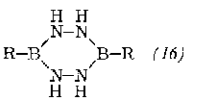
First attempts to prepare hydrazinoboranes date back to *Emeleus* [53] and *Schlesinger* [54], but it was not until 1961 that *N,N'*-diborylhydrazine $H_2B-NH-NH-BH_2$ was obtained; it was then made by pyrolysis of the adduct of diborane onto hydrazine [55]. Hydrazinoboranes substituted at the boron atom were obtained in good yield by the action of tetraalkyldiborane $(R_2BH)_2$ on hydrazine at 100–150 °C [56].

$$(R_2BH)_2 + N_2H_4 \rightarrow R_2B-NH-NH-BR_2 + 2\,H_2$$
*(13)*

Adducts of the amine-borane type $R_3B{\cdot}N_2H_4$ are primarily formed in an exothermic reaction on treating trialkylborane with hydrazine. They decompose above 170 °C. In the presence of excess $BR_3$, *N,N'*-diborylhydrazines of type *(13)* are formed.

Hydrazinolysis of diorganochloroboranes does not always proceed unequivocally. $R_2BCl$ and *N,N*-dimethylhydrazine form $R_2B-NH-NMe_2$ in a smooth reaction. With free hydrazine, however, mainly a salt-like compound *(14)* is formed.

*(14)*

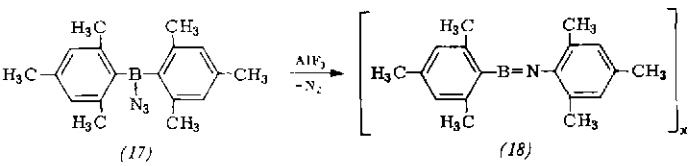


The best preparative results were obtained by hydrazinolysis of a BN bond.

$$R_2B-NR'_2 + N_2H_4 \rightarrow R_2B-NH-NH_2 + HNR'_2$$
*(15)*

The hydrazinoborane *(15)* decomposes in an equilibrium reaction.

$$2\,R_2B-NH-NH_2 \rightleftharpoons R_2B-NH-NH-BR_2 + N_2H_4$$
*(16)*



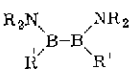
The formation of compounds of type *(15)* also occurs with substituted hydrazines, and trisaminoboranes, bisaminoboranes [22d], and mercaptoalkylboranes [57] can be utilized instead of the monoaminoborane. Although hydrazinolysis of bisaminoboranes with *N*-substituted hydrazines readily yields bishydrazinoboranes $RB(NH-NR'_2)_2$, a new ring system *(16)* is formed [22d] with free hydrazine.

*(16)*

Derivatives of *(16)* were recently obtained by reducing azobenzene with diborane [58] and by the reaction of dichlorophenylborane with symmetrical dilithium diphenylhydrazine [58] or with hydrazobenzene in the presence of triethylamine [59].

All the hydrazinoboranes investigated so far are monomeric. They are sensitive towards hydrolysis and oxidize readily. A detailed review of hydrazinoboranes has been compiled by *Nöth* [58].

Azidoboranes have not yet been characterized. However, a reaction of dimesitylfluoroborane with aluminum azide has been reported [60], which should result in the corresponding azidoborane. A strong absorption near 2100 cm$^{-1}$ was assigned to an asymmetrical vibration of an azido group bonded to boron. Thermal decomposition of *(17)* yields *(18)*.



*(17)* *(18)*

### 5. Boron Subcompounds with Aminoborane-Type Linkages

Until recently, almost the only route leading to subcompounds of boron, *i.e.* compounds with B–B bonds, proceeded by way of diboron tetrachloride $B_2Cl_4$. Then a very simple preparation of amino derivatives of diboron by condensation of bisaminochloroboranes with metals was reported in two independent publications [61,62].

$$2\,(R_2N)_2BCl + 2\,Na \rightarrow (R_2N)_2B-B(NR_2)_2 + 2\,NaCl$$

Mixed substituted compounds of type *(19)* are also available by means of this method, and its preparative possibilities have been studied in detail [63–65]. Trans-

amination with primary or secondary amines [61,66] resulted in numerous new compounds, and alcoholysis yielded hypoborates $(RO)_2B-B(OR)_2$. Mixed amino-chloro compounds of diboron were obtained from tetrakisdimethylamino diboron and boron trichloride [65] and are also formed on treatment of tetrakisdimethylamino diboron with HCl [67].

The B- B bond in amino derivatives of diboron is pronouncedly more stable than that in other derivatives of diboron. This can be explained by back coordination of the free electron pair of the nitrogen to the boron, resulting in the formation of partial BN double-bond character. The vibration spectrum of tetrakisdimethylamino diboron was measured by *Becher* and co-workers [68]. Steric effects produce a structure in which the $N(CH_3)_2$ groups and both $BN_2$ groups are tilted against each other.

Trisaminoboranes and bisaminoboranes are formed on thermal decomposition of tetrakisamino diboron compounds; this has been investigated in detail with tetrakisdimethylamino diboron [69].

### D. Cyclic Aminoboranes

Dimeric aminohoranes were recognized by *Wiberg* [70], who proposed a cyclic structure *(20)*, which can be considered correct because the dimeric compounds are chemically not very reactive and the absorption of the BN bond in the infrared has been found at very low values (ca. 900 $cm^{-1}$). Thus, participation of the free electron pair of the nitrogen in a BN double bond can be excluded.

*(20)*

Dimeric aminoboranes are usually formed if one or more of the substituents is hydrogen or halogen. Aminodihalogenoboranes in particular dimerize very readily, apparently owing to steric factors [26]. The dimerization can be reversed by distillation [26] or sublimation [18]. Conventional molecular-weight determinations do not always give unequivocal results. $^{11}B$ nuclear magnetic resonance, however, permits elucidation of the degree of association [24,36,39]. Higher polymeric aminoboranes are also known, but have only recently been investigated [71]. They have no recognized technical importance.

Trimeric aminoboranes are of scientific interest because they can be considered as formal analogues of cyclohexane. The first trimeric compound was obtained in 1955 by *Bissot* and *Parry* [72] in small yield on pyrolysis of *O,N*-dimethylhydroxylamine-borane. Better yields are obtained on heating methylamine-borane to 100 °C.

$$3\ MeNH_2{\cdot}BH_3 \rightarrow 3\ H_2 + (MeHN{-}BH_2)_3$$

In 1957 a compound $(Me_2N)_3B_3H_4$ was described [73]. Two years later, however, a three-dimensional X-ray structural analysis [74] indicated that this compound is really trimeric dimethylaminoborane. The compound consists of alternating $BH_2$ and $NMe_2$ groups with a BN bond distance of 1.59 ± 0.02 Å [75]. An independent $^{11}B$ resonance investigation [76] indicated a 1:2:1 triplet signifying three equivalent $BH_2$ groups. It was also shown that the trimer is readily formed on heating dimeric dimethylaminoborane with higher boron hydrides to 100 -110 °C.

Recent investigations by *Schaeffer* [77] are based on the known property of borazine to add on HX. Compounds of the type $B_3H_3N_3H_3{\cdot}3HX$ are formed to which a cyclic structure had already been ascribed [1]. $B_3N_3H_6{\cdot}3HCl$ was reduced with sodium borohydride to $B_3N_3H_{12}$. Another possibility to obtain this compound was reported by *Shore* [71]. In liquid ammonia, the diammoniate of diborane reacts with strong bases such as sodium amide or sodium acetylide to yield crystalline compounds $(BH_2-NH_2)_x$, where $x = 2-10$, from which the trimer was isolated in 15 % yield. The structures of the higher members with $x > 3$ is still uncertain. Two steroisomeric compounds have been isolated from the trimeric methylaminoborane [77]. The equilibrium constant for their interconversion of 2.28 corresponds to a difference in free energy of - 0.51 kcal/mole. The symmetrical isomer with three methyl groups in the equatorial position is favored over the unsymmetrical one with one axial methyl group. These BN analogues of cyclohexane prefer the chair form, in contrast to cyclohexane derivatives.

### E. Pseudo-Aromatic Compounds with Aminoborane-Type Linkages

#### 1. Five-Membered Ring Systems

A new chapter in aminoborane chemistry has developed during the past five years. The preparation of numerous ring compounds in which an aromatic CC grouping is replaced by BN has been reported from various laboratories. The possibility of incorporating the BN group into carbon rings was recognized by *Goubeau* in 1955 [37], but was not investigated in detail. Only 2-methyl-

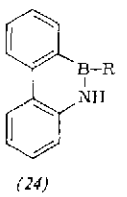
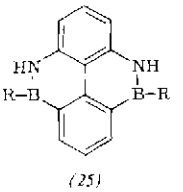
4,5-benzo-1,3,2-diazaboroline *(21)* was obtained [78] on reaction of *o*-phenylenediamine with trimethylborane. A general synthesis of this ring system by condensation of aromatic *o*-diamines with organoboric acids has been developed by *Letsinger* [79] and by *Soloway* [80].

*Hawthorne* [81] obtained analogous compounds from *o*-diamines and trialkylamine alkylboranes, and the preparation of *(21)* via transamination reactions has been reported [82,83]. Other systems in which one nitrogen is replaced by another hetero-atom, such as oxygen or sulfur, are known [84]. Functional aromatic nuclei [85,86] lead to structures such as *(22)*. Another interesting example *(23)* is obtained by condensation of phenyl-

*(22)*

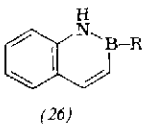


*(23)*

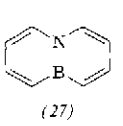


boric acid with an equimolar mixture of benzoin and aniline [87]. These few examples indicate the possibilities which still exist in this area for the synthetic chemist. Possible use of these boron-containing heterocycles in tumor therapy is being investigated at the Massachusetts General Hospital in Boston, Mass. (U.S.A.) [80].

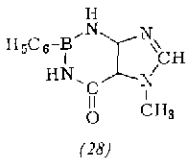
## 2. Six-Membered BN Heteroaromatics



Six-membered BN heteroaromatic compounds have been investigated by *Dewar* and co-workers with great success. Within a few years, more than twenty new ring systems were obtained in which one or more CC groupings are replaced by the isosteric BN combination. Because a detailed survey of this area of chemistry cannot be made here, the interested reader is referred to two articles by *Dewar*, one reporting work up to about 1961 [88], and the other reviewing more recent results [89]. Some examples of the compounds obtained are indicated by formulae *(24)–(28)*.



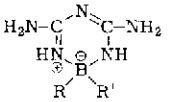
*(24)*



*(25)*

*(26)*

*(27)*



*(28)*

A general synthesis of the parent monocyclic 2,1-borazarene system *(28a)* has just been developed by dehydrogenation of the novel 1,2-azaboracyclohexanes [89a].

*(28a)*

Another interesting system of heteroaromatic boron compounds in which the boron is tetravalent should be mentioned. Such compounds, *e.g. (29)*, are obtained on treating biguanidine with aminoboranes or organoboric acids [90]. The high stability of heteroaromatic com-

*(29)*, R = $C_6H_5$, $C_4H_9$, $C_2H_5$, OH, $OCH_3$
R' = $C_6H_5$, OH, $OC_2H_5$, $OCH_3$

pounds containing boron and nitrogen compared with other organic boron-nitrogen compounds is most remarkable and indicates conjugation of the free electron pair of the nitrogen with the aromatic $\pi$-electrons.

Molecular-orbital calculations have been performed for a few samples. The Hückel method faces the known difficulties for calculations of compounds with hetero-atoms. The formal charges on boron and nitrogen have rather low values (< 0.2 electrons). Nevertheless, the resonance energies of the BN-containing ring systems cannot be neglected [89]. *Kaufman* [11] utilized Pariser-Parr and Pariser-Parr-Pople molecular orbital methods for analogous calculations. Various models based on possible resonance structures can be used as a basis for such calculations. Accurate conclusions cannot yet be made, owing to the lack of sufficient experimental data; these might be obtained, for instance, by NMR spectroscopy. However, calculations of the charge distributions seem to be relatively independent of the selection of the model, although calculations of the bond order indicate direct dependence on the model not only for BN, but also for CC.

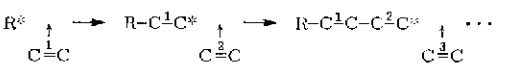
# The Mechanism of the Action of Organometallic Catalysts

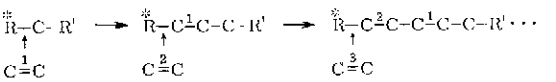
BY PRIV.-DOZ. DR. H. SINN AND PROF. DR. F. PATAT

INSTITUT FÜR TECHNISCHE CHEMIE DER TECHNISCHEN HOCHSCHULE MÜNCHEN (GERMANY)



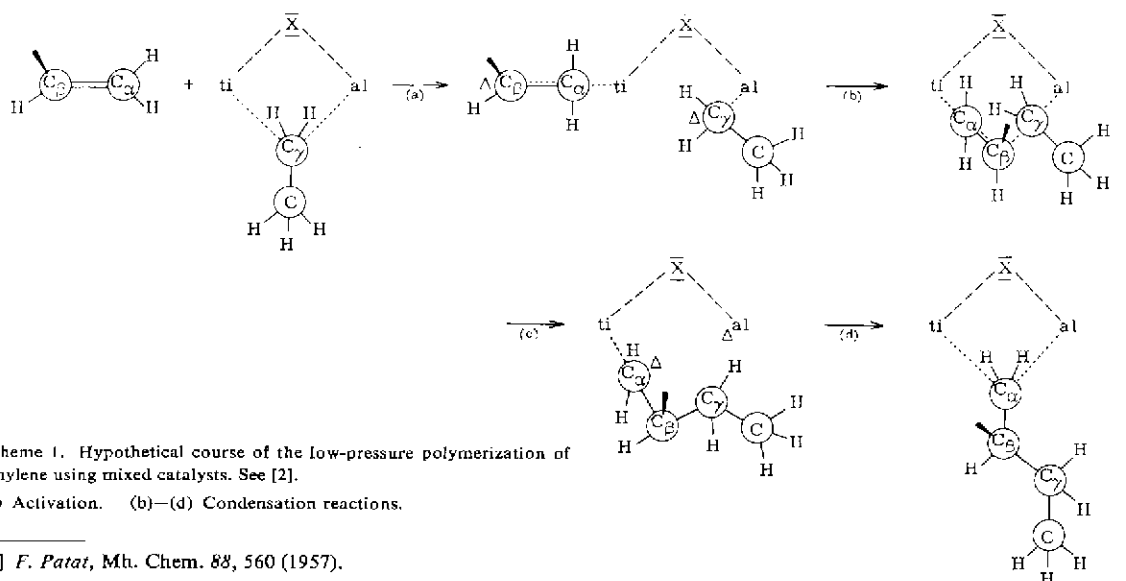
*Dedicated to Prof. Dr. Karl Winnacker on the occasion of his 60th birthday*

*Kinetic investigations of the polyreaction of isoprene with organolithium compounds as initiators in n-heptane as solvent indicate the following sequence of reactions: 1. formation of an adduct between a monomeric form of the organolithium compound and the isoprene and 2. reaction of this adduct with an associated form of the organolithium compound with insertion of the isoprene. The adduct formation is considered to be due to chemisorption, and proof of such chemisorption of a monomer (ethylene) is also demonstrated for a homogeneous Ziegler-type catalyst. All the reactions can be formulated in the form of cyclic structures with electron-deficient character. Postulation of such ring structures explains the surprising values obtained for the frequency factors and equilibrium constants.*



## 1. Introduction

The characteristics indicating relationships between liquids and solids should be determinable primarily by kinetic investigations in the liquid phase, since structural elements must play a more important part in kinetic measurements than in measurements of physical quantities, which can merely encompass such elements in an integral manner. Enzymatic reactions, too, indicate a dependence of the specificity and selectivity of the reaction on the structure of the catalyst, *viz.* the enzyme. From such considerations by one of us (F. P.) [1] we proposed a working hypothesis for the course of the low-pressure polymerization of ethylene with mixed Ziegler-type catalysts [2]. This hypothesis is shown in Scheme 1.



In contrast to the known polyreactions, such as polymerizations, polycondensations, and polyadditions [2a], where the monomer (which is at least bifunctional) is condensed within a growth cycle in a monofunctional manner (grain type reaction) [*],

in Scheme 1 the monomer combines bifunctionally within a growth cycle, *i.e.* it is inserted (insertion type reaction).

The activation step in Scheme 1 [Reaction (a)] is postulated to be chemisorption, for both heterogeneous and homogeneous systems (adduct formation by partial electron transfer).

Scheme 1. Hypothetical course of the low-pressure polymerization of ethylene using mixed catalysts. See [2].

(a) Activation. (b)—(d) Condensation reactions.

[1] *F. Patat*, Mh. Chem. *88*, 560 (1957).

[2] *F. Patat* and *H. Sinn*, Angew. Chem. *70*, 496 (1958).

[2a] This nomenclature is in accordance with the proposals presented in Makromolekulare Chem. *38*, 1 (1960).

[*] In this and the following equations, the asterisk designates the point of extension of the molecule.

It should also be pointed out that insertion of the monomer takes place only in organometallics which undergo association [*e.g.* 2 $AlR_3 \rightleftharpoons (AlR_3)_2$; 6 $LiR \rightleftharpoons (LiR)_6$]; insertion reactions of olefins do not take place with non-associating compounds such as $ZnR_2$, $BR_3$, or $Cl_3TiR$.

According to the kinetic investigation of the "Aufbau"-reaction

$$AlR_3 + H_2C{=}CH_2 \longrightarrow \begin{matrix} R \\ R \end{matrix}\!\!>\!Al{-}CH_2{-}CH_2{-}R$$

carried out by *Ziegler* [3] and to the studies of the insertion of isoprene into alkenyl-lithium compounds (polyisoprenyl-lithium) in hydrocarbons as solvent

$$Li(CH_2{-}CH{-}C(CH_3){-}CH_2)_n{-}R + H_2C{-}CH{-}C(CH_3){-}CH_2 \rightarrow Li(CH_2{-}CH{-}C(CH_3){-}CH_2)_{n+1}{-}R$$

carried out by our research group, for concentrations of organometallic of greater than 0.1 mole/l, the overall rate of reaction is

$$v_{tot} = k \cdot [M]\sqrt[n]{[(MO)_{titr}]} \qquad (1)$$

where k is the constant of proportionality, [M] the concentration of ethylene or isoprene, $[(MO)_{titr}]$ the total concentration of the organometallic compound as determined by titration, and n the degree of association (see below).

When the organometallic compound is triethylaluminum, which is almost completely dimeric in the concentration range investigated, then n in Equation (1) is equal to 2; if the organometallic compound is polyisoprenyl-lithium, which under these conditions is present substantially as the hexamer, then n is equal to 6.

In general,

$$[(MO)_{titr}] = \sum_n n[(MO)_n] \qquad (2)$$

where MO is the monomeric and $(MO)_n$ the associated form of the organometallic compound. The law of mass action can be applied to the equilibrium $nMO \rightleftharpoons (MO)_n$, so that

$$[MO]^n/[(MO)_n] = K_{ii} \qquad (3)$$

If almost exclusively associated forms are present (as is the case for aluminum and lithium alkyls at concentrations greater than 0.1 mole/l), then the following approximation may be considered:

$$n\,[(MO)_n] = [(MO)_{titr}] \qquad (4)$$

Combination of Equations (3) and (4) gives

$$[MO] = k'\sqrt[n]{[(MO)_{titr}]} \qquad (5)$$

Making use of Equation (5), the rate equation [Equation (1)] suggests that within the concentration range investigated (for which the approximation of Equation (4) is valid), it is the monomeric organometallics, and not the associated forms, which are either the sole or the rate-determining reaction promoters. Kinetic investigations alone cannot differentiate between these two alternatives, since in principle kinetic analysis cannot establish a fact but can merely concede its possibility. The postulate that the monomer forms are the sole reaction promoters is therefore correct until indications can be found that the rate-determining step of a reaction sequence has been measured. We have succeeded in finding such indications.

## 2. Formation of Polyisoprene with the Aid of Organolithium Compounds

### a) Preliminary Remarks

Lithium alkyls are soluble in hydrocarbons, and the degree of association reaches values of up to 6 in these solvents; saltlike organic compounds of alkali metals are insoluble in hydrocarbons. Polyisoprenes with more than 90 % 1,4-*cis*-structures can be obtained in hydrocarbons with organolithium compounds under homogeneous conditions; the molecular weights of the products justify the assumption that one molecule of polymer is formed for each atom of lithium used. The ratio of the weight-average to the number-average molecular weight was 1.04 for some products prepared at 0 °C [4].

In polar solvents, the organic compounds of both lithium and the other alkali metals gave rise to polyisoprenes which contained little 1,4-*cis*- but predominantly the 1,2-, 3,4- and 1,4-*trans*-structures. A typical yellow color occurs when the polyreaction is carried out in ether; this color is ascribed to the polyisoprenyl anion, for its spectrum is almost, but not entirely, independent of the nature of the alkali metal. The reaction in polar solvents at least is normally described as "anionic". However, conductivity measurements did not give any support to this designation [4a].

### b) Kinetic Investigations

Particularly clear relationships are obtained when lithium polyisoprenyls or oligoisoprenyls are used to initiate the formation of polyisoprene. This initiator is obtained by treating an alkyl-lithium with isoprene:

$$Li{-}R + CH_2{=}CH{-}CCH_3{-}CH_2 \rightarrow Li(CH_2{-}CH{=}CCH_3\ CH_2)R \quad (e)$$

$$Li(CH_2{-}CH{=}CCH_3{-}CH_2)_n{-}R + CH_2{-}CH\ CCH_3{=}CH_2 \rightarrow Li(CH_2{-}CH{=}CCH_3{-}CH_2)_{n+1}{-}R \quad (f)$$

The isoprene molecule is thus inserted at the metal-carbon bond, with the formation of an alkenyl-lithium LiR′ from the alkyl-lithium LiR, *i.e.* with the formation of a polyisoprenyl-lithium. If further molecules of isoprene are interspersed between the alkenyl radical and the lithium atom, the alkenyl-lithium structure is still preserved, so that the nature of the surroundings of the Li atom and hence the reactivity of the Li–C bond remains unchanged. It was demonstrated separately that the reactivity of the polyisoprenyl-lithium compounds is independent of their molecular weight.

[4a] *S. Bywater*, Pure appl. Chem. *4*, 319 (1962).

Various authors [5] agree that the formation of polyisoprene is a first order reaction with respect to the concentration of isoprene. On the other hand, the order with respect to the concentration of initiator varies with the latter [6], which was measured over the range of six powers of ten [7]. The reaction rates found for an isoprene concentration of 2.57 moles/l (our normal initial concentration) are shown in Fig. 1, in relation to the titratable concentration of the organolithium compound [cf. Equation (2)].

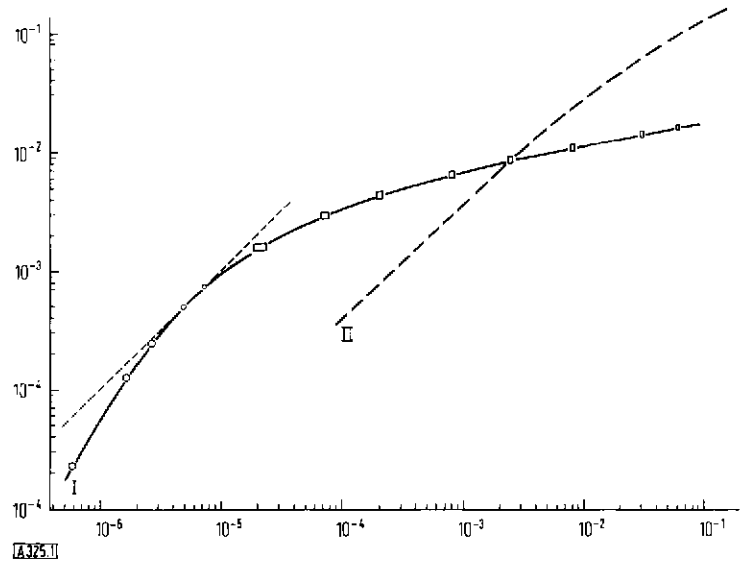

Fig. 1. The overall rate of the polyreaction of isoprene (ordinate) as a function of the initiator concentration (abscissa), at 20 °C. Alkenyllithium (polyisoprenyl-lithium) prepared according to reactions (e) and (f) was used as the initiator; the butyl-lithium content was < 1 %.

Curve I: in n-heptane
Curve II: in diethyl ether.

The broken-line plot represents the slope (order of reaction) which the curve would finally have to assume, or which it must not exceed, if the non-associated form (monomer) of the initiator is the sole reaction promoter.

Ordinate: $v_{tot}$ [moles/l/min]
Abscissa: Initiator concentration [moles/l].

The change in the order of the reaction with the initiator concentration (as shown by the slope of the curve in Fig. 1) is evidently related to the degree of association of the organolithium compound. The relationships in the upper region of concentration have already been discussed in the introduction. Complete dissociation of the associated lithium alkenyls takes place at sufficient dilution, and then the concentration of the monomeric form becomes identical with the titratable lithium concentration. In contrast to the approximation of Equation (4), the following relationship is now valid:

$$[MO] = [(MO)_{titr}] \qquad (6)$$

where [MO] = [alkenyl-lithium] = [LiR'].

This behavior is evidently the case for the concentration at which the slope of the curve in Figure 1 is equal to unity. The overall rate of reaction can thus be described by:

$$v_{tot} = k_w\,[\text{isoprene}]\,[LiR'] = k_w\,[\text{isoprene}]\,[(LiR')_{titr}] \qquad (7)$$

so that $k_w$ can be obtained from the corresponding point on the curve.

If the relationship

$$v_{tot} = k_w\,[\text{isoprene}]\,[LiR'] \qquad (8)$$

is considered to be valid for the entire curve above an alkenyllithium concentration of $10^{-5}$ mole/l, then, using Equation (8), any desired number of points taken from the curve at a known value of $k_w$ gives a corresponding number of pairs of values for [LiR'] and $[(LiR')_{titr}]$. Values of the equilibrium constant $K_n$ can then be found from these pairs using Equations (2) and (3). Surprisingly, it is found that only the monomeric, trimeric, and hexameric forms need to be considered for the calculation of the total concentration of the organolithium compounds; correspondingly, only three measurements are necessary for the determination of $k_w$, $K_3$, and $K_6$. With the aid of these three constants, the overall rate of reaction can then be calculated for any initiator concentration $[(LiR')_{titr}]$, and checked by means of the curve in Figure 1. The calculated and measured values agree within the thickness of the drawn line. Conversely, it is possible to determine experimentally the overall reaction rates corresponding to any desired values of $[(LiR')_{titr}]$, to calculate the LiR' concentration (in monomeric form) with the aid of $K_3$ and $K_6$, and to check the constancy (*i.e.* concentration independence) of $k_w$ using Equation (8). The results are shown in Table 1.

Table 1. The independence of the rate constant $k_w$ of the initiator concentration $[(LiR')_{titr}]$.

| $[(LiR')_{titr}]$ [mole/l] | $k_w\,[LiR']\cdot 10^3$ [l/min] | $[LiR']\cdot 10^5$ [mole/l] | $k_w$ [l/mole/min] |
|---|---|---|---|
| $6.0\times 10^{-2}$ | 6.72 | 17.0 | 39.6 |
| $1.5\times 10^{-2}$ | 5.22 | 13.0 | 40.0 |
| $2.4\times 10^{-3}$ | 3.50 | 9.0 | 39.0 |
| $8.0\times 10^{-4}$ | 2.77 | 7.0 | 39.6 |
| $4.0\times 10^{-4}$ | 2.20 | 5.6 | 39.4 |
| $2.0\times 10^{-4}$ | 1.70 | 4.3 | 39.5 |
| $7.0\times 10^{-5}$ | 1.14 | 2.9 | 39.4 |
| $2.0\times 10^{-5}$ | 0.7 | 1.8 | 39.0 |

$[(LiR')_{titr}]$ = titratable organolithium concentration.
$k_w[LiR']$ = the experimentally determined product of the rate constant and concentration of the monomeric form of the organolithium compound.
[LiR'] = concentration of the organolithium monomer, calculated from the equilibrium constants.
$k_w$ = rate constant (values in column 2 divided by values in column 3).

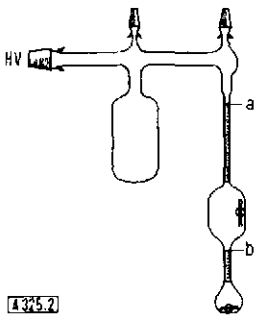
[7] *H. Sinn* and *O. T. Onsager*, Makromolekulare Chem. *55*, 167 (1962).

Below an initiator concentration of $10^{-5}$ mole/l, the organolithium compound is present almost exclusively as the monomer, so that, if Equation (7) is valid, a linear decrease in the overall rate of reaction with diminishing initiator concentration is to be expected. This, however, is not the case; instead, the order of the reaction with respect to $[(LiR')_{titr}]$ increases to values greater than unity.

The fact that minimum values are represented by the slope of the curve in Figure 1 when the initiator concentration is less than $10^{-4}$, *i.e.* that the values may only be greater but never smaller, was demonstrated by the following method.



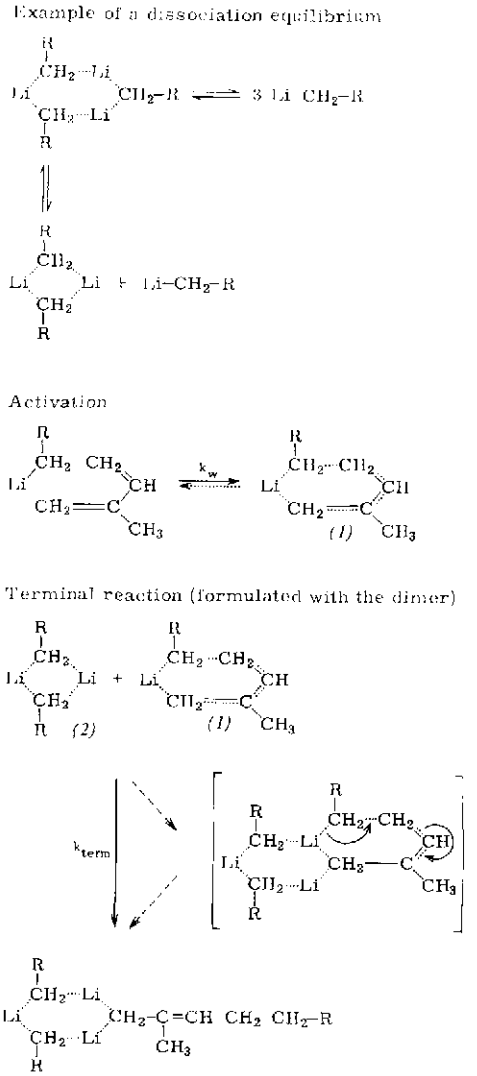


Fig. 2. Dilatometer for measuring the rate of polymerization at very low initiator concentrations.
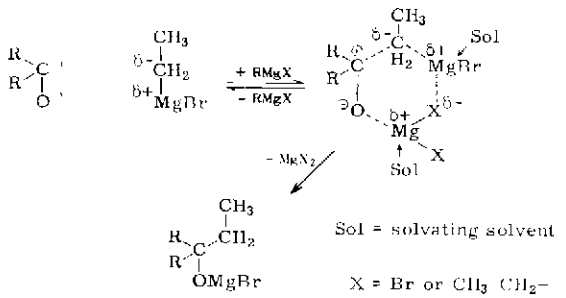
a, b = filling marks.
HV = vacuum connection.

The dilatometer was filled up to the mark a *in vacuo* by a quantity of initiator x and isoprene. After determining the overall rate of reaction, $v_{tot}$ the isoprene was evaporated off until the dilatometer was filled only up to the mark b. The initiator concentration is thus increased, although the absolute amount of initiator is not, so that for an initiator amount x', after removal of some of the isoprene by condensation, the relationship $x' \leqslant x$ must apply. A value of $v'_{tot}$ was determined for x'. The original amount x was chosen so that this value of $v'_{tot}$ lies on a known part of the curve; x' was determined from the measured value of $v'_{tot}$ for a known dilatometer volume, and the initial value of $v_{tot}$ was related to x', making allowance for the concentration factor. A detailed discussion is given by *Sinn* and *Onsager* [7].

If an analogous study to that made in the introduction is carried out for initiator concentrations below $10^{-5}$ mole/l, where the reaction order based on the titratable initiator concentration is greater than 1, application of Equations (2), (3), and (6) leads to the conclusion that associated forms of the organolithium compounds are either the sole or the rate-determining reaction promoters. However, since the monomeric forms in the one instance and associated forms in the other cannot be the sole reaction promoters, it can be postulated that a sequence of reactions takes place, either the first or the second stage of this sequence being the rate-determining step, depending on the concentration. These relationships can be represented by Scheme 2.

The quantity $k_w$ is therefore the rate constant for the formation of an adduct between the monomeric alkenyl-lithium and isoprene. The adduct *(1)*, in which the isoprene necessarily has the 1,4-*cis*-structure, reacts with an associated form, *e.g.* with the dimer *(2)*. Insertion of the isoprene takes place in the course of this reaction. This second stage is designated as a terminal step, and is



Scheme 2. Polyisoprene formation using alkenyl-lithium as initiator.

characterized by the rate constant $k_{term}$. Since $k_w$ is smaller than $k_{term}$, the activation reaction (adduct formation) is the rate-determining step in the normal concentration region ($> 10^{-5}$ mole/l); the overall rate of reaction is thus proportional to the concentration of the monomeric form of the organolithium compound. In the region of virtually complete dissociation, the associated form practically disappears from the solution, so that although $k_w < k_{term}$, $k_w [LiR']$ ultimately $> k_{term} [(LiR')_n]$, since $[LiR'] \gg [(LiR')_n]$. The terminal reaction with the participation of the associated form is therefore slower than the activation reaction, and is thus rate-determining.

At this point is should be mentioned that the participation of two molecules of an organometallic compound has also been observed [8] in the reaction (growth) cycle in Grignard addition reactions (Scheme 3).

If butyl-lithium is used as the initiator in place of separately prepared polyisoprenyl-lithium, then Reactions (e) and (f) take place side by side, (e) being termed the initial reaction. Since both reactions use up isoprene, the overall rate is obtained by summation of the ex-

[8] *C. G. Swain* and *H. B. Boyles*, J. Amer. chem. Soc. *73*, 870 (1951); cf. *P. Karrer:* Lehrbuch der organischen Chemie. Thieme, Stuttgart 1959, p. 101.

Scheme 3. Grignard addition reactions involving two molecules of the Grignard reagent [8].

pressions for the rates of the component reactions (e) and (f) [Equation (9)].

$$v_{tot} = k_i \cdot f \cdot [I]\,[(LiR)_{titr}] + k_w \cdot f \cdot [I]\,[(LiR')_{titr}] \qquad (9)$$

where $f = \frac{[LiR]}{[(LiR)_{titr}]} = \frac{[LiR']}{[(LiR')_{titr}]} = \frac{[Li]}{[(Li)_{titr}]}$,

$[LiR] + [LiR'] \equiv [Li]$,

$[(LiR)_{titr}] + [(LiR')_{titr}] \equiv [(Li)_{titr}]$,

and [I] = the concentration of isoprene.

The conversion of LiR into LiR′ according to Reaction (e) is given by the relationship

$$-\frac{d[(LiR)_{titr}]}{dt} = k_i \cdot f \cdot [I]\,[(LiR)_{titr}] \qquad (10)$$

Combination of Equations (9) and (10) and the assumption that equilibria between the monomeric and the associated forms of the organolithium compound are very quickly established permit predetermination and a complete description of the time-conversion curves determined experimentally.

The assumptions made in the calculation of f, *viz.* that LiR and LiR′ are associated in a similar manner and that all possible mixtures of associated structures between LiR and LiR′ are formed, have been confirmed by our kinetic measurements. Viscosity determinations have also shown that long polyisoprenyl chains do not (appreciably) alter the association of the organolithium compounds. Since small additions of tetrahydrofuran promote dissociation, the degree of association can be calculated from the viscometer efflux times before and after the addition of tetrahydrofuran. The degree of association found experimentally is in satisfactory agreement with that determined kinetically [9a].

Equation (10) was not merely found indirectly from the kinetics for the overall reaction, but was also obtained by an analytical study of the variation of the butyl-lithium content (chromatography of the gas produced by hydrolysis) with time in polyreactions initiated with pure butyl-lithium [9].

A list of all the constants which have so far been determined is given in Table 2. The rate constants are all given for a temperature of 20 °C with n-heptane as solvent.

In our opinion, the activation (adduct formation) is somehow related to the association – dissociation reaction of the organolithium compound, and the terminal reaction to the alkyl exchange reaction which proceeds at high rates in all organometallic systems capable of association. This relationship has already been indicated by the superposition of these reactions in Scheme 2. The validity of six-membered rings with electron-deficient bonding used throughout to describe the structures has not been proved, but it is a useful

Table 2. Constants for the polyreaction of isoprene using an organolithium compound as initiator.

| | |
|---|---|
| Rate constants for the formation of the adduct from butyl-lithium and isoprene (initial reaction) | $k_i = 0.003$ l/mole/sec |
| Activation energy of the initial reaction | $E_i = 15$ kcal/mole |
| Frequency factor of the initial reaction | $A_i = 10^{8.3}$ |
| Rate constant for the formation of the adduct from polyisoprenyl-lithium and isoprene | $k_w = 0.65$ l/mole/sec |
| Activation energy | $E_w = 19.2$ kcal/mole |
| Frequency factor | $A_w = 10^{14.2}$ |
| Rate constants for the terminal reaction (adduct with associated species) | $k_{term} = 1 \quad 10$ l/mole/sec |
| Activation energy of the terminal reaction | $E_{term} = 10$ kcal/mole |
| Frequency factor of the terminal reaction | $A_{term} = 10^{7.5}$–$10^{8.5}$ |
| Equilibrium constant for the equilibrium 3 LiR′ ⇌ $(LiR')_3$ | $K_3 = 1.86 \times 10^{-9}$ mole$^2$/l$^2$ |
| Equilibrium constant for the equilibrium 6 LiR′ ⇌ $(LiR')_6$ | $K_6 = 2.8 \times 10^{-21}$ mole$^5$/l$^5$ |

method of formulation, supported by the fact that according to kinetic investigations the associated forms are present as trimers and hexamers.

Considering the frequency factors shown in Table 2, the large difference between $A_i$ and $A_w$ is surprising, since the same transition state, *i.e.* the adduct of a monomeric form of alkyl-lithium or alkenyl-lithium and isoprene, is assumed for the respective reactions. Figure 3 gives a comparison of butyl-lithium *(4)* and polyisoprenyl-lithium *(5)* with the six-membered ring *(6)* and the cage structure of the associated forms *(7)*. While there is no reason that the butyl-lithium chain in *(4)* should be fixed in position (decrease in entropy), the interaction between the 6,7-double bond and the Li-C

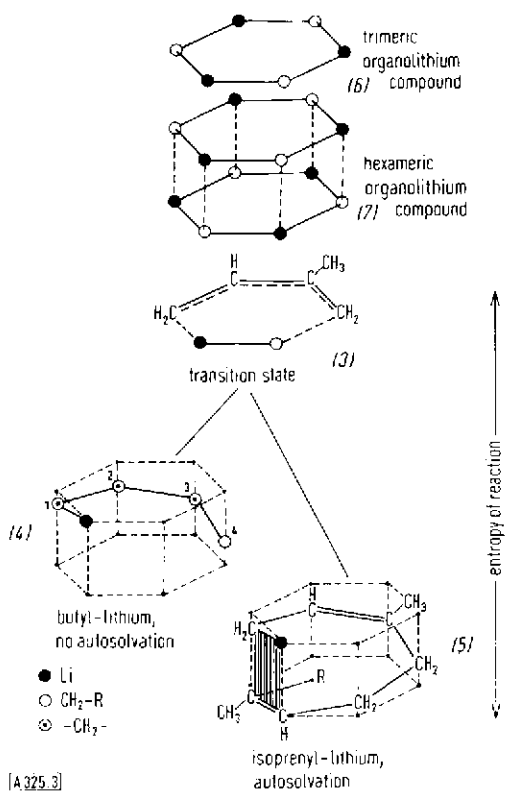

Fig. 3. Possible structures of associated organolithium compounds, the adduct of organolithium compounds and isoprene *(3)*, the monomeric form of butyl-lithium *(4)*, and the autosolvated monomeric form of polyisoprenyl-lithium *(5)*. See text for a discussion of the frequency factors.

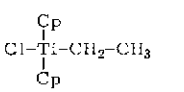
bond in the polyisoprenyl-lithium *(5)* requires fixation of the carbon chain and thus a loss of degrees of freedom.

The authors were able to confirm such relationships kinetically, and even better by infrared analysis. Splitting of the C–C bands of cyclohexene when dissolved in butyl-lithium was observed by *Craubner* [10]. If adduct formation with isoprene occurs with such an "autosolvated" monomeric form of the polyisoprenyl-lithium to give the transition state *(3)*, then the fixation of the polyisoprenyl chain is eliminated, *i.e.* degrees of freedom are gained in contrast to the corresponding reaction with butyl-lithium. This fact explains the difference in the frequency factors, because these contain the difference in entropy of the fundamental and the transition states (cf. the first sentence of this paper).

In all the results hitherto described, n-heptane was used as the solvent for the polyreaction. It has already been mentioned in the preliminary part of this paper that polar substances, such as ether or tetrahydrofuran, prevent a stereoregular course of reaction [10a]. Our own kinetic measurements in diethyl ether are shown in Curve II of Figure 1. Since Curves I and II intersect, it follows that they represent entirely distinct reactions. The rate constant for the reaction in ether is substantially smaller than that for the reaction in n-heptane. The rate equation is

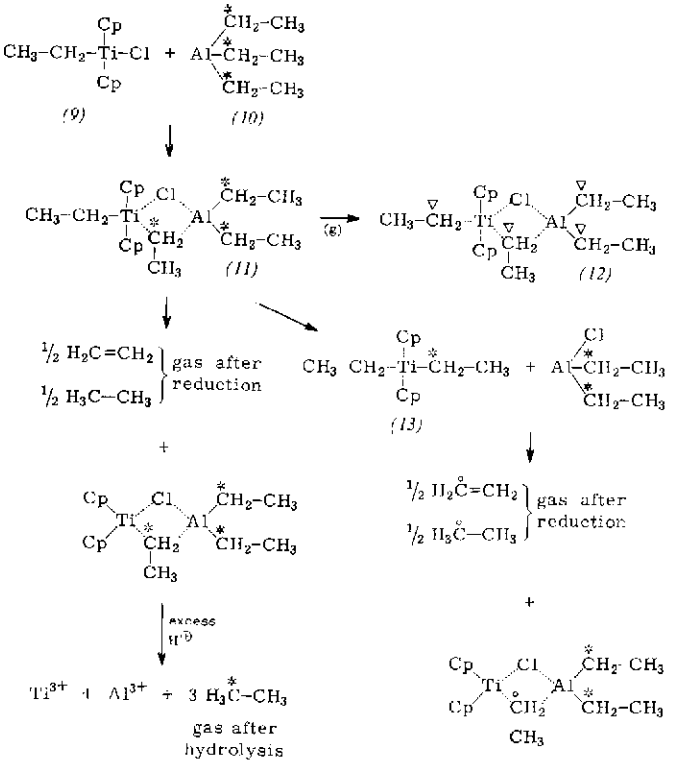


$$v_{t_{ot,\,ether}} = 0.03\ [(LiR)_{titr}]\ [isoprene] \qquad (11)$$

(Units in moles, litres, sec).

Structural considerations thus appear to play a far smaller role in the reaction in ether than in hydrocarbons.

## 3. The Mode of Reaction of Mixed Catalysts Based on Bis(cyclopentadienyl)titanium(IV) Compounds and Organoaluminum Compounds



In contrast to most mixed catalysts for Ziegler-type olefin polyreactions, catalysts based on bis(cyclopentadienyl)titanium(IV) compounds plus organoaluminum compounds are homogeneous [11]. Cryoscopic and spectroanalytical studies have shown that complex formation takes place when these components are mixed (in as little as 0.01 sec), if a small excess of the aluminum compound is present, provided that at least one halogen atom is available in the system for each titanium atom. It is immaterial whether this halogen atom is introduced as aluminum or titanium halide. If at least one alkyl group (containing at least two carbon atoms) is present for each titanium atom, then Ti(IV) is reduced to Ti(III) after complex formation, the rate of reduction increasing with increasing values of the ratio alkyl groups: Ti. The necessity for preliminary complex formation for the reduction is clearly shown by the fact that compound *(8)* is practically stable at room temperature, is rapidly reduced on addition of triethyl aluminum, and more slowly reduced on addition of ethylaluminum dichloride. On reduction, one alkyl group per molecule is split off (presumably as an alkyl radical) to give some olefin and some alkane. *Breslow* [12] found that this system is an initiator for the polymerization of ethylene only if Ti(IV) is still present.

*(8)*, Cp = Cyclopentadienyl

It is certain that this complex formation is related to a very rapid ligand exchange (excluding the cyclopentadienyl groups). Attempts to elucidate the site of active growth of the polymer chain from the positions in the polymer of the groups which were originally attached to the aluminum or titanium were therefore unsuccessful. It was however demonstrated that ethylene is inserted.

We assume that the complex formed from the bis-(cyclopentadienyl)titanium(IV) and organoaluminum compounds contains a halogen bridge and a carbon bridge, *i.e.* that it is an electron-deficient compound (Scheme 4).

Scheme 4. Reactions occurring on mixing bis(cyclopentadienyl)-ethyltitanium(IV) chloride *(9)* with triethylaluminum *(10)*.
Cp = cyclopentadienyl.
*C = radioactive carbon atom.
▽C = radioactivity equal to 3/4 of that of *C.
°C = radioactivity equal to 1/2 that of *C.
(g) = uniform distribution of radioactivity owing to ligand exchange.

A structure of this type has meanwhile been demonstrated by *Natta* [13] for the corresponding complex with Ti(III). This formulation explains the rapid ligand exchange that is well-known in electron-deficient compounds [14].

[10] *I. Craubner*, Institut für Technische Chemie, Technische Hochschule München, unpublished work.

[12] *W. P. Long* and *D. S. Breslow*, J. Amer. chem. Soc. *82*, 1953 (1960), where references to previous publications are given.

[13] *G. Natta* and *G. Mazzanti*, Tetrahedron *8*, 86 (1960).

[14] *N. Muller* and *D. E. Pritchard*, J. Amer. chem. Soc. *82*, 248 (1960).

The complex formation and reduction processes can be formulated as shown in Scheme 4.

During spectroanalytical investigations of the complex formation, we observed that the reduction is appreciably more dependent upon the temperature than the ligand exchange is. Investigations with radioactively labelled triethylaluminum and with unlabelled *(9)* on the gas obtained from the reduction and the hydrolysis (cf. Scheme 4) indicated the following: at −15 °C, ligand exchange (Reaction g) is practically complete before the reduction commences, whereas at + 40 °C, the reduction is completed before a uniform distribution of radioactivity has been attained (cf. Table 3).

Table 3. Radioactivity of the gases given off on reduction and hydrolysis at various temperatures. The activities are given in arbitrary but comparable units (counts per minute referred to the molecular weight per unit area of the gas chromatogram); the bracketed numbers underneath denote the number of determinations.

| | −15 °C | +40 °C |
|---|---|---|
| Specific activity of the ethane obtained on hydrolysis | 203 ± 4 (5) | 189 ± 10 (6) |
| Specific activity of the ethane obtained on reduction | 174 ± 1 (2) | 83 ± 1 (2) |
| Specific activity of the ethylene obtained on reduction | 175 + 9 (2) | 125 ± 1 (2) |
| Expected specific activity of the gases obtained on hydrolysis and reduction for equal distribution (calculated) [a] | 163 | 142 |

[a] In the calculation of the activity for equal distribution, an allowance was made at −15 °C for the excess of alkyl used, but not at + 40 °C.

The higher activity of the ethylene as compared with the ethane obtained will be discussed later. What is important here is that the specific activity of the reduced ethane in the experiment at 40 °C is less than half of the specific activity of the hydrolysed ethane. This means that the titanium atom [*e.g.* as in our formula *(11)*] must be linked to two unsymmetrical alkyl groups and that the reduction takes place not by decomposition of a preformed dialkyltitanium compound *(13)* but by elimination from *(11)* of the exocyclic ethyl group attached to the titanium.

These experiments therefore determine the location of the reduction and show that this technique is capable in general of differentiating between individual alkyl groups in the complex.

In an experiment at 20 °C, we succeeded in splitting the gas obtained on reduction – which is generated within 0.1 sec – into successive fractions. The results of chromatographic studies on the radioactive gas fractions are illustrated in Figures 4 and 5 and show that ethylene is given off more slowly and has a higher specific activity than ethane. Since both ethane and the ethylene must be formed simultaneously, as was shown by a reaction *in vacuo* using continuous pumping, the delayed liberation of ethylene can only be explained by assuming that the ethylene formed is initially chemisorbed on the tetravalent titanium that is still present (Scheme 5), and is only given up when this central atom is also reduced. The higher specific activity of the ethylene compared to that of the ethane is explained by a displacement reaction.

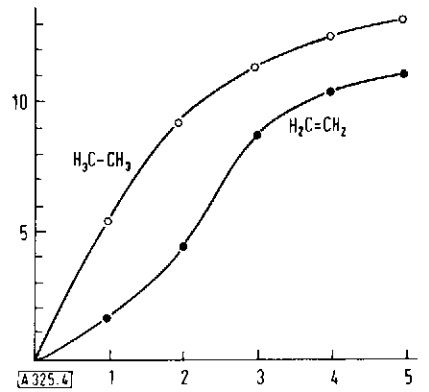

Fig. 4. Gas generated by reduction after mixing 1 mmole of bis(cyclopentadienyl)ethyltitanium(IV) chloride with 1.3 mmole of $^{14}C$ triethylaluminium *in vacuo*. The evolved gas was passed into evacuated vessels with a total volume of 5 litres, which were successively opened and closed. The divisions on the abscissa are not exactly linear for experimental reasons (from 0 5 = approx. 0.1 sec).

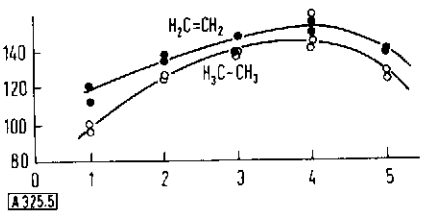
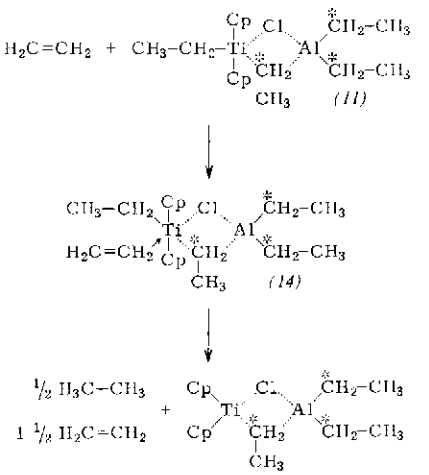
Ordinate: Volume [ml]
Abscissa: Time





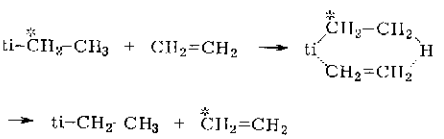


Fig. 5. Specific radioactivity of the fractions shown in Figure 4. The decrease of activity at abscissa values above 4 is caused by some undissolved crystals having zero-point conditions at their surfaces.

Ordinate: Specific radioactivity [arbitrary units, cf. Table 3].
Abscissa: Time [cf. Fig. 4].

Scheme 5. The delayed evolution of ethylene in the reduction according to Scheme 4.

If uniform distribution of activity [*(11)* ⇄ *(12)*] had occured before commencement of the reduction, then the activity of the ethylene would obviously be no greater than that of the ethane (cf. Table 3, experiment at −15 °C).

These results are clearly shown in Scheme 5. The titanium atom in complex *(11)* has a coordination number of 5, *i.e.* it is coordinately unsaturated. By chemisorp-

tion of a molecule of ethylene, it is transformed into the hexacoordinated, saturated state *(14)*. On reduction, the stable tetracoordinated state is formed, with simultaneous evolution of the chemisorbed ethylene. The chemisorptive nature of the link between the ethylene and the titanium atom follows from the aforementioned fact that in the experiment *in vacuo* with continuous pumping, no retardation in the liberation of ethylene could be observed.

The formation of compound *(14)* in Scheme 5 evidently corresponds to the activation stage in our hypothetical mechanism of the low pressure polyreaction of ethylene [cf. Reaction (a) in Scheme 1]. Consideration of the coordination gives a ready explanation of the results observed by *Breslow*, *i.e.* that tetravalent titanium [in the bis(cyclopentadienyl) compound] is essential for initiation. At any rate, these findings have confirmed that an activation step occurs in the mixed catalyst-ethylene system which is comparable with the adduct formation between alkenyl-lithium and isoprene.

Different groups of workers have proposed various mechanisms to explain the action of the mixed catalysts. These suggestions can be classified into two groups. One group postulates a specific mode of action of the complex catalyst [15], whilst the other ascribes a reactivity that is responsible for the polyreaction to the dissociation products of the complexes [16]. This last postulate evidently arose from the assumption that "simple organometallic addition" is a one-step reaction, but this cannot be taken as proven, considering the facts mentioned in the introduction and in the discussion of the alkenyl-lithium isoprene system. The products of dissociation of mixed catalysts, *e.g.* $Cl_3TiR$, $Cp_2TiClR$, or $Cp_2Ti(CH_3)_2$, which were eventually prepared in an indirect manner, were found to be catalytically inactive. The postulates of the first group (specific complex action) vary in their different emphasis of details. In this connection it is necessary to quote *Breslow*: "Actually, if the migration of the alkyl group and the formation of the new titanium-carbon bond is considered to be a concerted reaction, it is probably meaningless to postulate where the electrons come from." [17]

Now that the occurrence of an activation step associated with the complex has been demonstrated, it remains to clarify whether the insertion of the activated ethylene occurs into the same complex or into a second complex molecule, and to determine the identity of the bond at which this insertion takes place. Some indication has been obtained only with regard to the last point.

If this reaction is carried out not *in vacuo* but under an inert atmosphere, some of the ethylene added onto the titanium is inserted, so that butyl groups are formed from the ethyl groups. Butane is found in the reduced gas, as well as in the gas formed by the hydrolysis of the trivalent complex present after reduction, but the amount of butane in the hydrolysis gas exceeds that in the reduction gas by a factor of seven. Chromatographic investigations of the radioactive gas (shown in Table 4) suggest that the terminal reaction of the ethylene which is activated on the titanium atom does not occur at the exocyclic alkyl group linked to the titanium atom but either at the $CH_2$ group which forms the bridge between the titanium and the aluminum atoms or at the exocyclic alkyl group attached to the aluminum atom.

Table 4. Comparison of the activities of the gases liberated after the reduction by hydrolysis (ethane and butane) with the activities of the gases obtained on reduction. Data as in Table 3; here the activities are referred to one carbon atom of the stated compounds.

| | |
|---|---|
| Ethane from hydrolysis | $47 \pm 1$ (2) |
| Butane from hydrolysis | $40 \pm 3$ (4) |
| Ethane from reduction | $36 \pm 1$ (2) |
| Ethylene from reduction | $36 \pm 1$ (2) |

## 4. Summary

The successive stages of the activation and the subsequent terminal reaction have been demonstrated for both the alkenyl-lithium/isoprene and the homogeneous mixed catalyst/ethylene systems. For the alkenyl-lithium isoprene system, it has been established that after the induction period caused by the transformation of alkyl-lithium into alkenyl-lithium [Reaction (e)], a system with a constant number of active particles is present (particles with the Li–C bond). This fact distinguishes this system from polymerizations which are characterized by chain initiation, chain extension, and chain termination reactions, and also from polycondensation and polyaddition reactions, which are characterized by a decrease in the number of available functional groups at progressive degrees of conversion.

It seems noteworthy that in these organometallically initiated polyreactions it is not the actual monomer (isoprene or ethylene), but rather a monomer molecule that is modified by an adduct formation comparable to chemisorption, which undergoes combination. In consequence, copolymerization experiments give no indication of the relative reactivities of the free monomers but only differentiate the reactivities of the chemisorbed monomeric molecules. It may be assumed, and it is evident in the case of the isoprene/alkenyl-lithium adduct, that this adduct formation determines the configuration. If the combination reaction which follows such an activation corresponds to the insertion type of reaction (*i.e.* bifunctional combination) then the configuration obtained during the activation stage remains intact, *i.e.* stereospecific polymers are formed.

It must be stated that no evidence contradicting our initial postulate has been obtained [18]. Detailed aspects of this proposed mechanism, for example, the separate activation step, have been confirmed. It should be possible to locate the point of insertion with the mixed catalysts by further kinetic investigations. In conclusion, it must however again be stated that, in principle, kinetic studies cannot prove a fact but merely serve "not to exclude" it.

# The Biochemistry of Yeast Threonine Deaminase

BY PROF. DR. H. HOLZER, DR. M. BOLL, AND PROF. DR. C. CENNAMO [*]

BIOCHEMISCHES INSTITUT DER UNIVERSITÄT FREIBURG IM BREISGAU (GERMANY)

*Dedicated to Prof. Dr. Otto Warburg on the occasion of his 80th birthday*

*An optical assay, according to Warburg, for measuring the activity of the enzyme threonine deaminase (threonine → α-ketobutyrate + $NH_4^+$) is described. Some of the properties of the enzyme from yeast have been studied using this assay. Pyridoxal phosphate and pyridoxamine phosphate stabilize the enzyme in the crude extract. Valine, leucine, and isoleucine, and to a lesser extent threonine, $NH_4^+$, and $K^+$ protect the enzyme from inactivation when diluted with buffer. The enzyme is inhibited by isoleucine. The extent of the inhibition is dependent on the pH. Thus, in yeast, just as described for Escherichia coli by Umbarger, isoleucine exerts a control on its biosynthesis from threonine by means of a feed-back mechanism, the extent of the control being related to the consumption of isoleucine in protein synthesis. $NH_4^+$ represses the biosynthesis of threonine deaminase. This mechanism regulates the threonine deaminase-catalysed formation of $NH_4^+$ from threonine in accordance with the $NH_4^+$-requirements of the growing cell.*

## 1. Introduction

*Otto Warburg* discovered and developed the most important methods for the isolation of enzymes and the measurement of their activity [1]. In the last three decades, many enzymes have been characterized, and the most important metabolic pathways have been elucidated with the aid of these methods.

In general, it is found that any enzyme has a constant activity in a given biological material. However, measurements of enzyme activity in microorganisms have demonstrated that characteristic alterations in enzyme activity can occur owing to adaptation to environmental changes. For example, increased β-galactosidase activity is found in yeast cells after the addition of lactose to the nutrient medium. This adaptive process enables the yeast cells to hydrolyse lactose to galactose and glucose and thus to exploit this substance as a substrate capable of yielding energy and building materials. In the analysis of such adaptive processes, activation or inhibition of existing enzymes, and acceleration or deceleration of enzyme syntheses have been observed. The effects on existing enzymes are said to be due to feed-back mechanisms and those on enzyme synthesis to induction or repression of synthesis (for a summary, see *e.g.* [2]). In the present communication, changes in activity of this nature are described for yeast threonine deaminase [**]. They assist in the regulation of $NH_4^+$ metabolism by adapting to changes in the composition of the nutrient medium.

## 2. Position of Threonine Deaminase in Metabolism

In the presence of pyridoxal phosphate, threonine deaminase catalyses the irreversible conversion of threonine into α-ketobutyrate and $NH_4^+$. As shown in Figure 1, this is the initial reaction in the biosynthesis of isoleucine from threonine. However, α-ketobutyrate is not only an intermediate in the synthesis of isoleucine, but can also be degraded oxidatively to yield energy.

[1] *O. Warburg:* Wasserstoffübertragende Fermente. Verlag Dr. Werner Saenger GmbH., Berlin 1948.

[2] *H. Holzer*, Naturwissenschaften *50*, 260 (1963).

[**] In the "Report of the Commission on Enzymes of the International Union of Biochemistry 1961" the enzyme is designated under number 4.2.1.16, as "L-threonine hydro-lyase (deaminating)" with the trivial name "threonine dehydratase".

The first step of this latter path is oxidative decarboxylation to give propionyl-CoA [2a]. This substance is then broken down further in the citric acid cycle by way of succinyl-CoA. Not only α-ketobutyrate but also $NH_4^+$, the second product of the threonine deaminase reaction,

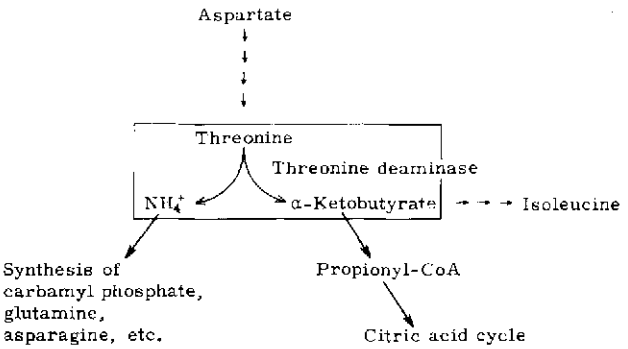

Fig. 1. Position of threonine deaminase in metabolism.

is employed as a building material in synthetic reactions. Together with ATP and $CO_2$, $NH_4^+$ gives rise to carbamyl phosphate, and with aspartic and glutamic acids, it yields asparagine and glutamine, respectively; it also brings about amidation of deamido-NAD to yield NAD. As shown in the present communication, the threonine deaminase-catalysed formation of $NH_4^+$ from threonine is always of particular importance when $NH_4^+$ is lacking in the nutrient medium and must therefore be provided from other nitrogenous sources. All the amino acids which yield aspartate by direct or indirect transamination with oxaloacetate can serve as the source of nitrogen for threonine and thus for $NH_4^+$. Since the carbon atoms of threonine can themselves be re-employed in the synthesis of aspartate, a cycle is obtained, as depicted in Figure 2. The conditions under which this "threonine cycle", which transforms amino-nitrogen into $NH_4^+$, is of biological importance have still to be determined.

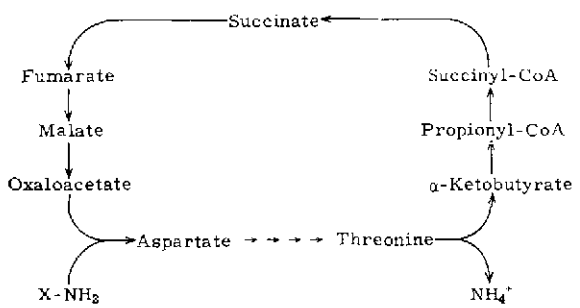

Fig. 2. Production of $NH_4^+$ from amino-nitrogen (X—$NH_2$) in the "threonine cycle".

The scheme reproduced in Figure 1 is valid for yeast, *Escherichia coli*, and many other microorganisms. In mammals, the transformation of aspartate into threonine and of α-ketobutyrate into isoleucine does not occur. For this reason, threonine and isoleucine are essential amino acids for mammals. However, threonine deaminase is probably of significance in mammals, too, since the decomposition of threonine by way of the citric acid cycle to yield energy and $NH_4^+$ are important processes. Evidence in support of this is provided by the characteristic changes in threonine deaminase activity which were measured in rat livers under varying dietary conditions (see *e.g.* [3]).

[2a] ATP = adenosine triphosphate; CoA = coenzyme A; EDTA = ethylenediamine tetraacetate; LDH = lactate dehydrogenase; NAD = nicotinamide adenine dinucleotide; NADH = reduced NAD; PALP = pyridoxal-5-phosphate; PAMP = pyridoxamine-5-phosphate.

## 3. Assay

The activity of threonine deaminase was hitherto determined by colorimetry of the 2,4-dinitrophenylhydrazone of α-ketobutyric acid. This assay does not allow the enzyme's activity to be followed continuously, since individual samples must be withdrawn and analyzed. We have employed the principle of the optical assay according to *Warburg* [4] for following the reaction. Since commercially available crystalline lactate dehydrogenase from rabbit muscle reduces α-ketobutyrate as well as pyruvate with NADH, the formation of α-ketobutyrate from threonine can be followed optically with the aid of this enzyme. The reactions forming the basis of this assay are:

(1) $CH_3-CHOH-CHNH_2-COOH$ (Threonine) $\rightarrow CH_3-CH_2-CO-COOH + NH_4^+$ (α-Ketobutyrate)

(2) $NADH + CH_3-CH_2-CO-COOH \rightarrow CH_3-CH_2-CHOH-COOH + NAD$ (α-Hydroxybutyrate)

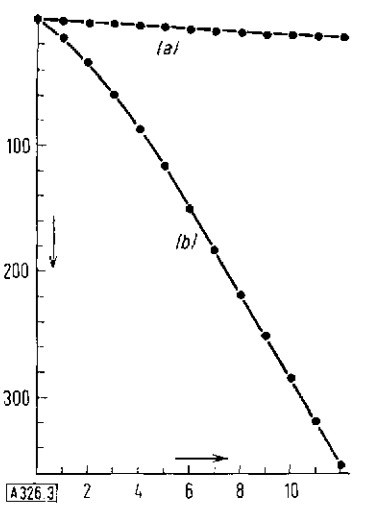

Fig. 3. Standard assay for threonine deaminase. Wavelength 366 mμ, light path 1 cm, total volume 3.00 ml, 22 °C. The following are pipetted *into the cuvette in the order given*: 2.74 *ml of* 0.1 *M triethanolamine*/HCl buffer (pH 7.9), 0.1 ml of 10 mg/ml NADH, 0.02 ml of a suspension of 5 mg of crystallized LDH in 1 ml of 2.2 M $(NH_4)_2SO_4$ (Boehringer), 0.02 ml of 0.01 M PALP, and 0.1 ml of 0.5 M L-threonine. After waiting at least 1 min until the change in extinction due to the formation of the Schiff base between threonine and PALP has gone to completion, the reaction is started with 0.02 ml of crude extract containing approx. 0.3 mg of protein. To prepare the crude extract, the yeast (*Saccharomyces cerevisiae* R 59 Ephrussi) was grown in a culture medium with DL-threonine as nitrogen source, centrifuged off, and washed; the cells were then ground with thrice their weight of aluminum oxide powder (AL-COA A 305), extracted with a threefold volume of 0.05 M phosphate buffer (pH 7.6; containing $10^{-3}$ M EDTA), and centrifuged for 1 hour at 34000 g (cf. [5]). Unless otherwise stated, a crude extract stabilized with $1\times10^{-3}$—$2\times10^{-3}$ M PALP was employed.
Curve (a): without threonine
Curve (b): with threonine
Ordinate: decrease in extinction at 366 mμ (= $\Delta E\times1000$)
Abscissa: time [min]

[3] *V. R. Potter* and *T. Ono*, Cold Spring Harbor Symp. quantitat. Biol. *26*, 355 (1961).
[4] *O. Warburg* and *W. Christian*, Biochem. Z. *287*, 291 (1936).

The kinetics of such an assay are reproduced in Figure 3. Only minute oxidation of NADH occurs when threonine deaminase, in the form of a crude extract from yeast, is added to the reaction mixture in the absence of threonine, whereas in the presence of threonine, the NADH is oxidized with increasing rapidity. The constant terminal velocity is reached after approximately 6 min. An "acceleration time" is required in order to reach the constant terminal velocity, which is limited by the activity of the threonine deaminase, because a certain quantity of α-ketobutyrate must first accumulate before the lactate dehydrogenase reaction can proceed with the necessary velocity. This "acceleration time" is relatively long, since lactate dehydrogenase has only a slight affinity for α-ketobutyrate. It can be shortened by increasing the amount of lactate dehydrogenase added (cf. Fig 4). Routinely, we use 0.1 mg (0.02 ml) of lactate

dehydrogenase per assay, and take the activity of the threonine deaminase to be represented by the constant terminal velocity reached after approximately 10 min. Figure 5 shows that the terminal velocity is proportional to the amount of crude extract added.

## 4. Stabilization of the Enzyme in the Crude Extract

Curve 1 in Figure 7 shows that a crude extract from yeast loses approximately half of its threonine deaminase activity at 0 °C within 12 hours. The decrease in activity is prevented by the addition of pyridoxal phosphate (Curve 3). We found that after storage for 54 hours,

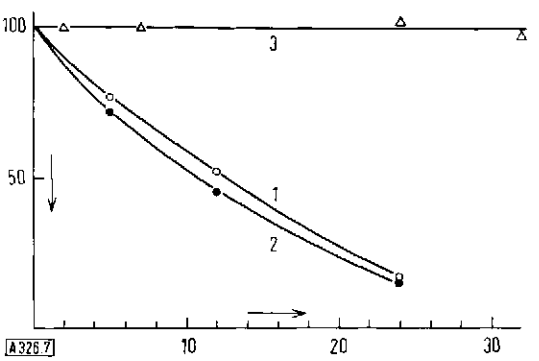

Fig. 7. Stabilization of the crude extract by PALP.

Abscissa: Duration of storage of crude extract at 0 °C [h]

crude extract with $10^{-3}$ M pyridoxal phosphate still contains 88 % of the activity of the fresh extract. Table 1 shows that even $10^{-5}$ M pyridoxal phosphate still has a definite stabilizing effect. Pyridoxamine phosphate also stabilizes the enzyme; unphosphorylated derivatives of vitamin $B_6$ are ineffective. L-Threonine, the substrate of the enzyme, as well as other amino acids, has no protective effect. Ammonium sulfate stabilizes only in unbiologically high concentrations (cf. Curve 2 in Fig.7). The decline in activity is irreversible: if pyridoxal phosphate or pyridoxamine phosphate is added to crude extract kept without stabilizer for 24 hours, no reactivation occurs. Approximately $10^{-5}$ mole of pyridoxal phosphate or pyridoxamine phosphate is

Table 1. Stabilization of the crude yeast extract by various additions. Activity assay: cf. Fig. 3.

| Substance added | Concentration [mole/l] | Activity after 22–24 h at 0 °C in percent of initial activity |
|---|---|---|
| – | – | 12 |
| PALP | $1\times10^{-3}$ | 100 |
| | $5\times10^{-4}$ | 92 |
| | $1\times10^{-4}$ | 80 |
| | $2\times10^{-5}$ | 55 |
| PAMP | $2\times10^{-3}$ | 72 |
| | $1\times10^{-4}$ | 48 |

| $(NH_4)_2SO_4$ | $1\times10^{-1}$ | 16 |
| | 1 | 52 |

found in one litre of yeast [6,7]. It is possible, therefore, that the stabilization of the enzyme by pyridoxal phosphate and pyridoxamine phosphate observed in our experiments is also of importance for the living cell.

## 5. Inactivation of the Enzyme Following Dilution

If the concentrated crude extract obtained by grinding yeast cells with aluminum oxide powder is diluted with buffer solutions, a very rapid decrease in enzyme activity is observed. If, for example, 0.02 ml of crude extract is diluted to 3 ml with 0.1 M triethanolamine buffer (pH 7.9), as routinely done during performance of the optical assay, then the activity decreases from 33 to 2 units [*], that is to less than 10 %, if the reaction mixture is allowed to stand for 15 min at 22 °C (cf. Table 2).

Table 2. Protection of the enzyme from inactivation following dilution of the crude yeast extract. The crude extract was diluted 1:150 with 0.1 M triethanolamine/HCl-buffer (pH 7.9), containing the additions indicated, and incubated for 15 min at 22 °C. Subsequently, measurement of the activity (see legend to Fig. 3) was started by the addition of LDH (suspended in $(NH_4)_2SO_4$) NADH, PALP, and threonine.

| Addition before incubation | Activity [$\Delta E\times1000$/min/0.02 ml of crude extract] |
|---|---|
| – | 2 |
| PALP $3\times10^{-4}$ M | $<1$ |
| L-Threonine $1.7\times10^{-2}$ M | 28 |
| D-Threonine $1.7\times10^{-2}$ M | 2 |
| L-Valine $1.7\times10^{-2}$ M | 29 |
| L-Serine $1.7\times10^{-2}$ M | 2 |
| L-Glutamate $1.7\times10^{-2}$ M | 1 |
| $(NH_4)_2SO_4$ $1.47\times10^{-2}$ M | 25 |
| $NH_4Cl$ $2.94\times10^{-2}$ M | 23 |
| KCl $2.94\times10^{-2}$ M | 15 |
| NaCl $2.94\times10^{-2}$ M | 2 |
| without incubation | 33 |

[7] *G. Schreiber, M. Eckstein, A. Oeser*, and *H. Holzer*, unpublished results.

[*] The unit is defined as $\Delta E\times1000$/min/0.02 ml crude extract.

Although pyridoxal phosphate, as demonstrated in the previous section, protects the concentrated enzyme in the crude extract from inactivation, it has no influence on the fast inactivation of the diluted enzyme. L-Threonine, on the other hand, does have a protective effect. L-Isoleucine, L-valine, and L-leucine protect the enzyme in even lower concentrations. If rather high concentrations of isoleucine and leucine are employed, then the protective effect is superimposed by the inhibition of enzyme activity described in the following section (cf. Fig. 8). L-Serine, L-glutamate, and D-threonine are

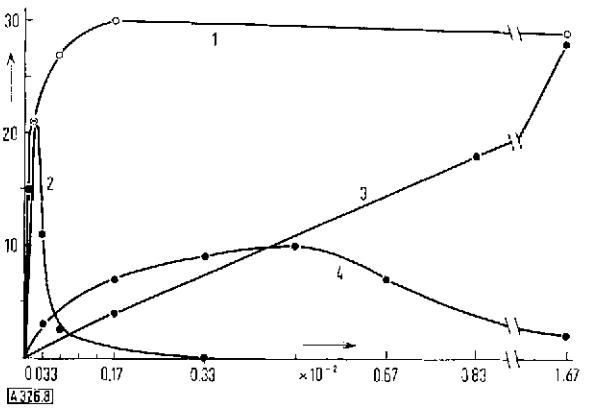

Fig. 8. Protection by various amino acids against inactivation of the enzyme following dilution of the crude yeast extract.

ineffective (Table 2). On the other hand, inactivation can also be prevented by high concentrations of ammonium sulfate (cf. Fig. 9). The sulfate anion is not of importance here, since ammonium chloride has the same effect (Table 2). The effect is not specific, for ammonium chloride or potassium chloride also have a protective action. Sodium chloride is inactive.

The effects reproduced in Table 2 and Figures 8 and 9 probably have no significance in the living cell, since they only occur after the enzyme solution has been diluted. However, they are of interest in connection with the analysis of the mechanism of the action and, in particular, with the biosynthesis of the enzyme. In addition to stabilization by substrates and coenzymes – a phenomenon known to occur in many other instances – in our case, the enzyme is also stabilized by amino acids (L-valine, L-isoleucine, and L-leucine) which do not serve as substrates, but on the contrary inhibit the biosynthesis of the enzyme (in *Salmonella typhymurium* and *E. coli*) by multivalent repression [8]. As a general rule, it must be borne in mind that when enzymes are in high dilution, as they usually are during assay, they can exhibit a quite different behavior from that in concentrated solution, in which they are found in the living cell.

The precautions to protect the enzyme from inactivation described in this and in the preceding section have enabled us to achieve enrichment of the enzyme [9]. However, since characteristic properties of the enzyme are altered by fractionation procedures, only experiments with crude extracts will be reported in this communication, which is concerned with the importance of the enzyme for the intact cell. We are unable to say to what extent the properties of the enzyme are already altered during the preparation of the crude extract. There is much that indicates that the remark of *Racker* [10], "First purify, then think; don't waste pure thinking time on dirty enzymes", is not valid in all cases. A certain amount about the behavior of an enzyme in the living cell can certainly be learned from a study of the purified enzyme, but not everything.

## 6. Inhibition of the Enzymatic Activity by L-Isoleucine

In 1956, *Umbarger* [11] found that the threonine deaminase reaction in *E. coli* extracts is inhibited by low concentrations of isoleucine. This is a "useful" regulation mechanism for the economy of the cell, since isoleucine is the final product of a synthetic sequence starting from threonine (cf. Fig. 1). If there is sufficient isoleucine available to satisfy the requirements of protein synthesis, then the isoleucine supply by synthesis is inhibited at the threonine deaminase step. If the isoleucine concentration declines as a result of consumption in protein synthesis, then the inhibition of the enzyme chain which synthetizes isoleucine from threonine is decreased. The concentration of isoleucine, and consequently the degree of inhibition exerted, are interrelated in such a way that the supply of isoleucine corresponds to the consumption of this amino acid. A "feed-back" mechanism is in fact in operation which is in some ways analogous to that of amplifying electronic tubes.

[10] *E. Racker,* Nachr. Chem. Techn. *9*, 348 (1961).

[11] *H. E. Umbarger,* Science (Washington) *123*, 848 (1956).

Table 3. Inhibition of threonine deaminase activity by various amino acids. Activity assay: cf. Fig. 3.

| Amino acid added | Final concentration [mole/l] $\times 10^3$ | [$\Delta E \times 1000$/min /0.02 ml of crude extract] | Inhibition [%] |
|---|---|---|---|
| – | – | 14 | 0 |
| L-Isoleucine | 10 | 0 | 100 |
| | 1.7 | 0 | 100 |
| | 0.67 | 1.5 | 93 |
| | 0.3 | 7 | 50 |
| | 0.17 | 12 | 15 |
| | 0.03 | 14.5 | $<5$ |
| D-Isoleucine | 10 | 14 | $<5$ |
| L-Leucine | 10 | 4 | 71 |
| | 0.67 | 14 | $<5$ |
| L-Valine | 10 | 14 | $<5$ |
| L-Serine | 10 | 14.5 | $<5$ |
| L-Aspartate | 10 | 14 | $<5$ |

Table 3 shows that yeast threonine deaminase, too, is inhibited by low concentrations of isoleucine. The effect is rather specific: all other amino acids tested so far inhibit only slightly or are without effect. The inhibition of the enzymatic activity by L-isoleucine is strongly dependent on the pH (cf. Fig. 10). $3 \times 10^{-4}$ M isoleucine

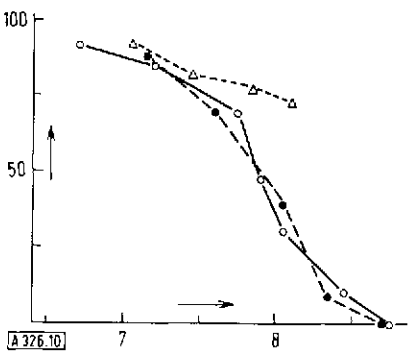

Fig. 10. Dependence on pH of the inhibition of activity by isoleucine: 15 min after starting the reaction with crude extract, 1 µmole of isoleucine was added per cuvette (final concentration $3.3 \times 10^{-4}$ M); after further 15 min, the constant terminal velocity was recorded.

○ = 0.1 M triethanolamine/HCl buffer

inhibits completely at pH 7, only 50 % at pH 7.9, and not at all at pH 8.7. The pH-dependence of the isoleucine inhibition may possibly be of significance for metabolic regulation in the living cell [*].

## 7. Repression of the Synthesis of the Enzyme by $NH_4^+$

We tested whether $NH_4^+$, like isoleucine, inhibits the enzyme, but found that this is not the case [**]. However, the $NH_4^+$ concentration does exert an effect on the extent of the threonine deaminase reaction in the living

[*] Note added in proof: It also suggests that an "allosteric" proton dissociating group with pK 7.9 participates in the mechanism of inhibition.

[**] A report on the activation by $NH_4^+$ ("reaction product activation") will be published elsewhere.

cell. The control in this case is brought about by influencing the rate of the synthesis of the enzyme. Differing threonine deaminase activities are found in yeast cells cultured in nutrient media containing different nitrogen sources, as shown in Table 4. It can be seen

Table 4. Specific activity of threonine deaminase after growing the yeast on nutrient media with various nitrogen sources [12].

| Nitrogen source | Activity [ΔE × 1000/min/ml of crude extract] | mg of protein/ml of crude extract | Specific activity [ΔE × 1000/min/mg of protein] | Specific activity [% of the value with $NH_4^+$ as nitrogen source] |
|---|---|---|---|---|
| $NH_4^+$ | 170 | 6.4 | 26 | 100 |
| $NH_4^+$ + DL-Threonine | 130 | 5.4 | 24 | 92 |
| DL-Threonine | 400 | 5.5 | 73 | 280 |
| DL-Serine | 530 | 6.9 | 77 | 295 |
| DL-Isoleucine | 400 | 7.0 | 57 | 220 |

that when $NH_4^+$ is present in the nutrient medium, the specific activity of the enzyme (and therefore its concentration) is low. When amino acids are the only source of nitrogen, the concentration of the enzyme is high. As threonine deaminase liberates $NH_4^+$ from the amino-nitrogen of amino acids (cf. Fig. 2), this effect is of advantage to the cell in the exploitation of its nitrogen supply: if $NH_4^+$ is already present in the medium, then the enzyme is not required. If amino acids are the sole source of nitrogen, then the enzyme is synthetized to mediate the supply of $NH_4^+$, which is necessary in particular for the formation of carbamyl phosphate.

Experiments with bacteria, in particular with *E. coli*, have shown that such changes in enzyme activity which are determined by altered environmental conditions are brought about by "induction" or "repression" of enzyme synthesis. In the case of induction, synthesis is initiated by certain substances in the nutrient medium, in the case of repression, it is inhibited; for a summary, see [13, 14]. The data reproduced in Table 4 make it probable that the velocity of the synthesis of threonine deaminase in yeast is subject to such control. If it is assumed that $NH_4^+$ suppresses synthesis of the enzyme, it can be understood why the enzyme occurs only with low specific activity, *i.e.* in low concentration, when the cells have been cultured in a medium containing $NH_4^+$. Similarly, it is clear why the enzyme is found to be highly active after the cells have been grown in the presence of nitrogen sources other than $NH_4^+$. In this case, repression of the synthesis of the enzyme by $NH_4^+$ is lacking ("derepression" is said to occur). The experiment in which $NH_4^+$ and the amino acid threonine were present in the medium together (Table 4) is particularly informative. Since a threonine deaminase activity is found under these circumstances that is just as low as that in the presence of $NH_4^+$ alone, it is apparent that the synthesis of the enzyme is repressed by the $NH_4^+$, and that increased synthesis is not being induced by amino acids.

Deamination of threonine is necessary for providing not only $NH_4^+$, but also α-ketobutyrate for the synthesis of isoleucine. With this in mind, it becomes clear why the synthesis of the enzyme is not completely repressed by $NH_4^+$. After growing the yeast in a medium containing $NH_4^+$, the activity of the enzyme is only about one-third of that found after culture with amino acids as nitrogen source. Presumably, therefore, one third of the enzyme activity suffices to provide that amount of α-ketobutyrate from threonine which is necessary for the synthesis of isoleucine.

## 8. Discussion

Like threonine deaminase, the NAD-dependent glutamate dehydrogenase, previously demonstrated by us to be present in yeast [15], provides $NH_4^+$ from amino-nitrogen:

$$\text{Glutamic acid} + \text{NAD} \rightarrow \alpha\text{-ketoglutarate} + \text{NADH} + NH_4^+$$

We found that similar conditions prevailed in the control of the activity of this enzyme as occur with threonine deaminase: synthesis is repressed by $NH_4^+$ [5, 16]. The activity of NAD-glutamate dehydrogenase in yeast cells grown in the presence of $NH_4^+$ is less than 5 % of that observed when amino acids are the nitrogen source. From this it would seem highly probable that the main biological function of the NAD-dependent glutamate dehydrogenase from yeast is the supply of $NH_4^+$ from glutamic acid. If $NH_4^+$ is not required, then neither is the enzyme. Glutamic acid, like aspartate (and consequently threonine) can acquire its amino group by transamination from all other amino acids. Thus, the glutamate dehydrogenase reaction, like the threonine deaminase reaction, assists in supplying the growing cell with $NH_4^+$ at the expense of amino-nitrogen. In Figure 11, the position of $NH_4^+$ in metabolism is summarized. The $NH_4^+$ is supplied from the amino-nitrogen of aspartic and glutamic acids, or of the other

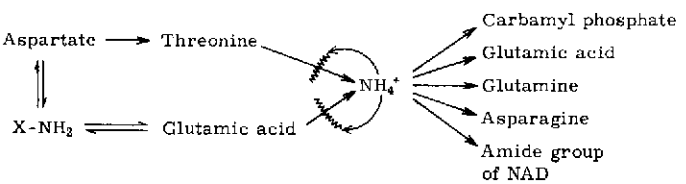

Fig. 11. Regulation of the $NH_4^+$ economy in yeast cells by repression of the synthesis of threonine deaminase and NAD-glutamate dehydrogenase.

amino acids which are in equilibrium with them by transamination, and is subsequently employed in the synthesis of carbamyl phosphate, glutamic acid, glutamine, and other cell constituents. The $NH_4^+$ requirements determine its production; increased $NH_4^+$ concentrations

cause the synthesis of the $NH_4^+$-supplying enzymes to be repressed.

Inhibition of threonine deaminase by isoleucine occurs rapidly. According to our observations, inhibition is complete in less than 1 min. In contrast, repression of the synthesis of the enzyme by $NH_4^+$ can only affect the enzyme content of the cells with that velocity with which dilution of the enzyme by cell multiplication, occurs. In the case of yeast, the time intervals are of the order of hours [16]. Since protein synthesis depends on maintenance of the level of L-isoleucine, it is clear that the synthesis of isoleucine must be regulated by a very rapid mechanism. Under natural conditions, changes in the $NH_4^+$ content of the nutrient medium will take place only gradually. It is sufficient then, if adaptation to a change in the $NH_4^+$ content of the nutrient medium occurs by a mechanism which comes into action only slowly *viz.* by control of the velocity of enzyme synthesis. Inhibition of activity by the feed-back mechanism is consequently a means of rapid "fine control" of metabolism; repression of enzyme synthesis, on the other hand, is a "rough control" whose effect develops over a long period [17].

*We wish to thank Prof. Dr. O. Wiss (Hoffman-La Roche, Basel) for supplying us with pyridoxal phosphate and pyridoxamine phosphate. We also wish to thank the Deutsche Forschungsgemeinschaft and the Bundesministerium für Wissenschaftliche Forschung for financial support.*

# Complex Formation with Organoaluminum Compounds

BY DR. H. LEHMKUHL [1]

MAX-PLANCK-INSTITUT FÜR KOHLENFORSCHUNG, MÜLHEIM/RUHR (GERMANY)

*Dedicated to Prof. Dr. Karl Ziegler on the occasion of his 65th birthday*

*From theoretical considerations of the Lewis-acid character of the organoaluminum compounds $AlR_3$ and $AlEt_2X$ and of possible combinations of these acids with Lewis bases chiefly anions combined with alkali metal ions – by reactions analogous to neutralizations, as well as on the basis of experimental findings, the compounds $AlEt_2X$ and the alkali salts MY can be arranged in the order of their tendency to form complexes, in dependence on the nature of X and Y, respectively. Numerous displacement reactions, in which a stronger complexing group replaces a weaker one, confirm these series. These reactions have led to the formation of new complex compounds of alkylaluminum with the hitherto unknown alkyls of calcium, strontium, and barium, and also to the preparation of $[NEt_4][AlEt_4]$ and $[SbEt_4][AlEt_4]$. Displacement of ethylsodium from $NaAlEt_4$ with the aid of NaOR – which is readily complexed – in the presence of benzene provides a simple mode of conversion of alkylaluminum into phenylaluminum compounds:*

$$NaAlEt_4 + 4\ C_6H_6 \xrightarrow{NaOR} NaAlPh_4 + 4\ C_2H_6$$

## 1. Tendency towards Complex Formation

As compounds of trivalent aluminum, unassociated monomeric alkylaluminum compounds are Lewis acids and will therefore combine with Lewis bases to form molecular compounds or complex anions. For example, tertiary amines, ethers, or hydride, ethyl, and halogen anions can function as electron donors. Compounds containing four-coordinate aluminum are obtained. Higher coordination numbers for organoaluminum compounds are not yet known.

Monomeric alkylaluminum compounds are usually unobtainable as such since they associate on account of their electron-deficiency to form dimers or trimers. Complex formation must therefore always be preceded by dissociation of the alkylaluminum associates, or at least the equilibrium (1) must be set up [*].

$$(1)\quad (AlR_2X)_2 \rightleftharpoons 2\ AlR_2X$$

The tendency towards formation of a complex ion according to Equation (2) is greater, the stronger the Lewis acid, *i.e.* the monomeric alkylaluminum, and the Lewis base, *i.e.* the added anion, involved.

$$(2)\quad AlR_2X + Y^- \rightarrow [AlR_2XY]^-$$

[1] Presented in part at the Hauptversammlung of the Gesellschaft Deutscher Chemiker in Heidelberg (Germany), September 1963.

[*] In this paper, the following abbreviations will be used: Me = $CH_3$; Et = $C_2H_5$; Ph = $C_6H_5$; R = alkyl; M = metal; Hal = halogen; THF = tetrahydrofuran.

An exchange equilibrium [Reaction (3)] must also be considered simultaneously with the complex formation.

(3) $AlR_2X + Y^- \rightleftharpoons [AlR_2]^+ + X^- + Y^- \rightleftharpoons AlR_2Y + X^-$
Acid I Base I Acid II Base II

One component in this equilibrium is the hypothetical cation $[AlR_2]^+$, which attempts to capture the substituent which is the best electron donor. When this occurs, the accepting capacity of the resultant acid II is diminished. Only the weaker base II is then available for the formation of the complex ion. If the basic and acidic strengths are large enough to provide the energy in the reaction, analogous to neutralization, to separate the reactants from their possible partners (these energies are for $X^-$ the lattice energy of the salt MX, and for $AlR_2Y$ the energy of association), then a complex anion can result. Otherwise complex formation either does not occur, or – if the reaction of MY with $AlR_2X$ is attempted – only an exchange reaction [Equation (4)] occurs instead.

(4) $AlR_2X + MY \rightleftharpoons AlR_2Y + MX$

## 2. 1:1 Complexes with Trialkylaluminum

*K. Ziegler* and co-workers [1a] investigated complexes of alkali metal halides and hydrides with trialkylaluminum and found that the tendency towards complex formation increases as the ionic radius of the alkali metal cation increases, but decreases as the anionic radius and the length of the alkyl chain increase (Figs. 1 and 2).

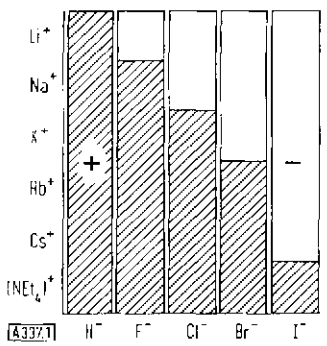

Fig. 1. Complexes of alkali metal hydrides and halides with triethylaluminum [1].

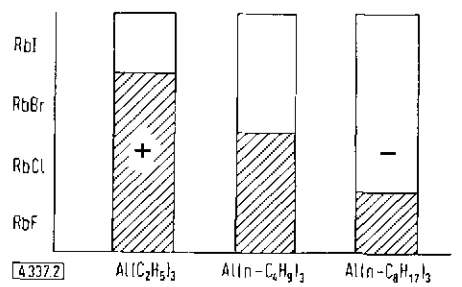

Fig. 2. Complexes of rubidium halides with trialkylaluminum [1].

Supporting these findings are the decrease in lattice energy from lithium halide to cesium halide in an alkali metal halide series with a given halide ion, and the decrease in the energy of reaction on addition of a halide ion to an alkylaluminum with increasing anionic radius (analogous to the energy of hydration of halide ions [2]) and with increasing length of the hydrocarbon chain.

The halides of the pseudo-alkali-metal cation $[NEt_4]^+$ are the salts with the largest "alkali metal" cation and thus display the greatest tendency towards complex formation. Tetraethylammonium iodide is the only "alkali metal" iodide to form a complex with triethylaluminum.

The capacity for complex formation of ethylaluminum chlorides increases as follows: $AlEt_3 < AlEt_2Cl < AlEtCl_2$ (Fig. 3). The adduct of KCl with $AlEt_3$ is only

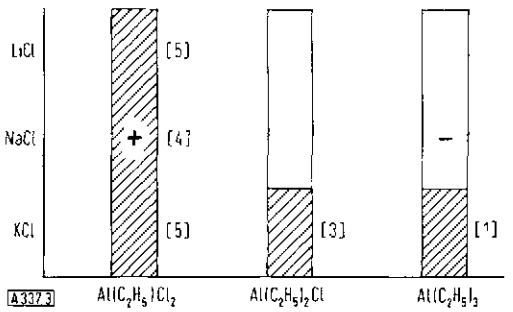

Fig. 3. Complexes of alkali metal chlorides with triethylaluminum and ethylaluminum chlorides.

slightly stable and dissociates into its components on heating *in vacuo* at 80–100 °C [1]. $K[AlEt_2Cl_2]$ is more stable and decomposes only above 150 °C, to a small extent into KCl and $AlEt_2Cl$ but mainly by disproportionation according to Equation (5) [3–5].

(5) $2\,K[AlEt_2Cl_2] \rightarrow KCl + KAlEtCl_3 + AlEt_3$

Since solutions and melts of alkali metal alkylaluminates are not completely dissociated into the ions (as indicated by their rather low electrical conductivity), complex formation is assisted by the interaction between the alkali metal ion and the anion, possibly with formation of electron-deficient bonds similar to those in associated alkylaluminum [6].

(6) $M^+ + [AlEt_4]^- \rightleftharpoons$ 

The change in free energy for the formation of $Na[AlEt_3F]$ and $K[AlEt_3F]$ can be calculated from the difference in lattice energies of NaF and KF [1] using the simplifying assumption that the melts of both compounds contain only ions and no undissociated molecules.

$1/2\,[AlEt_3]_2 \rightleftharpoons AlEt_3 + \Delta F_1$

$Na(K)F \rightarrow Na^+(K^+) + F^- + 218\ (195)$ kcal/mole

$F^- + AlEt_3 \rightarrow [AlEt_3F]^- + \Delta F_2$

(7) $NaF + 1/2\,(AlEt_3)_2 \rightarrow Na^+ + [AlEt_3F]^- + \Delta F_1 + \Delta F_2 + 218$ kcal/mole

(8) $KF + 1/2\,(AlEt_3)_2 \rightarrow K^+ + [AlEt_3F]^- + \Delta F_1 + \Delta F_2 + 195$ kcal/mole

By subtraction of Equation (8) from Equation (7), Equation (9) is obtained together with the difference in the energies of complex formation.

(9) $NaF + K[AlEt_3F] \rightleftharpoons KF + Na[AlEt_3F] + 23$ kcal/mole

This difference can be estimated independently by combination of thermodynamic values to give 8–10 kcal/

mole [7] (cf. p. 112). In practice, the difference is thus substantially lower than 23 kcal owing to different interactions between the cation and anion in the two complexes; the energy of interaction for the sodium compound must be about 15 kcal greater than that for the potassium compound. This effect, which opposes electrolytic dissociation, also accounts for the fact that the specific conductivity of a $Na[AlEt_3F]$ melt is less by a factor of ten than that of a $K[AlEt_3F]$ melt.

### 3. 1:2 Complexes with Trialkylaluminum

The complexes $M[AlR_3X]$ of aluminum trialkyls with alkali metal halides and hydrides can often add on a further mole of trialkylaluminum to form compounds of the type $M[Al_2R_6X]$, where X = H, F, Cl, Br, or I (Fig. 4) [1]. Aluminum alkyls higher than tri-n-butylaluminum do not form stable 1:2 complexes with NaF. However, definite 1:2 complexes are obtained from KF, RbF, or CsF and aluminum trialkyls up to tri-n-octylaluminum.

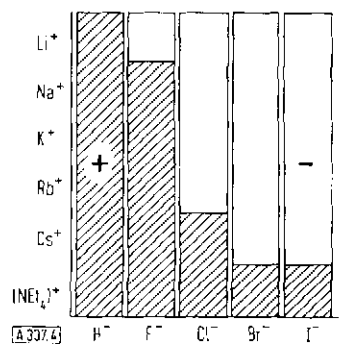

Fig. 4. 1:2 Complexes of alkali metal hydrides and halides with triethylaluminum [1].

Alkali metal cyanides [1] and azides [8] also form complexes with triethylaluminum, but here the 1:1 complexes do not appear to be stable. Interaction of equimolar quantities of $NaN_3$ with $AlEt_3$ yields a product having the approximate composition $NaN_3 \cdot 1.6AlEt_3$, together with undissolved $NaN_3$. The complex phase can be split into its components at 100 °C *in vacuo*. In the reaction of NaCN with $AlEt_3$ (molar ratio 1:1), a lot of NaCN also remains undissolved, but the supernatant liquid has approximately the composition of the 1:2 compound. In both cases, the 1:2 complexes seem to be more stable.

The structure proposed by *Ziegler* for the 1:2 complexes [9]

$$K^+[Et_3Al{:}\ddot{\underset{\cdot\cdot}{F}}{:}AlEt_3]$$

has meanwhile been confirmed by *Natta* [10] using X-ray structure analysis. According to this analysis, the coordination is tetrahedral about the aluminum with normal Al–C and C–C distances. The Al–F–Al bond is linear, and the interatomic distances correspond to those in $Na_3AlF_6$.

[7] *H. Lehmkuhl*, unpublished work.

[8] *E. Bonitz*, unpublished work; additional quantitative investigations from the author.

[9] *K. Ziegler*, International Conference on Coordination Chemistry, London, April 6th–11th, 1959.

[10] *G. Natta, G. Allegra, G. Perego* and *A. Zambelli*, J. Amer. chem. Soc. *83*, 5033 (1961).

There are no 1:2 complexes of alkali metal alkyls or alkoxides with trialkylaluminum; at 130 °C, molten sodium tetraethylaluminate dissolves only 0.28 mole of $AlEt_3$ per mole of complex. The partition coefficient of $AlEt_3$ between $NaAlEt_4$ and a high boiling, aliphatic hydrocarbon which is immiscible with the complex (*e.g.* liquid paraffin) is not constant but dependent on the concentration of $AlEt_3$ in $Na[AlEt_4]$ [7]. The system alkali metal fluoride (or hydride)/triethylaluminum/diethylaluminum hydride includes complexes with up to four moles of aluminum compound per mole of alkali metal salt [11].

### 4. Ethylaluminum Alkoxide Complexes

Diethylaluminum fluoride forms complexes more readily than triethylaluminum. Alkali metal alkoxides also have a greater tendency towards complex formation than alkali metal halides have. For example, lithium ethoxide reacts with triethylaluminum to give $Li[AlEt_3OEt]$, but lithium fluoride does not react [1]. It was to be expected that a sodium alkoxide would form a very stable complex with diethylaluminum fluoride – more stable than the known compounds $Na[AlEt_3F]$, $Na[AlEt_2F_2]$, or $Na[AlEt_3OEt]$. In fact, however, diethylaluminum alkoxide and sodium fluoride were obtained [12].

$$(10)\quad NaOR + AlEt_2F \rightleftharpoons NaF + AlEt_2OR$$

According to the postulated exchange equilibrium (3), $[AlEt_2]^+$ selects the more strongly basic alkoxide from the available anions $OR^-$ and $F^-$.

$$(11)\quad NaOR + AlEt_2F \rightleftharpoons [AlEt_2]^+ + Na^+ + F^- + OR^- \rightleftharpoons NaF + AlEt_2OR$$

In this manner, the electron density at the aluminum is increased and the acidic character of the aluminum compound is correspondingly weakened, so that the formation of a complex with sodium fluoride is no longer possible. The lattice energy of the sodium fluoride and the association energy of the $AlEt_2OR$ are greater than the gain in energy on complex formation. NaF does not react with diethylaluminum alkoxides, but KF and CsF do react since their lattice energies (NaF: 218, KF: 195, CsF: 185 kcal/mole) are smaller.

$$(12)\quad NaF + AlEt_2OR \not\longrightarrow$$

$$(13)\quad KF + AlEt_2OEt \rightarrow K[AlEt_2(OEt)F] \quad (m.p.\ 96–98\ ^\circ C)$$

$$(14)\quad CsF + AlEt_2OEt \rightarrow Cs[AlEt_2(OEt)F] \quad (m.p.\ \approx 40\ ^\circ C)\ [7]$$

The much decreased acidic character of diethylaluminum alkoxides is also shown in their reactions with sodium hydride, which is more readily complexed than sodium fluoride.

When diethylaluminum n-hexyloxide was heated with the equivalent amount of sodium hydride at 160–180 °C for 24 hours, 10–20 % (with the 2-ethylhexyloxide only about 2 %) of the NaH reacted according to Equation (15).

$$(15)\quad NaH + AlEt_2OR \rightarrow Na[AlEt_2(OR)H]$$

[11] *K. Ziegler, H. Lehmkuhl*, and *E. Lindner*, Chem. Ber. *92*, 2320, 2322 (1959).

[12] *R. Schäfer*, Ph.D. Thesis, Technische Hochschule Aachen, 1961.

Attempts to combine sodium alkoxide with diethylaluminum hydride resulted in conversion of 70–90 % of the sodium introduced into sodium hydride by the exchange equilibrium (3) [7].

(16) $NaOR + AlEt_2H \rightarrow Na[AlEt_2(OR)H] \rightleftharpoons 2\,NaH + 2\,AlEt_2OR$

The reaction of sodium diethyldihydroaluminate with sodium diethyldialkoxyaluminates, which should have resulted in the formation of $Na[AlEt_2(OR)H]$, yielded mixtures consisting mainly of sodium hydride and diethylaluminum alkoxide [Equation (17)] [7].

(17) $Na[AlEt_2H_2] + Na[AlEt_2(OR)_2] \rightarrow 2\,Na[AlEt_2(OR)H] \rightleftharpoons 2\,NaH + 2\,AlEt_2OR$

The lack of stability of $Na[AlEt_2(OR)H]$ was unexpected, since sodium hydride complexes of $AlR(OR)H$ and of triethoxyaluminum are known [14, 15]. According to *Schmitz-DuMont*, sodium hydride combines with α-$Al(OEt)_3$ only in the presence of ethers, but afterwards the ether-free compounds can be isolated. Sodium hydride also combines readily with diethylaluminum alkoxides in the presence of tetrahydrofuran (THF) [7]. During attempts to distil off the tetrahydrofuran, the stabilized tetrahydrofuranate complexes decompose again into solid sodium hydride and diethylaluminum alkoxide [Equation (18)].

(18) $NaH + AlEt_2OR + THF \longrightarrow Na[AlEt_2(OR)H] \cdot THF \xrightarrow{-THF} NaH + AlEt_2OR$

Suspensions of sodium hydride in diethylaluminum alkoxide in the presence of ethylene behave like stable complexes: sodium triethylalkoxyaluminate is obtained at about 140 °C with ethylene at several atmospheres pressure [13].

(19) $NaH + AlEt_2OR + C_2H_4 \rightarrow Na[AlEt_3OR]$

$Na[AlEt_3H]$ adds on ethylene under similar reaction conditions with comparable reaction rates [16].

On passing from diethylaluminum alkoxides to monoethylaluminum dialkoxides, $AlEt(OR)_2$, the tendency towards complex formation increases. $AlEt(OEt)_2$ reacts readily with NaH or KF (Fig. 5) to give $Na[AlEt(OEt)_2H]$, m.p. 160–162 °C, or $K[AlEt(OEt)_2F]$, m.p. 184 °C [7].

During the reaction of $K[AlEt_2(OEt)F]$ with $AlEt(OEt)_2$, the stronger complexing group displaces the weaker one [Equation (20)].

(20) $K[AlEt_2(OEt)F] + AlEt(OEt)_2 \rightarrow K[AlEt(OEt)_2F] + AlEt_2OEt$

Within the series $AlEt_3$, $AlEt_2OEt$, $AlEt(OEt)_2$, the minimum capacity for complex formation is observed at diethylaluminum ethoxide. A plausible explanation for this has not yet been put forward.

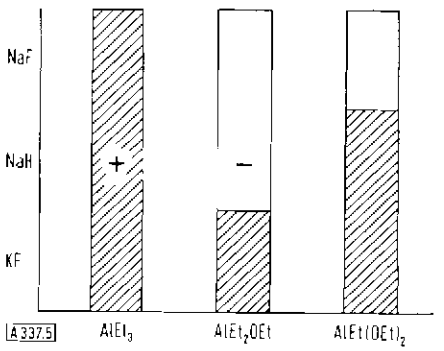

Fig. 5. Complexes of alkali metal hydrides and halides with triethylaluminum and ethylaluminum ethoxides.

## 5. Displacement of Weakly Complexed Organoaluminum Ligands

The displacement mentioned above of a complexed aluminum ligand by a more strongly complexing group (Equation 20) can be applied in general to organoaluminum compounds, *e.g.* as in Reaction (21), in which the stronger acid triethylaluminum displaces the weaker acid diethylaluminum alkoxide.

(21) $M[AlEt_3OR] + AlEt_3 \rightarrow M[AlEt_4] + AlEt_2OR$ (M = K or Na; [17, 18])

This reaction has been realized with all the alkoxides investigated, *viz.* ethoxide, n-butoxide, t-butoxide, n-hexyloxide, n-octyloxide, 2-ethylhexyloxide, and n-decyloxide; the reaction proceeded quantitatively in every case. The acidic properties of diethylaluminum phenoxide, $AlEt_2(OPh)$, and of diethylaluminum *N*-methylanilide, $AlEt_2N(CH_3)Ph$, are more pronounced than those of diethylaluminum alkoxides. As electron acceptors, both compounds resemble triethylaluminum.

Sodium tetraethylaluminate and sodium triethylphenoxyaluminate are sparingly soluble in cold benzene. On adding equivalent amounts of diethylaluminum phenoxide to the first and triethylaluminum to the second of these complexes, a clear solution in benzene results at room temperature, indicating the formation of a 1:2 complex of sodium phenoxide with two moles of triethylaluminum [12]:

(22) $Na[AlEt_4] + AlEt_2(OPh) \rightarrow Na[Al_2Et_6(OPh)]$

(23) $Na[AlEt_3(OPh)] + AlEt_3 \rightarrow Na[Al_2Et_6(OPh)]$

After removal of the solvent, one equivalent of triethylaluminum can be distilled off at 150 °C/$10^{-3}$ mm. The residue is sodium triethylphenoxyaluminate. This means that, with the phenoxy compound, Reaction (21) is reversed compared to that with diethylaluminum alkoxides. Probably an equilibrium is set up [Equation (24)] which can be shifted to the right by distilling off the triethylaluminum, which is more volatile than $AlEt_2(OPh)$.

(24) $Na[AlEt_4] + AlEt_2(OPh) \rightleftharpoons Na[AlEt_3(OPh)] + AlEt_3$

[13] Belg. Pat. 575595 (August 11th, 1959), inventors: *K. Ziegler* and *H. Lehmkuhl*; in addition unpublished work by *H. Dislich* and *H. Lehmkuhl*.

[14] German Published Patent Application 1122952 (Febr. 1st, 1962), inventors: *G. Hamprecht* and *M. Schwarzmann*.

[15] *O. Schmitz-DuMont* and *V. Habernickel*, Chem. Ber. *90*, 1054 (1957).

[16] German Pat. 917006 (June 4th, 1954), inventors: *K. Ziegler* and *H. G. Gellert*.

[17] *W. Eisenbach*, Ph. D. Thesis, Technische Hochschule Aachen 1961.

[18] Belg. Pat. 575641 (August 12th, 1959), inventors: *K. Ziegler* and *H. Lehmkuhl*.

Here the difference between diethylaluminum phenoxide and alkoxides is especially apparent. With the higher alkoxy compounds – *e.g.* $AlEt_2(OC_{10}H_{21})$, which is very difficult to volatilize – triethylaluminum cannot be distilled off.

An indication of the probable position of the equilibrium can be obtained when the 1:2 complex $Na[Al_2Et_6(OPh)]$ is washed for some time with hot hexane. After cooling, the residue consists of three components, *viz.* $Na[AlEt_4]$, $Na[AlEt_3(OPh)]$, and the unaltered 1:2 complex, in the molar ratio 1.2:1:1; thus, during the extraction with hexane, cleavage of the 1:2 complex occurs to almost equal extents according to Equations (25) and (26).

(25) $Na[Al_2Et_6(OPh)] \rightarrow Na[AlEt_4] + AlEt_2(OPh)$

(26) $Na[Al_2Et_6(OPh)] \rightarrow Na[AlEt_3(OPh)] + AlEt_3$

As these investigations show, the acidic character of diethylaluminum phenoxide is only slightly different from that of triethylaluminum (probably a little less marked). By complexing diethylaluminum phenoxide with NaEt in the presence of triethylaluminum, an exchange equilibrium reaction [Equation (27)] via the labile 1:2 complex is set up.

(27) $Na[AlEt_3(OPh)] + AlEt_3 \rightleftharpoons Na[Al_2Et_6(OPh)] \rightleftharpoons Na[AlEt_4] + AlEt_2(OPh)$

The 1.2:1 molar ratio favoring the tetraethyl complexes during extraction with hexane makes triethylaluminum appear to be a slightly stronger complex-forming acid than diethylaluminum phenoxide. Thus, for instance, diethylaluminum phenoxide dissolves both sodium fluoride and potassium fluoride to form complexes, but it does not react with potassium chloride [7]. Diethylaluminum *N*-methylanilide behaves in a similar manner to diethylaluminum phenoxide. All the triethylaluminum can be distilled off at 150 °C/$10^{-3}$ mm from a reaction mixture of triethylaluminum and $Na[AlEt_3N(CH_3)Ph]$ [7].

These results are in accordance with those considered earlier. As a consequence of the possibility of mesomerism in phenoxide and anilide ions, it was to be expected that the donor properties of both ions would be only weak. Thus, capture of a phenoxide (anilide) anion by the hypothetical $[AlEt_2]^{\oplus}$ cation ought to result in a stronger Lewis acid $AlEt_2Y$ than that obtained by capture of an alkoxide anion, which causes a greater electron density at the aluminum and hence weakens the acidic character of the $AlEt_2Y$. Aluminum compounds can be arranged in the order of decreasing tendency towards complex formation as follows:

(27a) $AlEt(Hal)_2 > AlEt_2(Hal) > AlEt_3 > AlEt_2(OPh) \approx AlEt_2N(CH_3)Ph > AlEt(OEt)_2 > AlEt_2(OR)$

## 6. Displacement of Complexed Bases

It is possible to replace a weaker electron donor $X^-$ in an organoaluminum complex by a stronger anion $Y^-$ by a process analogous to the displacement of a complexed Lewis acid by a stronger one.

(28) $[R_3Al \rightarrow X]^- + Y^- \rightleftharpoons [R_3Al \leftarrow Y]^- + X^-$

Examples are the cleavages of triethylaluminum etherates by sodium fluoride or potassium fluoride and of the aminates by potassium fluoride [1], the reaction of these aluminum compounds with sodium to split off the ether or the amine, and the displacement of sodium fluoride from complexes by sodium hydride [Equation (29)][19].

(29) $NaH + Na[AlEt_3F] \rightarrow NaF + Na[AlEt_3H]$

As a result of these and further investigations, a basicity series of some of the anions which function as Lewis bases can be drawn up; however, this series only applies to the behavior of the Lewis bases with organoaluminum compounds and not to the affinities of the members for protons.

(29a) $I^- < Br^- < Cl^- < F^- < H^- \leqslant Et^- \leqslant (OPh)^- < (OC_{2n+1})^-$

Moreover, the same Lewis base $Y^-$, which is an efficient donor and exhibits a strong tendency towards complex formation with organoaluminum compounds, may inhibit or even completely prevent complex formation if it occurs as a ligand of a dialkylaluminum compound whose acidic character is weakened. A base will displace from a complex any member standing on its left in the Series (29a). This applies, for example, in Reaction (30), in which the strongest base, a sodium alkoxide, displaces the more weakly complex-bound sodium hydride [7].

(30) $NaOC_{10}H_{21} + Na[AlEt_3H] \rightarrow NaH + Na[AlEt_3(OC_{10}H_{21})]$

Since sodium hydride and ethylsodium are almost equal in their complexing ability, sodium alkoxide would similarly be expected to displace ethylsodium from sodium tetraethylaluminate.

(31) $NaOR + Na[AlEt_4] \rightarrow NaEt + Na[AlEt_3(OR)]$

The ethylsodium liberated as in Equation (31) is not very stable thermally – it decomposes above 60 °C to give mainly sodium hydride and ethylene [20] – but it reacts with warm benzene to form phenylsodium [21]. Thus, the reaction of sodium alkoxide with sodium tetraethylaluminate in benzene should result in the production of a phenylmetal compound. First investigations indicate that, in accordance with Series (29a), the displacement of ethylsodium by sodium alkoxide does not proceed so readily as that of sodium hydride from sodium triethylaluminum hydride.

A suspension of sodium tetraethylaluminate and sodium 2-ethylhexyloxide in benzene does not yield ethylsodium spontaneously, as would be expected by analogy to the reaction with the production of sodium hydride, but ethane is only liberated at 80–90 °C [Equation (32)]. This ethane can be explained only in terms of the primary formation of ethylsodium according to Equation (31). The net reaction is shown in Equation (32).

(32) $Na[AlEt_4] + NaOR + C_6H_6 \rightarrow Na[AlEt_3(OR)] + NaPh + C_2H_6$

The reaction is not limited to the displacement of one ethyl group. All the available ethyl groups in the molecule can be replaced by phenyl groups, with a maximum yield of 75 % $Na[AlPh_4]$. Moreover, not only sodium

[19] Belg. Pat. 593386 (Jan. 25th, 1961), inventors: *K. Ziegler* and *H. Lehmkuhl*.

[20] *W. H. Carothers* and *D. D. Coffman*, J. Amer. chem. Soc. *51*, 588 (1929).

[21] *P. Schorigin*, Ber. dtsch. chem. Ges. *41*, 2723 (1908); *43*, 1938 (1910).

alkoxide, but also the phenylsodium formed in the reaction can displace ethylsodium from its complexes with alkylaluminum. This displacement reaction – catalysed by sodium alkoxide or phenylsodium – is a route [Equation (33)] leading to arylaluminum compounds via benzene and sodium tetraethylaluminate, which is readily obtainable by direct synthesis [12].

(33) $Na[AlEt_4] + 4\,C_6H_6 \xrightarrow{NaOR\ (NaPh)} Na[AlPh_4] + 4\,C_2H_6$

## 7. Cationic Exchange Reactions

Exchange reactions of cations by treatment of alkali metal alkylaluminum complexes with halides of other alkali metals were studied, mainly with the system $NaAlEt_4/KAlEt_4$.

Starting from sodium tetraethylaluminate and potassium chloride, a mixture of 80–90 mole-% $KAlEt_4$ and 20–10 mole-% $NaAlEt_4$ is obtained. In contrast, cation exchanges proceed practically to completion with pseudo-alkali-metal halides [7].

(34) $[NEt_4]I + Na[AlEt_4] \rightarrow [NEt_4][AlEt_4] + NaI$

(35) $[SbEt_4]I + Na[AlEt_4] \rightarrow [SbEt_4][AlEt_4] + NaI$

In our experience, the reaction of metallic potassium with organoaluminum compounds is a poor method for the preparation of potassium tetraethylaluminate. However, exchange reactions of sodium alkylaluminate complexes with potassium amalgam proceed readily according to Equation (36) [22].

(36) $Na[AlEt_4] + K(Hg)_x \rightarrow Na(Hg)_x + K[AlEt_4]$

The reaction proceeds almost quantitatively, although 0.6 % potassium amalgam at 90 °C has an energy of formation about 3.6 kcal higher than that of an equivalent sodium amalgam (0.35 %). In the exchange reaction with amalgam, the effect of the small ionization energy of potassium compared with that of sodium is predominant. The free energy of the exchange reaction [Equation (36)] has been determined ($\Delta F_{90\,°C} = -6.76$ kcal/mole) from the e.m.f. of appropriate galvanic cells [23]. From these data, the equilibrium constant

$$K_c = \frac{Na/Hg \cdot KAlEt_4}{K/Hg \cdot NaAlEt_4}$$

has been calculated to be $1.25 \times 10^4$. The experimental value found by mixing together equimolar quantities of sodium amalgam and potassium tetraethylaluminate is $K_c = 1.7 \times 10^4$ [17].

The transformation of $Na[Al_2Et_6F]$ into the potassium compound proceeds as readily as that of sodium tetraethylaluminate. The equilibrium constants of the reactions of $Na[AlEt_3F]$ or $Na[AlEt_3(OR)]$ with potassium amalgam are not as favorable towards the potassium complexes. The same is true for the addition of ethers [$(C_4H_9)_2O$ or THF] in the molar ratio 1:1 to $Na[AlEt_4]$; the equilibrium constants fall with increasing ether content to about $10^2$ (molar ratio 1:4). The effect is less marked for additions of triethylamine [7].

By calculating the free energies $\Delta F$ for the exchange from the equilibrium constants, eliminating the free energies for amalgam formation, and then substituting the ionization energies of the alkali metals, the free energy $\Delta F_2$ for Reaction (37) is obtained; it has positive values of 12–15 kcal/mole.

(37) $K^+_{gas} + Na[AlEt_3X] \rightleftharpoons Na^+_{gas} + K[AlEt_3X]$

Since Equation (37) can be expressed as the difference of Equations (37a) and (37b), which represent the interaction between the cation and the complex anion, the $\Delta F_2$ values signify that the equilibrium energy of reaction between the dissociated and undissociated forms is about 12–15 kcal greater for the sodium complexes.

(37a) $K^+_{gas} + [AlEt_3X]^- \rightleftharpoons K[AlEt_3X]$

(37b) $Na^+_{gas} + [AlEt_3X]^- \rightleftharpoons Na[AlEt_3X]$

## 8. Etherates of Alkali Metal Tetra-alkylaluminates

Although complexes of alkali metal halides with triethylaluminum are often split by ethers (*e.g.* $K[AlEt_3Cl]$ or $Rb[AlEt_3Br]$) or by triethylamine (*e.g.* $Na[AlEt_3F]$) [1], the alkali metal tetra-alkylaluminates dissolve readily in these solvents. When attempts were made to isolate the ether-free compounds from these solutions, it was found that the solvent was firmly bound in a molar ratio of 1:1. It was also observed that 1:1 molar mixtures of potassium tetraethylaluminate and diethyl ether are insoluble in pentane or hexane and two liquid phases result. The ether is not extracted by the hydrocarbon [23a].

This capacity for addition of electron donors onto alkali metal tetraethylaluminates is unexpected, since the four coordination sites of the aluminum in the complex anion are occupied, and since coordination numbers greater than four for organoaluminum compounds have not been observed hitherto.

Measurements of the transport number of the cation of potassium tetraethylaluminate in benzene solutions to which increasing amounts of dibutyl ether were added indicated that there is probably no coordinate linkage between the ether and the aluminum, but rather between the ether and the alkali metal cation, which can

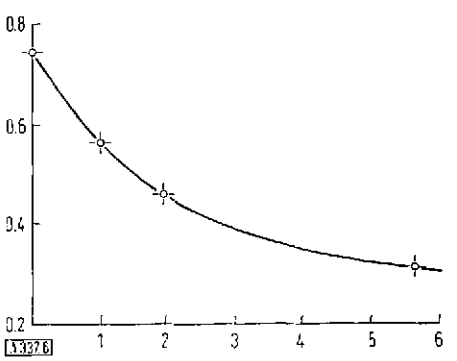

Fig. 6. Variation of the transport number $n_K$ of the cation in a 1 M solution of $K[Al(C_2H_5)_4]$ in benzene with the dibutyl ether content. Ordinate: Transport number $n_K$. Abscissa: Moles of dibutyl ether/mole of $K[Al(C_2H_5)_4]$

[22] *K. Ziegler* et al., Chemie-Ing.-Techn. *35*, 325, 328 (1963).

[23] *H. Lehmkuhl* and *W. Grimme*, Chemie-Ing.-Techn. *35*, 332 (1963).

[23a] *W. Eisenbach*, unpublished work.

also act as an electron acceptor. Whereas in a ca. 1 M solution of potassium tetraethylaluminate in benzene about 75 % of the electrical conductivity is due to the cation, the cation of $K[AlEt_4]\cdot 4Bu_2O$ in solution in benzene – which is much larger and therefore less mobile owing to solvation – transports only about 36 % of the current (Fig. 6) [7].

## 9. Alkaline Earth Tetra-alkylaluminates

In contrast to alkylmagnesium compounds, the organometallic compounds of calcium, strontium, and barium have only been investigated to a small extent. The diethyl metals are not known. Besides the preparation of a few compounds MRX [24], there is only one reference in the literature to crystalline products formed from alkaline earth metals with diethylzinc: their composition was given by *Gilman* as $Et_2M\cdot ZnEt_2$ [25]. *Ziegler* and *Holzkamp* [26] studied the reaction of dialkylmagnesium with trialkylaluminum or of ether-free Grignard compounds with trialkylaluminum and found two classes of complexes: $[RMg][AlR_4]$ and $MgR_2\cdot 2AlR_3$. In both classes, the bond between the trialkylaluminum and the dialkylmagnesium is weak. The compounds can be cleaved by distilling off the trialkylaluminum *in vacuo* at 100–115 °C, or by adding a powerful electron-donor, *e.g.* triethylamine, to the trialkylaluminum according to Equation (38) [27].

(38) $MgEt_2\cdot 2\,AlEt_3 + 2\,NEt_3 \rightarrow MgEt_2 + 2\,AlEt_3\cdot NEt_3$

On heating $[MeMg][AlMe_4]$ at 70–75 °C/$10^{-3}$ mm, the complex compound distills over. Some unsuccessful attempts were made to obtain calcium ethylaluminate compounds by treating calcium with triethylaluminum by analogy to the formation of sodium tetraethylaluminate [28, 29] from sodium and triethylaluminum. The discovery of the reaction of alkali metal alkoxides with triethylaluminum suggested that the synthesis of alkaline earth ethylaluminates using alkaline earth alkoxides may be possible. Various other methods of preparation of alkali metal tetra-alkylaluminates, *e.g.* the addition of alkali metal hydride onto triethylaluminum and subsequent reaction with an olefine according to Equation (39), had proved to be unsuitable for calcium compounds.

(39) $NaH + AlEt_3 \rightarrow Na[AlEt_3H] \xrightarrow{C_2H_4} Na[AlEt_4]$

Calcium hydride and calcium chloride and fluoride do not form complexes with triethylaluminum [7].

Like the alkali metal alkoxides, the alkoxides of calcium, strontium, and barium dissolve in warm triethylaluminum to form $M[AlEt_3(OR)]_2$ complexes. On treating the resultant viscous liquid compounds with further two moles of triethylaluminum per mole of complex, the triethylaluminum displaces the diethylaluminum alkoxide [30].

(40) $M[AlEt_3(OR)]_2 + 2\,AlEt_3 \rightarrow M[AlEt_4]_2 + 2\,AlEt_2(OR)$

After removal of the diethylaluminum alkoxide, which is no longer complexed, by distillation (a suitable lower alkoxide, *e.g.* $-OC_2H_5$, $-OC_3H_7$, $-O\text{-}n\text{-}C_4H_9$, will make the distillation easier) the analytically pure calcium and strontium compounds can be distilled off at reduced pressure ($10^{-3}$ mm).

$Ca[AlEt_4]_2$: m.p. 41 °C; b.p. 90–95 °C/$10^{-3}$ mm

$Sr[AlEt_4]_2$: m.p. 109 °C; b.p. 122–128 °C/$10^{-3}$ mm

$Ba[AlEt_4]_2$ decomposes on distillation; purification by recrystallization from hot benzene is preferable (m.p. 138 °C). All attempts to obtain pure, uncomplexed alkaline earth alkyls by thermal decomposition of the new complexes were unsuccessful, since together with triethylaluminum, ethylene was evolved, and alkaline earth hydrides were precipitated from the reaction mixture [7].

(41) $M[AlEt_4]_2 \xrightarrow[10\,mm]{130\,^\circ C} [MEt_2 + 2\,AlEt_3] \rightarrow MH_2 + 2\,C_2H_4 + 2\,AlEt_3$

Whether ethylene is split off and the unstable hydrocomplex $M[AlEt_3H]_2$ decomposes into $MH_2$ and $AlEt_3$ or whether an alkaline earth alkyl loses ethylene to leave the alkaline earth hydride cannot yet be established.

Calcium, strontium, and barium in contrast to magnesium [31] do not react perceptibly with diethylmercury to yield diethylmetals. However, the metals do react with a 1:2 mixture of diethylmercury and triethylaluminum [Equation (42)] to yield alkaline earth ethylaluminate complexes [7].

(42) $M + HgEt_2 + 2\,AlEt_3 \rightarrow M[AlEt_4]_2 + Hg$ [*]

Another route to alkaline earth alkylaluminate complexes involves the reaction of an alkaline earth chloride with sodium tetraethylaluminate.

(43) $MCl_2 + 2\,Na[AlEt_4] \rightleftharpoons M[AlEt_4]_2 + 2\,NaCl$

However, Reaction (43) is not quantitative; apparently an equilibrium is set up. In benzene, the forward reaction is about 70 % complete with calcium chloride, 30 % with strontium chloride, and 40 % with barium chloride. Nevertheless, this method is applicable to the preparation of the calcium and strontium compounds since separation is readily attained thanks to the good solubility of both complexes in cold benzene; unreacted sodium tetraethylaluminate is insoluble. Only in the case of barium is separation from the mixture difficult.

The distillability of the $M[AlEt_4]_2$ complexes of calcium and strontium and the volatility of the barium complex are unexpected, since these compounds are analogues of

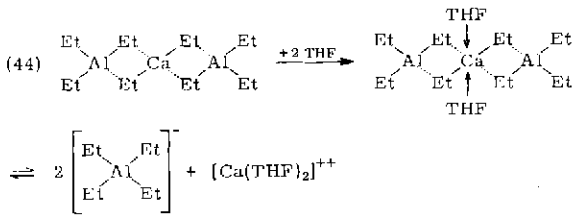
[29] *A. v. Grosse* and *J. M. Mavity*, J. org. Chemistry *5*, 111 (1940).

[30] *H. Lehmkuhl* and *W. Eisenbach*, Angew. Chem. *74*, 779 (1962); Angew. Chem. internat. Edit. *1*, 590 (1962).

[31] *Ph. Löhr*, Liebigs Ann. Chem. *261*, 48, 82 (1891).

[*] Calcium tetraethylborate $Ca[BEt_4]_2$ can be prepared similarly from a 1:2 mixture of diethylmercury and triethylboron with calcium [7].

sodium and potassium tetraethylaluminates and magnesium octaethyldialuminate $Mg[AlEt_4]_2$.



Sodium and potassium tetraethylaluminates are non-volatile salt-like compounds with high electrical conductivities (at 130 °C: $5.5\times10^{-2}$ and $13\times10^{-2}$ mho/cm). The magnesium compounds decomposed readily *in vacuo* to yield diethylmagnesium and triethylaluminum. Moreover, calcium octaethyldialuminate is soluble in aromatics and in polar solvents such as ethers, as well as in saturated hydrocarbons such as hexane or heptane (≈ 50 g/50 ml). Strontium octaethyldialuminate dissolves in hexane (≈ 0.8 g/50 ml); the barium compound is soluble on heating in aromatics but is insoluble in hexane. The salt-like character increases with atomic number as is clearly shown by comparing the specific conductivities.

$Ca[AlEt_4]_2$: $\varkappa < 10^{-7}$ mho/cm  $Sr[AlEt_4]_2$: $\varkappa = 3.7\times10^{-4}$ mho/cm
$Ba[AlEt_4]_2$: $\varkappa = 0.9\times10^{-2}$ mho/cm

The calcium and strontium compounds have little or no salt-like character; evidence for this is their volatility [**] and their solubility in non-polar solvents.

[**] The volatility of the Ca-Al complexes does not appear to be limited to these organometallic compounds. *Meerwein* [32] describes $Ca[Al(OEt)_4]_2$ as being distillable *in vacuo*.

Calcium octaethyldialuminate forms a stable crystalline addition compound $Ca[AlEt_4]_2\cdot2THF$ with tetrahydrofuran (m.p. 57–60 °C), the conductivity thereby increasing by more than a factor of 1000 [7]. After addition of the electron-donor THF, the electron density on the calcium is increased to such an extent – probably by solvation of the cation – that the electron-deficient bonds involved in the bridging ethyl groups between the calcium and the aluminum are broken and tetraethylaluminate ions are formed

# Recent Developments in the Chemistry of Pteridines

BY PROF. DR. W. PFLEIDERER

INSTITUT FÜR ORGANISCHE CHEMIE UND ORGANISCH-CHEMISCHE TECHNOLOGIE DER TECHNISCHEN HOCHSCHULE STUTTGART (GERMANY)

*The abundant experimental material available on the chemistry of the pteridines, as well as the reports given at the Third International Symposium on Pteridines have been reviewed and the most important results of the past ten years incorporated into the present article. Syntheses, reactions, and structural problems are reviewed and natural pteridines and their possible biochemical significance are discussed.*

Introduction

I. Syntheses
  1. pH-Dependent condensation of 4,5-diaminopyrimidines
  2. Syntheses involving nitrosopyrimidines
  3. Further syntheses via *o*-diaminopyrimidines
  4. Syntheses starting from pyrazine derivatives

II. Reactions
  1. Nucleophilic reactions
  2. Alkylations

III. Structural considerations
  1. Tautomerism
  2. Reversible hydration
  3. Results of physico-chemical studies

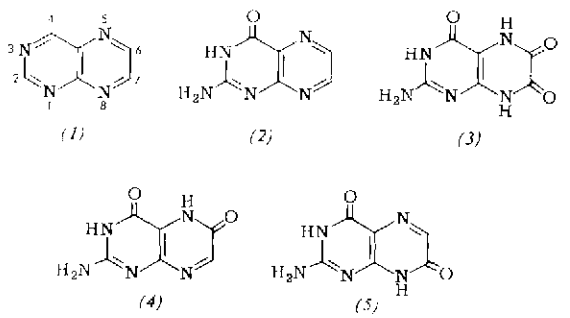
IV. Hydrogenated pteridines
  1. 5,6,7,8-Tetrahydro derivatives
  2. Direct synthesis of hydropteridines
  3. Reductions with boron hydrides
  4. Derivatives of 7,8-dihydropterin

V. Naturally occurring pteridines
  1. Erythropterin, pterorhodin, ekapterin, and lepidopterin
  2. Biopterin and ichthyopterin
  3. *Drosophila* pterins (sepia-, isosepia-, droso-, isodroso-, and neodrosopterin)
  4. Other natural and unnatural pteridines

VI. Biosynthesis of pteridines

VII. The biochemical role of unconjugated pteridines

## Introduction



Pteridine chemistry actually began with the studies on the pigments of butterfly wings carried out by *Hopkins* [1] at the end of the last century. Almost thirty years later, in 1924, *Wieland* urged on by *Schöpf*, his assistant and student at that time, began systematic studies in the endeavor to elucidate the chemical structure of butterfly pigments.

Although they soon succeeded in isolating and purifying the yellow pigment [2] from the wings of the brimstone

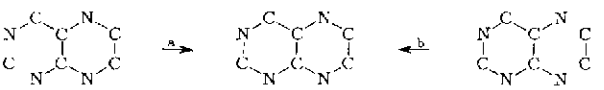
butterfly, and the colorless pigments [3] of the cabbage butterfly, they met with unexpected difficulties when they attempted to determine the structures of these two natural products, which were designated as xanthopterin *(4)* [2] and leucopterin *(3)* [3]. Not before 1940, 15 years later, was *Purrmann* [4] able to show that leucopterin [4], xanthopterin [5], and isoxanthopterin *(5)* [7] which was first described in1933 [6],were aminohydroxy derivatives of a bicyclic nitrogenous ring system, *viz.* of pyrimido[4,5-*b*]pyrazine, which *Wieland* [8] designated in 1941 as pteridine *(1)*.



*(1)* *(2)* *(3)* *(4)* *(5)*

We now know the basic structure of the pteridine nucleus and recognize the fact that insect pigments also include purine derivatives, phenoxazine derivatives, *viz.* the ommochromes [9], as well as brown to black pigments of the melanin type; it thus seems appropriate to revise the use of the word "pterins" as a collective term for butterfly wing pigments [2] or even for insect pigments in general [10]. The fortunate circumstance that all the natural pteridines designated by trivial names "....pterin" have a similarly substituted pyrimidine ring suggests the possibility of restricting the term "pterins" so as to include only derivatives of 2-amino-4-pteridone, *i.e.* of pterin *(2)*, in a special group.

A number of reviewers [11] have attempted to keep pace with the fast developments in the field of pteridine chemistry since 1940. The most recent reviews are those by *Albert* in 1952 [12] and 1954 [13]. Since then, much progress has been made from the chemical, biochemical, and biological points of view. This paper will therefore deal with the most important results obtained in recent years, as well as with some of the most recent reports [14].

Examination of the pyrimido[4,5-*b*]pyrazine structure of pteridines reveals two possible pathways for the synthesis of this ring system, namely, fusion of a pyrimidine ring onto a pyrazine derivative (Pathway a), or addition of a pyrazine ring onto a pyrimidine derivative (Pathway b). Since pyrimidines are relatively

easily accessible, the Isay reaction [15], *i.e.* condensation of a 4,5-diaminopyrimidine with a 1,2-dicarbonyl compound, continues to be of major importance [16–29].

Syntheses proceeding from 4,5-diaminopyrimidines and unsymmetrical 1,2-diketones, α-keto aldehydes, or α-keto acids or their esters yield mixtures of substituted pteridines which are isomeric in positions 6 and 7. Since separation of such mixtures involves losses of time and yield and often is extremely difficult, syntheses are sought which selectively produce a single isomer.

### 1. pH-Dependent Condensation of 4,5-Diaminopyrimidines

The principle of pH-dependent condensation, first recognized by *Purrmann* [7] and later applied generally [30], can well be explained in the case of 4,5-diaminouracil *(6)*, 2,4,5-triamino-6-oxodihydropyrimidine, and correspondingly substituted 4,5-diamino-6-oxodihydropyrimidines. Because of their different positions with respect to the 6-oxo group and to the nitrogen atoms in the ring, the amino groups present at carbon atoms 4 and 5 possess very different nucleophilic potentials [33]. In reactions with α-keto acids in neutral or

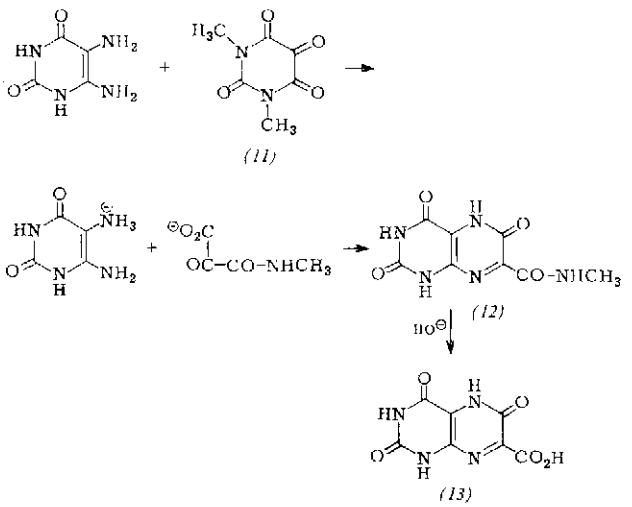
weakly acidic media [31–38] or in organic solvents [39], the primary condensation between the 5-amino and the keto groups produces 7-hydroxypteridines *(7)*, whereas in a strongly acidic medium, protonation of the more strongly basic 5-amino group leads to the opposite orientation of the substituents in the molecules, *i.e.* to the formation of 6-hydroxypteridines *(8)* [40–42]. Condensations with glyoxylic ester proceed particularly smoothly and uniformly if the 5-azomethinecarboxylic ester *(9)* is synthetized first and if then this Schiff base is cyclized under mild conditions in bicarbonate solution [33,35,43].



The easiest way to synthetize 2,4-disubstituted 6-hydroxy-7-methylpteridines [*(8)*, R = $CH_3$] is via 6-hydroxy-7-acetonylpteridines *(10)* which readily undergo acid hydrolysis in the presence of alkalis and which are obtained in pure form when 4,5-diaminopyrimidines are condensed with acetonyloxalic ester [42]. However, direct condensation with pyruvic acid always yields a mixture of isomers. Recent reports

indicate that 6-hydroxy-7-alkylpteridines can also be obtained from 2-trifluoromethyl-4-alkyl-5-oxazolones and 6-isopropoxy- or 6-oxodihydro-2,4,5-triaminopyrimidine [44].

7-Hydroxypteridine-6-carboxylic acids [*(7)*, R = COOH] can be synthetized in analogous manner using mesoxalic ester at a neutral pH [34,36,38,39,45] or alloxan in dilute aqueous alkali [46–48]. It is difficult to prepare the isomeric 6-hydroxypteridine-7-carboxylic acids [*(8)*, R = COOH] from the same starting materials, since changes in the pH merely shift the isomer ratio in the direction of the 6-hydroxy derivatives.

A novel synthetic possibility is presented by the reaction of 4,5-diaminopyrimidines with 1,3-dimethylalloxan *(11)* [49,50]. Dimethylalloxan is alkali-labile and is split by the heterocyclic base to yield the mono-N-

methylamide of mesoxalic acid which then forms a salt with the more strongly basic 5-amino group of the diamine, thereby assuming an orientation such that the formation of *N*-methylhydroxypteridine-7-carboxamide *(12)* is favored during the reaction leading to ring closure. The amides of type *(12)* can then be hydrolysed with alkali to form the acids *(13)*.

### 2. Syntheses Involving Nitrosopyrimidines

Pteridines can also be obtained via a method first developed by *Timmis* [51]. 4-Amino-5-nitrosopyrimidines such as *(14)* can be condensed not only with ketones [52–54,59] and aldehydes [54,59], but also with nitriles [55–61] and esters [59–61] that have an activated methylene group adjacent to the functional group.

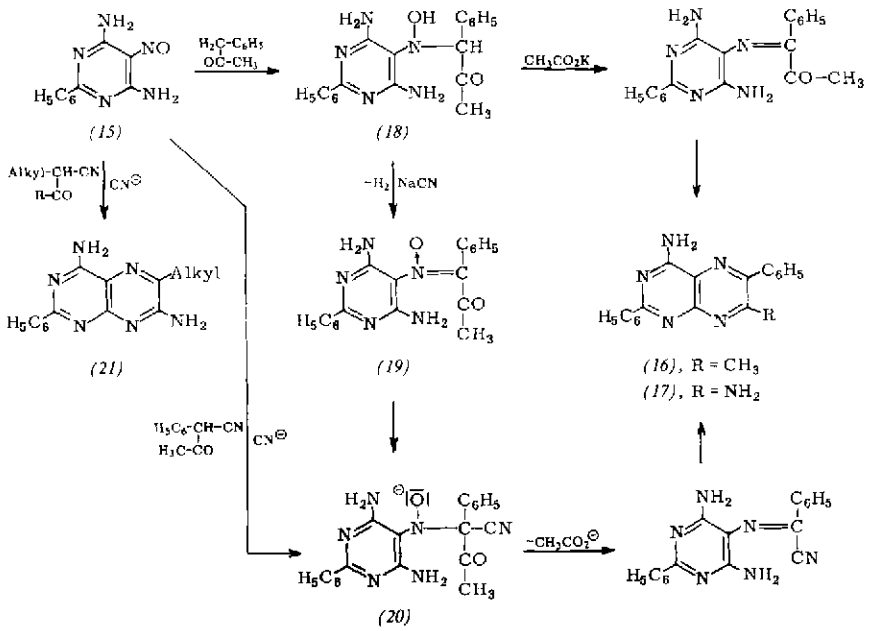
(a), $R^1 = CH_3$, $R^2 = C_6H_5$
(b), $R^1 = C_6H_5$, $R^2 = NH_2$

The recent work of *Pachter* has led to additional approaches to pteridine syntheses [59]. Reaction of 5-nitroso-4,6-diamino-2-phenylpyrimidine *(15)* with benzyl methyl ketone in the presence of potassium acetate gives 4-amino-7-methyl-2,6-diphenylpteridine *(16)*; however, if cyanide ions are present, 4,7-diamino-2,6-diphenylpteridine *(17)* is unexpectedly formed. Further examples of this reaction have shown that the cyanide ions, in analogy to earlier report [59], can displace the acyl groups in the ketone.

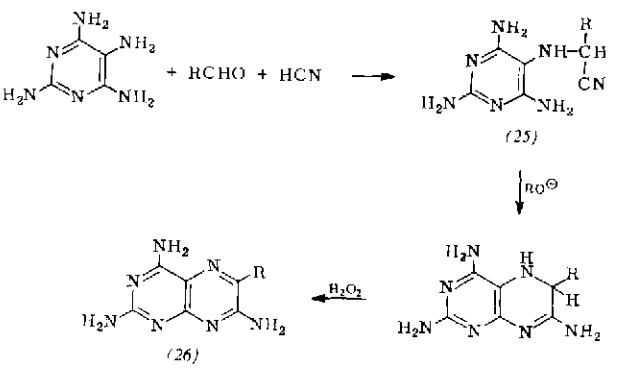
The preferential dehydrogenation of hydroxylamine derivatives of type *(18)* is not without parallel [62,63]. The occurrence of the intermediate *(20)* explains why compound *(17)* is so readily formed from *(15)* and α-phenyl-α-acetylacetonitrile in the presence of alkali. This reaction made it possible to prepare 6-alkyl-7-aminopteridines *(21)* from alkylacylacetonitriles, whereas insufficient activation prevented formation of this compound from 5-nitroso-4-aminopyrimidine and alkyl cyanides.



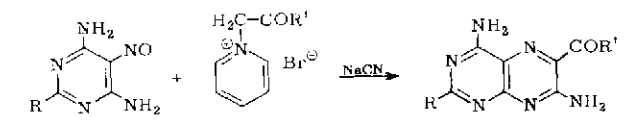
Both phenacylpyridinium and acetonylpyridinium salts are very suitable for the synthesis of 7-aminopteridyl ketones *(22)*, since in the presence of NaCN they behave like β-keto nitriles [64]. Pteridine-5-oxides *(24)* can be prepared in the same manner by reaction of the pyridinium salt *(23)* – resulting from α-cyanobenzyl benzenesulfonate and pyridine – with a 5-nitroso-4-aminopyrimidine.

(15) (23) (24)

### 3. Further Syntheses via *o*-Diaminopyrimidines



Another method of fusing the pyrazine ring onto a 4,5-diaminopyrimidine involves treatment of this *o*-diamine with aldehydes and HCN [59,65,66]. The first products are 4-amino-5-(α-cyanalkylamino)pyrimidines *(25)*.



(15) (18) (21) (19) (20)

(16), R = $CH_3$
(17), R = $NH_2$

These are then isolated, cyclized in alkali, and oxidized to form 7-amino-6-alkylpteridines *(26)*.

(25) (26)

R = H, $C_6H_5$, $SCH_3$ ; R' = $CH_3$, $C_6H_5$ (22)

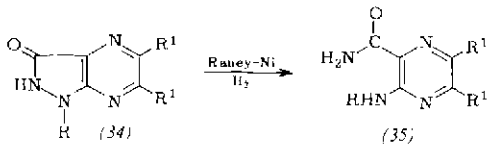
[67] *P. Schmidt* [14].

A novel type of ring closure is the reaction of 5-dichloroacetylamino-4-aminopyrimidine *(27)* with sulfur/morpholine under the conditions of a Kindler reaction [67]. The resulting 6-hydroxy-7-aminopteridines *(30)* are formed either via the thio-oxamide derivatives *(28)*

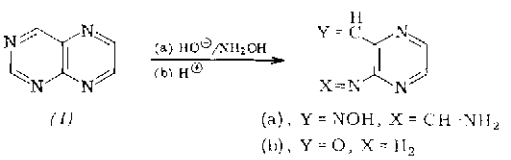


*(27)* *(28)* *(29)* *(30)*

– which cannot be isolated – or via the 7,8-dihydropteridines *(29)* which can be obtained with morpholine only.

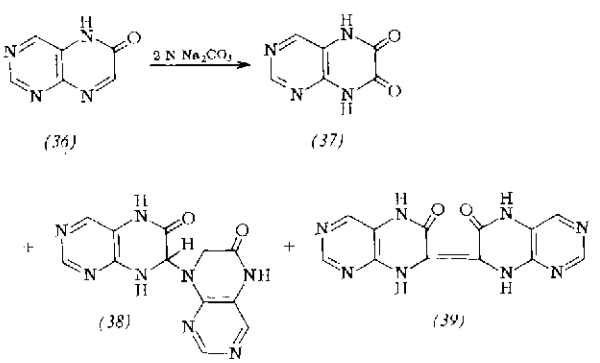
### 4. Syntheses Starting from Pyrazine Derivatives

Pteridine syntheses based on pyrazine derivatives have been used only rarely because the latter are not easily accessible. The reaction of 2-chloropyrazine-3-carboxylic esters with guanidine salts [68] can be used for the preparation of pterins. Cyclization of 2-aminopyrazine-3-hydroxamic acid or 2-aminopyrazine-3-carbohydrazide gives 3-hydroxy- [69] or 3-amino-4-oxodihydropteridine, respectively [70, 71].



Aminolytic or hydrolytic ring cleavage of suitable pteridine derivatives *(31)* leads to 2-aminopyrazine-3-carboxamides *(32)*, which can be cyclized to result in new pteridines *(33)*. This procedure is quite general and can be varied in many ways [72, 73]. A quite peculiar synthesis [74] of 2-aminopyrazine-3-carboxamides *(35)* is based on reductive cleavage of the ring of 3-hydroxypyrazolo[*b*]pyrazines *(34)*, which are obtained from 4,5-diaminopyrazolones and 1,2-dicarbonyl compounds.

*(34)* *(35)*



## II. Reactions

The reactions of the pteridines are determined by nature and number of their substituents. The basic nucleus, *viz.* pteridine *(1)*, is relatively unstable. The instability is caused by the accumulation of four nitrogen atoms in this ring system, by their special mutual spatial relationship, and by their interaction with the ten π-electrons, all resulting in a considerable reduction of the heteroaromatic character of this compound. Pteridine *(1)* can be degraded with ring opening by both acids and alkalis [75]; this tendency towards hydrolytic cleavage

*(1)* (a), Y = NOH, X = CH·NH$_2$ (b), Y = O, X = H$_2$

of the pyrimidine ring is confirmed by calculations based on its electron density distribution [76] which show that this diazine system has the greater polarity of the two rings. As the number of strong electron donor substituents (*e.g.* OH, $NH_2$, SH, $N(CH_3)_2$) increases, this electron deficiency becomes partially compensated, and the pteridine ring begins to assume the stability common for the natural pteridines [77]. The intermediate position of the monosubstituted pteridines is not just a matter of form, but also causes unexpected reactions, which

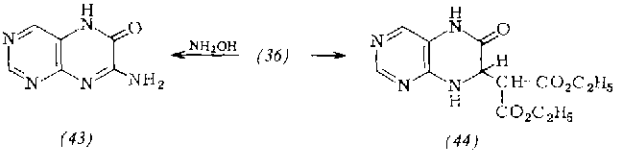
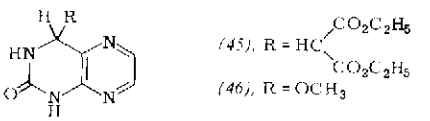
can be demonstrated, for example, with the monohydroxy derivatives. Thus, treatment of 6-hydroxypteridine *(36)* with boiling sodium carbonate leads to the formation of the three substances *(37)*, *(38)*, and *(39)* [78]. Treatment of the 2-hydroxy isomer *(40)* with boiling dilute alkali in an atmosphere of nitrogen leads to *(41)* [79]; treatment in air leads to lumazine *(42)*.



*(40)* *(41)* *(42)*

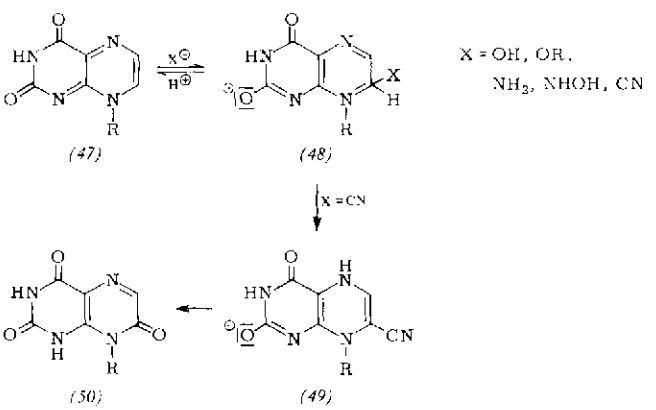
## 1. Nucleophilic Reactions

So far electrophilic substitutions at the ring carbon atoms, such as nitration, nitrosation, sulfonation, or halogenation, have not been reported in the pteridine series.



However, the nucleophilic displacement of chlorine atoms or of mercapto, alkylthio, amino, and substituted amino groups is one of the most common reactions of the pteridines. Chloropteridines, which can be prepared from hydroxypterines by treatment with either $PCl_5$/$POCl_3$ or $PCl_5$/$PCl_3$ [16,31,35,80–84], are very reactive because the chlorine atom is adjacent to the nitrogen atoms of the ring; hence, they react readily with ammonia [31,81,82], amines [16,31,80,84,85], alkoxides [16,31,35,82–84], and thiols [84]. The displacement of mercapto [80,86] and alkylthio groups [16,86] by amines is, in most cases, likely to involve a normal $S_N2$ reaction at the intact pteridine nucleus, even though there are reports suggesting the occurrence of intermediary cleavage of the ring by a process similar to that thought to occur in the conversion of amino into substituted amino groups [85].

Nucleophilic additions onto pteridines have also assumed significance, particularly because the pronouncedly polar character of the $\Delta^7$-double bond of 6-hydroxypteridines would seem to predestinate them for this reaction. Thus, 6-hydroxypteridine *(36)* not only adds on water, ammonia, hydroxylamine [to form *(43)*], a second molecule of 6-hydroxypteridine, or a molecule of 7,8-dihydro-6-hydroxypteridine [78], but in an alkaline medium it also adds on CH-acidic compounds [87] such as malonic ester [to form *(44)*], cyanoacetic ester, and acetone.

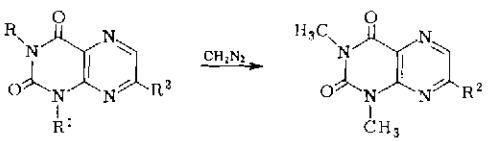


*(43)* *(36)* *(44)*

Under carefully controlled conditions, 2-hydroxypteridine *(40)* undergoes Michael additions [88] with acetylacetone or malonic, acetoacetic, or cyanoacetic ester, but not with acetone, to give, for example, compounds *(45)* and *(46)*.

*(45)*, R = $HC(CO_2C_2H_5)_2$
*(46)*, R = $OCH_3$

The resultant 7,8- and 3,4-dihydro derivatives do not undergo autoxidation. They thus differ from the corresponding addition compounds of multiply substituted 6-hydroxypteridines, *e.g.* xanthopterin *(4)* [89,90], whose dihydro compounds can usually not be isolated owing to their increased tendency to aromatize. 8-Alkyl-4-pteridones *(47)* also add on nucleophilic compounds in the 7-position [91,92]. Thus, *(47)* is transformed into the 7,8-dihydropteridine derivative



*(47)* *(48)* *(50)* *(49)*

*(48)* by loss of its quinonoid electron system. Such reactions are usually reversible in the absence of light. However, if substituents such as CN, which have a negative mesomeric effect, are introduced, a 7,5-prototropy occurs leading to the formation of a 5,8-dihydropteridine *(49)*. The latter then undergoes immediate autoxidation and is transformed into a 7-oxodihydropteridine *(50)*.

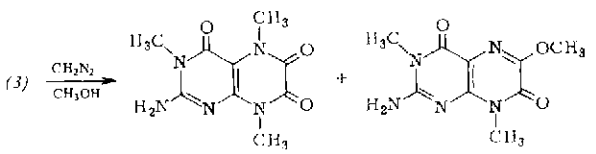
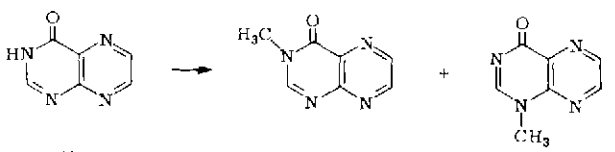
## 2. Alkylations



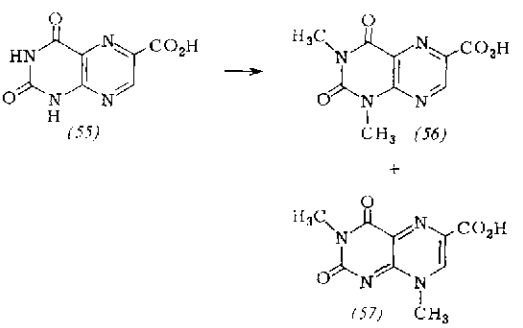
Alkylations, particularly those of the many hydroxypteridines, constitute a second major group of reactions. The arrangement of the nitrogen atoms in positions 1,3,5, and 8 of the pteridine ring leads to complications with the hydroxy derivatives, insofar as the proximity of the hydroxyl groups with at least one hetero-atom confers the ability to undergo lactam-iminol tautomerism. It is therefore to be expected that alkylation does not always lead to the same results, but may result in *O*- and/or *N*-substitutions, depending on the nature of the cyclic amide, the reaction conditions, and the compound used for the alkylation [93].



*(42)*, R = $R^1$ = $R^2$ = H
*(51)*, R = $R^1$ = $CH_3$, $R^2$ = OH

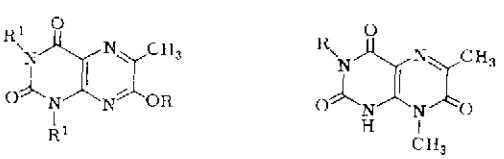
*(42a)*, $R^2$ = H
*(51a)*, $R^2$ = $OCH_3$

The result is least predictable in the case of methylation with diazomethane; exclusive *N*- [23,31,54] and exclusive *O*-methylations [32,34,42,94] have been reported, as exemplified, respectively, by lumazine *(42)* [23] and 1,3-dimethyl-7-hydroxylumazine *(51)* [34]. Mixtures of the possible *O*- and *N*-methyl derivatives have also been reported [75,95], *e.g.* with leucopterin *(3)*.



Methylations with dimethyl sulfate, carried out in dilute alkali [35,75,94,96–99] or in methanol in the presence of alkoxides [75], are much more predictable, since under these conditions, the mesomeric anions function as nucleophilic partners of the dimethyl sulfate. Because of the $S_N2$-character of this reaction, the anions react preferentially with the most nucleophilic centers, *viz.* the nitrogen atoms of the ring [93,100]. Because of the energy relationships in the system, *N*-methylation normally occurs on the nitrogen atom adjacent to the carbonyl group. However, because the nitrogen atoms in positions 1, 3, and 8 are capable of direct mutual interaction (since they are in *meta*-orientation to each other), it is not surprising that certain mesomeric anions of multivalent nature produce mixtures of *N*-methyl derivatives. The anion of 4-hydroxypteridine *(52)* [75], for example, yields both 3-methyl- *(53)* and 1-methyl-4-pteridone *(54)*.

*(52)* *(53)* *(54)*

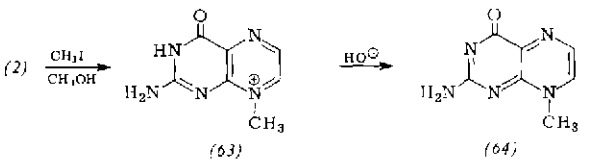


In the presence of excess dimethyl sulfate in alkali, lumazine-6-carboxylic acid *(44)* [97] produces a mixture consisting of 73 % of the 1,3- *(56)* and 16 % of the 3,8-dimethyl compound *(57)*.

*(55)* *(56)* *(57)*

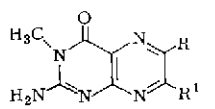
Steric factors also influence the course of the reaction. For example, 7-hydroxy-6-methyllumazine *(58)* normally undergoes *N*-methylation. However, its 1,3-dimethyl derivative *(59)* [33] undergoes exclusively *O*-substitution, leading to the formation of 1,3,6-trimethyl-7-methoxylumazine *(60)*.

Partial methylations of polyhydroxypteridines have shown that steric factors can also induce deviations from the physico-chemically determined sequence of dissociation of the acidic hydrogen atoms. Thus, 6,8-dimethyl-2,4,7-pteridinetrione *(61)* [94] does not yield a 1,6,8-trimethyl derivative, as would be expected from the N-1 > N-3 dissociation sequence but rather the 3,6,8-trimethyl derivative *(62)*.



*(58)*, R = $R^1$ = H
*(59)*, R = H, $R^1$ = $CH_3$
*(60)*, R = $R^1$ = $CH_3$

*(61)*, R = H
*(62)*, R = $CH_3$



If alkylations are carried out under the conditions normally used for quaternization, *e.g.* with methyl iodide in methanol [101,102] or with dimethyl sulfate in dimethylformamide in the presence of acetic acid [97,99], then the tertiary nitrogen atoms would be expected to react. In the case of pterin *(2)*, transannular methylation occurs at the nitrogen atom in position 8 [101,102]. The methiodide *(63)* can be transformed

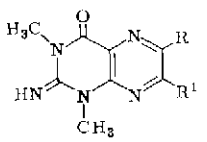
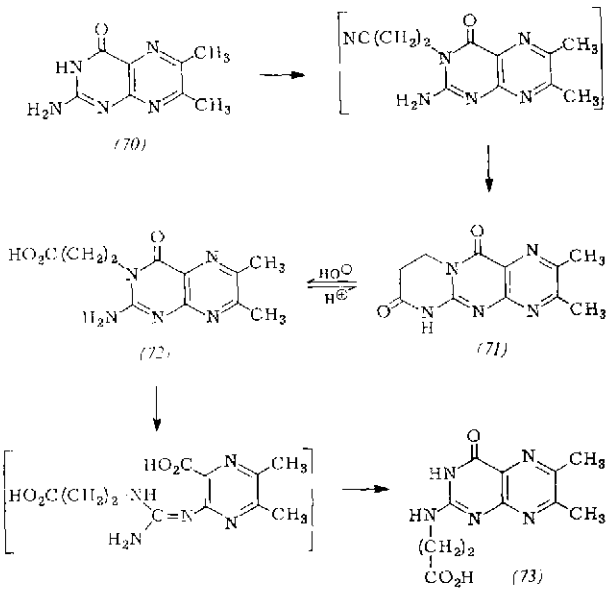
into the free quinonoid compound 8-methylpterin *(64)* by means of alkali. Steric hindrance due to adjacent



substituents was also observed in the quaternization of hydroxyaminopteridines. Treatment of 3-methyl-6-phenylpterin *(65)* with the system dimethyl sulfate/glacial acetic acid/dimethylformamide yields 63 % of the 3,8-dimethyl derivative *(66)* and only 13 % of the 1,3-dimethyl derivative *(67)*, whereas the same treatment of 3-methyl-7-phenylpterin *(68)* leads to exclusive formation of 1,3-dimethyl-7-phenyl-2-imino-4-oxotetrahydropterin *(69)* [99].

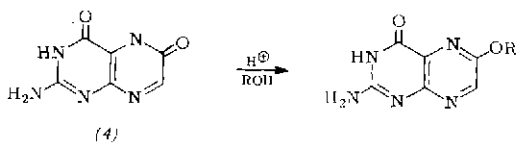
*(65)*, R = $C_6H_5$, $R^1$ = H
*(68)*, R = H, $R^1$ = $C_6H_5$

*(56)*



*(67)*, R = $C_6H_5$, $R^1$ = H
*(69)*, R = H, $R^1$ = $C_6H_5$

Alkylations of aminopteridines [102, 103] in the absence of bases lead to similar results, *i.e.* they are quaternized at the nitrogen atoms of the ring and are not substituted at the exocyclic amino groups.

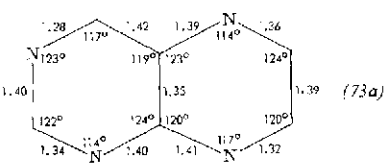


Cyanoethylation of hydroxypteridines with acrylonitrile in pyridine/water provides a parallel to the alkaline alkylations: substitution occurs at the nitrogen atoms of the lactam groups [98, 104]. Moreover, in the presence of suitable *ortho*-substituents, condensed ring systems of higher order may be produced. Thus, 6,7-dimethylpterin *(70)* may be converted into 2,3-dimethyl-7,11-dioxo-6,7,8,9,10,11-hexahydropyrimido[2,1-*b*] pteridine *(71)* [105].

Under mildly alkaline conditions, *(71)* is converted into 3-(β-carboxyethyl)-6,7-dimethylpterin *(72)*, which as an *N*-alkylpteridine can undergo a Dimroth rearrangement to 2-(β-carboxyethyl)amino-6,7-dimethylpterin *(73)*. The latter conversion occurs in hot 1 N sodium hydroxide and is analogous to the reactions of 3-methylpterin [28, 101] and of 3,6,7-trimethylpterin [25]. Dimroth rearrangements are not infrequent among heterocyclic nitrogen compounds [106–108].

*(70)* *(72)* *(71)* *(73)*

The transformation of 6-hydroxypterins such as *(4)*, which have two potentially tautomeric groups in the pyrimidine moiety of the molecule, into 6-alkoxy derivatives with alcohol/$H^+$ is a novel reaction of the pteridine system [109]. This is not an alkylation in the



*(4)*

usual sense, but is probably an acid-catalysed addition of the alcohol onto the amide group with subsequent dehydration.

## III. Structural Considerations

Formally, pteridine *(1)* is a 1,3,5,8-tetraaza derivative of naphthalene. Chemically, however, the two compounds have nothing in common, as is readily seen from their greatly differing stabilities to external influences. Because of their electronegative nature, the nitrogen atoms of the ring compete with the π-electrons of the system and partially localize the latter. This interferes with the cyclic resonance and reduces the aromatic stabilization of the compound. X-ray analysis [110] indicated a planar arrangement of the atoms in pteridine. Bond-angle and bond-length measurements [110, 111] have shown that pteridine is not centrally symmetric *(73a)*.

## 1. Tautomerism

The possibilities of tautomerism in this series have given rise to structural problems. Detailed studies of the tautomeric relationships existing in the hydroxypteridines [23, 31, 34, 38, 42, 49, 94, 112–114], particularly as the result of ultraviolet spectrophotometric comparisons with the corresponding *O*- and *N*-methyl derivatives, have shown that with only a few exceptions [33, 34, 94], the form favored at equilibrium from an energy point of view is the lactam. This agrees with the situation in most α- and γ-hydroxy nitrogenous heteroaromatics [115]. Inasmuch as all four monohydroxypteridines exist in the form of true cyclic amides *(74a)* and do not have the vinylogous amide structure [*(74)*, *(75)*], as might be possible for valence reasons for the 2-, 4-, and 7-hydroxypteridines, it can be concluded that mesomeric stabilization is greatest in compound *(74a)*. The rare

*(74)* *(74a)* *(75)*

situation where an iminole form predominates in the tautomeric equilibrium is encountered with 1,3-disubstituted and 1-monosubstituted 7-hydroxy-2,4-pteridinediones [33, 94] (Fig. 1) and with 7-hydroxy-2,4-pteridinedione-6-carboxylic acids [34].

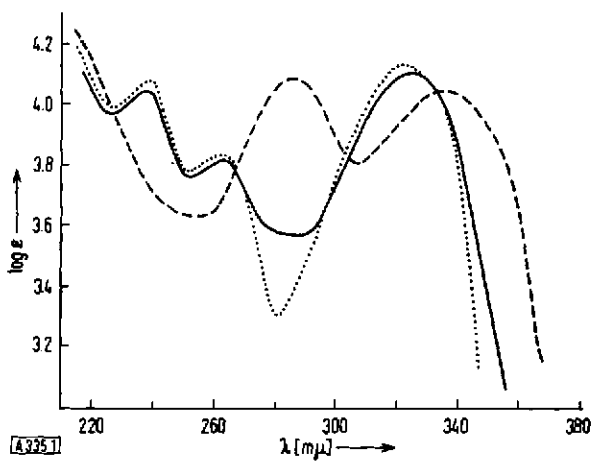

Fig. 1. Ultraviolet spectra of the neutral molecules of 1,3-dimethyl-7-hydroxy-2,4-pteridinedione at pH 1.0 (—), of 1,3-dimethyl-7-methoxy-2,4-pteridinedione at pH 5.0 (. . .) and of 1,3,8-trimethyl-2,4,7-pteridine trione at pH 6.0 (- - -).

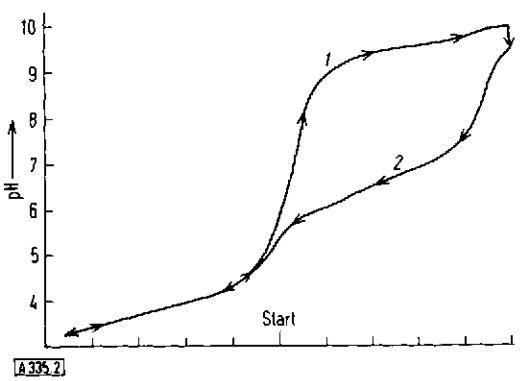
The situation is less complicated with the aminopteridines [31, 77, 103]. So far no instance is known where the normal exocyclic amino configuration *(76)* [115] has been displaced by a tautomeric iminodihydro configuration *(77)*. Comparison of the $pK_a$ values is the best method of determining which tautomeric form predominates at equilibrium.

*(76)* *(77)*

Without exceptions, pteridine molecules that have both amino and hydroxy substituents also obey the general rule. Because of energy considerations, the mutual interaction of their potentially tautomeric groups permits the existence of only the amino and lactam configurations. It is these two structural elements which largely determine the physical properties of the natural pterins [28, 35–37, 95, 102].

## 2. Reversible Hydration

Knowledge of the tautomeric configuration does not, however, completely solve the structural problems inherent in some pteridines. Additional factors can complicate the situation, as is indicated, for example, by the C=N hydration [117] first observed with 6-oxodihydropteridine *(37)* [31, 116]. Thus, the curve obtained when compound *(37)* is titrated potentiometrically with alkali is very different from the curve obtained by back-titration with acid (Fig. 2).



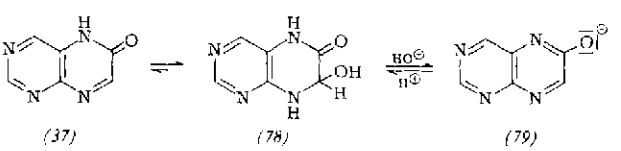


Fig. 2. Titration of 6-oxodihydropteridine with alkali (Curve 1) and back-titration with acid (Curve 2).

The $pK_a$ values of 9.7 and 6.7 derived from these two curves do not indicate cleavage of the ring nor tautomerism but rather that the neutral form of *(37)* is a hydrate *(78)* with covalently bound water, whereas the anionic form *(79)* tends to be anhydrous [78].

*(37)* *(78)* *(79)*

Ultraviolet and infrared spectroscopy and mild oxidation to 6,7-dioxotetrahydropteridine fixed the position of the water added [111]. Another means of determining the point at which the water is added is to carry out comparisons between the potentiometric and ultraviolet spectrophotometric meas-

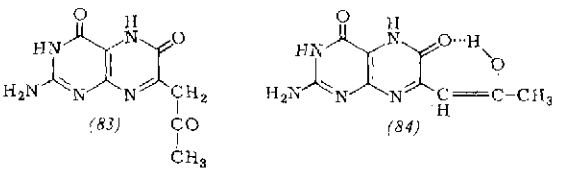
[117] *A. Albert* [14].

urements made on the basic compounds and on their corresponding C-methyl derivatives [88, 118]. For mainly steric reasons, the methyl groups in these compounds prevent hydration of the adjacent double bond. Considering that the covalent hydrates constitute dihydro derivatives of the anhydrous form, the differences in the ultraviolet absorption and in the acidic and basic strengths of the two series can be readily understood.

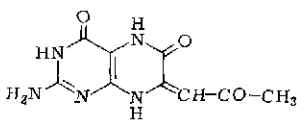
The reversible covalent hydration is not restricted to neutral molecules and to the 7,8-positions of 6-hydroxypteridines [119, 120]. It also occurs outside the pteridine series [116, 121–125], mostly with strongly polar, nonsubstituted C=N double bonds. Both the neutral molecule of 2-hydroxypteridine and the cation of 2-aminopteridine add on water in the 3,4-positions and thereby behave like pteridine *(1)* [126].

In aqueous solution, pteridine *(1)* is in equlibrium with its 4-hydroxy-3,4-dihydro form *(80)* which remains present in both acid and alkaline media as the anion *(81)* or cation *(82)*, respectively. This fact helps to explain the relatively high basic $pK_a$ value of pteridine and the existence of an anion.



*(1)*

*(81)* *(80)* *(82)*



### 3. Results from Physicochemical Studies

Polarographic studies [127–133] have also yielded valuable information on the pteridines. Because two-electronic potential steps normally occur, it is possible to recognize corresponding configurational characteristics of different molecules by means of their half-wave potentials. The relationships between the half-wave potentials of reduction, the dissociation constants, and the wave number of the second $\pi \rightarrow \pi$-transition band of the ultraviolet absorption, in conjunction with the additivity of the polarographically obtained substituent-dependent structural increments, allow preliminary evaluation of the relationships between polarographic reducibility and structure [131].

Proton resonance spectroscopy is another method for clarifying structural questions [134]. The spectra are mostly simple and can be simplified even further by deuteration. Thus, it was found that only structure *(85)* can correctly describe 7-acetonylxanthopterin *(83)*. This compound cannot possess a $CH_2$ group and it cannot exist in a tautomeric enolic form *(84)*.

*(85)*

## IV. Hydrogenated Pteridines

### 1. 5,6,7,8-Tetrahydro Derivatives

Only very recently, after the discovery of naturally occurring dihydro- and tetrahydropteridines, have hydrogenated pteridines assumed the importance that should be their due. The chemical and physical properties of these compounds can best be understood by considering 5,6,7,8-tetrahydropteridine *(86)*. The fact

*(1)*, R = H
*(87)*, R = Cl

*(86)*, R = H
*(88)*, R = Cl

that *(86)* can be produced either by reduction of *(1)* with $LiAlH_4$ or by stepwise reductive dehalogenation of 2,4,6,7-tetrachloropteridine *(87)* via 2,4-dichloro-5,6,7,8-tetrahydropteridine *(88)* [82] is in accordance with the behavior of the two diazines which make up the pteridine system, for pyrazines are reduced relatively easily [135], whereas pyrimidines are very difficult to hydrogenate, particularly in an alkaline medium [136, 137].

In contrast to pteridine *(1)*, which is unstable, the tetrahydro compound *(86)* is quite stable to boiling

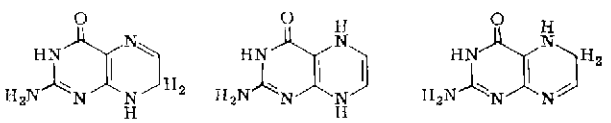
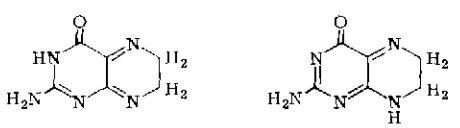
1 N HCl or 1 N NaOH; it also appears to be stable to light. So far, all attempts to reoxidize *(86)* to *(1)* have failed. The transition of the pteridine system to the 4,5-disubstituted pyrimidine derivative which occurs on reduction of the pyrazine ring must therefore effect an increase in heteroaromaticity - with the result that reoxidation of compound *(86)* to *(1)* can be achieved only under drastic conditions. These would lead in turn to further conversions of the oxidation product, so that *(1)* cannot be isolated.



If first-order substitutents are introduced in sequence into the 2- and 4-positions of dihydro- and tetrahydropteridines, the extreme stability of compound *(86)* gives way to sensitivity to oxidation which increase with any increase in the electron donor properties of the substituents.

Although the alkyl derivatives of 5,6,7,8-tetrahydropteridine are stable [138–141] and the 2- or 4-monosubstituted hydroxy and amino derivatives of dihydro- and tetrahydropteridines can be isolated [138, 139, 142, 143] and are stable as solids, 2,4-disubstituted 5,6,7,8-tetrahydropteridines [82, 143, 144, 145] undergo rapid autoxidation because of their potentially tautomeric groups.



If 5,6,7,8-tetrahydropterin *(89)*, which is obtained from *(2)* by catalytic reduction, is oxidized by air, three of the five theoretically possible dihydropterins *(90)–(94)* seem to be formed; however, so far only the structures of 7,8-dihydropterin *(90)* [146] and its 6-methyl derivative [147, 148] have been established.

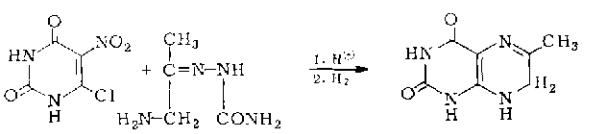
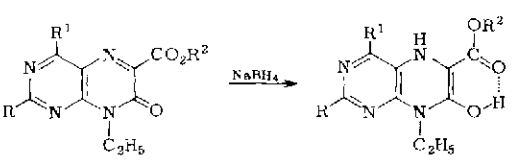
*Important contributions to the unsolved problems of the* hydrogenated pteridines are provided by systematic investigations of the reduction of mono- and polyhydroxypteridines [142] with potassium borohydride, sodium dithionate, potassium or sodium amalgam, or with hydrogen and Pt, Pd, or Raney-nickel catalysts.



## 2. Direct Synthesis of Hydrogenated Pteridines

The first direct synthesis of 5,6-dihydropteridines *(95)* was accomplished by reductive condensation of glyoxal monoacetal with 4,5-diaminopyrimidine [142]. The 7,8-dihydropteridine *(96)* can be obtained most readily via

*(95)*



the Boon synthesis [20, 142, 146, 147, 149–151], applied to either 4-chloro-5-nitropyrimidines or 4-chloro-5-benzazopyrimidines and α-amino esters, α-amino ketones, or α-amino aldehydes.

*(96)*

## 3. Reduction with Boron Hydrides

Reduction of 8-substituted 7-pteridone-6-carboxylic acid derivatives with sodium borohydride [48, 152] led to a surprising result: when position 4 is either free or bears an alkyl substituent, stable dihydropteridines result, whose ultraviolet absorption bands in the long-wave region exhibit a pronounced bathochromic shift. Since 5,6-dihydro- and 5,6,7,8-tetrahydropteridines behave spectroscopically in the same way as the corresponding 4,5-diaminopyrimidine derivatives, it was apparent that a novel chromophoric pteridine system had been obtained. A 5,8-dihydro structure *(97)* was proposed for this compound and was found to conform with all the pertinent chemical and physical findings.

R = OH, $NH_2$, $NHC_2H_5$, $N(CH_3)_2$
$R^1$ = H, $CH_3$
$R^2$ = H, $CH_3$, $C_2H_5$

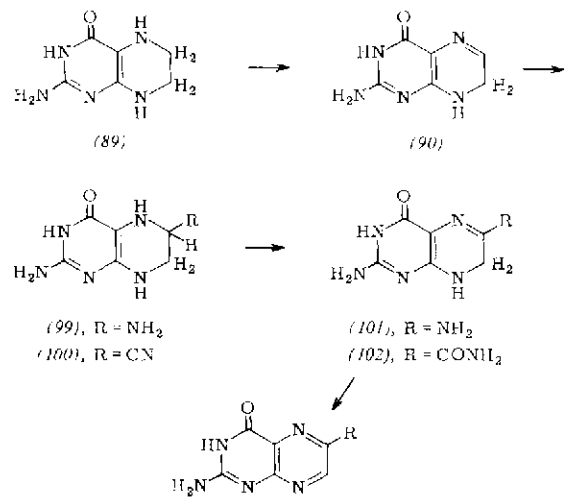
[149] Brit. Pat. 677342 (1952), inventors: *W. R. Boon* and *T. Leigh*.

[150] *W. R. Boon* and *W. G. Janes*, J. chem. Soc. (London) *1951*, 591.

[151] *T. Neilson* and *H. C. S. Wood*, J. chem. Soc. (London) *1962*, 44.

[152] *E. C. Taylor* [14].

Both the formation and stability of compound *(97)* can be explained by the added stability conferred upon it by intramolecular hydrogen bonding.



The reduction of 2-hydroxypteridine *(41)* to 3,4-dihydro-2-hydroxypteridine *(98)* [142] in alkaline medium was the first example showing that the pyrimidine ring can be reduced before the pyrazine ring is attacked.

*(41)* *(98)*

### 4. Derivatives of 7,8-Dihydropterin

Partially hydrogenated pteridines are chemically interesting and may be of biochemical significance [146, 153]. Reoxidation of 5,6,7,8-tetrahydropterin *(89)* in the presence of nucleophilic agents gives rise to 6-substituted pterins *(103)* [145, 146, 154–156]. This reaction probably proceeds via the 7,8-dihydropterin *(90)* [146] as an intermediate, since the latter is the most electrophilic compound.

*(89)* *(90)*

*(99)*, R = $NH_2$
*(100)*, R = CN

*(101)*, R = $NH_2$
*(102)*, R = $CONH_2$

*(103)*, R = $NH_2$, $CONH_2$, OH, $SO_3H$, SR'

This reaction sequence is confirmed, on the one hand, by the ready addition of ammonia onto *(90)* to form 6-amino-5,6,7,8-tetrahydropterin *(99)* and the oxidation of the latter via 6-amino-7,8-dihydropterin *(101)* to 6-aminopterin [*(103)* R – $NH_2$], and on the other, by the reaction of *(89)* [155] or of *(90)* [146] with KCN in the presence of oxidants. It was previously assumed that 5,8-dihydropterin-6-carboxamide was formed via *(100)* in the latter reaction; however, actually it is the relatively stable 7,8-dihydro derivate *(102)* that is formed [157]. Analogous additions of bisulfite [145], hydroxyl ions [156], thiols [146], and carbanions [146], as well as the oxidative conversion of the products into the corresponding 6-substituted pterins [*(103)*; R = $SO_3H$, OH, or SR] all serve to underline the general nature of this reaction.

### V. Naturally Occurring Pteridines

The widespread interest in the pteridines, which dates from the fundamental studies of *H. Wieland*, *C. Schöpf*, and *R. Purrmann*, is undoubtedly due to their widespread occurrence in both the animal and plant kingdoms. Naturally occurring pteridines can be recognized directly as pigments in the wings of insects, and in the eyes and skin of fish, amphibia, and reptiles [158]. Moreover, they usually possess a very characteristic fluorescence with allows them to be readily seen and identified. Consequently, it is not surprising that the number of pteridine compounds known has increased by leaps and bounds in recent years. However, it has been possible to determine the structures of only some of these newly described compounds. Although refined analytical and chromatographic techniques have simplified the isolation and purification of the pteridines enormously, potentially productive studies are limited by the small quantities of material normally available. It must therefore be considered fortunate that the three best-known butterfly pigments, *viz.* leucopterin *(31)*, xanthopterin *(4)*, and isoxanthopterin *(5)*, occur in relatively large concentrations in the wings of these insects. Hence, no better starting material could be found for the initial studies on the isolation and structure of the natural pteridines.

A great many other natural materials studied so far as potential sources of pteridines, including the skin of *Rana nigromaculata* frogs [159], of green snakes [160], of the fire salamander [161], or of various ornamental (tropical) fish [162], the larvae and eggs of the silkworm *Bombyx mori* [159, 163, 164], fruit-flies *Drosophila* [165, 166], the scales of Japanese carp [167], human urine [168], red ants [169], the flour moth *Ephestia kühniella* [170], various genotypes of *Plodia interpunctella* [171], and the heads and eyes of various *Lepidoptera* species [172], contain isoxanthopterin *(5)* in

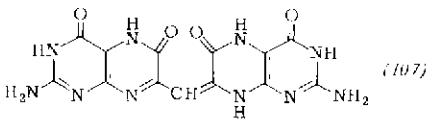
only small concentrations and only extremely minute quantities of the less common compound xanthopterin [171, 170, 172].

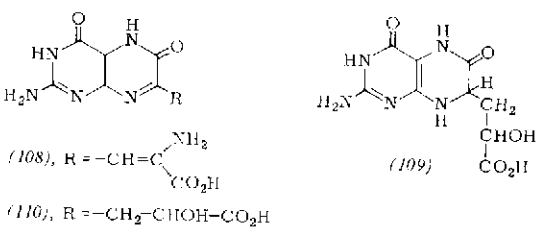
### 1. Erythropterin, Pterorhodin, Ekapterin, and Lepidopterin

Because the concentrations of erythropterin *(104)* that occur in the South American butterfly *Catopsilia argante* are relatively large, it has been possible to isolate this orange-red wing pigment first described by *Schöpf* and *Becker* [173] in pure form and to determine its structure [174]. Alkaline degradation to 7-methylxanthopterin *(105)* and oxalic acid served to confirm the existence of the pyruvate side chain which, in view of the optical behavior of the compound, is likely to exist in a tautomeric form, most probably the enol. Proton resonance spectra confirmed the absence of a $CH_2$ group and led to the proposal of formula *(106)* [134].



The synthesis of erythropterin *(104)* from xanthopterin *(4)* and oxaloacetic [175] or pyruvic acid [176, 177] makes use of the ability of the $\Delta^7$-double bond to add on nucleophilic agents.

It is very likely that compound *(104)* occurs in tubercle bacilli [179]; its occurrence in *Ephestia kühniella* Zeller [176, 178] and in *Pyrrhocoris apterus* L. [180] has been verified by chemical isolation.



Chrysopterin [181], which has been identified as a 7-methylxanthopterin *(106)*, is not a naturally occurring wing pigment, but must be considered as a product of hydrolysis of the erythropterin localized in the discoidal spot of the brimstone butterfly *Gonepteryx rhamni* [182].

Pterorhodin *(107)* is a newly isolated natural pigment found in butterfly wings [183]. In conjunction with erythropterin, it causes the intense red color of the wings of *Appias nero*, a pierid native to the islands of Java and Ceylon. Comparisons with synthetic materials [185–187] have shown that the red pigment found in the eyes of *Ephestia* and *Ptychopoda* [184] is also pterorhodin.

*(107)*

Knowledge of the true structure of erythropterin has helped in understanding the structure of ekapterin *(110)* and lepidopterin *(108)* [176–178]. As both of these pterins occur together with erythropterin in *Ephestia kühniella*, a structural relationship appeared likely. The conversion of *(104)* into *(108)* with $NH_3$, as well as its reduction to tetrahydroerythropterin *(109)* and the oxidation of the latter to *(110)* can be considered as evidence for the proposed structures.

*(108)*, R = $-CH=C(NH_2)-CO_2H$

*(110)*, R = $-CH_2-CHOH-CO_2H$

*(109)*

### 2. Biopterin and Ichthyopterin

A widely occurring natural pterin that was first isolated from human urine by *Patterson* et al. [188] and designated as biopterin has also been isolated from the fruit-fly *Drosophila melanogaster* [165, 189–191], from the crayfish *Astacus fluviatilis* [192], from the Mediterranian flour moth *Ephestia kühniella* [170], and from the royal jelly of the bee [193]. It also occurs in amphibia

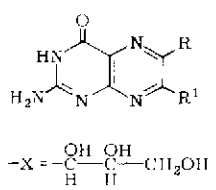
[194–196], in fish [197], and in red ants [169]. Synthesis confirmed that the structure of biopterin *(113)* is 6-(L-*erythro*-1′,2′-dihydroxypropyl)pterin [198].



*(111)* *(112)*

*(113)*, R = $-\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-CH_3$, $R^1 = H$

*(114)*, R = H, $R^1 = -\underset{OH}{\overset{H}{C}}-\underset{OH}{\overset{H}{C}}-CH_3$

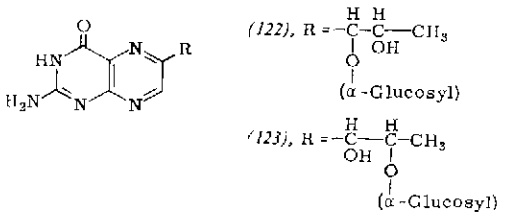
When 2,4,5-triamino-6-oxodihydropyrimidine *(111)* is condensed with rhamnotetrose *(112)*, the product is always a mixture of two isomers, *(113)* and *(114)* [133, 193, 198, 199, 201, 202]. The isomer ratio is largely independent of the conditions of the reaction [200] and is practically unaffected by addition of hydrazine [205], boric acid [198], or *p*-toluidine [206], all of which induce formation of the 6-isomers from hexoses but do not affect the corresponding reaction with pentoses [203, 204]. Partition chromatography on either silica gel [200, 201] or cellulose phosphate [202] has been used recently to isolate and purify the 15–30 % of biopterin present in the mixture.

It took a chromatographic study of the reactions [44] to show just how complex the condensation of compound *(111)* with carbohydrates really is. Although the reaction of *(111)* with 1-deoxy-1-(*p*-toluidino)-D-fructose *(115)* in the presence of hydrazine leads to the formation of a single compound, *viz.* 6-(D-*arabo*-tetrahydroxybutyl)pterin *(116)* [204], as many as six pterins [*(116)*–*(121)*] may be formed simultaneously under other conditions [44].

*(116)*, R = $-\underset{OH}{\overset{H}{C}}-X$, $R^1 = H$

*(117)*, R = H, $R^1 = -\underset{OH}{\overset{H}{C}}-X$

*(118)*, R = $-CH_2-X$, $R^1 = H$

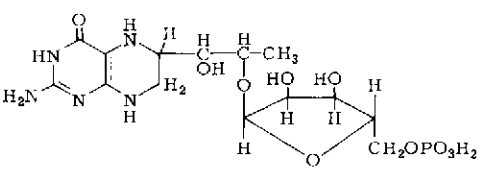


*(119)*, R = H, $R^1 = -CH_2-X$

*(120)*, R = X, $R^1 = CH_3$

*(121)*, R = $CH_3$, $R^1 = -X$

Biopterin differs from most of the other known simple pteridine derivatives by virtue of its biochemical activity. It stimulates growth in the flagellate *Crithidia fasciculata* [188, 207] and probably plays an important role in the process determining the transformation of a bee larva into a queen [133, 208–210]. Details of the special functions of biopterin are still unknown. The mere need of biopterin exhibited by *C. fasciculata* [211] and bee larvae does not indicate in what form the compound is found in the cell. Biopterin is not noticeably transformed to other fluorescent pterins in the process of selection of the queen bee [212]; it may therefore be assumed that biopterin itself is not the metabolically active form. It presumably acts as a cofactor in hydrogen transfers via the system tetrahydrobiopterin ⇌ dihydrobiopterin.



This hypothesis is supported by the fact that a derivative of tetrahydrobiopterin [213, 214] occurs as an extremely photosensitive compound in the eyes and skin of insects, in the skin of amphibia and fish [215 to 217], and in all likelihood also in algae [218]. An α-glucoside of biopterin has been isolated from the blue-green alga *Anacystis nidulans* [219]. Its structure is either *(122)* or *(123)*. Moreover, analogous biopterin glycosides, which differ in the carbohydrate moiety of the molecule, have also been isolated from blue-green algae [220]. Both of these observations may perhaps be

*(122)*, R = $-\underset{OH}{\overset{H}{C}}-\underset{O}{\overset{H}{C}}-CH_3$ (α-Glucosyl)

*(123)*, R = $-\underset{OH}{\overset{H}{C}}-\underset{O}{\overset{H}{C}}-CH_3$ (α-Glucosyl)

interpreted as indications of the structure of active biopterin. If it is true, as has been alleged [213], that ribose and phosphoric acid are linked to the photolabile tetrahydrobiopterin derivative, then a structure like that of compound *(124)* appears possible.

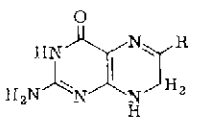
From a chemical point of view, biopterin *(113)* closely resembles ichthyopterin *(126)* [221], a compound first isolated in 1943 as the principal pigment of the blue-violet fluorescent materials found in the skin of *Cyprinidae* (carp). It occurs widely in the skin of whitefish [158,197,222–224] and ornamental tropical fish [162].

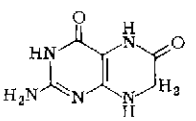
*(125)*, R = $-CH_2-CO-CH_3$
*(126)*, R = $-CHOH-CHOH-CH_3$

The structure of ichthyopterin was determined by its synthesis [225] from 6-acetonylisoxanthopterin *(125)*, the acetonyl grouping being converted into the 1′,2′-dihydroxypropyl side chain. Although it has proved possible to confirm the identity of the synthetic and natural compound by chromatography and ultraviolet spectroscopy [226], the absolute configuration of the side chain remains unknown. Until the hypothetical L-*erythro*-configuration of the side chain is confirmed, it would be best to speak of ichthyopterin as 6-(1′,2′-dihydroxypropyl)isoxanthopterin, rather than to designate it as 7-hydroxybiopterin.



### 3. Drosophila Pterins (Sepia-, Isosepia-, Droso-, Isodroso-, and Neodrosopterin)

The yellow to red pterins from the fruit-fly *Drosophila melanogaster* constitute another important group of natural pteridine derivatives. They represent some of the fluorescent materials which *Hadorn* et al. used to study the effects of genes in *Drosophila* [227] and *Ephestia* [228]. It was possible to show by means of chromatography that the *Drosophila* pterins consist of the yellow compounds sepiapterin [229] and isosepiapterin [230], as well as of the orange to red compounds drosopterin, isodrosopterin, and neodrosopterin [231–233]. A number of papers describing their distribution in nature have been published [234–242].

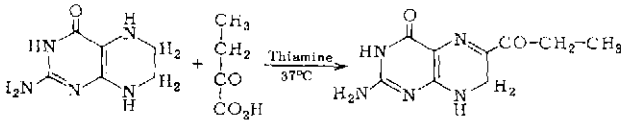


Sepiapterin *(127)* was isolated in the form of yellow crystals from *D. melanogaster*, whose *sepia* mutant accumulates it in large concentrations [243]. This pigment is occasionally designated as "yellow pterin" and is also found in amphibian skin [195,196,216,217,244 to 246], in fish [217,247–249], and in the epidermis of the *lem* mutant of the silk moth *Bombyx mori* [163]. The structure of sepiapterin *(127)* was determined by analysis of the products of its oxidative degradation, *viz.* 7,8-dihydroxanthopterin *(128)* and lactic acid. Under mild degradation conditions, the products were 7,8-dihydropterin-6-carboxylic acid *(129)* and acetaldehyde [250].

Because of this clear-cut chemical proof, previously proposed structures [230,232,233,243,251–253] must be abandoned in favor of that of 6-lactoyl-7,8-dihydropterin *(127)*. Additional confirmation of this structure comes from the close structural relationship between sepiapterin and isosepiapterin; NMR studies [254] confirmed the 7,8-dihydro structure of isosepiapterin *(130)*.

From a biochemical point of view, sepiapterin *(127)* may serve as the dihydro component in the hydrogen transfer system tetrahydrobiopterin ⇌ sepiapterin [213,214,217,255]. This hypothesis derives some support from the growth-promoting activity of compound *(127)* observed for *Crithidia fasiculata* [256,257].

*(127)*, R = $-CO-CHOH-CH_3$
*(129)*, R = $-COOH$



*(128)*

The other yellow fluorescent component, isosepiapterin *(130)*, was also isolated in crystalline form for the first time from the *sepia* mutant of *Drosophila* [230]. At first, structural studies were not very successful and merely indicated a partially hydrogenated pteridine

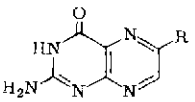
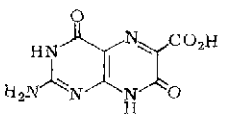
derivative with a $C_3$ side chain at position 6 [230,251]. These studies were advanced considerably when somewhat larger concentrations of isosepiapterin were found in the blue-green alga *Anacystis nidulans* [258], thus permitting chemical degradation and transformation studies. However, unequivocal proof that isosepiapterin has the structure of 6-propionyl-7,8-dihydropterin *(130)* came only recently with the aid of NMR spectroscopy [254]. Isosepiapterin and sepiapterin exhibit similar

*(89)* *(130)*



optical behavior. This can be considered as an additional argument for structural similarity between the two. The first synthesis of isosepiapterin was achieved starting from 5,6,7,8-tetrahydropterin *(89)*, α-ketobutyric acid, and thiamine [153,259]; this synthesis is of both chemical and biocbemical interest, as it may be the biosynthetic pathway for the formation of *Drosophila* pterins [153].

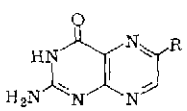
*Viscontini* [231] was the first to separate the water-soluble red eye-pigments of *Drosophila* [260] into drosopterin, isodrosopterin, and neodrosopterin. Structural studies [251,261,262], which were largely based on oxidative degradation and on reduction and reoxidation reactions, led to the suggestion that by analogy to sepiapterin and isosepiapterin, the three red pigments, also had a dihydropterin structure with a $C_3$ side chain at position 6. However, all of the structural formulae proposed so far [232,233,251,263] are not very convincing, since they fail to explain the characteristic absorption in the 475--505 mμ region of the spectrum.



Consideration of the optical behavior of these compounds, in conjunction with the small $R_F$ values they exhibit in the usual solvents, suggests that the red pigments may not be simple pteridines, but rather dipteridyl derivatives. It is conceivable that these highly colored compounds constitute a new class of natural pigments, since they occur in the eyes of certain *Drosophila* mutants, in the skin of some fish [162,217] and amphibia [217], as well as in the skin folds of various reptiles [264].

### 4. Other Natural and Synthetic Pteridines

Pterin *(2)* itself occurs widely as a natural pteridine derivative [160,165,166,168–171,192,195]. From a biosynthetic viewpoint, it is a precursor of isoxanthopterin *(5)* and therefore usually occurs in association with it. Pterin-6-carboxylic acid *(131)* [160,165,166,195] is more likely to be an artefact than a natural product, as it can very readily be formed from 6-substituted pterins by photolytic and oxidative degradation.



*(131)*, R = COOH
*(132)*, R = $NH_2$

*(133)*

The 6-aminopterin [54] isolated from *D. melanogaster* and from the algae *Anacystis nidulans* and *Nostoc muscorum* G. is also very probably an artefact. Its formation can be explained by assuming an addition of ammonia onto a 7,8-dihydropterin derivative with subsequent oxidation. Isoxanthopterincarboxylic acid *(133)* is a natural fish pterin and was first isolated from the scales of the Japanese carp [167].

Further indications of the widespread and diverse occurrence of the natural pterin derivatives came from the identification of hydroxymethylpterin *(134)* [220], which occurs as a glucose compound in the alga *Synchocystis*, of 6-(1′,2′,3′-trihydroxypropyl)pterin *(135)*, which has frequently been described as "bufochrome" [217] and which may be identical with the neopterin found in bee pupae [265], and finally of 6-(1′,2′,3′-trihydroxypropyl)pterin-3′-phosphate *(136)* [266] from *Escherichia coli*.

*(134)*, R = $-CH_2OH$
*(135)*, R = $-(CHOH)_2-CH_2OH$
*(136)*, R = $-(CHOH)_2-CH_2O[PO_3H_2]$

The constitution of urothione, the yellow urine pigment containing sulfur, is unknown. Attempts to solve the problem by synthesis [267–271] have failed to clarify the picture.

New aspects of pteridine chemistry have come from the work of *Masuda*, who isolated two new pteridine derivatives [*(137)* and *(138)*] from *Eremothecium ashbyii* [272,273]; later, these were also reported to occur in *Ashbya gossypii* [274,275]. Structural studies [276,277] and syntheses [274,275,278–282] later showed that

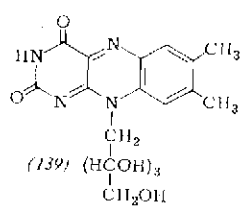
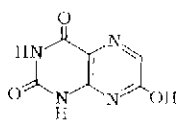
*(137)* and *(138)* are not derivatives of pterin *(2)*, but of 2,4-pteridinedione *(43)*, *i.e.* of lumazine. This demonstrated that the pterins are not the only natural products in the pteridine series, but that the possibility of varying the substituents on the pyrimidine nucleus is as great as in the case of the closely related purines.



*(137)*



*(138)*

The hypothesis [275, 283–285] that 8-ribityl-6,7-dimethyllumazine *(137)* is an intermediate in the biosynthesis of riboflavin, but that 8-ribityl-6-methyl-7-oxodihydrolumazine *(138)* does not take part in this biosynthesis, [286], is based on numerous studies of the enzymatic transformation of *(137)* into riboflavin [287]. Two molecules of 8-ribityl-6,7-dimethyllumazine *(137)* are joined by the catalytic action of the enzyme riboflavin synthetase to form one molecule of riboflavin *(139)* plus an unknown compound [288, 289]. Compound *(137)* reacts in this unusual biochemical reaction both as a donor and acceptor for a $C_4$ intermediate which consists of both the methyl groups and carbon atoms 6 and 7. Various 8-ribityl-6,7-dialkyl- and 8-glycityl-6,7-dimethyllumazines were synthetized in order to test the substrate specificity of this enzyme [290]. With the exception of 8-(D-5′-deoxyribityl)-6,7-dimethyllumazine, none of these substrates were transformed into an isoalloxazine derivative [289, 290], although they are all competitive inhibitors in the enzymatic transformation of *(137)* into *(139)*.

*(139)*

*(140)*

Very recently, a purely chemical synthesis of riboflavin *(139)* was achieved [291] by heating *(137)* for 15 hours in phosphate buffer at pH 7.3 under nitrogen; a 55 % yield of riboflavin was obtained. The isolation of 7-hydroxylumazine *(140)* [180] from *Pyrrhocoris apterus* C. indicates that in the future, derivatives of 2,4-pteridinedione will also have to be considered.

*Xenopus* larvae [292] are probably able to transform purines into pteridines. This observation provided the first experimental basis for the reasonable supposition that purines are precursors of pteridines. Earlier reports [293] had already suggested a possible biogenetic relationship between purines and riboflavin, and the transformation of purine into pteridine has been discussed [286, 294–301]. It was only recently that definitive proof was obtained [302] that the entire purine nucleus, with the exception of carbon atom 8, is incorporated into the pyrimidine and pyrazine moieties of riboflavin *(137)*, which is produced via 8-ribityl-6,7-dimethyllumazine. Inasmuch as natural pteridine derivatives, *i.e.* pterins and lumazines, are ultimately derivatives of 4-hydroxypteridine, it is possible that the latter is an intermediate in the biosynthesis of pteridine [303], particularly as 4-hydroxypteridine undergoes enzymatic oxidation to 7-hydroxylumazine *(140)* via lumazine *(43)* [304]. Purines have also been reported to play a role in the biosynthesis of folic acid [305, 306].

The present-day picture of the purine → pteridine transformation is the result of many years of study of the biosynthesis of leucopterin by *Weygand* et al. [307, 308]. By using $^{14}C$-labelled precursors in the caterpillars or pupae of the cabbage butterfly (*Pieris*), and as a result of degradation studies of the leucopterin isolated from the resultant butterfly wing pigment, it proved possible to establish the origin of the carbon atoms of the pteridine nucleus (the carbon atoms of the pyrimidine nucleus are derived from the same precursors as the corresponding carbon atoms of guanine, while carbon atoms 6 and 7 come from a pentose). The following picture emerged from this work (Scheme 1).

The first step results in the elimination of C-8 from either guanosine or guanylic acid *(149)*. Subsequently, the ribosyl residue of 2,5-diamino-4-β-D-ribofuranosyl-6-pyrimidone

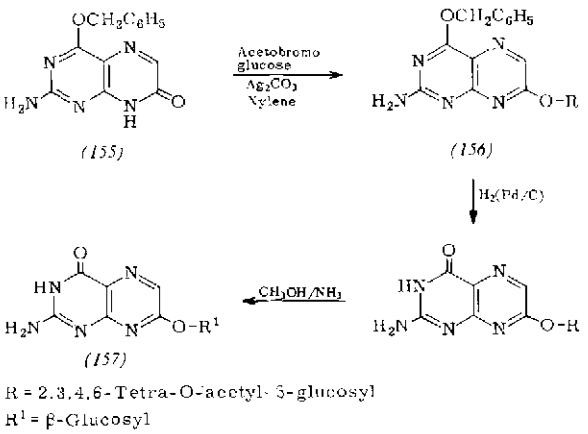
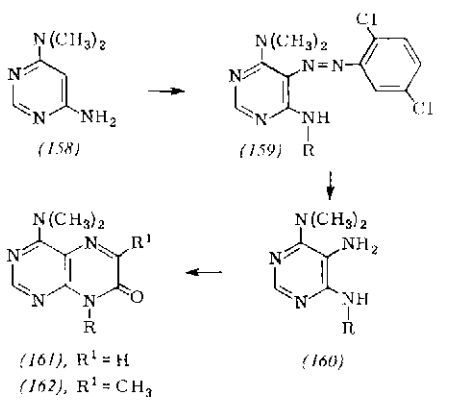
*(150)* is used for the formation of the pyrazine ring, presumably after an Amadori rearrangement [309] favored by the adjacent amino group. The $C_3$ side chain is then split off from *(153)*, and the resultant 6-hydroxy-5,6,7,8-tetrahydropterin *(154)* is transformed via xanthopterin *(4)* into leucopterin *(3)*, with attendant dehydrogenation and hydroxylation.



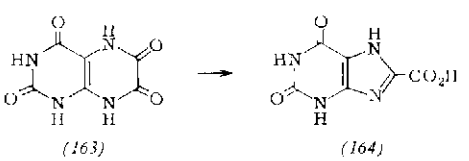
Scheme 1. Conversion of guanylic acid into pteridines.

Studies *in vitro* [310] have given support to the above reaction sequence. Attempts to isolate *(152)* have merely resulted in the isolation of 7,8-dihydroxanthopterin, formed by cyclization, elimination, and oxidation. According to Scheme 1, there is a possibility that *(154)* is dehydrated and that the resulting highly reactive 7,8-dihydropterin *(90)* is utilized for the synthesis of more complex pteridines, in analogy to the processes shown to occur in the isosepiapterin synthesis [153, 259].



An interesting variation of the purine → pteridine conversion occurs when the pyrazine ring is closed not by the ribosyl residue, as with *(150)*, but by a $C_2$ fragment obtained from a pentose. In that case, a pteridine-*N*(8)-riboside or ribotide *(151)* would then be the biosynthetic intermediate [311]. Attempts have been made to synthetize such pteridine derivatives in order to elucidate their chemical and physical properties [311].

Direct glycosidation of 7-pteridones with halogenated sugars by the methods used in nucloside synthesis yielded only 7-*O*-glycosides [312]. These are labile in both acid and alkali, with the result that isoxanthopterin-7-*O*-β-D-glucopyranoside *(157)* [83] can only be obtained from 2-amino-4-benzyloxy-7-pteridone *(155)* via *(156)*, which requires debenzylation and deacetylation.



A true pteridine-*N*(8)-glycoside was first synthetized [314] by an approach analogous to the Todd purine nucleoside synthesis [313]:

The first step was glucosidation of 4-amino-6-dimethylaminopyrimidine *(158)*, followed by transformation by coupling and acetylation into 5-(2′,5′-dichlorophenylazo)-6-dimethylamino-4-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glucopyranosylamino)-pyrimidine *(159)*. After reduction to *(160)*, the latter was condensed directly (without further isolation) with glyoxylic or pyruvic ester to form 8-(2′,3′,4′,6′-tetra-*O*-acetyl-β-D-glycopyranosyl)-4-dimethylamino-7-pteridone *(161)* or its 6-methyl analogue *(162)*.

Because these products exhibit the stability to alkalies and moderate stability to acids known for purine nucleosides, it is to be expected that if pteridine-*N*(8)-ribosides do occur in nature, they will be relatively stable compounds, capable of isolation. In connection with the enzymatic degradation of the pteridines, mention should also be made of the conversion of xanthopterin *(4)* and isoxanthopterin *(5)* into xanthine-8-carboxylic acid [315]. *genes faecalis*, which utilize *(4)* and *(5)* as sources of nitrogen and carbon, deaminate these substances to the respective lumazine derivatives, which then undergo oxidation to 2,4,6,7-pteridinetetraone *(163)*. The isomerization of *(163)* to xanthine-8-carboxylic acid *(164)* is achieved enzymatically.

### VII. The Biochemical Role of Unconjugated Pteridines

By his study of the enzymatic hydroxylation of phenylalanine to form tyrosine, *Kaufman* [317] has made a valuable contribution to the knowledge of the biochemistry of the pteridines [316]. He was able to show [317,318] that two enzymes are involved in the overall reaction

$$H^+ + TPNH + O_2 + \text{phenylalanine} \rightarrow TPN^+ + H_2O + \text{tyrosine}$$

(where TPN = triphosphopyridine nucleotide and TPNH = reduced TPN). One of the enzymes, isolated from rat liver, catalyses the hydroxylation; it contains a tetrahydrogenated, unconjugated pteridine as a cofactor. The second enzyme, obtained from sheep liver, acts in conjunction with TPNH to induce rehydrogenation of the dihydropteridine to the tetrahydro stage. Details of the structure of the cofactor are still unknown. The fact that the cofactor can be replaced by either 6-methyl- or 6,7-dimethyl-5,6,7,8-tetrahydropterin [319] or by tetrahydrobiopterin indicates that a 6-substituted tetrahydropterin is involved. The partially hydrogenated pteridine derivative [320] produced in the course of the hydroxylation is neither a 5,8- nor a 7,8- nor most probably a 5,6-dihydropterin. Hence, it is likely that an oxidation-reduction system is involved. This system may have compounds *(165)* and *(166)* as components.

*(165)*

*(166)*

This first example in which a simple unconjugated pteridine plays the role of a cofactor can be considered to be the beginning of a new chapter in the development of pteridine chemistry. It does not seem improbable that other biological functions of the pteridines will be discovered in the near future.

## Formyl Chloride

By Prof. Dr. H. A. Staab and Dipl.-Chem. A. P. Datta

Organisch-chemisches Institut der Universität
Heidelberg (Germany)

When dry HCl is passed into a solution of an imidazolide [1] in chloroform or methylene chloride, an acid chloride is obtained as a result of acylation of the hydrogen chloride. Although the transacylation reaction (a) is reversible, as is shown by the formation of imidazolides from acid chlorides and imidazole, the acid chlorides are formed in practically quantitative yield, since imidazolium chloride formed in a subsequent reaction precipitates out. Acid chlorides whose synthesis by the usual methods is attended by difficulties can be prepared by this route, since imidazolides are readily accessible from carboxylic acids and 1,1'-carbonyldiimidazole.

The long sought for formyl chloride *(1)* has now been obtained on a preparative scale for the first time. We passed HCl into a solution of 1-formylimidazole [2] in $CHCl_3$ at −60 °C and filtered off the quantitative precipitate of imidazolium chloride formed in the cold through a sintered glass filter in a closed apparatus. The chloroform solution of *(1)* obtained as filtrate was stable for one hour at −60 °C. After addition of methanol, methyl formate was isolated in 65–70 % yield. At −40 °C, we obtained only 9 % ester under otherwise identical conditions. The thermal decomposition of *(1)* into CO and HCl, which is still being investigated quantitatively, was also followed by direct determination of the carbon monoxide evolved.

## Dicyclopentadienyleuropium

By Prof. Dr. E. O. Fischer and Dipl.-Chem. H. Fischer

Institut für Anorganische Chemie der Universität München
(Germany)

Treatment of the blue solution of metallic europium in liquid ammonia with cyclopentadiene in a ratio of 1:3.1, thermal degradation of the yellow reaction residue at 200 °C *in vacuo*, and rapid heating to 420–440 °C affords yellow dicyclopentadienyleuropium in 20 % yield in the form of a crystalline sublimate. This is the first "sandwich" compound prepared

which contains a divalent lanthanide. The complex is formed in accordance with the equation

$$Eu + 3\,C_5H_6 \xrightarrow{\text{liq. } NH_3} Eu(C_5H_5)_2 + C_5H_8$$

It is soluble in liquid ammonia and in dimethylformamide, is extremely sensitive to air and moisture, and has a magnetic moment of 7.62 B.M. [1]. Its paramagnetism is thus practically equal to that anticipated for the $Eu^{2+}$ ion (7.9 B.M.). The salt-like character of the complex, which must be assumed on the basis of this observation, is only slightly affected by covalent centric $\sigma$-bonding contributions, as is shown by the position of the $\gamma_{CH}$-frequency at 739 $cm^{-1}$ in the infrared spectrum. The presence of symmetrical five-membered rings follows from the $\nu_{CH}$-band at 3077 $cm^{-1}$, the $\omega_{CC}$-band at 1435 $cm^{-1}$, and the $\delta_{CH}$-absorption at 1007 $cm^{-1}$. The similarity between $r_{Eu^{2+}} = 1.09$ and $r_{Sr^{2+}} = 1.10$ Å, and the comparable bond character are reflected in the agreement between the corresponding frequencies of $Sr(C_5H_5)_2$ [2] (739, 3077, 1435, and 1008 $cm^{-1}$) and of $Eu(C_5H_5)_2$.

## Hydrothermal Sintering

By Prof. Dr. R. Brill and I. Melczynski

Fritz-Haber-Institut der Max-Planck-Gesellschaft, Berlin (Germany)

Various methods for thermal sintering of metal powders are known. A similar effect may be obtained with some metal powders by treating them with water. This effect was discovered accidentally, when we tried to wash iron carbonyl powder with water in a Soxhlet apparatus. After extraction for several hours, the metal powder had formed a firmly cohering cake. We found that the iron particles always cake together if they are placed in close contact with one another and then treated with warm water or boiled with water. The hydrothermally sintered solids are strong enough to be turned on a lathe; the exposed surface acquires the typical appearance of iron. The surface may also be polished to a high gloss, but under the microscope the polished surface exhibits a grained structure. There are some particles with a strong, metallic lustre besides some weakly reflecting ones and some dark, void spaces. The X-ray diagram shows not only the lines for $\alpha$-iron, but also those of iron spinel. On heating with water, the surface of the iron particles has therefore evidently reacted with the water, yielding the anhydrous spinel phase $Fe_3O_4$ as the effective product which firmly cements the individual iron particles together.

Closely similar effects have been observed with aluminum and zinc, starting with commercial Al and Zn powders. X-Ray studies showed that the metal particles are joined together by Böhmite and ZnO respectively.

It is interesting that the caking of the above metal powder particles produces structures that have enough mechanical strength for considerable amounts of other metals, which do not sinter hydrothermally on their own, or even of inert substances to be embedded in the cake. The mechanical strength of hydrothermally sintered solids does not appear to be high enough for engineering purposes. During their preparation they may, however, be easily combined with non-metals such as paper and plastics.

We do not intend to continue studies on hydrothermal sintering effects from either the scientific or the commercial point of view.

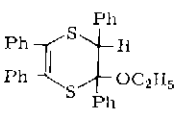
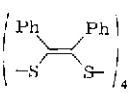
## Characterization and Stabilization of Dithiobenzil by Complex Formation

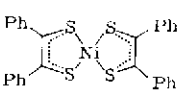


By Priv.-Doz. Dr. G. N. Schrauzer and H. W. Finck

Institut für Anorganische Chemie der Universität München (Germany)



According to *Mitra* [1], three compounds are formed in the reaction between benzoin and $H_2S$ in ethanolic HCl, *viz.* *(1)*, m.p. 195 °C, *(2)*, m.p. 126 °C, and *(3)*, m.p. 97 °C. As this author regarded *(3)* as monomeric dithiobenzil, we felt it desirable to check his claims, particularly since we were interested in *(3)* as a possible starting material for a new synthesis of bis(dithiobenzil)nickel *(4)*, which can also be obtained, for example, from nickel sulfide and tolane [2]. Although we were able to confirm *Mitra*'s results, a revision of the structures he suggests is necessary. In agreement with *R. Mayer* and *Nitzschke* [3], we found that *(1)* is tetraphenyldithiacyclohexadiene and that *(2)* is 5-ethoxy-2,3,5,6-tetraphenyl-1,4-dithiacyclohexene; however, we also



*(1)*

*(2)*

*(3)*

*(4)*

Ph = $C_6H_5$

succeeded in isolating *(3)* (softening point 105–110 °C, yield: 3 % based on benzoin) in solid, analytically pure, but non-crystalline form [4]. Molecular-weight determinations show that *Mitra*'s dithiobenzil is actually tetrameric. In the proton magnetic resonance spectrum only signals of the phenyl protons were detectable. Therefore, a cyclic structure with S–S bonds could be present. When heated, *(3)* decomposes into sulfur and tetraphenylthiophene. On treatment with $Ni(CO)_2 \cdot 2P(C_6H_5)_3$ in xylene, *(3)* gives the nickel complex *(4)* in good yield. The same complex is formed when benzoin is reacted with $H_2S$ under the above conditions in the presence of $NiCl_2$ (yield 10 % based on benzoin). In this reaction, the unstable precursor of *(3)*, dithiobenzoin, is trapped by the added metal salt.

## 1,2- and 1,4-Hydrostannation of Conjugated Dienes

By Priv.-Doz. Dr. W. P. Neumann and Dipl.-Chem. R. Sommer

Chemisches Institut der Universität Gießen (Germany)

Hydrostannation of $\alpha$-olefins [1] proceeds by way of radicals [1a, 2]. Therefore, it seemed worthwhile to examine the behavior of conjugated dienes in this reaction. Butadiene, substituted butadienes *(2)*, and cyclopentadiene are readily hydrostannated by a radical mechanism at 60–80 °C. Radical scavengers inhibit, radical-producing agents accelerate the reaction. The main product is the 1,4-adduct

*(3)* shown in Equation (a), together with only a small quantity of the 1,2-adduct *(4)* [3]. The product *(3)* has mainly the *trans*-configuration (strong absorption at 950 to 960

(a) $R_3SnH$ + $H_2C{=}CR^1{-}CR^2{=}CHR^3$ ⟶
*(1)* *(2)*
$R_3Sn{-}CH_2CR^1{=}CR^2{-}CH_2R^3$ + $R_3Sn{-}CH_2{-}CHR^1{-}CR^2{=}CHR^3$
*(3)* *(4)*

$cm^{-1}$). The trialkylstannyl group adds preferentially to the unsubstituted end of the conjugated system *(2)*. If, as in Equation (b), a primary carbon atom can become a radical center ($R^3 = H$), this reacts preferentially with the H of a further molecule of *(1)*; about 80 % of the 1,4-adduct *(3)* as obtained. If only secondary carbon atoms are radical centers

(b) $R_3Sn{-}CH_2{-}\dot{C}R^1{-}CR^2{=}CHR^3 \leftrightarrow R_3Sn{-}CH_2{-}CR^1{=}CR^2{-}\dot{C}HR^3$

($R^3$ = methyl), the yield of 1,2-adduct *(4)* rises to ca. 35 %. With dimethylbutadiene ($R^1 = R^2 = CH_3$), the tertiary carbon atom is apparently favored as a radical center [left-hand limiting structure in (b)], leading to an increased proportion of *(4)*. The same effect in the case of phenylbutadiene ($R^3 = C_6H_5$) probably causes its tendency to form the styrene system. Diisobutylstannane reacts analogously to *(1)*.

For analysis of the mixtures *(3)* + *(4)*, among other methods, titration with iodine at 0–20 °C was used for the selective estimation of *(3)*, for iodine splits off the allylic alkylstannyl group rapidly and quantitatively. We have also prepared a number of possible isomers by independent synthesis.

Table 1. Hydrostannation of dienes according to Reaction (a) at 70–75 °C. Catalyst: azoisobutyronitrile; excess of diene: 100 %.

| Diene | Organotin hydride | Adduct (Yield *(3)* + *(4)* = 75–96 %) b.p. [°C/mm Hg] | % 1,4- *(3)* | % 1,2- *(4)* |

Pollard* (Chem. and Ind. *1963*, 1493) expected to obtain only the 1,2-adduct on addition of trimethylstannane onto piperylene, without considering the possibility of 1,4-addition. They assumed that the geometric isomerism of piperylene was the reason for the appearance of several products.

## Synthesis of 1,3-Dithiole-2-thiones ("Isotrithiones")

By Prof. Dr. Roland Mayer, Dipl.-Chem. B. Gebhardt, Dipl.-Chem. J. Fabian, and A. K. Müller

Institut für Organische Chemie
der Technischen Universität Dresden (Germany)

1,3-Dithiole-2-thiones (1,3-dithiacyclopentene-2-thiones) arise by the simultaneous action of carbon disulfide and sulfur on acetylene in polar solvents at somewhat elevated temperatures or from sodium acetylides with carbon disulfide and sulfur (*e.g.* in acetonitrile) at room temperature. Mercaptoethynyl compounds [1], which are produced by the action of sulfur on sodium acetylides, also add on carbon disulfide in polar solvents at room temperature, and are cyclized by nucleophilic attack of the thiolic sulfur of the trithiocarbonate group on the triple bond.

*(1)*: R = $C_6H_5$
*(2)*: R = H

Average yields of 50–70 % are obtained. Thus, sodium phenylacetylide affords 60 % phenyl-1,3-dithiole-2-thione *(1)* when the reaction is performed in acetonitrile. The parent compound, *viz.* 1,3-dithiole-2-thione *(2)*, is accessible in 25 % yield from acetylene or sodium acetylide [2].

## Cyclopentadienyl-(benzene)-molybdenum

By Prof. Dr. E. O. Fischer and Dipl.-Chem. F. J. Kohl

Institut für Anorganische Chemie
der Universität München (Germany)

In the course of an investigation of the behavior of $[C_5H_5MC_6H_6(CO)]^+$ ions (M = Mo or W) [1] toward nucleophilic reagents, we discovered a new type of synthesis for $C_5H_5MC_6H_6$ π-complexes. If red $[C_5H_5MoC_6H_6(CO)]PF_6$ is treated with hydride ions as nucleophilic reagent, the carbonyl group is eliminated and cyclopentadienyl-(benzene)-molybdenum, m.p. 216–218 °C, is obtained according to the equation:

$$[C_5H_5MoC_6H_6(CO)]PF_6 \xrightarrow[0\,^\circ C]{LiAlH_4/THF} C_5H_5MoC_6H_6$$

The red compound is soluble in organic solvents, sublimes *in vacuo* above 50 °C, and is extremely sensitive to air. Evidence for its sandwich structure is provided by its infrared spectrum. In agreement with earlier studies carried out on $C_5H_5CrC_6H_6$ [2], typical absorptions are observed at 1404, 1096, 996, 814, and 791 $cm^{-1}$ for the covalently bonded, symmetrical $C_5H_5$-ligand (sym. $C_5v$) in Nujol/Hostaflon. Absorption bands at 1404, 977, 950, 838, and 761 $cm^{-1}$ may be assigned to the π-bonded undistorted benzene-ligand (sym. $C_6v$). The paramagnetism of the compound (1.68 B.M.) [3] corresponds to the value for one unpaired electron. The substance $C_5H_5(C_6H_6)MoH$ which would be a feasible intermediate between $(C_5H_5)_2MoH_2$ [4] and $(C_6H_6)_2Mo$ [5] in the isoelectronic series, was not observed.

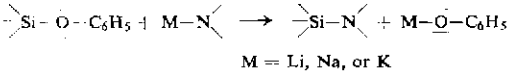
## Conversion of Si—O into Si—N Bonds [1]



By Prof. U. Wannagat, Dr. P. Geymeyer,
and Dipl.-Ing. G. Schreiner

Institut für Anorganische Chemie
der Technischen Hochschule Graz (Austria)

Silicon-nitrogen compounds are considered – sometimes mistakenly – to react with water; they are converted into silicon-oxygen compounds by alcohols and especially by acids.

We found that the reverse of this process occurs when phenoxysilanes are treated with alkali metal derivatives of amines.

M = Li, Na, or K

Stoichiometric amounts of the components in 400–500 ml of petroleum ether or benzene are heated to boiling for 2–3 hours for molar charges; the Na or K phenoxide formed precipitates out quantitatively and is then filtered off ($LiOC_6H_5$ is best converted with $(CH_3)_3SiCl$ into LiCl and $(CH_3)_3SiOC_6H_5$), the SiN compounds being obtained in over 75 % yield by fractional distillation.

$LiN(C_2H_5)_2$, $NaN[Si(CH_3)_3]_2$, or $KN(C_6H_5)_2$ removes only one phenoxyl group per Si atom; this limitation does not hold for $NaNH_2$.

A selection of previously unknown SiN compounds prepared by this procedure is given in Table 1.

Table 1. New Si–N compounds prepared from phenoxysilanes and substituted alkali amides

| Starting materials R = $CH_3$, R′ = $C_2H_5$, R″ = n-$C_3H_7$ | | Si—N compounds | B. p. [°C/mm] |
|---|---|---|---|
| $R_2Si(OC_6H_5)_2$ | $LiNR''_2$ | $R_2(C_6H_5O)SiNR''_2$ | 95–97/1 |
| $RSi(OC_6H_5)_3$ | $KN(C_6H_5)_2$ | $R(C_6H_5O)_2SiN(C_6H_5)_2$ | 162/2 |
| $R_2Si(OC_6H_5)NR'_2$ | $NaNH_2$ | $R_2Si(NH_2)NR'_2$ | 38–39/13 |
| $R_2Si(OC_6H_5)NHR'$ | $NaNH_2$ | $[R_2(R'NH)Si]_2NH$ | 46–48/1 |

## Elimination of HCl from Gaseous cis- and trans-Chlorostilbene [1]

By Dr. P. Andréu, Lic. E. Schmitz, and Dr. H. Noller [2]

Physikalisch-Chemisches Institut der Universität München (Germany)

The loss of HCl from alkyl halides in the liquid phase is a *trans*-α,β-elimination with an ionic mechanism. Eliminations on catalysts have so far been little studied.

We have now examined the elimination of HCl from *cis*- and *trans*-chlorostilbene (1,2-diphenylchloroethylene) in the vapor phase on several salt and oxide catalysts. Which mode of elimination occurs or is favored invariably depends upon the different reactivities of the two isomers. Both modes of elimination give rise to tolane (diphenylacetylene).

Table 1. The elimination of HCl from *cis*- and *trans*-chlorostilbene on various catalysts.

| Catalyst | Substrate | Arrhenius parameters E [kcal/mole] | Arrhenius parameters A (relative) | Temp. [°C] | Yield of [*] Tolane [%] | Yield of [*] Isomer [%] |
|---|---|---|---|---|---|---|
| $MnO_2$ | *cis*-chlorostilbene | 8 | $1.2\times10^5$ | 250 | 14 | 0 *trans*-chlorostilbene |
| | *trans*- | 24 | $4.8\times10^9$ | 250 | 5 | 0 *cis*- |
| $BaCl_2$ | *cis*- | 11 | $2.2\times10^6$ | 250 | 17 | 19 *trans*- |
| | *trans*- | 20 | $3.2\times10^8$ | 250 | 8 | 4 *cis*- |
| CdO | *cis*- | 9 | $5.5\times10^5$ | 260 | 100 | 0 *trans*- |
| | *trans*- | 8 | $1.5\times10^5$ | 260 | 8 | 1 *cis*- |
| MgO | *cis*- | 9 | $2.6\times10^5$ | 250 | 35 | 2 *trans*- |
| | *trans*- | 10 | $2.1\times10^5$ | 250 | 26 | 1 *cis*- |
| CaO | *cis*- | 9 | $7.8\times10^5$ | 283 | 11 | 0 *trans*- |
| | *trans*- | 7 | $5.6\times10^4$ | 283 | 12 | 0 *cis*- |
| $CaCl_2$ | *cis*- | 7 | $2.1\times10^5$ | 350 | 41 | 24 *trans*- |
| | *trans*- | 8 | $1.4\times10^5$ | 350 | 22 | 0 *cis*- |
| $Al_2O_3$ | *cis*- | – | – | 250 | 100 | 0 *trans*- |
| neutral | *trans*- | 10 | $1.4\times10^6$ | 250 | 0 | 0 *cis*- |

[*] The rest of the material was unchanged.

As Table 1 shows, the *cis*-isomer reacts more readily and, with few exceptions, its activation energy is lower. This means that both *cis*- and *trans*-elimination can occur, but that *cis*-elimination is favored.

Isomerization does not occur to any considerable extent on oxide catalysts, presumably because the HCl formed (without which isomerization cannot take place) is bound on the surface of the catalyst. Isomerization does occur on chlorides, but it is nevertheless apparent that the *cis*-isomer reacts directly and more easily.

Measurements were carried out by gas chromatography at 230–430 °C using the pulse technique; the catalyst chamber was interposed in the carrier-gas train before the chromatography column. The residence time of the chlorostilbene on the catalyst was about 0.1 sec. The amount of reactant injected as a saturated acetone solution was 1.0–1.5 µl for the *cis*-isomer and 3.0 µl for the *trans*-isomer; the amount of catalyst was about 2.5 g.

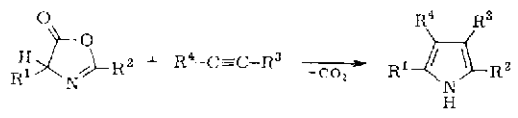
## Azlactones as 1,3-Dipoles; A New Pyrrole Synthesis

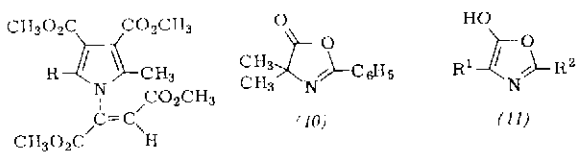


By Prof. Dr. R. Huisgen, Dr. H. Gotthardt,
and Dr. H. O. Bayer

Institut für Organische Chemie der Universität München (Germany)

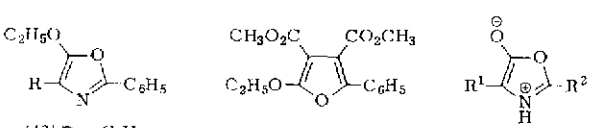
When the azlactone *(1)*, $R^1 = R^2 = C_6H_5$, is heated with dimethyl acetylenedicarboxylate in xylene at 100 °C, dimethyl 2,5-diphenylpyrrole-3,4-dicarboxylate *(2)* is formed in 83 % yield within 2 hr. Alkaline hydrolysis and decarboxylation of *(2)* lead to 2,5-diphenylpyrrole.

5-Oxazolones *(1)* with either aromatic or aliphatic substituents can be used in this reaction, and the acetylene dicarboxylic ester can be replaced by methyl propiolate. The same pyrrole derivative *(5)* is obtained from the azlactones



of either *N*-benzoylalanine or *N*-acetylphenylglycine. The preparative application of this new pyrrole synthesis is simplified by the fact that alkyloxazolones, which are unstable and difficult to purify [1], can be used *in situ*. Thus, *(5)* is obtained by the reaction of phenylglycine or *N*-acetylphenylglycine with dimethyl acetylenedicarboxylate in acetic anhydride.

*(1)* *(2)* to *(7)*



| | $R^1$ | $R^2$ | $R^3$ | $R^4$ | Yield [%] | M.p. [°C] |
|---|---|---|---|---|---|---|
| *(2)*: | $C_6H_5$ | $C_6H_5$ | $CO_2CH_3$ | $CO_2CH_3$ | 83 | 149–150 |
| *(3)*: | $o$-$NO_2C_6H_4$ | $C_6H_5$ | $CO_2CH_3$ | $CO_2CH_3$ | 60 | 158–160 |
| *(4)*: | $C_6H_5$ | $p$-$CH_3OC_6H_4$ | $CO_2CH_3$ | $CO_2CH_3$ | 98 | liquid |
| *(5)*: | $CH_3$ | $C_6H_5$ | $CO_2CH_3$ | $CO_2CH_3$ | 72 | 127–128 |
| *(5)*: | $C_6H_5$ | $CH_3$ | $CO_2CH_3$ | $CO_2CH_3$ | 78 | 127–128 |
| *(6)*: | $C_6H_5$ | $C_6H_5$ | $CO_2CH_3$ | H | 55 | 172–173 |
| *(7)*: | $CH_3$ | $C_6H_5$ | ($CO_2CH_3$, H) | | 98 | liquid |

The pyrrole derivatives which are formed similarly *in situ* from 2,4-dimethyl- or 4-benzyl-2-methyloxazolone and dimethyl acetylenedicarboxylate undergo nucleophilic addition onto a second molecule of the acetylenic ester to give *(8)* and *(9)*, respectively.

*(8)* R = $CH_3$
*(9)* R = $C_6H_5$–$CH_2$

This surprising pyrrole synthesis is similar to the 1,3-dipolar additions of sydnones, which yield pyrazoles with elimination of $CO_2$ [2]. The oxazolones *(1)* cannot be 1,3-dipoles as long as the 4-position retains its $sp^3$-character. The fact that the 4,4-disubstituted oxazolone *(10)* does not react with dimethyl acetylenedicarboxylate at 180 °C suggests that the preliminary stage is tautomerization of the oxazolone. 5-Hydroxyoxazole *(11)* cannot be the intermediate, as the 5-ethoxyoxazoles *(12)* and *(13)* react with dimethyl acetylenedicarboxylate by Diels-Alder addition and subsequent fission to give dimethyl 2-ethoxy-5-phenylfuran-3,4-dicarboxylate *(14)* and benzonitrile or acetonitrile

*(12)* R = $C_6H_5$
*(13)* R = $CH_3$
*(14)*
*(15)*

A moderate equilibrium concentration of the mesoionic tautomer *(15)* is essential for the 1,3-dipolar cycloaddition leading to pyrrole formation to occur [3].

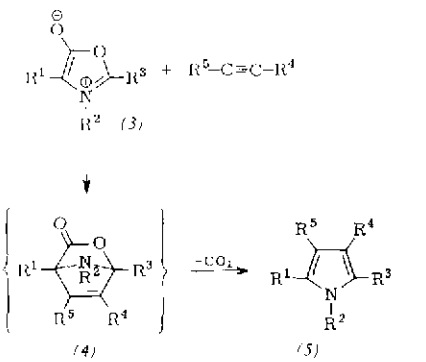
## A New Type of Mesoionic Aromatic Compound and Its 1,3-Dipolar Cycloaddition Reactions with Acetylene Derivatives

By Prof. Dr. R. Huisgen, Dr. H. Gotthardt, Dr. H. O. Bayer, and Dr. F. C. Schaefer

Institut für Organische Chemie der Universität München (Germany)



If *N*-benzoyl-*N*-methylphenylglycine *(1)* is treated with acetic anhydride at 55 °C for a few minutes, bright yellow crystals of the mesoionic compound *(2)* are obtained in 90 % yield. The synthesis of oxazole derivatives of this type, which can be formulated only as zwitterionic structures, is analogous to that of the sydnones from *N*-nitroso-*N*-alkylamino acids [1].

*(1)*
*(2)* $CH_3$ *(2a)* $CH_3$

The mesoionic [2] derivatives *(3)* of azlactones are readily hydrolysed and undergo the Dakin-West reaction with acetic anhydride at elevated temperatures; it is probably for these reasons that they have previously escaped notice. Anhydro-5-hydroxyoxazolium hydroxides *(3)* may provide the key to an understanding of the Dakin-West reaction [3].

The mesoionic oxazolones *(3)* undergo cycloadditions with acetylenecarboxylic esters at 0–70 °C to produce *N*-substituted pyrroles *(5)* with liberation of carbon dioxide. Phenyl- and alkyl-substituted acetylenes also react at 70–100 °C.

| H | $CH_3$ | $CH_3$ | $CO_2CH_3$ | $CO_2CH_3$ | 37 | 88–89 |
| H | $C_6H_5$ | H | $CO_2CH_3$ | $CO_2CH_3$ | 92 | 117–118 |
| $-(CH_2)_3-$ | | $CH_3$ | $CO_2CH_3$ | $CO_2CH_3$ | 76 | 102–103 |

The intermediate *(3)* need not be isolated. Since the cycloaddition reaction proceeds more rapidly than the Dakin-West reaction, the *N*-acyl-*N*-alkyl- or -*N*-arylamino acid *(1)*

is simply treated with the alkyne in acetic anhydride. Thus, dimethyl 5-methyl-1,2-trimethylenepyrrole-3,4-dicarboxylate is obtained in 76 % yield by merely warming proline with dimethyl acetylenedicarboxylate in acetic anhydride at 130 °C for 1 hr.

The kinetics of the release of carbon dioxide indicate that the acetylenic dipolarophile first combines with *(3)*, presumably to form the bicyclic adduct *(4)*; the elimination of $CO_2$ from *(4)* is a rapid subsequent reaction. Compound *(3)* belongs to the azomethine-ylide class of 1,3-dipoles [4], cf. the sextet structure *(2a)*; here the 1,3-dipole system is part of an aromatic ring. *H. Staudinger* [5] has proposed the term "nitrenes" for azomethine ylides. The first representatives have recently been described [6].

## Tris(biphenylenevinyl)methane [1]

By Prof. Dr. Richard Kuhn and Dr. Herbert Fischer

Institut für Chemie, Max-Planck-Institut für Medizinische Forschung, Heidelberg (Germany)

Bis(biphenylene)pentadienone *(1)* reacts with iodomethylenetriphenylphosphorane to give yellow needles of *(2)*, m.p. 152–153 °C. Condensation of *(2)* with fluorene in dimethylformamide in the presence of sodium hydroxide yields a hydrocarbon which crystallizes in colorless prisms, m.p. 235–237 °C (decomp.), molecular weight 540. This is tris(biphenylenevinyl)methane *(3a)*, somewhat contaminated by its structural isomer *(3b)*, judging by its ultraviolet spectrum [2]. The new hydrocarbon is about 300 times more acidic than the bis(biphenylene)pentadiene *(4)* described in our third communication [1] (pK of *(3a)* [*] in a 1:1 acetone/pyridine mixture: 6.2; pK of *(4)*: 8.8). The anion of *(3a)* has an absorption maximum at 645 mμ ($\varepsilon = 10^5$), *i.e.* at only slightly longer wavelength than that of the anion of *(4)* ($\lambda_{max}$ = 633 mμ). The high acidity of the hydrocarbon and the absorption band of the anion are in agreement with the predictions of the molecular orbital theory [3] (delocalization energy of *(4)*: 2.22 β, delocalization energy of *(3a)*: 2.50 β; calculated absorption band for the anion of *(3a)*: *ca.* 630 mμ).

$$(\text{BiphC=CH})_2\text{CO} + \text{Ph}_3\text{P=CHI} \rightarrow (\text{BiphC=CH})_2\text{C=CHI}$$
*(1)* *(2)*

$$\xrightarrow[\text{DMF/OH}^{\ominus}]{\text{BiphCH}_2} (\text{BiphC=CH})_3\text{CH} + (\text{BiphC=CH})_2\text{C=CH—CHBiph}$$
*(3a)* *(3b)*

$(\text{BiphC=CH})_2\text{CH}_2$ *(4)*

Biph = Biphenylene

The preparation of 1,1,5,5-bis(biphenylene)-3-(diphenylvinyl)-pentadiene *(6)* from 1,1-diphenyl-5,5-biphenylenepentadienone *(5)* was achieved similarly. In addition to *(6)*, two structural isomers are possible, one of which can also be expected to have geometric isomers. The anion of *(6)* absorbs at 675 mμ.

$$(\text{Ph})_2\text{C—CH—CO—CH=CBiph} \xrightarrow{\text{as above}} (\text{BiphC=CH})_2\text{CH—CH=CPh}$$
*(5)* *(6)*

1,1,5,5-Bis(biphenylene)-3-phenylpentadiene *(7)* was prepared by condensation of styrylfluorenol and methylfluorenol by the method of *Wawzonek* [4, 1] as colorless rods [5], m.p. 192–193 °C, and is at least 100 times less acidic than the pentadiene *(4)* (pK of *(7)* in a 1:1 acetone/pyridine mixture *ca.* 11). Its anion absorbs at 686 mμ ($\varepsilon = 82\times10^3$).

$$\underset{\text{OH}}{\text{BiphC—CH=CH—Ph}} + \underset{\text{OH}}{\text{CH}_3\text{—CBiph}} \rightarrow (\text{BiphC=CH})_2\text{CH—Ph} \quad (7)$$

The hydrocarbon *(3a)* is an analogue of tris-(β,β-diphenylvinyl)methane, which requires treatment with phenylisopropylpotassium to convert it into an anion [6].

## Bis(trimethylsilyl)aminodimethylarsine and Tris(dimethylarsino)amine

By Dr. O. J. Scherer and Prof. Dr. Max Schmidt

Institut für Anorganische Chemie der Universität Marburg/L., (Germany)

In connection with studies of hetero-tris(trimethylsilyl)amines [1], we have prepared bis(trimethylsilyl)aminodimethylarsine *(1)* in 75 % yield from dimethylchloroarsine and sodium bis(trimethylsilyl)amide [2] in dry ether according to the equation:

$$[(\text{CH}_3)_3\text{Si}]_2\text{NNa} + \text{ClAs}(\text{CH}_3)_2 \rightarrow \underset{(\text{CH}_3)_3\text{Si}}{\overset{(\text{CH}_3)_3\text{Si}}{\text{N—As}(\text{CH}_3)_2}} + \text{NaCl}$$
*(1)*

The product is a liquid (m.p. −46 to −44 °C, b.p. 45–46 °C/1 mm) which is colorless, sensitive toward oxygen and moisture, and is cleaved at the As–N bond by methyl-lithium with formation of $[(\text{CH}_3)_3\text{Si}]_2\text{NLi}$ and $\text{As}(\text{CH}_3)_3$. The NMR spectrum of *(1)* [two signals, area ratio 1 ($\delta = -77.8$ cps) : 3 ($\delta = -10.0$ cps)] shows that there is no migration of the silyl group from the nitrogen to the arsenic. Compound *(1)* is not cleaved even at 120 °C by excess chloroarsine.

$$(1) + 2\ \text{ClAs}(\text{CH}_3)_2 \not\rightarrow 2\ (\text{CH}_3)_3\text{SiCl} + \underset{\text{As}(\text{CH}_3)_2}{\overset{(\text{CH}_3)_2\text{As}}{\overset{|}{\text{N}}}}\!\!\diagdown\!\!\diagup\!\!\text{As}(\text{CH}_3)_2$$
*(2)*

We obtained tris(dimethylarsino)amine in 50 % yield as colorless prisms, m.p. 22–25 °C, b.p. 57–58 °C/1 mm, by heating bis(trimethylsilyl)amine with dimethylchloroarsine without solvent for 6 hours at 100–120 °C. Its NMR spectrum shows only one signal ($\delta = -69.0$ cps). Compound *(2)* is extremely sensitive towards oxygen and moisture.

## Preparation of Trimethyltin Methoxide

By Priv.-Doz. Dr. E. Amberger, Dr. Maria-Regina Kula, and Dipl.-Chem. J. Lorberth

Institut für Anorganische Chemie der Universität München (Germany)

Pure trimethyltin methoxide *(1)* cannot be secured by the reaction of trimethyltin chloride with sodium methoxide [1]. The pure product can however be prepared by careful methanolysis of trimethyltin diethylamide in diethyl ether at −50 °C.

$$(CH_3)_3SnN(C_2H_5)_2 + CH_3OH \rightarrow \underset{(1)}{(CH_3)_3SnOCH_3} + HN(C_2H_5)_2$$

After removal of volatile matter *in vacuo* at −50 to −10 °C, trimethyltin methoxide is left as a colorless powder in 95 % yield. It can be obtained as needles and prisms by sublimation at 0.1 mm. It decomposes gradually above 45 °C and, depending on the rate of heating, melts within the range 45 to 75 °C. Its NMR spectrum (Varian A 60, 32 °C, saturated solution in $CCl_4$) displays two peaks with an area ratio of 1 : 3 which are displaced about 209 and 21.5 cps to lower fields relative to TMS as internal standard. The spin-spin coupling constants are $J_{^{119}SnCH_3} = 56.7$ cps and $J_{^{117}SnCH_3} = 54.9$ cps. Coupling with the protons of the methyl group bound to the oxygen was not observed.

The infrared spectrum in Nujol has an Sn–O–C vibration at 1035 $cm^{-1}$, in accordance with earlier results [1].

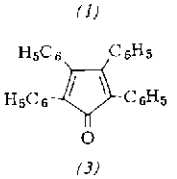
## Photolysis of 1-Tosylamino-1,2,3-triazole Anions; A New Synthesis of Alkynes

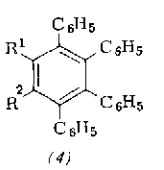
By Dr. F. G. Willey [1]

Organisch-Chemisches Institut
der Universität Heidelberg (Germany)

On photolysis of compounds containing more than two nitrogen atoms in a ring, expulsion of one mole-equivalent of nitrogen at the most has hitherto been observed [2].



Unsubstituted 1,2,3-triazoles, or those bearing only hydrocarbon groups at positions 4 and 5, are both thermally and photochemically stable [3]. 1-Amino-1,2,3-triazoles, the corresponding 1-sulfonylamino derivatives [4], and the salts of these sulfonamides *(1)* are also quite stable to heat. Thus, *(1a)* and *(1e)* are recovered unchanged after refluxing in ethylene glycol, but they lose nitrogen slowly on heating in the solid state to ca. 300 °C.



*(1)*

*(2)*

*(3)*

*(4)*

| | $R^1$ | $R^2$ |
|---|---|---|
| *(1a)*: | $C_6H_5$ | $C_6H_5$ |
| *(1b)*: | $-(CH_2)_4-$ | |
| *(1c)*: | $-(CH_2)_5-$ | |
| *(1d)*: | $-(CH_2)_6-$ | |
| *(1e)*: | $CH_3$ | $CH_3$ |

Ts = $H_3C-C_6H_4-SO_2$

| | $R^1$ | $R^2$ |
|---|---|---|
| *(4b)*: | $-(CH_2)_4-$ | |
| *(4c)*: | $-(CH_2)_5-$ | |
| *(4d)*: | $-(CH_2)_6-$ | |
| *(4e)*: | $CH_3$ | $CH_3$ |

Photolysis, on the other hand, of *(1)* [no maximum above 210 mμ, absorption begins at ca. 300 mμ, $\varepsilon_{220} = 3000-7000$] results in evolution of two mole-equivalents of nitrogen, with formation of an alkali metal toluenesulfinate and the corresponding alkyne, which can be trapped if necessary with tetraphenylcyclopentadienone *(3)*; cf. Table 1. Results obtained so far are summarized in Table 1.

| Experiment | Starting material | Conditions [b] | Yield of *(2)* [%] [a] | Yield of *(4)* [%] [a] |
|---|---|---|---|---|
| 1 | *(1a)* | [c] | 85 | — |
| 2 | *(1a)* [*] | [a] | 85 | ... |
| 3 | *(1b)* | [c,e] | — | *(4b)*, 54 |
| 4 | *(1c)* | [c,e] | — | *(4c)*, 56 |
| 5 | *(1c)* | [f] | . | *(4c)*, 26 |
| 6 | *(1d)* | [c] | — | *(4d)*, 77 |
| 7 | *(1e)* | [c,e] | — | *(4c)*, <2 |

[*] Cation K instead of Li.

[a] Based on nitrogen evolved or on starting material decomposed. Evolved $N_2$ + recovered starting material = 100 %.

[b] Irradiated with a Q 81 immersion lamp (Quarzlampengesellschaft m.b.H. Hanau, Germany) in a nitrogen atmosphere at 35–40 °C, unless otherwise specified.

[c] In absolute dioxan.

[d] In 90 % dioxan/10 % water.

[e] In the presence of one equivalent of *(3)*.

[f] In diglyme at ca. −25 °C.

In experiments 5 and 6, *(1c)* and *(1d)* respectively were irradiated, the lamp was switched off, and about two minutes later a solution of *(3)* was injected into the apparatus. Experiment 5 thus represents the first definite observation of free cycloheptyne, since here, as well as with *(1b)*, control experiments showed that no adduct was formed via thermal decomposition of *(1c)* or *(1b)*. Irradiation of *(1e)* leads to 2-butyne, which reacts only slowly with *(3)*; *(1e)*, *(1b)*, and *(1c)*, or any intermediates formed from them prior to nitrogen loss, would be expected to exhibit similar reactivities toward *(3)*. The low yield of adduct obtained upon irradiation of *(1e)* in the presence of *(3)* thus indicates that the adducts *(4)* are formed by reaction of free alkynes, and not of some nitrogenous intermediates, with *(3)*.

This method is of interest as a general synthesis of alkynes, particularly symmetrical ones. The results obtained support earlier work in which the formation of cycloalkynes was also postulated [4b, 5].

Further work on the mechanism of this decomposition, and on its extension to the generation of arynes is anticipated.

# Hauptversammlung der Gesellschaft Deutscher Chemiker (General Meeting of the German Chemical Society)

**Heidelberg, September 9th–14th, 1963**

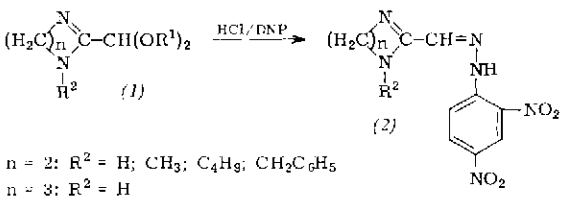
A General Meeting of the German Chemical Society is held every two years. Over 2700 chemists from Germany and abroad participated in the 1963 meeting, at which 9 plenary lectures were delivered and 202 short papers were read. The following is a selection of the most important results presented at this meeting.

## Preparation of Red α-Rhombohedral Boron

*E. Amberger* and *W. Dietze*, München (Germany)

Pyrolysis of boron triiodide on tantalum wires of 0.2–2 mm diameter at 800–1000 °C causes formation of a layer of coarse crystalline α-rhombohedral boron which has a thickness of up to 5 mm and which contains small amounts of amorphous glass-like black boron as tiny islands. The ruby-red transparent boron crystals are 2 mm long. Some warts of a grey tetragonal modification of boron are occasionally formed on the surface of the boron layer. The separation of red B can only be reproduced if certain experimental conditions are observed: use of purest grades of boron iodide, extremely pure pyrolysis atmosphere and Ta surface (in particular, free from O and C), and a constant wire temperature (the absolute value is however not critical). $BI_3$ is prepared by treating $LiBH_4$ with $I_2$ in n-hexane and is frozen out. It is then purified by zone melting. Foreign atoms were not detected by spectral analysis in either the $BI_3$ or the α-B. In the preparative method described, the α-boron is not formed from the vapor phase on the surface of the boron deposit to the same extent as the boron is formed pyrolytically from the $BI_3$, but crystallizes out in a secondary process from the very pure X-ray-amorphous boron which is initially formed. A further purification probably takes place thereby. If slightly less pure $BI_3$ is used to prepare the α-B, only microcrystalline α-B with significant proportions of impure boron is formed whereas $BI_3$ purified by zone melting forms predominantly coarsely crystalline α-B.

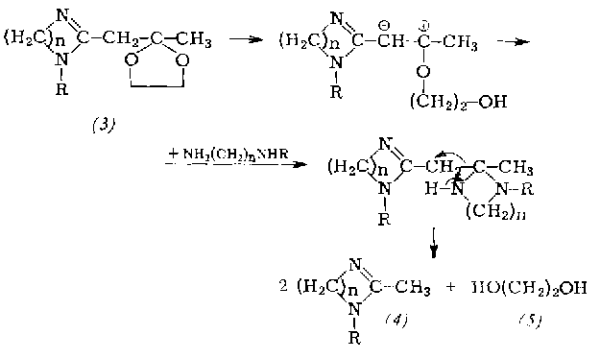
## Determination of Lithium by Activation Analysis



*D. C. Aumann* and *H. J. Born*, München (Germany)

A process for the determination of both traces of lithium and macroscopic lithium contents has been worked out, the nuclear reactions $^6Li(n,\alpha)^3H$ and $^{16}O(t,n)^{18}F$ being utilized. The irradiated specimens were worked up chemically in order to purify the fluoride obtained. Oxygen-free specimens were either mixed with an oxidizing agent or converted into oxygenated compounds before irradiation. The limit of detection of the method lies at $3\times10^{-8}$–$6\times10^{-8}$ g of lithium at a neutron flux of $5\times10^{12}$ n/cm²/sec. The dependence of the induced $^{18}F$ activity per unit weight of lithium on the number of oxygen atoms per cm³ ($N_0$) and on the range of the tritium nuclei (R) in the substance under investigation may be compensated using calculated values of the product $N_0\times R$. The substance to be alanysed and the standard need not have similar compositions; on the contrary, a pure lithium compound may serve as the standard.

## Fragmentations in the Imidazoline Series



*H. Baganz*, Berlin (Germany)

Following hydrolysis of acetals of the imidazoline and tetrahydropyrimidine series *(1)* in the presence of dinitrophenylhydrazine, the 2-carboxaldehydes were isolated as their dinitrophenylhydrazones *(2)*. In the absence of the carbonyl reagent, the aldehydes decomposed during hydrolysis in the strongly acidic medium, with regeneration of the original diamine and formation of formic acid, $CO_2$, and CO.

n = 2: $R^2$ = H; $CH_3$; $C_4H_9$; $CH_2C_6H_5$
n = 3: $R^2$ = H

On the assumption that the influence of the imidazoline system on the hydrolysis of an acetal or ketal group decreases with increasing distance, an attempt was made to obtain compounds of type *(3)* by treating ketals of β-ketocarboxylic esters with ethylenediamine derivatives or with trimethylenediamine. In these reactions, however, fragmentation of the molecule into lysidine derivatives *(4)* and ethylene glycol *(5)* in a ratio of 2:1 was invariably observed. On the basis of detailed experiments, it is assumed that, after formation of the imidazoline ring, the dioxolane ring is cleaved, and the ethylenediamine attacks the polarized double bond, with simultaneous elimination of ethylene glycol. The intermediate imidazoline ring is thereupon stabilized by prototropy.

n = 2: R = H, $CH_3$; $C_4H_9$; $CH_2C_6H_5$
n = 3: R = H

On the other hand, farther separation of the imidazoline ring from the carbonyl group has a stabilizing effect on the ethyleneketal structure. Thus, 3-(*N*-butyl-2-imidazolylethyl) methyl ketone ethyleneketal can be obtained and is convertible, after hydrolysis, into the γ-carbonyl compound.

## Systematic Examination of the System EuO-$Eu_2O_3$

*H. Bärnighausen*, Freiburg/Breisgau (Germany)

A new method for the preparation of EuO from europium oxide halides in accordance with the equation

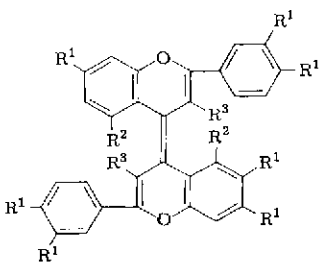
$$EuOX + LiH \rightarrow EuO + LiX + {}^1/_2\,H_2$$

has been developed. Samples with higher oxygen content were obtained by annealing finely powdered EuO–$Eu_2O_3$ mixtures of variable compositions at 800–900 °C in an

atmosphere of a carefully purified inert gas. X-ray identification of the annealed products showed that $Eu_3O_4$, which crystallizes in the orthorhombic system, occurs between EuO and $Eu_2O_3$.

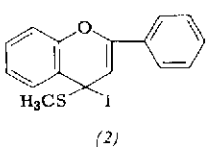
To carry out the analysis, a current of nitrogen containing bromine is passed over the samples at 400 °C. The divalent europium is converted into EuOBr so that it is possible to calculate the original composition from the increase in weight. X-ray examination of the system $EuOBr-Eu_2O_3$ led to the new compound $Eu_3O_4Br$, which also crystallizes in the orthorhombic system (a = 11.986, b = 11.854, c = 4.124 Å; possible space groups: Bbmm and $Bb2_1m$). EuOBr is isostructural with PbFCl.

## New Phosphorus Sulfide and Selenide Halides



*M. Baudler, G. Fricke*, and *K. Kipker*, Köln (Germany)

Diphosphorus tetraiodide and phosphorus(III) iodide react with sulfur in boiling $C_6H_6$ or $CS_2$ in diffuse daylight to form $P_4S_7$ and $I_2$. On standing for several days at room temperature with complete exclusion of light on the other hand, a different reaction takes place which leads to the formation of the new phosphorus sulfide iodides $P_2S_2I_4$, $P_2SI_4$, and $PSI_3$. These can also be obtained more simply by direct interaction of the elements in stoichiometric amounts in $CS_2$, on standing for several days with exclusion of light at room temperature or, in the case of $PSI_3$, at 0 °C. $P_2SI_4$ is the first inorganic compound in which a trivalent and a pentavalent phosphorus atom are bound directly to each other. The crystalline phosphorus sulfide iodides undergo disproportionation at room temperature within a short time to form $P_4S_7$ and $PI_3$; either $I_2$ or $P_2I_4$ is formed in addition. This transformation is strongly promoted by heat and in particular by light. $P_2S_2I_4$ and $P_2SI_4$ react with oxygen to form the polymeric phosphorus oxide iodide $(P_3I_2O_6)_n$ among other products. Reaction of the phosphorus iodides with selenium yields phosphorus selenide iodides $P_2Se_2I_4$, $P_2SeI_4$, and $PSeI_3$, which are also best obtained directly from the elements.

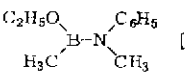


## Synthesis and Properties of Substituted Diflavylenes and Quercetylenes

*Ernst Bayer*, Tübingen (Germany)

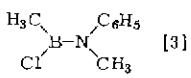
Diflavylenes are normally prepared from thioflavones by dimerization with copper powder or Raney nickel. These methods fail when there are substituents adjacent to the connecting double bond, *e.g.* with *(1)* where $R^2$ and $R^3$ = $OCH_3$. The steric hindrance can be overcome if methyl iodide is added during the dimerization. The compound *(2)* thereby formed then contains the sulfur on a tetrahedral carbon atom and the attack of the reagent is sterically possible.

*(1)*



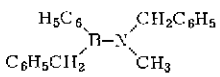
*(2)*

The diflavylenes are yellow but turn red on rubbing and assume partial free radical character. The latter phenomenon is termed piezomagnetism by analogy with piezochromism. Piezochromism and piezomagnetism fade away reversibly on standing. Neither effect occurs with the sterically strongly hindered derivative decamethylquercetylene [*(1)*, $R^1 = R^3 = OCH_3$]. The conversion of the yellow into the red form is attributed to conformational isomerism between a doubly folded and a twisted form, like that assumed by *Kortüm* and *Theilacker* [1] for dehydrodianthrone. It is to be concluded from the piezomagnetism that the rearrangement proceeds through a biradical.



## Structural Investigations of Phenylated Aminoboranes

*H. J. Becher*, Stuttgart (Germany)

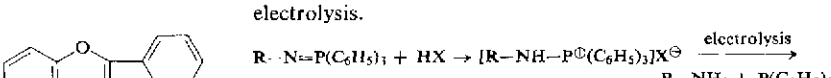


Proton magnetic resonance measurements show that an equilibrium exists in the asymetrically substituted aminoboranes

[2]

[3]

[4]



between the conformational isomers. The isomer ratio differs substantially in the three compounds listed, and evidently depends on the steric, inductive, and mesomeric effects of the substituents. Since all three compounds have phenyl groups on either the boron or the nitrogen atom, the interaction of these ligands with the B N bond was examined by evaluating vibrational spectra and by carrying out dipole measurements. The skeletal vibrations of the aminoboranes $(CH_3)_2BN(CH_3)_2$ and $(C_6H_5)_2BN(CH_3)_2$ as well as of $Cl_2BN(CH_3)_2$ and $Cl_2BN(C_6H_5)_2$ exhibit lowering of the B–N vibration frequency only in the case of the *N*-phenyl groups and not with the *B*-phenyl groups [5]. The dipole moments of the compounds $Cl_2BN(CH_3)_2$ and $Cl_2BN(C_6H_5)_2$ were found to be 2.95 and 2.57 Debye units, respectively [6]. The difference between these two values may be explained on the basis of inductive effects and does not justify the assumption that significant resonance takes place between the B–N bond and the phenyl groups.

## The Reaction of Alkylidenephosphoranes with C–C and C–N Double Bonds

*H. J. Bestmann* and *F. Seng*, München (Germany)

Alkylidenephosphoranes *(1)* can react with compounds having an activated double bond *(2)* to form cyclopropane derivatives or to give new alkylidenephosphoranes by a Michael addition [7]. The stereochemistry of the cyclopropane ring formed gives an indication of the nature of the primary product obtained from *(1)* and *(2)*.

With suitable substituents on the C=P double bond, alkylidenephosphoranes give olefins and iminophosphoranes with Schiff bases [8] in a manner analogous to a Wittig reaction. Triphenylphosphine can be recoverd by treating iminophosphoranes *(3)* with mineral acids followed by electrolysis.

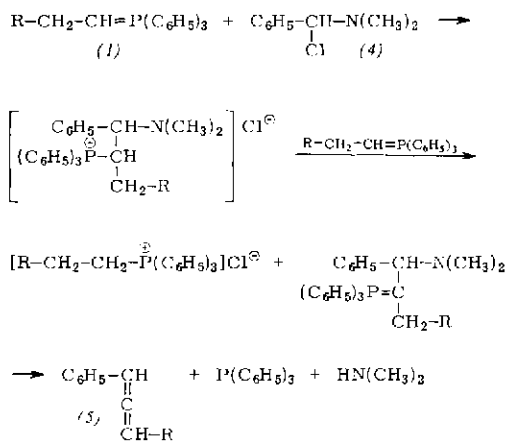
[3] *M. Kubo* et al., [2].

[4] *W. Brey* et al., [2].

[5] Cf. *H. T. Baechle*, Ph. D. Thesis, Technische Hochschule Stuttgart, 1963.



[6] *H. J. Becher* and *H. Diehl*, unpublished results.

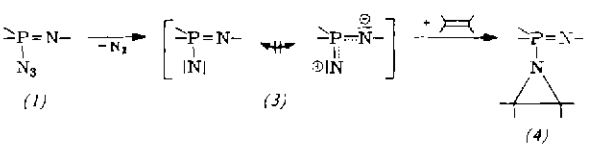
[7] *H. J. Bestmann* and *F. Seng*, Angew. Chem. *74*, 154 (1962); Angew. Chem. internat. Edit. *1*, 116 (1962).

[8] *H. J. Bestmann* and *F. Seng*, Angew. Chem. *75*, 475 (1963); Angew. Chem. internat. Edit. *2*, 393 (1963).

If the alkylidenephosphorane has a $CH_2$ group in the β-position relative to the phosphorus atom, reaction with Schiff bases first gives rise to an isolatable product which can be decomposed thermally to an amine, triphenylphosphine, and an allene.

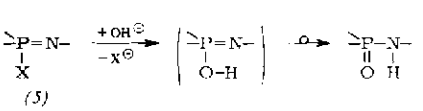
The same allene *(5)* is obtained by treating alkylidenephosphoranes *(1)* with α-aminobenzyl chlorides *(4)*, for instance

## The Reactivity of the P=N Double Bond



*H. Bock* and *W. Wiegräbe*, München (Germany)

Energetically favored addition reactions onto the P=N double bond of phosphazenes are intermolecular if the coordination number of the phosphorus is low. Otherwise they are intramolecular.

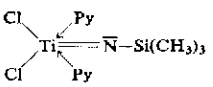


The aminophosphazenes $R_2N-PO=NR$ with a phosphorus of coordination number 3, which are described as monomers in the literature, were found to be dimeric with four-membered P–N rings. *P,P*-Diphenyl-*N*-tosylphosphazenyl azide *(1)* was prepared for the first time and does not exist in the phosphatetrazole form *(2)* according to infrared spectroscopic investigations.

The azene *(3)* remaining after thermal decomposition does not react as a 1,3-dipole. An ethyleneimine structure *(4)* was proved for the reaction product with dicyclopentadiene.

According to the hypothetical $S_N2$-mechanism, hydrolysis of phosphazene derivatives *(5)* should formally involve an intramolecular addition. Substituents showed remarkable effects on the rate of hydrolysis.

Comparison of the P=N stretching frequency of twenty new representative phosphazenes showed band shifts which are mainly caused by substituents on the nitrogen. The transfer of conjugation via the phosphorus atoms and the question whether suitable substituents increase the apparently low reactivity of the P=N double bond are still under investigation.



## Preparation of Titanium-Nitrogen Compounds by Addition and Substitution Reactions

*H. Bürger*, Graz (Austria)

Trialkoxytitanium chlorides *(1)* are not ammonolysed by liquid $NH_3$; instead, they form salt-like $NH_4^+[(RO)_3TiClNH_2 \cdot NH_3]^-$, which is converted into $(RO)_3TiCl \cdot NH_3$ at 40–60 °C and reverts to *(1)* via 3 $(RO)_3TiCl \cdot 2\,NH_3$ on further heating. With phenylhydrazine, *(1)* gives a 1:1 adduct (R = $C_2H_5$, m.p. 108 °C; R = i-$C_3H_7$, m.p. 76–77 °C). Dimethylhydrazine binds two molecules of *(1)* to form $(RO)_3TiCl-H_2NN(CH_3)_2-ClTi(OR)_3$. The chlorine in *(1)* is readily substituted by alkali disilylamides. Thus, *(1)* (in the following, R = i-$C_3H_7$) reacts with $NaN[Si(CH_3)_3]_2$ to form $(RO)_3Ti-N[Si(CH_3)_3]_2$, b.p. 93 °C/1 mm, and with $NaN[Si(OR)_3]_2$ to give $(RO)_3Ti-N[Si(OR)_3]_2$. Repeated substitution to yield $[(CH_3)_3Si]_2N-Ti(OR)_2-N[Si(CH_3)_3]_2$, m.p. 189 °C, is also possible. The extremely unstable compound *(2)*, which is formed in accordance with the equation

$$3\,TiCl_4 + 2\,NaN[Si(CH_3)_3]_2 \rightarrow Na_2TiCl_6 + 2\,Cl_3Ti-N[Si(CH_3)_3]_2 \quad (2)$$

is split by pyridine to give $(CH_3)_3SiCl$ and

Hexamethyldisilazane adds on 2 $TiCl_4$ below 20 °C, but reacts only at elevated temperatures to give $Cl_3Ti-NH-Si(CH_3)_3$. On heating the Ti–N Si compounds, which are not very thermostable, the Ti–N bond splits first; the same occurs on hydrolysis.

## Crystal Growth of Compounds with Incongruent Melting Points

*J. Bärmeister*, Aachen (Germany)

A new type of crystallizer, consisting of a storage vessel connected by a capillary to a small crucible-crystallizer, was described. The temperature of each component of the apparatus is independently variable. A melt with the composition of the desired compound is kept in the storage vessel. If solid is withdrawn from the crucible, equalization of the composition in the crucible by diffusion from the storage vessel is prevented by the capillary, and a composition corresponding to the peritectic transition point in the melt is established, which is in equilibrium with the desired compound. This method has been used successfully for the preparation of single crystals of thallium telluride ($Tl_2Te_3$).

## Fragmentation of Substituted Pyrrolidinium Salts

*H. Daniel*, München (Germany)

Quaternary pyrrolidinium salts are cleaved by phenyllithium into ethylene and vinylamine in a fragmentation reaction. The course of this reaction was studied with tritium-labelled pyrrolidinium salts; this excluded one possible mechanism involving a proton transfer from the α-position of the pyrrolidine ring to the *N*-methyl group. According to the kinetic isotopic effect of 1.4, the fragmentation is a two-stage reaction with formation of an α-ylide as the rate-determining primary step. Further attempts were made to influence the reaction by various substituents on the nitrogen or carbon of the pyrrolidine ring. Hexahydroisoindolinium salts gave long-chain unsaturated aldehydes. Increasing substitution causes side reactions, such as Hofmann elimination, substitution reactions, and Sommelet rearrangements.

Hofmann elimination and fragmentation are competing reactions with pyrrolidinium salts which contain β-hydrogen

atoms in addition to the β-hydrogen atom of the pyrrolidine ring, which cannot take part in the Hofmann elimination. The extent of the elimination increases with rising mobility of the β-carbon atoms.

### Preparation and Properties of Azide Chlorides

*K. Dehnicke*, Stuttgart (Germany)

Gaseous chlorazide reacts with anhydrous metal chlorides to form well-defined monoazide chlorides, *e.g.*:

$$TiCl_4 + ClN_3 = TiCl_3N_3 + Cl_2$$

The reactions are exothermic and proceed mildly below room temperature without side reactions. The reaction may be applied to the preparation of $SnCl_3N_3$, $VOCl_2N_3$, and $CrO_2ClN_3$. The azide chlorides are hygroscopic solids which explode when heated rapidly or struck. According to their infrared spectra, homopolarly bound azide groups with a tetrahedral structure around the metal atoms are mainly present.

Azide chlorides serve as starting materials for the preparation of nitrides, *e.g.*:

$$TiCl_3N_3 \rightarrow TiNCl + N_2 + Cl_2$$
$$VOCl_2N_3 \rightarrow VON + N_2 + Cl_2$$

Such reactions can be carried out carefully in boiling $CCl_4$. Provided care is taken to avoid fluctuations of pressure, work can be safely carried out with chlorazide diluted with nitrogen.

### Application of Chloronitrate for the Preparation of Oxide Fluorides

*K. Dehnicke, J. Weidlein*, and *K. Krogmann*, Stuttgart (Germany)

Well-defined fluoride nitrates were prepared using the following methods:

1. From mixed fluoride chlorides:

$$SbFCl_4 + 4\ ClNO_3 = SbF(NO_3)_4 + 4\ Cl_2$$

2. From lower fluorides:

$$SnF_2 + 2\ ClNO_3 = SnF_2(NO_3)_2 + Cl_2$$

The infrared and Raman spectra disclose in addition to the uniformity of the fluoride nitrates a certain intertwining of the $NO_2$ groups. Thermal decomposition leads directly to the oxide fluorides:

$$SbF(NO_3)_4 = SbO_2F + 4\ NO_2 + O_2.$$

In this manner, the oxide fluorides $SbOF_3$, $SbO_2F$, $SnOF_2$, $Sn_2OF_6$, InOF, and TlOF, most of which were unknown up to now, were obtained. $SnF_4$ and $SbOF_3$ are not isotypic. In contrast to $SnF_4$ (tetragonal, coordination number = 6; d = 4.78 g/cm³) [9], the powder diagram of $SbOF_3$ can be interpreted as being indicative of a cubic structure, with a lattice constant of a = 10.09 Å. The extinctions, the density (d = 3.70 g/cm³), and the infrared spectrum point to a coordination number of 4 for the antimony.

### Investigations of the Racemization of L-Amino Acid Derivatives

*H. Determann*, Frankfurt/Main (Germany)

It was shown by the Anderson test that racemization of acylated L-amino acids on activation of their carboxyl group by condensation with esters of chloroformic acid can be avoided by preparing the mixed anhydride rapidly in tetrahydrofuran at −15 °C and using the solution within a few minutes. About 50 % racemization occurs even after only 20 minutes. Of two suggested explanations – anhydride mesomerism or intermediate formation of oxazoles – only the latter is in accordance with all the experimental facts. The explanation of the differing effects that various acyl residues on the amino group have on the rate of racemization resides in the differing tendencies toward oxazole formation. The position of the carbonyl band in the infrared spectrum of the anilides of carbonic monoesters (ca. 1720 $cm^{-1}$) and of other acids (ca. 1680 $cm^{-1}$) indicates that the carbonyl oxygen is more nucleophilic in the latter. Amino acids protected with urethane groups do not therefore tend to cyclize and hence to racemize, whereas all other acylamino acids racemize to some extent when activated, a process that has been followed quantitatively in the case of L-phenylalanine derivatives.

### Preparation and Properties of Organometallic Onium Salt Complexes

*R. Dötzer*, Erlangen (Germany)

The addition of compounds RX, which undergo heterolytic cleavage, onto donor-acceptor molecule systems is favored energetically and leads to a simple method for preparing organometallic onium salt complexes, which are of interest as low-melting electrolytes for the galvanic separation of metals. Ammonium, phosphonium, stibonium, and telluronium salt complexes were prepared, alkyl compounds of Zn, Al, Ga, In, and Sn being used as acceptor molecules, in accordance with the equation

$$(C_2H_5)_3N + CH_3Cl + Al(C_2H_5)_3 \rightarrow [(CH_3)(C_2H_5)_3N][C_2H_5)_3AlCl]$$

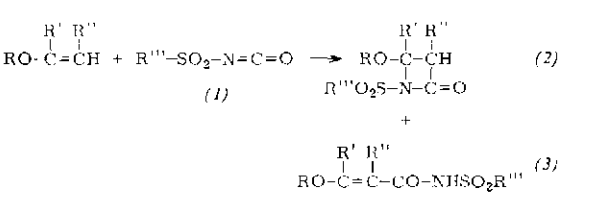
The coordination compounds and the RX/acceptor or RX/donor molecule mixtures are also capable of yielding colorless electrolytes which are sometimes no longer spontaneously inflammable in air:

$$(CH_3)_3N{:}Ga(C_2H_5)_3 + C_6H_5CH_2F \rightarrow [(CH_3)_3(C_6H_5CH_2)N][(C_2H_5)_3GaF]$$

$$(C_2H_5)_3Sb/C_2H_5Br + Al(C_2H_5)_3 \rightarrow [(C_2H_5)_4Sb][(C_2H_5)_3AlBr]$$

Melting ranges: −62 to −65 °C, and −18 to −20 °C, respectively.

Although the starting materials are non-conductors or poor conductors of electricity, the onium salt complexes exhibit specific conductivities of $10^{-3}$ to $10^{-2}$ mho/cm in the temperature range 20–160 °C.



Onium salts that are difficult to prepare can be obtained by solvolysis of onium salt complexes, for instance in accordance with the reaction

$$[(C_2H_5)_4Sb][(C_2H_5)_3AlBr] + 3\ CH_3OH \rightarrow [(C_2H_5)_4Sb]Br + Al(OCH_3)_3 + 3\ C_2H_5$$

### Reaction of Vinyl Ethers and Ketene Acetals with Isocyanates and *N*-Sulfinyl Compounds

*F. Effenberger* and *R. Gleiter*, Stuttgart (Germany)

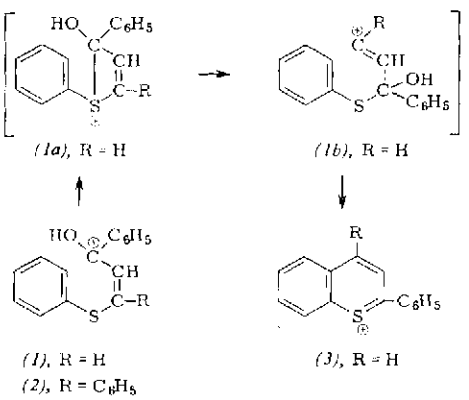
Sulfonyl isocyanates *(1)* react rapidly and quantitatively with vinyl ethers to give 4-alkoxyacetidin-2-one derivatives *(2)* or β-alkoxyacrylamide derivatives *(3)*. The proportions of *(2)* and *(3)* formed depend on the substituents and the reaction conditions.

*(1)* *(2)* *(3)*

[9] *R. Hoppe* and *W. Dähne*, Naturwissenschaften *49*, 254 (1962).

Alkyl, aryl, and acyl isocyanates do not react thus with vinyl ethers. Ketene diethylacetal (1,1-diethoxyethylene) reacts with sulfonyl and also with alkyl, aryl, and acyl isocyanates to give *N*-substituted carbamidoketene acetals (1,1-diethoxy-2-carbamidoethylenes) in good yields.

Reaction also takes place between *N*-sulfinyl compounds and vinyl ethers. The investigations carried out indicate that only cycloaddition occurs. The structure of the reaction product was discussed in the light of its infrared spectrum. The compounds resulting from the cycloaddition undergo various cleavage reactions.



## A New Synthesis of 1-Thianaphthalenium Salts [10]

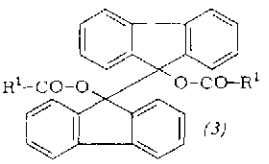
*N. Engelhard* and *A. Kolb*, Freiburg/Breisgau (Germany)

1-Thianaphthalenium perchlorate, which was hitherto accessible only by a multi-stage process, can now be obtained by cyclization of readily available β-(phenylthio)acrolein with perchloric acid. The synthesis is capable of general extension.

During the cyclization of 3-phenylthio-1-phenylprop-2-en-1-one, a new rearrangement was observed. It does not yield the expected 4-phenyl-, but instead 2-phenyl-1-thianaphthalenium perchlorate *(3)*. In contrast, 3-(3,4-dimethoxyphenylthio)-1-phenylprop-2-en-1-one can be cyclized with the expected result.

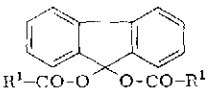
The carbonium ion *(1)* resulting from protonation probably alkylates the sulfur with formation of an unstable thiacyclobutene derivative *(1a)*. The carbonium ion *(1b)* is thus rendered sufficiently electrophilic to cyclize with the benzene ring to give *(3)*.There is a competition between this cyclization and the normal ring closure which occurs when the nucleus

*(1a)*, R = H — *(1b)*, R = H



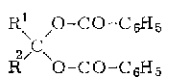
*(1)*, R = H
*(2)*, R = $C_6H_5$ — *(3)*, R = H

becomes more nucleophilic than the sulfur by the introduction of methoxy groups. In the condensation of thiophenol with dibenzoylmethane, the postulated intermediate *(2)* can be isolated; on treatment with water this is rapidly converted into 3-phenylthio-1,3-diphenylprop-2-en-1-one.

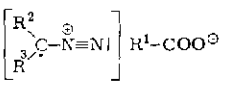


## The Reaction of Diazo Compounds with Diaroyl Peroxides

*E. Fahr* and *H. Lind*, Würzburg (Germany)



Diazofluorene *(1)* reacts with diaroyl peroxides $R^1CO-O_2-OCR^1$ *(2)*, where $R^1=C_6H_5$, $p$-$CH_3-C_6H_4$, or $p$-$H_3CO-C_6H_4$, to give derivatives of 9,9'-dibenzoyloxy-9,9'-bifluorenyl *(3)*. On the other hand, other diaroyl peroxides *(2)*, where $R^1 = p$-$O_2N-C_6H_4$ and $p$-$Cl-C_6H_4$, afford the 9,9-dibenzoyloxy derivatives *(4)* on reaction with *(1)*. Similarly, phenyldiazomethane and diphenyldiazomethane form the phenylated dibenzoyloxymethane derivatives *(5)* on reaction with benzoyl peroxide, while diazoketones ($R^2-CO-CHN_2$) and diazoacetic ester ($R^2OOC-CHN_2$) react with *(2)* to give the compounds $R^2$-CO-$CH_2$-O-CO-$R^1$ and $R^2OOC-CH_2-O-CO-R^1$, respectively.



*(3)*

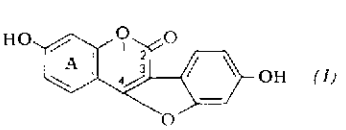
*(4)*

*(5)*

*(6)*

Determination of the order of reaction and of the rate constants of the reaction in relation to the substituents in the diaroyl peroxides shows that the diazo compound does not decompose into the corresponding carbene, which then reacts further with the peroxide or the radicals derived therefrom, but that compounds *(3)* to *(5)* are formed via an intermediate product, probably of structure *(6)*.

## Thermochemistry and Polymorphism of Selenium



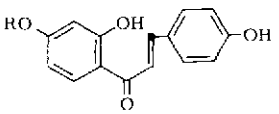
*G. Gattow*, Göttingen (Germany)

Combustion of various highly purified grades of selenium in the calorimeter bomb was used to ascertain the enthalpy of formation of $SeO_2$ at 25.0 °C and to compute the heats of transformation of selenium for feasible and hypothetical modification changes. Determinations of the heat contents by means of the drop method between −160 and + 280 °C showed that the individual types of selenium pass through several, hitherto unknown, reversible transformations, before turning into the thermodynamically stable modification of hexagonal selenium. Vitreous selenium: −145 °C ($L_t$ = 40 ± 20 cal/g-atom), + 11 °C ($L_t$ = 30 ± 20 cal/g-atom), and + 30 °C ($L_t$ = 0 ± 20 cal/g-atom); red amorphous selenium: −134 °C ($L_t$ = 160 ± 20 cal/g-atom) and + 10 °C ($L_t$ = 60 ± 20 cal/g-atom); monoclinic selenium (α + β): −120 °C, + 15 °C, and + 30 °C (with $L_t$ = 0 ± 20 cal/g-atom in each case). Hexagonal selenium, which melts at 221 °C, has a reversible transformation point at 106 °C ($L_t$ = 0 ± 20 cal/g-atom), which is reflected in the change in the lattice dimensions with temperature (c-constant).

## Investigations on the Biosynthesis of Coumestrol in Alfalfa

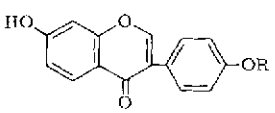
*H. Grisebach* and *W. Barz*, Freiburg/Breisgau (Germany)

Coumestrol *(1)*, which is isolated from leguminosae because of its estrogenic properties, belongs to the group of coumarano-coumarins.



*(1)*

The biosynthesis of *(1)* was investigated by administration of $^{14}C$-labelled precursors to alfalfa (*Medicago sativa* L.). The radioactivity of *carboxy*[$^{14}C$]cinnamic acid becomes localized in C-2 of *(1)*. On the other hand, after addition of [1-$^{14}C$]-acetate, the total activity is found in the ring A. The biosynthesis of *(1)*, therefore, proceeds analogously to that of the isoflavones and not like that of normal coumarins [11].

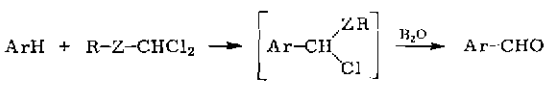


[10] Thia-aromatics, Part VIII; Part VII: *A. Lüttringhaus, M. Mohr*, and *N. Engelhard*, Liebigs Ann. Chem. *661*, 84 (1963).

[11] *H. Grisebach* and *W. D. Ollis*, Experientia (Basel) *11*, 4 (1961).

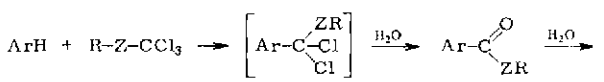
On administration of the labelled (•) chalcone-*O*-glucoside *(2)*, compound *(1)* is formed with a specific radioactivity which is of the same order of magnitude as that of the isoflavones, formononetin *(3)* and daidzein *(4)*, which also occur in alfalfa. The glucoside *(2)* is a common precursor for coumestrol and the isoflavones.

R = Glucose
*(2)*



*(3)*, R = $CH_3$
*(4)*, R = H

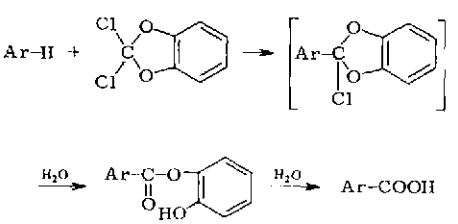
## New Syntheses of Aldehydes and Carboxylic Acids Using α-Halogen Ethers



*H. Gross*, Berlin-Adlershof (Germany)

Aromatic hydrocarbons, phenols, phenyl ethers, and aromatic heterocyclics can be formylated or carboxylated easily by treatment with α-chloro ethers or α-chloro thioethers under Friedel-Crafts conditions. Dichloromethyl alkyl ethers or sulfides, for instance, give the corresponding aldehydes in good yield:

(Z = O, S)

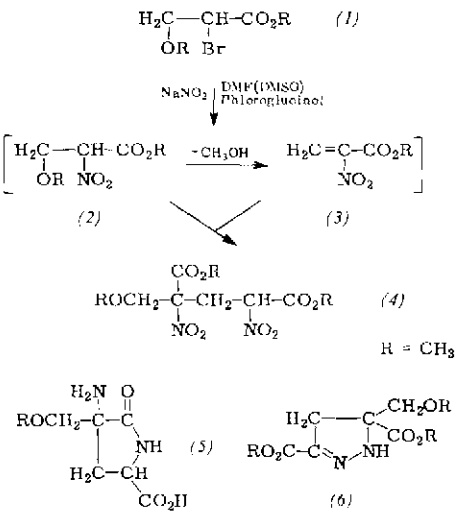


Polyhydroxybenzenes can be formylated smoothly with orthoformates and $AlCl_3$. Trichloromethyl alkyl ethers and sulfides react analogously to form carboxylic acids.

(Z = O, S)

Ar–COOH

The 1,2-*O*-dichloromethylene ether of pyrocatechol is particularly suitable for direct carboxylations. The pyrocatechol orthoester of the aromatic acid chloride is obtained first and is then smoothly hydrolysed by alkali to give the carboxylic acid.



## Investigations of α-Nitro-β-alkoxypropionic Esters; α-Nitroacrylic Ester as Intermediate

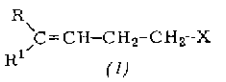
*K. D. Gundermann*, Münster (Germany)

The reaction of methyl α-bromo-β-methoxypropionate *(1)* with sodium nitrite in dimethylformamide or dimethyl sulfoxide in the presence of phloroglucinol (Kornblum method [12]) gives dimethyl α-methoxymethyl-α,α′-dinitroglutarate *(4)*, which is formed from methyl α-nitro-β-methoxypropionate *(2)* and methyl α-nitroacrylate *(3)* by Michael addition as a non-isolable intermediate.

[12] *N. Kornblum, R. K. Blackwood*, and *J. W. Powers*, J. Amer. chem. Soc. 79, 2507 (1957).

The diester *(4)* is also obtained by oxidation of methyl α-oximino-β-methoxypropionate, which is prepared from *O*-methyl-DL-serine methyl ester, again via *(2)* and *(3)*. The structure of *(4)* is afforded by its reduction and hydrolysis to give α-methoxymethyl-α,α′-diaminoglutarolactam *(5)* which was synthetized independently by hydrogenation of *(6)*.

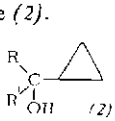
## Cinnoline Compounds as By-products in the Formation of Osazones from Aldoses



*H. J. Haas*, Heidelberg (Germany)

When glucose phenylosazone is prepared from D-glucose and phenylhydrazine in dilute acetic acid by the method of *E. Fischer*, 3-(D-*arabo*-tetrahydroxybutyl)cinnoline *(1)* is obtained as a by-product. The yield of *(1)* can be increased to 20 % by working in dilute hydrochloric acid. The structure was confirmed by degradation to 3-methylcinnoline which is known. The same by-product is formed in the preparation of glucosazone from D-mannose, but not from D-fructose, 1-deoxy-1-*p*-toluidino-D-fructose, or the hydrochlorides of D-glucosamine or D-isoglucosamine. 3-(D-*lyxo*-Tetrahydroxybutyl)-cinnoline and 3-(D-*threo*-trihydroxypropyl)-cinnoline are formed in addition to the osazones when D-galactose and D-xylose are treated with phenylhydrazine. Their structures were confirmed by degradation to cinnoline-3-carboxaldehyde.

## Investigations on Cyclopropane Compounds



*M. Hanack, H. Eggensperger, K. Görler, S. Kang*, and *H. J. Schneider*, Tübingen (Germany)

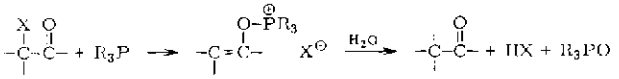
Homoallyl compounds of general structure

*(1)*

rearrange under the conditions of a kinetically controlled reaction, with anchimeric assistance of the double bond, to form cyclopropyl carbinol derivatives. This reaction was studied: Homoallyl halides of structure *(1)* (R = $CH_3$, $R^1$ = H; R = $R^1$ = $CH_3$; R = H, $R^1$ = $C_6H_5$; R = H, $R^1$ = $FC_6H_4$; R = H, $R^1$ = cyclopropyl; R = $R^1$ = cyclopropyl; X = Cl and Br) rearrange practically quantitatively on hydrolysis with aqueous potassium carbonate or with silver oxide to give cyclopropyl carbinols of structure *(2)*.

*(2)*

Solvolysis of homoallyl tosylates [*(1)*, X = OTos] in methanol leads to only 30–40 % of the cyclopropyl carbinol owing to the more nucleophilic nature of the solvent. In addition, some

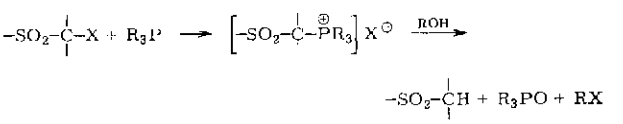


non-rearranged homoallyl ether [*(1)*, X = $OCH_3$] is formed. The anchimeric assistance of the double bond in open-chain homoallyl derivatives is shown in the solvolysis of 5-(*p*-nitrobenzoyloxy)-2-methyl-2-pentene *(1)*, R = $R^1$ = $CH_3$; X = $OCOC_6H_4NO_2^-$. The alkyl-oxygen bond is split and cyclopropylisopropanol [*(2)*; R = $R^1$ = $CH_3$] is formed.

When the naphthylsulfonate of 2-cyclopentenyl carbinol is rearranged in methanol, glacial acetic acid, or dioxan/water, anchimeric assistance of the double bond occurs and bicyclo[3,1,0]hexan-2-ol as well as $\Delta^3$-cyclohexenol are formed. The influence of the solvent on the course of the reaction in comparison with the deamination of 2-cyclopentenyl carbinylamine is being investigated. Furthermore, the kinetics of the reaction with various substituted homoallyl naphthylsulfonates in several solvents, were examined and compared with those of the saturated compound. Although the anchimeric assistance of the double bond leads to cyclopropyl carbinol compounds, the rate of solvolysis of the homoallyl compounds is only slightly increased.

## Reductive Dehalogenations Using Tertiary Phosphines

*H. Hoffmann* and *H. J. Diehr*, Mainz (Germany)

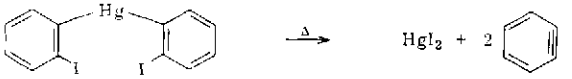


Tertiary phosphines react with various α-halogenocarbonyl compounds, to give enol phosphonium salts. These compounds are very susceptible to hydrolysis. They are decomposed with water to the simple dehalogenated carbonyl compounds, hydrogen halide, and tertiary phosphine oxides.

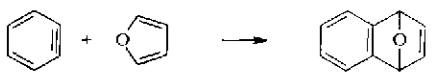
During the formation of the enol phosphonium salt, the halogen is split off as a cation, as in the analogous Perkow reaction. α,β-Dihalogenocarbonyl compounds react with tertiary phosphines to yield α,β-unsaturated carbonyl compounds and phosphine dihalides.

α-Halogenophosphonium salts and α-halogenophosphine oxides are dehalogenated by tertiary phosphines in the presence of protons.

α-Halogenosulfones are dehalogenated in the presence of water or alcohol, but in benzene or acetonitrile are converted into *C*-phosphonium salts.



## Detection of Dehydrobenzene in the Gas Phase

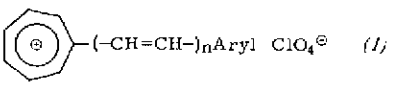


*R. W. Hoffmann* and *H. F. Ebel*, Heidelberg (Germany)

The intermediate existence of dehydrobenzene in solution can now be considered as assured. It remained, however, unestablished to what extent the dehydrobenzene molecule is stabilized in solution by solvation or complex formation. In order to prove the existence of free dehydrobenzene, it had to be prepared in the vapor phase and identified by chemical means.

Bis-(*o*-iodophenyl)mercury was evaporated in a stream of argon of 8 mm Hg and then decomposed at 700 °C.

The gases leaving the zone of decomposition were cooled and then brought into contact with furan vapor. Dihydronaphthalene-*endo*-oxide was formed and was then isomerized



and identified as α-naphthol. It was ascertained by experiment and by calculation that the amount of furan which diffuses against the gas flow into the zone of decomposition is considerably smaller than the actual yield of naphthol. As the zones of decomposition of the substrate and of reaction with the trapping agent are far apart, the existence of a reactive particle, which is considered to be dehydrobenzene, must be postulated.

## Preparation and Investigation of Substituted Tropylium Salts

*Ch. Jutz*, München (Germany)

The cations *(1)* with the tropylium system as acceptor and substituted aryl residues as donors were used as relatively simple models for studying the stability (pK values) and color (spectra) of this type of salt.

Such salts (n = 0, aryl = $-C_6H_4-X$) were obtained via the corresponding tropilidines by treating arylmagnesium bromides with 7-methoxytropilidine or by electrophilic substitution of phenol or anilines with tropylium ion (from methoxytropilidine in acetic acid) followed by dehydrogenation. Salts of *(1)* with n = 1 (aryl = substituted phenyl, naphthyl, phenanthryl, anthranyl) and n = 2, 3, 4 (aryl = diphenyl) were obtained by condensation of aldehydes with methyltropylium perchlorate. The pK values (measured in acetonitrile/water, 1:1) of the ions of *(1)* with n = 0, aryl = $C_6H_4$–X (with X = H, *p*-$CH_3$, *m*-$CH_3$, *p*-$C(CH_3)_3$, *p*-$OCH_3$, *m*-$OCH_3$, *p*-OH, *p*-$OCOC_6H_5$, *p*-$C_6H_5$, *m*-$C_6H_5$, *p*-$N(CH_3)_2$, *p*-$NHCOC_6H_5$, *p*-F, *p*-Cl, *p*-Br, *m*-F, *m*-Cl, *m*-Br, *m*-$CF_3$) follow the Hammett σ-relationship closely with ρ = + 2.4.

## Chelate Complexes of Plutonium with 8-Hydroxyquinoline

*C. Keller* and *S. Eberle*, Karlsruhe (Germany)

In their ability to form metal chelates with 8-hydroxyquinoline (oxine) and some of its derivatives, the transuranium elements exhibit a significant difference from the remaining

| Reaction of | Oxine | 5-Chlorooxine | 5,7-Dichlorooxine | 2-Methyloxine |
|---|---|---|---|---|
| with: Np(IV) | $Np(R^1)_4$ | $Np(R^2)_4$ | $Np(R^3)_4$ | $Np(R^4)_4$ [a] |

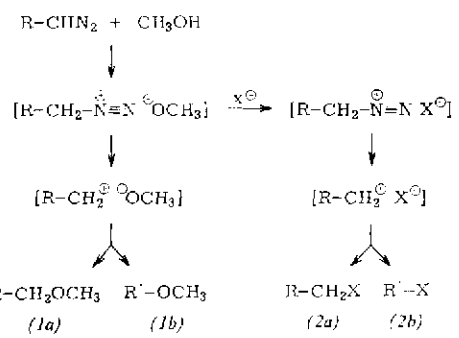
| Am(III) | $Am(R^1)_3$ | $Am(R^2)_3$ | $Am(R^3)_3$ | |

[a] Basic chelates $R^4$: M = 3.2–3.7.

actinide elements, thorium and uranium. Pu(VI) and Np(VI) solutions are reduced to Pu(V) and Np(V) by 8-hydroxyquinoline at pH ≈ 2. $HPuO_2R^1_3$, which *Harvey* et al. [13] regarded as a Pu(VI) chelate, is actually a chelate of Pu(V): $H_2[PuO_2(R^1)_3]$.



Precipitation of a Pu(IV) salt from its buffered solution with 8-hydroxyquinoline produces basic chelates $Pu(OH)_x(R^1)_{4-x}$, which are soluble in chloroform up to $x = 2$.

$Pu(R^1)_4$ and $Np(R^1)_4$ are obtained by precipitating a buffered solution of 8-hydroxyquinoline with an acidified solution of Pu(IV) or Np(IV). When oxygen is excluded, Pu(III) forms the complex $Pu(R^1)_3$. The table lists the chelates of transuranium elements obtained.

## Substitution of Aliphatic Diazonium Groups

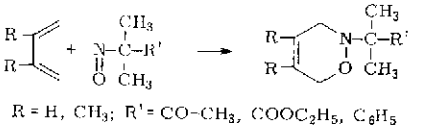
*W. Kirmse*, Marburg/Lahn (Germany)

The reaction of aliphatic diazonium ions with nucleophilic reagents was investigated by the following method: aliphatic diazo compounds are protonated by alcohols even in alkaline medium to form primarily diazonium alkoxide ion pairs from which ethers *(1)* are obtained. Anions $X^-$ (halides, azide, thiolates) added in the form of their lithium salts can only be effective after displacement of the alkoxide since the acid HX does not occur under the conditions chosen.

The following systems are particularly instructive:

a) The isobutyl system. Besides isobutyl derivatives, t- and s-butyl derivatives ($R'-OCH_3$, $R'-X$) are formed in this case by rearrangement of the carbonium ion. The formation of the substitution products *(2)* is accompanied by less isomerization than the formation of the ethers *(1)* [*(2a)*: *(1a)* > *(2b)*:*(1b)*]. With increasing nucleophilicity of the added anion, the rearrangement is increasingly supressed and the yield of substitution products *(2)* increases.

b) The crotyl/methallyl system. The fraction of crotyl derivative formed from 1-diazo-2-butene increases with increasing nucleophilicity of the added anion. An analogous effect is not observed with 3-diazo-1-butene.



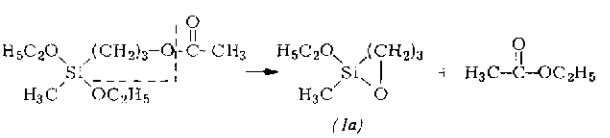
These results indicate an anion exchange at the stage of the diazonium ion, not at the carbonium ion stage. Some results are best explained by partial $S_N2$-character of the substitution; however, the assumption of an ion-pair process is generally adequate.

## Diels-Alder Syntheses with Nitroso Compounds

*D. Klamann, P. Weyerstahl*, and *M. Fligge*, Hamburg (Germany)

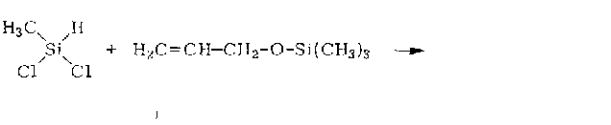
The hitherto known Diels-Alder syntheses using *C*-nitroso compounds are limited to aromatic nitroso and aliphatic geminal chloronitroso and cyanonitroso compounds; nitrosoisobutane does not react with dienes. Aliphatic α-nitroso ketones, α-nitrosocarboxylic esters, and aromatically substituted aliphatic nitroso hydrocarbons react with dienes to yield 3,6-dihydro-1,2-oxazines.

9-Nitrosotriptycene is thermally extremely stable but is sterically hindered and thus reacts by the Diels-Alder method only under vigorous conditions. Trichloronitrosomethane reacts smoothly with dienes in the presence of alcohols even



R = H, $CH_3$; R' = $CO-CH_3$, $COOC_2H_5$, $C_6H_5$

down to −25 °C to give 3,6-dihydro-1,2-oxazines (95 % yield) and tetraalkyl orthocarbonates. Aliphatic 1,1-nitronitroso compounds react in an analogous step, even in the presence of excess urea, to give *N*-nitroso-3,6-dihydro-1,2-oxazines and the appropriate ketals. The Diels-Alder reaction is synonymously influenced by increases in the positivity of the nitrogen atom and thermal stability of the nitroso compounds. Inorganic nitroso compounds, such as nitrosylsulfuric acid, yield the salts of the corresponding 1,2,6*H*-oxazines with 2,3-dimethylbutadiene after 1,4-addition and spontaneous rearrangement with ring closure. All the oxazines prepared or their derivatives may be hydrogenated in good yields to the isomer-free 1,4-aminobutanols.



## Synthesis and Polymerization of 1-Oxa-2-silacyclopentane Derivatives

*G. Koerner* and *G. Rossmy*, Essen (Germany)

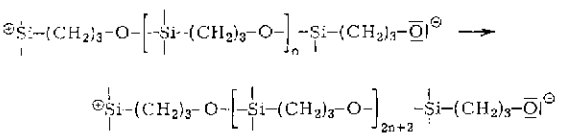
1-Oxa-2-silacycloalkanes [14,15] can be obtained by two new routes, leading to *(1a)* and *(1b)*.

*(1a)*

*(1b)*

Both syntheses allow many variations. The 1-oxa-2-silacyclopentane derivatives polymerize on standing at room temperature. The polymers can be quantitatively reconverted into the monomers by heating.

An equilibrium is established in solution in inert solvents, *e.g.* $CCl_4$. Solutions of *(1a)* have a constant monomer content of 24 g/l at total concentrations of over 100 g/l. The presence of dimeric compounds (ten-membered rings) was also established in some compounds.



The viscosity of catalyst-free samples of *(1)* which were, stored in sealed vessels at room temperature shows considerable increases after the monomer content has fallen to its final value. This is presumably caused by the appearance of intermediate zwitterions.

[13] *B. G. Harvey, H. G. Heal, A. G. Maddock*, and *E. L. Rowley*, J. chem. Soc. (London) *1947*, 1010.

[14] *W. H. Knoth* and *R. V. Lindsey*, J. Amer. chem. Soc. *80*, 4106 (1958); *J. L. Speier, M. P. Davind*, and *B. A. Eyon*, J. org. Chemistry *25*, 1637 (1960).

[15] U.S.-Pat. 2983745 (May 9th, 1961), Dow Corning Corp., inventor: *J. L. Speier*; U.S.-Pat. 2888454 (May 26th, 1959), Union Carbide Corp., inventor: *D. L. Bailey*.

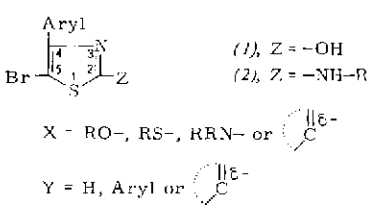
The fact that strong bases alkoxides or Lewis acids ($AlCl_3$) accelerate the polymerization (but also cause depolymerisation) is in agreement with this picture.

## Structure of Anomalous Oxalato Complexes of Platinum

*K. Krogmann*, Stuttgart (Germany)

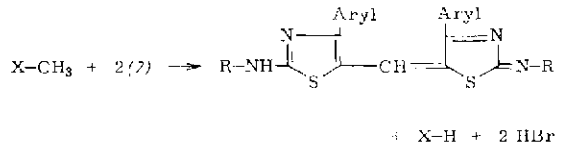
The crystal structures of $K_2[Pd(C_2O_4)_2] \cdot 4\ H_2O$, $K_2[Pt(C_2O_4)_2] \cdot 2\ H_2O$ ("yellow salt"), and $K_{1.6}[Pt(C_2O_4)_2] \cdot 2.5\ H_2O$ ("violet salt") were examined. The yellow salt and the Pd compound contain isolated planar complex ions. In the violet salt, the complex ions are superposed one upon another; this leads to short Pt-Pt distances (2.75 Å). The Pt thereby has a mean oxidation number of 2.4. It is not possible to distinguish crystallographically between $Pt^{2+}$ and $Pt^{4+}$. The same oxidation number is observed in the "violet acid" $H_{1.6}[Pt(C_2O_4)_2]$and in the new compounds $H_{1.6}[Pt(OH)_2C_2O_4$ and $H_{1.6}[Pt(OH)_4]$. The "yellow acid" $H_2[Pt(C_2O_4)_2]$, which is only stable in the absence of air, was also prepared for the first time. On contact with air it forms the "violet acid". The reactions of these compounds in solutions, which have been regarded as rearrangements, can be interpreted on the basis of these new results.

## Refining of Titanium and Titanium Alloys by Melt Electrolysis Using a Liquid Lead Electrode



*H. Kühnl*, Gießen (Germany)

Crude titanium or titanium alloys were refined by melt electrolysis in a cell in which two separate chambers were connected through a liquid lead bielectrode. The electrolyte consisted of an NaCl melt at 850 °C containing dissolved lower titanium chlorides. The current densities at the mechanically stirred bielectrode amounted to 0.05 A/cm² at the most. The lead content of the refined titanium was below 0.005 %. About 0.1–0.3 % Fe contaminant was derived from the material of the crucible. When a titanium alloy with 5 % manganese was refined, only 0.7 % Mn was deposited in comparison with 2.71 % Mn in a conventional electrolysis cell. When a titanium alloy with 5 % chromium was used, a maximum of 0.05 % Cr passed over into the refined titanium (without the lead electrode, the amount is more than 0.8 % Cr).



## "Thiazolizations" Using 2-Hydroxy- or 2-Amino-4-aryl-5-bromothiazole

*W. Lässig*, Leverkusen (Germany)

2-Hydroxy- *(1)* or 2-amino-4-aryl-5-bromothiazole *(2)* reacts in the melt at approximately 160 °C with compounds of general formula $X-CH_2-Y$.

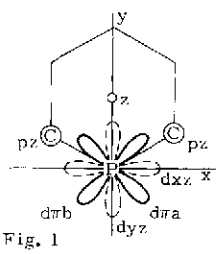
One or both hydrogen atoms in $X-CH_2-Y$ are substituted by the thiazoyl residue, with vigorous evolution of hydrogen bromide. This new reaction may be suitable for the preparation of bis-5,5'-(2-aminothiazolyl)methane dyes according to the equation

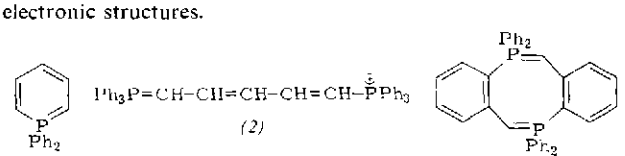
## Cyclic Methylenephosphoranes

*G. Märkl*, Würzburg (Germany)

The synthesis of 1,1-diphenyl-1-phosphanaphthalene [16] and 1,1-diphenyl-1-phosphabenzene *(1)* [17] demonstrated that it is possible to obtain stable methylenephosphoranes of a new type by introduction of the $d_\pi$-$p_\pi$-double bond into a cyclic conjugated system.

An illustration of the bond proportions is attempted in Figure 1. Using the concepts developed by *Dewar* [18], linear combination of both the $d_{xz}$ and $d_{yz}$ orbitals concerned in the formation of the $d_\pi$-$p_\pi$-double bond yields two new orbitals $d_{\pi a}$ and $d_{\pi b}$ in the direction of the σ-bond axes; each of these can only interact with the pz orbital of a neighboring carbon atom. This regulation causes the phosphorus atom to act as an insulator in the cyclic conjugated





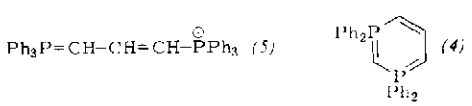


Fig. 1

system. As both of the d-orbitals together have only one electron to contribute, stabilization by means of the mesomeric energy gain of a delocalized π-electron system can be envisaged; these d-orbitals can participate as either electron donors or acceptors. Such a system of bonding should be regarded as an "internal cyanine". The close similarity between the ultraviolet spectra of *(1)* ($\lambda_{max}$ = 409 mμ in $CHCl_3$) and of the open-chain pentamethinephosphacyanine *(2)* ($\lambda_{max}$ = 432 mμ in $CHCl_3$) confirm the analogy of the electronic structures.

The working hypothesis that cyclic conjugated methylenephosphoranes are stabilized independently of the size of the ring if "internal cyanine" structures are possible is supported by the formation of *(3)* and *(4)* in aqueous solutions of the corresponding phosphonium salts. The resemblance of the ultraviolet spectra of the trimethinephosphacyanine *(5)* ($\lambda_{max}$ = 349 mμ in $CHCl_3$) and of *(4)* ($\lambda_{max}$ = 384 mμ in ether) is in accordance with the views expressed.

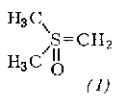
## The Existence and Constitution of Ternary Compounds between PbO, $SiO_2$, and Lead Halides



*L. Merker*, Würzburg (Germany)

Starting with melts of composition 2 $PbO{\cdot}SiO_2$, it is possible to replace about one-quarter of the molar PbO content by lead halides without the formation of two phases or without impairing solidification to a glass. These halogen-containing glasses exhibit pure anion conductivity. Devitrification experiments between 375 and 450 °C lead in all four series (F, Cl, Br, and I) to separations of hitherto unknown hexagonal pyromorphite-like structures. The dependence of the lattice constants a and c on the composition of the melts and the type of halogen as well as on the chemical behavior (substitutability of the surface halogen in the iodine-containing phase by ethoxyl; detected by Zeisel's method) suggests that the substances separated are a series of mixed crystals lying between the limiting compositions of $Pb_5(SiO_4)(SiO_3Hal)_2$ and $Pb_5(SiO_3Hal)_3Hal$, by analogy with the compounds $Pb_5(SiO_4)(PO_4)_2$ and $Pb_5(PO_4)_3Hal$, which form crystals of the pyromorphite type. Crystalline compounds, in which partial substitution of the oxygen contained in the $SiO_4$ tetrahedron by halogen must evidently be assumed, have thus been prepared for the first time.

## Reactions of Sulfur Ylides [19]

*H. Metzger*, Ludwigshafen/Rhein (Germany)

On the basis of the observation of *Corey* et al. that dimethyloxosulfonium methylide *(1)* reacts with carbonyl compounds

*(1)*

to form oxiranes, reactions of *(1)* with some C=N multiple bond systems and with α,β-unsaturated amides were investigated. Whereas *(1)* yields mainly aziranes [20] with *N*-benzylideneaniline and benzaldazine, it reacts with benzaldehyde phenylhydrazone to form benzaldehyde *N*-methyl-*N*-phenylhydrazone. Aliphatic and aromatic isocyanates yield 1:1 and 1:2 adducts with *(1)*, depending on the reaction conditions. In this way, new sulfur ylides are formed which are stable even towards hot water; these are dimethyloxosulfurylene-acetamides and -malonamides, and they can be reductively desulfurized to the acetamides and malonamides. As expected, the 1:1-adducts were converted into 1:2-adducts with further isocyanate. Certain aromatic nitriles react with *(1)* by 1:1 addition to yield (β-amino-β-aryl)-vinyldimethyloxosulfonium salts. These can be hydrolysed to ketones. In this way, for example, benzonitrile can be converted into acetophenone [20a].

When *(1)* was treated with α,β-unsaturated amides, cyclopropanecarboxamides or, by ring closure, pyrrolidone derivatives were obtained, depending on the nature of the amide. In this reaction, the yield of pyrrolidones is best with acrylamides. Cinnamanilide yielded a mixture of cyclopropane derivatives and pyrrolidone derivatives, whereas cinnamamide yielded only phenylcyclopropanecarboxamide [20].

## Isomerization of Cyclic Mono- and Diolefins during the Koch Carboxylic Acid Synthesis

*K. E. Möller*, Mülheim/Ruhr (Germany)

If cycloalkenes are subjected to the Koch carboxylic acid synthesis [21], carboxylic acids containing an additional carbon atom or their methyl esters are formed by condensation with CO and $H_2O$ or $CH_3OH$, respectively, in the presence of strongly acidic catalysts. Starting from cyclopentene, cyclohexene, or cyclododecene it is possible to obtain the corresponding secondary cycloalkanecarboxylic acids exclusively or preponderantly when catalysts containing boron fluoride are used; however, with cycloheptene, over 90 % tertiary 1-methylcyclohexane-1-carboxylic acid is formed by isomerization with ring contraction. Cyclooctene yields exclusively 1-methylcycloheptane-1-carboxylic acid and 1-ethylcyclohexane-1-carboxylic acid. In addition to only 10 % of a mixture of tertiary $C_{11}$ acids, the reaction of cyclododecene gives 32 % higher acids and – presumably by hydride transfer [22] – 22 % of a mixture of *cis*- and *trans*-decalin-9-carboxylic acids.

*cis*-Bicyclo[3,3,0]octane-1-carboxylic acid (pentalanecarboxylic acid) is formed under extremely mild conditions from 1,5-cyclooctadiene. Both 1,5- [23] and 1,6-cyclodecadiene [24] can be converted into *cis*- and *trans*-decalin-9-carboxylic acids in very good yields. A mixture containing 82 % 1,2,3,4,5,6,7,8-octahydronaphthalene and 18 % 2,3,4,5,6,7,8,10-octahydronaphthalene is obtained almost quantitatively by isomerization of the cyclodecadienes in boiling *n*-hexane with boron trifluoride etherate as catalyst.

## The Szilard-Chalmers Process in $K_2ReBr_6/K_2OsCl_6$ Mixed Crystals

*Horst Müller*, Freiburg/Breisgau (Germany)

Following neutron activation of $K_2ReBr_6$ and dissolution of the target, 28 % of the radioactive rhenium atoms obtained are present as perrhenate, the remainder as hexabromorhenate (retention). In order to elucidate the cause of the retention, the chemical reactions following the $^{185}Re(n,\gamma)^{186}Re$ nuclear process were investigated in $K_2ReBr_6/K_2OsCl_6$ mixed crystals. At low rhenium contents, 37 % of the active rhenium atoms are found in the form of perrhenate, the remainder as $ReCl_nBr_{6-n}$ ($6 \geqslant n \geqslant 0$), *viz.* 14 % $ReBr_6^{2-}$, 4 % $ReCl_6^{2-}$, and 45 % mixed hexa(chloro/bromo)rhenates. This shows that of the three mechanisms under discussion, *viz.* 1) no bond rupture, $*ReBr_6^{2-}$ is preserved, 2) billiard impact: $*Re + OsCl_6^{2-} \rightarrow *ReCl_6^{2-} + Os$, and 3) hot-zone reaction: $*Re + nCl^- + (6-n)Br^- \rightarrow *ReCl_nBr_{6-n}^{2-}$, the third is the main one, while the second is inefficient. The marked enrichment of the bromine in the complex ions representing the retention fraction relative to the bromide content of the mixed crystals leads to the conclusion that the formation of the retention fraction occurs in a very small zone around the original position of the recoil atom, the diameter of which can be estimated at 5 Å. The non-statistical distribution of the mixed hexa(chloro/bromo)rhenates proves that the atoms remain unmixed within the reaction zone.

## Disproportionation Reactions of Diboron Compounds

*H. Nöth, P. Fritz, K. H. Hermannsdörfer, W. Meister, H. Schick*, and *G. Schmidt*, München (Germany)

Diboron compounds decompose in accordance with the disproportionation scheme:

$$nB_2X_4 \rightarrow n\,BX_2 + B_{n+2}X_{n+4}$$

In addition boron(I) compounds $[BX]_m$ and products that are even richer in boron are formed.

When X = OR, $NR_2$, or R, decompositions and elimination reactions involving hydrogenation compete with the disproportionation. The order of stability

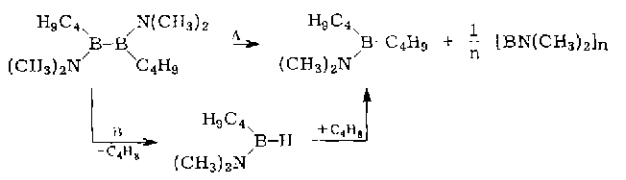
$$B_2[N(CH_3)_2]_4 > B_2(OR)[N(CH_3)_2] > B_2Cl[N(CH_3)_2]_3 \approx B_2Cl_2[N(CH_3)_2]_2 > B_2R[N(CH_3)_2]_3 > B_2R_2[N(CH_3)_2]_2 > B_2H[N(CH_3)_2]_3 > B_2F_4 > B_2Cl_4 > B_2R_2(OR)_2$$

[19] The observations described in this paper were originally submitted to Angewandte Chemie as a short communication on August 16th, 1963.

[20] *H. Metzger* and *K. Seelert*, Z. Naturforsch. *18b*, 335 (1963); Angew. Chem. internat. Edit. *2*, 624 (1963).

[20a] *H. Metzger* and *H. König*, Z. Naturforsch. *18b*, 976, 987 (1963).

[21] *H. Koch*, Brennstoff-Chem. *36*, 321 (1955); Fette, Seifen einschl. Anstrichmittel *59*, 493 (1957).



[22] *W. Haaf* and *H. Koch*, Liebigs Ann. Chem. *638*, 122 (1960).

[23] *G. Wilke*, Angew. Chem. *75*, 10 (1963).

[24] *G. Wilke* and *P. Heimbach*, unpublished results.

indicates the influence exerted by polarity and by π-bonds on the tendency towards disproportionation, which increases with any decrease in the electron density on the boron atoms.

The decomposition products which can be isolated depend on the reaction conditions.

+ polymeric products

A: sealed tube, 230°C
B: ambient pressure, 250°C

Polymeric products are formed via low molecular-weight straight-chain boron subcompounds, *e.g.* $C_4H_9[(CH_3)_2N]$-B–B[$N(CH_3)_2$]–B[$N(CH_3)_2$]$C_4H_9$, which can be isolated.

Dehalogenation of $B_2Cl[N(CH_3)_2]_3$ with liquid Na/K alloy leads to a tetraboron hexakisdimethylamide, $B_4[N(CH_3)_2]_6$, which on thermal decomposition yields $B_2[N(CH_3)_2]_4$ as a readily volatile main decomposition product together with a small amount of $B[N(CH_3)_2]_3$.

## Ring Syntheses Using Enamines and Ketene-N,N-acetals

*G. Opitz*, Tübingen (Germany)

Cycloaddition of ketenes onto enamines yielding 3-aminocyclobutanones proceeds smoothly in the aliphatic series. Although hetero-substituents in the ketene are not detrimental, aromatic substituents in ketenes and at the nitrogen atom of the enamine exert an inhibiting effect. Starting from ketene-*N,N*-acetals [$H_2C$=$C(NR_2)_2$] and ketene, 4-dialkylamino-6-methylcoumalines are obtained; these yield 1,3,5-triphenylbenzene with phenylmagnesium bromide and are degraded by sodium hydroxide, by way of triacetic acid, into acetone, acetic acid, and the dialkylamine.

Sulfenes, which are produced either from aliphatic sulfonyl chlorides and triethylamine or from a diazoalkane and $SO_2$ *in situ*, react with diazoalkanes to yield ethylenesulfones, and with enamines to yield β-aminotrimethylenesulfones. Cyclization to four-membered rings also occurs with 3-dialkylaminovinyl ketones and dienamines. On treatment with mesyl chloride-triethylamine, 1,1-dimorpholinoethylene yields 3-morpholinothietene-1,1-dioxide, via a cycloaddition and elimination of amine.

β-Amino-β-lactams, which are accessible from enamines and isocyanates, are also formed by cycloaddition of ketenes (produced *in situ*) onto amidines.

## Method for the Preparation of Complex Compounds of Elements in Higher Valence States

*Sw. Pajakoff*, Vienna (Austria)

The desired complexes are obtained by dissolving the stabilized and active oxides, oxo- and fluorometallates (*i.e.* oxocerate, fluoroterbate, *etc.*) of tetravalent Ce, Pr, Tb, Pb, Mn, Co, Ni, and Ag in complexing agents such as polyacetic acid, citric acid, trihydroxyglutaric acid, or aconitic acid, particularly in solutions of pH 8–10. The metal : ligand ratio in the solid complexes has a value of 1 : 1.

Stable fluorometallates of these tetravalent elements are obtained by fluorination of a mixture of the fluorides of the elements, alkali halides, and thermostable alkali fluorometallates at temperatures above 500 °C. The solid complex compounds of tetravalent Ce, Pr, Tb, Pb, Mn, Co, Ni, and Ag are very strong oxidizing agents; they are stable in air and are readily soluble in weakly alkaline solutions of pH $\leq$10. Above pH 11, the oxide hydrates of Ce(IV), Pr(IV), Tb(IV), and Pb(IV) [all yellow], and of Co(IV) [red-brown] precipitate out. On acidification of the complex solutions of tetravalent Ce, Pr, Tb, and Pb, which have a pH of 8.4–8.6, the sparingly soluble fluorides of tetravalent Pr, Ce, Tb, and Pb separate out in the form of yellow amorphous precipitates. Dioxides of Ce, Pr, Tb, Pb, Ni, Co, and Ag are obtained by thermal decomposition of the lower-valent metal nitrates in an oxidizing alkali nitrate melt. Individual reaction products are isolated by organic solvents, in particular, tributyl phosphate *(1)*. In this manner, tetravalent prascodymium and terbium nitrates and oxonitrates were isolated for the first time:

$Pr(NO_3)_4 \cdot 2BuO_3PO$; $PrO(NO_3)_2$; $Tb(NO_3)_4 \cdot 2BuO_3PO$; $TbO(NO_3)_2$.

Selective extraction of mixtures of higher oxides of Ce, Pr, Tb, Mn, Pb, Co, Ni, or Ag in complexing solutions yields the very pure dioxides of these elements. In the selective extraction of the oxoterbate $Tb_4O_7$ with 0.1 M EDTA solution, a reddish-brown highly colloidal oxoterbate(IV) was isolated. The method is also suitable for the preparation of pure oxometallates of the transition elements in higher oxidation stages [25]. Alkaline earth hydroxides in excess are very rapidly and completely removed with dilute complexing solutions of pH 9–9.5.

## Alkylgallium Derivatives

*G. Raab*, Erlangen (Germany)

Coordination compounds of tertiary amines with gallium trialkyls or dialkylgallium halides were prepared.

| Compound | B.p. [°C/mm Hg] | M.p. [°C] |
|---|---|---|
| $(C_2H_5)_3Ga \cdot N(CH_3)_3$ | 92/15 | – 28 |
| $(C_2H_5)_3Ga \cdot N(C_2H_5)_3$ | 52–54/$10^{-2}$ | – 6 |
| $(C_2H_5)_3Ga \cdot NC_5H_5$ | 62–65/$10^{-2}$ | ca. –40 |
| $(nC_4H_9)_3Ga \cdot N(CH_3)_3$ | 70/$10^{-3}$ | ca. –50 |
| $Cl(C_2H_5)_2Ga \cdot N(CH_3)_3$ | 74/$10^{-3}$ | ca. 0 |
| $Cl(C_2H_5)_2Ga \cdot NC_5H_5$ | 95–100/$10^{-2}$ | – 5 |
| $Cl(C_2H_5)_2Ga \cdot H_2NC_2H_4NH_2$ | | 170–180 (decomp.) |
| $Cl(nC_4H_9)_2Ga \cdot N(CH_3)_3$ | 80–85/$10^{-3}$ | ca. 0 |

Whereas pure gallium trialkyls and dialkylgallium halides possess practically no conductivity ($<10^{-8}$ mho/cm), the amine coordination compounds of these substances exhibit specific conductivities which are sometimes quite substantial and which are due to the amine-stabilized dialkylgallium ions.

$$2\ ClR_2Ga \cdot NR'_3 \rightleftarrows [R_2Ga(NR'_3)_2]^+ + [R_2GaCl_2]^-$$

This interpretation is confirmed for instance by the salt-like properties of the compound $[(C_2H_5)_2Ga\ en]^+\ Cl^-$ (en = ethylenediamine).

In the case of the alkylgallium dihalides, which also exhibit conductivity, ion formation is presumably caused by the strong tendency to form the $[GaX_4]^-$ ion and by the stabilization of $[R_2Ga]^+$ made possible by this ion.

$$(RGaX_2)_2 \rightleftarrows [R_2Ga]^+ + [GaX_4]^-$$

The following order of specific conductivities was determined:

| Compound | [mho/cm] at 80 °C |
|---|---|
| $(C_2H_5)_3Ga \cdot NC_5H_5$ | $6.0 \times 10^{-7}$ |
| $Cl(C_2H_5)_2Ga \cdot N(CH_3)_3$ | $1.3 \times 10^{-4}$ |
| $Cl(C_2H_5)_2Ga \cdot NC_5H_5$ | $8 \times 10^{-4}$ |
| $(C_2H_5)GaCl_2$ | $5.3 \times 10^{-3}$ |

[25] *R. Scholder* and *W. Klemm*, Angew. Chem. 66, 461 (1954).

## A Synthesis of Vomicine

*P. Rosenmund*, Frankfurt/Main (Germany)

According to *H. Wieland* and *R. Robinson*, the structure of vomicine, a minor alkaloid of *Strychnos nux vomica* L., is that of 4-hydroxy-*N*-methylpseudostrychnine. This formula has been confirmed by synthesis. 2-Bromostrychnine was nitrated in the 4-position [26], and the resulting bromonitrostrychnine was reduced with sodium amalgam to 4-aminostrychnine. The latter was converted on diazotization and boiling into 4-hydroxystrychnine in good yield, obviously thanks to a neighboring group effect. 4-Hydroxypseudostrychnine can be obtained through the *N*-oxide of this compound by a chromate-catalysed Polonovski reaction, and then be methylated by methyl iodide in methanol to give vomicine in 15 % yield. The ultraviolet absorption curves show that the deviation in absorbance of vomicine from that of 4-hydroxystrychnine is due to the methylation (the last step of the synthesis) and can be explained by the approach of the negatively charged oxygen atom of the zwitterionic form closer to the benzene nucleus.

## A Novel Decomposition of Peresters

*C. Rüchardt* and *H. Schwarzer*, München (Germany)

t-Butyl 2,4,6-cycloheptatrieneperoxycarboxylate *(1)* [27] and t-butyl 2,3-dipropylcyclopropenylperoxycarboxylate *(2)* are split into t-butanol, $CO_2$, and tropylium or dipropylcyclopropenium cations respectively by acid catalysis.

$$R{-}CO{-}O{-}O{-}t\text{-}C_4H_9 \xrightarrow[\text{Acetonitrile}]{HClO_4,\ 0\,^\circ C} R^+ + CO_2 + t\text{-}C_4H_9{-}OH$$

t-Butyl 2,3-benzo-2,4-norcaradiene-7-peroxycarboxylate *(3)*, 7*H*-cycloprop[*a*]acenaphthylene-7-peroxycarboxylate *(4)*, diphenylperoxyacetate *(5)*, and *exo*-bicyclo[2,2,1]hept-5-ene-2-peroxycarboxylate *(6)* do not undergo this fragmentation.

The thermal decomposition of *(1)* and *(2)* proceeds via a radical fission, since the rate of decomposition is little

$$R{-}CO{-}O{-}O{-}t\text{-}C_4H_9 \rightarrow R^\cdot + CO_2 + t\text{-}C_4H_9O^\cdot$$

influenced by the polarity of the solvent and since no cycloheptatrienyl methyl ether or dipropylcyclopropenyl methyl ether could be detected when the decomposition was carried out in methanol. In inert solvents compound *(1)* decomposes sixty times faster than *(5)*, and *(2)* ten times faster than *(5)* [28]; this is due to the more favorable entropy of activation of *(1)* and *(2)* and to a polar effect [29]. Esters *(3)* and *(4)* undergo thermolysis solely by fission of the peroxide bond in the rate-determining step of the reaction.

## Attempts to Prepare $C_6O_6$

*J. Sauer*, München (Germany)

Judging from kinetic studies [30], it might be expected that the double anhydride $C_6O_6$ *(1)* of ethylenetetracarboxylic acid *(2)* would exhibit dienophilic activity comparable to that of tetracyanoethylene *(3)*. Various methods of preparing *(1)* from *(2)* by dehydration failed. The Diels-Alder adduct *(4)* of $C_6O_6$ and 9,10-dimethoxyanthracene was prepared in 85 % yield by an independent route and decomposed in $10^{-3}$ M solution in dioxan to give about 20 % dimethoxyanthracene *(5)* and *(1)*; in the presence of one mole equivalent of cyclopentadiene, the decomposition proceeds even in $10^{-4}$ M solution in up to 95 % conversion and is strictly of the first-order; *(1)* accordingly possesses considerable dienophilic activity.

In preparative experiments, *(1)* may be trapped from decomposing *(4)* with dienes in the form of Diels-Alder adducts: cyclopentadiene (81 % adduct), 2,3-dimethylbutadiene (91 %), dimethylfulvene (56 %), diphenylfulvene, chloroprene (60 %), and 1,4-diphenylbutadiene (81 %); *(5)* resulting from *(4)* was isolated to 80–100 %. With bicycloheptadiene, the homo-Diels-Alder adduct (81 %) resulted. On boiling *(4)* in dioxan or toluene, up to 78 % of a pure isomerization product was isolated to which the structure of a Diels-Alder adduct of *(1)* at the 1,4-positions of *(5)* was assigned. Compound *(3)* is unable to undergo 1,4-addition under analogous conditions. The Diels-Alder adducts of *(3)* and 9-phenyl-, 9-chloro-, 9-methoxy-, and 9,10-dimethoxyanthracene are cleaved in dioxan at 20 °C partly spontaneously and partly at a measurable rate. Attempts to prepare solutions of free *(1)* are in progress.

## Compounds of Niobium with Elements of the 5th and 6th Main Groups

*H. Schäfer* and *W. Fuhr*, Münster (Germany)

The compounds NbX and $NbX_2$ (X = S, Se, or Te) can be transported chemically with iodine in a temperature gradient (900/1050 °C). NbX migrates to the higher and $NbX_2$ to the lower temperature zone.

$$NbX + 2\,I_2,\ g = NbI_4,\ g + 0.5\,X_2,\ g;\ \Delta H\,^\circ(R)\ \text{negative}$$

$$NbX_2 + 2\,I_2,\ g = NbI_4,\ g + X_2,\ g;\ \Delta H\,^\circ(R)\ \text{positive}$$

This makes it possible to carry out syntheses and separations and to grow crystals. The arsenides and antimonides of niobium can also be transported with iodine.

If closely neighboring compounds are present, or if non-stoichiometric (or doped) phases of definite composition are to be obtained, it is advisable to effect transportation with a "buffered gas phase", *e.g.* to transport the niobium oxides with a $Br_2$–$NbBr_4$–$NbBr_5$ gas phase.

## Preparation of New N-Silylaminosulfanes by Nucleophilic Rupture of S—S Bonds

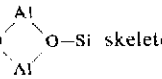
*O. Scherer* and *Max Schmidt*, Marburg/Lahn (Germany)

In connection with the problem of strengthening the bond between the nitrogen and silicon in the silylated alkali amides prepared by *Wannagat* and collaborators [31] by means of the lone pair of electrons on the nitrogen, we studied the nucleophilic behavior of these substances toward sulfur-sulfur bonds. It was thereby found that sodium bistrimethylsilylamide $NaN[Si(CH_3)_3]_2$ is not only suitable for effecting removal of elemental sulfur [32] but also splits disulfanes even under mild conditions. In addition to the sodium thioxide, a considerable number of new types of *N*-silylaminosulfanes are thereby made readily accessible according to the equation

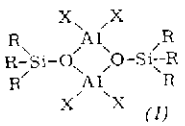
$$[R_3Si]_2NNa + x{-}S{-}S{-}x \rightarrow (R_3Si)_2N{-}S{-}x + Na{-}S{-}x$$

x = $C_2H_5$; n-$C_4H_9$; $C_6H_5$; $C_6H_5CO$; $C_2H_5{-}O{-}CO$; i-$C_3H_7{-}O{-}CS$; $(CH_3)_2N{-}CS$ and NC

As is to be expected, replacement of R = $CH_3$ by i-$C_3H_7O$ leads to a substantial decrease in the reactivity of the silylamide towards sulfur, on account of the greater demand placed by the silicon on the lone electron pair of the nitrogen.



[31] For example, *U. Wannagat* and *H. Niederprüm*, Chem. Ber. *94*, 1540 (1961).



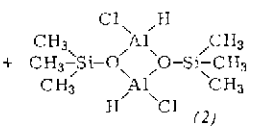
[32] *O. Scherer* and *M. Schmidt*, Naturwissenschaften, in the press.

## Trimethylsiloxychloroalane, a Crystalline, Distillable Compound with a Four-membered Ring Structure

*H. Schmidbaur* and *F. Schindler*, Marburg/Lahn (Germany)

Molecular-weight determinations and infrared as well as NMR spectroscopic investigations carried out on trialkylsiloxydichloro- and trialkylsiloxydibromoalanes have proved that these compounds possess a dimeric structure

with a $d_\pi$-$p_\pi$-stabilized planar  skeleton and the formula *(1)*.



*(1)*

R = alkyl, X = Cl, Br

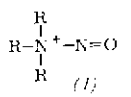
Cleavage of hexaalkyldisiloxanes with $AlI_3$ has now made it possible to prepare the isostructural diiodo compounds (X = I), which were hitherto regarded as being non-existent, in a pure state in the form of stable crystalline substances.

Treatment of such compounds *(1)* with $LiAlH_4$ and subsequent decomposition by distillation of the aluminohydride complexes formed have revealed a pathway to new types of stable aluminum-hydrogen compounds. Thus, trimethylsiloxydichloroalane *(1)*, R = $CH_3$, X = Cl, reacts with two equivalents of $LiAlH_4$ to form polymeric aluminohydride as well as *(2)*, m.p. 20.5 °C, b.p. 63–65 °C, the structure of which was determined by analysis, molecular-weight determination, and infrared and NMR spectra.

$$[(CH_3)_3SiOAlCl_2]_2 + 2\ LiAlH_4 \longrightarrow 2\ LiCl + 2\ (AlH_3)_n$$

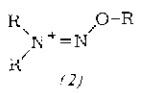
*(2)*

Compound *(2)* can be methylated with $LiCH_3$ to give stable trialkylsiloxyalkylaluminohydrides [*(1)*, R = $CH_3$, X = H, $CH_3$] and can be hydrogenated further.



## Alkoxydiazenium Salts

*A. Schmidpeter*, München (Germany)



Methyl iodide reacts with dimethylnitrosamine according to the equation

$$2\ CH_3I + (CH_3)_2NNO \rightarrow [(CH_3)_4N]I + NO + \tfrac{1}{2}I_2$$

This suggests an initial alkylation of the nitrosamine at the amino nitrogen *(1)*. On the other hand, Lewis acids generally add the to the oxygen of the nitrosamine system [33] and therefore, by analogy, *O*-alkylation *(2)* was to be expected.

*(1)*

*(2)*

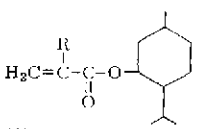
Trialkyloxonium hexachloroantimonates and dialkylnitrosamines yield salts of the composition $[R_3N_2O]SbCl_6$. Proton magnetic resonance spectra establish the dissimilarity of the three alkyl groups and hence structure *(2)*. In contrast to the trialkylnitrosylammonium salts *(1)*, the new 1,1-dialkyl-2-alkoxydiazenium salts *(2)* are very stable.

A simple way to prepare compounds of type *(2)* is the reaction of dimethyl sulfate with dialkylnitrosamines at room temperature.

$$(CH_3)_2SO_4 + R_2NNO \rightarrow [R_2NNOCH_3]SO_4CH_3$$

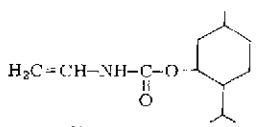
The reaction is reversible; the starting compounds are recovered by vaccum distillation. Crystalline methoxydiazenium salts are precipitated from solutions of the resulting 1,1-dialkyl-2-methoxydiazenium methyl sulfates by anions such as $SbCl_6^-$, $TeCl_6^{2-}$, $PF_6^-$, and $B(C_6H_5)_4^-$.

The course of the protonation of dialkylnitrosamines is of interest in view of their acid-catalysed hydrolysis. The crystalline compound obtained by addition of HCl onto dimethylnitrosamine is shown by its PMR spectrum to have the proton bound to the oxygen. HCl combines with the dimethylnitrosamine/antimony pentachloride adduct to give a compound which decomposes again *in vacuo*.



$$(CH_3)_2NNOSbCl_5 + HCl \rightleftarrows [(CH_3)_2NNOH]SbCl_6$$

Its reaction with diazomethane to the methoxy compound $[(CH_3)_2NNOCH_3]SbCl_6$ shows that the adduct is 1,1-dimethyl-2-hydroxydiazenium hexachloroantimonate.



## Radiochemical Polymerization of Some Optically Active Monomers

*R. C. Schulz*, Mainz (Germany)

The optically active monomers *(1)*–*(3)* were obtained by treating L-menthol with acrylic acid, methacrylic acid, or vinyl isocyanate.

*(1)*: R = H
*(2)*: R = $CH_3$

*(3)*

Esters *(1)* and *(2)* can be polymerized in bulk or in solution with azoisobutyrodinitrile, Grignard reagents, or $\gamma$-radiation from a Co source. Compound *(3)* also undergoes radical polymerization either in the melt or in solution; it could also be polymerized by $\gamma$-radiation in solution, but not in the crystalline state.

All the polymers of *(1)*–*(3)* are optically active. The direction of rotation is the same as with the monomers, but the value of the rotation is less. It is possible to obtain translucent, optically active molded solids by bulk polymerization initiated by radiation.

## Formation of Novel Organotin-Phosphorus Compounds by Reactions of Tetraphenyltin with Elemental Phosphorus

*H. Schumann*, *H. Köpf*, and *Max Schmidt*, Marburg/Lahn (Germany)

Tetraphenyltin and phosphorus react in an evacuated sealed tube at temperatures up to about 260 °C to form diphenylstannylenetriphenylphosphorane $(C_6H_5)_2Sn{-}P(C_6H_5)_3$, which on working up in air gives rise to diphenyltin oxide and triphenylphosphine oxide. Between 260 and 280 °C, depending on the quantitative ratio, triphenylphosphine and various phenyltin phosphides are obtained which are oxidized to organotin phosphates with air. Triphenylstannyldiphenylphosphine $(C_6H_5)_3Sn{-}P(C_6H_5)_2$ and polymeric phenyltin phosphides $[(C_6H_5)SnP]_x$ can be isolated. Their structure is proved by cleavage of the oxidation products with alcoholic sodium hydroxide:

$$(C_6H_5)_3Sn{-}P(C_6H_5)_2 \xrightarrow{O_2} (C_6H_5)_3Sn{-}O{-}\overset{O}{\overset{\|}{P}}{-}(C_6H_5)_2$$

$$\xrightarrow{OH^\ominus} (C_6H_5)_3SnOH + (C_6H_5)_2\overset{O}{\overset{\|}{P}}{-}ONa$$

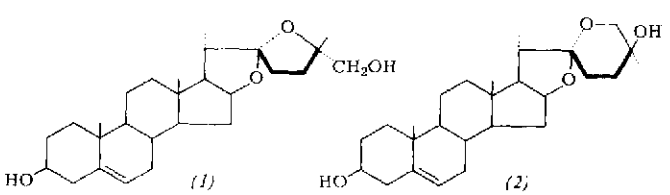
$$[(C_6H_5)SnP]_x \xrightarrow{2\,O_2} [(C_6H_5)SnPO_4]_x \xrightarrow{OH^\ominus}$$

$$(C_6H_5)SnOONa + Na_3PO_4$$

[33] *A. Schmidpeter*, Chem. Ber. *96*, 3275 (1963).

Triphenylstannyldiphenylphosphine is also obtained from triphenylchlorostannane and lithiodiphenylphosphine or from triphenylstannyl-lithium and diphenylchlorophosphine. Above 280 °C, tetraphenyltin and phosphorus form only triphenylphosphine and alloy-like tin phosphides of variable composition.

### The Constitution of the Horse-Chestnut Saponin Aescin



*R. Tschesche, U. Axen,* and *G. Snatzke,* Bonn (Germany)

When aescin is completely hydrolysed, it yields aescigenin, glucose, xylose, glucuronic acid, tiglic acid, and acetic acid [34]. Following acidic hydrolysis of aescin, in addition to aescigenin, a product was isolated which still contained both fatty acids in the genin. The structure of this "deglycoaescin" was determined by chemical reactions to be that of 28-(α-methyl-β-acetoxybutyryl)aescigenin; this was confirmed by its mass spectrum. The linkage of the sugar was elucidated by methylation and subsequent hydrolysis of the unaltered glycoside, of the glycoside after reduction at the carboxyl group of the glucuronic acid moiety, and of the partially hydrolysed glycoside. It appears that the xylose is attached at C-2 and the glucose at C-4 of the glucuronic acid. The glucuronic acid is probably bound glycosidically to the OH at C-3 of the aescigenin.

### The Constitution of a Cholegenin Analogue from the Vegetable Kingdom

*R. Tschesche* and *K. H. Richert,* Bonn (Germany)

A saponin was isolated from the roots of *Solanum sisymbriifolium* which was not precipitated with cholesterol. On hydrolysis with acid, this yielded a new genin, nuatigenin *(1)*, $C_{27}H_{42}O_4$, the first cholegenin analogue of plant origin. Mineral acids rearrange it to the structural isomer isonuatigenin *(2)*. This was related via its 24,25-anhydro compound to diosgenin and tigogenin. The constitutional formula suggested is that of *(20S,22S,25S)*-Δ⁵-spirostene-3β,25-diol.

From this it follows that the structure of nuatigenin is that of *(20S,22S,25S)*-22,25-epoxy-Δ⁵-furostene-3β,27-diol, as inversion of configuration at C-25 is excluded in the rearrangement of *(1)* to *(2)*.

### Geometrically Isomeric Pairs with Preferred cis-Configurations Among Substituted Ethylenes and 1,3-Butadienes

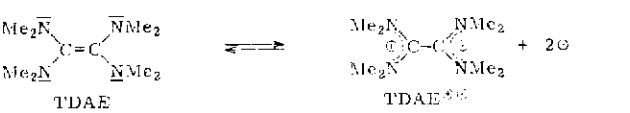
*H.-G. Viehe,* Brussels (Belgium)

Until now, it has been generally accepted that, under equilibrium conditions, the substituents on the spine of a molecule of both saturated and olefinic compounds prefer to take up positions furthest removed from one another. In the case of geometric isomers at least, this picture is false in many instances. Instead, the following can be considered as a first working hypothesis: the forces of attraction predominate between substituents, provided H–H interaction (as in pure hydrocarbons) or extreme overcrowding are absent.

Thermal isomerization of 2-bromo-1-iodoethylene at 175 and 225 °C proves that the *cis*-isomer is the more stable, contrary to previous steric descriptions. Moreover, of the ten possible 1,2-dihalogenoethylenes, *trans*-configuration is favored only in 1,2-diodoethylene. Furthermore, when 2-bromo-1-iodoethylene is warmed, an equilibrium is attained between the isomeric pairs of 1,2-dibromo-, 1,2-diodo-, and 2-bromo-1-iodoethylene via intermolecular halogen exchange. The equilibrium is experimentally attainable from all sides. 2-Fluoro-1-iodoethylene is formed analogously from 2-fluoro-1-bromoethylene by warming the latter with sodium iodide, and its formerly unknown *trans*-isomer can be isolated. Photochemical addition of 2-fluoro-1-iodoethylene onto ethylene and fluoroethylene permits the synthesis of 1-fluoro-1,3-butadiene and 1,4-difluoro-1,3-butadiene. Like their chloro analogues, both show *cis*-preference when subjected to isomerization with iodine in benzene solution.

### The Structure of the so-called "Alkali Carbonyls"

*E. Weiss* and *W. Büchner,* Geneva (Switzerland)



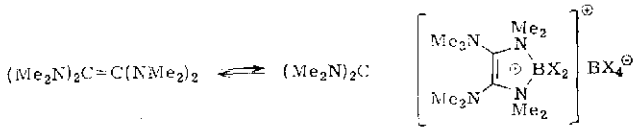
In liquid ammonia, carbon monoxide and alkali metals interact to give highly reactive, pyrophoric products of gross formula $(MCO)_x$ where M = Na, K, Rb, or Cs. These consist of an organometallic compound plus the metal derivative of dihydroxyacetylene $MOC{\equiv}COM$ (main constituent). On hydrolysis, both substances yield glycolic acid. The dihydroxyacetylene derivatives crystallize tetragonally (space group I 4/mmm-$D_{4h}^{17}$) with two formula units to each cell. The most important structural element is the linear anion $^{\ominus}|\overline{O}-C{\equiv}C-\overline{O}|^{\ominus}$ with approximate interatomic distances of C–C = 1.20 Å and C–O = 1.28 Å. Each oxygen atom is surrounded by five cations (tetragonal pyramid with O at the center of the base). The same environmental relationships occur in potassium methoxide (space group P 4/nmm-$D_{4h}^{7}$; 2 $KOCH_3$ per cell). Sodium methoxide, however, crystallizes in the $LiOCH_3$ lattice form, where each oxygen atom is surrounded by four cations. When, on the other hand, about 30 % NaOH is introduced (statistical distribution by partial hydrolysis of $NaOCH_3$), the $KOCH_3$ lattice is formed.

### Chemistry of Tetrakis(dimethylamino)ethylene

*N. Wiberg* and *J. W. Buchler,* München (Germany)

Tetrakis(dimethylamino)ethylene (TDAE) is a strong electron donor. Depending on the nature of the electron acceptor, the electron pair of (a) the double bond, (b) the nitrogen atom, or (c) the complete electronic system may be involved in the following reactions.

a) Strong oxidizing agents [35] convert TDAE into the dication $TDAE^{\oplus\oplus}$:

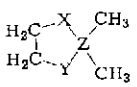


From the chemical point of view, TDAE is thus opposed to tetracyanoethylene (TCNE), which takes up electrons with extreme ease. Accordingly, TDAE reacts with TCNE with complete electron transfer, to yield the salt $[TDAE^{\oplus\oplus}][TCNE^{\ominus}]_2$. The radical cation $TDAE^{\oplus\ominus}$, corresponding to the radical anion $TCNE^{\ominus}$, was identified by mass spectroscopy.

[34] See *J. Wagner* and *J. Bosse,* Hoppe-Seylers Z. physiol. Chem. *320,* 27 (1960), where further references are given.

[35] *N. Wiberg* and *J. W. Buchler,* Angew. Chem. *74,* 490 (1962); Angew. Chem. internat. Edit. *1,* 406 (1962); Chem. Ber. *96,* 3223 (1963).

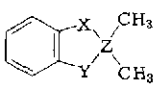
b) With Lewis-acids [36], *e.g.* $BX_3$, where X = F or H, TDAE forms cyclic "borazylammonium" salts *(1)*. This type of reaction (b), together with (a), disproves the existence of a carbene equilibrium.



*(1)*

c) A compound in which the entire electron system of TDAE is involved in bond formation is encountered in the crystalline electron donor-acceptor complex $TDAE(TNB)_2$, where TNB = *s*-trinitrobenzene. Spectroscopic results suggest a sandwich arrangement of the molecules.

## New Heterocycles Containing Germanium and Silicium

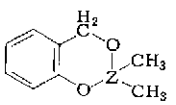


*M. Wieber* and *Max Schmidt*, Marburg/Lahn (Germany)

Bifunctional halogenoalkyl-germanes and -silanes may be converted practically quantitatively into the heterocycles *(1)* by means of glycol or its monothio or dithio analogue.

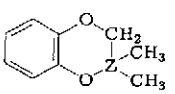
*(1)* Z = Ge or Si; X = Y = O; X = Y = S; X = O, Y = S

Catechol or its amino or thio analogue similarly furnish the new ring-compounds fused onto a benzene ring.



Z = Ge or Si; X = Y = O; X = Y = NH; X = O, Y = NH; X = S, Y = NH

*(2)*



*o*-Hydroxybenzyl alcohol yields heterocycles of type *(3)*. Their isomeric molecules *(4)* are formed from chloromethyl-dimethyl-chlorogermane or -chlorosilane and catechol.

*(3)*

Z = Ge or Si

*(4)*

## Novel Dienylation Reactions

*D. Wittenberg*, Ludwigshafen/Rhein (Germany)

Hardly any substitution reactions on dienes have been reported up to now. Novel types of dienylation reactions were reported in which a 1,3-diene is added onto carbon-carbon multiple bonds in the form of the dienyl and hydrogen radical.

$$CH_2{=}CH{-}CH{=}CH_2 + RCH{=}CHR' \rightarrow CH_2{=}CH{-}CH{=}CH{-}CHR{-}CH_2R'$$

*(1)*: R = H, R' = H

*(2)*: R = $-CH{=}CH_2$, R' = H

*(3)*: R = H, R' = $-COOR''$

The brown solutions of "cobalt – diene complexes" formed on reduction of cobalt compounds with metal alkyls in the presence of 1,3-dienes are used as catalysts.

Butadiene is converted into a mixture of straight-chain oligomers. The reaction can be controlled so as to give 3-methyl-1,4,6-heptatriene *(2)* and 1,3,6-octatriene as main products. Butadiene and ethylene form 1,3-hexadiene *(1)*, butadiene and acrylic esters give 4,6-heptadiene-1-carboxylic esters *(3)*. Isoprene and acrylic ester give 6-methyl-4,6-heptadiene-1-carboxylic ester. 1,8-Diphenyl-1,3,5,7-octatetraene, the product of two-fold dienylation, is formed from phenylacetylene and butadiene.

Hydrocarbons and ether are used as solvents. The preferred reaction temperature lies between 30 and 100 °C.

[VB 750/109 IE]

German version: Angew. Chem. *75*, 1106 (1963)

[36] *N. Wiberg* and *J. W. Buchler*, J. Amer. chem. Soc. *85*, 243 (1963); Chem. Ber. *96*, 3000 (1963).

## Isomerism of Hydroxylamine Derivatives

*O. Exner*, Prague (Czechoslovakia)

The infrared spectra of hydroxylamine derivatives confirm the correctness of the formula R–CO–NHOH preferred today for hydroxamic acids rather than R–C(NOH)OH; however, a new formula had to be put forward for the anion. It had previously been assumed that the hydrogen linked to the oxygen dissociates; thus, all the *O*-derivatives were called esters. However, it was shown by comparison of the dissociation constants (in 80 % methyl cellosolve) of *O*- and *N*-substituted benzhydroxamic acids that it is the hydrogen atom bound to the nitrogen that is acidic. If the pK values of a number of *O*-substituted benzhydroxamic acids are plotted against the Taft inductive constants of the substituents, the point for the unsubstituted acid lies on the same streight line. On the other hand, the *N*-derivatives are mostly much weaker acids; their acidity depends not only on the inductive but also on the steric effects of the substitutents. The Hammett ρ-constant for benzhydroxamic acids that are substituted in the nucleus, as well as for *O*-benzoylbenzhydroxamic acid derivatives, is about equal to that of benzoic acids, because the acidic hydrogen atom in all of these compounds bears the same relationship to the benzene nucleus. As expected, the ρ-constant for *N*-methylbenzhydroxamic acid derivatives is about half as great.

The structure of the hydroxamic acid anion $R{-}CO{-}\overset{\ominus}{N}OH$ was further proved by its infrared spectrum in Nujol suspension and dioxan solution. The presence of the OH-group in the lithium salt followed from comparison with *O*- and *N*-derivatives as well as with deuterated compounds. Finally, it appears from the ultraviolet spectra of *p*-nitrobenzhydroxamic acid and its *O*- and *N*-derivatives in neutral and alkaline media that the structure of the unsubstituted acid and of the *O*-derivatives alters in the same way on dissociation, whereas the *N*-derivatives show no alteration.

[GDCh-Ortsverband Marburg (Germany), November 8th, 1963] [VB 767/113 IE]

German version: Angew. Chem. *76* (1964), in the press.

## Mass-Spectroscopy of Inorganic Systems at High Temperatures [1]

*P. Goldfinger*, Brussels (Belgium)

The vaporization equilibria of numerous inorganic substances have been examined by mass spectroscopy during the last ten years [1a].

A narrow molecular beam of the vapor under examination effuses from a Knudsen cell of a few ml volume, in which a solid/gas or liquid/gas equilibrium is established. The

[1] Sponsored in part by the Aeronautical Systems Division, AFSC, through the European Office, Aerospace Research, U. S. Air Force.

[1a] *M. G. Ingram* and *J. Drowart*: High Temperature Technology. McGraw-Hill, New York 1960; *P. Goldfinger*: Compound Semiconductors. Reinhold, New York 1962; *J. Drowart* and *P. Goldfinger*, Annual Rev. Phys. Chem. *13*, 459 (1962).

molecules are ionized in the ion source of a mass spectrometer by electrons of variable energy, accelerated to about 2000 volt, submitted to magnetic mass analysis in a 60° sector instrument (radius of curvature: 20 cm), and the intensities measured with a secondary electron amplifier. The qualitative composition of the gaseous phase in the Knudsen cell is determined from the mass of the ions, their isotope distribution, and their appearance potentials. The quantitative composition and absolute pressure are obtained from the ion intensities, the total quantity of substance effused, and the relative ionization cross-sections [2].

Our results are summarized in Table 1. It was possible to determine the dissociation energies of $S_2$ and $Se_2$ [3], which have been the subject of long-standing controversy, from the equilibrium values (a) and (b); M = Ca, Sr, or Ba. The results can be corroborated by means of the equilibrium values (r) to (u) and other data. The equilibrium values (f) to (h) and (i) to (l) yield the dissociation energy of SO.

Table 1. Energies of formation of gaseous compounds.

| | Equilibrium | Compound formed | ΔH [kcal/mole] | Ref. |

German version: Angew. Chem. 76, 150 (1964)

## The Structure of Silicate Glasses

*H. Wondratschek*, Freiburg/Breisgau (Germany)

It has been customary for some time to consider the hypotheses of *Zachariasen* on the structure of glasses as outmoded. Two assertions always seem to recur; 1. a three-dimensional (Si,Al)-O lattice is not necessarily present in silicate glasses, and 2. the glass constituents are not homogeneously distributed in the glass, but form clusters. There is even occasional mention of complete phase separation. Examination of *Zachariasen*'s work shows that he did not postulate a three-dimensional lattice, nor did he make any assertions on the homogeneity of the distribution of glass constituents. Criticism of his views on that score is therefore unfounded.

When the details of the glass structure that are known with certainty are assembled, and the reliability of the analytical procedures employed is investigated, it soon becomes apparent that the evidence derived from the results obtained up to now has been highly overrated. Using X-ray crystallographic analysis, for instance, it is not possible to determine the coordination number of Si in silica glass more closely than "as lying between 3 and 5". Other procedures are equally uncertain, with the possible exception of the chromatographic method for the determination of the length of the phosphate chains in high-alkali $P_2O_5$ glasses. Most promising are feasibility studies in which glasses are compared with crystals of corresponding composition.

Electron micrographs of glass-fracture planes are often cited as evidence for inhomogeneity and phase separation. There are glasses which will actually give complete phase separation after sufficiently long time intervals, but statistical experiments show that even a completely random distribution of the different kinds of particles in the glass leads to relatively great inhomogeneity. It is not known how the fracture planes of such glasses would appear. Furthermore, cluster formation can already occur above the critical separation point, that is, certainly in the uniphase region, without phase separation ever taking place. It is at present not possible to distinguish with certainty between such a tendency to separate and statistical distribution or incipient separation.

Certain far-reaching assertions on the structure of the vitreous state, which are frequently encountered, should therefore be viewed with considerable caution. New and unexpected results (*e.g.* with glasses in the system $Pb_2SiO_4/PbSO_4$, examined in conjunction with *L. Merker*, or with the $Pb_2SiO_4/PbHal_2$ glasses found by *Merker*) show again how uncertain predictions in the field of glass chemistry can often be.

## The Constitution of Rifamycins

*V. Prelog*, Zürich (Switzerland)

Rifamycins (formerly known as rifomycins) are metabolic products isolated from cultures of *Streptomyces mediterranei*. Under certain growth conditions, rifamycin B is the main product of this group of compounds. It is, however, unstable and is oxidized in buffered neutral solutions by mild oxidizing agents, or even in air, to rifamycin O with loss of two hydrogen atoms. Rifamycin S is obtained from rifamycin O by treatment with acid in aqueous solution, one molecule of glycolic acid being removed hydrolytically. Rifamycin O is transformed by mild reducing agents, *e.g.* ascorbic acid, into rifamycin B; rifamycin S undergoes the same reaction to give rifamycin SV, the sodium salt of which has found clinical application under the commercial name rifocin®.

Extensive investigations by *W. v. Oppolzer* in our laboratory have led to the constitutional formulae *(1)*–*(4)* for the four rifamycins mentioned above. These are based mainly on the results of chemical degradations of rifamycin S (methanolysis of the iminomethyl ether of rifamycin S; degradation of rifamycin S by ozone and subsequent treatment with performic acid; oxidation of tetrahydrorifamycin S with nitric acid) and on the analysis by NMR spectroscopy of the molecule and its degradation products obtained by these and other reactions.

*(1)* Rifamycin B

*(2)* Rifamycin O

*(3)* Rifamycin S

*(4)* Rifamycin SV

+ $HOCH_2CCOH$

According to formulae *(1)–(4)*, the rifamycins represent naturally occurring ansa-compounds in which an aliphatic bridge spans an aromatic system. One consequence of this ansa-constitution is that methyl groups of the aliphatic bridge are placed in the magnetic field of the aromatic π-electron current, and are therefore more or less shielded, depending on their exact positions. The doublets attributed to two of the four $CH_3CH$-groups of rifamycins O and S do indeed lie at unusually high magnetic fields, *viz.* $\delta = 0.22$ and 0.67 ppm.

Their constitutions suggest that biogenetically the rifamycins are built up largely from acetate and propionate or their biochemical equivalents.

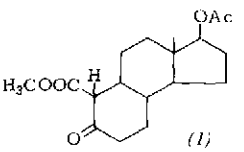
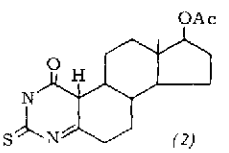
# SELECTED ABSTRACTS

**Decarbobenzoxylation with liquid hydrogen bromide** was achieved by *M. Brenner* and *H. Ch. Curtius*. They treated carbobenzoxyamino acids and peptides with 10–20 parts of condensed HBr at −80 °C and evaporated off the HBr by removal of the coolant, moisture being excluded. The resultant hydrobromide was then recrystallized. This method is particularly suitable for labile compounds and sparingly soluble carbobenzoxy peptides, for liquid HBr is an excellent solvent and can be removed under mildest conditions. Peptides containing thioester groups, for instance, can be decarbobenzoxylated to give pure compounds in 70–90% yield. / Helv. chim. Acta *46*, 2126 (1963) / –Dc. [Rd 792/208 IE]



**The steric configuration of 1:2-metal-dye complexes** with 6-coordinate metal central ions ($Cr^{3+}$, $Co^{2+}$) was studied by *G. Schetty*. Diarylazo and diarylazomethine dyes (*e.g.* 2-hydroxy-6-carboxyazobenzene) were used as tridentate ligands. By incorporation of the central ion, each dye molecule forms either two annelated six-membered rings or a five-membered ring annelated with a six-membered ring via its three coordinating atoms A, B, and C. In the 6-6 rings, the dye molecules of the complex lie one on top of the other in a sandwich structure; in the 5-6 rings, the molecule planes are perpendicular to each other. Both these structural possibilities (A, B, and C are at the corners of an equilateral or isosceles triangle) are also apparent in atomic models. With the aid of the bonding angles and interatomic distances, the dimensions of the ABC coordination triangles can be calculated and compared with the theoretical values of the coordination octahedron. The complex *(1)* is a borderline case in which both

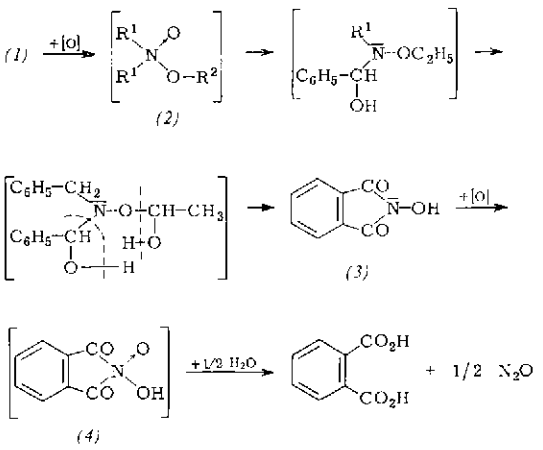


*(1)*

structures are feasible. The 6-6 systems are more labile and yield stereoisomers; they are further distinguished from the 5-6 systems by their ultraviolet absorption spectra. Chemically as well as stereoisomerically differing complexes may be separated chromatographically on Alox columns. The 6-6- and 5-6 systems can be differentiated by means of possibly stereoisomeric mixed complexes (there are two different dye molecules in the complex). Equilibria between 1:2- and 1:1-complexes and the free dye were determined optically. / Helv. chim. Acta *46*, 1132 (1963) / –Jg. [Rd 781/203 IE]

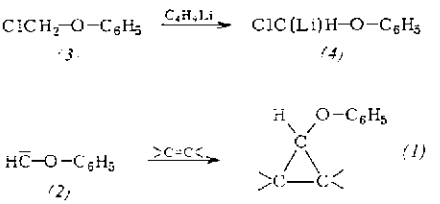
**Heterocyclic steroids in which ring A is replaced by a pyrimidine ring** have been prepared for the first time by *E. Caspi* and *D. M. Piatak*. Degradation of 19-nortestosterone was performed by condensation with ethyl formate, acetylation to form 17-β-acetoxy-2-acetoxymethylene-Δ⁴-oestren-3-one, and ozonolysis to yield the γ-keto acid, followed by conversion

*(1)*



*(2)*

into a diphenyleneketo steroid; splitting of the diphenylene ketal with $RuO_4/NaIO_4$ then led to *(1)*, the key intermediate. Compound *(1)* can be condensed with thiourea to give 17-β-acetoxy-2,4-diaza-Δ⁴-oestren-1-one-3-thione *(2)*, $C_{18}H_{24}N_2O_3S$, m.p. > 300 °C, $\lambda_{max} = 219$ (ε = 12000) and 280 mμ (21000) in methanol. / Experientia (Basel) *19*, 465 (1963) / –De. [Rd 779/202 IE]



**The effect of liquid $NH_3$ on phosphoric esters** has been investigated by *R. Klement* and *A. Wild*. On ammonolysis, $OP(OR)_3$ (R = alkyl) yields $NH_4PO_2(OR)_2$ after some weeks at room temperature, but more rapidly at 60–70 °C. The C–O–P bond is therefore cleaved between the C and the O, in contrast to aryl esters, which yield $OP(NH_2)_2$, the C–O–P bond being cleaved between the P and the O. The ammonolysis appears to proceed step-wise. Tetraethyl pyrophosphate yields quantitatively the ammonium salt and amide of diethylphosphoric acid. The tetraphenyl ester produces phosphoric triamide and ammonium diphenylphosphate. The reaction products were examined by paper chromatography. / Chem. Ber. *96*, 1916 (1963) / –Kr. [Rd 778/201 IE]

**The possibility of the existence of dialkyl- and diacylnitronic acids** was investigated by *F. Klages, R. Heinle, H. Sitz,* and *E. Specht.* All attempts to prepare dialkyl- and diacylnitronic acids, $R_2NOOH$, led to side reactions, but the reaction products indicated intermediate formation of compounds of the desired formula. Decomposition also occurs even under very mild conditions, but the different courses of this reaction could largely be elucidated. Nitronic acids with two organic substituents on the nitrogen atom are not capable of existence.

Reaction of *N,N*-dibenzyl-*O*-ethylhydroxylamine *(1)* with less than the theoretical amount of peroxyacetic acid yielded equimolar amounts of benzaldehyde and acetaldehyde (20 to 25 %) as well as *N*-benzylhydroxylamine (75 %), probably by oxidation of *(1)* to dibenzylnitronic acid *(2)* followed by rearrangement. Oxidation of *N*-hydroxyphthalimide *(3)* with $H_2O_2$ or $PbO_2$ gave $N_2O$ and phthalic acid, possibly via the primarily formed nitronic acid derivative *(4)*. *N,N*-Di-t-butylhydroxylamine and its *O*-acetyl derivative always gave a nearly quantitative yield of 2-nitroisobutane with peroxycarboxylic acids. An intermediate blue color seems to indicate transient formation of 2-nitrosoisobutane. / Chem. Ber. *96*, 2387 (1963) / –Ma. [Rd 733/204 IE]

**The synthesis of phenoxycyclopropanes** (1) from phenoxycarbene *(2)* and olefins is reported by *U. Schöllkopf, A. Lerch,* and *J. Paust.* The carbene *(2)* is produced in the reaction mixture by elimination of hydrogen chloride from chloromethyl phenyl ether *(3)* with butyl-lithium, lithiochloromethyl phenyl ether *(4)* probably occurring as an intermediate.

The carbene *(2)* apparently acts as an electrophilic reagent, for the yields of cyclopropane compounds are greater, the higher the electron-density at the olefinic double bond. The addition takes place stereospecifically as *cis*-addition. / Chem. Ber. *96*, 2266 (1963) / Sk. [Rd 775/199 IE]

# BOOK REVIEWS

**Atlas d'équilibres électrochimiques à 25 °C** (Atlas of Electrochemical Equilibria at 25 °C), by *M. Pourbaix*, in collaboration with a number of scientists. Gauthier-Villars and Cie., Paris 1963. 1st edit. 644 pp., numerous illustrations, linen, NF. 140.– (about $ 28. –).

This atlas presents equilibrium data for a large number of electrochemical reactions, which characterize the behavior of metals and metaloids in aqueous solutions at 25 °C. The equilibria are, in general, represented graphically, the reversible electrode tension being plotted against pH (tension-pH diagrams). For every element, a number of reactions, particularly those involving hydroxide or oxide formation, has been considered in most cases.

In the introduction, *Van Rysselberghe* develops concisely and clearly the thermodynamic fundamentals of the book; he uses the concepts of chemical, electrochemical, and electrical tension, recommended by the CITCE nomenclature commission, which allow elegant derivation of the main basic relationships. In a further section, *Pourbaix, Valensi, Charlot, Hoar,* and *Garrels* discuss the most important applications of the tension-pH diagrams. These are primarily of interest in connection with corrosion, but also with general inorganic chemistry, analytical chemistry, the deposition and dissolution of metals by electrolysis, and even geology. Numerous diagrams show the regions in which metals corrode and those in which they are immune or passive (immunity being understood as the state in which corrosion by an adjacent liquid is thermodynamically impossible, whereas in the case of passivity, corrosion is prevented by a change in the surface characteristics of the metal, owing, for instance, to the formation of a compact surface layer). In general, the equilibrium diagrams and analytical relationships given allow one to state whether, for a given set of conditions, an electrochemical reaction can take place or not. This does not mean, of course, that a thermodynamically possible reaction will in fact occur, because its rate may be impracticably slow.

However, this restriction in the use of the diagrams is also encountered in the utilization of all the usual chemical free energy tables in general. Compared to the latter, which even to-day are often rather incomplete, the number of data collected in the atlas under review is remarkable. Virtually all the elements have been covered. This is the fruit of years of relentless efforts on the part of *M. Pourbaix* and of the Cebelcor [*] of which he is director. This comprehensive, well arranged volume will be welcome, particularly to those interested in corrosion and passivity. The printing and general appearance are good, the price can be regarded as modest for a book of this kind. *N. Ibl* [NB 135/63 IE]

# Protonic States in Chemistry [*]

BY PROF. DR. H. ZIMMERMANN [**]

PHYSIKALISCH-CHEMISCHES INSTITUT
DER TECHNISCHEN HOCHSCHULE MÜNCHEN (GERMANY)

*Dedicated to Prof. Dr. G. Scheibe on the occasion of his 70th birthday*

*Protons are subject to the wave/particle dualism of matter. Hitherto, only the corpuscular picture has been generally used in chemistry for describing protons. In contrast, the wave picture is considered in the present article. Protonic states, proton delocalization, and the tunnel effect in chemistry are discussed and illustrated by examples.*

## I. Introduction

Of all the elementary particles, electrons and protons claim special interest in chemistry. The electrons in atoms, ions, and molecules occupy well-defined states that may be computed, in principle, as solutions of the Schrödinger equation. According to wave mechanics, it is not possible to indicate accurately the position occupied by an electron at a given time. All that can be made is a statement of the probability of its location. In the view of wave mechanics, therefore, the electron is not located at any definite spot but is delocalized, *i.e.* distributed, over the whole range of the electronic state.

Fundamentally, any elementary particle may be described as a wave or as a corpuscle. For the treatment of problems concerning electrons in chemistry, the wave-mechanical approach has proved particularly helpful. Conversely, the corpuscular picture is of less importance in describing electrons. The opposite situation prevails in the treatment of problems concerning protons in chemistry. The proton as the nucleus of the hydrogen atom is generally represented as a corpuscle, which is fixed in a definite position in a molecule. This differentiated treatment of electrons and protons seems appropriate because of the difference in mass of the particles, *viz.* $M_{H^+}/M_e = 1836$. However, the proton, in turn, differs from the atoms and ions of the remaining elements of the periodic system. In the form of a bare atomic nucleus, it has a radius of the order of $10^{-13}$ cm, whereas atoms and ions generally have radii of the order of $10^{-8}$ cm. Accordingly, the proton is smaller by about five orders of magnitude than other atoms. It is therefore to be expected that it exhibits properties that, on the one hand, differ from those of other atoms and ions and, on the other, show analogies to the behavior of electrons. It therefore seems reasonable, to base the description of protons in chemistry on the wave picture as well. According to this view, states are supposed to exist for protons, much as in the case of electrons, in which protons are delocalized. States of this kind will be discussed in the following with several examples.

## II. Protonic States of a Harmonic Oscillator

The simplest model for the discussion of protonic states is the harmonic oscillator. This will now be briefly discussed [1,2].

Let us consider a molecule A–H, in which a hydrogen atom H is linked by a homopolar bond to a residue A. The bonding electrons are derived from the residue A as well as from the hydrogen atom. The proton is held in the negatively charged electron cloud of the bonding

[*] Excerpts from this paper were given in a lecture to the annual meeting of DECHEMA, Frankfurt/Main (Germany), 1962.

electron state. If the bond is stable, the proton is placed in a potential trough, the shape of which in the neighborhood of the potential minimum can be easily estimated.

According to classical mechanics, a particle reaches its lowest energy state at the potential minimum. If it deviates from its position of rest by an amount x, a force K is generated which tends to return the particle to its equilibrium position and is approximately proportional to x:

$K = -f\,x$, where f = directing force.

A shift dx causes the particle to gain the potential energy $dU = -K\,dx$. This yields the potential function

$$U = \tfrac{1}{2} f x^2,$$

As a particle of mass m deviates from its position of rest, it can be excited to undergo harmonic vibrations around its equilibrium position, with the frequency

$$\nu = \frac{1}{2\pi}\sqrt{f/m}$$

According to classical mechanics, vibrations of any amplitude and, therefore, of any energy are feasible.

If the proton in its ground state were to remain at the potential minimum, as is postulated by classical mechanics, the position (x = 0), momentum (p = 0), and energy (E = 0) of the particle would be clearly defined. However, the proton is an elementary particle and as such is subject to Heisenberg's uncertainty principle, according to which both the position and the momentum of any particle cannot be accurately known at the same time.

We must therefore discard the classical view and employ wave mechanics. For this purpose, we must look for solutions of the Schrödinger equation which we obtain for a proton moving in a parabolic potential. The limiting condition that the proton is always at a finite distance from the equilibrium position implies quantization of its energy. In contrast to classical mechanics, the proton cannot possess any indescriminate energy of vibration, but can only assume discrete energy levels (energy eigenvalues):

$E_n = h\nu\,(n + \tfrac{1}{2})$, where $n = 0, 1, 2, \ldots$.

In its lowest energy state (n = 0), the proton has still got a minimum amount of energy, its zero-point energy, as a direct consequence of the uncertainty principle.

A place-dependent eigenfunction $\Psi_n(x)$ may be ascribed to each of the discrete protonic energy states $E_n$. These eigenfunctions are obtained as solutions of the Schrödinger equation. By substituting $\xi = 2\pi x\sqrt{m\nu/h}$, eigenfunctions of the following type result:

$$\Psi_n(\xi) = \exp(-\xi^2/2)\cdot P_n(\xi).$$

The Hermite polynomials $P_n(\xi)$ for the lowest states are given by

$P_0(\xi) = 1$

$P_1(\xi) = \xi$

$P_2(\xi) = \xi^2 - 1$

The square of the eigenfunction $\Psi_n(x)$ or $\Psi_n(\xi)$ is a measure of the probability of the presence of the proton in the n-th state at position x or $\xi$, respectively (Fig. 1).

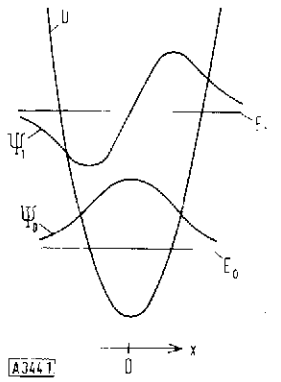

Fig. 1. Potential U, energy eigenvalues E, and eigenfunctions $\Psi$ of a harmonic oscillator.

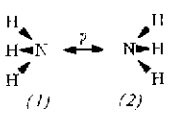
Figure 1 shows the lowest energy eigenvalues and eigenfunctions (n = 0, 1) for a proton moving in a parabolic potential field. Let us consider the ground state of the particle. As can be seen from Figure 1, $\Psi_0(x)$, and therefore also $\Psi_0(x)^2$, has a maximum at the position of the potential minimum (x = 0). This is, therefore, where the proton is most probably to be found. This shows a certain analogy to classical mechanics, according to which the particle in its ground state should be at the potential minimum. In contrast to the classical view, the proton pictured by wave mechanics has a finite probability of occurrence even on either side of the maximum $\Psi_0(0)^2$. It may even penetrate into the potential wall, a phenomenon that contradicts classical mechanics and can only be understood in terms of wave mechanics. The proton, therefore, is not fixed at a definite location but is delocalized over the range of the protonic state. Protons, in other words, behave just like electrons. A very good illustration is given by comparison of the different protonic states $\Psi_n(x)$ with the vibration states of the molecule A–H. Energy absorption and emission can cause proton transitions between these states. These transitions can be determined experimentally by means of infrared and Raman spectroscopy.



Protonic states occur widely in nature in the form just described. They are present whenever there is only one potential trough for a proton in a molecule. In particular cases, several potential troughs for a solitary proton can also exist. Protonic states are then probably formed that extend over a range encompassing all of these potential troughs. Such protonic states will be dealt with in the following, as they are of particular importance in chemistry.

## III. Protonic States of the Ammonia Molecule

The ammonia molecule is the classical example for the discussion of protonic states extending over two potential troughs [3]. Ammonia has a pyramidal structure with the nitrogen atom at the peak, and with three valence

[3] *G. Herzberg*, [2], p. 221.

bonds to the hydrogens radiating downward from it. This arrangement is not rigid, however, *i.e.* the molecule can invert, in which case the hydrogen atoms pass from one side of the nitrogen to the other. This inversion is a very common occurrence. It can be shown that the life period of any configuration is only $10^{-11}$ sec (approx.) [3]. The actual state of the molecule must therefore be described by superimposition of configurations *(1)* and *(2)* which are only limiting structures of the molecule. A similar situation is therefore encountered in describing the protonic states of the ammonia molecule as with the electronic states of molecules. Electronic states may be tentatively described by quantum-mechanical superimposition of basic functions (*viz.* by superimposition of mesomeric structures in the valence bond (VB) method or by linear combination of atomic eigenfunctions in the LCAO method). Protonic states may be represented by superimposition of basic functions formed from the various configurations of the molecule. This tentative description of protonic states by linear combination of protomeric structures of the molecule shall be called protomerism and characterized by the symbol $\overset{P}{\leftrightarrow}$.

*(1)* *(2)*

Quantum-mechanical calculations of the protonic states of ammonia have been carried out by various authors [4–10]. Their treatments differ essentially in the potentials used in the calculations. The following illustration is intended to clarify the close connection between the treatment of protonic states and electronic states according to the LCAO method. Since inversion is not limited to ammonia alone, it is better to examine the general problem of a pyramidal molecule $AH_3$.

A molecule may be in its ground state or in an excited vibrational state. The law of conservation of the centre of gravity holds for all states of the molecule. Since A is considerably larger in mass than the proton, it is primarily the protons that will be in motion in an excited vibration state, while A is approximately at rest. For a tentative consideration of inversion it will therefore suffice to follow the motion of the protons.

Let us consider a proton of the molecule $AH_3$, and let us first suppose that configurations *(1)* and *(2)* have an infinite life period. The proton will have two stable positions, *i.e.* there are two potential troughs $U_I$ and $U_{II}$ for the proton, which may be ascribed to the two configurations *(1)* and *(2)*. $U_I$ and $U_{II}$ can be roughly described by parabolic potentials such as we have met in the treatment of the harmonic oscillator (Fig. 2). Energy eigenvalues $E_{In}$ and $E_{IIn}$ as well as eigenfunctions $\Psi_{In}$ and $\Psi_{IIn}$ may be ascribed to the potential troughs, ($n = 0, 1, 2 \ldots$). Configurations *(1)* and *(2)* being energetically equivalent, the two energy eigenvalues $E_{In}$ and $E_{IIn}$ for any given value of n are equal for each pair and are thus degenerate ($E_{In} - E_{IIn} - E_n$).

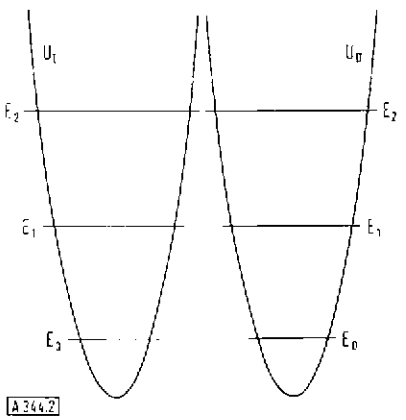


Fig. 2. Potential U and energy states E of a system consisting of two non-interacting harmonic oscillators.

If we now consider the case that configurations *(1)* and *(2)* interconvert rapidly, a change in position of the proton between the potential troughs $U_I$ and $U_{II}$ must occur. The proton will move in a potential that may be represented by superimposition of the partial potentials $U_I$ and $U_{II}$ (Fig. 3). The resulting potential has two minima of equal height, separated by a wall. Generally, there are two possible mechanisms for this change in position.

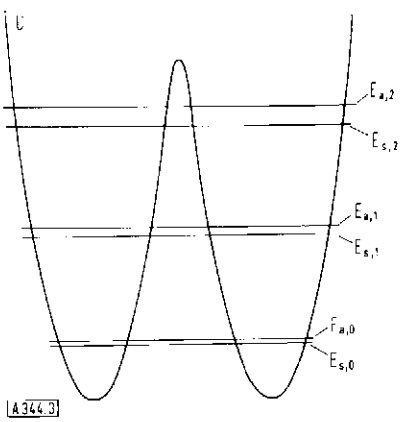

Fig. 3. Potential U and energy states E of a system consisting of two interacting harmonic oscillators.

The proton is either supplied with activation energy and leaps over the potential wall, or it penetrates through the potential wall (tunnel effect), in which case no activation energy is required. It can be shown that the proton transfer actually takes place by means of the tunnel effect in the case of the ammonia molecule [11].

Let us consider a pair of degenerate protonic states $\Psi_{In}$ and $\Psi_{IIn}$ that are ascribed to the neighboring potential troughs $U_I$ and $U_{II}$. Since protons are able to penetrate into a potential wall to a certain extent, the states $\Psi_{In}$ and $\Psi_{IIn}$ extend into the range of the potential wall sep-

arating the potential troughs. If the potential wall is sufficiently thick, there is no substantial overlapping of $\Psi'_{In}$ and $\Psi'_{IIn}$; the states are independent of each other. However, if the potential wall is thin, $\Psi'_{In}$ and $\Psi'_{IIn}$ may overlap, *i.e.* the states $\Psi'_{In}$ and $\Psi'_{IIn}$ interact. Fresh eigenfunctions have to be set up in order to describe this system. These may be adequately represented, in close approximation, by linear combination of $\Psi'_{In}$ and $\Psi'_{IIn}$. $\Psi'_{In}$ and $\Psi'_{IIn}$ are thus basic functions of the protonic state. Since the potential is arranged symmetrically around the centre, $\Psi'_{In}$ and $\Psi'_{IIn}$ may be linearly combined either symmetrically (s) or anti-symmetrically (a). Two fresh eigenfunctions result for each value of n, by interaction of the protomeric structures (N = normalizing constant):

$$\Psi'_{s,n} = N(\Psi'_{In} + \Psi'_{IIn})$$

$$\Psi'_{a,n} = N(\Psi'_{In} - \Psi'_{IIn})$$

Figure 4 shows the states $\Psi'_{s,n}$ and $\Psi'_{a,n}$ for n = 0, 1. All the states extend over both potential troughs. The probability of the occurrence of the proton is equal for the

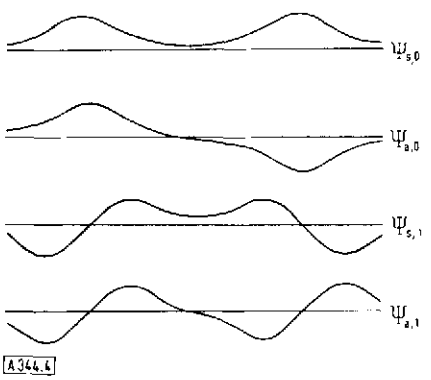

Fig. 4. Protonic states for a potential with a symmetrical double minimum.

two potential minima. It is impossible, in wave mechanics, to state in which potential trough the proton will be at a given time. The proton is delocalized over the range of both potential troughs and changes its position between the two potential minima by means of a tunnel effect.

An energy $E_{s,n}$ or $E_{a,n}$ may be ascribed to each of the states $\Psi'_{s,n}$ and $\Psi'_{a,n}$ with the aid of the Schrödinger equation,

$$E = \int \Psi_H \Psi d\tau / \int \Psi^2 d\tau .$$

Starting approximately from orthogonally normalized eigenfunctions $\Psi'_{In}$ and $\Psi'_{IIn}$, one obtains in simple fashion

$$E_{s,n} = E_n + \omega_n$$

$$E_{a,n} = E_n - \omega_n$$

$$E_{s,n} - E_{a,n} = 2\omega_n$$

The integral

$$\omega_n = \int \Psi'_{In} H \Psi'_{IIn} d\tau$$

describes the interaction between the protomeric structures $\Psi'_{In}$ and $\Psi'_{IIn}$.

Without going into detail about the special form of the Hamiltonian operator H, $\omega_n$ may be easily considered qualitatively. A measure of the interaction between $\Psi'_{In}$ and $\Psi'_{IIn}$ is the tunnel effect. The latter is facilitated by increased interaction, depends on thickness and height of the potential wall, and occurs the more readily, the thinner and lower the potential wall (calculated from the energy level of the particle). It follows from this that the value of $\omega_n$ increases on approaching the peak of the potential wall, *i.e.* the higher the quantum numbers n. In this way, the term system of the proton may be considered qualitatively.

If no interaction occurs between $\Psi'_{In}$ and $\Psi'_{IIn}$, *i.e.* if configurations *(1)* and *(2)* have long lives, no tunnel effect is in operation, *i.e.* the proton is able to occupy only one of the doubly degenerate energy states $E_{In} = E_{IIn} = E_n$ at a time. If there is interaction between $\Psi'_{In}$ and $\Psi'_{IIn}$, however, *i.e.* if configurations *(1)* and *(2)* have short lives, then there is a tunnel effect, *i.e.* the degeneracy of the terms disappears. In place of the degenerate terms $E_{In}$ and $E_{IIn}$, the split terms $E_{s,n}$ and $E_{a,n}$ are observed (inversion doubling). The splitting of the terms, namely

$$E_{s,n} - E_{a,n} = 2\omega_n$$

increases with rising n (Fig. 3). The splitting of the terms has been determined experimentally for ammonia [11]. This renders it certain that, during inversion, the protons of the molecule move in potentials with a double minimum and that the proton transfer takes place by means of the tunnel effect.

## IV. Protonic States in Hydrogen Bonds

An intermolecular or intramolecular hydrogen bond arises from the interaction of the particles A–H and B.

$$A{-}H\cdots|\,B \qquad (3)$$

A–H supplies a proton to the hydrogen bond and is called a proton donor. B supplies a free electron pair to the bond and is described as an electron donor.

A hydrogen bond therefore represents the joining of a Brönsted acid/base pair. Accordingly, it is reasonable to suppose that proton transfer may take place within the bond from A–H to B, resulting in a polar form of the bond:

$$\overset{\ominus}{A}|\cdots H{-}\overset{\oplus}{B} \qquad (4)$$

If there is conduction between A and B through a π-electron system within a molecule with intramolecular hydrogen bonds, charge equalization can take place by means of an electron shift.

Some limiting conditions can be given for the potential and for the proton states in the bond:

1. The potential has two minima around A and B.

1a) For weak proton donors and acceptors, the potential trough at A is considerably lower than that at B. The proton, in its ground state, remains around A. The bond

is characterized by the limiting structure *(3)*. Only energy absorption enables the proton to reach the potential trough B (Fig. 5a).

1b) For strong proton donors and acceptors, the potential trough at B is considerably lower than that at A. The proton, in its ground state, remains in the potential trough at B. The bond is characterized by the limiting structure *(4)*. Energy absorption makes proton transfer into the potential trough at A possible (Fig. 5b).

1c) For medium-strength proton donors and acceptors, the two potential troughs may have the same or almost the same height. The probabilities of occurrence of the proton in the two potential minima are approximately equal. The bond can be characterized by superimposition of the limiting structures *(3)* and *(4)*. Proton transfer is possible by a proton leap or by the tunnel effect (Fig. 5c).

2. In extremely short hydrogen bonds, the two potential minima may merge to one joint potential trough. The proton in its ground state stays about half-way between A and B (Fig. 5d).

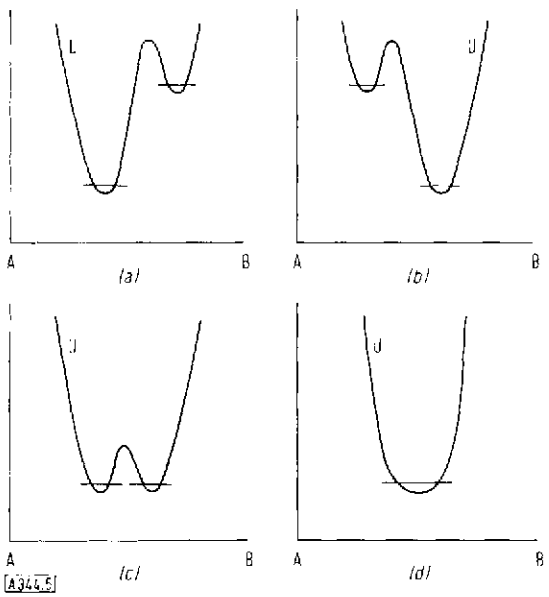

Fig. 5. Limiting states for the potential of the proton in a hydrogen bond.
(a) Hydrogen bond between weak proton donor (A) and weak proton acceptor (B).
(b) Hydrogen bond between strong proton donor (A) and strong proton acceptor (B).
(c) Hydrogen bond between medium-strength proton donor and acceptor.
(d) Extremely short hydrogen bond.

The potentials and the protonic states of hydrogen bonds have been investigated by numerous authors, both theoretically [12–25] and experimentally [12, 13, 26–45]. For a discussion of proton delocalization, those bonds are of particular interest in which proton transfer takes place by a tunnel effect between two roughly equal potential troughs. The proton states may be represented, by analogy to the ammonia molecule, by protomerism between the structures *(3)* and *(4)* of the bond.

$$\underset{(3)}{A{-}H\cdots|B} \overset{p}{\leftrightarrow} \underset{(4)}{A^{\ominus}|\cdots H{-}B^{\oplus}}$$

The tunnel effect in hydrogen bonds with double minima has formed the subject of several studies [33, 34, 37, 40–46]. It ought to be possible to detect the tunnel effect experimentally by splitting of the vibrational terms of the bond. However, it is extremely difficult to identify this splitting in the spectrum.

In the case of the hydrogen bond of imidazole, by combination of various experimental methods, it was possible to detect a potential with a double minimum and to furnish strong indications of the tunnel effect of the proton [43, 44].

Imidazole associates in non-polar solvents by means of intermolecular hydrogen bonds to form *(5)* [47, 48]. Each molecule is able to act as both a proton donor and a proton acceptor, and the degree of association is thus high.

Crystalline imidazole, too, contains associated molecules. It was possible to determine the structure of the molecular chains both in solution and in the crystalline state by means of X-ray analysis [49, 50].

(5)

Infrared and Raman spectra of crystalline imidazole were used to ascertain the frequencies of the vibrational bands of the hydrogen bond. Analysis of these bands led to a term system for the vibrational states of the bond [43], which exhibits normal and combination vibrations. The terms of the normal vibrations are represented in Figure 6a. For the interpretation of the term system, the possible vibrational states of a hydrogen bond have to be considered.

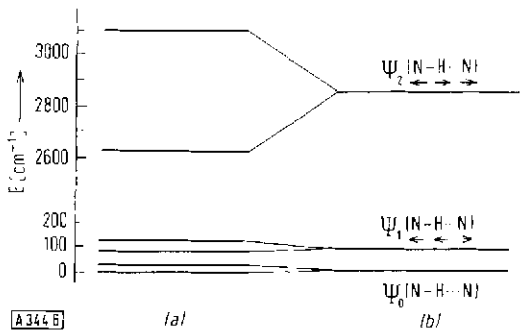

Fig. 6. (a) Experimental and (b) theoretical term system of the hydrogen bond of imidazole.

X-ray structural analysis showed that the hydrogen bond of imidazole is almost linear. A linear three-mass system can undergo the following normal vibrations [51]:

$\Psi'_1$ (N–H···N) ← ← →

$\Psi'_2$ (N–H···N) ← → →

$\Psi'_3$, $\Psi'_4$ (N–H···N) ↓ ↑ ↓

$\Psi'_2$ must be considered as an NH-valence vibration that is modified to some extent by the hydrogen bond. The nitrogen and hydrogen atoms of the NH-group are linked by a normal covalent $\sigma$-bond. Accordingly, their excited vibrational state is rich in energy (Fig. 6b). $\Psi'_1$ is to be regarded as a valence vibration of the hydrogen bond. This bond is very weak. Little energy is required to excite its vibration. The term $\Psi'_1$ lies just above the ground state $\Psi'_0$.

$\Psi'_3$ and $\Psi'_4$ are degenerate deformational vibrations of the hydrogen bond. Deformational vibrations are generally much less rich in energy than valence vibrations. Since it is already difficult to detect even the low energy valence vibration $\Psi'_1$ of the hydrogen bond, there is little hope of experimental detection of the even lower energy deformational vibrations $\Psi'_3$ and $\Psi'_4$.

Thus, only the three states $\Psi'_0$, $\Psi'_1$, and $\Psi'_2$ should appear in the experimental term system. In actual practice, however, six terms are observed, but these are due to term splitting (Fig. 6) [43].

A similar type of term splitting of vibrational states has already been discussed in connection with the inversion of the ammonia molecule. It was explained by supposing that the protons of the molecule move in potential fields with double minima and are carried from one potential trough to the other by a tunnel effect. It must therefore be concluded from the term splitting of the vibrational states of the hydrogen bond of imidazole that the hydrogen bond proton also moves in a potential field with a double minimum. The term system shows that the two potential minima lie at about the same height. The distance between the potential troughs and the height of the potential wall may be estimated to be comparable to those for the ammonia molecule. Accordingly, the change of position of the proton in the hydrogen bond should again be caused by the tunnel effect. Protonic states will then be formed that extend over the range of both potential troughs and in which the proton is delocalized. These states may be described by linear combination of the protomeric structures of the bond. The ground state is then given by

$$\Psi' = a\,\Psi'(\mathrm{NH\cdots N}) + b\,\Psi'(\overset{\ominus}{\mathrm{N}}\cdots\overset{\oplus}{\mathrm{HN}}).$$

The basic functions $\Psi'(\mathrm{NH\cdots N})$ and $\Psi'(\overset{\ominus}{\mathrm{N}}\cdots\overset{\oplus}{\mathrm{HN}})$ are energetically not absolutely equivalent. They share in the linear combination to different extents a and b, but a and b do not differ much, since the two potential minima of the bond have practically the same height.

The tunnel effect depends on the mass of the tunnelling particle and is inhibited if the hydrogen atom of the bond is replaced by deuterium. In view of the fact that the tunnel effect is also responsible for the term splitting, it ought to be possible to produce spectroscopic evidence for an isotope effect in the term splitting. It is, in fact, possible to recognize spectral differences in the infrared bands of hydrogen and deuterium bonds, which may be attributed to a reduction in the term splitting in the deuterium bond. This result shows that the tunnel effect is most probably operative in the bond [43].

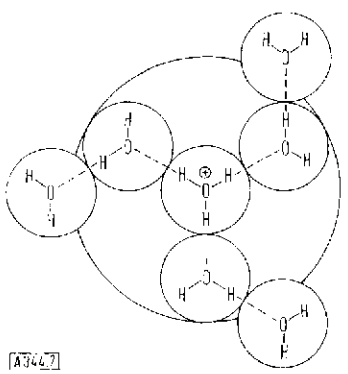
The proton states of the bridge bond have been described by linear combination of protomeric structures. One structure is strongly polar. This form shares in the linear combination to about the same extent as the non-polar structure. The resulting protonic state should exhibit a large dipole moment. Dipole-moment measurements have shown that the hydrogen bond of imidazole is, in fact, exceptionally strongly polar [43].

The change in position of the proton between the two potential troughs within the hydrogen bond can be proved by measurement of its nuclear resonance. Generally speaking, NH-groups show very broad signals as a result of interaction between the proton and the nitrogen nucleus. It is known from model experiments, however, that the proton and the nitrogen nucleus become uncoupled by rapid changes in the position of the pro-

[49] *H. Zimmermann*, Liebigs Ann. Chem. *612*, 193 (1958).
[50] *G. Will*, Nature (London) *198*, 575 (1963).
[51] *G. Herzberg* in [2], p. 111.

ton [52,53]; the NH-signal is sharpened as a result. A sharp NH-signal is observed for the NH···N hydrogen bond of imidazole [43,44]. It must be concluded that the proton in the hydrogen bond changes its position between the two potential troughs.

Proton delocalization is also encountered in the proton states in aqueous solution and in ice. In aqueous solution, a proton first becomes attached to a water molecule with formation of a $H_3O^{\oplus}$ ion, which promotes the formation of hydrogen bonds to three further water molecules. In this process, a $H_9O_4^{\oplus}$ complex is formed, which is solvated by further, loosely bonded molecules of water (Fig. 7) [54–57]. Kinetic investigations of the neutralization reaction [58,59] and investigations of the infrared



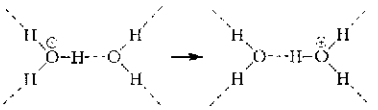


Fig. 7. Hydrated proton in aqueous solution [54].

spectra of strong acids in aqueous solutions have shown that the "excess" proton in the $H_9O_4^{\oplus}$ ion has virtually free movement. The same result was obtained by infrared spectroscopic measurements on hydrated polystyrenesulfonic acid, in which $H_7O_3^{\oplus}$ complexes are formed [60,61]. The excess proton is delocalized in the $H_7O_3^{\oplus}$ ion just as in the $H_9O_4^{\oplus}$ complex. Proton delocalization may be described by superimposition of the appropriate limiting structures [60].

Proton conductivity is observed in ice. The rate-determining factor for the conductivity is the proton transfer in a hydrogen bond with a double minimum [56,62,63].

The mobility of protons in ice is remarkably high, being only less by one or two powers of ten than the mobility of electrons in metals. The protons in ice therefore resemble electrons rather than other ions. Moreover, the mobility of the proton, and hence the proton transfer in the hydrogen bond, is almost independent of temperature [63]. This suggests that the proton transfer takes place by means of the tunnel effect.

## V. Protonic States in Prototropic Reactions

Finally, the proton transfer occurring in a Brönsted acid/base pair will be considered. Let us suppose that the reaction

$$A{-}H + B \rightleftharpoons A^{\ominus} + B{-}H^{\oplus}$$

be divided into the following partial steps:

1. Formation of a complex between the acid and the base, with participation of a hydrogen bond;
2. Proton transfer within the hydrogen bond;
3. Decomposition of the complex.

$$A{-}H + B \rightleftharpoons A{-}H\cdots B \rightleftharpoons A^{\ominus}\cdots H{-}B^{\oplus} \rightleftharpoons A^{\ominus} + B{-}H^{\oplus}$$

(Charges of the individual forms are not shown.)

The proton in the bond of the complex has two positions of maximum proton density and, again, moves in a potential field with a double minimum. If the two potential minima lie close to each other and are of approximately equal height, proton transfer can take place by the tunnel effect.

These conditions are only fulfilled in exceptional cases. Let us therefore consider, quite generally, a reaction in which the potential troughs are so far apart and have such unequal heights that the tunnel effect cannot take

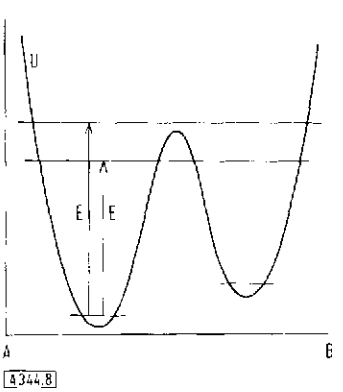

Fig. 8. Potential U and energy states E in a prototropic reaction $AH + B \rightleftharpoons A + BH$.

place in the ground state of the complex (Figs. 5a and 5b, Fig. 8). The proton is located in either one or the other potential trough and A-H···B and A···H-B are molecular entities of long life.

[63] *H. Chr. Spatz*, Diploma Thesis, Universität Göttingen, 1962.

The proton has to change its position between the two potential minima in this reaction. For this purpose, it will make use of any protonic states linking the two potential troughs. As can be readily appreciated, corresponding terms exist above the peak of the potential wall. These states may be occupied with the help of an activation energy E. From the classical standpoint, the reaction is described as a proton leap, and the velocity constant obeys Arrhenius' law:

$$k = A \exp(-E/RT)$$

Below the peak of the potential wall, however, there are similar states covering both potential troughs, since there the potential barrier is sufficiently thin to permit a tunnel effect. If the reaction passes beyond these states, less activation energy is required than would be expected according to the classical approach ($E' < E$).

According to these considerations, the prototropic reaction again passes through states in which protons are free to move within the range of both potential troughs. The proton delocalization in the transition state may be approximately described by a linear combination of the wave functions:

$$\Psi = a\,\Psi_{(A-H\cdots B)^*} + b\,\Psi_{(A\cdots H-B)^*}$$

The protomeric states $\Psi$(A-H···B)* and $\Psi$(A···H-B)* are formed by excited vibrational states of the complex. The transition state is therefore characterized by the participation of all the reactants.

It was possible to confirm the classical proton leap mechanism experimentally by numerous examples [64]. However, indications were also obtained of the occurrence of tunnel effects in prototropic reactions [64].

It is possible to distinguish between the two mechanisms on the basis of the following considerations. Proton transfer will be easier in states above the potential barrier than in states below the peak of the potential wall, where proton transfer is feasible only by way of the tunnel effect. At sufficiently high temperatures, the reaction should therefore proceed predominantly according to the classical proton leap mechanism, as long as the terms above the potential barrier remain adequately occupied by absorption of energy. At low temperatures, however, the high energy states are only sparsely occupied, in comparison with the low energy terms below the peak of the potential wall. The tunnel effect then competes with the classical mechanism. In the presence of a tunnel effect, the activation energy E*, measured as the mean value of E and E' ($E' < E$), is therefore always smaller than would be expected according to the classical mechanism ($E^* < E$). E* consequently diminishes with decreasing temperature.

It can be shown similarly that the frequency factor A* is smaller in the presence of a tunnel effect than would be expected on the basis of the classical mechanism ($A^* < A$) (literature see [64]). Conclusions about the tunnel effect may therefore be drawn from the influence of temperature on E* and A*. However, the reaction velocity must be followed very accurately over a large temperature range in order to obtain experimental data on the deviations from the classical Arrhenius' law.

A second experimental possibility for investigating the tunnel effect in prototropic reactions is afforded by the isotope effect (literature see [64]). Deuterons penetrate a potential wall much less easily than protons do. Deuterium transfer therefore proceeds predominantly according to the classical mechanism ($A_D^* \approx A_D$). The condition for proton transfer however is $A_H^* < A_H$. If the tunnel effect is neglected, the theory yields a ratio of the frequency factors $A_H/A_D \approx 0.5$–$1.0$; if the tunnel effect is taken into account, $A_H^*/A_D^* < 0.5$–$1.0$. Thus, the influence of the tunnel effect in any reaction becomes apparent in an unusually low ratio $A_H^*/A_D^*$.

On the basis of these criteria, it was possible to demonstrate the existence of a tunnel effect in the base-catalysed bromination of 2-ethoxycarbonylcyclopentanone. The rate-determining step is the proton transfer from the substrate to the catalyst [64–66]. Examination of the reaction kinetics showed that the rate of reaction at low temperatures is much higher than is to be expected according to the classical mechanism. This deviation from Arrhenius' law points to a non-classical effect. The existence of a tunnel effect of the proton was also strongly suggested in other reactions [64].

The tunnel effect of the proton has so far been given little consideration in chemistry as it can only be detected by means of extremely careful and painstaking measurements. A more sophisticated approach toward reaction mechanisms, however, will make it indispensable to allot it due consideration.

# Structure and Aromatic Character of Non-benzenoid Cyclically Conjugated Systems

BY PROF. DR. K. HAFNER

INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT MÜNCHEN (GERMANY)

*Dedicated to Professor Dr. Karl Ziegler on the occasion of his 65th birthday*

*The chemistry of aromatic compounds was originally confined to benzenoid hydrocarbons and their derivatives but has been enriched in the last decade by the discovery of numerous non-benzenoid, cyclically conjugated systems that are more or less like benzene in their properties. This has necessitated a new conception of "aromatic character". Theoretical and experimental studies have been applied to this problem. In this connection, several selected representatives of this class of compound are described, mostly from studies by the author's own group, and relationships between structure and "aromatic character" are indicated.*

## Introduction

At an early stage in organic chemistry the characteristic differences in physical properties and chemical reactivity between benzenoid hydrocarbons and their acyclic analogues induced *Kekulé* [1] to make his fundamental studies on the structure of benzene. Since that time, the theory of "aromatic character" has attracted the interest of organic chemists to an ever-increasing degree. Alongside the benzenoid compounds numerous non-benzenoid heterocyclic and carbocyclic systems with very similar properties have appeared, which have robbed the classical aromatic substance, benzene, of its special position and have necessitated a wider and deeper definition of the concept of "aromatic character". In this thorough studies of the chemical and physical properties of new kinds of non-benzenoid, cyclically conjugated compounds and numerous theoretical investigations have made very significant contributions [2].

The theory of "aromatic character" has thereby undergone manifold changes. The empirical generalization of the "aromatic sextet" [3] was followed by Hückel's rule [4], which was based upon quantum-mechanical considerations. According to this rule, benzenoid properties should be displayed not only by compounds with a $\pi$-electron sextet but also by any fully conjugated, planar, monocyclic polyolefin with $4n-2$ $\pi$-electrons ($n = 0, 1, 2, 3, 4, \ldots$).

Chemical reactivity was often the preferred criterion of "aromatic character", *i.e.* "aromaticity" was associated with thermal stability and reluctance to undergo addition reactions; as a result, it was the energy content of the excited state which was chiefly considered. However, more recently, greater importance has been assigned to those physical quantities which depend upon the extent of delocalization of the $\pi$-electrons of a cyclically conjugated system and which permit statements concerning its ground state. Thus "aromatic" compounds are characterized not only by the shift of their light absorption to longer wavelengths compared with olefinic systems, but also by a ready polarizability, by anisotropy of their diamagnetic susceptibility, by changes in bond lengths and charge distribution related to delocalization of the $\pi$-bonds, and by their resonance energy. This latter criterion of "aromatic character" in particular allows a limited statement only, despite its widespread use, because the value for the resonance energy is empirical, derived as it is from thermochemical data. The total stabilization represented by the thermochemical data is certainly not only related to the dynamic behavior of the electrons, which largely determines the properties of a molecule [5].

Recent investigations of cyclically conjugated, non-benzenoid compounds have revealed the difficulties associated with the definition of "aromatic character" and the often very different behavior of non-benzenoid, cyclically conjugated molecules in the ground and excited states. A high degree of electron delocalization, *i.e.* a strong ring current of the $\pi$-electrons, does not always guarantee benzene-like reactivity and stability. It therefore appears justified to distinguish between "aromatic character" of the ground state and "aromatic" reactivity and stability. This is impressively borne out *inter alia* by the investigations of annulenes [6] and the

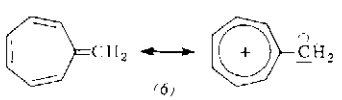
manifold studies of cyclically conjugated systems with either 4n+2 or 4n π-electrons; among these, special interest was attached to the charged ring systems, the cyclopropenium cation *(1)* [7], the cyclopentadienyl anion *(2)* [8], the tropylium cation *(3)* [9], and the most recently discovered cyclooctatetraenyl dianion *(4)* [10].

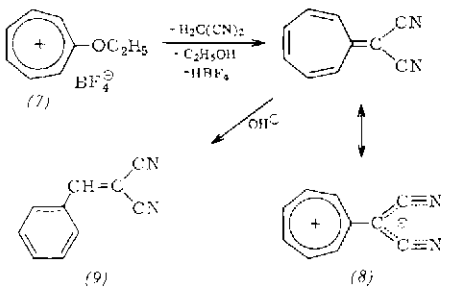
*(1)* *(2)* *(3)* *(4)*



Investigations of various compounds derived from these monocyclic systems have broadened our knowledge of the relationships existing between structure and "aromatic character". In this connection the relationships between derivatives of the cross-conjugated fulvene system and their isomeric benzenoid counterparts were summarized from this point of view in a recent article [11]. Investigations of several mono- and polycyclic conjugated 5- and 7-membered ring systems are described in the following discussion.

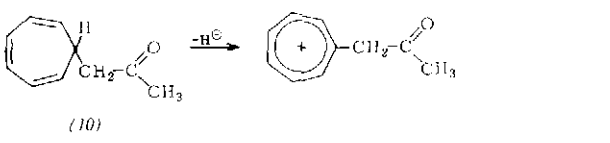
## Cross-conjugated 7-Membered Ring Systems

The cross-conjugated fulvene system *(5)* [11] should be compared with that of heptafulvene *(6)* [12]. Like fulvene itself, the 7-membered ring system synthetized by



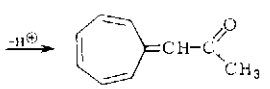
*(5)*

*(6)*



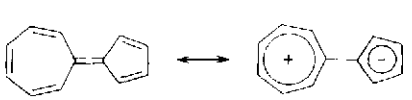
*Doering* and *Wiley* [13] is distinguished by its very low thermal stability, which for a long time prevented its isolation.

Nevertheless, introduction of electron acceptors on the exocyclic carbon atom of heptafulvene *(6)* effects an increase in the cyclic conjugation of the 7-membered ring together with a considerably greater chemical stability just as the electron sextet in fulvene is stabilized by electron donors on the exocyclic carbon atom. This is shown particularly clearly by 8,8-dicyanoheptafulvene *(8)* [14,15], which is stable up to 300 °C and reacts neither with dienophiles nor with electrophilic reagents. Com-



*(7)* *(9)* *(8)*

pound *(8)* is obtained by condensation of the alkoxytropylium fluoroborate *(7)* [14] with malononitrile. In contrast to its inertness toward the reagents already mentioned, it undergoes ring contraction to give the dicyanostyrene *(9)* under the influence of bases. Similar but smaller sextet stabilization in the 7-membered ring occurs in several other heptafulvenes [15] with one or two electron-attracting substituents on the exocyclic carbon atom. The 8-acetyl derivative *(11)* [16] obtained from tropylacetone *(10)* is the simplest stable representative



*(10)*

*(11)*

of this class of compounds; another example is 8,8-diphenylheptafulvene, which was prepared by *Dauben* [16a] in a similar way.

Surprisingly, it has not yet been possible to isolate sesquifulvalene *(12)*, for which theory predicts [12, 17] a

*(12a)* *(12b)*

high delocalization energy and which should be stabilized by the two sextet systems in the dipolar structure *(12b)*. Only some benzo- and polyphenyl-substituted

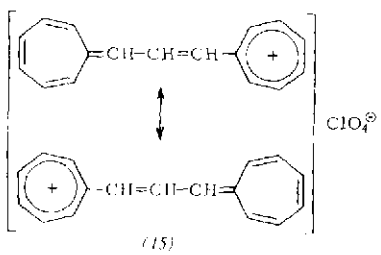
derivatives of this hydrocarbon possess the expected thermal stability [18]. 8-Benzylsesquifulvalene *(13)*



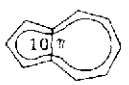
*(13)*

*(14)*

neatly prepared by *Prinzbach* and *Rosswog* [19] has poor stability and polyene character; this suggests that the parent substance *(12)* itself may lack the supposed resonance stabilization, possibly owing to a non-planar arrangement of the 5- and 7-membered rings relative to one another. Such twisting of the central C-C bond should be inhibited in the tricyclic derivative *(14)*, a non-benzenoid isomer of fluorene, in which resonance in the sesquifulvalene moiety might perhaps confer some stability.

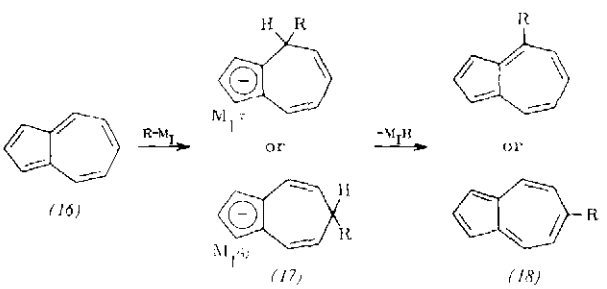
In contrast to *(12)*, the heptafulvene system with a resonance-stabilized sextet typified by the deeply colored

*(15)*



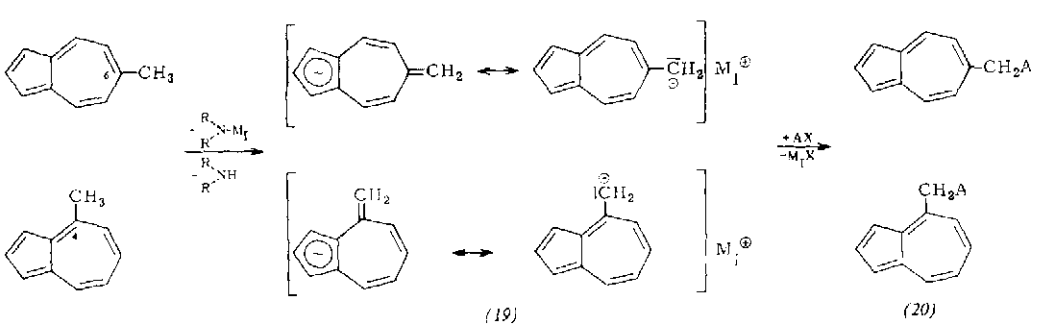
polymethine salt *(15)* [14] is distinguished by remarkable stability. Compound *(15)* reacts only with nucleophilic reagents with loss of conjugation [20].

## Azulene



A formal combination of two charged monocyclic sextet systems, *viz.* the cyclopentadienyl anion and the tropylium cation, is encountered in the 10 π-electron system of azulene *(16)* [2a–c,2e,21], whose properties are largely determined by structures with charge separation. The ultraviolet spectrum [22] of azulene and its electron delocalization energy [22] of *ca.* 35 kcal/mole indicate a state of bonding very similar to that

*(16)*



in benzenoid systems and show the relationship of this non-alternant hydrocarbon to its isomer naphthalene. The similarity between azulene and the cyclopentadienyl anion is made particularly clear by two characteristic reactions of the bicyclic hydrocarbon. With organometallic compounds of the alkali metals it reacts readily to form isolable cyclopentadienylmetal compounds of type

*(16)* *(17)* *(18)*

*(17)* [23] which are intermediates in the nucleophilic substitution at the 4-, 6-, or 8-position of the 7-membered ring, since they reafford the bicyclic decet system *(18)* with loss of a molecule of alkali metal hydride. The second reaction depends upon the acidity of primary or secondary alkyl groups in the 4-, 6-, and 8-positions, the positions of least electron density in azulene. The alkyl groups are activated by the positively polarized 7-membered ring of the azulene. Strong bases are able to extract a proton from these positions to form resonance-

*(19)* *(20)*

stabilized alkylideneazulenate salts *(19)* [24], in which the heptafulvene system is fused to the cyclically conjugated 5-membered ring. These salts react with electro-

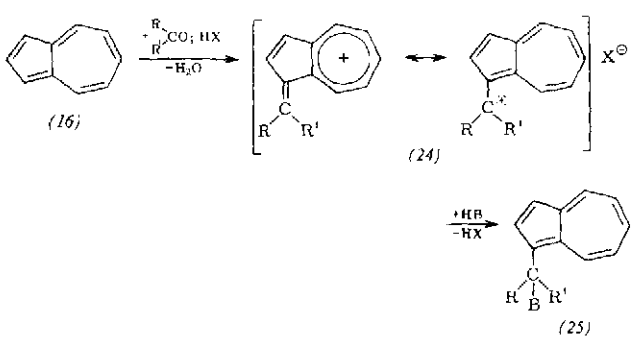
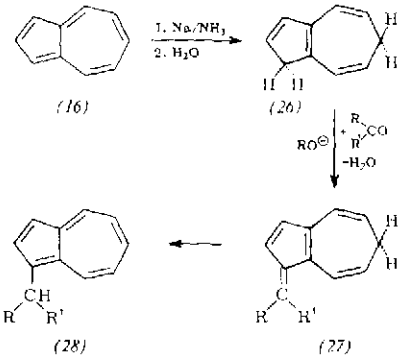
philic reagents reforming the azulenoid system *(20)*; with ferrous chloride, on the other hand, the heptafulvene structure is fixed in the blue-green ferrocene derivative *(21)* [25] which is formed.



*(21)*

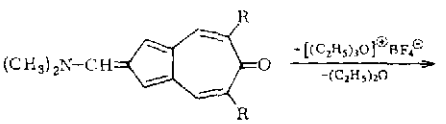
Conversely, it is also possible for azulene to form the tropylium cation. Addition of protons or onium ions at the 1- or 3-positions of the 5-membered ring – the positions of highest electron density – yields isolable azulenium salts of type *(22)* [26], which as intermediates in the electrophilic substitution readily give up a proton to reform the bicyclically conjugated system *(23)*. Condensation with carbonyl compounds in presence of acids

*(16)* *(22)* *(23)*



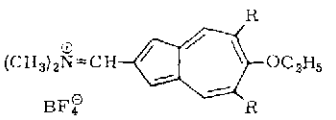
can also convert the decet system into the sextet system of the tropylium cation via a hydroxyalkylation. The alkylideneazulenium salts *(24)* [27] thereby obtained contain the cross-conjugated fulvene system fused to the cyclically conjugated 7-membered ring. With nucleophilic reagents these compounds can reform the bicyclic azulene system *(25)*.

*(16)* *(24)* *(25)*



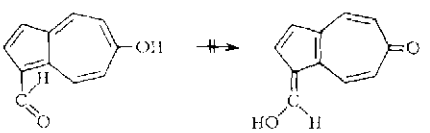
These conversions of the 5- and 7-membered fulvenoid systems of conjugation into the azulenoid system are evidently energetically favored, and furthermore the bicyclic system of 10 $\pi$-electrons is less favored energetically than the benzenoid sextet. These factors determine the reactivity of the fulvenoid system which will be illustrated by three further examples.

The dihydro derivative *(26)* is readily accessible by Birch reduction [28] of azulene with sodium in liquid ammonia [29]. This derivative reacts with carbonyl compounds in the presence of base to yield stable fulvenes of structure *(27)*, which are readily rearranged into the



*(16)* *(26)* *(28)* *(27)*

azulenoid system *(28)* (formally by migration of a hydride ion) in the presence of suitable hydride-ion acceptors and donors [29]. This simple conversion of the cross-conjugated fulvene system into the cyclically conjugated decet system is also encountered in the alkylation



*(29)*

*(30)*

of fulvenotropones of structure *(29)*, which are thereby rapidly transformed into the azulene system of conjugation *(30)* [30].

As expected, the reverse transformation of the azulene derivative *(31)* into the fulvenotropone system *(32)* by proton migration [31] is not possible.

*(31)* *(32)*

However, the cyclic conjugation of the azulenoid system of 10 $\pi$-electrons is readily disrupted if a possibility exists of forming the benzenoid sextet. This is borne out not only by the thermal isomerization [32] of azulene to naphthalene, but also by the synthesis of the tricyclic hydrocarbon *(35)*. The product expected from intramolecular ring-closure of the ketone *(33)* is *(34)*, in which the azulene is fused to a cyclohexadiene system.

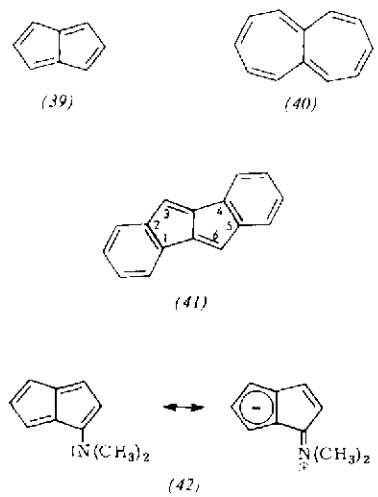
(33) (34) (35)

Isolation of this compound is prevented by its isomerization to the benzoheptafulvene derivative *(35)* [33] with loss of the bicyclic conjugation of azulene. Compound *(35)* is a non-benzenoid isomer of phenalene [34], and like the latter, can be transformed by proton-abstraction with strong bases into the anionic system *(36)*

(35) (38) (36) (37)



containing 14 π-electrons, and can form the cation *(37)* [35] containing 12 π-electrons under the influence of hydride-ion acceptors. The heptafulvene system in *(35)* is stabilized in a characteristic manner by addition of a proton to give the benzotropylium ion *(38)* [33].

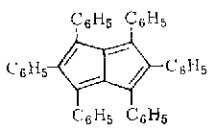
[35] *K. Hafner* and *H. Schaum*, unpublished experiments. MO-LCAO calculations for the cation, anion, and free radical of *(35)* have recently been carried out by *R. Zahradnik*, *C. Parkanyi*, and *J. Michl*, Prague (personal communication from Dipl.-Ing. *R. Zahradnik*).

The two non-alternant hydrocarbons, pentalene *(39)* and heptalene *(40)*, are cyclically conjugated systems of 8 and 12 π-electrons, respectively, and therefore belong

(39) (40) (41) (42)

to the systems of 4n π-electrons which, according to Hückel's rule, should possess no "aromatic character", *i.e.* only low delocalization energy and no benzene-like reactivity. Although this hypothesis was confirmed by the experimental results of several groups of workers, theoretical calculations led to different conclusions [36]. The marked olefinic properties of dibenzo[*a*,*e*]pentalene *(41)* [37] (ring-closed *trans*-1,4-diphenyl-1,3-butadiene) suggest that the resonance stabilization lacking in pentalene (in contrast to azulene) may be compensated by electron-releasing substituents, as, for example, in *(42)*. Pentalene derivatives of type *(42)* are not yet known, however. Nevertheless, the tricyclic pentalene derivative *(43)* was synthetized by attachment of a 5-membered ring across the 1,8-positions of azulene [38]. The 7-membered ring in this derivative can formally accept a partial positive charge, whereas the two 5-membered rings are



(43) (43a) (44)

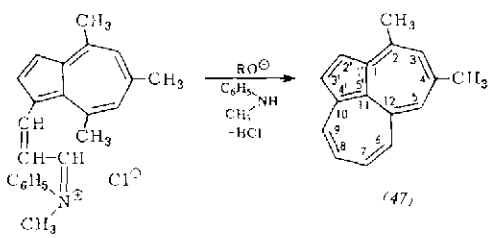
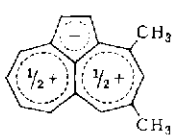
negatively polarized according to formula *(43a)*. Probably as a result of the angle strain at carbon atom 6 or 7 caused by the ethylene bridges in the 2,3- or 4,5-positions, the hydrocarbon does not show the properties of its underlying azulene system, but behaves like a polyolefin, which is prone to spontaneous addition of dienes or dienophiles onto one of the double bonds in the two 5-membered rings, with reformation of the cyclic conjugation of azulene *(44)* [38]. This behavior of the "stabilized" pentalene derivative *(43)* as well as that of the hydrocarbon *(41)* confirms the theoretical predictions, according to which no "aromatic character" is to be expected of the parent substance *(39)*, whose synthesis has not yet been accomplished despite numerous attempts. Neither hexaphenylpentalene *(45)*, which was recently prepared by *Le Goff* [39], nor the pentalene dianion *(46)*, which contains 10 π-electrons and was prepared by *Katz* [40], permit assertions concerning the unsubstituted, uncharged bicyclic system *(39)*.

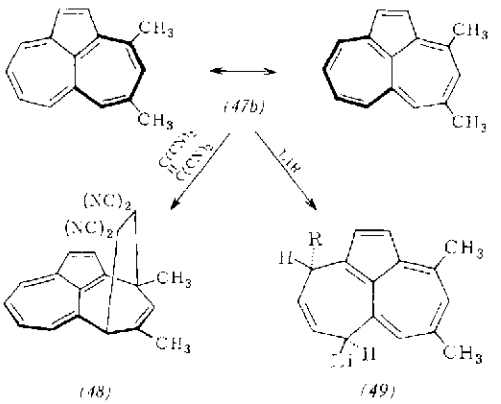


*(45)*



*(46)*

It was also possible in the case of heptalene *(40)* [36] to confirm predictions based on the relations between constitution and "aromatic character". In the tricyclic heptalene derivative *(47)* [38,41,42], the 5-membered ring bears a partial negative charge which should stabilize the bicyclic heptalene to a certain extent by affording an additional opportunity for resonance in the sense of the collective structure *(47a)*; compound *(47)*

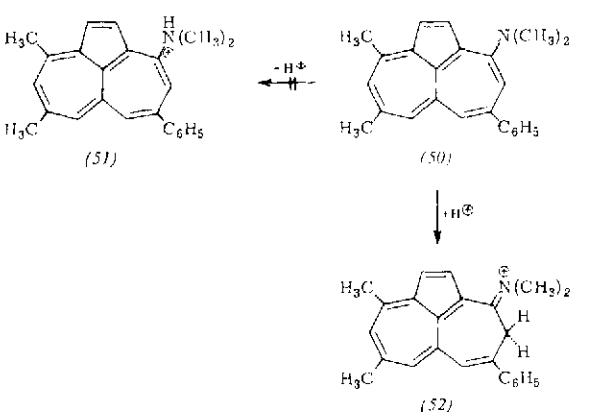


*(47)*

*(47a)*

allowed valuable statements to be made about the parent substance, which have recently been confirmed by an elegant synthesis of the latter [43].

The thermally stable hydrocarbon *(47)* is readily accessible by fusion of a further 7-membered ring onto azulene across the 1,8-positions and shows chemical and spectroscopic properties unlike those expected of the analogue of acenaphthylene, "aceheptylene" [44], since the ethylene bridge forming the 5-membered ring has no olefinic character. In accord with MO-LCAO calculations [45], *(47)* is much more like an azulene with a diene bridge across the 1,8-positions, in which the π-electrons of the conjugated diene participate more or less



*(47b)* *(48)* *(49)*

in the resonance of the bicyclic decet system of the azulene *(47b)*.

This is indicated by the electrophilic substitution which takes place at the 3'-carbon atom of the 5-membered ring, the Diels-Alder reaction of the diene system of the dimethylated 7-membered ring with tetracyanoethylene (or similarly with maleic anhydride) to give the adduct *(48)*, the formation of blue azulene derivatives of type *(49)* by 1,4-addition of lithium alkyls onto the more electrophilic unsubstituted 7-membered ring, and the bathochromically shifted absorption spectrum of the hydrocarbon, which is nevertheless characteristic of the azulene system [38,41].

This picture is further confirmed by the course of the protonation of the dimethylamino derivative *(50)*. Formation of the ammonium salt *(51)* with tricyclic conjugation does not occur; instead, compound *(50)* reacts as an enamine adding a proton at the β-position relative to the amino group, whereby the system of 14 π-electrons is transformed into the preferred decet system of the azulene *(52)* [42].

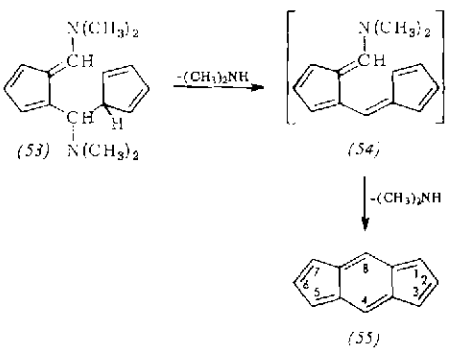
The energetic advantage of the π-electron decet of azulene over the 12 π-electron system of heptalene is confirmed by the typically olefinic character of the very thermolabile parent substance *(40)*, and by its NMR spectrum, in which the location of the ring-proton signals in the frequency range that is characteristic of olefinic protons (between 4 and 5 τ) [43] indicates very little π-electron delocalization.

protons. Catalytic hydrogenation below 0 °C rapidly transforms the hydrocarbon into the benzenoid derivative, 1,5-dihydro-*s*-indacene *(56)*, and hydrogenation at 20 °C gives *s*-hydrindacene *(57)* [49], with gains in resonance energy.



In agreement with *Brown*'s predictions [47], nucleophilic attack takes place at the 4- and 8-positions of the tricyclic system. The reaction profits from the energy gain

## *s*-Indacene

*s*-Indacene *(55)* [46] was often the subject of theoretical and experimental studies, because it is a further example of a system of 4n π-electrons related to the still unknown pentalene and one which allows the relations between structure and "aromatic character" to be clearly recognized. According to LCAO calculations carried out by *R. D. Brown* [47], this hydrocarbon should possess an electron delocalization energy similar to that of the tropylium cation, yet the system can be expected to show high reactivity on account of the low energy difference between its ground and excited states. A simple synthesis of *s*-indacene was effected recently [11] which has allowed the theoretical predictions to be tested.

The surprisingly great tendency of the fulvene *(53)* to form the tricyclic compound *(55)* by way of the non-isolable intermediate *(54)* even below −30 °C (a fine

example of the effectiveness of the "principle of rigid groups" [48]) stands in contrast to the remarkably small thermal stability of this system. Limited π-electron delocalization is indicated by the NMR spectrum of *s*-indacene, which displays signals between 2.4 and 3.7 τ in the intensity ratio 1:2:1 corresponding to the 8 ring

associated with the formation of the two isolated sextet systems of cyclopentadienyl anions. Compound *(55)* reacts with methyl-lithium even at −30 °C to give the stable, isolable lithium salt *(58)* [50]. Birch reduction [28] of *s*-indacene *(55)* with sodium in liquid ammonia leads to the disodium salt *(59)* of the tricyclic system. As befits a system of 14 π-electrons obeying Hückel's rule, like the dianion *(4)* with 10 π-electrons prepared in the same way by *Katz* et al. [10] from cyclooctatetraene, the salt *(59)* can be isolated as a thermally stable, but air-sensitive, colorless compound [50]. On hydrolysis, it yields 1,5-dihydro-*s*-indacene *(56)* of established structure. As a cyclopolyene, *(55)* reacts with silver nitrate to form a red, crystalline metal π-complex of only low thermal stability [50].

The properties of *s*-indacene *(55)* give reason to suppose that its still unknown asymmetrical isomer *(60)* [47, 51] is subject to even less resonance stabilization. In contrast to the two equivalent Kekulé structures of *s*-indacene, the asymmetrical isomer can be described only as a resonance hybrid of the two canonical forms *(60a)* and *(60b)*, which are *p*- and *o*-quinonoid, respectively.

## Heterotropilidenes

Whereas bi- and polycyclic non-benzenoid systems of 4n π-electrons (such as pentalene derivatives, heptalene, and *s*-indacene) have been synthetized and recognized (by their ultraviolet and NMR spectra, thermochemical

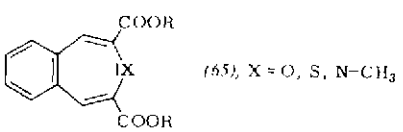
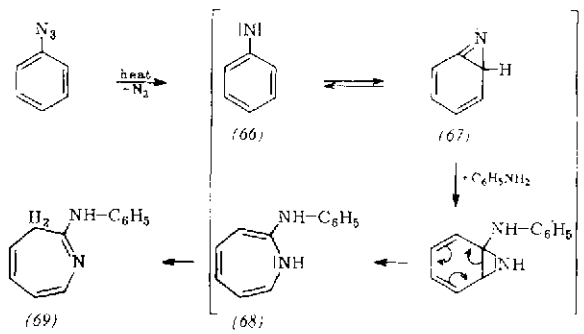
properties, and reactivities) as representatives of a class of compounds that differ considerably from the systems with 4n+2 π-electrons, only a few observations are available concerning monocyclic conjugated systems with 4n π-electrons. These include studies by different groups of workers on compounds which are isoelectronic with the cycloheptatrienyl anion *(64)* and which differ from it in replacement of one of the methine groups by a hetero-atom. These are oxepine *(61)*, thiepine *(62)*,



*(61)* *(62)*

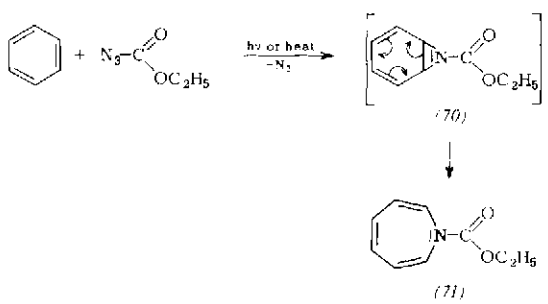
*(63)* *(64)*

and azepine *(63)*. None of these three heterotropilidenes has been prepared as yet. On the other hand, the cycloheptatrienyl anion *(64)* was recently detected by *Dauben* [52], and its heptaphenyl derivative by *Breslow* and *Chang* [53]. Both systems of 8 π-electrons prove to be thermally very unstable. Further investigations of the fine structure and reactivity in these octet systems are necessary in order to recognize similarities to and differences from the corresponding tropylium cations.



So far only several mono-, di-, and tribenzo derivatives of the three heterotropilidenes *(61)* to *(63)* have been prepared as well as some polysubstituted derivatives stabilized by additional opportunities for resonance, and various dihydro derivatives [54, 55]. Only limited conclusions are permissible from the chemical and physical

*(65)*, X = O, S, N–$CH_3$



behavior of the benzoheterotropilidenes *(65)* studied by *Dimroth* and *Freyschlag* [54] concerning the properties of the hypothetical monocyclic compounds *(61)* to *(63)*, because in the bicyclic derivatives *(65)* stabilization of the benzene moiety by its electron sextet presumably far outweighs any stabilization of the heterocyclic 7-membered ring.

On the other hand, the investigations of *Huisgen* et al. [55] are of greater significance in this connection. Thermolysis of phenyl azide in aniline yielded a monocyclic isomer of azepine, the cyclic amidine or azatropilidene derivative *(69)* [*]. According to these workers' findings, the aryl nitrene *(66)*, *i.e.* the reactive intermediate arising from the aryl azide by elimination of nitrogen, is supposedly converted in an equilibrium reaction into the similarly highly reactive bicyclic azirine *(67)*, which then undergoes a first (but still incomplete) stabilization to 2-anilino-1*H*-azepine *(68)* by addition of one mole of aniline and subsequent isomerization to the 7-membered ring. The 1*H*-azepine *(68)* rapidly rearranges into the tautomeric form *(69)* which is energetically favored by amidine resonance.

*(66)* *(67)* *(69)* *(68)*

A synthesis recently discovered in our laboratory [56] of a simple azepine derivative and a study of its properties give an answer to the question of the "aromatic character" of this octet system. *N*-Ethoxycarbonylazepine *(71)* can be prepared readily by either photochemical or thermal ring-expansion of benzene with ethyl azidoformate in a reaction analogous to that of *Buchner* [57]. The azepine derivative *(71)* is presumably formed by way of the intermediate aziridine *(70)*, its valence-isomer.

*(70)* *(71)*

The NMR spectrum of this heterocycle displays a multiplet at 4.0–4.7 τ due to the six ring protons. Compared with the spectrum of the homologous *N*-ethoxycarbonylpyrrole (ring-proton signals at 3.0 and 4.0 τ), this indicates some π-electron delocalization (ring current), the extent of which has still not been determined exactly,

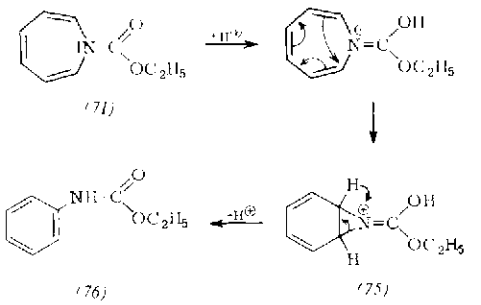
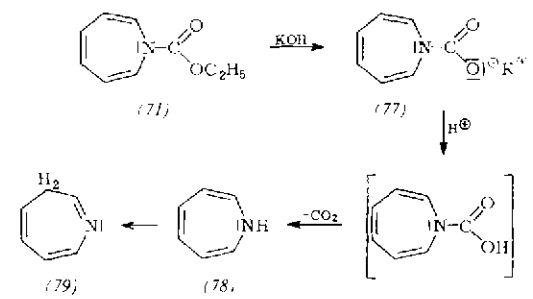
and thus a difference in degree only, but not in kind, between systems with 4n+2 and 4n π-electrons. At the same time, however, the urethane resonance also contributes to the stabilization of *(71)*. This is borne out by the extreme thermal instability of *N*-methylazepine *(72)*,

*(71)* *(72)*



which is accessible by reduction of the azepine derivative *(71)* with lithium aluminum hydride, and whose cyclic system of 8 π-electrons is not stabilized by functional groups. The structureless ultraviolet spectrum of this vinylogue of *N*-methylpyrrole is like that of the 5-membered parent heterocycle with a π-electron sextet but shifted bathochromically by about 30mμ, in accordance with the extension of the conjugated system [58].

In contrast to the 7-membered carbocyclic sextet systems, the ethoxycarbonylazepine *(71)* reacts rapidly with dienophiles to form adducts. According to present findings, the product obtained with tetracyanoethylene [58] is the 1,6-adduct *(73)*, and not the equally conceivable tricyclic Diels-Alder adduct *(74)* which could arise from a mobile equilibrium of the two valence-isomeric



*(71)* *(70)* *(73)* *(74)*

forms *(70)* and *(71)* analogous to the comparable reaction of tropilidene [59]. The lower stability of the π-electron octet than that of the benzenoid π-electron sextet is confirmed by the reaction of *N*-ethoxycarbonylazepine *(71)* with acids. This rapidly leads to ethyl *N*-phenylurethane *(76)*, which is presumably formed after initial protonation of the oxygen by way of the aziridine intermediate *(75)*, from which the benzenoid system is then formed irreversibly with a considerable gain in resonance energy [60].

*(71)* *(76)* *(75)*

Alkaline hydrolysis of the azepine derivative *(71)* offers a route to 1*H*-azepine *(78)* itself. The alkali metal salt of the carbamic acid *(77)* which is initially formed decarboxylates readily under the influence of dilute acids.

*(71)* *(77)* *(79)* *(78)*

1*H*-Azepine *(78)* thereby obtained in solution is thermally very unstable; spectroscopically, like its *N*-methyl derivative, it resembles pyrrole. Its formation is followed rapidly by a rearrangement, presumably into the tautomeric 3*H*-azepine *(79)* [61], effecting stabilization as in the preparation of *Wolff* and *Huisgen*'s azepine derivative *(69)* [55], although the latter compound also profits from the gain in resonance energy associated with the formation of the amidine system. On the other hand, the driving force for the transformation of the double enamine *(78)* with its 8 π-electrons into the azatriene system *(79)* should possibly be sought in the accompanying rebybridization of the nitrogen atom and its involvement in the conjugation.

# Transformations of Organoboranes at Elevated Temperatures

BY DR. R. KÖSTER
BASED ON WORK CARRIED OUT BY G. BENEDIKT, R. KÖSTER, W. LARBIG, K. REINERT, AND G. ROTERMUND

MAX-PLANCK-INSTITUT FÜR KOHLENFORSCHUNG, MÜLHEIM/RUHR (GERMANY)

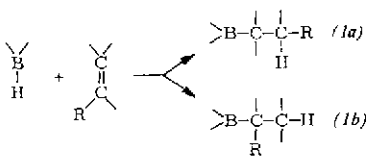
*Dedicated to Professor Dr. Karl Ziegler with respect and gratitude on the occasion of his 65th birthday*

*Trialkylboranes with identical or different groups on the boron are stable to alkyl exchange at room temperature. Mixed trialkylboranes only undergo disproportionation in the presence of catalysts such as aluminum trialkyls and boron-hydrogen compounds. At temperatures above 100 °C, organoboranes such as trialkylboranes and B-alkylboracyclanes isomerize as a result of migration of the boron along the aliphatic hydrocarbon radical via dehydroboration-hydroboration equilibria. Alkyl, cycloalkyl, as well as aralkyl and certain arylboranes can be converted irreversibly by pyrolysis at 200–300 °C into other organoboranes (methylboranes and boron-heterocycles of various structures).*

## Introduction

Advances made in organic preparative methods have rendered organoboranes, in particular trialkylboranes, much more readily accessible [1,2]. This has led to a growing interest in these substances in recent years.

In some of their chemical properties, trialkylboranes exhibit certain analogies to trialkylaluminum [3,4], *e.g.* exchange with olefins (displacement reactions), as well as oxidation and hydrogenation of B-C bonds. In many respects, however, they differ from the aluminum compounds. In particular, the catalytic properties exhibited by organoaluminum compounds with regard to the transformation of olefins [5] are only observed to a very slight extent in the corresponding boron compounds (addition of the boron-carbon bond onto C=C double bonds). The transformation of organoboron compounds at elevated temperatures sometimes also leads to products completely different from those obtained with organoaluminum compounds – mainly on account of the greater thermal stability of the B-C and B-H bonds.



Besides isomerization, the most important thermal reaction of organoboron compounds, in which boron is bound only to carbon, is the splitting of C-C or C-H bonds leading to widely differing boron compounds, especially boron heterocycles. Since generally mixtures are obtained, analysis of the products is of great importance. Gas-chromatographic separation of boron compounds [6–8] and their identification by mass spectrometry [9] and infrared spectroscopy has proved to be particularly satisfactory.

## I. Organoboranes at Room Temperature

Boron-carbon bonds are mainly formed in two ways: 1. by the reaction of alkylmetal or arylmetal with boron halides or with boric esters [4]; 2. in the aliphatic series, by addition of B-H compounds onto alkenes or alkynes, *i.e.* by hydroboration [10,11].

An essential factor governing the composition and structure of organoboron compounds is the temperature of their formation. In addition, the agent used for hydroboration (*e.g.* diborane or alkyldiborane) exerts an influence. *H. C. Brown* and collaborators [11] have made a detailed study of the rules governing hydroboration.

If, for instance, an α-olefin is hydroborated at room temperature with diborane, uniform tri-1-alkylboranes

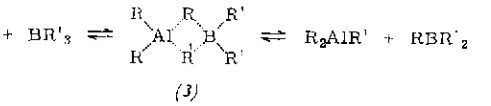
[11] Review: *H. C. Brown:* Hydroboration. W. A. Benjamin Inc., New York 1962.

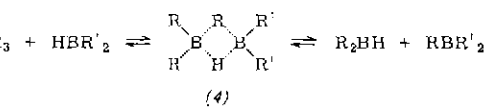
*(1a)* are not obtained, since addition may take place in two ways. The amount of 2-alkylboranes *(1b)* formed is, however, generally not very great. Practically pure tri-1-alkylboranes *(1a)* are formed when hydroboration is carried out with tetraalkyldiborane [12,13] followed by catalytic disproportionation at a lower temperature of the mixed trialkylboranes *(2)* initially formed [12,14].



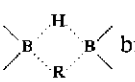
In contradiction to the opinion put forward by *Brown* and *Zweifel* [13], the use of bulky alkyl groups is not essential for selective hydroboration [12,27], since tetraethyldiborane and other tetra-1-alkyldiboranes react with α-olefins to give almost exclusively primary alkyl groups on the boron.

If an α-olefin is hydroborated above 100 °C, *e.g.* with trialkylamine-boranes [16,41], the proportion of secondary alkyl groups on the boron in the final product is usually considerably higher than in the product of hydroboration at low temperatures. This is due to the dehydroboration [4,15,16] which then becomes possible [Equation (2a)]. The reaction conditions during formation suffice to lead to thermal equilibria between different trialkylboranes.

In contrast to trialkylaluminum, trialkyl- and triarylboranes do not exchange hydrocarbon radicals [17] at room temperature. For this reason, it is possible to obtain pure, stable, constant boiling samples of mixed trialkylboranes ($R_2BR'$), which can be readily differentiated from mixtures of two different uniform trialkylboranes ($2R_3B + R'_3B$) having the same overall composition. This significant difference between boron and aluminum trialkyls may be related to the fact that associated aggregates containing electron-deficient bonds bring about the exchange. Such associated forms have been known for a long time in the case of organoaluminum compounds but have not been observed with trialkylboranes. Trialkylboranes have always been found to be completely monomolecular [18,19]. The non-occurrence of rapid spontaneous alkyl exchange between trialkyl- and triarylboranes may be regarded as a final absolute proof that these compounds are not associated even in traces (*i.e.* below the limit of detection).



Trialkylboranes exchange alkyl groups with trialkylaluminum at a rate corresponding to that of ionic reactions [17]. This leads to the conclusion that the formation of mixed associates *(3)* with electron deficient bonds between aluminum and boron trialkyls is possible. Aluminum trialkyls are therefore extremely effective catalysts for alkyl exchange between trialkylboranes. Addition of minute amounts of trialkylaluminum to a mixture of $BR_3$ and $BR'_3$ leads to establishment of the equilibrium [17]:



*(3)*

$$BR_3 + BR'_3 \overset{AlR_3}{\rightleftharpoons} R_2BR' + RBR'_2$$

Besides $AlR_3$, boron hydrides also catalyse mutual ligand exchange between boron compounds [17,20,21]. The formation of associated forms such as *(4)* must therefore be assumed as an intermediate stage in this equilibration.

*(4)*

Since catalytically active B-H compounds must necessarily be present during the hydroboration of olefins, exchange of alkyl groups on the boron must also take place simultaneously. The composition of the trialkylboranes formed depends on the rate of exchange as well as on the composition of the equilibrium mixture. Alkyl groups with secondary carbon atoms on the boron (*e.g.* 2-propyl groups) are transferred from one boron atom to the other via the  bridge in *(4)* much more slowly than primary alkyl groups, evidently for steric reasons [20].

## II. Transformations of Organoboranes at Elevated Temperatures

### 1. Thermal Isomerizations

Trialkylboranes isomerize at temperatures above 100 °C via dehydroboration-hydroboration equilibria to give mixtures of trialkylboranes containing primary and seconday alkyl groups on the boron [20,22,23], the $B\text{-}C_{primary}$ bond *(5a)* being strongly preferred to the $B\text{-}C_{secondary}$ bond *(5b)*.

[23] *H. C. Brown* and *B. C. Subba Rao*, J. org. Chemistry *22*, 1137 (1957).

(5a) (5b)

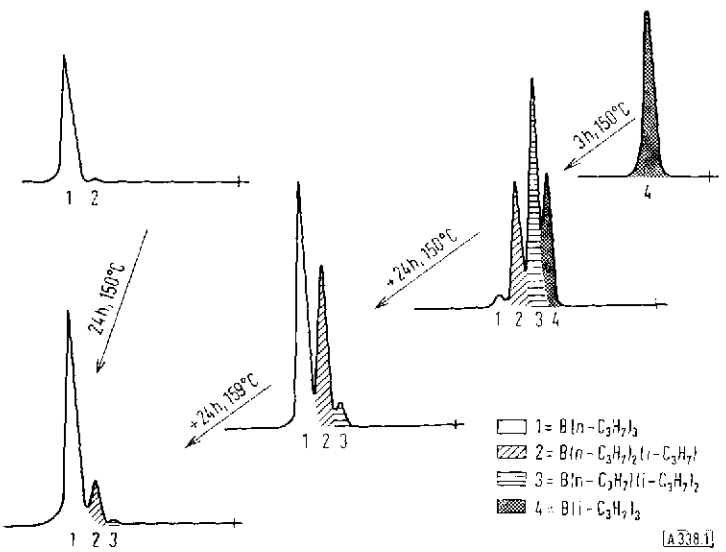
$B\text{-}C_{tertiary}$ bonds generally cannot be detected in the isomerized products since these bonds are evidently subject to dehydroboration at about room temperature [23a, 23b] and are converted into $B\text{-}C_{primary}$ or $B\text{-}C_{secondary}$ bonds. The rate-determining process in attaining the equilibrium is the elimination of the olefin (dehydroboration) [15]. The addition of B-H compounds, *e.g.* alkyldiboranes, onto the C=C double bonds of olefins (hydroboration) takes place very rapidly, even at room temperature [24–27], whereas dehydroboration generally takes place to a significant extent only above 100 °C. The composition of equilibrium mixtures of the simplest trialkylboranes (tripropylborane, tributylborane) can be determined by gas chromatography [6–8] (cf. Table 1).

Table 1. Equilibrium mixtures of simple trialkylboranes at 160 °C.

| Tri-n-propylborane | Tri-n-butylborane |
|---|---|
| 83 % ppp | 94 % bbb |
| 16 % ppi | 6 % bbs |
| 1 % pii | 0 % bss |

p = 1-propyl; i = 2-propyl; b = 1-n-butyl; s = 2-n-butyl.

The attainment of equilibrium, *e.g.* with the tripropylboranes, can also be readily followed by gas chromatography [8] (cf. Fig. 1).



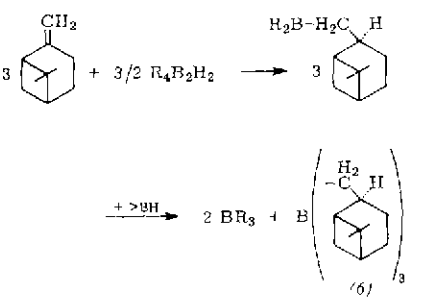


Fig. 1. Thermal isomerization of tripropylboranes. Gas-chromatographic analysis (column: silicone oil DC 710 on Chromosorb 0.3–0.4 mm; 90 °C; He current velocity: 105 ml/min; approx. 5 µl sample).

With increasing temperature, the proportion of boron bound to secondary carbon atoms in the equilibrium mixture increases slightly. Thus, in the case of tripropylborane, the ratio of 1-propyl to 2-propyl groups is of the order of 16:1 at 160 °C, but about 12:1 at 220 °C [17].

Trialkylboranes with longer alkyl chains contain predominantly 1-alkyl groups together with a small amount of 2-alkyl groups at equilibrium. Boron is practically not bound to carbon atoms further away from the terminal position. It is therefore possible to prepare alkylboranes with terminal boron atoms from olefins containing a C–C double bond in the interior of a long alkyl chain. Subsequent olefin exchange (displacement reaction [26, 28–30]) makes it possible to split off the olefins with the terminal C=C double bond from the thermally isomerized trialkylborane.

If the alkyl chain of the alkylboranes is branched, the boron atom is preferably bound to that carbon atom which is furthest removed from the point of branching. Frequently, however, the tendency of the boron atoms to become attached to different chain ends is too similar and an alkylborane cannot therefore be readily converted quantitatively into another one.

In the meantime, considerable knowledge has been gained about the thermal migration of boron atoms along alkyl chains of alkylboranes [31]. It is interesting to note that thermal isomerizations occur in which the boron atom remains bound to a given carbon atom of an alkyl group and simply changes its steric position with respect to it [32]. Thus, tri-(*cis*-myrtanyl)borane *(6)* is obtained at room temperature from tetraethyldiborane and β-pinene by hydroboration followed by disproportionation in the presence of excess B-H groups [27]. Compound *(6)* is formed by *cis*-addition of the B-H group onto the terminal C–C double bond [32]. If the pure crystalline compound *(6)* (m.p. 94 °C) is heated above its melting point, it undergoes isomerization to form tri-(*trans*-myrtanyl)borane *(6a)*, which is a liquid at room temperature. This rearrangement is due to differences in the rates of the dehydroboration and hydroboration reactions [27] (cf. Scheme 1).

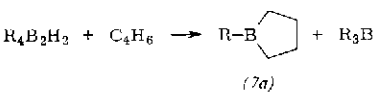
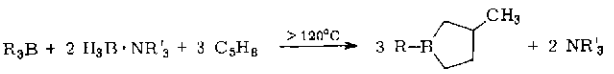
Scheme 1. The formation of sterically isomeric pinanes via trimyrtanylboranes as intermediate products.



The boron atom thus passes from the sterically more hindered side (isopropylidene group) to the less hindered side of the same carbon atom.

The recently observed thermal isomerization of trialkylboranes catalysed by B-H compounds [33] is possibly due to the fact that alkyl group exchange via the  bridge precedes the rate-determining dehydroboration. The di-s-alkylmono-1-alkylboranes and tri-s-alkylboranes which are formed anew in the mixtures evidently split off olefin much more rapidly than the mono-s-alkyldi-1-alkylboranes or tri-1-alkylboranes (cf. Scheme 2).

Scheme 2. Rate of dehydroboration as a function of the degree of branching of the alkyl groups.



Equilibria similar to those prevailing in the case of the simple trialkylboranes also occur with simple boron heterocycles, *e.g.* the *B*-alkylboracyclanes *(7a)* and *(7b)* [20,27,38]. The compounds are readily prepared

*(7a)*

by hydroboration of dienes with alkyldiboranes at low temperatures [27] or with trialkylamine-boranes in the presence of trialkylboranes above 120 °C [20,38,41].

The alkyl group of the *B*-alkylboracyclanes occupying the third valence of the boron atom also isomerizes at elevated temperatures. However, here the equilibrium mixture contains a larger amount of secondary groups

*(7b)*

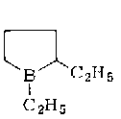
than is observed with boranes containing only open-chain substituents; this may be due to steric effects [35]. Thus, in the case of *B*-n-butylborolane, about 15 % of the butyl groups are secondary at 160 °C, as compared to about 6 % of the "third" butyl groups in tri-n-butylborane.

This side-chain isomerization of alkyl radicals bound to boron is accompanied in boron heterocycles by isomerizations in which rings of different sizes are interconverted. The same influences are in operation here as in the side-chain isomerization, *viz.* dehydroborationhydroboration equilibria and steric factors. Different boracyclanes are therefore in equilibrium with one another at elevated temperatures as a result of ring contraction or ring enlargement. Seven-membered as well as five- and six-membered rings are formed. In addition, stereoisomerism due to the rings is observed [27].

General statements regarding the relative stabilities of boracyclanes cannot be made readily, since the ring stability depends on the ring size as well as on the type of the B–C bonds. At all events, it can be stated that boracyclanes in which the formation of a six-membered ring with two $B-C_{primary}$ bonds or with a $B-C_{primary}$ bond and a $B-C_{secondary}$ bond is possible possess the greatest thermal stability. The difference in the rates of dehydroboration is involved here. In fact, the stabilizing influence of the ring size may be so great that $B-C_{tertiary}$ bonds are formed in some particularly favorable cases (cf. Table 2).

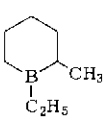
Table 2. Distribution [a] in equilibrium at 160 °C of the *B*-ethylboracyclanes which are formed in the hydroboration of dienes with tetraethyldiboranes

| Diene | Five-membered ring [%] | Six-membered ring [%] | Seven-membered ring [%] |
|---|---|---|---|
| Isoprene | 100 % | — | — |
| 2,3-Dimethyl-1,3-butadiene | 30:70 [b] | — | — |
| 1,4-Pentadiene | 2.8 | 97.2 | — |
| 1,5-Hexadiene | 1.0:2.7 [b]; 3.8 | 79.9 | 12.6 |
| 2,5-Dimethyl-1,5-hexadiene | 66.3 | 23.0 [c] | 10.7 |



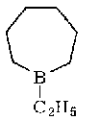
[a] Gas-chromatographic analyses; the percentage areas of the peaks from the gas chromatograms correspond approximately to the percentages by weight of the isomers.
[b] Cis-trans isomers.
[c] Contains an unknown amount of a borepane isomer.

Thus, when 1,5-hexadiene is hydroborated with tetraethyldiborane at low temperature,



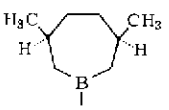
$$C_6H_{10} + (C_2H_5)_4B_2H_2 \rightarrow C_2H_5BC_6H_{12} + B(C_2H_5)_3,$$

[33] See [11], pp. 137–138.
[34] *K. A. Saegebarth*, J. Amer. chem. Soc. *82*, 2081 (1960).
[35] *R. Köster* and *G. Rotermund*, unpublished work; cf. [43].

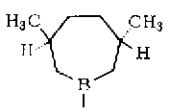


the triethylborane formed is accompanied by a mixture of boracyclanes, $C_2H_5BC_6H_{12}$, not containing any five-membered rings. The reason for this is that the formation of five-membered rings from the olefin requires a dehydroboration step which proceeds at a significant rate only above 120 °C. The hydroboration mixture obtained at low temperatures therefore consists of 97 % of the seven-membered ring compound, *B*-ethylboracycloheptane *(10)*, together with 3 % of the six-membered ring compound, *B*-ethyl-2-methylboracyclohexane *(9)* [27]. At 160 °C, a 7.5 %:79.9 %:12.6 % mixture of the *B*-ethylboracyclanes, *(8)*, *(9)*, and *(10)*, is obtained [20] (cf. Table 2).

*(8)*

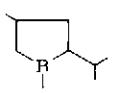


*(9)*

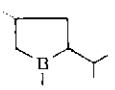


*(10)*

Hydroboration of 2,5-dimethyl-1,5-hexadiene with tetraethyldiborane at low temperature yields the two sterically isomeric *B*-ethyl-3,6-dimethylboracycloheptanes *(11a)* and *(11b)* in a molar ratio of 1:1 [36].

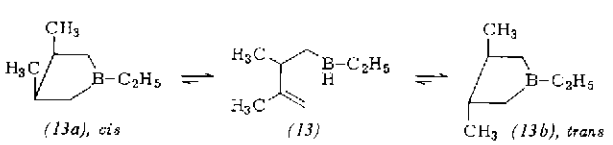


*(11a), cis*



*(11b), trans*

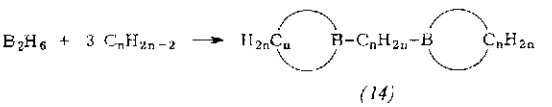
Following oxidative degradation with alkaline hydrogen peroxide, only 2,5-dimethyl-1,6-hexanediol is isolated, but this presumably consists of a mixture of the racemate and the *meso*-form which cannot be separated by gas chromatography. On heating to temperatures above 120 °C, isomerization takes place. At elevated temperatures, the proportion of the two seven-membered ring compounds changes first of all. Subsequently, the six-membered ring compound can be detected. After about 3 hours at 120 °C, the five-membered ring compound appears which finally, at 160 °C, forms the main constituent of the isomeric mixture and which can be split into the *cis*- and *trans*-isomers *(12a)* and *(12b)*.



*(12a), cis*

*(12b), trans*

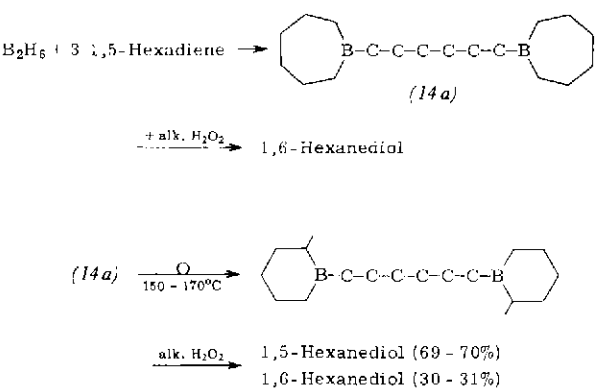
Oxidation followed by hydrolysis of the boracyclane mixture also yields a 1,4- and 1,5-diol in addition to 1,6-diols. The six-membered boracyclane which is the parent compound of the 1,5-diols, can only result when the boron atom is bound to a tertiary carbon atom.



A further good example involving steric isomerism is the borolane formed from 2,3-dimethyl-1,3-butadiene and ethyldiboranes [37]. At low temperatures, the *cis*- and *trans*-*B*-ethyl-3,4-dimethylborolanes *(13a)* and *(13b)* (b.p. 55–56 °C/50 mm) are obtained in a 1:1 ratio. If this mixture is heated for 4 hours at 160 °C, the ratio changes to about 3:7. The equilibrium is attained via the dehydroboration stage *(13)*.

*(13a), cis* *(13)* *(13b), trans*

This change in the composition is probably due to a difference in the rates of dehydroboration of the two isomers; the hydroboration rate is likely to be practically the same for both compounds also at elevated temperatures. The change of the isomer ratio is then due to the difference in the influence exerted on the borolane ring by the two vicinal methyl groups when in *cis*- and in *trans*-relationship.



Bis-*B*-boracyclylalkanes *(14)* [34,38] are readily prepared by hydroboration of dienes with diborane at low temperature [34] or with trialkylamine-boranes at elevated temperatures [38] but isomerize on heating in an

*(14)*

analogous manner to the *B*-alkylboracyclanes. The composition of the compounds $B_2(C_nH_{2n})_3$ (n = 5 or 6) was examined before and after thermal isomerization by oxidation to the diols [34].

A bis-*B*-boracyclylalkane which was prepared at room temperature from 1,5-hexadiene or 1,4-hexadiene and diborane and then heated to 160 °C yielded on oxidation and subsequent hydrolysis two-thirds 1,5-alkanediol together with about one-third 1,6-alkanediol. The 1,5-alkanediol is probably derived mainly from the resultant six-membered heterocycles, and the 1,6-alkanediol from the alkylene group to which the two boron atoms are attached in the bis-*B*-boracyclylalkane. The composition of the compounds prepared at room temperature from diborane and 1,3-pentadiene, 1,4-pentadiene, and 1,5-hexadiene [34] was investigated. On oxidation and hydrolysis, the product prepared at low temperature from 1,5-hexadiene *(14a)* yields mainly 1,6-hexanediol. Thus, here again the seven-membered ring with two $B-C_{primary}$ bonds is preferred in the first instance. Six-membered ring compounds are hardly formed in the low-temperature hydroboration of 1,5-hexadiene.

Exact determination of the thermal equilibria of bis-*B*-boracyclylalkanes *(14)* and generally of mixtures containing compounds with several boron atoms is more difficult than in the case of simple *B*-alkylboracyclanes, since gas-chromatographic separation is no longer possible on account of the low vapor pressures.

On heating of bis-*B*-boracyclylalkanes, migration of the *B*-borolane ligand along the alkylene chain between the two boron atoms (side-chain isomerization) might be anticipated in addition to ring isomerization. However, isomerization of bis-(3'-methyl-*B*-borolanyl)-2-methylbutane *(15)* evidently proceeds not only in this direction [39]. This isomerization is accompanied by dispropor-

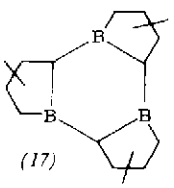
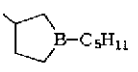
tionation of the alkylene radicals. Mono- and trifunctional groups are formed from the bifunctional alkylene

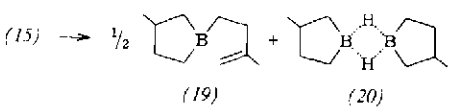


(15)

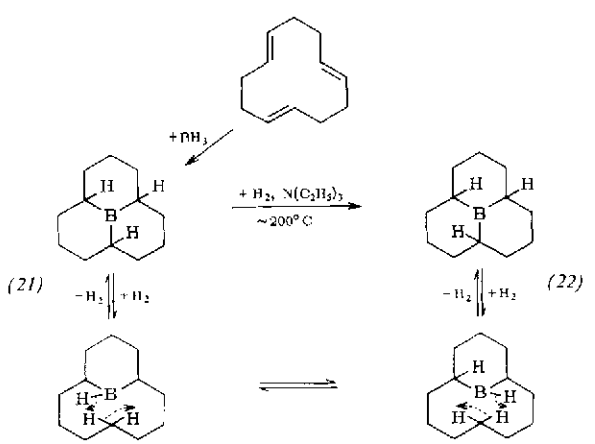


(16)

groups. Starting from *(15)*, a compound of constitution *(16)* is obtained which on further heating is converted into a boron compound (mol. weight 240) containing 3 boron atoms; this must be a triboracylohexane derivative *(17)*. *B*-Isopentyl-3-methylborolane *(18)* is formed as a further disproportionation product.



(17)



(18)

The postulated first step, *viz.* dehydroboration of the bicyclic boron compound *(15)*, can be realized experimentally. At reduced pressure, *B*-isopentenyl-3-methylborolane *(19)* is obtained together with bis-(3-methylborolane) *(20)* at about 150 °C [39,40].

(19) (20)

*cis,cis,cis*-Perhydro-9$^b$-boraphenalene *(21)* [41] may be prepared by hydroboration of *trans,trans,trans*-1,5,9-cyclododecatriene [51] and may be converted into an isomeric form by treatment with hydrogen under pressure for several hours at 200–220 °C in the presence of a tertiary aliphatic amine, *e.g.* triethylamine [42.43]. The liquid

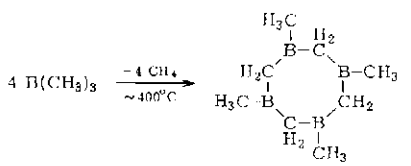
compound *(21)* yields an isomer of identical composition, b.p. 110 °C/9 mm, which forms beautiful crystals, m.p. 31 °C. Hydrogen and amine are not consumed during this transformation. The crystalline isomer is *cis, cis, trans*-perhydro-9$^b$-boraphenalene *(22)*. In this case, isomerization probably takes place via hydrogenation of a B–C bond [21,26], followed by a conformational change and transanular dehydrogenation. The infrared spectra of the two centroboron compounds *(21)* and *(22)* exhibit characteristic differences.

During the attainment of the hydrogenation-dehydrogenation equilibrium between the two isomers, the trialkylamine probably acts as a stabilizer for the boron-hydrogen compounds formed as intermediates. In the absence of amine, the boron-carbon bonds undergo hydrogenation, and cyclododecane is then isolated together with other saturated hydrocarbons (particularly methane as well as ethane, propane, butane, *etc.*) [43].

Isomerization of the two perhydro-9$^b$-boraphenalenes cannot be achieved simply by heating since these boron heterocycles evidently only undergo dehydroboration at temperatures at which the intermediates (13-borabi-

cyclo[7,3,1]tridecenes) *(23)* decompose irreversibly. This example therfore indicates the limits of the thermal transformation of organoboranes.



*(23)*

## 2. Irreversible Reactions

On heating alkyl- or aralkylboranes to 200 °C and above, varying structures are obtained – depending on the type and length of the groups bound to the boron – as a result of an irreversible reaction.

a) *Pyrolysis of Trialkylboranes with Small Alkyl Groups (Methylboranes)*

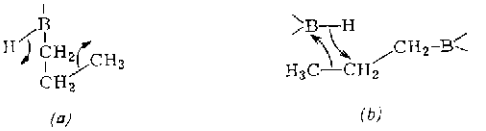
On pyrolysis, trimethylborane [44] forms boron heterocycles in addition to polymeric compounds of varying composition. Among the numerous reaction products formed at about 400 °C, an eight-membered ring containing four carbon and four boron atoms can be

*(24)*

isolated *(24)*. Other low trialkylboranes can be converted into trialkylboranes containing new alkyl groups at comparatively low temperatures, sometimes in surprisingly good yield [45].

Pyrolysis at about 300 °C of trialkylboranes containing more than one, but fewer than four carbon atoms in the main alkyl chain (*e.g.* triethyl-, tripropyl-, and tri-isobutylborane) yields methyl- and other alkylboranes by dehydroboration via dialkylborohydrides as a result of C-C splitting [45].

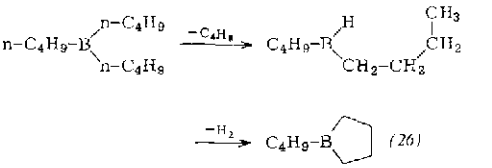
Triethylborane yields ethylene and methylethylboranes, while tri-isobutylborane gives isobutene and methylpropylboranes:



$$B(i\text{-}C_4H_9)_3 \rightarrow BH(i\text{-}C_4H_9)_2 + i\text{-}C_4H_8 \rightarrow i\text{-}C_4H_9B(CH_3)(C_3H_7).$$

As a result of the simultaneous occurrence of alkyl exchange on the boron atom, mixtures of all possible trialkylboranes are isolated after pyrolysis. Propyl groups bound to boron are present partially in the form of 1-propyl groups and partially in the form of 2-propyl groups (equilibrium mixture [20]). The pyrolysis products generally do not contain any B–H bonds, yet boron hydrogen compounds such as *(25)* constitute the actual reactive intermediates of the thermal transformation of trialkylboranes.

*(25)*



It has not yet been proved whether C–C splitting in the presence of B–H compounds is an intramolecular (a) or intermolecular (b) process.

*(a)* *(b)*

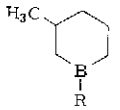
b) *Pyrolysis of Trialkylboranes with Medium-Sized and Long Alkyl Groups (Mono- and Bicyclic Boron Heterocycles)*

Trialkylboranes containing at least four carbon atoms in the main alkyl chain may be converted in high yields into boron heterocycles by heating to 200–300 °C [46, 48]. As a result of dehydroboration (elimination in particular of 2-butene) a mixture of *B*-butylboracyclopentanes $C_4H_9BC_4H_8$ *(26)* is obtained at about 300 °C in yields of up to 90 % together with hydrogen. The mixture consists of two isomers which can be separated by

*(26)*

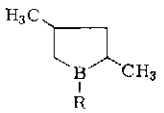
gas chromatography [7], *viz.* 85 % 1-n-butylborolane and 15 % 2-n-butylborolane. Oxidation and hydrolysis (for instance with alkaline $H_2O_2$) yields 1-n-butanol and 2-n-butanol, as well as 1,4-butanediol.

The composition of the products of pyrolysis of trialkylboranes becomes progressively more complex with increasing numbers of carbon atoms in the alkyl groups. With an increase in the length of the alkyl chain bound to the boron, a lower pyrolysis temperature can be chosen (*e.g.* tri-n-hexylborane undergoes rapid decomposition with elimination of hydrogen at about 280 °C; with tri-n-undecylborane, this takes place at about 220 °C) [43].



High yields are obtained when the products of pyrolysis are removed as rapidly as possible from the hot zone. In addition the work must be carried out with only partial conversion, particularly when it is not possible to separate off the cyclic compounds immediately after pyrolysis. Reaction mixtures containing higher trialkylboranes assume a brown color at about 75–80 % conversion and those of the triaralkylboranes (cf. p. 182) at about 90 % conversion. The simple cyclization products are then accompanied by polymeric boron compounds. In the initial stages of pyrolysis, the trialkylborane

[44] *J. Goubeau* and *R. Epple*, Chem. Ber. *90*, 171 (1957).
[45] *R. Köster* and *W. Larbig*, Angew. Chem. *73*, 620 (1961).
[46] *R. Köster* and *G. Rotermund*, Angew. Chem. *72*, 138 (1960).
[47] *R. Köster* and *G. Rotermund*, Angew. Chem. *72*, 563 (1960).

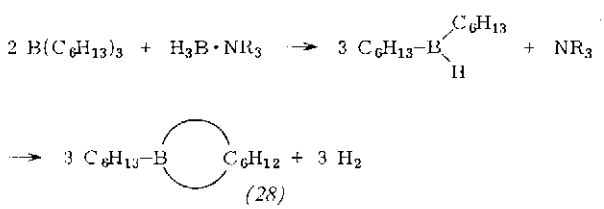


is present in large excess and substantially prevents intramolecular reactions of the heterocycles formed (dilution effect).

On pyrolysis, most trialkylboranes yield mixtures of cyclic isomers, as is to be anticipated on the basis of the thermal equilibria observed with boracyclanes (cf. p. 178) [46,47]; thus, the number of atoms in the ring (n = 5,6,7) and the position at which the side chain is attached to the boron differ (cf. p. 177).

Tri-(2-methyl-1-pentyl)borane yields four isomers of empirical formula $C_6H_{13}BC_6H_{12}$, with elimination of hydrogen and, predominantly, 2-methyl-2-pentene; these isomers contain about 80 % isohexylboracyclohexanes *(27a)* (2 compounds, two different hexyl radicals R) and about 20 % isohexylmethylboracyclopentane *(27b)* (4 compounds, 2 different

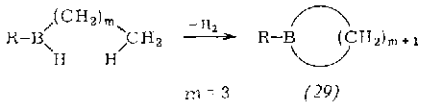
*(27a)*



*(27b)*

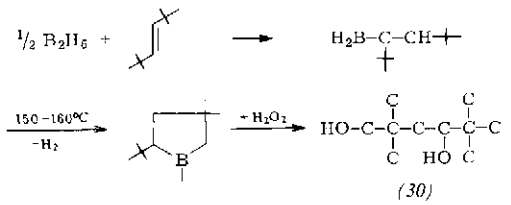
hexyl radicals R; *cis*- and *trans*-isomers) [46]. As a result of migration of the boron atom to the other end of the carbon chain, R also consists of the 4-methyl-1-pentyl group [46].

Tri-(2-ethyl-1-hexyl)borane [35] can be converted in a similar manner into a fairly complex mixture of boron heterocycles which has not been examined in detail up to now. It is likely to consist of mainly six-membered rings. Three different alkyl groups come mainly into consideration for the side chain R; in addition to the 2-ethyl-1-hexyl group, 3-methyl-1-heptyl radicals and, in particular, 5-methyl-1-heptyl radicals are present after heating. Alkyl radicals in which the boron atom is bound to a non-terminal carbon atom cannot be detected. On the other hand, the olefin mixture obtained in the pyrolysis contains almost exclusively branched alkenes with a non-terminal C=C double bond: 3-methyl-2-heptene and 3-methyl-3-heptene.



Boracyclanes can also be prepared by pyrolysis of a mixture of trialkylboranes and trialkylamine-boranes [35, 46]. Thus, if 1 mole of triethylamine-borane and 2 moles of tri-n-hexylborane are heated at about 200 °C, an isomeric mixture of three boron heterocycles *(28)* is obtained. No olefin is formed. The five-membered (borolane) and six-membered (borinane) rings are accompanied by a small amount of the seven-membered boracyclane (borepane) (cf. p. 178). Oxidation (*e.g.* with

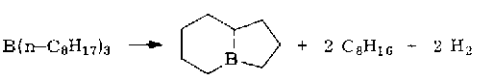
*(28)*



alkaline $H_2O_2$) yields, in addition to 1,4-hexanediol and 1,6-hexanediol, mainly 1,5-hexanediol. The side chain R consists predominantly of the 1-hexyl group. Secondary hexyl groups on the boron are present only to a small extent.

Dialkylboranes are intermediates in the pyrolysis of trialkylboranes to boron heterocycles, since alkyldiboranes $B_2H_{6-n}R_n$ (n = 1–4) are converted into boron heterocycles *(29)* at 150–200 °C with elimination of hydrogen [46,47,50].

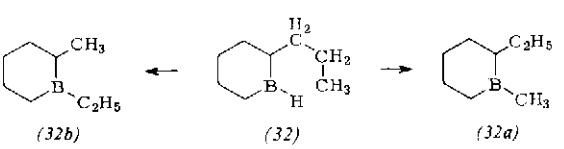
*(29)*



Diborane and 1,2-di-t-butylethylene (*trans*-2,2,5,5-tetramethyl-3-hexene), for instance, react to give an alkyldiborane which on prolonged heating (20 hours, 160–165 °C) forms a heterocyclic boron compound from which 2,2,5,5-tetramethyl-1,4-hexanediol *(30)* is formed on oxidation with hydrogen peroxide [49].

*(30)*

Although dialkylboranes are evidently intermediates in the preparation of heterocycles from trialkylboranes, the trialkylboranes nevertheless give better yields [46]. Apparently the concentration of the B–H groups must not be high since otherwise polymers and other by-products (*e.g.* methylboranes) are readily formed. In the presence of trialkylamine-boranes as B–H group source, aminoboranes $R_2B{-}NR_2$ are also isolated [43].



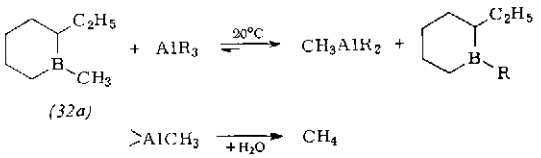
In the pyrolysis of trialkylboranes and alkyldiboranes with eight and more carbon atoms in the main alkyl chain, bicyclic as well as monocyclic boron compounds are formed [43,47]. Starting from tri-n-octylborane one obtains 8-borahydrindane *(31)*, albeit in small yields, via octylborohydrides after loss of two moles of hydrogen.

*(31)*

The octenes given off contain predominantly non-terminal C–C double bonds. The reaction products also include polymers. Furthermore, it is impossible to avoid C–C bond splitting.

If the carbon chain is not long enough – as is the case with tri-n-octylborane – the second stage of the pyrolysis involves methylborane formation [43], as is also observed with the lower trialkylboranes [45] (cf. p. 180). The

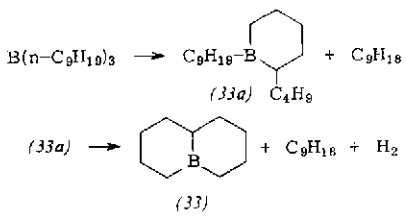
*(32b)* *(32)* *(32a)*



molecular weights of these secondary products can be determined by mass spectrometry [43]. Furthermore, the

[48] *P. F. Winternitz* and *A. A. Carotti*, J. Amer. chem. Soc. *82*, 2430 (1960).

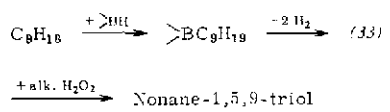
[49] *T. J. Logan* and *T. J. Flautt*, J. Amer. chem. Soc. *82*, 3446 (1960).



[50] *R. Köster* and *G. Rotermund*, Angew. Chem. *74*, 252 (1962); Angew. Chem. internat. Edit. *1*, 217 (1962).

newly formed small alkyl groups present on the boron *(32a)* can be readily detected by alkyl exchange with aluminum trialkyls. Methyl groups are particularly

*(32a)*



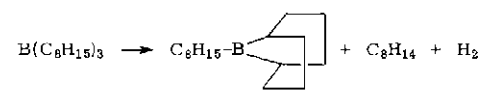
readily detected thereby since they are preferably bound to aluminum in the $BR_3/AlR_3$ equilibrium mixture [17]. These complexes play a less significant part in the pryolysis of tri-n-alkylboranes with more than eight carbon atoms in the alkyl groups. Under suitable conditions (cf. p. 180), 9-boradecalin *(33)* is obtained between 250 and 300 °C from tri-n-nonylborane in 80 % yield [47].

The monocyclic boranes *(33a)* are formed first as intermediates. As the pyrolysis progresses, *(33a)* is then converted into the bicyclic compound.

Higher trialkylboranes are converted by pyrolysis to 1-alkyl-9-boradecalins (*e.g.* tri-n-undecylborane → 1-ethyl-9-boradecalin) [42,43].

1,5,9-Alkanetriols are readily prepared from the 9-boradecalins *(33)*. A method is thus available for synthetizing well-defined alkanetriols from monoolefins, *e.g.* 1,5,9-nonanetriol from n-nonene, in accordance with the reaction scheme:

c) *Pyrolysis of Tricycloalkylboranes (Boron Heterocycles with endo-Boron Atoms)*



Cycloalkylboranes rapidly split off cycloolefins at 180 to 200 °C, first forming dicycloalkylborane [50]. The further course of the reaction depends on the ring size of the cycloalkyl group.

Tricyclohexylborane yields cyclohexane, cyclohexene, hydrogen, and polymeric products containing boron:

$$B(C_6H_{11})_3 \rightarrow [C_6H_{11}B]_x + C_6H_{10} + C_6H_{12} \quad \text{(also: } C_6H_{10} + H_2\text{)}$$

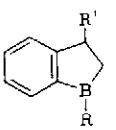
7-Borabicyclo[2.2.1]heptane is not formed.

Tricyclooctylborane on the other hand yields *B*-cyclooctyl-9-boratricyclo[3.3.1]nonane *(34)* [50] in good yields:

*(34)*

The cyclooctyl compounds are best pyrolyzed in the presence of a trialkylborane, $BR_3$. The third boron valence which does not participate in the ring is then saturated with the group R, as for instance in *(34)*.

When heated to 220 °C, 1 mole of tricyclododecylborane yields a perhydro-9$^b$-boraphenalene *(21)* [50] with elimination of 2 moles of cyclododecene (*cis*- and *trans*-isomers) and 2 moles of hydrogen in accordance with the equation:



$$B(C_{12}H_{23})_3 \rightarrow 2\,C_{12}H_{22} + (21) + 2\,H_2$$

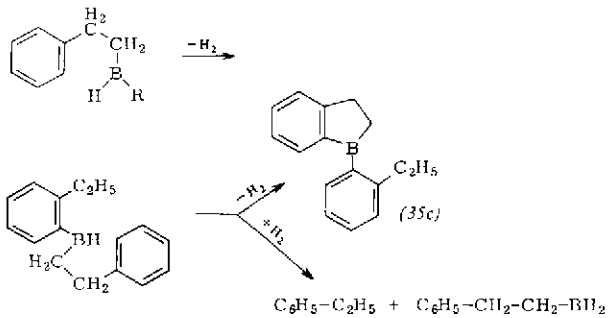
Compound *(21)* is also formed on hydroboration of *trans,trans,trans*-cyclododeca-1,5,9-triene (cf. p. 179) [42,51].

d) *Pyrolysis of Aralkylboranes (1-Boraindanes and 1-Boratetralins)*

Although alkyldiboranes and olefins are formed when trialkylboranes are heated above 180 °C (dehydroboration), certain triaralkylboranes cannot be converted into aralkyldiboranes at elevated temperatures, even under strongly reduced pressure [4]. The olefin (arylalkene) produced is accompanied by hydrogen [52]. The presence of B–H bonds cannot be proved in the boron-containing dehydroboration products of the triaralkylboranes. On heating aralkylboranes, boron heterocycles are often obtained directly in yields of over 90 %. The temperatures required for cyclization lie between 180 and 250 °C.

For instance, 1 mole of tri-(2-phenylpropyl)borane decomposes at 180–200 °C and a pressure of $10^{-1}$–$10^{-3}$ mm to form 1 mole of α-methylstyrene and 1 mole of hydrogen as well as a boron compound $BC_{18}H_{21}$, a colorless liquid which is sensitive to air and which has a well defined boiling point [52]. The compound was identified as *B*-(2-phenylpropyl)-3-methylboraindane *(35a)* [52] and has a $B-C_{aryl}$ bond which is readily detected by its reaction with mercuric chloride [53].

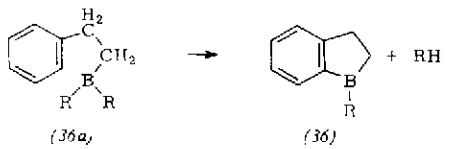
*(35a)*: R = $CH_2$–$CH(CH_3)$–$C_6H_5$, R' = $CH_3$
*(35b)*: R = $CH_2$–$CH_2$–$C_6H_5$, R' = H



Tri-(2-phenethyl)borane is converted similarly into *B*-(2-phenethyl)boraindane *(35b)*, ethylbenzene being formed in addition to styrene and hydrogen. The hydrocarbon evidently arises as a result of hydrogenation of the aralkylborane and not from styrene produced by dehydroboration, since pyrolysis of 2-phenethylboron compounds yields not only boraindanes with aralkyl groups on the boron, but also derivatives *(35c)* with alkaryl (*e.g.* 2-ethylphenyl) groups. This indicates that dehydrogenations and hydrogenations in accordance with Scheme 3 take place during pyrolysis.

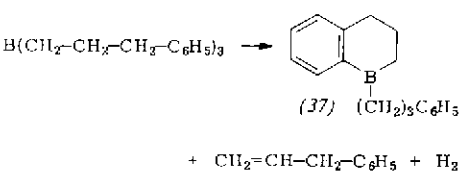
Direct elimination of hydrocarbons (*e.g.* ethylbenzene) is also possible but evidently plays a decisive part only in

[51] *G. Wilke*, Angew. Chem. *75*, 10 (1963); Angew. Chem. internat. Edit. *2*, 105 (1963).



[52] *R. Köster* and *K. Reinert*, Angew. Chem. *71*, 521 (1959).

[53] *G. Wittig, C. Keicher, A. Rückert*, and *P. Raff*, Liebigs Ann. Chem. *563*, 110 (1949).

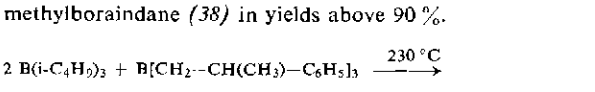


Scheme 3. Hydrogenations and dehydrogenations taking place during the pyrolysis of tri-(2-phenethyl)borane.

special cases (cf. p. 184), since RH-elimination [*(36a)* → *(36)*] proceeds at a substantially slower rate than the liberation of hydrogen from B–H compounds.

*(36a)* *(36)*

The six-membered rings corresponding to *(36)* (1-boratetralins) can be prepared by the same method. Tri-(3-phenylpropyl)borane and tri-(2-methyl-3-phenylpropyl)-borane split off hydrogen and allylbenzene and methallylbenzene, respectively, at temperatures above 200 °C under reduced pressure. *B*-(3′-Phenylpropyl)boratetralin *(37)* and *B*-(2′-methyl-3′-phenylpropyl)-3-methylboratetralin, respectively, are obtained.



*(37)*

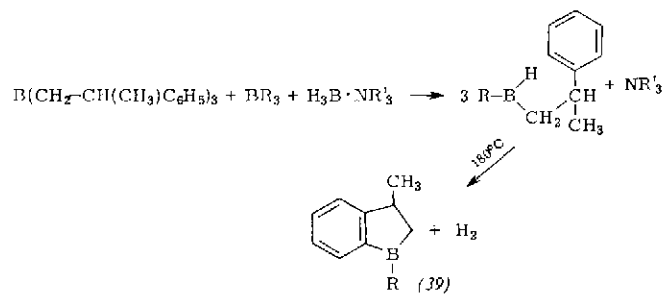
1-Boraindanes or 1-boratetralins are always formed pyrolytically if at least one aralkyl group bound to the boron is suitable for formation of the five- or six-membered ring. The two other ligands on the boron may be different; but one of them should, on account of the reasons mentioned, either be a B–H group or be capable of conversion into a B–H group by dehydroboration. The third valence of the boron compound may be varied as desired. It determines the group attached to boron outside the ring in boron heterocycles.

For this reason, mixed dialkylmonoaralkylboranes, as well as triaralkylboranes may be converted into boraindanes and boratetralins [52]. Instead of the compound with different ligands, mixtures of a trialkylborane and a triaralkylborane may be used (exchange of ligands). In this manner all the aralkyl groups can be utilized for the formation of the boron heterocycles.

At about 230 °C, 2 moles of tri-isobutylborane and 1 mole of tri-(2-phenylpropyl)borane interact to form 1-isobutyl-3-methylboraindane *(38)* in yields above 90 %.

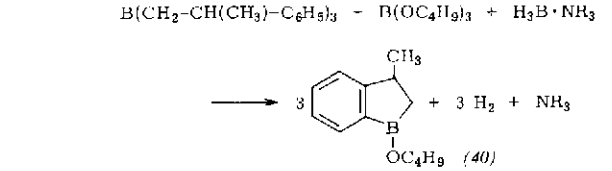
*(38)*

Since the isobutene which is given off thereby is volatile, the reaction can be carried out at atmospheric pressure.



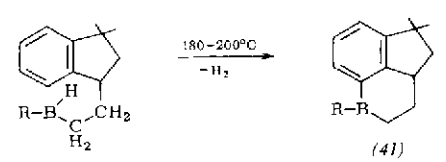
1-Aralkylboraindanes *(35a, b)* and 1-aralkylboratetralins *(37)* are readily converted into any 1-alkyl compound [54]. Tetraalkyldiboranes or a mixture of trialkylamine-borane and trialkylborane react at about 180–190 °C with elimination of hydrogen to give 1-alkylboraindanes *(39)* or 1-alkylboratetralins in yields of 70–80 %.

*(39)*



Aralkyldiboranes form 1-boraindanes or 1-boratetralins at about 150 °C with elimination of hydrogen. This method of preparation is, however, not very convenient from a practical point of view, since too many side reactions (*e.g.* formation of polymeric products) take place at high borohydride concentrations. If, however, the borohydrides are stabilized by Lewis bases such as trialkylamines, useful results are obtained. Practically no aminoboranes are formed if the mixtures (*e.g.* triaralkylborane + triethylamine-borane) are not exposed to high temperatures for excessively long periods.

As a result of exchange of the substituents on the boron, a mixture of equimolar amounts of triaralkylborane, trialkylborane, and triethylamine-borane reacts like a monoaralkyl-monoalkylborane to give 1-alkyl-1-boraindanes *(39)* or 1-alkyl-1-boratetralins [52].



*(39)*

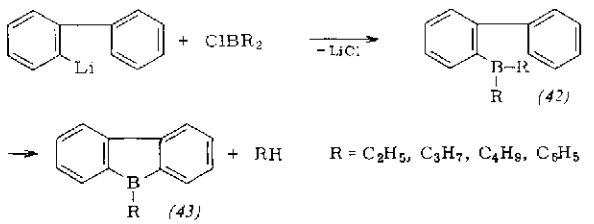
When the trialkylboranes are replaced by trialkoxyboranes, 1-alkoxy-1-boraindanes are formed directly. At 190 °C, for instance, one obtains 1-n-butoxy-3-methyl-1-boraindane *(40)* in approximately 85 % yield [55].

*(40)*

The ring-closure method is of a very general application. Thus, in the presence of tri-isobutylborane, a mixture of tri-[2-(3′,3′-dimethylindanyl)ethyl]borane and triethylamine-borane forms a tricyclic compound *(41)* [55].

*(41)*

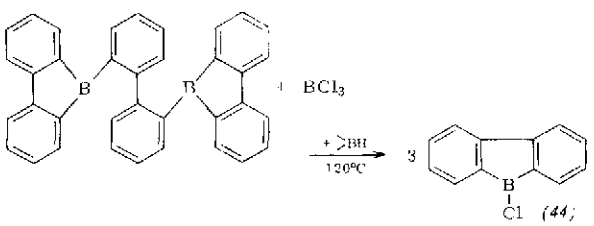
e) *Pyrolysis of Arylboranes (9-Borafluorenes)*



On heating 2-biphenylyldialkylboranes *(42)* or 2-biphenylyldiphenylborane, 9-borafluorenes *(43)* [56] are formed with elimination of alkane or benzene.

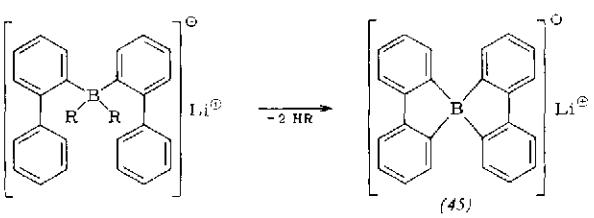
[54] *R. Köster*, unpublished work.

[55] *R. Köster* and *K. Reinert*, unpublished work.



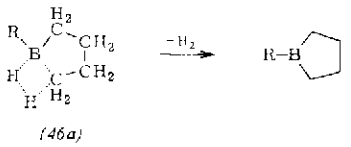
[56] *R. Köster* and *G. Benedikt*, Angew. Chem. *75*, 419 (1963); Angew. Chem. internat. Edit. *2*, 323 (1963).

On heating 2-biphenyldiethylborane, which is readily prepared from 2-biphenylyl-lithium and diethylchloroborane, at about 180 °C, 9-ethylborafluorene is obtained in the form of an intensely yellow crystalline compound in approx. 65 % yield [56].



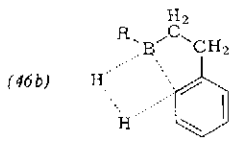
As a result of pyrolytic dehydroboration, compounds containing higher alkyl radicals (*e.g.* propyl or isobutyl) also yield alkenes and B–H compounds which are then converted into 9-alkylborafluorenes with elimination of hydrogen. The $B-C_{aryl}$ bond is thereby partly hydrogenated with elimination of biphenyl (yields: 42 % 9-propylborafluorene, 40 % 9-isobutylborafluorene). 9-Alkylborafluorenes are also formed from biphenylyl-monoalkylboranes even at 120 °C, only hydrogen being evolved [56a].

2-Biphenylyldiphenylborane (m.p. 31 °C; prepared from 2-biphenylyl-lithium and diphenylchloroborane) gives off benzene only at 280–300 °C, yielding yellow 9-phenylborafluorene in approx. 55 % yield. The orange-yellow products obtained as residue in the pyrolysis yielded yellow 9-chloroborafluorene *(44)* when trichloroborane was passed in at about 120 °C in the presence of B–H compounds [14].



When 2-biphenylyl-lithium and dialkyl- or diarylchloroborane are heated in a molar ratio of 2:1 [56], the lithium salt of the known bis-(2,2'-biphenylidene)boranate *(45)* [57] is obtained, in which the boron atom is bound as in a spirane.

## III. Mechanism of Pyrolytic Ring Formation

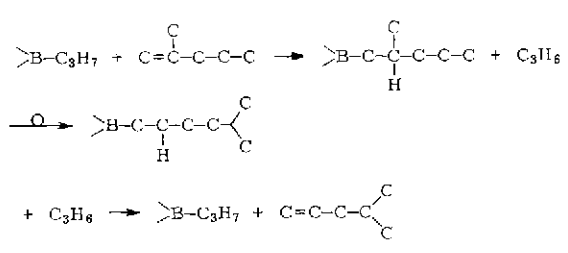


A radical mechanism of the type initially discussed [48] does not appear to be likely for the pyrolysis. Pyrolysis of some trialkylboranes (such as tri-1-butylborane and tri-1-nonylborane) may proceed extremely smoothly in one direction. A reaction involving a radical mechanism should, however, yield a large number of decomposition products. Thus, it would be anticipated, for instance, that not only certain definite C–H bonds and C–C bonds would undergo splitting. The relatively low pyrolysis temperature of about 200 °C also forms evidence against the likelihood of a radical mechanism.

Elimination of hydrogen from dialkylboranes evidently proceeds via a concerted mechanism, *e.g.* a four-center transition state *(46a)*.

*(46a)*

The formation of boron heterocycles containing $B-C_{aryl}$ bonds (pp. 182–184) which takes place with elimination of hydrogen or hydrocarbons (alkane, benzene) is also likely to be based on a concerted mechanism involving an intramolecular four-center transition state *(46b)*.



*(46b)*

The fact that intramolecular ring closure with formation of boraindanes, boratetralins, borafluorene, *etc.* takes place particularly readily becomes more understandable if it is assumed that the conformation required is particularly easily attained by interaction of the π-electrons of an aromatic ring with the unoccupied orbital of the $sp^3$-hybridized boron.

Intermolecular reactions between aromatic hydrocarbons and borohydrides do take place but of course at a much slower rate than the cyclizations dealt with here [58, 59].

## Outlook

At the beginning it was pointed out that the migration of boron along alkyl chains that is brought about via dehydroboration-hydroboration equilibria can be used for isomerizing alkenes or for preparing certain functional derivatives of hydrocarbons (*e.g.* alcohols) from alkenes via alkylboranes. The method can, however, be applied only in those cases where the equilibria of the alkylboranes formed are accurately known. The following reaction sequence can then often be employed in accordance with Scheme 4: alkyl-olefin exchange → isomerization → alkyl-olefin exchange (displacement):

Schema 4. Sequence of olefin-exchange and isomerization reactions of alkylboranes.

[56a] *R. Köster* and *G. Benedikt*, unpublished work.

[57] *G. Wittig* and *W. Herwig*, Chem. Ber. *88*, 962 (1955).

[58] *D. T. Hurd*, J. Amer. chem. Soc. *70*, 2053 (1948).

[59] *R. Köster*, *K. Reinert*, and *K. H. Müller*, Angew. Chem. *72* 78 (1960).

In addition to thermal isomerization, pyrolytic reactions also make it possible to convert alkenes into compounds (*e.g.* diols and triols) in which the functional groups are bound to certain carbon atoms depending on the boron heterocycles formed as intermediates.

The pyrolytic transformations of organoboranes are not limited to compounds containing B–C and B–H bonds. Well-defined B–N heterocycles can also be prepared from organic compounds containing boron-nitrogen bonds [60]. In the case of compounds containing oxygen in addition to boron, the possibilities of preparing the corresponding B–O heterocycles appear to be slight. In this case, boroxines are mostly formed instead of heterocycles containing boron and oxygen as well as carbon.

## Investigations on the Synthesis of Cyclooctatetraene by the Method of W. Reppe

BY PRIV.-DOZ. DR. G. N. SCHRAUZER
IN COOPERATION WITH P. GLOCKNER AND S. EICHLER
INSTITUT FÜR ANORGANISCHE CHEMIE DER UNIVERSITÄT MÜNCHEN (GERMANY)

*The relationship between the structure and the catalytic activity of nickel(II) complexes in the synthesis of cyclooctatetraene by the method of W. Reppe is discussed. The cyclotetramerization of acetylene takes place within labile Ni(II)-acetylene π-complexes. Inhibition tests have made it probable that four molecules of acetylene are grouped around the nickel ion in the transition state, in a configuration which favors the formation of the eight-membered ring.*

### Introduction

The synthesis of cyclooctatetraene discovered in 1940 by *Reppe* [1] belongs to the most fascinating reactions of modern chemistry. The simple starting material acetylene is converted by means of certain nickel(II) complexes into cyclooctatetraene, the unsaturated hydrocarbon which *Willstätter* [2] managed to prepare only in small quantities from pseudo-pelletierine at the beginning of the century by an extremely tedious and laborious sequence of reactions. *Reppe*'s synthesis permits production of this compound on a technical scale. Since benzene is the main product of uncatalysed thermal polymerization of acetylene, it is particularly surprising that largely selective cyclotetramerization takes place under substantially milder conditions in the presence of nickel(II) complexes. *Reppe* [1] suggested that the formation of the eight-membered ring occurs within labile nickel-acetylene complexes. More detailed investigations on the mechanism of this reaction were not reported until very recently. The attempts made by various authors to explain the reaction remained necessarily speculative, since decisive new knowledge of the complex chemistry of nickel was only obtained in recent years. The observation [3,4] that cyclooctatetraene was also formed in the presence of certain Ni(0) complexes, *e.g.* bis(acrylonitrile)Ni(0), was the starting point of our own investigations, first reports on which appeared in 1961 and 1962 [5,6]. Meanwhile, further data have been obtained, so that the present comprehensive report contains hitherto unpublished material.

### I. Conditions and Scope of Reaction

The formation of cyclooctatetraene occurs between 80 and 120 °C (optimum at 85–95 °C) at an acetylene pressure of 15–25 atm. The Ni(II) complexes most commonly used as catalysts are the acetylacetonate, cyanide, salicylaldehydate and the enolates of acetoacetic esters [1,7]. Cyclooctatetraene is obtained in 70 % yield (calculated on the quantity of acetylene used) together with varying amounts of benzene (up to 15 %), a resinous polymer, and a dark brown, insoluble, cuprene-like mass ("niprene") [1]. Small quantities of styrene, 1-phenyl-1,3-butadiene, vinylcyclooctatetraene [1,8,9], and traces of azulene are also formed.

[9] *A. C. Cope* and *S. W. Fenton,* J. Amer. chem. Soc. *73,* 1195 (1951).

The reaction has no induction period and the catalysts need not be subjected to any contact development. All the catalysts known up to the present are relatively short-lived. Of the side-reactions which deactivate the catalysts, that leading to the formation of niprene is particularly noteworthy.

The reaction is essentially confined to unsubstituted acetylene. Under the same conditions, substituted acetylenes always yield linear polymers or derivatives of benzene. However, a few mono- and disubstituted cyclooctatetraene derivatives have been produced catalytically by mixed cyclooligomerization of acetylene with monosubstituted and disubstituted alkynes. Up to now, only one substituted alkyne could be incorporated into the eight-membered ring at a time [10, 11], to give the compounds *(1a)* to *(1e)*.

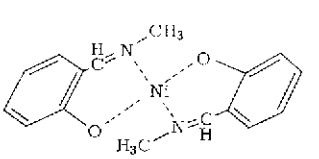
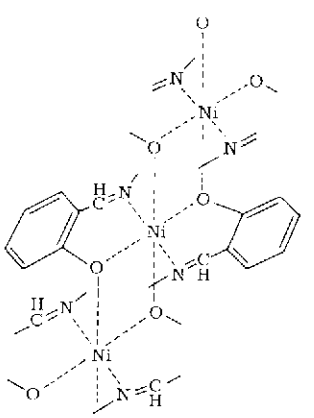
## II. Properties of the Catalysts

All hitherto known catalytically active Ni(II) complexes have octahedral or planar structures. In octahedral complexes, the 3d level is split to give one triply degenerate ($t_{2g}$) and one doubly degenerate ($e_g$) term. Since there are eight 3d electrons available in the Ni(II) ion, the $e_g$ level contains only two electrons and the complexes are therefore paramagnetic. The degeneracy of the levels is destroyed by any distortion of the octahedral symmetry, or by unequal changes in the ligand strength [12]. Particular importance is attached to the cases where the coordination octahedron is distorted axially or the ligand strength is increased tetragonally on the octahedral base. In the extreme case, in which the axial ligands are completely removed, or where the tetragonal ligand strength is greatly increased, the splitting of the levels becomes that of a diamagnetic planar complex (Scheme 1).

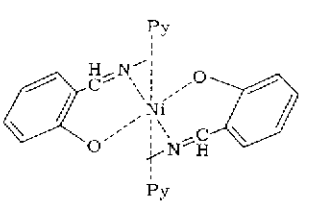


Examples of these two extreme types of complexes are the paramagnetic bis(acetylacetonato)Ni(II) with its octahedral configuration in the solid state, and planar, diamagnetic bis(dimethylglyoximato)Ni(II). When the distortions of the octahedral symmetry are only small, the paramagnetism is maintained; this status prevails until the distance $\Delta'$ becomes so large that thermal promotion to a higher level is no longer possible.



Scheme 1. Tetragonal distortion of octahedral complexes.

A large number of Ni(II) complexes lie in the immediate vicinity of the singlet-triplet transition point; either of the two states may then become the ground state, since the energy difference between them is very small. Complexes of this type exhibit markedly anomalous magnetic behavior. Particular examples of such compounds are the Ni complexes of *N*-alkylsalicylaldimine. Initially, we shall consider only complexes containing straight-chain alkyl groups.



The *N*-methyl derivative *(2)* crystallizes in two diamagnetic low-temperature modifications, and forms a buff colored, insoluble, and paramagnetic high-temperature modification *(3)*, in which the coordination number of the nickel ion is probably 6 [13, 14]. However, in this and in other cases, the transition from the planar diamagnetic form into the paramagnetic modification takes place immediately on dissolution. The paramagnetism of the dissolved complex may be caused either by solvation, association, or a combination of these two ef-

*(2)*

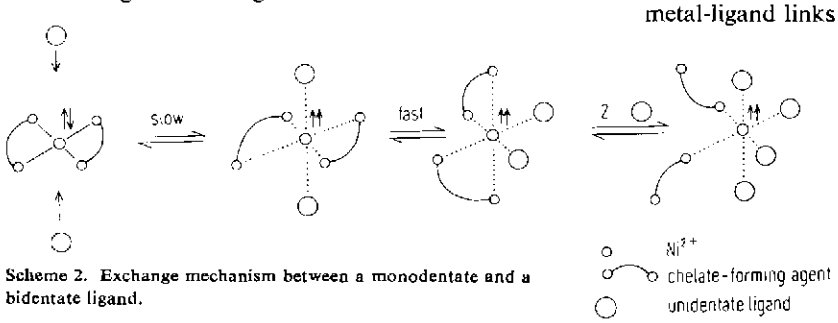
fects. With pyridine, for example, bis(*N*-methylsalicylaldiminato)Ni(II) forms a paramagnetic 1:2-adduct *(4)* [15].

However, the same complex is also paramagnetic in non-coordinating solvents, but the magnetic moment depends on the concentration and the temperature. Molecular-weight determinations indicate the presence of associated species in which the nickel ion achieves the axial perturbation by interaction with the oxygen atoms of adjacent molecules [16]. The anomalous magnetic behavior was traced back to the dependence of the degree of association on temperature, concentration, and solvent [17].



In the synthesis of cyclooctatetraene, the only complexes that are catalytically active are those which are octahedral, or which can easily assume this configuration (Table 1). Complexes with extremely strong tetrahedral coordination are inactive, since in contrast to the octahedral complexes, they are largely inert with respect to ligand-exchange reactions. Ligand-exchange reactions are still possible with planar nickel complexes with moderately strong coordination, since the energy required for their conversion into the octahedral type of complex is only small. The spin decoupling of planar Ni(II) complexes takes place with participation of polar solvents [18] and leads to a weakening of the original nickel-ligand bonds. A somewhat simplified representation of a ligand-exchange is shown in Scheme 2.

Table 1. Classification of cyclooctatetraene catalysts containing divalent nickel [6].

| | Weak ligand field | Intermediate range | Strong ligand field |
|---|---|---|---|
| Configuration | octahedral | octahedral and planar | planar |
| Magnetic behavior | paramagnetic | anomalous | diamagnetic |
| Ligand exchange | rapid | moderately rapid to rapid | very slow |

Scheme 2. Exchange mechanism between a monodentate and a bidentate ligand.

Whereas *N*-alkylsalicylaldiminato complexes with straight-chain alkyl groups may occur only in the octahedral and the planar configuration, it has recently been shown [18–20] that the analogous complexes with branched hydrocarbon residues also form tetrahedral structures. Thus, the bis-(*N*-cyclopentyl)-, bis-(*N*-cyclohexyl)-, and bis-(*N*-cyclooctylsalicylaldiminato)Ni(II) complexes are diamagnetic and planar in the solid state, but more or less strongly paramagnetic in solution. In this case, the spin decoupling is caused not only by association, but also by the rearrangement into the tetrahedral configuration. Although the formation of tetrahedral complexes of Ni(II) is not energetically favored, this configuration may still be realized if the ligands carry bulky substituents. Thus, bis-(*N*-t-butylsalicylaldiminato)Ni(II) *(5)*, exists almost completely in the tetrahedral form both in solution and in the solid state [18]. The tetrahedral bis-(*N*-alkylsalicylaldiminato)Ni complexes undergo relatively rapid ligand exchange and are also active catalysts for the formation of cyclooctatetraene, a property which will be described in greater detail.

## III. Transition State and Rate-Determining Step

If the formation of cyclooctatetraene is to occur within a nickel-acetylene complex, the original coordinate nickel-ligand bonds must first be broken and new such bonds must be formed with acetylene molecules. It was therefore assumed [5,6] that the loosening of coordinate metal-ligand links is the rate-determining step for both the ligand-exchange reaction and the cyclooctatetraene synthesis. This appears to be indeed the case and may be illustrated by two examples: The paramagnetic and kinetically labile bis(salicylaldehydato)Ni(II) is a good catalyst for the formation of cyclooctatetraene, whereas the bis(salicylaldiminato)Ni(II) is kinetically inert and virtually ineffective as a catalyst.

[20] *R. H. Holm* and *K. Swaminathan*, Inorg. Chem. *2*, 181 (1963).

As early as 1952, *Hagihara* [21] suspected a connection between the magnetic properties and the catalytic activity of Ni(II) complexes in the synthesis of cyclooctatetraene, but an interpretation of his results has only recently become possible.

Since the polar solvent participates in the ligand exchange reactions of Ni(II) chelates (the reactions proceed more rapidly in tetrahydrofuran, for example, than in benzene), the formation of cyclooctatetraene also depends on the polarity of the medium [5,6]. The yields are generally larger in dioxan than in tetrahydrofuran, and are least in benzene. More strongly solvating solvents than dioxan or tetrahydrofuran are unsuitable, since the acetylene may no longer displace the solvent molecules that are clustered around the Ni(II) ion; thus, no cyclooctatetraene is formed in solvents such as pyridine, benzonitrile, or water. Four coordination sites can be made available in the nickel complexes by cleavage of the coordinate linkages, and these can be occupied by acetylene molecules. In the resultant, approximately octahedral complex, these molecules can assume a steric configuration which favors the formation of cyclooctatetraene (Scheme 3).

Scheme 3. Assumed transition state in the formation of cyclooctatetraene on Ni(II) complexes.

The basic strengths of the lower straight-chain alkylamines alternate. *Sacconi* et al. [22] were able to show that the magnetic moments of the bis-(*N*-alkylsalicylaldiminato)Ni(II) chelates alternate in parallel with the basic strengths of the alkylamines. The yield of cyclooctatetraene from acetylene with these chelates as catalysts also varies with the effective ligand field strengths. The N-methyl compound is the most strongly paramagnetic chelate of this series and gave the highest yields [5,6]. This result shows that the same rate determining step is involved in the formation of cyclooctatetraene and in the apparently entirely unrelated ligand exchange reaction. This step is most probably the reaction of the catalyst with the first acetylene molecule, during which the coordination number of the Ni(II) ion may vary from four to six, with the simultaneous conversion into the paramagnetic form. This view is supported by the results of recent measurements of the kinetics of the reaction between bis-(*N*-alkylsalicylaldiminato)Ni(II) and dimethylglyoxime. The reaction, in which bis(dimethylglyoximato)Ni(II) is the product, is of second order. The rate is controlled by the addition of the first molecule of dimethylglyoxime to the original Ni(II) complex, which would also explain why small differences in the effective ligand strengths have such a pronounced effect on the rate [23].

## IV. Synthesis of Benzene by Inhibition of the Formation of Cyclooctatetraene

Since the rate of formation of cyclooctatetraene is controlled by a slow ligand-exchange process, no evidence regarding the structure of the transition state can be gained from kinetic measurements. If the transition state is in fact that represented by Scheme 3, the synthesis of cyclooctatetraene should be effectively inhibited by electron donors. When the reaction is carried out with acetylene and the usual catalyst in the presence of triphenylphosphine (molar ratio 1:1 to the catalyst), no cyclooctatetraene is produced, but instead, benzene is obtained in high yield [5,6]. Benzene formation is not in-

hibited by the addition of even large amounts of triphenylphosphine. Triphenylphosphine is evidently capable of blocking a coordination site in the complex in the manner represented by Scheme 4A. The interaction of triphenylphosphine with the catalysts was also directly demonstrated by preparative methods [23]. The reaction of triphenylphosphine with $Ni(CN)_2$ in alcohol yields a pale yellow, diamagnetic bis(triphenylphosphine)nickel cyanide. The triphenylphosphine is only loosely bonded in this compound, and is re-eliminated in refluxing benzene. It is a powerful catalyst for the polymerization of acetylene, but produces only benzene. The analogous complex of the more strongly basic diphenylethylphosphine is more stable and a much less effective trimerization catalyst [23].

Scheme 4. Inhibition of the formation of cyclooctatetraene (A) by the association of competing electron donors with the Ni(II) ion (cf. Scheme 3). With bifunctional electron donors, even benzene is no longer formed (B).

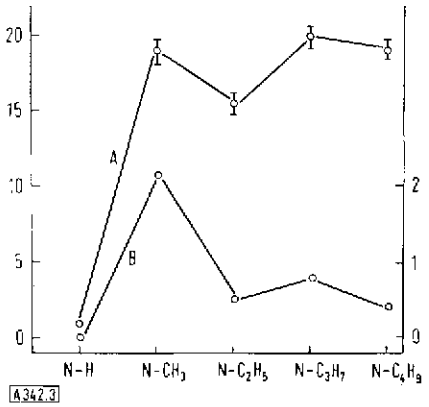
Inhibitors which block not only one, but two *cis*-positions in the active complex, *e.g.* $\alpha,\alpha'$-bipyridyl, 1,10-phenanthroline, or 1,2-bis(diphenylphosphino)ethane $[(C_6H_5)_2P-C_2H_4-P(C_6H_5)_2]$, completely poison all catalysts. Even benzene is no longer formed, and no acetylene is consumed. The effect of basic additives increases in the order:

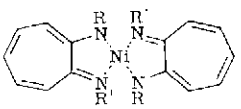
(Dioxan) < trimethylamine < pyridine < triphenylphosphine < diphenylethylphosphine < tributylphosphine.

The order of this series permits certain conclusions to be drawn regarding the bonding of the acetylene in the active complex. Relatively weak $\sigma$-bonds with only small $\pi$-bond contributions are formed between the acetylene and the Ni(II) ion, since the formation of cyclooctatetraene is inhibited even by trimethylamine or pyridine, both of which are $\sigma$-donors but at most only weakly $\pi$-bonding ligands. *Yamazaki* and *Hagihara* [24] recently established a similar series: dimethylaniline < pyridine < $Bi(C_6H_5)$ < $Sb(C_6H_5)_3$ < $As(C_6H_5)_3$ < $P(C_6H_5)_3$. Under the conditions of the cyclooctatetraene synthesis, the acetylene behaves towards the Ni(II) ion as a ligand with a weak field. The Ni(II) ion should therefore remain paramagnetic in the transition state and should exist in an approximately octahedral ligand field.

Water is also an inhibitor, but its effect is much weaker than that of the weakly $\pi$-bonding pyridine. In tetrahydrofuran, with bis(acetylacetonato)Ni(II) as catalyst, about 50 moles of water per mole of catalyst are required to reduce the yield of cyclooctatetraene to one-half, whereas only 2 moles of pyridine are necessary to achieve the same result.

In the synthesis of benzene on triphenylphosphine-poisoned catalysts, the same process is rate-determining as in the absence of the inhibitor. The dependence of the yield of benzene on the magnetic moments of the bis(*N*-alkylsalicylaldiminato)Ni(II) complexes is shown in Figure 3.





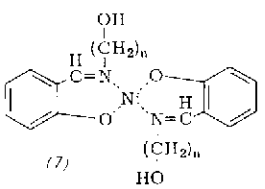


Fig. 3. Dependence of the yield of benzene (in tetrahydrofuran at 95 °C and a $C_2H_2$ pressure of 25 atm) on the magnetic moments of the bis-(*N*-alkylsalicylaldiminato)Ni(II) chelates. Left-hand ordinate (for curve A): yield of benzene [g] per 5 mmoles of catalyst in 15 hours. Right hand ordinate (for curve B): Magnetic moments [Bohr magnetons] of the catalyst complexes in dioxan.

## V. Influence of the Structure of the Catalyst

The *N*-alkylsalicylaldimine-Ni(II) chelates with branched alkyl residues, which exist in equilibrium with tetrahedral structures, are also active catalysts for the formation of cyclooctatetraene. The yields of cyclooctatetraene are again roughly proportional to the rate of ligand exchange with dimethylglyoxime. It is noteworthy that benzene is produced in somewhat larger quantities (up to 30 % relative to the yield of cyclooctatetraene) than with the analogous catalysts containing straight-chain alkyl groups. Evidently the bulkier branched substituents partially inhibit the formation of the transition state required for the cyclotetramerization of acetylene.

*(6a)*: R = R' = $CH_3$
*(6b)*: R = R' = $C_2H_5$

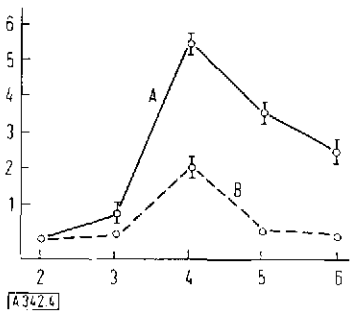
*(7)*

The bis-(*N*,*N'*-dialkylaminotroponiminato)Ni(II) complexes *(6)* recently described contain tetrahedral chelates with stronger ligand fields than those of the *N*-alkylsalicylaldimines. Compound *(6a)* is diamagnetic

[24] *H. Yamazaki* and *N. Hagihara*, J. chem. Soc. Japan, ind. Chem. Sect. *61*, 21 (1958); Chem. Abstr. *53*, 18885e (1959).

and planar; *(6b)* is paramagnetic and, again for steric reasons, tetrahedral [25]. Both complexes undergo ligand exchange only slowly in inert solvents, and react with acetylene to yield only traces of cyclooctatetraene [23]. Thus, the catalytic activity of Ni(II) complexes for the cyclization of acetylene is essentially a function of the effective ligand-field strengths.

Complexes of type *(7)* with n = 2, 3, 5, and 6 are not at all or only slightly active. For n = 4, a relatively large quantity of benzene (about 40 % relative to the yield of cyclooctatetraene) is formed in addition to cyclooctatetraene. Additional chelate rings are presumably formed between the nickel ion and the oxygen atoms of the side-chains; these may be exceptionally stable for n = 4, and thus block one coordination site in the transition state much more frequently (cf. Fig. 4) [23].



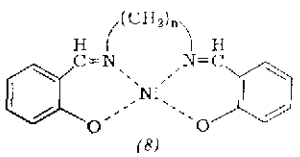


Fig. 4. Yields of cyclooctatetraene (curve A) and benzene (curve B) with catalysts of type *(7)*, in tetrahydrofuran at 95 °C and a $C_2H_2$ pressure of 25 atm.
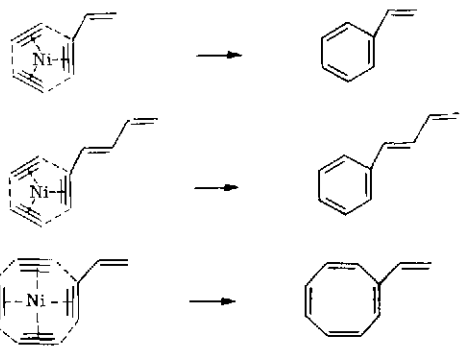
Ordinate: Yield [g] per 5 mmoles of catalyst in 15 hours.
Abscissa: Chain length [number of carbon atoms].

Complete inactivity results if the mobility of the ligands around the Ni(II) ion is restricted, as with chelates of type *(8)* in which n = 6. At n = 7 and n = 8, the com-



*(8)*

plexes again become slightly active and yield small quantities of cyclooctatetraene [23].

## VI. Formation of By-products

As shown by the inhibition experiments, the cyclooctatetraene synthesis can be easily "switched over" to yield only benzene. It is therefore not surprising that small quantities of benzene are almost always produced as a by-product. The formation of styrene, phenylbutadiene, and vinylcyclooctatetraene can be attributed to mixed cyclooligomerization of acetylene with vinylacetylene and higher linear oligomers of acetylene, which are formed in small quantities under the conditions of the reaction [26] (Scheme 5). The formation of niprene is a metal-catalysed polymerization of acetylene, brought about either by the nickel catalyst itself or by its decomposition products (metallic nickel).

Scheme 5. Formation of the by-products styrene, phenylbutadiene, and vinylcyclooctatetraene.

## VII. Formation of the New Carbon-Carbon Bonds

To explain the above results one has to assume that cyclooctatetraene and benzene are formed within labile acetylene-Ni(II) π-complexes. In the transition state the acetylene molecules appear to be both activated and drawn closely together. Activation of the acetylenic carbon atoms presumably occurs with formation of the π-complex, whereby the sp-hybridized carbon atoms acquire a larger amount of p-character. This would facilitate their rehybridization to $sp^2$, which gives the acetylene molecule the reactivity of a biradical. It is likely that the formation of the products does not involve any further intermediate, even if the new carbon-carbon bonds are not all formed simultaneously.

## VIII. The Cyclobutadiene Hypothesis

Another aim of the present work was to search for some indication of the intermediate formation of cyclobutadiene. No such indication was found; on the contrary, some of the observations were incompatible with this hypothesis. *E. D. Bergmann* [27] was the first to suggest the possibility that cyclooctatetraene is formed from acetylene by dimerization of two molecules of cyclobutadiene. *Kuri* and *Shida* [28] subsequently postulated the formation of cyclobutadiene as an intermediate in the photo-polymerization of acetylene, which yields benzene plus a small quantity of cyclooctatetraene. In their famous paper on the possible existence of π-complexes of cyclobutadiene, *Longuet-Higgins* and *Orgel* [29] also expressed the opinion that cyclooctatetraene is obtained

[25] *D. R. Eaton, W. D. Phillips,* and *D. J. Caldwell,* J. Amer. chem. Soc. *85*, 397 (1963). The author is indebted to Dr. *R. E. Benson,* Wilmington, Del. (U.S.A.), for two samples of these complexes.

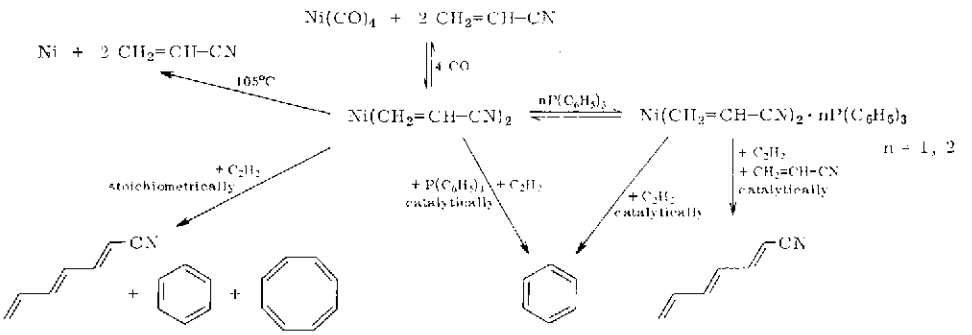
[29] *H. C. Longuet-Higgins* and *L. E. Orgel,* J. chem. Soc. (London) *1956*, 1969.

from two molecules of cyclobutadiene that are formed on the nickel catalyst. *Criegee* and *Schroeder* were able to verify this hypothesis by thermolysis of tetramethylcyclobutadiene-$NiCl_2$ [30], but a temperature of 190 °C was required. Although traces of cyclooctatetraene are actually formed in the reaction of "cyclobutadiene-mercury" with bis(acetylacetonato)nickel it is not certain whether these really arise by dimerization of cyclobutadiene [31].



As a consequence of its electronic structure, cyclobutadiene must be considered a strongly π-bonding ligand. Intermediate cyclobutadiene-Ni(II) complexes would therefore be diamagnetic and kinetically more stable than the parent catalyst molecules. The rate of cyclooctatetraene formation would then be controlled by the consecutive reactions of the cyclobutadiene complex, a fact which cannot be reconciled with the experimental evidence.

The results of the inhibition experiments are likewise incompatible with the cyclobutadiene hypothesis. There is no logical explanation for the assumption that the cyclobutadiene formed in catalytic quantities on the nickel catalyst should dimerize selectively to cyclooctatetraene, despite the large excess of acetylene present, yet in the presence of triphenylphosphine should yield almost exclusively benzene. It must be concluded that the formation of cyclooctatetraene in *Reppe*'s synthesis does not involve cyclobutadiene as an intermediate.

## IX. The Formation of Cyclooctatetraene on Ni(0) Complexes

Bis(acrylonitrile)nickel(0) is a coordinately unsaturated π-complex, and reacts with acetylene to form heptatriene nitrile, benzene, and cyclooctatetraene [3,4] (Scheme 6).

However, the yields are only approximately stoichiometric. On reaction with acetylene, the complexes of the 1,1-dicyano- and 1,1,2-tricyanoethylene derivatives – which have meanwhile been isolated – [32] also give small quantities of benzene and cyclooctatetraene. In these complexes, the catalytically active particle is the zerovalent nickel atom, which rapidly loses its activity [4,33] because it is difficultly resolvated by acetylene.

Scheme 6. Reactions of bis(acrylonitrile)nickel(0).

Electron donors such as triphenylphosphine stabilize atomic nickel [4,33] and thereby catalyse the formation of both heptatriene nitrile and benzene [4]. The yield of benzene can be considerably increased in this way, but the formation of cyclooctatetraene is completely suppressed. Trialkylphosphines also inhibit the formation of benzene on Ni(0) catalysts, since with the latter they form more stable complexes [34] than, for example, triphenylphosphine. Ni(0) complexes of the type $Ni(PX_3)_4$ (where X = Cl or F) cyclize acetylenemonocarboxylic esters mainly to benzene derivatives, but small quantities of 1,2,4,6- and 1,3,5,7-tetraalkoxycarbonylcyclooctatetraenes are also formed [35]. The yields of cyclooctatetraene and benzene in the reaction of acetylene with the Ni(0) complexes of unsaturated nitriles, dinitriles, and trinitriles were found to be independent of the polarity of the solvent. They remain practically the same in benzene, tetrahydrofuran, and dioxan [34]. It can therefore be concluded that in these reactions the catalytically active species is the unchanged nickel atom.

*The author is deeply indebted to Prof. W. Reppe for his valuable advice and discussions, and to the Badische Anilin- und Sodafabrik AG for the generous support of this work. On behalf of his colleagues and himself, he further wishes to thank Prof. E. Wiberg for the help given at the Münchner Institut. Thanks are also due to the Deutsche Forschungsgemeinschaft for financial support.*

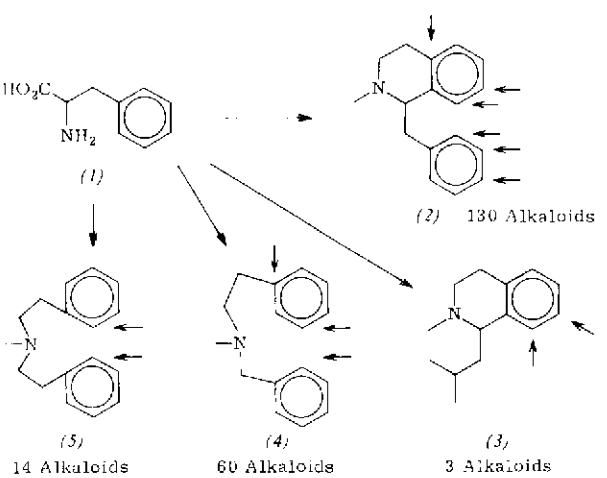
# Oxidative Condensation of Quaternary Phenolic Bases [*]

BY PROF. DR. B. FRANCK [**], DIPL.-CHEM. G. BLASCHKE, AND DIPL.-CHEM. G. SCHLINGLOFF

ORGANISCH-CHEMISCHES INSTITUT DER UNIVERSITÄT GÖTTINGEN AND
INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT KIEL (GERMANY)



*Dedicated to Prof Dr. H. Brockmann on the occasion of his 60th birthday*

*Provided they contain quaternary nitrogen, simple phenolic bases can undergo oxidative condensation under conditions similar to those of biogenesis to form alkaloids of the isoquinoline series with good yields. By means of such oxidative condensations, more than sixty alkaloids of various structural types have become more easily obtainable. Of the numerous possible condensations of the intermediate mesomeric radicals only those which lead to naturally occurring alkaloids give good yields and few by-products. The results suggest that oxidative condensations of quaternary bases are also involved in the biosynthesis of alkaloids in the plant cell.*

## I. Introduction

The structures of some 1700 naturally occurring alkaloids are known at present. More than 200 of these can be formed in plant cells by oxidative condensation of simple phenolic bases, which are derived from the amino acid phenylalanine [1,2,4–8]. No simple syntheses have yet been devised for these alkaloids, which include morphine and the tube curare poisons [3]. Despite their methodical ingenuity, the multistep syntheses described up to now seem unsatisfactory when compared to the paths used by nature. This problem has intrigued many workers, and numerous attempts have been made to imitate the biosynthesis and to form the alkaloids via oxidative condensation of simple precursors such as tertiary [9–13], secondary [14], or *N*-acylated [15] bases. In all of these attempts, the condensation either failed to give the desired products or the yields were lower than one percent.

In the course of systematic studies of the alkyl- and benzyltetrahydroisoquinoline alkaloid series, we have discovered a method for carrying out these long-sought biogenetic-type alkaloid syntheses, which is of interest both for preparative reasons as well as for an understanding of the fundamental processes involved in alkaloid biosynthesis.

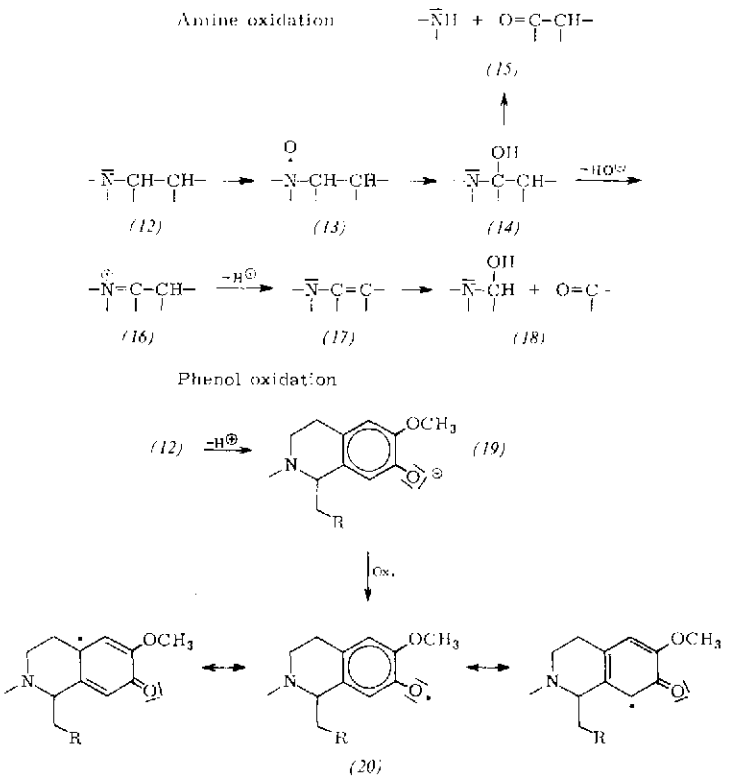
Before describing this work, let us consider in a simplified, schematic way the role of oxidative condensation in the biosynthesis of alkaloids. These biogenetic relationships have been described in greater detail in some excellent reviews [2, 4, 7]. Scheme 1 shows the precursors of the benzyltetrahydroisoquinoline alkaloids *(2)*, the cactus alkaloids of the lophocerine type *(3)*, the *Amaryllidaceae* alkaloids *(4)*, and the *Erythrina* alkaloids *(5)*, all of which can be derived from phenylalanine *(1)* by condensation with an aldehyde. On oxidative condensation at the positions indicated by the arrows, these precursors yield the representatives of these classes of alkaloids so far known (the number of individual compounds of known constitution in each class is shown below the respective formulae).

As can be seen in Scheme 2, the possibilities for oxidative condensations are extremely versatile in the biosynthesis of the benzyltetrahydroisoquinoline alkaloids [1, 4, 6, 7]. These alkaloids are derived from the simple benzyltetrahydroisoquinoline skeleton *(2)* by formation of either additional



Scheme 2. Oxidative condensations which lead from benzyltetrahydroisoquinoline *(2)* to alkaloids. Bonds formed by oxidative condensations are denoted by heavy lines.

carbon-carbon bonds or new ether bridges as indicated in formulae *(6)* to *(11)* by heavy lines. The 80 monomeric condensation products of this class include alkaloids of the aporphine *(6)*, cularine *(7)*, morphine *(8)*, and cryptaustoline *(9)* types. The dimeric condensation products have more complex structures; more than 60 of these are known. In such structures the two benzyltetrahydroisoquinoline units are linked together by ether bridges either in a parallel [berbamine type *(10)*] or an antiparallel [tubocurarine type *(11)*] arrangement.

## 2. Oxidation Experiments

In the past, oxidative condensations have given unsatisfactory results chiefly because of side reactions at the nitrogen. Oxidizing agents which react with phenolic bases can cause either amine oxidation at the nitrogen

or phenol oxidation at the aromatic nucleus. The oxidation of secondary and tertiary amines *(12)* may lead, possibly via the *N*-oxides *(13)* [16, 17], to the α-hydroxylamines *(14)* [17], which can undergo cleavage to give *(15)* [11, 18], dehydration to form *(16)* or *(17)* [17, 19], or further oxidation with elimination of the C-1 substituents in the form of aldehydes to yield *(18)* [11]. On the other hand, phenols may be transformed via the phenolate anion *(19)* into mesomeric radicals *(20)*, which can condense with other radicals at the phenolic oxygen or at the *o*- or *p*-carbon atoms [4]. Many combinations are possible in the condensation, since each phenolic hydroxyl group may produce as many as four different radical positions in this manner.

Thus, to achieve a biogenetic-type alkaloid synthesis by oxidative condensation, it appeared necessary to suppress the amine oxidation and to promote the phenol oxidation. We attempted to solve this problem by:

1. varying the conditions of oxidation,
2. reducing the oxidizability of the nitrogen,
3. promoting and directing the condensation in the phenolic moiety, by varying the number and position of the free hydroxyl groups.

We investigated the behavior of more than twenty benzyltetrahydroisoquinolines in 25 oxidation systems, whereby the oxidizability of the precursor was varied in a systematic fashion. The best oxidizing agents proved to be manganese dioxide, potassium ferricyanide, and ferric chloride. The reaction mixtures, which were frequently dark and tarry, were

[18] *E. F. Curragh*, *H. B. Henbest*, and *A. Thomas*, J. chem. Soc. (London) *1960*, 3559.

[19] *N. J. Leonard* and *W. K. Musker*, J. Amer. chem. Soc. *82*, 5148 (1960).

resolved by means of paper and thin-layer chromatography. The analytical results showed that these oxidations actually proceed much better than had been expected on the basis of first impressions. If the oxidation conditions were chosen sufficiently mild, so that about 20 % of the starting material remained unchanged at the end of the reaction, the product consisted of only a few components, which could almost always be separated by simple means.

Initially we attempted to synthetize dimeric condensation products of the berbamine *(10)* or tubocurarine *(11)* types. Thus, coclaurine *(21)* and similar secondary bases were oxidized, since in these cases intramolecular condensation is unlikely because of the arrangement of the hydroxyl groups. These oxidations proceeded best when a fivefold quantity (by weight) of active manganese dioxide [20] was used in boiling chloroform [21]. Coclaurine *(21)* and 4′-*O*-methylcoclaurine *(22)* yielded compounds with intensely green fluorescence in addition to polymeric, poorly soluble products. They were purified by partition chromatography on cellulose powder impregnated with potassium dihydrogen phosphate using butanol/1 % formic acid as solvent. The compounds proved to be isoquinoline derivatives *(23)* of coclaurine, which had been formed by dehydrogenation.

*(21)*, R = H
*(22)*, R = $CH_3$

*(23)*

This same dehydrogenation also took place in other secondary tetrahydroisoquinolines under extremely mild conditions, even on standing in air. It therefore seemed impossible to avoid amine oxidation in the secondary bases. Tertiary amines [22] and *N*-acylated bases [15, 22] behaved similarly. Further systematic investigations showed, however, that phenolic bases may be condensed in a biogenetic-type alkaloid synthesis, provided the following conditions are observed [23]:

a) To prevent condensations or dehydrogenation at the nitrogen, the latter must be quaternary.

b) The oxidizing agent should be ferric chloride or potassium ferricyanide. The oxidation should be conducted in aqueous solution at 20 °C using at the most one equivalent of oxidizing agent for intermolecular, or two equivalents for intramolecular condensations.

c) The phenyl nuclei undergoing condensation must be derived from pyrocatechol or guaiacol. Monohydroxyphenyl residues do not condense under mild conditions resembling those of biosynthesis.

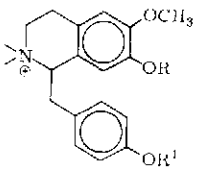
## 3. Dimeric Isoquinoline Ether Alkaloids



The quaternary coclaurine *(24)*, which occurs in various kinds of magnolia as magnocurarine, is accessible in large quantities by nine conventional synthetic steps, starting from vanillin. Its oxidation with potassium ferricyanide gave a crystalline dehydrogenation product, m.p. 225 °C [24]. We shall now proceed to consider various possibilities for its structure.

With its two free phenolic hydroxyl groups, magnocurarine can have seven potential radicals sites (shown by arrows), by which a total of 28 dimerization products can conceivably be formed. This number may be even higher if more than one new bond is created during the dimerization.

*(24)*

In order to establish how the two magnocurarine monomers are bonded to each other, the two magnocurarine derivatives *(25)* and *(26)*, which differ in the position of the non-methylated hydroxyl group, were oxidized under identical conditions. Only 4′-*O*-methylmagnocurarine *(25)* gave an oxidation product, armepavine

*(25)*, R = H, $R^1 = CH_3$
*(26)*, R = $CH_3$, $R^1$ = H

methiodide *(26)* remained unchanged. Therefore, oxidation occurs exclusively at the free hydroxyl group of the isoquinoline residue. Thus the oxidation products of *(24)* and *(25)* can contain only one bond between the isoquinoline residues and should both yield an identical pentamethyl ether. This was indeed the case.

What remained to be explained was whether the linkage between the two magnocurarine molecules is a carbon-carbon or an ether bond. If the latter were the case, then it would be possible to conceive of condensation products which would contain more than two benzyltetrahydroisoquinoline units per molecule. The well-established method of determining the structure of isoquinoline ether alkaloids by selective aryl ether cleavage of the permethylated alkaloids, using sodium or potassium in liquid ammonia [25–27], is applicable only to tertiary bases. The identification of the quater-

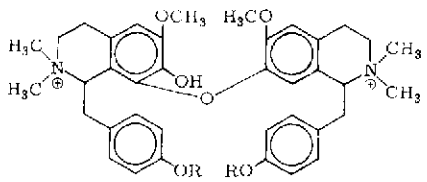
nary oxidation products described here and in later sections was accomplished more simply and reliably by proton resonance measurement in deutcrated sodium hydroxide solution. This method can be carried out rapidly with small quantities and without the need for model substances. Unlike degradation reactions [28], it permits reliable determination of the number of monomer units contained in an isoquinoline ether alkaloid. The nuclear magnetic resonance data, which by themselves are sufficient for the structural determination, were confirmed by methylation experiments and infrared spectra.

As shown in Table 1, the possible structures *(27)* to *(30)* for our dehydrogenation product can be distinguished by the number and intensity ratios of the $OCH_3$ signals

*(27)*



*(28)*, n = 0
*(29)*, n = 1
*(30)*, n = 2

Table 1. Identification of condensed benzyltetrahydroisoquinoline derivatives of the magnocurarine type by $OCH_3$ proton resonance, methylation, and the symmetrical diaryl ether C—O—C stretching frequency.

| Structure | δ-Values (ppm) and number of $OCH_3$ protons | | Methylatable OH groups/ N atoms | $^{\nu}$C—O—C (sym) at 1070 $cm^{-1}$ |
|---|---|---|---|---|
| | 5.52 | 5.66 | | |
| *(27)* | 6 | -- | 4/2 | — |
| *(28)* | 3 | 3 | 3/2 | + |
| *(29)* | 3 | 6 | 4/3 | + |
| *(30)* | 3 | 9 | 6/5 | + |

to be expected in the NMR spectrum, by the number of methylatable hydroxyl groups per nitrogen, and by a symmetrical diaryl ether vibration at 1070 $cm^{-1}$.

In the case of a C-C linkage *(27)*, four methylatable hydroxyl groups and only one signal in the NMR spectrum would be expected, since both $OCH_3$ groups would be in identical surroundings. The two $OCH_3$ groups of the dimeric isoquinoline ether *(28)* are no longer equivalent, and should be identifiable by two NMR signals of equal intensity at 5.52 ppm (at ring A) and 5.66 ppm (at ring A') [29]. In addition to this, only three methylatable hydroxyl groups would be present and the infrared spectrum should contain a C—O—C absorption band. The oxidation product of magnocurarine actually

*(31)*, R = H
*(32)*, R = $CH_3$

exhibits the properties just enumerated. Trimeric *(29)* and tetrameric *(30)* isoquinoline ethers may be excluded from consideration since they would exhibit different intensity ratios of the $OCH_3$ signals as well as a different number of methylatable hydroxyl groups.

Thus, the oxidation product of magnocurarine has structure *(31)*. The dehydrogenation product of 4'-*O*-methylmagnocurarine has the analogous structure *(32)*. In these compounds the two isoquinoline systems are linked by an ether bridge, as they are in berbamine and in seventeen naturally occurring alkaloids similar to berbamine. In addition, most of these alkaloids contain an ether bridge between the benzyl residues.

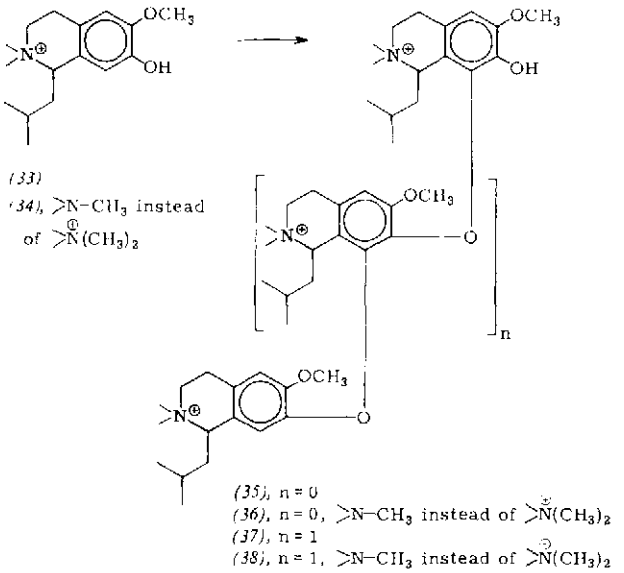
## 4. Pilocereine and Isopilocereine

The pillar cacti of the Arizona desert grow as tall as a house. Because of their giant size, they are among the natural wonders of the United States. *Djerassi* et al. [30–32] isolated the alkaloid pilocereine from *Lophocereus* species, which belong to the same cactus family, and tentatively ascribed to it the dimeric structure *(36)* [27].

*Djerassi* recently determined the structure of this new type of alkaloid. It has actually the trimeric structure *(38)*, and the dimeric formula *(36)* was then assigned to isopilocereine, a degradation product obtained by treatment of pilocereine with potassium in liquid ammonia. As far as the ether bond between the isoquinoline groups is concerned, pilocereine and isopilocereine correspond to the oxidation product *(31)* of magnocurarine. We therefore attempted to prepare the methiodides *(35)* and *(37)* of isopilocereine and of pilocereine by mild biogenetic-type oxidation of the monomer, quaternary lophocerine *(33)*. Since pilocereine *(38)* was isolated together with lophocereine *(34)* from *Lophocereus schottii*, it is highly probable that its biosynthesis proceeds from a lophocereine-like compound via this oxidation route [32].

When lophocerine *(33)* was oxidized in the form of its methiodide in the same fashion as magnocurarine *(24)*

[28] *C. Djerassi, H. W. Brewer, C. Clarke,* and *L. J. Durham,* J. Amer. chem. Soc. *84*, 3210 (1962).



[29] The assignment of the $OCH_3$ signals in the NMR spectrum agrees with the findings of *I. R. C. Bick,* J. *Harley-Mason, N. Sheppard,* and *M. J. Vernengo,* J. chem. Soc. (London) *1961*, 1896.

[30] *C. Djerassi, C. R. Smith, S. P. Marfey, R. N. McDonald, A. J. Lemin, S. K. Figdor,* and *H. Estrada,* J. Amer. chem. Soc. *76*, 3215 (1954).

[31] *C. Djerassi, N. Frick,* and *L. E. Geller,* J. Amer. chem. Soc. *75*, 3632 (1953).

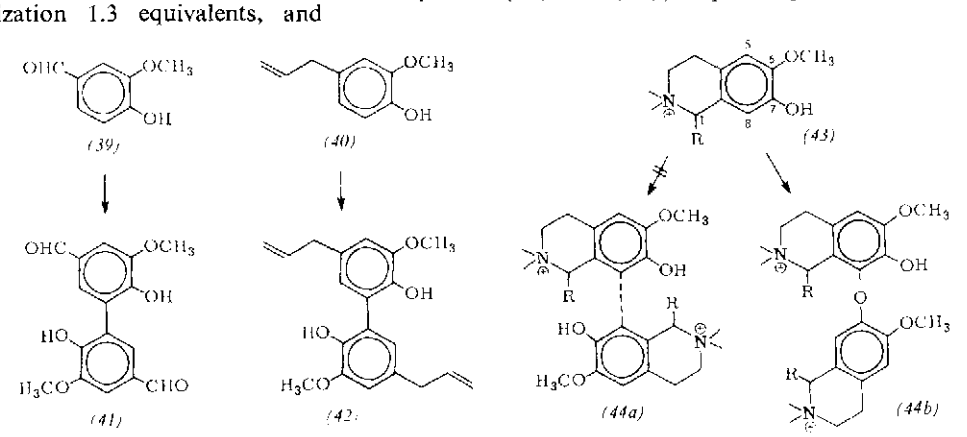
[32] *C. Djerassi, T. Nakano,* and *J. M. Bobbitt,* Tetrahedron *2*, 58 (1958).

with one mole of potassium ferricyanide at 20 °C in dilute sodium carbonate, a 45 % yield of a product was obtained which must have arisen by oxidative dimerization through a carbon-carbon or an ether linkage.

*(33)*
*(34)*, $>N-CH_3$ instead of $>\overset{\oplus}{N}(CH_3)_2$

*(35)*, n = 0
*(36)*, n = 0, $>N-CH_3$ instead of $>\overset{\oplus}{N}(CH_3)_2$
*(37)*, n = 1
*(38)*, n = 1, $>N-CH_3$ instead of $>\overset{\oplus}{N}(CH_3)_2$

In contrast with the starting material, it does not form an azo dye with diazotized sulfanilic acid and hence cannot have a free phenolic hydroxyl group together with unoccupied *o*- or *p*-positions. Just as in the determination of the structure of the magnocurarine dehydrogenation product, the NMR spectrum in deuterated sodium hydroxide was again helpful. This spectrum indicates three isolated aromatic protons and two non-equivalent methoxy groups. This, the results of elemental analysis, and the ultraviolet and infrared spectra show that only the dimeric structure *(35)* is acceptable. The structure of the compound was, therefore, confirmed by comparison with isopilocereine methiodide [33] from naturally occurring pilocereine [34].



Oxidative dimerization of phenolic compounds requires one equivalent, trimerization 1.3 equivalents, and oxidative polymerization two equivalents of oxidizing agent per molecule of phenol. Hence at least 1.3 moles of potassium ferricyanide must be used in order to trimerize lophocerine methiodide *(33)* to pilocereine methiodide *(37)*. When analysed by thin-layer chromatography, the product obtained on oxidation of lophocerine methiodide with two moles of potassium ferricyanide contained isopilocereine methiodide plus a slower moving fraction in a ratio of 2:3. The latter fraction was in fact identical with pilocereine methiodide *(37)* [33].

These oxidations yielded almost no polymeric products. There are kinetic reasons for this. The dimer *(35)* and the trimer *(37)* cannot generate any condensable carbon radicals on further oxidation and consequently cannot condense with themselves. Thus, they can only condense with any monomer *(33)* that is still available, forming ether bridges. Polymerization could only occur as a series of single steps, and for this reason, as well as on steric grounds, it practically does not take place because the monomers condense much faster with themselves.

These biogenetic-type syntheses of quaternary isopilocereine and pilocereine from lophocerine methiodide [34] show that the actual plant-cell synthesis of these alkaloids could proceed via this route. In an independent study, *Bobbitt* et al. [35] were able to prepare isopilocereine *(36)* and pilocereine *(38)* by oxidation of the tertiary compound lophocerine *(34)*. *Tomita* [36] recently described a multistep synthesis of *O*-methylisopilocereine, which does not resemble that occurring in nature.

## 5. Specificity of the Isoquinoline Ether Formation

In view of current concepts of phenol oxidations [4, 37], it is surprising that the intermolecular condensation of the quaternary coclaurine and lophocerine derivatives *(43)* proceeds exclusively via C–O linkage and thus leads to naturally occurring alkaloids. One would rather expect a C–C condensation to form the biphenyl derivative *(44a)*, just as in the oxidation of other guaiacol derivatives. For example, vanillin *(39)* [38] and eugenol *(40)* [39] are dehydrogenated to give the C–C dimeric compounds *(41)* and *(42)*, respectively. The unusual

*(39)* *(40)* *(43)*
*(41)* *(42)* *(44a)* *(44b)*

[33] We are extremely grateful to Prof. Dr. *C. Djerassi*, Stanford, for the samples of isopilocereine and pilocereine.

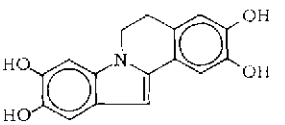
[36] *M. Tomita*, *T. Kikuchi*, and *K. Bessho*, Tetrahedron Letters *1962*, 127.

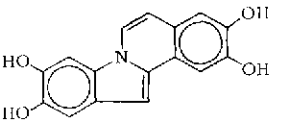
[37] *H. Erdtman* and *C. A. Wachtmeister* in: Festschrift A. Stoll. Birkhäuser, Basel 1957, p. 144.

[38] *J. M. Gulland* and *G. U. Hopton*, J. chem. Soc. (London) *1932*, 439.



[39] *H. Erdtman*, Biochem. Z. 258, 172 (1933).

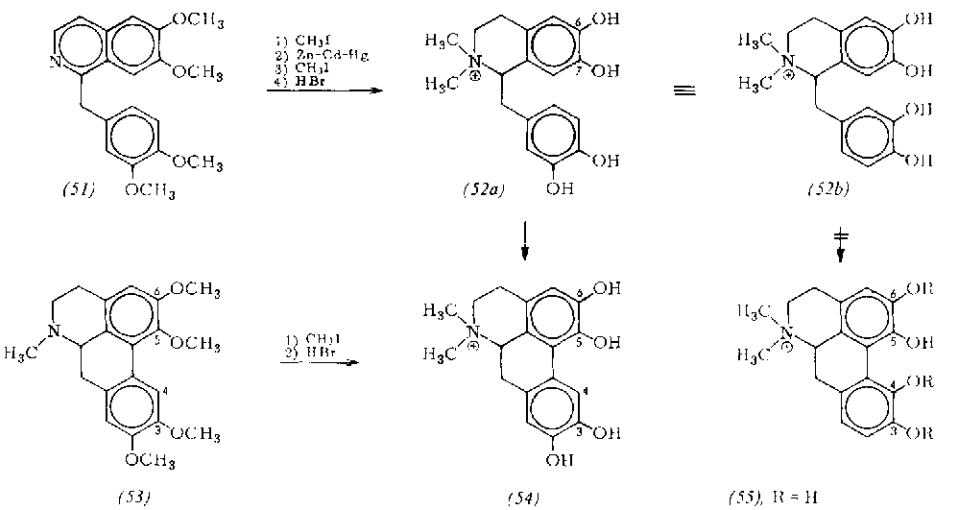
formation of diphenyl ethers *(44b)* on dehydrogenation of the quaternary tetrahydroisoquinoline *(43)* has steric causes. The carbon radical at C-8 of the isoquinoline moiety, which is produced in the oxidation, is sterically hindered by substituents at C-1 and C-7. It can apparently condense with a second isoquinoline residue *(44b)* only if the latter is held at a distance by an interposed oxygen atom. It is perhaps for this reason that in all of the 64 bisalkyl- and bisbenzyltetrahydroisoquinoline alkaloids identified so far, the isoquinoline residues are linked via ether bridges.



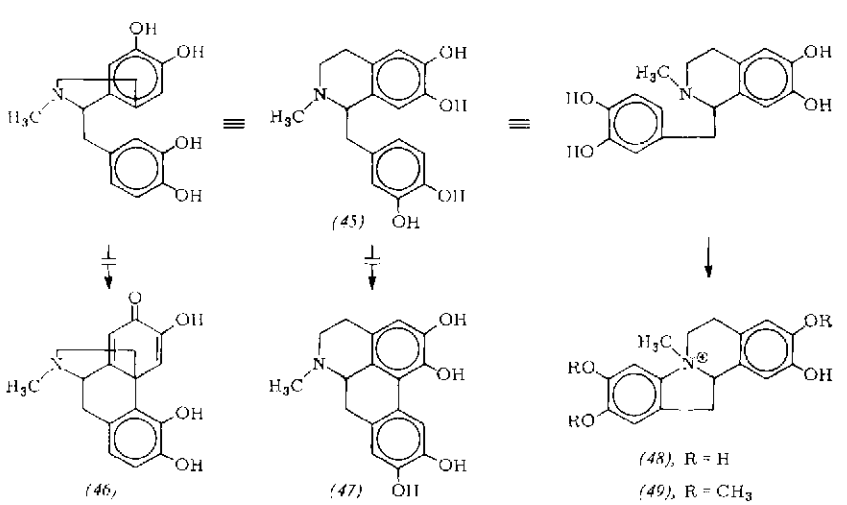
## 6. Synthesis of an Aporphine

In 1932, *Schöpf* and *Thierfelder* [9] and independently, *Robinson* and *Sugasawa* [10] attempted to condense laudanosoline *(45)* oxidatively to form morphine *(46)* and aporphine derivatives *(47)*. However, instead of the desired C–C linkage, they obtained the dibenzotetrahydropyrrocoline derivative *(48)*, formed by nucleophilic addition of the nitrogen onto the *o*-quinone grouping in the benzyl moiety of *(45)*, which occurs as an intermediate stage. Twenty years later, the alkaloid cryptaustoline *(49)*, which also has the structure of *(48)*, was isolated from the Australian *Lauraceae* species *Cryptocarya bowiei* [40], thus proving that the C–N condensation of laudanosoline also plays a role in alkaloid biosynthesis.

On oxidation, the secondary norlaudanosoline [*(45)*, >NH in place of >N–$CH_3$] behaved similarly to laudanosoline, in that it was dehydrogenated to tetrahydroxydibenzodihydropyrrocoline *(50a)*. This was rapidly oxidized further by atmospheric oxygen to form violet dibenzopyrrocoline *(50b)* [41].



*(50a)*



*(50b)*

By using quaternary laudanosoline undesirable C–N condensation should be inhibited. To test this idea, laudanosoline methiodide *(52)* was prepared in four simple steps from papaverine *(51)* and treated in aqueous solution at 20 °C with the calculated amount of ferric chloride in order to remove two electrons. After

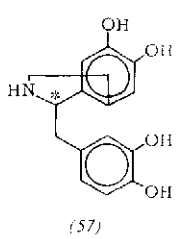
*(51)* *(52a)* *(52b)* *(53)* *(54)*

*(55)*, R = H
*(56)*, R = $CH_3$; >N–$CH_3$ instead of $\overset{\oplus}{N}(CH_3)_2$

*(46)* *(47)* *(45)* *(48)*, R = H *(49)*, R = $CH_3$

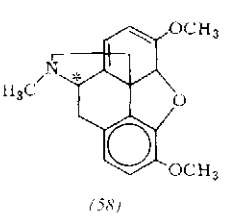
[40] *J. Ewing, G. K. Hughes, E. Ritchie*, and *W. C. Taylor*, Nature (London) *169*, 618 (1952); Austral. J. Chem. *6*, 78 (1953).

[41] *J. Harley-Mason*, J. chem. Soc. (London) *1953*, 1465.



20 hours the solution was evaporated and the dehydrogenated product crystallized out in a yield of 62 %. Judging from the characteristic ultraviolet spectrum of this compound, the long-sought aporphine condensation had occurred [42].

However, the formation of two aporphines, *viz. (54)* and *(55)*, was possible. These differ in the position of the hydroxyl groups on the benzyl moiety and correspond, respectively, to the naturally occurring alkaloids glaucine *(53)* and corydine *(56)*. The two alkaloids are readily distinguishable by their ultraviolet spectra, since the biphenyl system of corydine *(56)* is more strongly twisted by the substituents at the 4- und 5-positions than that of glaucine *(53)*, where C-4 is unsubstituted. The central absorption band of corydine, at 268–270 mμ, is thus some 14 mμ lower than that of glaucine, which lies at 282 mμ [43].

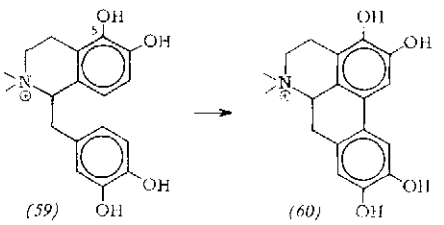


The ultraviolet spectrum and all the other properties of the dehydrogenation product obtained from laudanosoline methiodide were identical with those of the quaternary *O*-demethyl base *(54)* of glaucine *(53)*, which was prepared by a Pschorr phenanthrene synthesis according to the method of *Gadamer* [44] and has therefore the structure *(54)*. Accordingly, the oxidative condensation of quaternized laudanosoline proceeds preferably from the sterically less hindered conformation *(52a)*. In the non-biogenetic type method of glaucine synthesis, the yield of the Pschorr phenanthrene ring closure is much lower, being only 15 %.

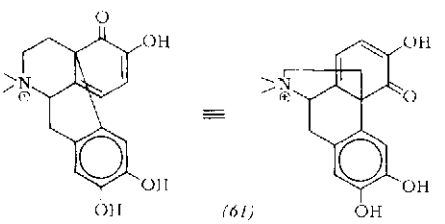
## 7. The Oxidative Ring Closure of Morphinane

For methodological and biosynthetic reasons, it would be of great interest to see whether morphine alkaloids could also be prepared by oxidative condensation. In this case, the oxidation of a laudanosoline derivative *(52)* would have to lead to a condensation at the *p*-position of the isoquinoline moiety (relative to the activating hydroxyl group at C-7) rather than at the *o*-position. Such a ring closure appears to be possible in the plant cell, since *Battersby* [7,45] found that [1-$^{14}$C]-norlaudanosoline *(57)* is successively transformed into

*(57)*



*(58)*



thebaine *(58)*, codeine, and morphine in the poppy (*Papaver somniferum*) and the position of the labelled carbon atom is in agreement with the assumption of an oxidative condensation.

For this reason, we investigated the oxidation of two laudanosoline derivatives, *(59)* and *(62)*, with ferric chloride, in which altered positions of the hydroxy groups would be expected to favor a morphinane ring closure [46]. Both compounds are conceivable biogenetic precursors.

Compound *(59)* has a hydroxyl group at C-5, *i.e.* in *o*-position to the carbon atom at which the morphinane ring closure should occur. Its dehydrogenation could lead either to an aporphine *(60)* or to a morphinane derivative *(61)*. In fact, a crystalline monomeric oxidation product was formed, which proved to be the aporphine *(60)* [47]. Since no further dehydrogenation products were obtained, morphinane ring closure could not have taken place.

*(59)* *(60)*

*(61)*

The second laudanosoline derivative *(62)* has an additional hydroxyl group at C-8. Here, the apparently easy condensation to aporphine should not be possible, so that either a cularine alkaloid *(63)* or a morphinane derivative *(64)* should be formed. Compound *(62)* was prepared for the first time in large quantity from trimethoxybenzaldehyde via mescaline [47]. Its oxidation with ferric chloride again gave a crystalline dehydrogenation product, which was, surprisingly, neither a cularine nor a morphinane derivative. Instead, it was identical with the aporphine alkaloid *(54)* obtained by oxidation of laudanosoline methiodide *(52)* [47]; elimination of the 8-hydroxyl group of *(62)* must therefore have occurred.

It is possible that condensation to give the morphinane derivative *(64)* does in fact occur as a first step in the oxidation of *(62)*. The resulting dienone could then rearrange in the acidic oxidation medium, aromatize, and lose a hydroxyl cation to form the aporphine derivative *(54)*. This is analogous to the morphine/apomorphine rearrangement. Since a hydroxyl cation is finally eliminated, the overall reaction effected by ferric chloride is not an oxidation, but merely a condensation with elimination of water. Those aporphines *(54)* and *(60)* formed from the laudanosoline derivatives *(52)* and *(59)* could also have arisen by rearrangement of an initially produced morphinane derivative, *e.g. (61)*, just as in the oxidation of *(62)*. Further experiments are needed to

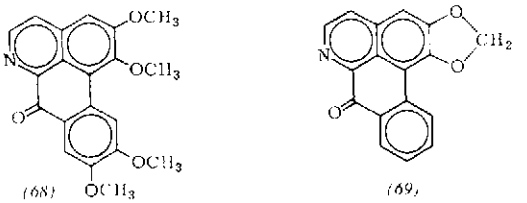
show whether the dienone system of such a morphinane can be obtained by especially careful isolation or stabilization through reduction of its carbonyl group.

(54) (62) (63) (64)

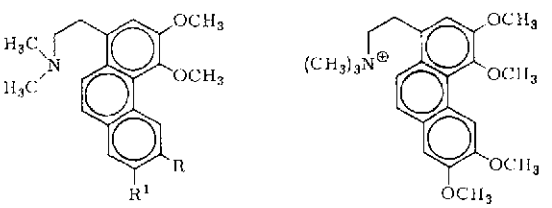
## 8. Biosynthesis of the Aporphine Alkaloids



The biogenetic-type aporphine syntheses described here permit the assumption that aporphine alkaloids can arise in the plant cell by oxidative condensation of quaternary benzyltetrahydroisoquinolines. This assumption is impressively confirmed by the occurrence in nature of definite classes of alkaloids:

(65) (66), R = H, $R^1$ = OH
(67), R = OH, $R^1$ = H

1. The alkaloids coclanoline *(65)* [48], laurifoline *(66)* [49], and magnoflorine *(67)* [50] have been isolated from *Cocculus laurifolius*. Of these, the aporphines *(66)* and *(67)* are quaternary, conforming to the requirements for their formation by oxidative condensation. Furthermore, their structures correspond exactly to the two possible modes of condensation of coclanoline. Holewort (*Corydalis cava*) also contains both of these condensation species in the form of glaucine *(53)* and corydine *(56)*.



2. If aporphines do arise by oxidative condensation, products of further oxidation should also occasionally occur in plants. This is the case in the magnolia tree (*Liriodendron tulipifera* L.) which occurs abundantly in the Eastern USA. The decorative yellow color of its wood is caused by two colored alkaloids *(68)* and *(69)*, whose structure has recently been elucidated by *Taylor*

(68) (69)

[51]. These alkaloids are oxidized aporphine derivatives *(68)* one of which could be formed from the major alkaloid glaucine *(53)* which is also present in the magnolia tree. If the nitrogen atom of the aporphine derivative that is initially formed in *L. tulipifera* were quaternary, this oxidation would not occur, as the experiments described above showed. Thus, the wood would be colorless.

3. Quaternary aporphines readily undergo Hofmann elimination, since the double bond formed is fitted into a stable phenanthrene system. Thus, for example, de-*O*-methylglaucine methiodide *(54)* is transformed under mild, weakly alkaline methylation conditions into the phenanthrene derivative *(72)* [42]. If aporphines

(70), R = $R^1$ = H
(71), R, $R^1$ = –O–$CH_2$–O–
(72)

arise in quaternary form during biosynthesis, the occurrence of such Hofmann elimination products in plants should be expected. Such alkaloids, *e.g. (71)*, have indeed been found in *Thalictrum thunbergii* [52] together with quaternary aporphines, *e.g. (67)* [53], and benzyltetrahydriosoquinolines [54]. They were also found in *Cryptocarya angulata (70)* [55].

## 9. Conclusion

The studies described here show that simple tetrahydroisoquinoline precursors need only be quaternized for the long-sought biogenetic-type oxidative condensations to alkaloids to be carried out. Up to now, this surprisingly smooth condensation has made it possible to execute simple syntheses of six skeletal types in the isoquinoline alkaloid family, thus making more than sixty alkaloids more readily accessible. Sir *Robert Robinson*, to whom the modern chemistry of natural products is indebted for many stimulating predictions, indicated this possibility thirty years ago [10]. If the phenolic hydroxyl

groups are located at the correct positions and are activated by *o*-hydroxy or *o*-methoxy groups, the desired alkaloids are formed in good yield and with hardly any by-products.

The greater the complexity of the natural products which can be isolated and structurally identified by modern techniques, the more important does it become to learn to synthetize them as simply and as rapidly as in the cell. The photosynthesis experiments of *Calvin* [56] have shown that starting from $CO_2$, algae can perform a total synthesis of complicated natural products within ten seconds. Only by imitating such synthetic methods can the increasing demand for physiologically active biological products be met more efficiently than by the time-consuming extraction from the plant cell.

*We wish to offer our sincere thanks to the Fonds der Chemischen Industrie, the Deutsche Forschungsgemeinschaft, and to the Elberfeld Works, of Farbenfabriken Bayer for their generous support of this investigation.*

About 8000 publications have appeared in the 15 years following the isolation of crystalline vitamin $B_{12}$ by *Folkers* and coworkers [1] in the USA and by *E. L. Smith* and *Parker* [1a] in England (see reviews [1b–8]). This field has recently received new impetus because of partial chemical syntheses and the discovery and elucidation of the structures of coenzyme forms of the Vitamin $B_{12}$ group.

## A. Nomenclature [9, 10]

Vitamin $B_{12}$ contains a macro-ring with four nitrogen atoms. This macro-ring was named **corrin** *(1)*. Compounds containing this ring system are called **corrinoids**. All the corrinoids found so far in nature contain cobalt as the central atom. They also have acetic and

propionic acid groups in the same positions as type III porphyrins and are especially similar in this respect to uroporphyrin III *(2)*. However, ring C of the corrinoids has a methyl group instead of an acetic acid residue.

Cobyrinic acid *(3)* has six additional methyl groups –which are underlined in formula *(2a)* of the basic skeleton [*] – and six double bonds. All further compounds of this series can be named as derivatives of cobyrinic acid. Trivial names are used for the most important substances [formulae *(3)* to *(10)*]: When all the carboxyl groups except the one at position f in *(2a)* are amidated, the compound is called cobyric acid *(4)* [10] (Factor $V_{1a}$). In cobinic acid *(5)*, the carboxyl group at f is amidated with D$_g$-(–)-1-aminopropan-2-ol, while the other carboxyl groups are free. In cobinamide *(6)*, the f-carboxyl group is amidated with 1-aminopropan-2-ol and all the others are amidated with ammonia. In cobamide *(7)*, the hydroxyl group of cobinamide is esterified with 3'-phospho-D-ribofuranose [R = H in *(7)*]. However, corrinoids containing an *N*-glycosidylimidazole base whose second nitrogen atom is coordinated with the Co atom are also called cobamides; these cobamides may contain a benzimidazole, naphthimidazole, imidazole, or purine base. When the base is 5,6-dimethylbenzimidazole, the compound is called cobalamin *(8)*. Other ligands on the Co may be water or anions: *e.g.* in cyano-5,6-dimethylbenzimidazolylcobamide [cyanocobalamin *(8)*, L = $CN^{\ominus}$], hydroxo(aquo)adenylcobamide *(7)* [L = $HO^{\ominus}$ or $H_2O$, OR = adenine bound to N-7], diaquocobinamide, and monocyanomonoaquocobyric acid [10a].

*(3)*, R = R' = OH
*(4)*, R = $NH_2$, R' = OH
*(5)*, R = OH,

R' = –NH–$CH_2$–C(H)(–OH)–$CH_3$

*(6)*, R = $NH_2$,

R' = –NH–$CH_2$–C(H)(–OH)–$CH_3$

*(9)*, R = $NH_2$,

R' = NH–$CH_2$–C(H)($H_3C$)–O–P(OH)(=O)–OH

*(2a)*

*(7)*

*(8)*

The basis for characterization and classification of corrinoids is the presence (or absence) of a hetero base which is capable of coordination. When such a base is present, the corrinoids are said to be complete, in its absence, they are said to be incomplete [11]. The two groups have significantly different physicochemical properties [11].

The coenzyme forms of the corrinoids do not contain water or anion ligands, but instead have a 5'-deoxyadenosyl residue. Thus, the simplest designation for the vitamin $B_{12}$ coenzyme *(10)* is *Co*-(5'-β-deoxyadenosyl)-cobalamin.

*(10)*

[*] In this article, the designation [Co] will be used henceforth to indicate the ring system *(2a)*. In some cases with substituents, as in *(3)* to *(6)*, the meaning of [Co] is evident from the text.

## B. Natural Corrinoids and Their Biogenetic Relationships [12]

So far, no naturally occurring, cobalt-free corrinoids have been isolated. The corrin ring is apparently biosynthetized in the same manner as the porphyrin ring. Thus, the explanations for the "reverse" order of acetic and propionic acid residues on ring C of the porphyrins [13, 14] should also hold for the corrinoids. The

[10a] Designations such as benzimidazolyl- or adenylcobamide cyanide are considered unconventional, at least in German nomenclature, since the substitution involves an *N*-glycosidic linkage. Furthermore, it is customary to use the prefix (*e.g.* "cyano-" and not "cyanide") in the chemistry of inorganic complex ions functioning as ligands. See *H. Remy*, Angew. Chem. *71*, 515 (1959).

[11] *K. Bernhauer* and *W. Friedrich*, Angew. Chem. *66*, 776 (1954).

[12] *K. Bernhauer*, *O. Müller*, and *F. Wagner* in [6], p. 37.

[14] *J. H. Mathewson* and *A. H. Corwin*, J. Amer. chem. Soc. *83*, 135 (1961).

additional methyl groups of the corrinoids are introduced by direct C-methylation. However, it is not yet known at which point of the biosynthesis this happens. It is also unclear when rings A and D are interlinked, when the Co atom is introduced, and when the acetic acid group originally probably present at C-12 is decarboxylated [14a, b]. The first part of the biosynthesis of corrinoids can be considered complete with the formation of cobyrinic acid *(3)*, even though this compound has not yet been found in nature.

The carboxyl groups a to e and g in *(3)* are amidated stepwise, and the f-carboxyl group is connected to D-(−)-1-aminopropan-2-ol, which is produced by decarboxylation of L-threonine. The intermediates produced in these reactions are cobyric acid *(4)*, several partly amidated cobinic acids *(5)*, and incompletely amidated cobyric acids. Experiments *in vivo* and *in vitro* with *P. shermanii* seem to indicate that cobyrinic acid *(3)* and its monoamide are not natural intermediates [14c]. Complete amidation leads to cobinamide *(6)*, which is the most ubiquitous intermediate in the biosynthesis of cobamides.

Occasionally a nucleotide or a part of a nucleotide is connected with a partially amidated cobinic acid, as shown by the appearance of mono-, di-, and tricarboxylic acids of cobalamin in cultures of *Propionibacterium shermanii*. It is probable that the carboxyl group e is the last to be amidated.

Cobinamide *(6)* is not directly combined with nucleotides, *e.g.* with α-ribazole phosphate at the formation of vitamin $B_{12}$. However, α-ribazole [14d] is incorporated directly at its biosynthesis [15] and was also found in cultures of *P. shermanii* [16]. In *Nocardia rugosa*, both cobinamide phosphate *(9)* and cobinamide pyrophosphate-guanosine *(10a)* are used for the biosynthesis of cobamides. It cannot yet be decided whether the pyrophosphate is the immediate precursor of the cobamides. For example, in experiments comparing the effect of acetone powders of *P. shermanii* on *(6)*, *(9)*, or *(10a)*,

*(10a)*

with 5,6-dimethylbenzimidazole, α-ribazole, or α-ribazole phosphate added, the highest conversion was obtained with the combination of *(9)* and α-ribazole [17].

Another possibility is that the initial product is cobamide *(7)*, R = H, and that its synthesis is followed by attachment of a hetero-base to the Co atom, the final step being the combination of this base with the ribose moiety via a glycosidic linkage. Several findings support this pathway. A final decision as to the mechanism will be afforded by the use of labelled substrates, which are now accessible by chemical synthesis (see below). It is quite possible that the incorporation of the nucleotide moiety follows a different pathway in the benzimidazole and purine series; it may also depend on the type of microorganism used.

It is the bases of the nucleotide moiety which account for the great variety of the cobamides, as well as for their differing physicochemical and biological properties. The strength of the bond between the bases and the Co atom decreases from a high value in 5,6-dimethylbenzimidazole and linear naphthimidazole to intermediate values in other benzimidazoles and imidazoles and a low value in the purines, thus roughly paralleling the biological activity of the respective cobamides [4]. Which base can be incorporated depends on its structure and on the type of microorganism involved [18–20]. A plausible picture of the biogenesis of benzimidazole and naphthimidazole bases emerges when it is assumed that this biosynthesis proceeds analogously to the synthesis of the benzenoid ring in riboflavin [12]. It is remarkable that under anaerobic conditions, *P. shermanii* synthetizes almost solely cobinamide *(6)*. However, in the presence of small amounts of oxygen, the same organism synthetizes 5,6-dimethylbenzimidazole and thus cobalamin *(8)* [21]. The bases of the purine series probably originate as 9-β-nucleotides, which are then hydrolysed to the free bases so that these can be incorporated into the cobamide molecule by a 7-α-glycosidic linkage.

## C. Syntheses in the Vitamin $B_{12}$ Field [22]

Recent studies in this field were aimed at the synthesis of the macrocyclic corrin system and at partial syntheses of corrinoids. The object was to obtain intermediates of the biosynthesis of vitamin $B_{12}$, as well as compounds with new biological properties.

### I. The Corrin Ring

Several routes have been followed for the synthesis of corrin and its derivatives. *Todd* and coworkers [23, 24] studied the reactions of $\Delta^1$-pyrroline-1-oxides, which yield dipyrrolinylmethane derivatives by condensation with the activated methyl group of 2-methyl-$\Delta^1$-pyrroline-1-oxide. In the presence of strong bases, the $\Delta^1$-pyrroline-1-oxides dimerize to 2,2′-dipyrrolidinyl derivatives. So far no one has reported the combining of pairs of the dipyrrolinylmethane or the 2,2′-dipyrrolidinyl derivatives or the introduction of the six adjoining and three isolated asymmetric centers into the corrin system.

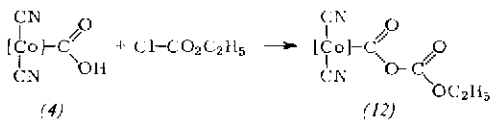
[23] For a review, see *A. W. Johnson* in [6], p. 1.

[24] *V. M. Clark*, Angew. Chem. *74*, 881 (1962).

*Johnson* and coworkers [23] synthetized pentadehydrocorrin derivatives. Even though macrocyclic compounds of structure *(11a)* were prepared from *(11)* in the presence of palladium or copper salts, these compounds



*(11)* *(11a)*

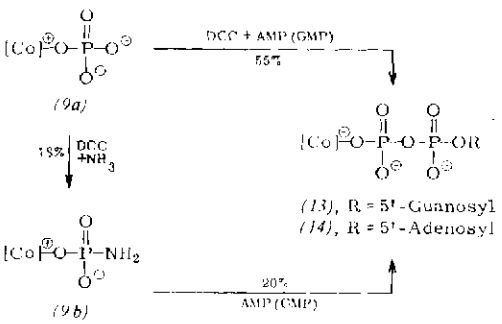
R = O, NH, N–$CH_3$, N–$NH_2$, S

contain an oxygen, nitrogen, or sulfur bridge between rings B and C. However, it was impossible as yet to introduce a methine bridge [24a]. The stereoselective synthesis of rings A and D of corrin is being attempted [24b].

## II. Partial Synthesis of Corrinoids

Almost all partial syntheses start with cobyric acid *(4)*. The latter was isolated from digested sewage sludge [25] and obtained in crystalline form [26]; it also appears as an intermediate in the biosynthesis of vitamin $B_{12}$ by *P. shermanii* [27] and a *N. rugosa* mutant [28]. For purely chemical syntheses [29], the carboxyl group of cobyric acid is activated by treatment with ethyl

*(4)* *(12)*



chloroformate in anhydrous dimethylformamide in the presence of triethylamine to give the mixed anhydride *(12)*, which is treated with a nucleophilic reagent without preliminary isolation. This procedure, well known in peptide chemistry, gives the best yields and is superior to the carbodiimide method [30].

### 1. *Incomplete Corrinoids*

Treatment of *(12)* with D-(−)-1-aminopropan-2-ol yields natural cobinamide [30]. This reaction also serves as a proof of the structure of cobyric acid *(4)*. Similarly, reactions of *(12)* with other alkanolamines yield a series of cobinamide analogues [31, 32], some of which are very strong competitive antagonists of cobinamide in *Escherichia coli* 113-3 (see below).

Reactions of *(12)* with α-amino-β-hydroxycarboxylic acids (*e.g.* serine or threonine) yield the corresponding cobinamide carboxylic acids [33]; with α-amino-β-hydroxycarboxylic acids with phosphorylated hydroxyl groups, the phosphoric esters are obtained [34]. These compounds are not metabolized by *P. shermanii* and therefore cannot be biosynthetic intermediates [34].

Cobinamide phosphate and *P*(1)-cobinamide-*P*(2)-guanosine-5′-pyrophosphate were isolated during the study of the biosynthesis of vitamin $B_{12}$ [35]. Synthesis of these compounds from cobyric acid *(4)* proved their structure. Thus DL-cobinamide phosphate *(9a)* [*] [36] was obtained in good yield by treatment of *(12)* with DL-1-amino-2-propyl phosphate, and was in turn converted into DL-cobinamide phosphoamide *(9b)* by treatment with ammonia and *N*,*N*′-dicyclohexylcarbodiimide (DCC) [37]. Both of these substances can be used for the synthesis of *P*(1)-DL-cobinamide-*P*(2)-guanosine-5′-pyrophosphate *(13)* and *P*(1)-DL-cobinamide-*P*(2)-adenosine-5′-pyrophosphate *(14)*. The reaction of DL-cobinamide phosphate with adenosine-5′-phosphate

*(9a)* *(9b)*

*(13)*, R = 5′-Guanosyl
*(14)*, R = 5′-Adenosyl

(AMP) or with guanosine-5′-phosphate (GMP) in the presence of DCC does – contrary to expectation [38, 39] – not yield symmetric DL-cobinamide pyrophosphate [37] since DL-cobinamide phosphate is dipolar and ionic. Recently, natural cobinamide *(6)* was phosphorylated directly by condensing it with β-cyanoethyl phosphate and DCC in anhydrous dimethylformamide/pyridine to yield β-cyanoethylcobinamide phosphate, which gave cobinamide phosphate *(9)* upon alkaline hydrolysis [40].

These methods permitted preparation of other phosphorylated cobinamide derivatives, including radioactively labelled preparations. These are valuable for elucidating the mode of biosynthesis of the nucleotide moiety of the complete cobamides.

### 2. *Complete Corrinoids*

*Friedrich* et al. [41] were the first to synthetize cobalamin *(8)*, starting from cobyric acid *(4)*: α-ribazole phosphate [(1-α-D-ribofuranosyl-5,6-dimethylbenzimidazolyl)-3′-dihydrogen phosphate] was converted into α-ribazole-2′,3′-cyclophosphate *(15)* by reaction with dicyclohexylcarbodiimide. Compound *(15)* was then

reated with a large excess of an alkanolamine (*e.g.* D-1-aminopropan-2-ol in the synthesis of cobalamin) in the presence of sodium butoxide. This gave a 70 % yield of a mixture of equal parts of the 3′- and 2′-nucleotide esters *(16a)* and *(16b)*. The next reaction, in which the mixture was treated with one mole of *(12)* in anhydrous dimethylformamide, was complete at 0 °C within a few seconds giving a 60–70 % yield of the complete corrinoid [43].

This same method [41] was used to prepare 5-methoxybenzimidazolylcobamide and 2-methyladenylcobamide [42]. The complete cobamides obtained by treatment of the 3′-(D-1-amino-2-propyl)nucleotide ester proved to be identical with the corresponding natural products. This is a further proof for the structure determined analytically.

The mixture of isomers *(16a)* and *(16b)* can be separated by chromatography on DEAE-cellulose or on paper. Alternatively, the mixture is treated with *(11)* and the 3′- and 2′-vitamin $B_{12}$ derivatives are separated by paper electrophoresis at pH 2.7 [43].

This synthetic pathway permits the preparation of numerous vitamin $B_{12}$ derivatives [43] in which the D-1-aminopropan-2-ol group of cobalamin is replaced by other alkanolamines (see below). These products, which are not found in nature, may help in the elucidation of the biochemical function of the D-1-aminopropan-2-ol group. Some of these compounds were shown to be exceptionally strong competitive antagonists of cobalamin (see below).

In addition to the purely synthetic 2′-isomer of cobalamin [41], the 5′-isomer of cobalamin was recently prepared [40] by condensation of cobinamide phosphate and 2′,3′-isopropylidene-α-ribazole with dicyclohexylcarbodiimide, followed by removal of the isopropylidene group. The 5′-isomer was also synthetized by condensation of α-ribazole-5′-phosphate with 1-(benzyloxycarbonylamino)-2-propanol in the presence of dicyclohexylcarbodiimide, hydrogenolytic cleavage of the carbobenzoxy group and reaction of the diester so obtained with *(12)* [43a]. Direct phosphorylation of cobalamin by the method described for cobinamide yields cobalamin-5′-phosphate [40].

## D. Coenzyme Forms of the Corrinoids

The commercial cyano form of cobalamin is an artefact. It is obtained by the action of cyanide ions on natural precursors of the vitamin during the isolation of the latter. Only the hydroxo (aquo) form can be isolated from natural substrates, provided cyanide ions are rigidly excluded. Because of its good depot properties, it is preferred over the cyano form [44–45], and it is in that form that vitamin $B_{12}$ is commonly used. However, the naturally occurring vitamin actually exists in the coenzyme form discovered several years ago.

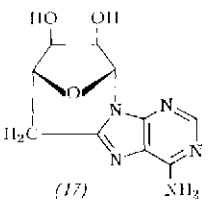
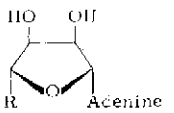
## I. Occurrence and Isolation of the Coenzymes [46]



The corrinoid coenzymes were discovered by *Barker* et al. [47] during a study of the enzymatic conversion of glutamic acid into β-methylaspartic acid. The enzyme is light-sensitive and is deactivated by daylight or by cyanide ions. The coenzyme forms of 5,6-dimethylbenzimidazolylcobamide, benzimidazolylcobamide, and adenylcobamide were the first to be isolated [47]. Later, coenzyme forms of cobinamide [48,49], cobinamide-pyrophosphate-guanosine [48], cobyric acid [50], and several biosynthetic cobamides [51,52] were isolated from microorganisms. Vitamin $B_{12}$ also exists in its coenzyme form *(10)* in the liver of humans, sheep, rabbits, and chickens [53].

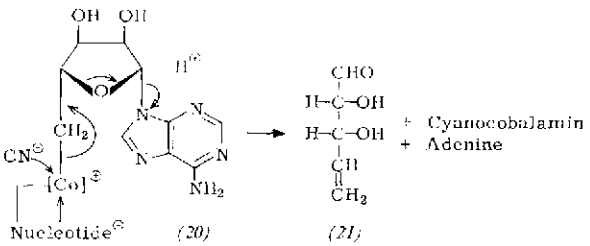
To isolate the coenzyme forms, bacteria are extracted with boiling 70–80 % ethanol or a neutral aqueous buffer [46], or with 60 % aqueous acetone at room temperature [54]. Acetone powders of bacteria are extracted with water [48]. After concentration, the solutions are extracted with mixtures of phenol and chloroform or *o*-dichlorobenzene (40:60 w/w). The organic phase is washed several times with water, treated with chloroform and n-butanol. The corrinoid coenzymes can then be extracted with water. Residual phenol is removed with chloroform. The aqueous solution is concentrated *in vacuo*, and usually contains mixtures of the coenzymes. These can be separated by column chromatography on cellulose, by paper electrophoresis, or by ion exchange [46, 54].



## II. Properties and Degradation of the Coenzymes

The extreme sensitivity to light of the isolated coenzymes and their peculiar cleavage by cyanide are their most remarkable properties. The coordinate bond between cobalt and the imidazole nitrogen is ruptured at pH $< 6$ if the hetero base is a purine and at pH $< 2.5$ if the coenzyme contains benzimidazole [46].

It is concluded from the valence of the cobalt in the cobalamin coenzyme (see below) and from the appearance of a reduced form of cobalamin ($B_{12r}$) after exposure to light in the absence of oxygen [55,56] that the ligand containing adenine is split off as a radical. In the absence of oxygen, the radical is stabilized by formation of the cyclic nucleoside *(17)* [57,57a]. In air, the 8,5′-cyclic adenosine is only partially formed; some of the radicals react with oxygen to form adenosine-5′-aldehyde *(18)* [58] or adenosine-5′-carboxylic acid *(19)* [59]. In air, vitamin $B_{12r}$ is oxidized within a few seconds to hydroxo (aquo) cobalamin. The corrinoid coenzymes are much more stable when bound to proteins than in their free form.



*(17)*

*(18)*, R = CHO
*(19)*, R = COOH

Cyanide converts the cobalamin coenzyme *(20)* [= *(10)*] into cyanocobalamin [46,59,59a] by splitting off adenine and *erythro*-3,4-dihydroxy-1-penten-5-al *(21)*. This reaction is not affected by atmospheric oxygen [55].

*(20)* *(21)*

The other corrinoid coenzymes are cleaved by light and cyanide in the same manner as the cobalamin coenzyme, but at considerably different rates [60].

The action of iodine on the cobalamin coenzyme in aqueous solution results in the formation of iodinecobalamin and 5′-iodo-5′-deoxyadenosine [54].

## III. Structure of the Coenzymes

The structure of the cobalamin coenzyme *(10)* was first elucidated by means of X-ray analysis [61] and was then confirmed by partial synthesis (see below).

In the cobalamin coenzyme, the 5′-deoxyadenosyl residue assumes the sixth coordination position, which is occupied by cyanide in vitamin $B_{12}$. It is connected to the Co atom by a covalent bond at C-5′. X-ray diffraction studies on the cobalamin coenzyme have shown that, like vitamin $B_{12}$, it contains $Co^{3+}$ [62]. This is in agreement with its electrophoretic behavior. The presence of $Co^{3+}$ is further indicated by the electron spin resonance spectrum of the cobalamin coenzyme [62a].

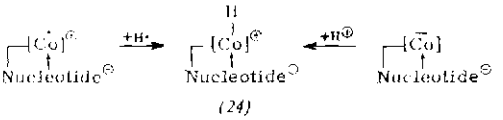
Thus, magnetochemical results which were obtained with aqueous solutions of the cobalamin and cobinamide coenzymes and which indicate $Co^{2+}$ [63–65] are probably due to other phenomena.

The cobinamide coenzyme contains a hydroxo (aquo) group instead of the nucleotide. The cobinamide coenzyme obtained by degradation of cobalamin coenzyme *(10)* with cerium(III) hydroxide [66] is identical with the natural product; this proves the position of the nucleoside.

At first it was not clear whether the corrin ring of the coenzyme forms had the usual six double bonds. The bond system and the number of hydrogen atoms in the corrin skeleton of the cobalamin coenzyme cannot be determined exactly by X-ray analysis [61]. The partial synthesis of the coenzyme forms involves reduction of the Co atom and thus, does not yield any definite conclusions about the structure of the corrin ring.

The synthesis of *Co*-methylcobalamin in water-containing tritium leads to a radioactive product [67] with tritium in the methyl group bound to the cobalt. This was shown [67a] by aerobic photolysis and trapping of the produced formaldehyde in the form of its adduct with dimedone. This results seems to indicate that the conjugated system of the corrin ring in the coenzyme form is identical with that of the cyano forms [67a].

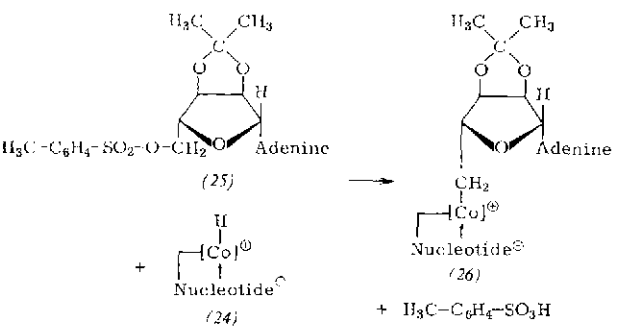
It was shown, however [67], that the coenzyme forms do not undergo the same reactions as cyano- or hydroxocobalamin do on account of activation of C-8 (CN double bond in the allylic position). Thus, in alkaline solution, cyanocobalamin *(8)*, L = CN, is dehydrogenated by atmospheric oxygen to the lactam *(22)* [68] while cobalamin coenzyme, cobalamin sulfonate or *Co*-methylcobalamin are not dehydrogenated under the same conditions. Equimolar



*(22)*, X = NH
*(23)*, X = O

quantities of chloramine-T or bromine water oxidize cyanocobalamin to the lactone *(23)*. Halogenation occurs only when chloramine-T or bromine water is present in excess. On the other hand, the coenzyme forms are not oxidized by one mole of chloramine-T, but are converted into a uniform monochloro derivative [67]. The first equivalent of bromine water or *N*-bromosuccinimide has an analogous effect [68a].

## IV. Partial Chemical Syntheses of Corrinoid Coenzymes and Their Analogues



When vitamin $B_{12}$ is reduced with zinc in $NH_4Cl$ [69], NaOH, or acetic acid solution, yellow $B_{12r}$ is initially formed, provided oxygen is rigorously excluded. After prolonged reaction times, the reduction proceeds further, yielding a light blue to green product. This product can also be obtained with other reducing agents, *e.g.* chromium(II) salts or sodium borohydride [70, 71]. Cobalamin reduced in this way reacts with diazomethane to yield *Co*-methylcobalamin and is thus a cobalt hydride *(24)* [60]. It is formed in the reaction of the $Co^{2+}$-complex with nascent hydrogen, or from the intermediate $Co^{I}$-complex by addition of a proton. The addition reactions of the reduced product also seem to indicate a cobalt-hydrogen bond.

*(24)*

Provided oxygen is absent, cobalamin hydride is stable in aqueous solution. In air, it is converted within a few seconds to hydroxo(aquo)cobalamin.

Hydrides of other corrinoids, such as benzimidazolylcobamide, adenylcobamide, and cobinamide, can be obtained in a similar manner. The reduction to the hydride causes the cobalt atoms of the corrinoids to become nucleophilic and thus to react with compounds having an electrophilic center.

*(25)* *(26)* *(24)*

The synthesis of the cobalamin coenzyme proceeds by reaction of cobalamin hydride *(24)* with 2′,3′-isopropylidene-5′-tosyladenosine *(25)* to yield *(26)*, followed by removal of the isopropylidene group with dilute acid [60, 72, 73, 73a]. Similarly, reaction of cobalamin hydride and 2′,3′-isopropylidene-5′-tosylinosine yields the hypoxanthine analogue [72, 74] of the cobalamin coenzyme. This analogue had been previously prepared by deamination of the cobalamin coenzyme [75]. The uridine [72] and guanosine [74] analogues of cobalamin coenzyme have also been obtained. It is noteworthy that synthetic cobinamide coenzyme is identical with the natural product. This implies that the hydrogen atom attached to the Co in the hydrides is always on the same side of the molecule.

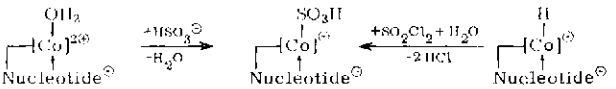
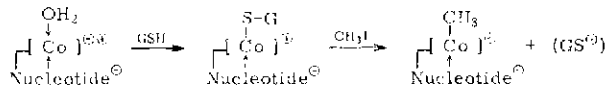
## V. Other Corrinoids with Cobalt-Carbon Bonds

Alkylated cobalamin compounds are obtained by treatment of cobalamin hydride with alkyl halides, dialkyl sulfates, or *p*-toluenesulfonic esters [60, 72–74]. At room temperature, the reactions are finished within a few minutes. Sulfonium compounds such as methylmethionine or *S*-adenosylmethionine can also be used to prepare *Co*-methylcobalamin [74, 75a]. In addition, acetylenic and olefinic compounds add onto cobalamin hydride. For example, reaction with acrylic acid yields *Co*-β-carboxyethylcobalamin [73a, 75b], while that with tetrahydrofuran yields *Co*-δ-hydroxybutylcobalamin [74]. As expected from their structures, the properties of the *Co*-alkylcorrinoids resemble those of the corrinoid coenzymes. In air, they are photolysed to the corresponding hydroxo(aquo)corrinoids. The ultraviolet absorption spectra of the *Co*-alkylcorrinoids are also very similar to those of the corresponding corrinoid coenzymes. However, in contrast to the coenzymes, the *Co*-alkylcorrinoids are not cleaved by cyanide.



The corrinoid hydrides also react with acylating agents such as acid anhydrides and acyl halides, producing acyl *Co*-derivatives. These are also sensitive to light and cyanide and, in addition, to alkali [60]. It is noteworthy that the ultraviolet spectrum of *Co*-ethoxycarbonylcobalamin, which is obtained by the reaction of cobalamin hydride with ethyl chloroformate, is much more similar to the ultraviolet spectrum of cyanocobalamin than to that of the coenzyme forms [74].

But even Cyano- or hydroxocorrinoids with $Co^{3+}$ as central atom can be directly converted into coenzyme-like derivatives, when compounds are used which are soluble in inert solvents and which can therefore be reacted with Grignard reagents or lithium alkyls. For example, treatment of heptaethyl cobyrinate with excess methylmagnesium iodide in tetrahydrofuran/ether and decomposition of the reaction product with diluted acetic acid yields a *Co*-methyl derivative of the corresponding tertiary alcohol [67a].



## VI. Corrinoids with Cobalt-Sulfur Bonds

The action of sulfite or sulfurous acid on cyano- or hydroxo(aquo)corrinoids yields substances which are very similar to the corrinoid coenzymes [76–80]. These are again light-sensitive, have similar ultraviolet spectra, and are converted by cyanide into cyanocorrinoids. The derivatives of cobalamin and cobinamide were obtained in crystalline form [76, 79, 79a]. These same products are also produced on treatment of cobalamin hydride or cobinamide hydride with sulfuryl chloride [79]. These reactions, as well as the appropriate infrared spectra, show that these corrinoids contain a cobalt-sulfur bond. Until the nomenclature of this new class of compounds is fixed, we will designate these substances respectively

as cobalamin *Co*-sulfonate and cobinamide *Co*-sulfonate. *Co*-*p*-Toluenesulfonyl- and *Co*-benzenesulfonylcobinamides were prepared in the same manner. However, these compounds are not light-sensitive [79].

Treatment of aquocobalamin with glutathione (GSH) yields *Co*-(*S*-glutathionyl)cobalamin as intermediate which reacts with electrophilic agents, *e.g.* with methyl iodide to give *Co*-methylcobalamin [67a].

## VII. Biosynthesis of the Corrinoid Coenzymes

All the corrinoids occurring in nature apparently exist in the coenzyme form. This form presumably arises soon after the synthesis of the corrin ring and the incorporation of the Co atom, perhaps at the stage of a pentacarboxylic acid *(3)*, which, just like other related polycarboxylic acids, can be converted enzymatically into its coenzyme form [81]. Further biogenesis to the complete cobamides probably takes place at the coenzyme level. Alternatively, it may involve forms having the essential characteristics of the coenzyme structure (see below).

The biosynthesis of the 5′-deoxyadenosyl moiety and its binding to the Co atom was studied mainly with enzymes obtained from microorganisms. These studies were first conducted with acetone powders [82–84], later with extracts of bacteria [85–89], and finally with

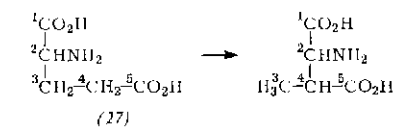
a purified enzyme preparation which had been enriched 337 times [90]. When this preparation is used, the synthesis of the coenzyme requires $Mn^{2+}$, $K^+$, reduced flavin-adenine dinucleotide and a sulfhydryl compound, in addition to a corrinoid and ATP. Studies with ATP labelled with radiocarbon show that this is the source of the 5′-deoxyadenosyl residue of the coenzyme [87–90]. However, the manner in which the 5′-deoxyadenosyl residue is transferred is unknown. The enzymatic conversion of cyanocobalamin into the cobalamin coenzyme is supposed to take place in one step [91]. However, by starting with cobinamide, it was possible to isolate a labile, light-sensitive, yellow, apparently reduced intermediate, with physicochemical properties reminiscent of reduced cobinamide. This product then yielded the cobinamide coenzyme in a second reaction step which took place in the presence of ATP and dihydroflavin mononucleotide ($FMNH_2$) [92,93].

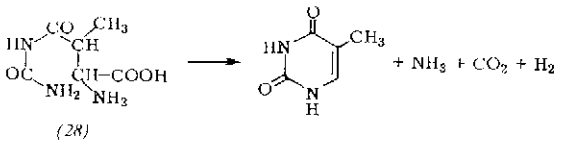


## E. Enzymatic Functions of Vitamin $B_{12}$

### I. Intramolecular Rearrangements in which Cobamide Coenzymes are Involved

The enzymatic reactions in which cobamide coenzymes participate are mainly intramolecular isomerizations.

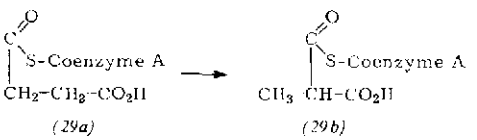
#### 1. *Conversion of Glutamate into Methylaspartate*



The study of this reaction in *Clostridium tetanomorphum* led to the discovery of the coenzyme forms of the cobamides [46]. The glutamate isomerase reaction can be conceived as an intramolecular reversible transfer of a glycine group from the β- to the α-carbon of the propionic acid moiety of glutamic acid *(27)*, with simultaneous shift of a hydrogen atom in the opposite direction

*(27)*

[46]. Only cobamide coenzymes are active in this reaction; the incomplete forms are inactive [94,94a].



In protozoa, the carbamyl derivative *(28)* of methylaspartate is a precursor of thymine, which may explain why vitamin $B_{12}$ is required for DNA synthesis [95]. However, this pathway of thymine biosynthesis does not apply to rats [96].

*(28)*

#### 2. *Conversion of Succinyl-CoA into Methylmalonyl-CoA*

This reaction is catalysed by methylmalonyl-coenzyme-A isomerase and involves transfer of the thioester group from the β- to the α-carbon of the propionic acid moiety of the molecule [*i.e. (29a)* → *(29b)*], as was shown with labelled substrates [97,98]. When purified isomerase

*(29a)* *(29b)*

was used, the reaction product did not take up tritium from labelled water [99]. For the reaction mechanism, see also [99a,b].

This reaction plays an important role in the biological utilization of propionic and other fatty and amino acids [100–102b]. It is noteworthy that in human megaloblastic anemia, ten to twenty times the normal amount of methylmalonate is excreted in the urine. Thus, accumulation of methylmalonate in the tissues could be the cause of the symptoms of pernicious anemia [103].

#### 3. *Conversion of 1,2-Diols into Deoxyaldehydes*

This intramolecular redox reaction was realized with cell-free extracts of *Aerobacter aerogenes* or *Clostridium perfringens* in the presence of some cobamide coenzymes; examples are: propane-1,2-diol → propionaldehyde and ethylene glycol → acetaldehyde [104,104a]. During this study, it was shown by experiments with heavy water that the rearrangement involves an intramolecular shift of hydrogen (as hydride ion) with simul-

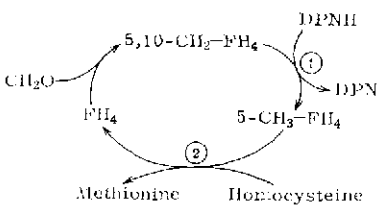
taneous displacement of an OH group [105]. Recently, acetaldol was suggested as an intermediate in the reation [106]. Extracts of lactobacillus convert glycerol to β-hydroxypropionaldehyde [106a, b].



### II. Degradation of Lysine to Fatty Acids and Ammonia

$$H_2N-(CH_2)_4-CH(NH_2)-CO_2H \rightarrow H_3C-(CH_2)_2-CO_2H + H_3C-CO_2H + 2NH_3$$

To accomplish this reaction, which is effected by *Clostridia*, cell preparations that have been aged or treated with activated charcoal require pyruvate, diphosphopyridine nucleotide, $Fe^{2+}$, acetyl coenzyme A, and cobalamin coenzyme [107, 107a].

### III. The Role of Vitamin $B_{12}$ in Methionine Synthesis

A cobalamin enzyme is involved, in addition to several other co-factors, in the transfer of a methyl group from *N*(5)-methyltetrahydrofolic acid to homocysteine [108 to 112a]. This process is part of a cycle which explains the close biochemical relationship known to exist between folic acid and vitamin $B_{12}$ (Scheme 1).

Scheme 1. The role of vitamin $B_{12}$ in the transfer of a methyl group in the synthesis of methionine.

(1) 5,10-methyleneetetrahydrofolate reductase
(2) $B_{12}$-enzyme, DPNH, $FADH_2$, ATP, $Mg^{2+}$

It is possible that this enzymatic system is a main metabolic function of vitamin $B_{12}$ in animal cells and perhaps even the key to various anemias, for in vitamin $B_{12}$ deficiency, the level of methyltetrahydrofolic acid in blood rises to a value several times above the normal. Thus the synthesis of many cell components (purines, pyrimidines) may be inhibited by blockage of the folic acid cycle [112].

In methionine synthesis, the active portion of the vitamin $B_{12}$ enzyme appears to be *Co*-methylcobalamin. If this is incubated with homocysteine and a purified apovitamin $B_{12}$ enzyme, methionine is synthetized and the methyl group bound to cobalt is utilized [113, 113a].

Methionine can also be synthetized nonenzymatically by anacrobic photolysis of *Co*-methylcobalamin in the presence of homocysteine. Under identical conditions, homocysteine is converted by the cobalamin coenzyme into *S*-adenosylhomocysteine [114]. These photolytic reactions can be explained by a free radical mechanism.

The activity of the coenzyme forms in the above enzyme systems explains only a part of the manifold and vital functions of vitamin $B_{12}$ [115]. Moreover, the vitamin also acts as a cofactor in the reduction of ribonucleosides to deoxyribonucleosides [116–118], in the incorporation of amino acids into protein [119, 120], and in carbohydrate and fat metabolism [121, 122].

### IV. Enzymatic Synthesis of Methane

In the presence of pyruvate, an enzyme system from *Methanosarcina barkeri* converts the methyl group of *Co*-methylcobalamin stoichiometrically to methane, as was shown with labelled substrates [122a]. The same reaction occurs with extracts of *Methanobacillus omeianskii* in the presence of ATP [122b].

## F. Molecular Biology of Vitamin $B_{12}$

The biochemical function of the various portions of the vitamin $B_{12}$ molecule was elucidated primarily – as for other vitamins – by demonstration of the biological activity of analogues which were prepared chemically. Analogues with antagonistic activity may be suitable for the treatment of leukemia or other malignant diseases (for reviews, see [123, 124]).

## I. The Cobalt Atom and the Corrin Ring

In contrast to the porphyrins, the metal atom in vitamin $B_{12}$ is held so tightly that it has not yet been possible to remove it without destroying the molecule. The Co atom participates in the resonance of the corrin ring system. When coordinated nucleotides are present, the Co atom is so deeply imbedded in the cobamide coenzymes that it cannot come into direct contact with substrate. Contact is probably made via a peripheral part of the molecule [46, 125].

The difference in reactivity of the two coordination positions of the Co atom in incomplete corrinoids gave the first insight into the significance of the corrin ring. Thus, X-ray analysis has shown that the cyano group in the monocyanomonochlorohexacarboxylic acid [126] or in monocyanomonoaquocobyric acid *(4)* [127] is coordinated at the same position as the nucleotide in cobalamin *(8)*. Furthermore, in dicyanocobinamide *(6)*, which has two CN groups as ligands, one CN group is bound tightly and the other loosely [77]. It is remarkable that the coenzyme form obtained by chemical synthesis from cobinamide is identical with the natural product and that no other isomer is obtained [74]. Parallel to this, *P. shermanii* converts synthetic *Co*-butylcobinamide into the same *Co*-butylcobalamin as can be synthetized directly from cobalamin [74]. Thus, hydride formation in cobinamide can take place only in the "upper" coordination position in the formulae shown here; this requirement must hold for both incomplete and complete corrinoids. It is possible that the not exact planarity of the corrin ring [126] or the *trans*-effect [128] is of importance in this connection.

## II. The 1-Aminopropan-2-ol Group

Surprisingly, the 1-aminopropan-2-ol group is of special molecular-biological significance, as was shown by experiments with many analogues containing a modified alkanolamine moiety [124]. The most important representatives are shown in Table 1. The stimulation of the growth of *E. coli* 113-3 by chemically and in part biochemically synthetized analogues is similar to that by cobalamin [130] and cobinamide [32], provided the C-1 of the 1-aminoethan-2-ol group carries no substituent (Table 1). If they are not too large, substituents on C-2 do not reduce growth stimulation significantly, compared with the natural products. However, substitution on C-1 results in strong competitive antagonism. This is also true for the coenzyme forms of cobinamide analogues

Table 1. Effect of cobalamin and cobinamide analogues on *E. coli* 113-3 (tube-test experiments).

| 1-Aminoethan-2-ol group with substituent on | | Effect on growth, compared to | | Inhibition Index [129] | |
|---|---|---|---|---|---|
| C-1 | C-2 | Cobalamin = 100 | Cobinamide = 100 | Cobalamin | Cobinamide |
| H | H | 83 | 71 | – | – |
| H | $CH_3$ (D) | 100 | 100 | – | – |
| H | $CH_3$ (L) | 60 | 80 | – | – |
| H | Phenyl (DL) | 0.01 | 0.01 | 17 | 32 |
| H | 2 $CH_3$ | 45 | 36 | – | – |
| $CH_3$ | $CH_3$ | 1 | 36 | – | – |
| $CH_3$ | H | 0.1 | 0.01 | 6 | 7 |

| 2 $CH_3$ | H | 0.1 | 0.01 | 3 | 3 |

[32] and of cobalamin analogues [130a]. Cobalamin antimetabolites also inhibit the growth of *Ochromonas malhamensis* and are antierythropoetic in decompensated pernicious anemia patients [130]. Cobinamide analogues which stimulate the growth of *E. coli* are converted into cobalamin analogues by *P. shermanii* in the presence of 5,6-dimethylbenzimidazole. This is not so with cobinamide antagonists [32].

## III. The Carboxamide Groups

The carboxyl groups in positions a–e and g [see formula *(2a)*] must be amidated for vitamin $B_{12}$ to be biochemically active; cobalamincarboxylic acids are inactive or antagonistic towards *E. coli* [123, 131]. The individual carboxamide groups are, however, of differing biochemical significance. The strongest antagonist to *E. coli* [123, 132] is the cobalaminmonocarboxylic acid which is the last intermediate in the biosynthetic amidation [81, 132] and is also the one which is the predominant product of mild acidic hydrolysis of cobalamin. Its carboxyl group in position e is presumed to be the one that is free [81]. Its inhibition index (see [129]) with *E. coli* is 40 [133]. The alkylamides of cobalamin which are synthetized by alkylamidation of the carboxylic acids are also antagonistic to *E. coli*. The most active representatives are the monomethylamide and the hydrazide of that monocarboxylic acid which is the main product of hydrolysis of cobalamin (inhibition index = 50) [123].

## IV. The Nucleotide Moiety

Only cobamide coenzymes which contain nucleotides apparently have biochemical activity *in vivo*; the incomplete forms are only intermediates of the biosynthesis. In biological systems in which the incomplete forms are active (*e.g.* in growth tests), they are converted beforehand into complete cobamide coenzymes.

[127] *D. C. Hodgkin*, personal communication.

[128] *J. V. Quagliano* and *L. Schubert*, Chem. Reviews *50*, 201 (1952).

[129] The inhibition index indicates the mole ratio of antagonist to cobalamin (or cobamide) which inhibits the growth stimulated by the latter to 50%.

[130] *H. C. Heinrich*, *W. Friedrich*, and *P. Riedel*, Biochem. Z. *334*, 284 (1961).

[130a] *W. Friedrich*, *H. C. Heinrich*, *E. Königk*, and *P. Schulze* in [7a].

[131] *E. L. Smith* in [3], p. 1.

[132] *K. Bernhauer*, *E. Becher*, *G. Gross*, and *G. Wilharm*, Biochem. Z. *332*, 562 (1960).

[133] *A. M. Kelemen*, *E. Czanyi*, and *A. Simon*, Acta physiol. Acad. Sci. hung. *21*, 177 (1962).

The nature of the base in the nucleotide portion is of minor importance in bacteria, but is very important in the protozoon *O. malhamensis* and in animals. Here, only cobamides of the benzimidazole and naphthimidazole series are active. Although many cobamide analogues containing various non-naturally occurring bases have been synthetized [4, 18, 19], it was impossible to obtain a cobalamin antagonist with a good inhibition index in this way. The 3′-phosphoric acid bond in the nucleotide permits the base to coordinate with the cobalt [see formula *(8)*], so that the molecule becomes "complete" – a fact which appears to be of biochemical importance. The 2′-analogues, in which the bond between Co and the imidazole ring is weakened, are biologically less active [124].

V. The 5′-Deoxyadenosyl Group of the Coenzyme Forms

The 5′-deoxyadenosyl group is necessary for the activity of the coenzyme forms in the enzyme systems mentioned above. Its replacement by other ligands, such as 5′-deoxyinosine, 5′-deoxyuridine, or alkyl groups, leads to loss of activity or to competitive antagonism [72, 100]. However, the presence of the 5′-deoxyadenosyl group is not necessary for the biosynthesis of the vitamin $B_{12}$ molecule, for *Co*-ethyl- and especially *Co*-butylcobinamide are converted into the *Co*-alkylcobalamines by *P. shermanii in vivo* if 5,6-dimethylbenzimidazole is present. Only afterwards they are converted into cobalamin coenzymes [74].

# New Methods of Preparative Organic Chemistry IV [*]

## Cyclization of Dialdehydes with Nitromethane [1]

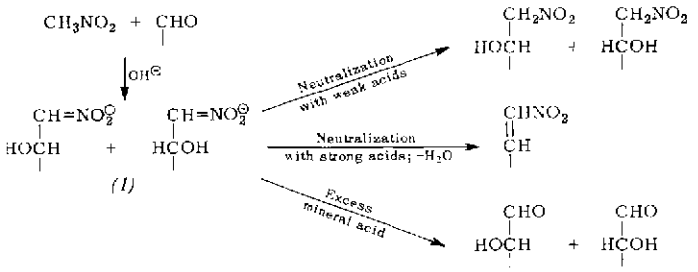
BY PRIV.-DOZ. DR. F. W. LICHTENTHALER

INSTITUT FÜR ORGANISCHE CHEMIE DER TECHNISCHEN HOCHSCHULE DARMSTADT (GERMANY)

*Dedicated in memoriam to Hermann O. L. Fischer, whose initiative started the developments in this field*

*Condensation of nitromethane with suitable dialdehydes in alkaline medium provides a general method of cyclization, in which the methyl group of the nitromethane is incorporated into the ring. This method leads to 5-, 6-, and 7-membered rings and is equally applicable to aliphatic, aromatic, and sugar dialdehydes. For example, glyoxal is converted into 1,4-dideoxy-1,4-dinitro-neo-inositol, and glutaraldehyde into trans-2-nitrocyclohexane-1,3-diol, while the corresponding cyclization of xylo-trihydroxyglutaraldehyde leads to deoxynitroinositols having the scyllo, myo-1, and muco-3 configurations. – In the case of aromatic dialdehydes, the cyclization is accompanied by elimination of water. Thus, phthalaldehyde, naphthalene-2,3-dicarboxaldehyde, and homophthalaldehyde yield, respectively, 2-nitroindenol, 2-nitrobenzindenol, and 2-nitronaphthalene. – Application of the method to sugar dialdehydes (aldehydic diglycol derivatives of monosaccharides formed by periodate oxidation) constitutes an excellent synthesis of 3-amino sugars, since 3-deoxy-3-nitropyranoses are formed smoothly on cyclization, and the corresponding 3-amino derivatives are obtained by hydrogenation. Thus, the reaction sequence: periodate oxidation → cyclization with nitromethane → hydrogenation, leads in the case of α- and β-D-pentosides to 3-amino-3-deoxy-D- and -L-pentosides, respectively, with ribo, xylo, and arabino configurations. α-D-Hexosides afford 3-amino-3-deoxy derivatives of glucose, mannose, and talose, while β-D-hexosides give derivatives with gluco, manno, and galacto configurations. 3-Amino-3,6-dideoxyglucosides of the D- and L-series are obtained from 6-deoxy-D- or -L-hexosides, respectively, and 3-aminohexosans with gulo, ido, and altro configurations are obtained from 1,6-anhydro sugars. Cyclization of the dialdehydes obtained from sedoheptulose and methyl 4,6-O-ethylidene-α-D-glucoside by periodate oxidation, leads to 3-nitro and, after hydrogenation, to 3-amino derivatives of 3-deoxyheptopyranoses.*

### Introduction



The base-catalysed condensation of an aldehyde with nitromethane, a reaction analogous to the aldol condensation, has been used for the synthesis of a variety of products since its discovery by *Henry* [2] in 1895. The primary products of the reaction are *aci*-nitro salts *(1)*. Neutralization of the latter with weak acids results in a

[*] The preceding papers of this series have been published in a revised and extended form in three volumes by Verlag Chemie GmbH., Weinheim/Bergstr. (Germany), and by Academic Press, New York and London.

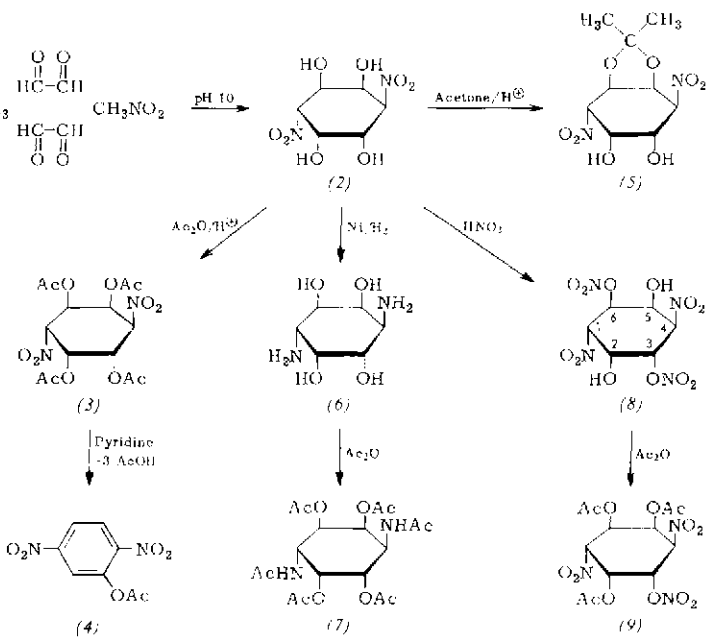
[1] Extended version of lectures given at the Department of Biochemistry, University of California, Berkeley (May, 1961), the Department of Agricultural Chemistry, University of Kyoto (July, 1961), the meeting of chemistry lecturers at Bonn (September, 1962), and at the Technische Hochschule, Darmstadt (November, 1961 and December, 1962).

[2] *L. Henry*, C. R. hebd. Séances Acad. Sci. *120*, 1265 (1895).

mixture of two epimeric nitro alcohols [3–5], while strong acids generally produce nitro olefins with elimination of water [4]. On treatment of the *aci*-nitro salts with excess mineral acid, the Nef reaction [6] occurs, resulting in a mixture of epimeric hydroxy aldehydes. This reaction has attained great importance, principally in sugar chemistry, where it has been used to synthetize aldoses [5,7,8], 2-deoxyaldoses [5], and aldosamines [5,9], which are otherwise difficultly accessible.

With suitable dialdehydes, a cyclizing nitromethane condensation can occur. This was first demonstrated in 1910 in the case of *o*-phthalaldehyde [10]. Condensation of this compound with nitromethane in the presence of alcoholic potassium hydroxide, followed by acidification, yields a 2-nitroindenol. In 1952, *McCasland* et al. [11] obtained a cyclic product from the reaction of glutaraldehyde with nitromethane, although in impure form and only 3 % yield. Stepwise cyclizations of dialdehydes

with nitromethane, starting with trihydroxy- or aminodihydroxyglutaraldehydes blocked at one aldehyde group, were described by *Grosheintz* and *Fischer* [12], and by *Wolfrom* et al. [13]. In these cases, condensation with nitromethane and subsequent release of the second aldehyde group produced mixtures of 6-nitrohexoses or 6-nitrohexosamines, respectively. Under the influence of alkali, the carbonyl and nitromethylene functions of these compounds cyclize intramolecularly to form nitroinositols [12] or nitroinosamines [13].



*Baer* and *Fischer* [14] postulated that direct combination of sugar dialdehydes with nitromethane should likewise lead to cyclization, and demonstrated this for the first time with the dialdehydes derived from methyl pentosides by periodate oxidation. Since then, this synthetic method has been extended to many dialdehydes – partly derived from sugars – and has resulted in the preparation of 2-nitro- and 2-amino-1,3-diols which are otherwise inaccessible.

This article presents a survey of the development and the scope and limitation of cyclizing condensations with nitromethane [*].

## I. Cyclization of Aliphatic Dialdehydes

### 1. Glyoxal

Condensation of nitromethane in aqueous sodium carbonate with glyoxal, whose tendency to form cyclic products is well known [15], led to cyclization and the formation of a mixture of isomeric 1,4-dideoxy-1,4-dinitroinositols. Because of its insolubility in water, one uniform isomer was isolated [16]; of the fourteen theoretically possible configurations (eight *meso* and six racemic forms), the *neo*-1,4-configuration *(2)* was assigned to this isomer [17].

The proof of the configuration of *(2)* is based on the following experiments:

1. *(2)* yielded a tetraacetate *(3)* on acid-catalysed acetylation; on treatment with pyridine, *(3)* aromatized to *O*-acetyl-2,5-dinitrophenol *(4)*, with elimination of three moles of acetic acid [17].

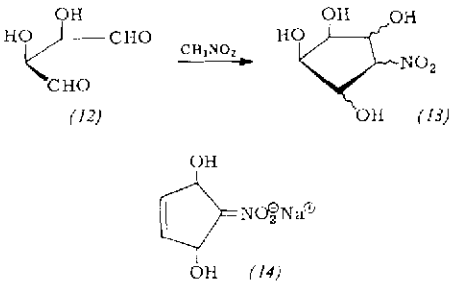
[16] The yield of *(2)* is 10 % if it is assumed that the 30 % aqueous glyoxal used contains only monomer, but is 72 % when based on the actual content of monomeric glyoxal in solution [17].

[17] *F. W. Lichtenthaler* and *H. O. L. Fischer*, J. Amer. chem. Soc. *83*, 2005 (1961).

2. Treatment of *(2)* with acetone yielded a mono-*O*-isopropylidene derivative, the ketal *(5)*. This establishes the presence of a *cis*-diol grouping at one side of the ring, but does not exclude a second such grouping at the other side, even though its presence cannot be proved by formation of a di-*O*-isopropylidene compound (the latter would require the compound to transform from its chair form to the thermodynamically unstable boat form with an axial nitro group [17]). The elimination of a nitrate ester group [18] on acetylation of the dinitrate *(8)* to give *(9)* may be similarly attributed to steric hindrance [19].

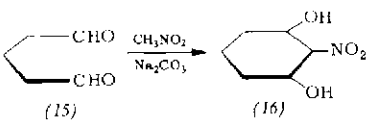
3. The NMR spectrum of the tetraacetate *(3)* [20] has two signals of equal intensity at 7.88 and 7.98 τ, which have to be ascribed to two axial and two equatorial acetoxy groups. The six ring hydrogens gave a 1:2:1 intensity triplet at 3.78 τ, indicating two equatorial hydrogen atoms flanked on both sides by axial hydrogen atoms, as well as four doublets of equal intensity in the region of 5.0–4.0 τ, which denote four axial ring protons. The data can be correlated only with the *neo*-1,4-configuration. Analogous results were obtained from the NMR spectrum of the hexaacetylinosadiamine *(7)* produced by hydrogenation of *(2)* to *(6)* and subsequent acetylation of *(6)* [17].

The first intermediate in the cyclization of glyoxal with nitromethane is probably 3-nitrolactaldehyde *(10)*, which may condense either directly via intermediate *(11)* to form *(2)*, or may react with glyoxal to give the intermediate 2,5-dihydroxy-3-nitroglutaraldehyde, which likewise leads via *(11)* to *(2)*. The aldehyde *(10)* was in fact prepared by *Fischer* et al. [21,22] and subsequently cyclized in sodium carbonate solution to give a mixture of isomeric dinitroinositols, from which *(2)* was isolated in 17 % yield [23].



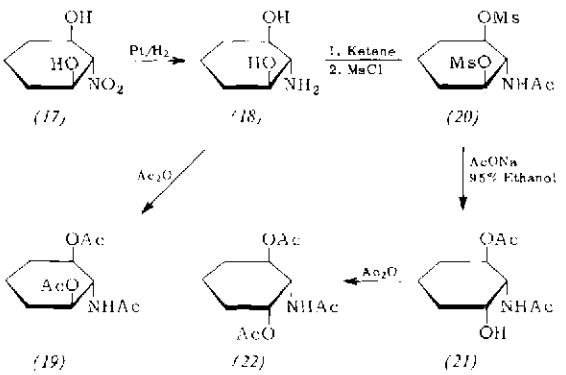
*(10)* *(11)*

## 2. 1,4-Dialdehydes



Cyclization of tartaraldehyde *(12)* with nitromethane afforded a mixture of isomeric nitrocyclopentanetetraols *(13)* [24], whose configurations are still unclear.

Maleic aldehyde yielded an *aci*-nitro salt of probable structure *(14)* on condensation with nitromethane in sodium methoxide. The 2-nitrocyclopentadienol expected by analogy with the *o*-phthalaldehyde-nitromethane condensation could not, however, be isolated even on careful neutralization, since it polymerizes extremely readily [23].



## 3. 1,5-Dialdehydes

Glutaraldehyde *(15)* condenses with nitromethane in sodium carbonate solution to yield a mixture of isomeric 2-nitrocyclohexane-1,3-diols *(16)*, from which a chromatographically uniform isomer can be isolated in 51 % yield by extraction with ether. Three configurations (*trans*, DL, and *cis*) are theoretically possible, but the compound was assigned the *trans*-configuration *(17)* on the basis of NMR evidence [25].

The diacetate of *(16)* gives a sharp peak in the NMR spectrum at 7.99 τ, which indicates two equatorial acetoxy groups. The triacetate *(19)*, obtained by hydrogenation of *(17)* followed by acetylation, shows a doublet with a 2:1 intensity ratio in this region – a proof of the equatorial position of the two acetoxy (7.95 τ) and the acetamino (8.07 τ) groups.

The inversion of sulfonic ester groups which are *trans* to a vicinal acetamido group [26] has repeatedly been used [31,51 55] as a chemical proof of an all-*trans*-configuration, such as

[18] On the basis of its infrared spectrum, the dinitrate, which has four theoretically possible configurations, is assigned configuration *(8)* (esterification of equatorial hydroxyl groups in the 3,6-position [19]).

[22] In his Ph. D. Thesis (University of Basel, 1937), *H. Nidecker* described the reaction of *(10)* with barium hydroxide, but did not obtain definite products on subsequent acidification of the barium salt formed in the reaction. In the preparation of the diethylacetal of *(10)* from glyoxal semiacetal and nitromethane, he obtained 2,5-dinitrophenol as a by-product. Undoubtedly, under the conditions of the reaction (20 min at 110 °C in concentrated potassium carbonate solution), the acetal groups were partially hydrolysed, so that 2,5-dinitrophenol was produced via the intermediates *(10)*, *(11)*, *(2)* and subsequent aromatization of *(2)*.

that shown in *(18)*. When this procedure was applied to the *N*-acetyl dimesylate *(20)*, both mesyl groups were indeed eliminated, but the expected *N*-acetyl-*cis*-diol was not obtained. Instead, the product was 3-*O*-acetyl-DL-2-acetamidocyclohexane-1,3-diol *(21)*. The DL-structure was established on the basis of the NMR spectra of *(21)* and *(22)*. The acetyl signals at 7.90, 7.97, and 8.08 τ indicate an axial and an equatorial acetoxy group adjacent to the equatorial acetamido group. Thus, in the case of the dimesylate *(20)*, one mesyl group was eliminated with inversion, the other with retention of configuration, apparently because of the greater mobility of the cyclohexane ring in comparison with the more highly substituted systems of *(36)*, *(75)*, and *(92)* [25].

*xylo*-Trihydroxyglutaraldehyde *(24)* [27], which is obtained from 1,2-isopropylidene-α-D-glucofuranose by oxidation with periodate [28] to *(23)* and removal of the acetone moiety of *(23)* in acidic solution [29,30], undergoes condensation with nitromethane and barium hydroxide to yield a mixture of *aci*-nitro barium salts. On acidification, these yield three deoxynitroinositols with *scyllo*- *(25)*, *myo*-1- *(26)*, and *muco*-3-configurations *(27)*, respectively [30]. The same mixture of isomers had been prepared earlier [12,31] by condensation of *(23)* with nitromethane to form *(28)* and *(29)*, followed by hydrolytic removal of the isopropylidene group to yield a mixture of 6-deoxy-6-nitrohexoses having the L-ido- *(30)* and D-*gluco*-configurations *(31)* [32] and, finally, intramolecular cyclization of the latter with barium hydroxide. If the cyclization of the dialdehyde *(24)* or of the nitrohexose mixture *(30)* *(31)* is carried out with sodium hydroxide, the nitroinositol mixture contains only the *scyllo* *(25)* and *myo*-1 *(26)* isomers [12,30].

The proof of the configurations of the three deoxynitroinositols *(25)*, *(26)*, and *(27)* is based on the following data.

1. Deoxynitro-*scyllo*-inositol *(25)*: Hydrogenation in acidic solution yields an inosamine identical with the *scyllo*-inosamine *(32)* prepared by other means [33,34]. Furthermore, *(32)* can be converted by direct deamination [34] (8 % yield) or, better, by deamination of its penta-*O*-acetyl derivative *(33)* and subsequent acetylation (70 % yield) into hexaacetyl-*myo*-inositol *(34)* [35,36]. The reaction sequence: *(23)* → *(28)* + *(29)* → *(30)* + *(31)* → *(25)* → *(32)* → *(33)* → *(34)* [35], as well as its simplification [36] in the last steps, *i.e.* *(25)* → *(35)* → *(33)* → *(36)*, has been used for the preparation of [2-$^{14}$C]*myo*-inositol by introducing $^{14}$C-labelled nitromethane at the step *(23)* → *(28)* + *(29)*.

2. 1-Deoxy-1-nitro-DL-*myo*-inositol *(26)*: The inosamine obtained by catalytic hydrogenation of *(26)* in acidic medium differed in chromatographic behavior from the *scyllo*-, *myo*-2-, *myo*-4-, *neo*-2-, and *muco*-3-isomers, but was identical

[27] In solution, *(23)* probably exists predominantly in a cyclic hemialdal form [cf. *R. D. Guthrie*, Advances Carbohydrate Chem. *16*, 105 (1961)].

[31] *F. W. Lichtenthaler*, Chem. Ber. *94*, 3071 (1961).

[32] In the crystalline state *(31)* exists in the α-D-glucopyranose form. Its configuration was proved by its mutarotation from $[\alpha]_D$ = +45 ° to +25 ° [12]. Its infrared spectrum showed the presence of the pyranose ring: OH absorption at 3550 cm$^{-1}$ and, hence, the essentially complete absence of hydrogen bridges. If the furanose form were present, strong hydrogen bonds would exist between the nitro and the C-5 OH groups, resulting in a shift of the OH absorption to longer wavelengths; cf., for example, those in *(29)* (OH bands at 3530 and 3300 cm$^{-1}$) [23].

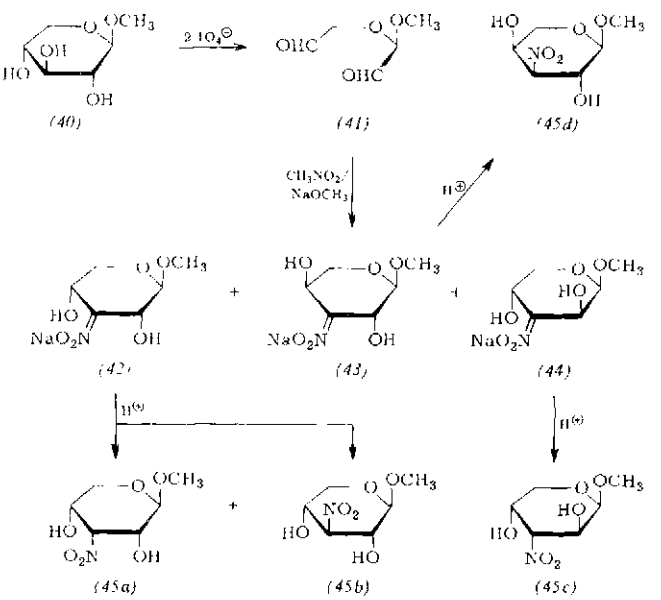
with the *myo*-1-inosamine prepared independently [37]. The NMR spectrum of the hexaacetate likewise indicated the *myo*-1-configuration [31].

3. 3-Deoxy-3-nitro-*muco*-inositol *(27)*: The formation of a di-*O*-isopropylidene compound from *(27)* demonstrated the presence of two *cis*-(e,a)-hydroxyl groups on each side of the ring above the plane, which is possible only with the *muco*-3- or the *epi*-3-configuration. The latter could be rejected, however, firstly because the penta-*O*-mesyl-*N*-acetyl derivative of *epi*-3-inosamine *(38)* – prepared from *scyllo*-inosamine *(32)* via *(36)* and *(37)* – was not identical with the pentamesylate *(39)* prepared from *(27)*, and secondly, because good agreement in physical properties was observed between genuine hexaacetyl-*muco*-3-inosamine synthetized independently [38] and the compound obtained from *(27)* by hydrogenation and acetylation.

## II. Cyclization of "Sugar Dialdehydes"



### 1. L′-Methoxydiglycolaldehyde

L′-Methoxydiglycolaldehyde *(41)*, which is easily obtainable by periodate oxidation of methyl β-D-xylopyranoside *(40)* [39], cyclizes smoothly with nitromethane/sodium methoxide in aqueous alcohol. The product is a mixture of isomeric sodium salts of methyl 3-*aci*-nitro-3-deoxy-β-D-pentoside, from which one isomer can be isolated in crystalline form in 43 % yield. Configuration *(42)* must be ascribed to this isomer, since the nitropentoside mixture obtained on acidification by trituration with solid potassium hydrogen sulfate consists predominantly of methyl 3-deoxy-3-nitro-β-D-riboside *(45a)* plus an admixture of some 3-nitroxyloside *(45b)* [14]. In the mother liquors remaining after removal of *(42)* there are two other *aci*-nitro salts of configurations *(43)* and *(44)*, respectively. These were not isolated, but their existence is established by the formation of methyl 3-deoxy-3-nitro-β-D-arabinoside *(45c)* and methyl 3-deoxy-3-nitro-α-L-arabinoside *(45d)* on acidification [40].

Proof of the configurations of these compounds was based on comparison of the 3-aminopentosides obtained therefrom by catalytic hydrogenation with the corresponding known [41, 42] 3-amino sugar derivatives.

There are four theoretically possible *aci*-nitro salts. Since one of these, namely *(42)*, is formed in 43 % yield, this cyclization possesses a considerable stereospecificity. The preferred equatorial orientation of the hydroxyl group on C-2 in *(42)* and in its derivatives *(45a)* and *(45b)* is attributable to the effect of the substituents at C-1 and can be deduced from Cram's rule [43]. However, no similar directing effect applies in the orientation of the hydroxyl on C-4; thus the *aci*-nitro salts present in the condensation solution would be expected to contain a compound with an axial hydroxyl on C-4 besides compound *(42)*, whose 4-hydroxyl is equatorial. This prediction is confirmed by the occurrence of *(45d)* in the nitropentoside mixture.

On the other hand, the steric course of the acidification of the *aci*-nitro salt *(42)* is surprising. In contrast to all

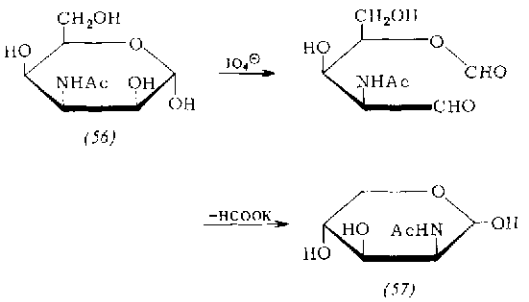
other nitromethane cyclizations previously investigated, which yield products having equatorial nitro groups, the main product of acidification of *(42)* is not the all-equatorial *xylo*-compound *(45b)*. Instead, the product is *(45a)*, which has an axial nitro group. This phenomenon has not as yet been explained.

### 2. D'-Methoxydiglycolaldehyde

A stereochemically analogous course is followed in the cyclization of D'-methoxydiglycolaldehyde *(46)*, which is obtained from methyl α-D- or β-L-pentopyranosides by oxidation with periodate [39]. Condensation with nitromethane/sodium methoxide yields a mixture of *aci*-nitro salts, from which a uniform isomer can be isolated in crystalline form. It has configuration *(47)*, since on acidification and subsequent catalytic hydrogenation it is converted into methyl 3-amino-3-deoxy-β-L-ribopyranoside *(48)* and methyl 3-amino-3-deoxy-β-L-xylopyranoside *(49)* [14]. Acidification of the mother liquor remaining after isolation of *(47)* results in isolation of two further isomers. These are the β-L- and α-D-arabinopyranoside derivatives [40].



### 3. D'-Methoxy-D-hydroxymethyldiglycolaldehyde

The dialdehyde *(51)*, which is readily accessible by periodate oxidation of methyl α-D-glucopyranoside *(50)* (or methyl α-D-pentopyranosides) [44] yields an *aci*-nitro compound upon condensation with nitromethane/sodium methoxide in methanolic solution. When the *aci*-nitro compound is acidified with a cation exchange resin, a mixture of isomeric methyl 3-deoxy-3-nitro-α-D-hexopyranosides *(52)* is obtained in 75 % yield. This mixture does not crystallize, but three crystalline 3-aminohexosides are formed on catalytic hydrogenation. These have the *manno- (53)*, *gluco- (54)*, and *talo- (55)* configurations [45,46].

The three compounds were isolated and their configurations determined in the following manner [45,46]:

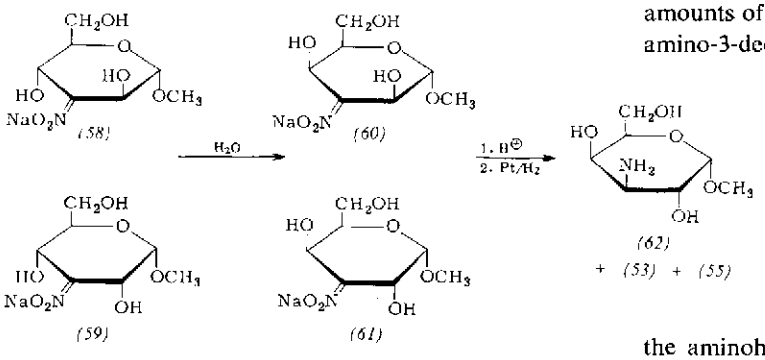
Methyl-3-amino-3-deoxy-α-D-mannopyranoside *(53)*: A methyl 3-amino-3-deoxyhexoside crystallized in 33–36 % yield from the mixture of isomers obtained by hydrogenation of *(52)* [47]. On acid hydrolysis and *N*-acetylation, a 3-acetamido-3-deoxyhexose was obtained. This was identical with a 3-acetamido-3-deoxymannopyranose synthetized by independent means [48]. Methyl 3-amino-3-deoxy-α-D-gluco- and -D-talopyranosides *(54)* and *(55)*: The mother liquor remaining after removal of *(53)* was chromatographed on a cellulose column giving two crystalline 3-amino-3-deoxyhexoside hydrochlorides in addition to *(53)*. Acetylation of one of these hydrochlorides produced a tetraacetate identical with methyl 2,4,6-*O*-3-*N*-tetraacetyl-3-amino-3-deoxy-α-D-glucopyranoside [49]. The other aminohexoside hydrochloride was subjected to hydrolysis with acid and *N*-acetylation, giving *(56)*, which was oxidized with periodate to *N*-acetyl-D-lyxosamine *(57)*. Since the reaction conditions were such that *(57)* could have been produced only from 3-acetamido-3-deoxy-D-talose or -galactose, and since the latter possesses different physical properties, the isomer in question must have the *talo*-configuration *(55)*.

[44] Compounds *(51)* and *(63)* do not exist in the open-chain dialdehyde form, but have either a hemiacetal or a hemialdal structure [cf. *R. D. Guthrie*, Advances Carbohydrate Chem. *16*, 124 (1961)].

[45] *H. H. Baer* and *H. O. L. Fischer*, J. Amer. chem. Soc. *82*, 3709 (1960); *H. H. Baer*, Angew. Chem. *73*, 532 (1961).

[46] *H. H. Baer*, J. Amer. chem. Soc. *84*, 83 (1962).

[47] Larger quantities of *(53)* can be prepared by this method via the simplified procedure of *A. C. Richardson* [J. chem. Soc. (London) *1962*, 373]. This gives *(53)* in 20–30 % yield.

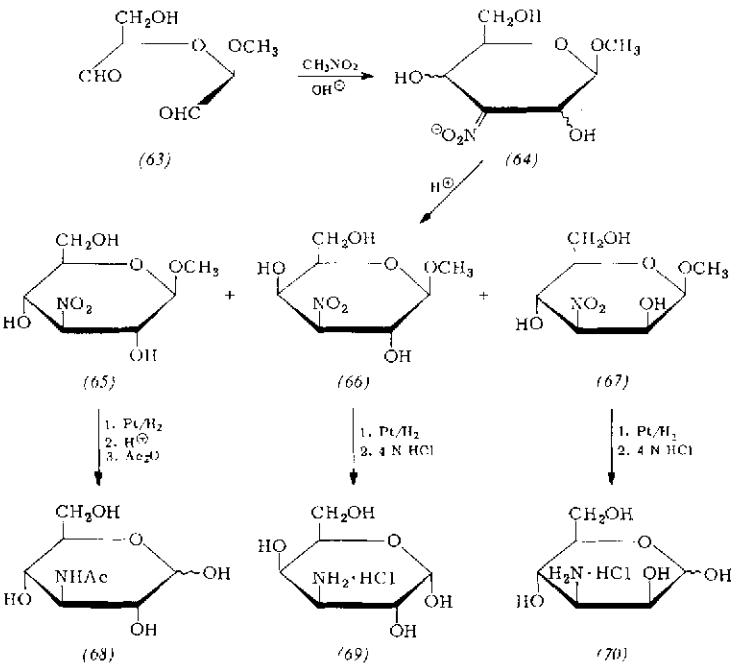


[48] *R. Kuhn* and *G. Baschang*, Liebigs Ann. Chem. *628*, 206 (1959).

[49] *S. Peat* and *L. F. Wiggins*, J. chem. Soc. (London) *1938*, 1810; *H. Ogawa*, *T. Ito*, *S. Kondo*, and *S. Inoue*, Bull. agric. chem. Soc. Japan *23*, 289 (1959); *R. D. Guthrie*, Proc. chem. Soc. (London) *1960*, 387.

Condensation of *(51)* with nitromethane and potassium bicarbonate in aqueous solution yielded a mixture of nitrohexosides of similar composition. After catalytic hydrogenation, the 3-aminomannoside *(53)* was isolated in 23–31 % yield, while *(54)* was obtained in 30 % yield in the form of its tetraacetate. Further column chromatographic fractions which also contained *(54)* brought its total yield up to about 60 % [46].

An aminohexoside mixture of totally different composition is obtained if *(51)* is condensed with nitromethane and sodium methoxide in methanol and the resulting *aci*-nitro salt comprising mostly *(58)* and *(59)* – is dissolved in water. Over a period of 90 hours, mutarotation from $[\alpha]_D = +4.33°$ to $+5.95°$ takes place. Acidification and catalytic hydrogenation yielded only 10–12% of the 3-aminomannoside *(53)* plus traces of *(54)*; the major products were *(55)* and a new isomer, methyl 3-amino-3-deoxy-α-D-galactopyranoside *(62)*, which were obtained in 40 % and 30 % yields, respectively. Thus, it must be concluded that the dissolution of the mixture of *(58)* and *(59)* in water resulted in extensive epimerization at C-4 to give *(60)* and *(61)*. The mechanism of this reaction, which is probably induced by the change in pH, has not yet been explained [46].



As far as the steric course of the cyclization is concerned, the configurations at C-2 and C-4 in the main product should be predictable from Cram's rule [43]. Application of the rule to the dialdehyde *(57)* indicates that the most favorable isomer is the *aci*-nitro salt having the *manno*-(*altro*)-configuration *(58)*; *i.e.* the nitrohexoside mixture obtained on acidification should contain principally the mannoside or altroside isomers. However, the yields of aminohexosides actually isolated show that the nitrohexoside mixture obtained by direct condensation contains only about 30 % of the mannoside isomer, the main product (60 %) being the glucoside compound.

The acidification of the *aci*-nitro salt mixture, however, proceeds via a definite stereochemical path. Whether obtained directly by condensation or by subsequent epimerization, the exclusive products are nitro- or aminohexosides with *manno*-, *gluco*-, *talo*-, and *galacto*-configurations, *i.e.* compounds with equatorial nitro or amino groups. No C-3 epimeric compounds with *altro*-, *allo*-, *ido*-, and *gulo*-configurations, *i.e.* with the nitro group in the axial orientation, are formed. Thus, the nitro group obtained by acidification of the *aci*-nitro salts preferentially assumes the equatorial position; *i.e.* the proton is attached from the axial side [46].

### 4. L'-Methoxy-D-hydroxymethyldiglycolaldehyde

The dialdehyde *(63)* which is obtained by oxidation of methyl β-D-hexopyranosides or methyl β-D-pentofuranosides with periodate [44] can be cyclized analogously with nitromethane. A mixture of isomeric 3-nitrohexosides is formed via the *aci*-nitro salt *(64)*. The composition of the mixture varies, depending on the solvent or condensing agent used [50a, b].

On condensation with sodium methoxide in methanol and subsequent acidification with cation exchange resin, the product crystallizing in 40 % yield from the mixture of nitrohexoside isomers is methyl 3-deoxy-3-nitro-β-D-glucopyranoside *(65)*. The residue contains large amounts of the galactoside isomer *(66)*, since methyl 3-amino-3-deoxy-β-D-galactoside *(69)* was isolated from the aminohexoside mixture after hydrogenation [50a]. Cyclization with potassium bicarbonate in water proceeds via a stereochemically similar path since it was possible to isolate 32 % of the nitroglucoside *(65)* after acidification of the nitrohexoside mixture [50a].

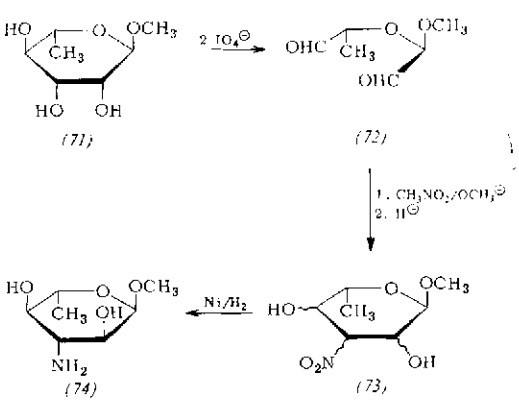
On the other hand, if the *aci*-nitro salt mixture obtained by condensation with sodium methoxide in methanol is allowed to stand in water before acidification, or if the cyclization is conducted from the outset in aqueous solution in the presence of a molar equivalent of sodium hydroxide, then only 25 % of the nitroglucoside *(65)* can be isolated. The major product becomes methyl 3-deoxy-

[50a] *H. H. Baer*, Chem. Ber. *93*, 2865 (1960).

3-nitro-β-D-galactoside *(66)* – 34 % yield of crystals – along with about 13% methyl 3-deoxy-3-nitro-β-D-mannoside *(67)*.

The configurations of the three nitrohexosides were determined in the following manner [50b, 51].

Methyl 3-deoxy-3-nitro-β-D-glucopyranoside *(65)*: Catalytic hydrogenation of *(65)* yielded an aminohexoside, which was converted by acid hydrolysis and *N*-acetylation into an *N*-acetate identical with 3-amino-3-deoxy-D-glucose *(68)* (*N*-acetylkanosamine [52]). In addition, *(68)* was transformed by periodate oxidation and alkaline hydrolysis into the known compound *N*-acetyl-β-D-arabinosamine.

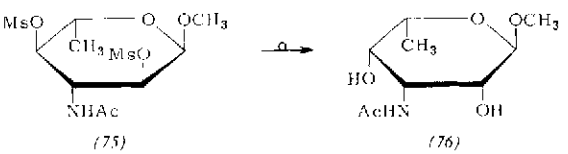


Methyl 3-deoxy-3-nitro-β-D-galactopyranoside *(66)*: In this case, catalytic hydrogenation followed by acid hydrolysis gave a 3-aminohexose hydrochloride, which was identical with the known compound [53] 3-amino-3-deoxy-D-galactose hydrochloride *(69)*.

Methyl 3-deoxy-3-nitro-β-D-mannopyranoside *(67)*: The *manno*-configuration of this isomer was established from the identity of the product of its hydrogenation and acid hydrolysis with the 3-amino-3-deoxy-D-mannose hydrochloride *(70)* obtained by other means [45].

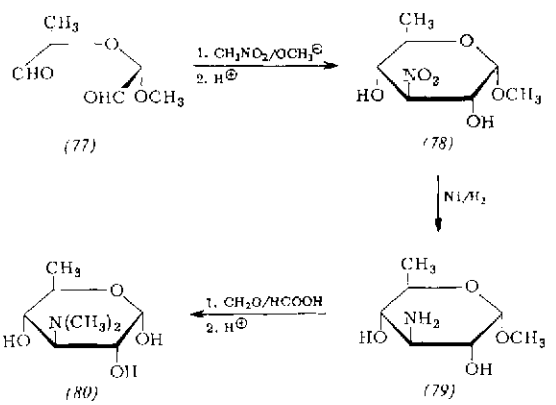
Cram's rule [43] predicts that the cyclization of dialdehyde *(63)* should yield the *gluco*-isomer *(65)* as the principal component of the nitrohexoside mixture. The fraction actually obtained (40 %) in condensations with potassium bicarbonate and sodium methoxide agrees well with this prediction.

### 5. L'-Methoxy-L-methyldiglycolaldehyde



Dialdehyde *(72)* is readily prepared by periodate oxidation of methyl-α-L-rhamnoside *(71)* [54]. Nitromethane condensation of *(72)* with sodium methoxide, followed by acidification (addition of cation exchange resin in the $H^+$ form), yielded a 3-nitropyranoside mixture *(73)* which failed to crystallize. Catalytic hydrogenation of the mixture on Raney nickel gave a mixture of 3-aminopyranosides, from which methyl 3-amino-3,6-dideoxy-α-L-glucoside *(74)* crystallized in 25–31 % yield [based on *(71)*]. No other crystalline compounds have as yet been isolated from the mother liquor of *(74)* [55a, 55b].

The L-*gluco*-configuration of *(74)* was established from the following data [55a, 55b]:



1. The NMR spectrum of the triacetate of *(74)* showed the peak distribution expected for the L-*gluco*-configuration, with signals at 8.10 τ (equatorial acetamido group) and at 7.91 and 7.93 τ (two equatorial acetoxy groups). Furthermore, the NMR signals of the two epimeric tetraacetyl-3-amino-3,6-dideoxypyranoses formed from *(74)* by hydrolysis with acid and acetylation are explainable only by assuming *gluco*-configuration for *(74)*.

2. The *N*-acetyl-2,4-di-*O*-mesyl derivative *(75)* is obtained from *(74)* by *N*-acetylation and subsequent mesylation. Inversion of mesyl groups, which are *trans* to an acetamido group causes elimination of the mesyl groups [26, 31]. Such elimination occurs with *(75)*, hence, both its sulfonic ester groups must be *trans* to the acetamido group, a requirement which is consistent only with the L-*gluco*- or L-*ido*-configuration. Comparison of the molecular rotation of *(74)* and that of the *N*-acetate and triacetate of *(74)* with the $[M]_D$ values of related gluco- and idopyranosides excluded the L-*ido*-configuration. Hence, *(75)* possesses the L-*gluco*-, and *(76)* the L-*talo*-configuration.

### 6. D'-Methoxy-D-methyldiglycolaldehyde

Application of the nitromethane cyclization to the corresponding dialdehyde of the D-series *(77)* [54], prepared by periodate oxidation of methyl 6-deoxy-α-D-glucoside, resulted in a mixture of isomeric 3-nitropyranosides. This contained at least 25 % of the 3-nitroglucoside *(78)*, since catalytic hydrogenation produced methyl 3-amino-3,6-dideoxy-α-D-glucoside *(79)*. The infrared spectrum of the latter was identical with that of *(74)* [56]. Dimethylation of the amino group with formaldehyde/formic acid followed by acid hydrolysis produced *(80)* in good yield. Since *(80)* was identical with the amino sugar derivative mycaminose isolated from

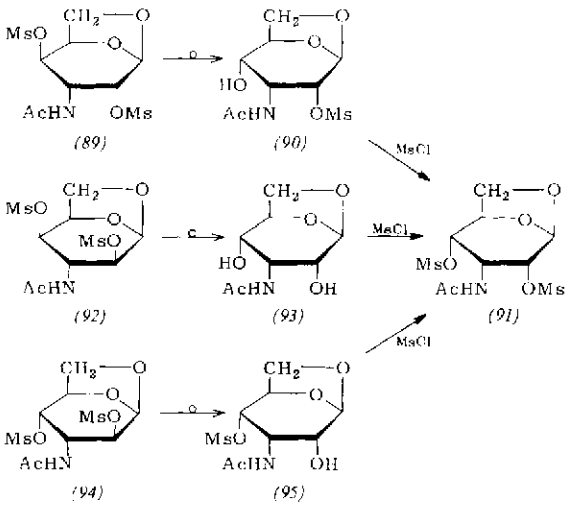
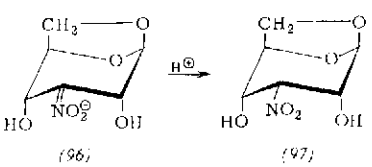
the antibiotic magnamycin [57], its configuration is established as 3-dimethylamino-3,6-dideoxy-D-glucose *(80)* [56].

### 7. cis-1,3-Dioxolan-2,4-dicarboxaldehyde

This dialdehyde *(82)* is readily obtainable by periodate oxidation of levoglucosan *(81)* [58]. Cyclization with nitromethane/sodium methoxide and subsequent acidification produced a mixture of 3-nitrohexosans having the *gulo- (83)*, *ido- (84)*, and *altro- (85)* configurations [59].



The isolation of and assignment of configuration to the nitro compounds *(83)*, *(84)*, and *(85)* or the corresponding amino derivatives were carried out as follows [59]:



1,6-Anhydro-3-deoxy-3-nitro-β-D-gulopyranose *(83)*: A crystalline isomer was isolated from the 3-nitrohexosan mixture in 13.5 % yield [based on *(81)*]. Catalytic hydrogenation of this isomer yielded a 3-aminohexosan *(86)*, whose optical rotation indicated the D-*gulo*-configuration. The exact proof was accomplished by inversion of the mesyl group *trans* to a vicinal acetamido group [26,31]. The required 3-*N*-acetyl-2,4-di-*O*-mesyl derivative *(89)* is easily prepared from *(86)* by *N*-acetylation and subsequent *O*-mesylation. The *O*-mesyl group at C-4 was eliminated by heating with sodium acetate in 95 % 2-methoxyethanol, 3-acetamido-2-*O*-mesyl-allosan *(90)* being formed. The product of mesylation *(91)* of this compound was identical with 1,6-anhydro-3-acetamido-3-deoxy-2,4-di-*O*-mesyl-β-D-allopyranose *(91)*, which was also obtained in a similar way from *(92)* and *(94)*.

1,6-Anhydro-3-amino-3-deoxy-β-D-idopyranose *(87)*: Compound *(84)* was present in the nitrohexosan mixture to the extent of at least 7.5 %, since catalytic hydrogenation of the mother liquor remaining after removal of *(86)* gave a 7.5 % yield of 3-aminoidosan *(87)*. Since the product of acetylation of *(87)* was identical with the triacetate of *(87)* which was prepared by other means [60], and since demesylation of the 3-*N*-acetyl-2,4-di-*O*-mesyl derivative *(92)* gave 3-acetamido-allosan *(93)*, compound *(87)* must have the *ido*-configuration.

1,6-Anhydro-3-amino-3-deoxy-β-D-altropyranose *(88)*: Acidification with HCl of the aminohexosan mixture remaining after isolation of *(87)* resulted in crystallization of the hydrochloride of *(88)* in 15 % yield [based on *(81)*]. The altro pyranose structure was indicated by comparison of *(88)* with a genuine sample [61], as well as by conversion of the 3-*N*-acetyl-2,4-di-*O*-mesyl derivative *(94)* into the 3-aminoallosan derivatives *(95)* and *(91)*.

The fact that only cyclization products with *gulo- (83)*, *ido- (84)*, and *altro- (85)* configurations were isolated, as well as the relative proportions of the individual isomers in the mixture, leads to some interesting stereochemical conclusions [59]. Since the dialdehyde *(82)* is relatively rigid because of the 1,6-anhydro bridge, one would expect the substituents at C-6 and C-1 (vicinal to the aldehyde groups) to have a much greater effect here on the configuration at C-2 and C-4 than the corresponding substituents in the cyclization of dialdehydes derived from simple hexoses or pentoses. Thus, according to

Cram's rule [43], the most probable product of cyclization would be 3-*aci*-nitro-3-deoxy-*allo(gulo)*hexosan *(96)*, in which both hydroxyl groups are axial. In addition, the nitro group should assume the equatorial position on acidification. Thus, the principal product should be the *allo*-isomer *(97)*. The *gulo* and *altro*-isomers, each have one equatorial hydroxyl group and should occur in smaller, but approximately equal amounts, while the *ido*-compound, with its two equatorial hydroxyl groups, should be formed in only very small yield. Although a compound with the *allo*-configuration *(97)* has not been isolated from the products of cyclization, the observed ratio of the other three isomers supports the above assumptions. The yields of *gulo-* and *altro*-compounds amounted to about 15 % each, while that of the *ido-*

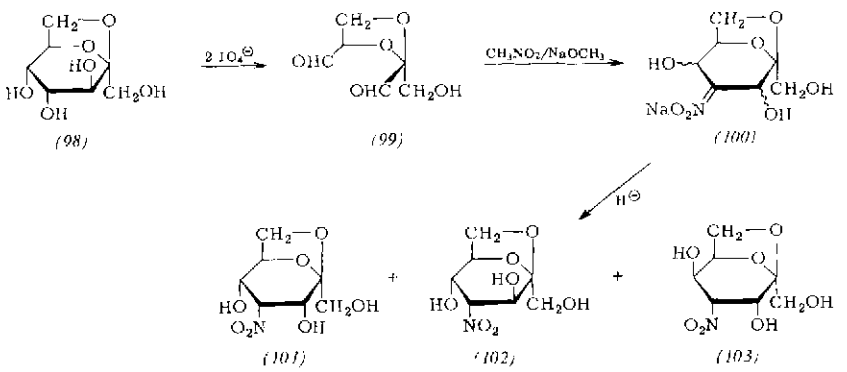
hexosane was 8 %. It is, therefore, probable that the remaining 60 % of the condensation mixture contained a considerable amount of the *allo*-isomer *(97)*.

### 8. 2-Hydroxymethyl-cis-1,3-dioxolan-2,4-dicarboxaldehyde

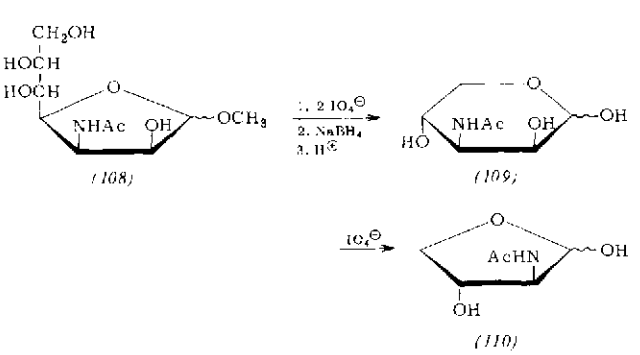


The dialdehyde *(99)*, which is related to *(82)* and which is readily obtainable from sedoheptulosan *(98)* by periodate oxidation, also undergoes cyclization with nitromethane. The condensation carried out with sodium methoxide in methanol affords a mixture of isomeric *aci*-nitro salts *(100)*, which can be partially isolated in crystalline form. When treated with a cation exchange resin in the $H^+$ form, the mixture yields a total of three pure 2,7-anhydro-4-nitro-4-deoxy-D-D-heptulosans [62]. The NMR spectra of the tetraacetyl-4-amino-4-deoxyheptulosans obtained on catalytic hydrogenation and acetylation show that the compounds have the *allo*- *(101)*, *altro*- *(102)*, and *gulo*- *(103)* configurations [62a].

The cyclization with nitromethane can also be carried out in aqueous solution in the presence of a molar equivalent of sodium hydroxide; the 4-nitroheptulosan mixture is then formed directly upon acidification [62].

*(104)* *(105)* *(106)* *(107)*

*(106)*, followed by acid hydrolysis, affords a syrup of 3-amino-3-deoxy-D-glycero-D-mannoheptopyranose *(107)*, which can, however, be crystallized as its *N*-acetate.



*(98)* *(99)* *(100)* *(101)* *(102)* *(103)*

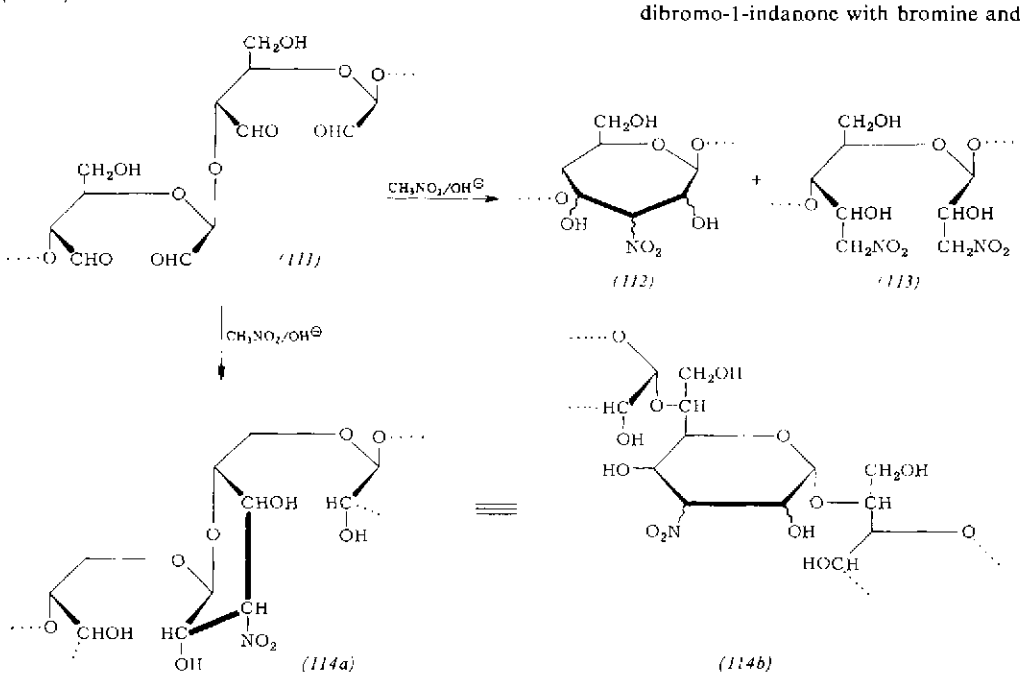
### 9. Dialdehyde from Methyl 4,6-O-Ethylidene-α-D-glucoside

Cyclization of 1,6-dialdehydes by condensation with nitromethane should lead to seven-membered rings provided ring closure were to occur at all. Although such a cyclization has not yet been achieved with simple aliphatic dialdehydes, *Baschang* [43] was able to verify this hypothesis on the dialdehyde *(105)* obtained from methyl 4,6-*O*-ethylidene-α-D-glucoside *(104)* by periodate oxidation. On condensation of *(105)* with nitromethane/sodium methoxide and subsequent acidification with a cation exchange resin, he obtained a 41 % yield of a single nitroheptoside which has the configuration of methyl 3-deoxy-3-nitro-5,7-*O*-ethylidene-D-glycero-D-α-mannoseptanoside *(106)*. Catalytic hydrogenation of

On the basis of Cram's rule, the principal product of the condensation of *(105)* would be expected to have the D-*glycero*-D-*talo*- or the D-*glycero*-D-*manno*-configuration. The exact proof in favor of the D-*glycero*-D-*manno*-configuration for *(106)* and *(107)* was furnished by the following results [43]:

The optical rotation (mutarotation from +3 ° to −11 °) of the *N*-acetate of *(107)* was not identical with any of the four known 3-acetamidoheptoses. The chromatographic behavior of *(107)*, too, did not correspond to that of the 3-acetamidoheptoses. Of the four possible isomers remaining, three could

*(108)* *(109)* *(110)*



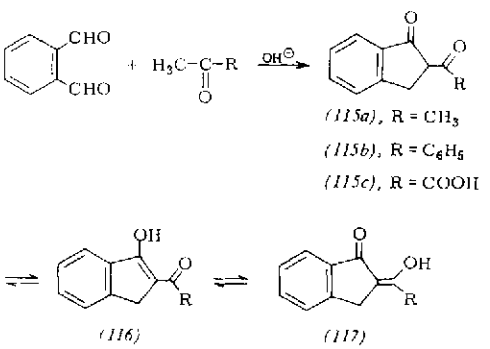
[62] *H. H. Baer*, J. org. Chemistry *28*, 1287 (1963).

[62a] *H. H. Baer*, Lecture at the General Meeting of the Gesellschaft Deutscher Chemiker in Heidelberg, September 1963; cf. Angew. Chem. *75*, 1124 (1963).

be eliminated by conversion of *(107)* into a derivative of 3-aminolyxose *(109)*: treatment of the *N*-acetate of *(107)* with methanolic HCl leads to a 3-acetamidoheptofuranoside *(108)*, subsequent periodate oxidation, reduction with sodium borohydride, and mild hydrolysis to a 3-acetamidopentose, whose *lyxo*-configuration *(109)* was proved by its chromatographic behavior as well as by periodate degradation to 2-acetamido-2-deoxy-D-threose *(110)*. These results can only be explained by assuming the D-*glycero*-D-*manno*-configuration for *(106)* and *(107)*.

### 10. Poly(dialdehydes) from Cellulose

Treatment of the poly(dialdehyde) *(111)* formed by periodate oxidation of cellulose with nitromethane and sodium hydroxide in aqueous solution gave products which contained 3.4–5.0 % nitrogen, depending on the concentration of alkali (0.32–1.44 %) and the reaction time at room temperature (20–48 hours). The structure of these products has not been defined unequivocally [63]. It was assumed that the major reaction was cyclization to a seven-membered ring *(112)*, together with the formation of products of the type *(113)* and of compounds resulting from condensation of two cellulose dialdehyde chains [63]. However, cyclization of the aldehyde groups of neighboring "glucose dialdehyde" units seems more likely. This would lead to the sterically more favorable six-membered ring. The condensation product *(114a)* formed in this way would then be a polysaccharide chain composed of D-heptopyranoside units *(114b)*.



The condensation of starch dialdehyde with nitromethane had been investigated some time ago by *H. O. L. Fischer* and co-workers [64], but this also led to ill-defined products.

## III. Cyclization of Aromatic Dialdehydes

### 1. *o*-Phthalaldehyde

The studies of *Thiele* [65–67] on the condensation products of *o*-phthalaldehyde had shown that treatment with reactive methylene compounds such as acetone, acetophenone, and pyruvic acid resulted in ready cyclization, with formation of 2-acyl derivatives of 1-indanone *(115)*.

The condensation products give a positive ferric chloride reaction, which indicates at least partial existence of the enol forms *(116)* and *(117)*. The structures *(115)*, *(116)*, *(117)* for these compounds were proved by the following observations:

1. Being a β-diketone, *(115c)* is readily cleaved with alkali to give 1-indanone and oxalic acid, and can be resynthetized from the cleavage products [66, 68].

2. All three compounds *(115a)*, *(115b)*, and *(115c)* give 2,2-dibromo-1-indanone with bromine and alkali [65–67].

3. The NMR spectra of *(115b)* and *(115c)* and of the enol acetates of *(115b)* and *(115c)* show a signal around 6 τ which corresponds to the two protons of a $CH_2$ group [69].

[63] *Z. I. Kuznetsova, U. S. Ivanova*, and *N. N. Shorygina*, Dokl. Akad. Nauk SSSR *1962*, 2087.

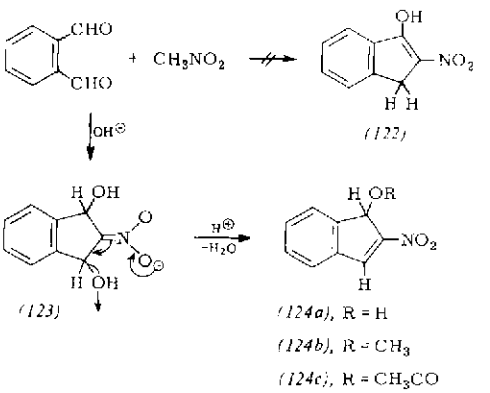
[67] *J. Thiele* and *E. Weitz*, Liebigs Ann. Chem. *377*, 1 (1910).

[68] *H. Leuchs* and *G. Kowalski*, Ber. dtsch. chem. Ges. *58*, 2289 (1925).

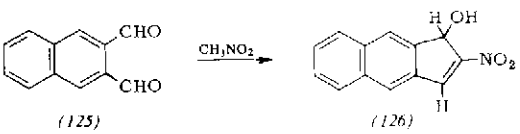


Compounds *(115)* ⇌ *(116)* ⇌ *(117)* are, however, not direct condensation products, but are produced by rearrangement following cyclization. The mechanism of this process can be readily explained by assuming that the primary cyclization product *(118)* is transformed in alkaline solution via the intermediates *(119)* or *(120)* into the stable indenyl anion *(121)*. The product formed from *(121)* on acidification, however, is not the 1-hydroxyindene derivative *(120)*, but the 3-derivative *(116)*.

The fact that the 3-hydroxyindene *(116)* must be the more stable compound is shown by the alkali-induced (and evidently irreversible) rearrangements of 1-alkylindene derivatives to the corresponding 3-alkylindenes [70]. These rearrangements may be readily explained by assuming the intermediate formation of an indenyl anion, just as in the case of formation of 1-alkylidene-3-hydroxyalkylindene derivatives by reaction of indene with benzaldehyde [71–73], *p*-nitro- or *p*-methoxybenzaldehyde [72], cinnamaldehyde [71], furfural [74], and acetone [75]. The rearrangement of 5-indenylhydroxyacetic acid to the 6-isomer proceeds by an analogous mechanism [76]. The same applies to the last step in the formation of terracinoic acid by alkaline degradation of terramycin [77].

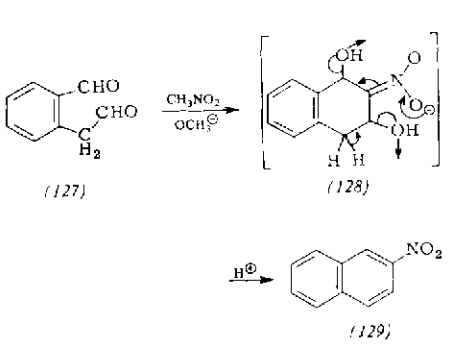
In contrast, when *o*-phthalaldehyde is cyclized with nitromethane/alcoholic potassium hydroxide [67], the reaction product obtained on acidification with mineral acid is not 2-nitro-3-indenol *(122)* or its ketone, as would be expected by analogy to *(116)* [67, 78], but instead 2-nitro-1-indenol *(124a)*. This was shown unequivocally by the NMR spectra of compounds *(124a)*–*(124c)* [69].

The NMR peaks of *(124a)*, *(124b)*, and *(124c)* indicated four aromatic hydrogen atoms plus an olefinic proton at about $\tau$ = 2.1 and another signal, corresponding to one proton, at $\tau$ = 4.36 [*(124a)*], 4.53 [*(124b)*], and 3.16 [*(124c)*]. This



peak can only be ascribed to the α-proton of a secondary alcohol. If structure *(122)* were present, a signal would be observed at 6 $\tau$ corresponding to two protons, as required for a $CH_2$ group, in much the same manner as with *(115b)*.

Hence, the *o*-phthalaldehyde/nitromethane cyclization does not proceed via an indenyl anion. This is evidently due to the stronger electron attraction of the nitro group compared to the acyl residue *(118)*. Thus acidification of the primary cyclization product *(123)* with mineral acid leads to direct dehydration and formation of *(124a)*.



### 2. Naphthalene-2,3-dicarboxaldehyde

Like *o*-phthalaldehyde, naphthalene-2,3-dicarboxaldehyde *(125)* undergoes ready cyclization with nitromethane/sodium methoxide in dioxan to form 2-nitrobenzinden-1-ol *(126)* in 77 % yield upon acidification with mineral acid. Condensation with acetophenone gave 2-benzoylbenzinden-3-ol. The structure was again proved by NMR spectra [69].

### 3. Homophthalaldehyde

Owing to the ease of aromatization of the intermediate nitrotetralin-1,3-diol *(128)*, the condensation of homophthalaldehyde *(127)* with nitromethane led to 2-nitronaphthalene *(129)* in 25 % yield and auto-condensation

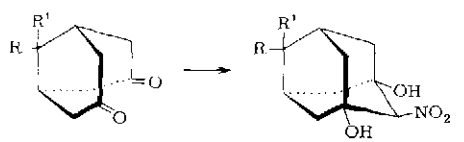
products of *(127)* [69]. The mechanism proposed for the formation of *(129)* from *N*-methylisoquinolinium iodide and nitromethane [79] is thus proved to be correct.

## IV. Concluding Remarks



In view of the variety of modifications which the condensation of nitromethane with monoaldehydes can assume by using nitroethane, nitroethanol, *etc.* [5], extension of the dialdehyde/nitromethane cyclization to other nitromethylene compounds is an obvious development. This possibility has not yet been studied in detail. However, the presence of three reactive hydrogens may possibly be required for a cyclizing condensation to occur (two hydrogen atoms for linking the two C-C bonds and one atom for the formation of the *aci*-nitro salt). It is perhaps for this reason that the condensation of dinitromethane with glyoxal or succinaldehyde does not lead to cyclization, but rather to a condensation at each aldehyde group giving the dicondensation products 1,1,4,4-tetranitrobutane-2,3-diol and 1,1,6,6-tetranitrohexane-2,5-diol *(130)*, respectively [80].

n = 2, 3 *(130)*

However, the condensation of dialdehydes with acetonitrile should produce cyclic 2-cyano-1,3-diols. Preliminary experiments [23] indicated that cyclization does in fact occur under suitable conditions, but further work is required to develop a preparatively useful method.

In view of the ability of nitromethane to condense with ketones, especially alicyclic ketones [81], a cyclizing condensation of nitromethane with suitable diketones should also be theoretically possible. This reaction has already been verified with the two bicyclo[1,3,3]nonane-3,7-diones *(131a)* and *(131b)*, which on treatment with nitromethane/sodium methoxide afforded the corresponding 2-nitroadamantane-1,3-diols *(132)* in 79 % and 63 % yield, respectively [82]. Further experiments are required to determine whether this reaction can be extended to other diketones whose carbonyl groups are not as favorably oriented for cyclization.

*(131a)*, R = R' = H *(132)*

*(131b)*, R = $CH_3$; R' = $CHCl_2$

## V. Preparative Procedures

1,4-Dideoxy-1,4-dinitro-*neo*-inositol *(2)* [17]:

A mixture of 200 ml of nitromethane, 500 ml of 30 % aqueous glyoxal, 1000 ml of methanol, and 1000 ml of water is cooled in ice, and a solution of 210 g of sodium carbonate in 800 ml of water is added with stirring over a period of 10 minutes. On scratching the walls of the vessel with a glass rod, a precipitate begins to separate. After standing for 5 h at 5 °C, the latter is suction filtered, washed with copious quantities of water, and dried over $P_4O_{10}$. The yield of *(2)* is 30–35 g. After storage overnight in a refrigerator, additional 5 g of *(2)* can be isolated from the mother liquor, which contains some 500 ml of wash water. The yield of crude *(2)* is 10 % [16]. Recrystallization from methanol (20 g/liter) gives crystals which become brown at 250 °C and decompose at about 270 °C.

*neo*-Inosadiamine 1,4-dihydrochloride *(6)* [17]:

A solution of 20 g of dinitroinositol *(2)* in 250 ml of dimethyl formamide is mixed with 250 ml of glacial acetic acid and hydrogenated at normal pressure over 15 g of nickel T-4 catalyst [83]. After 5 h (consumption of 11.2 l of hydrogen) the mixture is filtered, the residue (the inosadiamine is insoluble in DMF/acetic acid) is carefully treated with 2 N hydrochloric acid and filtered by suction. Ethanol is added to the filtrate until incipient turbidity and the solution is stored overnight at 5 °C. The precipitated inosadiamine dihydrochloride is then sucked off and washed with ethanol. Yield of *(6)* as dihydrochloride: 14.1 g. Evaporation of the mother liquor to dryness, dissolution of the greenish residue in a little water, and addition of ethanol yields additional 7.5 g. The total yield of *(6)* as the dihydrochloride is 90 %.

2-Nitrobenzinden-1-ol *(126)* [23]:

A solution of 2.4 g of naphthalene-2,3-dicarboxaldehyde *(125)* [84] in 100 ml of dioxan is treated with 1.4 ml nitromethane. A solution of 0.3 g of sodium in 20 ml of methanol is added dropwise with cooling in ice. Stirring is continued for 1.5 hours, 100 ml of water is added, and the mixture is neutralized with 1 N hydrochloric acid. The yellow precipitate is suction filtered, washed with water, and dried over $P_4O_{10}$. The yield of *(126)* is 77 %. Decomposition point 182–185 °C. Recrystallization from chloroform affords yellow needles which decompose at 190–195 °C.

Methyl 3-amino-3-deoxy-α-D-mannopyranoside hydrochloride *(53)* [47]:

Sodium metaperiodate (220 g) is slowly added with stirring to a solution of 100 g of methyl α-D-glucoside in 500 ml of water, the temperature being kept below 20 °C by addition of ice as needed. Stirring is continued for 1 h, the formic acid produced is neutralized with 40 g of sodium bicarbonate, and the mixture, from which sodium iodate has crystallized out, is poured into 500 ml of ethanol and filtered with suction. The filtrate is concentrated to a thin syrup, taken up in 800 ml of ethanol and refiltered. Nitromethane (60 ml) is added, followed by a solution of 12 g of sodium in 600 ml of meth-

anol. The mixture is left standing at room temperature for 20 min, and approximately 700 ml of Amberlite IR-120 in its $H^+$ form are added with stirring to effect neutralization. After filtration, the solution is concentrated to an oil, treated with 400 g of hot ethyl acetate, insoluble material removed by filtration, and the filtrate once again concentrated to a wine-red syrup. A solution of this syrup in 300 ml of ethanol is hydrogenated over 10–20 g of nickel T-4 catalyst [83] at an initial pressure of 4 atm [85]. At the end of the hydrogenation (1–8 hours), the catalyst is removed and the filtrate treated with 30 ml of conc. hydrochloric acid, whereupon *(53)* slowly crystallizes out and is filtered off after 1 h at 0 °C. The yield of *(53)* is 21 %; decomposition range 210–240 °C; $[\alpha]_D^{20} = +60°$ (c = 2 in water).

Methyl 3-deoxy-3-nitro-β-D-glucopyranoside *(65)* [50a]:

Sodium metaperiodate (2.14 g), 1.0 g of potassium carbonate, and 0.55 ml of nitromethane are mixed with about 40 ml of water and stirred at 0 °C. Methyl β-D-ribofuranoside [86] (1.64 g) is then added in portions, resulting in a clear solution within a few minutes. The temperature of the solution is allowed to rise gradually to 23 °C, and is kept there for 3 hours. The pH of the solution is then brought to about 4 with a just sufficient amount of Amberlite IR-120 in its $H^+$ form. Addition of a threefold volume of ethanol precipitates most of the inorganic salts. The filtrate is concentrated, again treated with ethanol, filtered, and the process repeated once more. The final product is a colorless syrup, which crystallizes on scratching. After two evaporations in ethyl acetate, the crude product is allowed to stand overnight at 0 °C under some ethyl acetate, and a 32 % yield of *(65)* is obtained in the form of colorless, needle-like prisms, m.p. 200–201 °C (decomp.), $[\alpha]_D^{20} = -14.4°$ (c = 1.5 in water). Recrystallization from ethyl acetate/methanol gives a purified product, m.p. 202–204 °C (decomp.), $[\alpha]_D^{24} = -12.4°$.

[85] At normal pressure, too, the hydrogenation is complete in 5–8 hours (*F. W. Lichtenthaler* and *B. Küspert*, unpublished results).

[86] *R. Barker* and *H. G. Fletcher, Jr.*, J. org. Chemistry *26*, 4607 (1961).

Methyl 3-amino-3,6-dideoxy-α-L-glucoside *(74)* [55b]:

A stirred solution of 25 g of methyl α-L-rhamnopyranoside *(71)* [87] in 250 ml of water is treated portionwise with 60 g of sodium metaperiodate, the temperature being kept at 20–30 °C by addition of ice. After 1 h, the mixture is carefully neutralized with 11.5 g of sodium bicarbonate and poured into 750 ml of ethanol; the salts precipitated are removed by suction filtration, and the filtrate is concentrated to a syrup which is extracted first with 250 ml and then with 120 ml of ethanol. After standing overnight in a refrigerator, the combined extracts are filtered and treated with 20 ml of nitromethane followed by a solution of 4 g of sodium in 300 ml of methanol. After standing for 40 min at room temperature, the solution is neutralized by stirring with about 250 g of Amberlite IR-120 resin in its $H^+$ form, filtered, and evaporated to dryness. The oily residue is taken up in 200 ml of ether, filtered through Hyflo-Supercel to remove insoluble material, and concentrated to a golden-red syrup. This is hydrogenated in 300 ml of methanol over about 10 g of nickel T-4 catalyst [83] at an initial pressure of 3 atm. The hydrogenation is complete after about 30 min. The catalyst is filtered off and washed with methanol. Evaporation of the filtrate leaves a crystalline residue, which is refluxed with 100 ml of ethyl acetate for 5 min. Although solution is not complete, the mixture is now cooled, allowed to stand overnight in the refrigerator, and filtered. Pale colored crystals of *(74)*, m.p. 175–176 °C, are obtained. The yield is 7.8 g (31 %). One recrystallization from ethanol gave pure *(74)*, m.p. 177–178 °C, $[\alpha]_D^{20} = -145°$ (c = 1.9 in water).

*The author's own work described in portions of this paper was aided by the United States Public Health Foundation and the Deutsche Forschungsgemeinschaft. I wish to thank Prof. Dr. F. Cramer for his interest and generous support and Miss G. Olfermann for her most skillful assistance.*

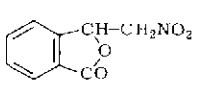
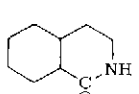
## Synthesis of the Isoquinoline System from o-Phthalaldehyde and Nitromethane



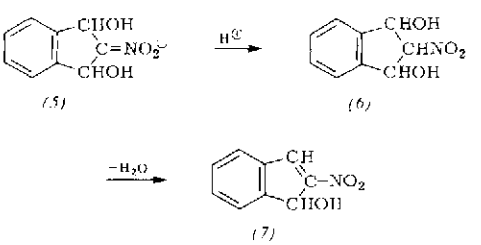
By Prof. Dr. H. H. Baer and Barbara Achmatowicz, M. Sc.

Department of Chemistry, University of Ottawa, Ottawa (Canada)



The primary product of the condensation of *o*-phthalaldehyde and nitromethane, *viz.* 2-(1-hydroxy-2-nitroethyl)benzaldehyde *(1)*, becomes stabilized as the intramolecular hemiacetal *(2)*, m.p. 121–123 °C, in the absence of hydroxylic solvents. The condensation proceeds with 80 % yield in excess nitromethane within 15 h. at room temperature in the presence of dry sodium carbonate. With 2,4-dinitrophenylhydrazine, *(2)* yields a red, highly insoluble 2,4-dinitrophenylhydrazone derived from *(1)*, m.p. 205–207 °C. Oxidation of *(2)* with potassium dichromate and sulfuric acid produces the nitrolactone *(3)*, m.p. 132 °C, in 80 % yield. Catalytic hydrogenation of *(3)* over Pt affords first the corresponding aminomethyl lactone, which can be isolated as its hydrochloride, m.p. approx. 260 °C, and then octahydroisocarbostyril *(4)*, m.p. 147 °C. In order to characterize *(4)* further, it was reduced with $LiAlH_4$ to decahydroisoquinoline, the picrate of the *cis*-form, m.p. 150 °C, being isolated [1].

(2)



(3)

(4)

Alcoholic alkali causes instantaneous rearrangement of *(2)* to the nitronate *(5)* of 1,3-dihydroxy-2-nitroindane *(6)*. On acidification with aqueous HCl, the colorless nitronate *(5)* produces yellow 2-nitro-3-hydroxyindene *(7)*, m.p. 148 °C. On the other hand, deionization with a methanolic suspension of Amberlite IR-120 ($H^+$) gives a separable mixture of *(7)* and colorless *(6)*, m.p. 163–165 °C. The structures of *(6)* and *(7)* were proved by the NMR spectra of their crystalline acetates, m.p. 90–91 °C and 130 °C, respectively. 2-Nitro-1-hydroxyindene [2] is not formed [3].

## Differentiation of Strong Acids by Conductometric Titration in Glacial Acetic Acid

By Dr. B. Sansoni

Chemisches Institut der Universität Marburg/Lahn (Germany)

Strong acids are buffered by water to the acid strength of the hydroxonium ion $OH_3^{\oplus}$, so that titration of a mixture of $HClO_4$, $H_2SO_4$, $HNO_3$, and $CCl_3COOH$ with $OH^{\ominus}$ ion produces only a single end-point. On the other hand, in glacial acetic acid which is a substantially more weakly basic solvent, the solvated hydrogen ion $CH_3COOH_2^{\oplus}$ is more acidic than $OH_3^{\oplus}$ in water, and an equilibrating buffer effect begins only at correspondingly higher acid strength. In glacial acetic acid, $HClO_4$, $H_2SO_4$ (first dissociation stage), $p$-$CH_3$–$C_6H_4$–$SO_3H$, and HCl have pK values of 4.87, 7.24, 8.46, and 8.55, respectively, and according to other data [1], the relative strengths of 0.005 N $HClO_4$, HBr, $H_2SO_4$, HCl, and $HNO_3$ are 400:160:30:9:1. These differences in acid strength, as well as the differing tendencies of the individual acids to undergo ion association to ion pairs or triple ions [2], make it possible to achieve conductometric differentiation of strong acids in glacial acetic acid.

Titration of $H_2SO_4$ in glacial acetic acid yields two distinct equivalence points corresponding to $HSO_4^{\ominus}$ and $SO_4^{2\ominus}$; differentiation of binary mixtures, for example of $H_2SO_4$ and HCl, is also possible [3]. Conductometric titration with 0.5 M sodium acetate in glacial acetic acid can be used to differentiate complex mixtures of strong acids. The apparatus used entailed a high-precision bridge with logarithmic indicating amplifier (Type WBR + TAV) and unplatinized Pt-electrodes, and measurements were made in analytical grade glacial acetic acid (0.1–0.2 % $H_2O$) in an adjustable cell at 20.0 ± 0.1 °C with exclusion of moisture. The mixtures $HClO_4/H_2SO_4/HSO_4^{\ominus}$, $HClO_4/HNO_3$, $H_2SO_4$ + HBr/$HSO_4$, $HClO_4/H_2SO_4/HNO_3/HSO_4^{\ominus}$ and $HClO_4/H_2SO_4/HNO_3/HSO_4^{\ominus}/CCl_3COOH$ all gave reproducible, analytically evaluable points of inflection. Finally, as many as six points of inflection are recognizable in the titration of the mixture $HClO_4/p$-$CH_3$–$C_6H_4$–$SO_3H/H_2SO_4/HNO_3/HSO_4^{\ominus}/CCl_3COOH$ (Fig. 1).

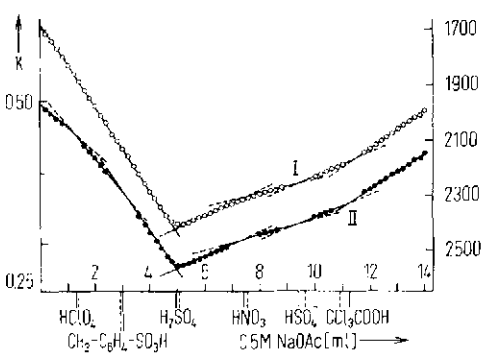

Fig. 1. Conductometric titration of a mixture of 0.69 mmole of $HClO_4$ (70 %)/0.78 mmole of $p$-$CH_3$–$C_6H_4$–$SO_3H$/1.05 mmole of $H_2SO_4$ (97 %)/1.23 mmole of $HNO_3$ (100 %)/0.62 mmole of $CCl_3COOH$ in 99 ml of glacial acetic acid + 1 ml of water with 0.5 M $CH_3COONa$.

——— experimental measurements.

- - - - - - - - theoretical equivalence points.

Curve I (left-hand ordinate) × [$10^4$ mho $cm^{-1}$].

Curve II (right-hand ordinate) scale degrees (measurements were a nonlinear function of ×).

The sequence of equivalence points generally corresponds roughly to the acid strengths in glacial acetid acid. The best conditions were obtained with the addition of about 1 % water. Figure 1 shows the most extensive differentiation of strong acids known to us that has been obtained using acid-base titrations [4]. A mixture of the acids $CH_2ClCOOH/CHCl_2COOH/CCl_3COOH$ gave three equivalence points; commercial $H_4P_2O_7$, containing mono- to pentaphosphoric acids as impurities (from Messrs. Riedel De Haen), gave four points of inflection.

Corresponding titrations in propionic acid with sodium propionate proceeded unfavorably; probably both the acidity and dissociation are too low in this case. Formic acid also proved unsuitable; it is, of course, a stronger acid than glacial acetic acid, but its high autoprotolysis constant ($1.0 \times 10^{-6}$, cf. acetic acid: $3.5 \times 10^{-15}$) [1], indicates a very high basic strength. This produces a buffering effect similar to that which occurs in water.

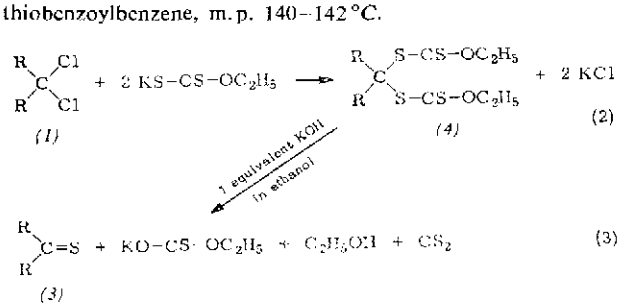
## Reaction of Potassium Xanthate with Diaryldichloromethanes, a New Thioketone Synthesis [*]



By Prof. Dr. A. Schönberg and Dipl.-Chem. E. Frese

Fakultät für allgemeine Ingenieurwissenschaften der Technischen Universität Berlin (Germany)

Diaryldichloromethanes *(1)* react with one equivalent of potassium xanthate to give diarylchloromethyl xanthates *(2)*, which cannot be isolated; these decompose exothermically according to Equation (1) to form thioketones *(3)* and *O*-ethyl chlorothioformate. The reaction in boiling petroleum (b.p. 100–140 °C) or in hot dimethylformamide, in which potassium xanthate is readily soluble, is complete in ca. 1 h; at room temperature, it requires ca. 24 hours. The yields of the resultant thioketones, which were shown by melting-point determination and analysis to be almost pure, are consistently greater than 90 %.

Examples of compounds prepared by this route are $p,p'$-dimethoxythiobenzophenone, xanthione, and 1-thioxanthione, and the previously unknown deep blue-green, solid 1,4-bis-thiobenzoylbenzene, m.p. 140–142 °C.

Reaction of two equivalents of potassium xanthate with diaryldichloromethanes according to Equation (2) gives the little-known *gem*-dixanthoylmethanes *(4)*, examples of which are diphenyldixanthoylmethane, m.p. 156 °C and bis-(4-methoxyphenyl)dixanthoylmethane, m.p. 146 °C.

These react with one equivalent of ethanolic potassium hydroxide according to Equation (3) to give thioketones *(3)*, *O*-potassium *O'*-ethyl thiocarbonate, and xanthic acid, which decomposes spontaneously into ethanol and $CS_2$. Thermolysis of the above dixanthoylmethanes also yields thioketones *(3)*.

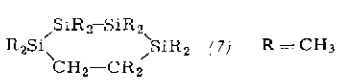
## The Formation and Reactions of Dimethylsilylene, a Silicon-Analogue of the Carbenes



By Dr. O. M. Nefedov and cand. chem. M. N. Manakov

N. D. Zelinskii Institute of Organic Chemistry of the Academy of Sciences of the U.S.S.R., Moscow (U.S.S.R.)

When dimethyldichlorosilane is treated with lithium in tetrahydrofuran at 0–10 °C and ethylene is passed through the reaction mixture, 1,2-dimethyl-1-silacyclopentane *(5)* and 1,1,4,4-tetramethyl-1,4-disilacyclohexane *(6)* are obtained in small yields (2–5 %) in addition to solid and liquid high molecular-weight silicon hydrocarbons *(3)* and *(4)*. Compounds *(5)* and *(6)* are also formed from $(H_3C)_2SiCl_2$, metallic sodium in benzene, and $C_2H_4$ in an autoclave at temperatures of 105–120 °C, as well as on thermal degradation of polydimethylsilylene *(2)* [1] at 300 °C in the presence of $C_2H_4$. The formation of the Si-containing heterocycles *(5)* and *(6)*, the telomers *(3)*, and the polymers *(4)* can only be explained by the assumption of transient formation of dimethylsilylene, since Li does not add onto the C–C double bond of monoolefins under the conditions employed [2], and ethylene does not react at 105–120 °C with Si-Li bonds such as those in *(1)* [3].

When ethylene is replaced by isobutylene, 1,1,2,2,3,3,4,4,5,5-decamethyl-1,2,3,4-tetrasilacyclohexane *(7)*, m.p. 44–45 °C, separates out, whereas the presence of cyclohexene or 1-hexene leads to the formation of liquid telomers containing oxygen, such as $C_6H_{10}[Si(CH_3)_2]_4O_2$, b.p. 74 °C/0.3 mm, or $C_7H_{14}[Si(CH_3)_2]_4O_2$, b.p. 96 °C/2 mm.

Intermediary formation of silylenes must always be expected when diaorganyldichlorosilanes are treated with alkali metals [1,4]. Dimethylgermene can be formed from $R_2GeCl_2$ with Li and added onto olefins analogously.

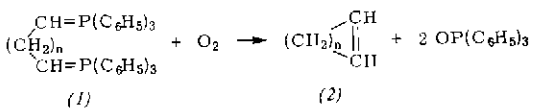
## Autoxidative Ring Closure of ω,ω'-Bis(triphenylphosphorylidene)alkanes

By Priv.-Doz. Dr. H. J. Bestmann, Dipl.-Chem. H. Häberlein, and Dr. O. Kratzer

Institut für Organische Chemie der Technischen Hochschule München (Germany)

The action of oxygen on alkylidenetriphenylphosphoranes of structure $R-CH=P(C_6H_5)_3$ yields olefins $R-CH=HC-R$ [1]. Under the same conditions, autoxidation of ω,ω'-bis(triphenylphosphorylidene)alkanes *(1)* can lead to cycloalkenes *(2)*. Examples are given in Table 1.



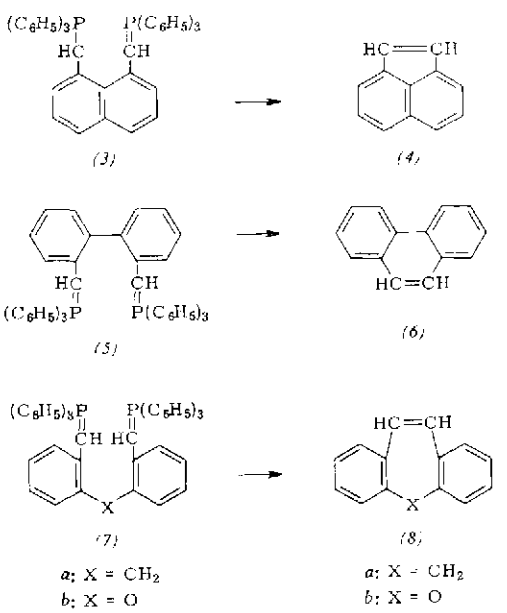


Table 1. Cycloalkenes *(2)* obtained by autoxidation of ω,ω'-bis(triphenylphosphorylidene)alkanes *(1)*.

| n | Cycloalkene *(2)* | Yield of *(2)* [%] |
|---|---|---|
| 5 | Cycloheptene | 61 |
| 4 | Cyclohexene | 60 |
| 3 | Cyclopentene | 68 |
| 2 | 1,5-Cyclooctadiene | 52 |

When n = 2, cyclizing dimerization occurs to give the eight-membered ring. Polycyclic rings can be synthetized analogously:

Acenaphthylene *(4)* is obtained in 30 % yield from the naphthalene derivative *(3)*, and phenanthrene *(6)* in 45 %

yield from the biphenyl derivative *(5)*. On autoxidation, *(7a)* gives dibenzo[*a*,*e*]cyclohepta-1,3,5-triene *(8a)*, m.p. 133 °C (45 %), and *(7b)* gives dibenzo[*e*,*f*]oxepin *(8b)*, m.p. 111 °C (52 %).

## Cocarcinogen A 1 — the First Pure, Highly Active Constituent of Croton Oil

By Doz. Dr. E. Hecker, Dipl.-Chem. H. Bresch, and Dipl.-Chem. Ch. v. Szczepanski

Max-Planck-Institut für Biochemie, München (Germany)

The pharmacologically active principle of croton oil [1,2] contains the substance groups A and B which cause the toxic, inflammatory, and cocarcinogenic activity [3] of the oil. Substance group A can be separated further by countercurrent distribution into the inactive component A2, m.p. 72 °C, and the pure, highly active component A1.

The pure cocarcinogen A1 [*] $C_{36}H_{56}O_8$ is a colorless resin, that is insoluble in water but dissolves in nearly all organic solvents; $[\alpha]_D^{24} = +49°$ (1 % in dioxan); $\lambda_{max} = 232$ and 333 mμ, $\varepsilon_{max} = 5400$ and 73 in ethanol; infrared spectrum in KBr: hydroxyl 2.96 μ, ester carbonyl 5.75 μ, ketone carbonyl 5.80–5.85 μ, C=C double bonds 6.15 μ; NMR spectrum δ = 0.9, 1.3, 1.7, 2.1, 2.5, 3.2, 3.9, 4.3, 5.2, 5.4, 5.6, 7.5 ppm (in $CCl_4$ with tetramethylsilane as internal standard).

Cocarcinogen A1 is not aromatic, contains an α,β-unsaturated carbonyl group that does not react with 2,4-dinitrophenylhydrazine or semicarbazide, as well as three free and two esterified hydroxyl groups. The latter carry an acetic and a myristic acid residue, respectively [2]. One of the free hydroxyl groups may be esterified practically quantitatively with 4'-nitroazobenzene-4-carbonyl chloride [4]. Fission of this ester ($C_{49}H_{63}O_{11}N_3$), m.p. 86–87 °C [2], with $KMnO_4$ affords the corresponding ester of glycolic acid. The esterifiable hydroxyl group is therefore primary and occurs in an allyl configuration; the two remaining free hydroxyl groups are tertiary. Other chemical data (see [5]) have been obtained for compounds which have not yet been shown to be pure.

Cocarcinogen A1 may be degraded by fission of the ester linkages to give a crystalline parent alcohol $C_{20}H_{28}O_6$, m.p. 238–40 °C, $[\alpha]_D^{29} = +116°$ (0.4 % in dioxan); $\lambda_{max} = 234$ and 335 mμ, $\varepsilon_{max} = 5000$ and 75 in ethanol; infrared spectrum in KBr: hydroxyl 2.87 and 3.05 μ, carbonyl 5.88 μ, C=C double bonds 6.10 μ; NMR spectrum: δ = 0.52, 0.88, 1.10, 1.67, 2.32, 2.91, 3.77, 4.17, 5.44, 7.52 ppm (in perdeuterodimethyl sulfoxide, standard: tetramethylsilane). A triacetate $C_{26}H_{34}O_9$, $[\alpha]_D^{28} = +68°$ (1 % in dioxan), is obtained by acetylation. The spectral and chemical properties of the parent alcohol show that it is not aromatic and contains a carbonyl as well as five hydroxyl groups, one of which is primary and allylic; two other are tertiary.

The natural product A1 proved to be highly active in the toxicity test in frogs ($LD_{50}$), in the inflammation test on mouse ears (I.U.), and in the cocarcinogen test on the back skin of mice, but does not produce any papillomas within 12 weeks without pretreatment with subthreshold doses of a carcinogen. The substance loses its biological activity on treatment with acids or alkalies. The parent alcohol *(1)* is not active in the amounts applied (Table 1), while the triacetate *(2)* shows a strongly decreased — but still significant — activity compared with A1.

Table 1. Biological activity of the pure cocarcinogen A1, of its parent alcohol *(1)*, and of the triacetate *(2)* of *(1)*. Tests according to [3].

| Substance | $LD_{50}$ [μg/50 g] | I. U. [μg/ear] | Cocarcinogen test [a] | |
|---|---|---|---|---|
| | | | μg/application [b] | papilloma/mouse [c] |
| A 1 | 10 | 0.009 | 10 | 9 |
| *(1)* | 5000 | 2.4 | 500 | 0 |
| *(2)* | 150 | 1.5 | 50 | 0.1 |

[a] Carcinogen: 1 μmole of 9,10-dimethylbenzanthracene.

[b] Application: twice weekly for 12 weeks.

[c] After 12 weeks.

## Deaminothiamine Pyrophosphate, a Strong Carboxylase Inhibitor [1]

By Dr. habil. A. Schellenberger and Dr. W. Rödel

Institut für Organische Chemie der Universität Halle-Wittenberg (Germany)

Deaminothiamine *(1)* was synthetized as follows: 4-Chloro-5-ethoxycarbonylmethyl-2-methylpyrimidine [2] was converted with NaSH into the 4-mercapto compound, m.p. 185 °C, in 91 % yield. Elimination of the mercapto group with Raney nickel in boiling water gave 5-ethoxycarbonylmethyl-2-methylpyrimidine, b.p. 104 °C/3 mm, in 34 % yield; this was converted via the hydrazide, m.p. 160 °C, 98 % yield, by twofold treatment with $NaNO_2$ into 5-hydroxymethyl-2-methylpyrimidine, m.p. 105 °C, in 31 % yield. Heating this with HBr and glacial acetic acid at 100 °C gave the bromide which reacted unpurified with 5-(β-hydroxyethyl)-4-methyl thiazole to give deaminothiamine bromide (hydrobromide?). When this was shaken with a suspension of AgCl in methanol, the chloride (hydrochloride?) was produced and was purified by chromatography on a cellulose column (Schleicher and Schüll, No. 123a). The product crystallized after standing for several weeks. Deaminothiamine can be obtained analytically pure as its perchlorate, m.p. 204 °C (decomp.), which crystallizes well.

Phosphorylation of *(1)* with anhydrous orthophosphoric acid [3] yielded a mixture of the mono-, di-, and triphosphoric esters in addition to inorganic phosphate. This mixture was separated using paper or thin-layer electrophoresis. The separated fractions were eluted with water.

If deaminothiamine pyrophosphate is added to resynthetized carboxylase in a molar ratio cocarboxylase:deaminococarboxylase = 0.96:1, the activity of the enzyme is reduced by 84 % (optical assay according to [4]). If, however, the inhibitor is added in the resynthesis of carboxylase before thiamine pyrophosphate, then the inhibition is almost complete.

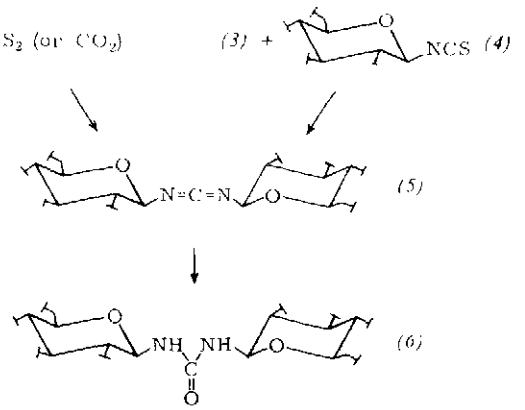
## Triphenylphosphine N-Acetylglycosylimides and N,N'-Bis(acetylglycosyl)carbodiimides

By Dr. A. Messmer, Dipl.-Chem. I. Pintér, and Dipl.-Chem. F. Szegö

Central Research Institute of Chemistry of the Hungarian Academy of Science, Budapest (Hungary)

Research on the application to sugar chemistry of the phosphine imide reaction of *Staudinger* [1] led to the synthesis of phosphine-imido derivatives of sugars. 2,3,4,6-Tetra-*O*-acetyl-β-D-glucosyl azide *(1)* [2] reacts with triphenylphosphine *(2)* in absolute ether even at room temperature with loss of a molecule of nitrogen to give triphenylphosphine *N*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucosyl)imide *(3)* which forms macroscopic crystals. The structure of *(3)* was proved by Zemplén hydrolysis [3] and by its reaction with *p*-nitrobenzaldehyde to give *N*-(*p*-nitrobenzylidene)-2,3,4,6-tetra-*O*-acetyl-β-D-glucosylamine [4].

*(1)* *(2)* *(3)*



The triphenylphosphine-imido derivatives of acetylated sugars prepared in this way are shown in Table 1.

Table 1. Properties of triphenylphosphine *N*-acetylglycosylimides.

| R = | R–N=P(C$_6$H$_5$)$_3$ M.p. [°C] | $[\alpha]_D$ in dioxan [°] | Yield [%] |
|---|---|---|---|
| 2,3,4,6-Tetra-*O*-acetyl-β-D-glucosyl- | 136 | −18.2 | 85 |
| 2,3,4,6-Tetra-*O*-acetyl-β-D-galactosyl- | 129 | −4.1 | 82 |
| 2,3,4-Tri-*O*-acetyl-β-D-xylosyl- | 128 | −23.8 | 89 |
| 2,3,6,2',3',4',6'-Hepta-*O*-acetyl-β-D-cellobiosyl- | 90–95 (amorph.) | +15.7 | 70 |

By analogy to the aliphatic phosphine imides [1], triphenylphosphine *N*-(tetraacetyl-β-D-glucosyl)imide *(3)* reacts with $CO_2$ or $CS_2$ to give a high yield of the same crystalline substance as is formed from *(3)* and tetraacetyl-β-D-glucosyl isothiocyanate *(4)* [5]. The analytical data tally with the formula of *N,N'*-bis-(2,3,4,6-tetra-*O*-acetyl-β-D-glucosyl)-carbodiimide *(5)*, although the compound is not converted into a diglucosylurea derivative *(6)* like a normal carbodiimide when treated with water [6] or acids, or with methanol in the presence of CuCl [7].

Thus, as well as *(5)*, the isomeric *N,N*-bis(tetraacetyl-β-D-glucosyl)cyanamide structure must be considered. The infrared spectrum does not permit a decision, for the absorption line at 2180 cm$^{-1}$ may come from either the carbodiimide or the cyano group. Like bistriphenylmethylcarbodiimide [8], *(5)* adds on a molecule of water in benzene/glacial acetic acid, and *N,N'*-bis-(2,3,4,6-tetra-*O*-acetyl-β-D-glucosyl)urea *(6)* [9] is formed in 98% yield. This proves the carbodiimide structure.

The syrupy product obtained from *(5)* by Zemplén hydrolysis is to be regarded as *N,N'*-bis-(β-D-glucosyl)isourea methyl ether and the crystalline substance obtained from this by acetylation as *N,N'*-bis-(2,3,4,6-tetra-*O*-acetyl-β-D-glucosyl)-isourea methyl ether (m.p. 161 °C, $[\alpha]_D = -2.7°$ in $CHCl_3$). The bisglycosylcarbodiimides prepared and the bisglycosylurea derivatives obtained under *Bredereck*'s conditions [8] are shown in Table 2.

Table 2. Properties of bis(acetylglycosyl)carbodiimides and bis(acetylglycosyl)carbamides.

| R = | R–N=C=N–R M.p. [°C] | $[\alpha]_D$ in $CHCl_3$ [°] | Yield [%] | R–NH–C(=O)–NH–R M.p. [°C] | $[\alpha]_D$ in $CHCl_3$ [°] | Yield [%] |
|---|---|---|---|---|---|---|
| 2,3,4,6-Tetra-*O*-acetyl-β-D-glucosyl- | 178 | −43.0 | 86 | 162 | −3.6 | 98 |
| 2,3,4,6-Tetraacetyl-β-D-galactosyl- | syrup | | | 225 | −16.7 | 67 |

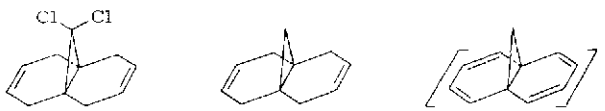
## The Cyclodecapentaene System

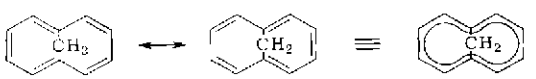
By Prof. Dr. E. Vogel and Dipl.-Chem. H. D. Roth

Institut für Organische Chemie der Universität Köln (Germany)



Cyclodecapentaene *(1)*, which contains 10 π-electrons, can be expected according to *Hückel*'s rule [1] to possess aromatic character. High resonance stabilization does not, however, seem possible in *(1)*, since the hydrocarbon cannot assume a planar configuration because of overlapping of the van der Waals radii of the hydrogen atoms at positions 1 and 6 on the *trans* double bonds.

*(1)* *(2)*



Atomic models indicate that replacement of the two internal hydrogen atoms in *(1)* by a methylene group should result in the formation of an almost, if not completely planar structure of the cyclodecapentaene skeleton.

The synthesis of 1,6-methanocyclodecapentaene *(2)* [or of (5)] started from 1,4,5,8-tetrahydronaphthalene [2]. The triene adds on dichlorocarbene (generated from $CHCl_3$ and K-t.-butoxide) at the central double bond with a high degree of selectivity [3] affording *(3)*, m.p. 83–84 °C. Sodium in liquid ammonia converts *(3)* into *(4)*, b.p. 80–81 °C/11 mm, and this reacts with bromine in the cold to form a tetrabromide, m.p. 128–129 °C. This compound reacts with bases, *e.g.* alcoholic KOH, to give a good yield of the desired hydrocarbon $C_{11}H_{10}$ as colorless crystals, m.p. 28–29 °C.

*(3)* *(4)* *(5)*

Three structures of the hydrocarbon are possible: a) *(5)*; b) *(2)* with a fluctuating structure according to *(6)* ⇌ *(5)* ⇌ *(7)*; and c) *(2)* with a delocalized π-electron system [*(6)*–*(8)*].

*(6)* *(7)* *(8)*

The ultraviolet spectrum of the hydrocarbon has maxima at 256 mμ (ε = 68000), 259 mμ (ε = 63000), and 298 mμ (ε = 6200); this suggests an extensive conjugated system [not compatible with *(5)*]. The NMR spectrum is particularly revealing: it shows an $A_2B_2$ system (8 protons) in the range 2.5–3.2 τ, centred at 2.8 τ, and a sharp signal at 10.5 τ (2 protons). The absorption of the olefinic protons at very low field, combined with strong shielding of the $CH_2$-protons above the peripheral ten-membered ring, can be considered as evidence [4] for the presence of a ring current and, therefore, for the 1,6-methanocyclodecapentaene structure *(6)* to *(8)* [5]. 1,6-Methanocyclodecapentaene is highly strained, however, and is certainly not an aromatic compound in the classical sense, because it exhibits olefinic reactivity just like the [18]- and [30]annulenes [6].

## Rearrangements of *p*-Quinols in Trifluoroacetic Anhydride

By Doz. Dr. E. Hecker and E. Meyer

Max-Planck-Institut für Biochemie, München (Germany)

*p*-Alkylphenols of biochemical importance are oxidized during intermediary metabolism to *p*-quinols [1], which rearrange to alkylhydroquinones under the influence of enzymes.

Rearrangements of *p*-quinols in trifluoroacetic anhydride yield the same products. The *p*-quinolide compound is dissolved in trifluoroacetic anhydride at room temperature and, after some time, the reagent is evaporated. On short hydrolysis with dioxan/water, the phenolic products of rearrangement are usually obtained in quantitative yield and in pure form. Some of the labile trifluoroacetates of the phenolic products of rearrangement can be isolated before hydrolysis.

*(1)* *(2)* *(3)*

*(4)* *(5)*

*p*-Toluquinol *(1)* yields toluhydroquinone *(2)* and resorcinol *(3)*, but rearrangement of the methyl and tetrahydropyranyl ethers of *p*-toluquinol yields only the hydroquinone and no resorcinol derivative. Tetralin-*p*-quinol *(4)* and its ethers rearrange exclusively to 5,8-dihydroxytetralin *(5)* or its monoethers, with 1,3-migration of the alkyl substituent. The acetates and benzoates of *p*-toluquinol and tetralin-*p*-quinol are converted exclusively into the monoesters of the corresponding resorcinol derivatives.

The rearrangements can be explained by assuming that even at room temperature trifluoroacetic anhydride contains a sufficient concentration of $CF_3CO^{\oplus}$ ions to cause electrophilic attack on the carbonyl group of the dienone system and thereby to initiate anionic migration of substituents and consequent aromatization. With *p*-quinols and their ethers, the alkyl group migrates preferentially; with quinol esters, the acyl group migrates considerably faster than the alkyl group. The exceptional behavior of *p*-toluquinol (and other monocyclic *p*-quinols) can be explained by assuming that esterification of the hydroxyl group competes with the migration of the alkyl group, and that subsequent rapid migration of the attached trifluoroacetyl group occurs. The high rate of esterification [2] of *p*-toluquinol and the small rate of migration of the alkyl group can be established by kinetic measurements [3].

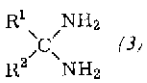
## Thermal Dehydrogenation of C,C-Dialkyldiazacyclopropanes

By Dr. A. Jankowski and Dr. S. R. Paulsen

Bergbau-Forschung GmbH., Forschungsinstitut des Steinkohlenbergbauvereins, Essen-Kray (Germany)

*C,C*-Dialkyldiazacyclopropanes *(1)* are dehydrogenated by oxidizing agents (yellow mercuric oxide, permanganate, chromic acid) to give *C,C*-dialkyldiazacyclopropenes *(2)* [1,2].

$R^1 = CH_3, C_2H_5$
$R^2 = C_2H_5$



*(1)* *(2)*

We have found that compounds of type *(1)* can also be dehydrogenated to *(2)* simply by heating to 125 °C. In addition to *(2)*, ammonia and a high molecular-weight nitrogenous residue are formed.

On addition of Cu(I) or Cu(II) salts to solvent-free *(1)*, strongly exothermic dehydrogenation starts, according to the type of the groups R, either spontaneously at room temperature or on warming to 60 °C. In the presence of water and copper or copper salts, 1 mole of *(1)* is converted in 96.5 % yield into 0.5 mole of *(2)*, 1 mole of $NH_3$, and 0.5 mole of a ketone with the same carbon skeleton as *(1)*.

The products were separated by distillation and identified by infrared spectroscopy, gas chromatography, and refractive indices.

We assume that in this reaction 1 molecule of *(1)* is dehydrogenated by a second molecule of *(1)*, giving rise to *(2)* and the *C,C*-diamino compound *(3)*. The latter condenses to high molecular-weight compounds with loss of

*(3)*

ammonia or, in the presence of water, is hydrolysed to the ketone and ammonia.

## Syntheses with β-Alkoxyacrylyl Chlorides

By Dr. F. Effenberger and Dipl.-Chem. W. Hartmann

Institut für Organische Chemie und Organisch-Chemische Technologie der Technischen Hochschule Stuttgart (Germany)

The interaction of β-alkoxyacrylyl chlorides *(1)* [1] with alcohols, phenols, thiophenols, hydrazines, and amines has afforded new derivatives of β-alkoxyacrylic acids, some of which are suitable for the synthesis of otherwise difficultly accessible heterocyclic compounds.

When the anilides *(2)* are ground with concentrated mineral acids, carbostyrils *(5)* are obtained smoothly within a few minutes in good yields. Table 1 gives a list of examples.

The action of concentrated acids on the naphthalides *(3)* gave benzoquinolones *(6)* [$R^2$ = H, m.p. 257 °C, 100 % yield; $R^2$ = $CH_3$, m.p. 240 °C, 95 % yield] and on the phenylhydrazides *(4)* gave 1-phenylpyrazol-3-ones *(7)* [$R^2$ = H, m.p. 153 °C, 98 % yield].

Table 1. Examples of the reaction *(2)* → *(5)*

| Anilide *(2)* $R^1$ | $R^2$ | $R^3$ | $R^4$ | Yield of *(5)* [%] | M.p. [°C] |
|---|---|---|---|---|---|
| $C_2H_5$ | H | H | H | 100 | 199 |
| $C_2H_5$ | H | $CH_3$ | H | 73 | 72 |
| $C_2H_5$ | $CH_3$ | H | H | 82 | 238 |
| $C_2H_5$ | H | H | *p*-$CH_3$ | 100 | 241 |
| $C_2H_5$ | H | H | *o*-$CH_3$ | 89 | 224 |
| $C_2H_5$ | H | H | *p*-Cl | 100 | 275 |
| $C_2H_5$ | H | H | *o*-Cl | 100 | 210 |
| $C_2H_5$ | $CH_3$ | H | *o*-$CH_3$ | 98 | 180 |

Starting with aminoanthracene or aromatic diamines, we obtained more highly condensed ring systems.

## Inversion of the Triphenylamine Molecule

By Dipl.-Phys. P. Knobloch and Dipl.-Phys. M. Stockhausen

Physikalisches Institut der Universität Mainz (Germany)

Conclusions can be drawn from the relaxation time of dipole orientation in dilute solution about the mechanism by which the electrical moment of a polar molecule orientates in the applied electrical field. Moments that are rigidly incorporated into the molecule can only orientate by rotation of the whole molecule, resulting in a relatively long relaxation time. However, if intramolecular adjustment can occur making more rapid dipole orientation possible, without the whole molecule having to move, the relaxation time is less.

Table 1. Relaxation times $\tau$ of the dipole orientation and dipole moments $\mu$ of triaryl derivatives of Group V elements in benzene.

| Compound | $\tau$ [sec] | $\mu$ [Debye] |
|---|---|---|
| Triphenylarsine | $77 \times 10^{-12}$ | 1.18 |
| Triphenylphosphine | $60 \times 10^{-12}$ | 1.52 |
| Triphenylamine | $0.7 \times 10^{-12}$ (approx.) | 0.66 |
| Tribenzylamine | $70 \cdot 10^{-12}$ | 0.7 |

Our relaxation measurements [1] yielded direct information about the different modes of behavior of triphenylamine and the triaryl derivatives of the higher elements of Group V. Results obtained for solutions in benzene are shown in Table 1.

Relaxation times of the magnitude shown for the first two substances in Table 1 were to be expected, in view of the rotatory orientation of the entire molecule. This could be

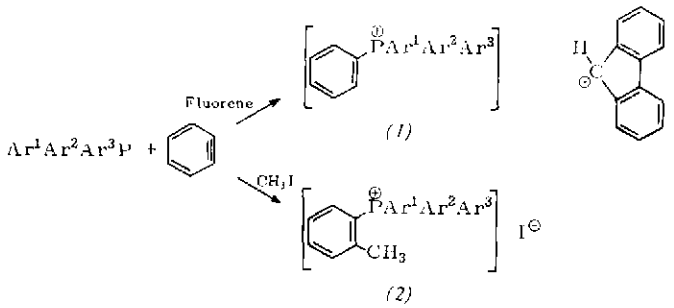
estimated from the molecular volumes and data derived from a large amount of experimental material [2]. In contrast, the considerably shorter relaxation time for triphenylamine can only be explained by internal mobility. Evidently inversion takes place, facilitated by the arrangement of the N-Ph bonds in a pyramid that is flatter than those of the other two molecules. The low dipole moment of triphenylamine also implies very close approximation to a flat structure, with valence angles greater than the tetrahedral angle. These determinations assure that any inversion in triphenylarsine and triphenylphosphine should be at least 100 times less probable than in the amine. Moreover, the values for tribenzylamine show that inversion evidently occurs only when the nitrogen is linked to an aromatic ring [*].

The relaxation times were determined by microwave absorption. For this purpose, dilute solutions (about 1 mole-%) in benzene were examined at 20 °C at frequencies varying between 500 Mc ($\lambda$ = 60 cm) and 115 Gc ($\lambda$ = 2.6 mm).

Received, January 8th, 1964 [Z 651/482 IE]
German version: Angew. Chem. 76, 186 (1964)

[1] For apparatus and methods of measurement, see *H. Kramer*, Z. Physik *157*, 134 (1959); *F. Hufnagel* and *G. Klages*, Z. angew. Physik *12*, 202 (1960).

[2] *F. Hufnagel*, Z. Naturforsch. *15a*, 723 (1960); *F. Hufnagel*, *G. Klages*, and *P. Knobloch*, ibid. *17a*, 96 (1962), where further references are given.



[*] This may be explained as follows: The bonding state of the nitrogen atom may contain $sp^2$-hybridization which is energetically favored because of mesomeric interaction between the phenyl groups and the lone electron pair at the nitrogen atom. Since the gain in energy due to mesomerism is greatest in the planar form of the molecule, inversion will be facilitated.

## A New Approach to Tetraarylphosphonium Salts

By Prof. Dr. G. Wittig and Dipl.-Chem. H. Matzura

Institut für Organische Chemie der Universität Heidelberg (Germany)

A recent note dealing with the interaction of dehydrobenzene with diphenylmethylphosphine [1] prompts us to report results we obtained some time ago. *o*-Fluorophenyl-lithium prepared according to *Gilman* and *Gorsich* [2] does not react with triarylphosphine at −75 °C. On being allowed to thaw in the presence of fluorene, the reaction mixture affords the tetraarylphosphonium salt at −40 °C in 67 % yield. Analogous reactions with methyl iodide in place of the fluorene produce the *o*-methyl derivatives, also in good yield.

*(1)* *(2)*

a) $Ar^1 = Ar^2 = Ar^3$ = phenyl
b) $Ar^1$ = phenyl, $Ar^2$ = p-tolyl, $Ar^3$ = p-biphenylyl

Compound *(1a)* was characterized as its bromide, m.p. 288–290 °C, and iodide, m.p. 330–332 °C. The structures of the iodides *(2a)*, m.p. 294–296 °C, and *(2b)*, m.p. 271–273 °C, were confirmed by elemental analyses and infrared spectra. The new method [3] is being applied principally for the preparation of pentaarylphosphoranes with five non-identical substituents for the purpose of studying their stereochemistry.

## The Crystal Structure of Titanium Phosphide $Ti_5P_3$

By Prof. Dr. G. Brauer, Dr. K. Gingerich, and Dipl.-Chem. M. Knausenberger [1]

Chemisches Laboratorium der Universität Freiburg/Breisgau (Germany)

and The Pennsylvania State University, Dept. of Chemistry, University Park, Penns. (U.S.A.)

We have found a hitherto unknown Ti/P phase with about 68.5 % (by weight) Ti and 30.3 % P. The X-ray powder diagrams of samples of this and similar composition display a consistently characteristic diffraction pattern, which is easily distinguishable from those of neighboring phases. A single crystal was isolated from one of the samples. X-ray examination of this crystal and of the powdered material indicated a hexagonal unit cell with dimensions a = 7.234 Å; c = 5.090 Å; c/a = 0.704 Å. The phase appears to have a range of homogeneity. From the density of the substance (d = 4.85 g/cm³) we calculated that the unit cell contains 10 Ti and 6 P atoms. This leads to the formula $Ti_5P_3$ and a crystal structure of the $D8_8$ type ($Mn_5Si_3$); space group $P6_3/mcm$. This structure was confirmed by intensity measurements on integrated Weissenberg photographs. The free parameters $x_{Ti}$ = 0.251 and $x_P$ = 0.610 of the six-fold point of symmetry (g) in the space group $P6_3/mcm$ were obtained from the electron density distribution along the line parallel to the x-axis and passing through the point $0,0,{}^1/_4$ (unidimensional Fourier analysis using three-dimensional data).

Received, January 21st, 1964 [Z 650/472 IE]
German version: Angew. Chem. 76, 187 (1964)

## Methylgermylamines

By Dr. Ingeborg Ruidisch and Prof. Dr. Max Schmidt

Institut für Anorganische Chemie der Universität Marburg (Germany)

We have obtained 1,1,1,3,3,3-hexamethyldigermazane *(1)* in dry ether as a colorless liquid, b.p. 47 °C/17 mm, which reacts readily with the slightest trace of moisture to yield the isosteric germoxane and ammonia.

$$2\,(CH_3)_3GeCl + 3\,NH_3 \rightarrow (CH_3)_3Ge\cdot NH\cdot Ge(CH_3)_3 + 2\,NH_4Cl$$

*(1)*

The NMR spectrum of *(1)* has $\delta_{(CH_3\text{-}Ge)}$ as a sharp singlet at −13 cps, $J_{^1H,^{13}C}$ = 126.5 cps [1,2]; its infrared spectrum has peaks at 3390, 2960, 2861, 1405, 1234, 1183, 819, and 780 $cm^{-1}$ [3]. Trisdimethylchlorogermylamine *(2)* is obtained from $(CH_3)_2GeCl_2$ under analogous conditions according to the equation

$$3\,(CH_3)_2GeCl_2 + 4\,NH_3 \rightarrow [(CH_3)_2GeCl]_3N + 3\,NH_4Cl$$

*(2)*

(together with polymeric dimethylgermazanes and amines) as colorless crystals, m.p. 62 °C, subl. p. ≈ 75 °C/2 mm, which are quantitatively hydrolysed by water, albeit more slowly than *(1)*.

Its NMR spectrum has $\delta_{(CH_3\text{-}Ge)}$ sharp at −63.5 cps, $J_{^1H\text{-}^{13}C}$ = 130.0 cps [1]; its infrared spectrum has characteristic bands at 1247, 839, and 816 $cm^{-1}$ [3].

With methyl-lithium, *(2)* reacts according to the equation

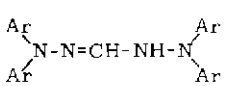
$$[(CH_3)_2GeCl]_3N + 3\ LiCH_3 \rightarrow \underset{\displaystyle N}{\overset{(CH_3)_3Ge}{\overset{|}{}}}\!\!\!\!\!\!\!\!\begin{matrix} Ge(CH_3)_3 \\ | \\ Ge(CH_3)_3 \end{matrix} + 3\ LiCl \qquad (3)$$

to form tristrimethylgermylamine *(3)*, a colorless liquid (b.p. 60 °C/2 mm), which is slowly decomposed by moisture into germoxane and ammonia. The NMR spectrum of *(3)* has $\delta_{(CH_3\text{-}Ge)}$ sharp at −18 cps, $J_{^1H\text{-}^{13}C}$ = 126.5 cps [1]; its infrared spectrum has peaks at 2985, 2924, 1441, 1235, 817, and 754 $cm^{-1}$ [3].

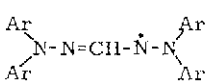
Received, January 27th, 1964 [Z 653/479 IE]
German version: Angew. Chem. 76, 229 (1964)

[1] In 5% solution in $CCl_4$, Varian A 60 (60 Mc); standard: tetramethylsilane.

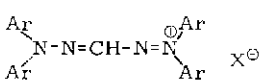
[2] An N–H proton signal is not observed on account of the strong broadening due to H-$^{14}$N coupling.



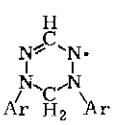
[3] Perkin-Elmer Infracord spectrophotometer, Model 137; the spectrum of *(2)* was taken in Nujol suspension.



## Tetraazapentenyl Radicals



By Prof. Dr. Richard Kuhn, Dr. F. A. Neugebauer, and H. Trischmann



Institut für Chemie, Max-Planck-Institut
für Medizinische Forschung, Heidelberg (Germany)

Condensation of orthoformic esters with N,N-diphenylhydrazine in the presence of $BF_3$ affords the colorless compound 1,1,5,5-tetraphenyl-1,2,4,5-tetraaza-2-pentene *(1)*, m.p. 121–123 °C (decomp.), in 69 % yield. On dehydrogenation (*e.g.* with $O_2$, $PbO_2$, or $Ag_2O$), *(1)* gives the bluish-green free radical 1,1,5,5-tetraphenyl-1,2,4,5-tetraazapentenyl *(2)*, which crystallizes from benzene/petroleum ether as nearly black prisms, m.p. 115–116 °C (decomp.); its magnetic moment $\mu_{eff}/\mu_B$ = 1.65 (found), its electron spin resonance spectrum has a very large number of lines (> 64) at intervals of about 0.7 gauss [1].

*(1)* 

*(2)* 

*(3)* 

*(4)*

In their chemical and physical behavior, the new free radicals of type *(2)* are closely related to the cyclic verdazyl radicals *(4)* [2]. Like these substances they undergo disproportionation to form leuco compounds *(1)* and violet salts *(3)* in the presence of acids. Their longest-wavelength absorption maxima are:

| Ar | Radicals *(2)* in dioxan | Cations *(3)* in formic acid |
|---|---|---|
| Phenyl | 631 mμ | 537 mμ |
| *p*-Tolyl | 646 mμ | 567 mμ |
| *p*-Bromophenyl | 645 mμ | 566 mμ |

In accordance with theoretical expectations, the fact that the tetraazapentenyls can be prepared shows that the $CH_2$-bridge in the verdazyls (through which no ring current can pass) is only of limited importance for the remarkable readiness with which they are formed and for their great stability [2].

The open-chain free radicals *(2)* are, however, much less stable. On melting or on prolonged standing in solution, radical *(2)* (R = phenyl) decomposes to give diphenylamine, an orange red azo compound (m.p. 240–241 °C), and polymeric products:

$$(2) \longrightarrow Ar\text{–}NH\text{–}Ar + (Ar)_2N\text{–}N{=}CH\text{–}N\text{–}N\text{–}CH{=}N\text{–}N(Ar)_2$$

Received, February 3rd, 1964 [Z 657/485 IE]

## Preparation of P(III) and P(III/V) Oxides

By Prof. Dr. E. Thilo, Dr. D. Heinz, and Dr. K.-H. Jost

Institut für Anorganische Chemie der Deutschen Akademie der Wissenschaften zu Berlin, Berlin-Adlershof, and I. Chemisches Institut der Humboldt-Universität, Berlin (Germany)

Large quantities of the hitherto only difficultly accessible phosphorus(III) oxide $P_4O_6$ have been prepared by a continuous process in yields of up to 50 % by oxidation of white phosphorus with $N_2O$ at *ca.* 70 mm and 600 °C [1].

Attempts to obtain $(PO_2)_n$ [2] by thermal decomposition of $P_4O_6$ resulted in the formation of at least two phosphorus(III/V) oxides with different compositions and crystal structures. Rhombohedral mixed crystals of $P_4O_9$ and $P_4O_8$ molecules (α-form) and monoclinic mixed crystals of $P_4O_8$ and $P_4O_7$ molecules (β-form) were obtained. This was demonstrated by examination of the hydrolysis products [P(III) acids, P(III)–O–P(III) and P(III)–O–P(V) acids or compounds, and mono-, di-, tri-, and trimeta-phosphoric acids] [3] and X-ray structural investigations [4]. The stoichiometric composition of the α-form is $P_4O_{8-9}$, and that of the β-form is $P_4O_{7-8}$. Pure $P_4O_7$ has not yet been prepared. The $P_4O_9$, $P_4O_8$, and $P_4O_7$ molecules are structurally similar to the $P_4O_{10}$ molecule but lack respectively one, two, or three of the terminal oxygen atoms. The lattice constants are independent of the composition, but the densities vary accordingly.

The phosphorus(III/V) oxides are diamagnetic. Their mean molecular weights in the vapor phase corresponds to the compositions found.

Phosphorus(III/V) oxides can also be obtained by the reaction between phosphorus(V) oxide and elemental phosphorus in an inert gas atmosphere.

Received, January 30th, 1964 [Z 656/484 IE]

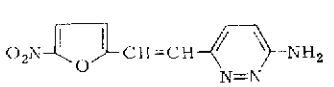
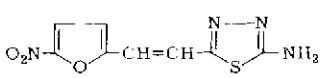
# Third International Congress of Chemotherapy

The Third International Congress of Chemotherapy was held in conjunction with the first general meeting of the International Society for Chemotherapy in Stuttgart (Germany) from July 22nd to 27th, 1963. The congress was attended by over 1000 scientists from 43 countries and included 376 papers; this represents a considerable increase in support for the society, which was founded only a few years ago. The previous meetings were at Geneva in 1959 with about 400 participants and 18 papers, and at Naples in 1961 with 600 participants and 186 papers.



The congress was principally concerned with the chemotherapy of bacterial infections (including tuberculosis), virus diseases, and neoplasmata. In addition, the chemoprophylaxis and chemotherapy of radiation damage, the chemotherapy of tropical and autoimmune diseases, to a lesser extent the chemotherapy of mycosis and haemochromatosis, the relation of chemotherapy to embryopathies, *etc.*, were discussed. Outside the actual agenda were questions on the control of drugs and especially on the international exchange of information on antibiotics.

A considerable part of the proceedings was taken up with questions of the practical application of drugs, their actions and side-effects, dosages, the possibilities of combination therapy, the circumvention of resistance phenomena, the distribution of drugs in the tissues, experimental assay methods, *etc.* A large number of contributions was devoted to the scientific basis of chemotherapy, including investigations of the biochemistry of drug action, the kinetics of drug action, the causes of resistance, and the improvement of clinical testing methods. A third and smaller part of the proceedings dealt with new chemotherapeutic agents. Only this part will be reported below; some of the newer preparations and their specific actions will be described [*].

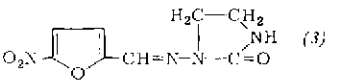


## New Chemotherapeutic Agents for the Treatment of Bacterial Infections

With regard to drugs for treating bacterial infections, there were reports on new nitrofuran compounds and sulfonamides as well as on various other synthetic compounds and some new antibiotics.

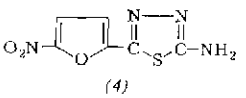
The *in vitro* and *in vivo* bactericidal and bacteriostatic action of two new nitrofuran derivatives, designated HB 115 *(1)* and HB 126 *(2)*, was described by *W. Vömel*, Mannheim (Germany). These substances showed $10^1$–$10^2$ times higher antibacterial activity *in vitro* than known nitrofuranes. Full use

*(1)*



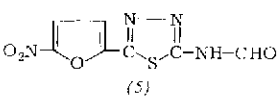
*(2)*

can be made of this increase in external applications. Oral administration results in a high antibacterial activity in the excreta; both substances are thus best suited for treating urinary and intestinal infections. Levels effective against general bacterial infections are not attained in blood or tissues.



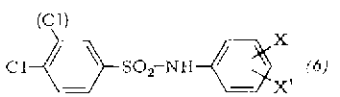
[*] The proceedings of the congress will be published by Thieme-Verlag, Stuttgart (Germany), and are due to appear early in 1964.

*J. R. O'Connor* and coworkers, Norwich (England), also introduced a new nitrofuran compound with urinary activity, *viz.* NF 246 *(3)*; this differs from Furadantin® by replacement of the hydantoin ring by an imidazolidinone ring. NF 246 is especially suitable for the treatment of chronic urinary infections which, in contrast to acute infections, can only be treated with difficulty.



*(3)*

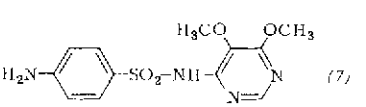
*K. Skagius*, Uppsala (Sweden), and other workers reported on investigations with 5-(5′-nitro-2′-furyl)-2-amino-1,3,4-thiadiazoles. The most active proved to be 2-amino-5-(5′-nitro-2′-furyl)-2-amino-1,3,4-thiadiazole *(4)* and 2-formylamino-5-(5′-nitro-2′-furyl)-1,3,4-thiadiazole *(5)*, which were tested under the code numbers Ph 778/1B and Ph 778/78. They have



*(4)*

*(5)*

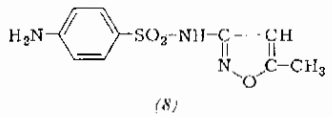
been used with considerable success in the treatment of intestinal infections by *Coli*, *Salmonella*, and *Schigella* bacteria.



Among the reports on new sulfonamides was that of *E. Jeney* and *T. Zsolnai*, Debreczen (Hungary), dealing with the bacteriostatic action of *N*-arylmethanesulfonamides and *N*-aryl-3,4-dichlorobenzenesulfonamides. Some of these compounds with a halogen substituent in the *m*- and/or *p*-position of the *N*-aryl ring have a more or less bacteriostatic action both on *Staphylococcus aureus* strains that are sentitive to sulfanilamides and on resistant *Staph. aureus* and *Staph. albus* strains. They are ineffective against Gram-negative bacteria. The majority of compounds investigated also showed fungistatic activity. On the basis of results obtained *in vitro*,

*(6)*

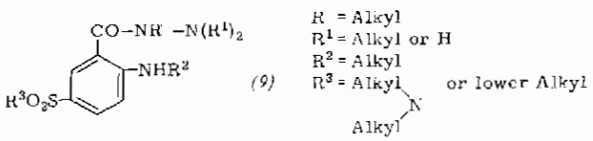
some of the halogen substituted [X = X′ = halogen in *(6)*] *N*-phenyl derivatives of 4-chloro- and 3,4-dichlorobenzenesulfonamides are at present being tested clinically against pyodermias, which are caused by Gram-positive bacteria, and for local treatment of skin mycosis.



*E. Böhni* and coworkers, Basel (Switzerland), investigated the relationships between constitution and chemotherapeutic action in substituted 2-, 4-, and 5-sulfanilamidopyrimidines. Activity is closely related to structure. Only methyl, methoxy, dimethoxy, methyl plus methoxy, halogen, or halogen plus methoxy substituents in the pyrimidine ring raise the activity of the standard preparation, sulfadiazine. 4-Sulfanilamidopyrimidines with a methoxy group in the 6- or two methoxy groups in the 5- and 6-positions are most active. 4-Sulfanilamido-5,6-dimethoxypyrimidine *(7)* has been tested

*(7)*

clinically for some time now as the preparation Ro 4-4393, and several reports on it were given. It is characterized by an especially long lasting action. Sulfonamide activity was observed up to a week after doses of 1 to 1.5 g.

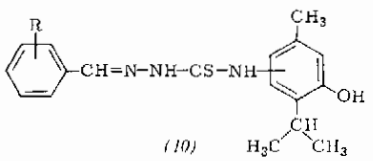


A promising sulfonamide, sulfamethoxazole or 5-methyl-3-sulfanilamidoisoxazole *(8)*, is being tested clinically under the test designation Ro 4-2130 (Gantanol®). According to a

*(8)*

report from *J. H. Peters*, Lackland Air Force Base, it has proved to be especially suitable for treating acute febrile pharyngitis caused by *Streptococci*.

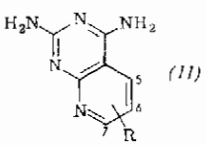
Among the new synthetic compounds, chemotherapeutically active anthranilohydrazides having a dialkylsulfamyl residue *para* to the amino group appear to be interesting. These substances were the subject of a report by *P. Schmidt* and



*(9)*

$R$ = Alkyl
$R^1$ = Alkyl or H
$R^2$ = Alkyl
$R^3$ = Alkyl, Alkyl, Alkyl or lower Alkyl

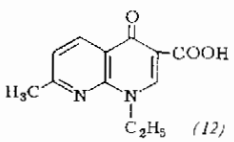
*I. Neipp*, Basel (Switzerland). The compounds *(9)* are active against *Staph. aureus* and *Diplococcus pneumoniae*, but activity is restricted to compounds with small alkyl groups.



Another new group of active substances are the thymolylthiosemicarbazones *(10)*, which were described by *B. Prescott* and coworkers, Bethesda, Md. (U.S.A.). Fourteen

*(10)*

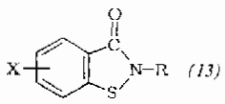
derivatives showed definite action against *Staph. aureus*. Four thymolylthiosemicarbazones, namely those of salicylaldehyde, 5-chlorosalicylaldehyde 5-nitrosalicyclaldehyde, and 3-ethoxy-4-hydroxybenzaldehyde, showed marked antibacterial activity at concentrations of 4 μg/ml.



*G. H. Hitchings* and coworkers, Tuckahoe, N.Y. (U.S.A.), presented 2',4'-diaminopyrido[2.3-*d*]pyrimidines *(11)* as a new group of antibacterial agents that are effective both *in vitro* and *in vivo*. Like other 2,4-diaminopyrimidines, these

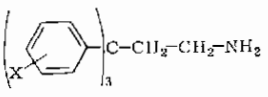
*(11)*

are regarded as folic reductase inhibitors. Investigations with the 5-, 6-, and 7-alkyl, -aryl, or -aralkyl substituted compounds showed that activity is markedly dependent on the form and size of the 6-substituent and somewhat less on those of the 5-substituent. The influence of 7-substituents is slight.



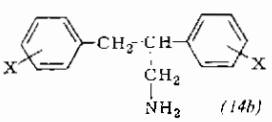
*G. Y. Lesher* and coworkers, Rensselaer, N.Y. (U.S.A.), reported on investigations of 1-alkyl-1,8-naphthyridine-4-one-3-carboxylic acids. By far the most active of these compounds was 1-ethyl-7-methyl-1,8-naphthyridine-4-one-3-carboxylic acid, or nalidixinic acid *(12)*, which has been successfully

*(12)*

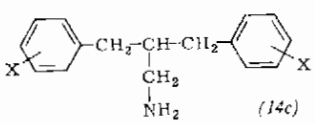


tested *in vitro* and *in vivo* against Gram-negative bacteria, especially *E. coli*, *Proteus rettgeri*, *P. mirabilis*, *Aerobacter aerogenes*, *Klebsiella pneumoniae*, *Pasteurella multocida*, *Shigella flexneri*, and *Salmonella typhimurium*. Several reports confirmed that nalidixinic acid is well tolerated by man.

The bacteriostatic and fungistatic actions of derivatives of 1:2-benzisothiazolones *(13)* were investigated by *R. Fischer*, Bern (Switzerland). Suitably substituted compounds have a wide spectrum of action against both Gram-positive and Gram-negative bacteria and against fungi. 6-Chloro-1,2-benzisothiazolone [X = 6-Cl, R = H in *(13)*] is especially active.

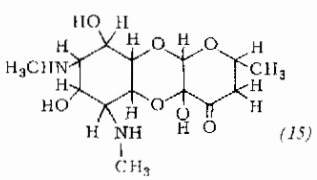


*(13)*



The halogenoaralkylamine derivatives *(14a)* to *(14c)* dealt with by *M. Schorr*, Frankfurt (Germany), also have high chemotherapeutic activity and show pronounced antibacterial and antimycotic actions.

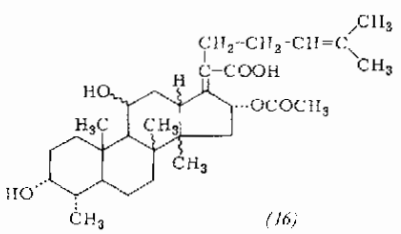
*(14a)*



*(14b)*

*(14c)*

With regard to antibiotics, the semi-synthetic penicillins produced from 6-aminopenicillanic acid were well to the fore. Actinospectacin and fusidinic acid were introduced as new antibiotics.

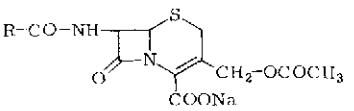


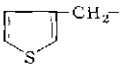
*G. M. Savage*, Kalamazoo, Mich. (U.S.A.), obtained good results using actinospectacin *(15)*, a broad-spectrum antibiotic isolated from *Streptomyces spectabilis*. It shows hardly

*(15)*

any side effects and no clinically significant toxicity, but can only be applied parenterally.

*J. Meyer-Rohn*, Hamburg (Germany), reported on the successful application of fusidinic acid *(16)* to the treatment of staphylococcal skin infections and other pyodermias. Only



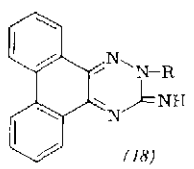


*(16)*

one out of 200 *Staphylococcus* strains proved resistant to fusidinic acid. This antibiotic (m.p. 193 °C) was isolated from the mold *Fusidium coccineum*.

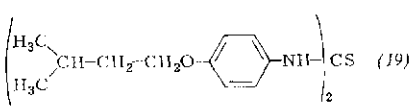
*R. S. Griffiths*, Indianapolis, Ind. (U.S.A.), obtained favorable results using cephalothin *(17a)*, a product developed from the antibiotic cephalosporin C *(17b)*. It was active against Gram-positive and Gram-negative bacteria and has proved especially effective clinically against urinary infections.

Resorption is very small on oral administration, but adequate concentrations are easily attained by parenteral application. Cross resistance with other antibiotics was not observed.



*(17a)*: R = 

*(17b)*: R = $HOOC-CH(NH_2)-(CH_2)_8-$



## Chemotherapy of Tuberculosis

*H. Umezawa* and coworkers, Tokyo (Japan), reported on a new antibiotic, ilamycin, which inhibits mycotic bacteria. Ilamycin is isolated together with another antibiotic, ilamycin B, from *Streptomyces islandicus*. L-Alanine, L-leucine, L-*N*-methylleucine, and L-3-nitro-4-hydroxyphenylalanine were detected after hydrolysis of ilamycin. Ilamycin inhibits the growth of *Mycobact. tuberculosis* at a concentration of 0.5 μg/ml. However, investigations on experimental tuberculoses did not give consistent results, and ilamycin is thus still of no practical importance.

*(18)*

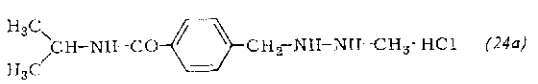
2-Alkyl-3-iminophenanthrotriazines *(18)* have strong tuberculostatic activity *in vitro* and were discussed by *W. H. Wagner*, Frankfurt (Germany). They also show distinct activity against tuberculosis in mice. The highest activity was obtained with 2-ethyl-3-imino[9,10-*e*]phenanthro-1,2,4-triazine hydrochloide, a yellow microcrystalline substance (m.p. 183 °C), which showed stronger inhibition of the human and bovine tubercle bacilli strains investigated in the various media than INH did. However, the prophylatic and therapeutic action in mice infected with tubercle bacilli is less than that of INH or streptomycin. Hardly any therapeutic action was demonstrable against tuberculosis in guinea pigs and rabbits.

*(19)*

4,4'-Diisoamyloxythiocarbanilide, DATC, or (isoxyl) *(19)*, is a new antitubercular agent of the thiocarbanilide series and was presented by *L. Eidus* and *E. J. Hamilton*, Ottawa, Canada. It is well tolerated, but since it attains only low blood levels, it must be used in combination with other drugs.

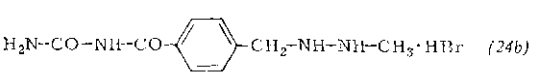
## Therapy of Neoplastic Growths

In the field of the chemotherapeutic treatment of neoplasmata, the contributions were mainly concerned with further details of known carcinostatic substances, *e.g.* of alkylating compounds, antimetabolites, steroids, carcinostatic antibiotics, and some plant materials, such as the vinca alkaloids. In addition, various new antineoplastic antibiotics and synthetic substances were described; however, these mostly showed no marked advantage over previous materials.



Two new antibiotics with pronounced antineoplastic activity are enomycin and pbleomycin, which were investigated by *H. Umezawa*, Tokyo (Japan), and coworkers. Enomycin is obtained from a culture filtrate of *Streptomyces mauvecolor* mainly by chromatographic separation. It is a peptide with a molecular weight of 2000–5000 and produced a clear antitumor action in subtoxic doses against the Ehrlich ascites tumor and Yoshida sarcoma. Phleomycin consists of a mixture of antibiotics containing copper and is produced from cultures of *Streptomyces verticillus*. It is active against experimental animal tumors, *e.g.* Ehrlich carcinoma in mice, and inhibits growth of hela cell cultures and Yoshida sarcoma cells. It influences the synthesis of DNA but not protein synthesis.

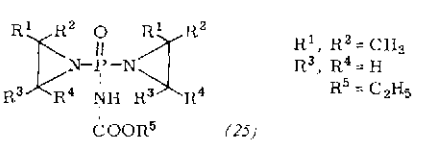
*G. F. Gause*, Moscow (U.S.S.R.), reported on recent results obtained by *M. G. Brazhnikova* and coworkers with the new antitumor antibiotic, olivomycin. This antibiotic is isolated from *Actinomyces olivoreticuli* by extraction with butyl acetate at pH 5.0. It markedly inhibits growth of many animal tumors, and has also given positive results in clinical trials on a series of malignant tumors, *e.g.* melanoma and bronchial carcinoma. Olivomycin crystallizes in yellow needles. It consists of at least three different substances.



*A. di Marco*, Milan (Italy), reported on daunomycin, a new antibiotic of the rhodomycin group. This also acts against animal tumors, especially against Ehrlich carcinoma, sarcoma 180, Yoshida sarcoma, hepatoma AH 130, and myeloma. It clearly increased the period of survival of animals with tumors.

Iyomycin, another new antitumor antibiotic was described by *H. Kentaro*, Tokyo (Japan). It is extracted from a culture medium containing *Streptomyces pheoverticulatus* and is a marcomolecular substance. The antitumor activity is distinctly higher and the toxicity lower than that of other antitumor antibiotics, *e.g.* carcinophilin, mitomycin, and melanomycin. Sarcoma 180 can be reduced or healed by daily intraperitoneal or intravenous subtoxic doses. Iyomycin is therefore a very promising new substance.

*W. Bollag*, Basel (Switzerland), introduced methylhydrazine compounds as a new class of syntbetic cytostatic agents. 1-Methyl-2-(*p*-isopropylcarbamoyl)benzylhydrazine hydrochloride *(24a)* and 1-methyl-2-(*p*-allophanoyl)benzylhydrazine hydrobromide *(24b)* proved to be most active. These preparations (Ro 4-6467 and Ro 4-6824) inhibit the growth of

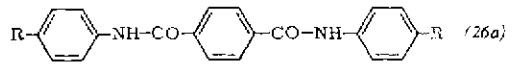


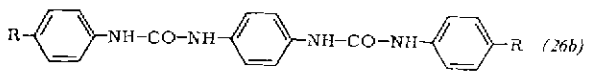
*(24a)*

*(24b)*

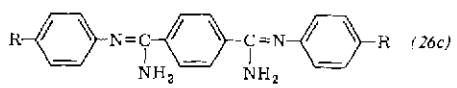
Ehrlich carcinoma, Ehrlich ascites carcinoma, Crocker sarcoma S 180, Walker carcinosarcoma 256, and uterus ephithelioma T8 after parenteral and oral administration.

*T. J. Bardos* and coworkers, Buffalo, N.Y. (U.S.A.), described new cytostatic agents of the alkylated carbamate type. In particular, preparation AB-132 *(25)* was found to be active against various transplanted and virus-induced tumors

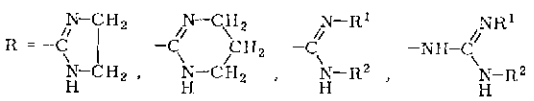




$R^1, R^2 = CH_3$
$R^3, R^4 = H$
$R^5 = C_2H_5$



*(25)*



in rodents, with very little toxic action on the hematopoetic system. On hydrolysis, AB-132 yields urethane, 2-amino-t-butanol and a substance containing phosphorus that is structurally similar to cholinesterase inhibitors, which also contain phosphorus. AB-132 therefore acts like a cholinesterase inhibitor. At present attempts are being made to avoid these side effects by addition of antagonists to the cholinesterase inhibition.

*R. Hirt*, Bern (Switzerland), described polybasic compounds with antileucaemic activity. Derivatives of the structural types *(26a)* to *(26c)* were the most active of a series of several hundred substances. They have a strong inhibitory action on leucaemia induced experimentally in mice with L 1210. Some of these substances are at present undergoing clinical trials in the U.S.A.

*(26a)*

*(26b)*

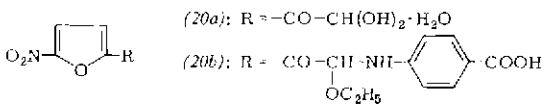
*(26c)*

*H. Fujimori*, Osaka (Japan), described the antitumor action of cobalt protoporphyrin (COPP), which has already been tested clinically for stomach, lung, and uterus cancer. Regression of the tumors was found in about 39 % and subjective improvement in 50 % of the cases. Side effects occur comparatively infrequently and only with too high dosages. Liver function is not affected, and there were no noticeable changes in the blood constituents.

## Oncolysis

A fundamentally new approach to cancer therapy was presented by investigations reported by *J. R. Möse*, Graz (Austria), into the oncolysis produced by *Clostridia*. In these experiments, spores of an anaerobe, *e.g. Clostridium butyricum* strain 55, were administered intravenously to animals with tumors. The spores then germinated selectively in the tumor tissue and multiplied there extremely rapidly. They thus destroyed the surrounding tissue by proteolysis so that it could be sucked off after a few days as a liquid necrotic material. Since oncolysis depends on the type of tumor and the species of animal (*e.g.* only some mice tumors respond, rat tumors are insensitive), an attempt is at present being made to find spores that are better suited to individual types of tumor. According to investigations by *G. E. Boxer* and *H. Thiele*, Rahway, N.J. (U.S.A.), good results were obtained in the therapy of experimental animal tumors if the treatment with spores was combined with the use of cytostatics. Tumor regression was accelerated, and the loss of weight encountered with spore treatment alone was eliminated. *D. Gericke* and *K. Engelhart*, Frankfurt (Germany), established that tumors have a high porphyrin content, which stimulates the resporulation of *Clostridia* both *in vitro* and *in vivo* and so brings the oncolytic process to a standstill. Porphyrin formation can be blocked by parenteral and para- or intratumoral administration of heavy metal compounds. By this means, the extent and speed of tissue breakdown is considerably raised. Since there are still many unsolved problems relating to clostridial oncolysis, *e.g.* the completeness of oncolysis or the elimination of toxic by-products, it is still too early to assess its future importance in practical carcinotherapy.

## Therapy of Virus Diseases

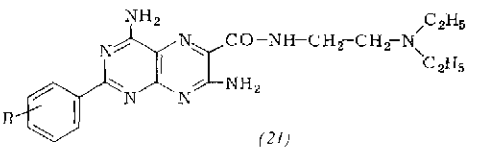


Some new approaches to the problems of chemotherapy in virus diseases were discussed, but successful treatment can still only be claimed in a few cases.

*H. Kaufman*, Gainesville, Fla. (U.S.A.), reported on the already well established treatment of *Herpes simplex* keratitis with 5-fluoro- and 5-iodouracil deoxyribosides. These act as thymidine antagonists and block the DNA synthesis of the viruses, thus inhibiting their multiplication. However, this action is limited to viruses containing DNA and no activity is obtained against RNA forms. On account of the high toxicity of the ribosides, only external application is possible. The drugs are used for example in *vaccinia* and *herpes* keratitis of the rabbit and human eye and in *Herpes labialis*.

Another nucleoside, cytosine arabinoside (CA), was tested by *G. E. Underwood*, Kalamazoo, Mich. (U.S.A.), against *herpes* keratitis in the rabbit and against *vaccinia* virus infections. Cytosine arabinoside is comparable to 5-iodouracil deoxyriboside in its virostatic activity.

*J. Wollensak*, Erlangen (Germany), tested other materials for the treatment of virus diseases of the cornea. He reported favorable results with *p*-fluorophenylalanine, 3,6-diaminoacridine (proflavine), and 4-ethylthio-2-aminobutyric acid (ethionine). However, it was not possible to confirm the initial extremely favorable therapeutic results completely on a great number of herpetic diseases of the cornea. There are obviously strains of *Herpes simplex* which are not completely inhibited by the above antimetabolites.

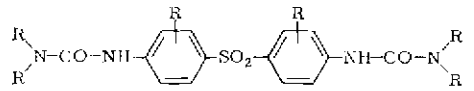


The activity of derivatives of 5-nitro-2-furylglyoxal against two strains of influenza virus in chick embryos were tested by *B. Babudieri* and coworkers, Rome (Italy). While some of the compounds show virostatic action only if they are applied simultaneously with the virus, others, such as *(20a)* and *(20b)*, are also active if they are administered after virus infection.

*(20a)*: R = $-CO-CH(OH)_2 \cdot H_2O$

*(20b)*: R = $-CO-CH(OC_2H_5)-NH-C_6H_4-COOH$

*W. Cutting* and *E. Furasawa*, Stanford, Calif. (U.S.A.), reported on investigations with propionin, a virostatic material which was discovered in *Bacterium propioni Freudenreichii*. Application of the crude extract to mice infected with Columbia SK virus reduced the average mortality by 70 %. Propionin could not yet be produced pure.

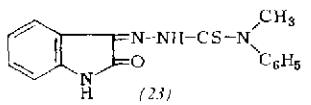


*C. P. Hegarty* and coworkers, Radnor (Wales), observed a clear increase in the period of survival in mice experimentally infected with Columbia SK, Semliki-Forest, *Herpes simplex*, and influenza PR-8 and NWS viruses when treated with 2-aryl-4,7-diamino-*N*-dialkylaminoalkyl-6-pteridinecarboxamide derivatives *(21)*. Small chemical changes in the

*(21)*

aryl ring effect specific alterations in the spectrum of activity towards the various viruses. Thus a reproducible relation between constitution and activity was found. All these substances proved to be inactive in tissue cultures.

A new antibiotic, julimycin B 11, possessing a chemoprophylactic action against polio infection in mice, was isolated by *K. Katagiri* and *J. Shoji*, Osaka (Japan), from cultures of *Streptomyces* No. 222; it was obtained as orange-yellow crystals. Its virostatic activity *in vitro* is very low. Julimycin has also an inhibitory action on the development of Ehrlich ascites tumors as well as on various bacteria.



*G. Michael*, Stolberg (Germany), described the actions of diphenyl sulfone derivatives against model virus infections in tissue cultures and *in vivo*. Urea derivatives *(22)* of the diphenyl sulfone B 662, which were tested clinically under the

(22)

designation CG 662, have proved especially useful. As several of the reports given indicated, the cure of *Herpes simplex* and *Herpes zoster* infections and of viral influenza was noticeably accelerated by the use of diphenyl sulfone derivatives.

*D. G. O'Sullivan* and coworkers, London (England), dealt with the virostatic activities of the β-(4',4'-dialkylthiosemicarbazones) of isatin. These show high chemotherapeutic activity against *Ectromelia* virus after subcutaneous application to mice. Isatin β-(4'-methyl-4'-phenylthiosemicarbazone) *(23)* proved to be the most active agent of this class.

(23)

## General Discussion on the Chemotherapy of Virus Diseases

Some subjects of the Congress had also been discussed at an informal round-table meeting at Schloss Reinhartshausen on July 20th, 1963, for which Farbwerke Hoechst had invited a number of scientists. In addition to oncolysis, the discussion was on the chemotherapy of virus diseases, with *A. Wacker*, Frankfurt (Germany), in the chair.

*H. J. Eggers*, New York (U.S.A.), reported his investigations with 2-(α-hydroxybenzyl)benzimidazole (HBB) and guanidine. These two substances have the property of selectively inhibiting RNA-containing, lipid-free viruses of the Picorna group, without any toxic damage to the cells themselves. It accomplishes complete inhibition of RNA and protein synthesis in the virus, and that even only within the cell. Inhibition of extracellular viruses with these substances is not possible. The course of RNA synthesis in the virus can be followed using tritium-labelled nucleotides if RNA synthesis in the cell has first been inhibited by actinomycin. The selective inhibition of the RNA synthesis in the virus by HBB can be followed in this system. Apparently, the formation of a specific RNA polymerase occurs shortly before the maturation of the virus and is independent of the intracellular DNA; this polymerase is found only in the ribosome fraction of infected cells and has a short life. The polymerase fraction can be concentrated by various purification procedures from the ribosomes and has the ability of incorporating nucleoside triphosphates into a polymeric RNA in a cell-free system in the presence of ATP. Whether this is identical with virus RNA has still to be proved.

Some observations indicate that it is the virus-induced polymerase which synthetizes the specific virus RNA. Nothing is known as yet of the mechanism of HBB inhibition. It is however possible that HBB attacks specific positions on the RNA, so that the gene or cystrone occurring there is no longer capable of forming polymerase. In any case, the high specificity of the inhibitor is remarkable; thus, for example, the benzimidazole nucleus is absolutely essential. All the HBB derivatives previously tested have less activity. Changes at the asymmetric carbon atom also diminish the inhibitory action. The discussion of the significance of these observations for use in virus chemotherapy did not give room for great expectations, since HBB acts only on RNA-containing viruses of the Picorna group and resistant mutants are also often found. Finally, a marked depression of total protein synthesis is observable in later stages of the experiments and the infected cells die.

*A. D. Welch*, New Haven, Conn. (U.S.A.), referred to the possibility of chemotherapy with 5-iododeoxyuridine (IUDR), 5-iododeoxycytidine (ICDR), and the corresponding monophosphates. Normally, thymidine is incorporated into the DNA inside the cell via the mono-, di-, and triphosphates with the help of the polymerase. Monophosphotymidylic acid (TMP) is formed in turn by the action of a thymidylic synthetase from deoxyuridyl monophosphate. If IUDR or its monophosphate is provided, the iodinated compound enters into the metabolism instead of the TMP and is incorporated into the DNA as a false constituent. ICDR acts in a similar way; it is deaminated in the cell to IUDR and is then incorporated as above.

Local treatment of *Herpes simplex* infections in rabbit eyes with IUDR produces complete inhibition of the virus, even though the mechanism does not appear to proceed by incorporation of the antimetabolite into virus DNA, as was shown later. On the basis of these results, *H. Kaufman* developed a therapy for corneal keratitis in man using IUDR and has achieved a large number of excellent cures.

Further exeprimental results were presented on the inhibition of *vaccinia* virus in rabbit skin by IUDR. The strongest inhibition was obtained with a dose of 80 mg/kg at 8 hour intervals. No toxic side-effects were produced with this dosage.

Further investigations were carried out on new-born hamsters which were infected with *adenovirus* type 12 shortly after birth. If 0.5 mg of IUDR is given at the same time as the virus inoculation and treatment is continued for 30–60 days, tumor formation is definitely inhibited. Repeated subcutaneous application is also clearly successful. Similarly, a single dose of IUDR reduces the number of neoplasms formed in the experimental series. Even if the treatment with IUDR begins a day after the virus infection, there is still a destinct reduction in the number of tumor-bearing animals. ICDR shows similar inhibition of tumors after intraperitoneal doses of 1 mg (5 injections), because it undergoes slow deamination to give IUDR. Experiments with hela cells indicate selective inhibition of the virus DNA replication by IUDR.

*R. Thiel*, Frankfurt (Germany), remarked that IUDR found application in his clinic not only for herpetic corneal infections, but also for patients with tumors in order to secure restriction of X-ray therapy.

An extensive discussion developed on the possible teratogenic action of IUDR. According to *A. D. Welch*, an intravenous dose of 120 mg/kg in man produced toxic effects, including loss of hair, stomatitis, and disturbances of bone marrow function. IUDR induces a definite increase in the rate of mutation in bacteria and a microscopically detectable change in the chromosomes in *Drosophila*. On the other hand, IUDR is degraded very rapidly after subcutaneous application, iodide being released.

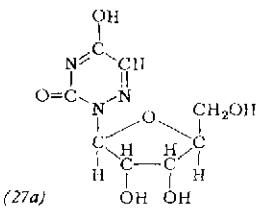
*H. Kaufman* mentioned that there had never been any sign of cancer formation or similar disturbances as a result of IUDR treatment for corneal ceratitis in a great number of adults and children. It was shown that no radioactivity was detectable in the blood only 4 hours after administration of 120 mg of $^{125}$IUDR. Iodine was then found only in the bone marrow, but not bound to DNA.

Isatin thiosemicarbazone was favorably accredited with regard to any possible eventual teratogenic side-effects. It is a virus inhibitor with which DNA and protein synthesis apparently continue normally but which prevents maturation of the virus.

Later in the discussion, *J. Škoda*, Prague (Czechoslovakia), gave a review of his work with 6-azauridine (AzUR). This compound is converted into its monophosphate in the cell; this inhibits the normal metabolic conversion of orotidyl monophosphate into uridyl monophosphate. AzUR, but not azauracil or the corresponding deoxyriboside, has an antileucaemic action. On injection into animals with tumors, AzUR is taken up predominantly by the tumor tissue and accumu-

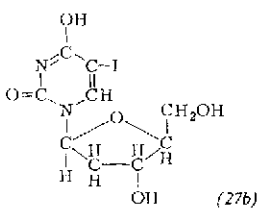
lates there. In some cases, there is thus a reduction of neoplastic tissue during the period of treatment. This substance is exceptionally well tolerated; 40 g per day in man is without toxic side-effects. AzUR also causes sharp reduction of the uridine kinase activity in *vaccinia* viruses. *Mycosis fungoides* (apparently a form of skin cancer) is completely healed with AzUR. Mention must also be made of the antiseptic, antiepileptic, and abortive actions of this compound. Administration is by intravenous injection, the blood level of the antimetabolite falling to practically nil within four hours. With 2,3,5-triacetyl-AzUR a high blood level can be maintained for a longer period after oral administration.

*H. Kaufman* spoke on his clinical experience in the treatment of *Herpes simplex* ceratitis of the eyes using IUDR. He indicated that there were many compounds which destroyed viruses in cultures. However, this was mostly a matter of specific anticulture activity, and these compounds have no therapeutic interest. Earlier work on folic acid antagonists was unsuccessful as they only worked if they were already present before the virus infection. On the other hand, destruction of the virus without simultaneously killing the host cell is hardly conceivable. The search for a compromise acceptable from all points of view calls for combined scientific efforts.



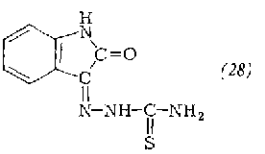
*Kaufman* dealt further with the mechanism of IUDR action, stating that this compound is apparently not incorporated as a false constituent into virus DNA. Thus, for example, cytosine acts in a similar fashion to IUDR and is not incorporated into DNA. On the other hand, 5-fluorodeoxyuridine (FUDR) has no inhibitory effect on virus development. It is known that cytosine arabinoside and cytidine inhibit the phosphorylation of deoxycytidine in the cell. From this and other considerations, the action of IUDR, and also to a lesser extent of BUDR and CUDR, is to be sought in the possible specific inhibition of phosphorylation of nucleosides and of nucleotide polymerization.

This view was supported by *A. D. Welch*, who mentioned that AzUR acts via its 5'-phosphate to block the phosphorylation of orotic acid or the decarboxylation to give uridylic acid. FUDR inhibits the conversion of deoxyuridine monophosphate into thymidine monophosphate, and IUDR inhibits the incorporation of thymidine monophosphate into DNA. From these findings, virus chemotherapy with two combined antimetabolites seems especially promising. The combination of IUDR and FUDR and to a lesser extent of IUDR and AzUR in the treatment of *Herpes simplex* syndromes yields a considerable increase in activity. Thus, the activity of IUDR can be increased almost one-hundredfold by addition of FUDR.



Another substance, which was successfully used for the inhibition of viruses, is the amino acid analogue, *p*-fluorophenylalanine.

*G. E. Boxer*, Rahway, N.J. (U.S.A.), indicated the possibility of using a hydroxylamine derivative HO–NH–CH($CH_3$)–COOH to inhibit the synthesis of AMP in the cell in a competitive fashion.



In conclusion, *K. Herzberg*, Frankfurt (Germany), recalled his earlier experiments on the inhibition of *vaccinia* virus in rabbit skin with metal salts plus dyes. Methylene blue with silver salts seemed especially suitable, the metal salt being absolutely essential. His impressive color slides showed that complete inhibition of the virus infection and healing of the erythema were obtained by this treatment. Since the process takes place under the skin of the animal and the animals were kept in the dark, the influence of visible light on the course of the cure was eliminated.

*(27a)*

*(27b)*

*(28)*

The World Health Organisation is at present preparing large scale experiments which are to be carried out in India with the object of investigating the chemotherapy of virus diseases on a broad front. Compounds which are to be used in particular are 6-azauridine *(27a)*, 5-iododeoxyuridine *(27b)*, and isatin thiosemicarbazone *(28)*.

# Joint Meeting of Swiss and Austrian Chemists

## Innsbruck (Austria), October 3rd–5th, 1963

From the proceedings:

### Chemical Investigation of Interferon

*G. Bodo* and *C. Jungwirth*, Vienna (Austria)

Two interferon preparations produced by different virus strains (Influenza A MEL and Influenza B LEE) in chorioallantoic membranes of hen's eggs were subjected to an initial purification [1]. The behavior of the two preparations during column chromatography on sulfoethylcellulose at pH 2.0 and on DEAE-cellulose at pH 6.6 and 4.5 was quite identical. Starch-gel electrophoresis of the purified preparations yielded several protein bands. On account of the adsorption of interferon onto starch gel, it was not possible to elute the biologically active components. It was evident that this method of purification did not yield pure interferon preparations.

Effective purification was obtained by column chromatography on Sephadex G-100 of preparations subjected to preliminary purification. The molecular weight of the interferon was estimated by comparing the position of the maximum of biological activity in the elution pattern with the elution behavior of pure proteins. On this basis, the main components of both preparations were found to have molecular weights between 25000 and 35000. This relatively low molecular weight is in contrast to earlier determinations (*Burke* [1]: 63000) and agrees with recent data obtained with the ultracentrifuge (*Lampson* et al. [2]: 20000–34000; *Rotem* et al. [3]: 20000–25000).

## Five- and Seven-Center Fragmentation of γ-Oximino Ketones

*C. A. Grob, W. Eisele,* and *E. Renk,* Basel (Switzerland)

γ-Oximino ketones (see Reaction a) are ethylogues of α-oximino ketones (see Reaction b), the *p*-toluenesulfonic esters (tosylates) of which are decomposed by hydroxide ion to give an acid, a nitrile, and tosylate ion. While the second fragmentation reaction (b) involves five atomic centers, seven centers participate in the fragmentation of the γ-tosyloximinoketones (a), which give an olefinic fragment in addition.

In order to test whether the originally hypothetical reaction (a) was actually possible, the *p*-toluenesulfonic esters of 1-oxo-5-oximino-*trans*-decalin [*(1)*, R = H] and its 9-methyl derivative [*(1)*, R = $CH_3$] were prepared and treated with a number of bases in aqueous ethanol. The tosyl oximino compound *(1)*, where R = H, reacted with strong bases such as potassium t.-butoxide to give 2-(γ-cyanopropyl)cyclohexen-2-one *(4)* by 5-center fragmentation of the mesomeric anion *(3)*. With hydroxide and cyanide ions, 7-center fragmentation to give 9-cyano-5-nonenoic acid [*(6)*, R = H] also occurred to a small extent. With the 9-methyl derivative [*(1)*, R = $CH_3$], which cannot undergo the competing 5-center fragmentation because of the absence of a hydrogen atom on C-9, hydroxide ion effected as major reaction the desired 7-center fragmentation to 9-cyano-6-methyl-5-nonenoic acid [*(6)*, R = $CH_3$].

In the absence of base, both γ-tosyloximino ketones [*(1)*, R = H or $CH_3$] undergo only Beckmann rearrangement to the lactams [*(2)*, R = H or $CH_3$]. Both the 5- and 7-center fragmentations are thus base-induced, indicating the occurrence of the anionic intermediates *(3)* and *(5)*.

## The Behavior of Some Indicators in Aprotic Solvents

*V. Gutmann* and *H. Hubacek,* Vienna (Austria)

A number of indicators, chiefly those of the sulfophthalein class, give reversible color changes in phosphorous oxychloride, thionyl chloride, and acetyl chloride which are determined by the activity of the chloride ions of the solution. In acidic media, which are poor in chloride ion, these indicators are red, whereas in basic media, which are rich in chloride ion, they are yellow. The absorption spectra are independent of the nature of the chloride ion acceptor or the chloride ion donor and show the same characteristics as those in aqueous medium. The indicators react in phosphorous chloride such that two phenolic hydrogen atoms are replaced by $[POCl_2]$-groups (formation of a symmetrical molecule). In basic medium, a $[POCl_2]$-group is split off with reformation of undissociated $POCl_3$ (formation of an asymmetrical molecule).

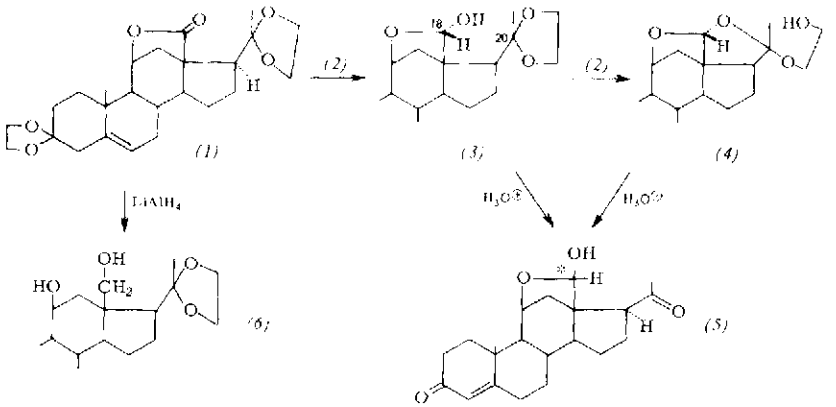
Crystal violet gives reversible color changes not only in the acid chlorides mentioned but also in solvents which do not normally ionize, such as acetone or acetonitrile. Chloride ion acceptors, such as $SbCl_5$, are thereby coordinated directly at the amino nitrogen, and this group is simultaneously blocked thus giving rise to the spectrum of malachite green and finally to that of the triphenylcarbonium ion. On adding chloride ions, the color change takes place in the opposite direction since the formation of a chloro-complex is favored by the appropriate donation of chloride ions.

## Polymerization of Germanic Acid

*J. Haas, Nelly Konopik, F. Mark,* and *A. Neckel,* Vienna (Austria)

To elucidate the polymerization behavior of germanic acid in aqueous solution, high-precision potentiometric titrations were carried out on 0.00159 -0.02388 M solutions of germanic acid at 25 °C and constant ionic strength (0.5 M $NaClO_4$), using a glass electrode. The Ge concentration was kept constant during a given titration.

A special measuring method made it possible to obtain hydrogen ion concentrations from the measured potentials. The concentration of free germanic acid, which could not be determined experimentally, and the total concentration of complex molecules were calculated. These data make it possible to evaluate the number of hydroxyl groups taken up per Ge atom, as well as the mean charge of the complexes and the mean degree of polymerization. These values indicate that only a few combinations of complexes carrying different amounts of negative charge and having different degrees of polymerization are probable. The combination which best reproduced the experimental results was selected from these by the least-squares curve fitting method, using an electronic computer. The mathematical analysis gave the following results: in solutions of concentration greater than 0.004 M, the undissociated monomeric species $Ge(OH)_4$, and the monomeric ions $GeO(OH)_3^-$ and $GeO_2(OH)_2^{2-}$ are accompanied by a polymeric anion containing eight Ge atoms and carrying a charge of −3. The



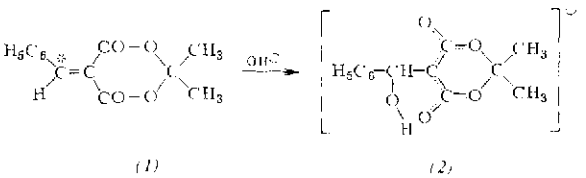
following equilibrium reactions and constants were determined:

$$Ge(OH)_4 + OH^- \rightleftharpoons GeO(OH)_5^- + H_2O \quad \log K_{11} = 4.71_1 \pm 0.002$$
$$Ge(OH)_4 + 2\,OH^- \rightleftharpoons GeO_2(OH)_2^{2-} + H_2O \quad \log K_{21} = 6.00 \pm 0.25$$
$$8\,Ge(OH)_4 + 3\,OH^- \rightleftharpoons (Ge(OH)_4)_8(OH)_3^{3-} \quad \log K_{38} = 29.55 \pm 0.01$$
$$-\log K_W\ (0.5\ M\ NaClO_4) = 13.72 \pm 0.01$$

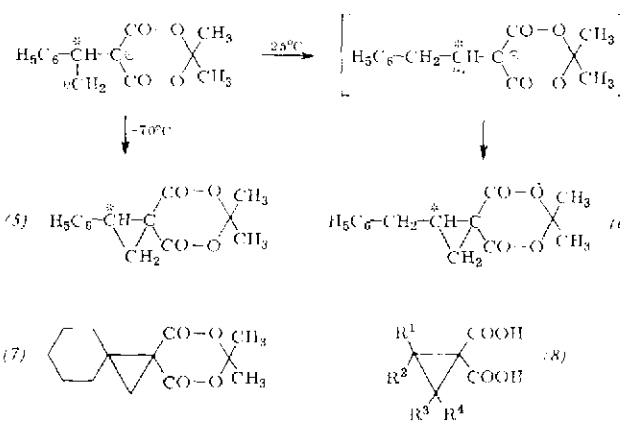
## A Novel Intramolecular Displacement Reaction

*J. Schmidtlin* and *A. Wettstein*, Basel (Switzerland)

When the strongly hindered lactone *(1)* is reacted with a quarter of a mole equivalent of lithium aluminum hydride in tetrahydrofuran, mainly full reduction to the diol *(6)* occurs, thus leaving about half the amount of the starting material unchanged [1]. Thus, the desired cyclohemiacetal *(3)* is formed as a by-product only. However, if the reduction of *(1)* is carried out with diisobutyl aluminum hydride $(i\text{-}C_4H_9)_2AlH$ *(2)* or triisobutyl aluminum [2] in toluene at −20 °C, the hitherto difficultly accessible cyclohemiacetal *(3)* is produced in excellent yield.



The reduction of the lactonic carbonyl group in *(1)* with *(2)* proceeds stereospecifically as shown by the subsequent conversion of *(3)* into the hydroxyethyl ketal *(4)* in the reaction solution even at room temperature. The molecular models reveal that such a transformation requires *(3)* to have the *(18S)*-configuration. As expected, both compounds *(3)* and *(4)* are smoothly deketalized by acid hydrolysis to the diketocyclohemiacetal *(5)* with still unknown configuration at C-18. Prerequisites for the aprotic intramolecular displacement reaction *(3)* → *(4)* are the immediate proximity of hydroxyl oxygen and C-20 and the presence of a Lewis acid, such as the diisobutyl aluminum cation which can form a complex with one of the ketalic oxygens. The structures of the isomeric compounds *(3)* and *(4)* and the corresponding *O*-acetyl derivatives have been confirmed by their proton resonance spectra.



## A New Class of Acidic Compounds and Their Use in the Synthesis of Cyclopropane Derivatives

*F. Wessely* and *A. Eitel*, Vienna (Austria)

Condensation of aldehydes or ketones with cyclic acylals affords compounds, *e.g. (1)*, which can be titrated in aqueous methanol as monobasic acids. On acidification of the alkaline solution, compound *(1)* is recovered almost quantitatively. It contains no active hydrogen. Formulation of the anion present in the alkaline solution as structure *(2)* agrees with quantummechanical calculations made by *O. E. Polansky*. In addition to *(1)*, analogous compounds were synthetized with various ketones, *e.g.* with cyclopentanone *(3)* or cyclohexanone *(4)*. All can be titrated as monobasic acids.

Solutions in ether of *(1)*, *(3)*, and *(4)* react vigorously with diazomethane without a catalyst, with evolution of nitrogen. However, this reaction does not yield pyrazoline compounds, which might be expected on the basis of the α,β-unsaturated ester constitution of *(1)*. Instead, *(1)* yields the cyclopropane derivatives *(5)* and *(6)* at −75 and 25 °C, respectively. These were characterized by synthesis of the two compounds by another route, and by degradation experiments using $^{14}C$-labelled *(1)*. These experiments also showed that after addition of the first methylene group onto *(1)*, migration of the phenyl anion leads to a new electrophilic centre which reacts further with diazomethane to give the cyclopropane derivative *(6)*. The formation of *(7)* from *(3)* is explained in a similar manner.

Other diazoalkanes, *e.g.* dimethyldiazomethane and diazoacetic ester, also react with *(1)* to give analogous compounds. Since the primary reaction products of the diazoalkanes can be hydrolysed to the corresponding cyclopropane-1,1-dicarboxylic acids, it is in principle possible to use cyclic acylals and the described reaction sequence to prepare compounds of general structure *(8)*, which can naturally be further altered by known methods.

## New Types of Low Molecular-Weight Heterosiloxanes

*H. Schmidbaur*, Marburg (Germany)

Low molecular-weight model substances of well-defined composition were prepared for the first time in connection with an investigation of the principles of structure and bonding in heterosiloxanes. Examples of such compounds are $R^1_3SiOXR^2_3$, $(R^1_3SiO)_2XR^2_2$, $(R^1_3SiO)_3XR^2$, and $(R^1_3SiO)_4X$, where X = Si, Ge, Sn, or Pb, $R^1 = CH_3$ or $C_2H_5$, and $R^2 = CH_3$, $C_2H_5$, *etc.* Specific heterolytic cleavage reactions with Lewis acids or nucleophilic reagents, as well as infrared and NMR spectroscopic examinations carried out on such heterosiloxanes have shown that, within the Si–O–X grouping, the X–O– bond invariably possesses the greater polarity and the lower proportion of π-bond character. In particular, the regular changes in the chemical shifts and the coupling constants of the NMR spectra demonstrate that this polarization is in accordance with $\rightarrow Si-O \leftarrow X \leftarrow$ and increases regularly in the order X = Si < Ge < Sn < Pb. This result is thus in contradiciton to the assumption that the electronegativities of these elements alternate [1]. The NMR spectra have particularly high numbers of peaks as a result of the presence of the magnetically active isotopes $^1H$, $^{13}C$, $^{29}Si$, $^{117}Sn$, $^{119}Sn$, and $^{207}Pb$.

Heterosiloxanes of the trivalent elements of group V of the periodic table, which are of the general type $R^1_3SiOYR^2_2$ (Y = P, As, or Sb) with a lone pair of electrons on the heteroatom, are very sensitive to hydrolysis and oxidation and belong to the thermally least stable types of heterosiloxanes. Derivatives of the same elements in the pentavalent state $[R^1_3SiOYR^2_4$ and $(R^1_3SiO)_2YR^2_3]$ on the other hand exhibit high thermal stability (in particular if Y = Sb).

Heterosiloxanes of the elements of group III, $R^1_3SiOZR^2_2$ (Z = Al or Ga), with an electron deficiency on the hetero-atom occur exclusively in the dimeric form. The planar four-membered ring systems *(1)* exhibit comparatively high thermal and chemical stability on account of the stabilization which is possible with this arrangement.

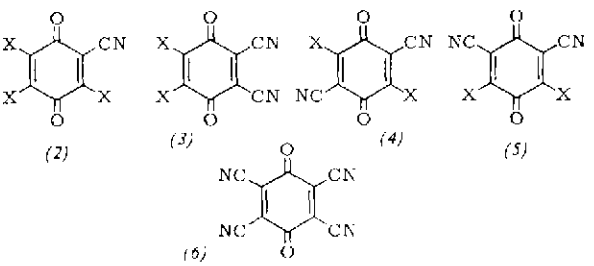
## Recent Developments in Cyanocarbon Chemistry

*K. Wallenfels*, Freiburg/Breisgau (Germany); experimental work with *G. Bachmann*, *H. Diekmann*, *K. Friedrich*, *D. Hofmann*, and *R. Kern*

1. *Dihydropyridines and Tetracyanoethylene*: Reduced diphosphopyridine nucleotide (DPNH) and model compounds (PyH) reduce tetracyanoethylene (TCNE) to the radical anion $TCNE^{\cdot\ominus}$, which can be detected and determined quantitatively by its characteristic "coxcomb spectrum", which contains twelve maxima between 350 and 500 mμ. The intensity of this absorption depends upon the apparent redox potential of the corresponding $Py^{\oplus} \rightleftharpoons PyH$ system [2]. The transient deep coloration which occurs on mixing PyH with TCNE can be explained by the formation of a charge-transfer complex. The reduction to a radical is interpreted as a hydride-ion transfer. This leads to $TCNEH^{\ominus}$, which equilibrates with TCNE.



$$TCNEH^{\ominus} + TCNE \rightleftharpoons 2\,TCNE^{\cdot\ominus} + H^{\oplus}$$

This system is the aliphatic analogue of a quinone/hydroquinone equilibrium for which the high stability of the semiquinone stage is characteristic. Treatment of PyH with 4 moles of TCNE in acetonitrile and subsequent dilution with water yield crystalline pyridinium pentacyanopropenide *(1)* in approx. 90 % yield.

*(1)*

2. *Cyanoquinones*: Of the six possible cyano-substituted benzoquinones, the compounds *(2)*–*(6)*, where X = Cl, Br, I, OH, or OR, were synthetized. The electron affinity of the halogeno- or hydrogeno-substituted compounds increases with increasing substitution by CN; the dissociation of the hydroxylated quinones and hydroquinones increases correspondingly.

*(2)* *(3)* *(4)* *(5)* *(6)*

3. *Cyanoarenes*: Similar changes in the physical properties are found with increasing substitution of the benzene ring with cyano groups. Pentacyanotoluene shows high C–H acidity; it forms a deep blue anion which is unstable in the presence of water. The pyrene complexes of tetracyano-*m*-xylene, pentacyanotoluene, and hexacyanobenzene [3] are yellow, red, and blue-green, respectively (color of solution in acetonitrile). In a differential thermoanalysis, hexacyanobenzene was found to be stable up to 475 °C. It sublimes rapidly without decomposition at this temperature.

[Organic Chemistry Colloquium, Universität Basel (Switzerland), November 29th, 1963] [VB 772/115 IE]

German version: Angew. Chem. *76*, 275 (1964)

## Electron Spin Resonance Measurements on Irradiated Bacteriophages and Their Nucleic Acids

*A. Müller*, Karlsruhe (Germany)

Bacteriophages are particularly suitable for studying radiation damage because of their primitive organization, high nucleic-acid content, and great sensitivity to radiation. Radicals were produced in dry bacteriophages and nucleic acid prepared therefrom, by irradiation with X-rays (50 kr/min) or γ-rays ($^{60}Co$; 10 krep/min) and examined qualitatively and quantitatively by means of their ESR absorption spectra; the results were compared with measurements on phage proteins and nucleic-acid components (nucleotides, nucleosides, free bases).

In whole phages of strains T1 and T2, radicals which show different ESR-spectral types are produced in high yield (G = 2–10) by irradiation. Radicals are formed in comparable yield from T2-phage nucleic acids and give ESR spectra which correspond to those observed in whole phages. The radical concentration in irradiated phage nucleic acid increases with dose according to an exponential function up to a saturation value lying between $10^{18}$ and $10^{19}$ radicals/g (63 % of the saturation concentration is reached after doses of 0.4–1.4 Mr).

[1] Cf. also *H. Schmidbaur*, Lecture delivered at the VII. European Congress on Molecular Spectroscopy, Budapest 1963, Abstract p. 86.

[2] *K. Wallenfels*, *H. Diekmann*, and *F. Kuhowitz*, Liebigs Ann. Chem. *621*, 174 (1959).

[3] *K. Wallenfels* and *K. Friedrich*, Tetrahedron Letters *1963*, 1223.

The radicals of the T2-protein are equal in concentration and spectral frequency to those of other sulfur-free proteins (*e.g.* gelatin). D-2-Deoxyribose gives a radical yield of G = 4. The radicals produced in the nucleosides do not show a spectrum typical of D-2-deoxyribose, but spectra which are similar to those of the free bases.

Whilst the radical yield of irradiated nucleotides corresponds to that from nucleic acids (G = 2–15), the radical yield in the case of irradiated nucleosides is less (G = 0.4–1.0) and still smaller in the case of the pure nucleic-acid bases (G = 0.1 to 1.0). The radical yield increases particularly strongly on passing from thymine via thymidine to thymidine-5-monophosphate. Directly after irradiation, the spectrum of the phosphate, like that of thymine, has a large number of lines, but on keeping changes into a quartet, which appears very like that of stored nucleic acid.

The radical concentrations in the bases, nucleosides, and nucleotides show a similar dependence on the radiation dose as those in the nucleic acid and all the other substances investigated. It is probable that the primary radiation damage occurs at the thymine unit of the nucleic acid.

## Investigations on Highly Substituted Glycols

*H. H. Inhoffen*, Braunschweig (Germany)

Birch reduction of 3,4-di-*p*-anisylhexane-3,4-diol gives a bis-enol-ether which is converted into *(1)* by mild treatment with acid. The reaction of *(1)* with alcoholic sulfuric acid affords a mixture from which a racemate of molecular formula $C_{18}H_{22}O_2$, m.p. 70–71 °C, and with ultraviolet maxima at $\lambda = 303$ mμ, $\varepsilon = 19000$, and $\lambda = 224$ mμ, $\varepsilon = 14300$, can be isolated in 30 % yield. This compound was shown to have the *spiro*-ketone structure *(2)*.

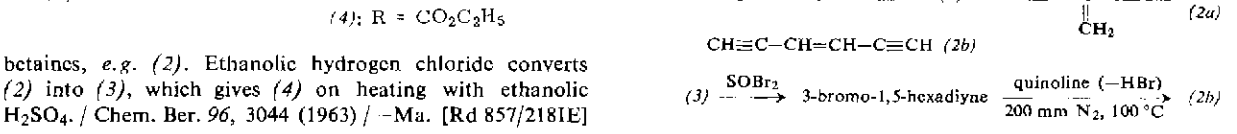
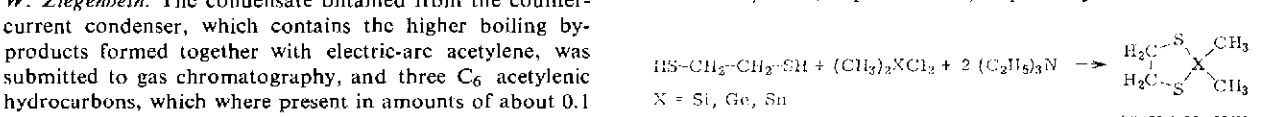
# SELECTED ABSTRACTS

**Tetracyanoethylene oxide** has been synthetized by *A. Rieche* and *P. Dietrich*. Tetracyanoethylene reacts with hydrogen peroxide in ether at room temperature to give tetracyanoethylene oxide *(1)*, m.p. 174 °C (sealed tube), in quantitative yield. Compound *(1)* is also formed from tetracyanoethylene and alkyl hydroperoxides in warm benzene. Hydrolysis of *(1)* readily affords a black product (polymeric hydrocyanic acid). With pyridine bases, *(1)* forms crystalline pyridinium



*(1)* *(2)* *(3)*: R = CN; *(4)*: R = $CO_2C_2H_5$

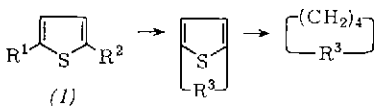
betaines, *e.g.* *(2)*. Ethanolic hydrogen chloride converts *(2)* into *(3)*, which gives *(4)* on heating with ethanolic $H_2SO_4$. / Chem. Ber. *96*, 3044 (1963) / –Ma. [Rd 857/218IE]



**The most potent animal venom known** is found in the skin of the Columbian arrow-poison (kokoi) frog *Phyllobates bicolor*. *F. Märki* and *B. Witkop* found that 0.05 γ of the 60-fold enriched poisonous principle was sufficient to kill a mouse of 10 g weight. The poison is a chloroform-soluble base with a mol. weight of 399240. Molecular weight and elemental composition have recently been determined on a sample of only 40 γ with the aid of a double-focussing mass spectrometer. / Experientia *19*, 329 (1963) / W. [Rd 794/214 IE]

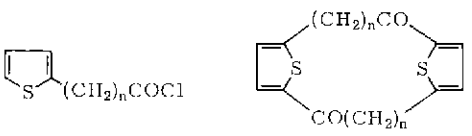
**The isolation, identification, and synthesis of isomeric hexene-diynes from electric-arc acetylene** is reported by *T. Böhm-Gössl*, *W. Hunsmann*, *L. Rohrschneider*, *W. M. Schneider*, and *W. Ziegenbein*. The condensate obtained from the counter-current condenser, which contains the higher boiling by-products formed together with electric-arc acetylene, was submitted to gas chromatography, and three $C_6$ acetylenic hydrocarbons, which where present in amounts of about 0.1 to 1.0 %, were isolated. Ultraviolet, infrared, and mass spectra showed that triacetylene was present. The main component (1.3 %) ($\lambda_{max}$ = 270, 255, and 242 mμ) had a mass spectrum corresponding to $C_6H_4$. It contained a vinyl double bond in conjugation with an acetylenic bond, a central and a terminal acetylenic group, and two types of protons, bound to doubly and triply bonded carbon. The ratio of acetylenic to olefinic protons was 1:3 and corresponds to the formula of 1-hexene-3,5-diyne *(1)*. The NMR spectrum excludes all other possible constitutions. The third $C_6$ acetylene (0.1 %) was separated on polypropylene glycol as stationary phase. Structures *(2a)* and *(2b)* were possible according to infrared and mass spectra. Compound *(2a)* was synthetized from 1,4-pentadiyne-3-ol, and *(2b)* from 1,5-hexadiyne-3-ol *(3)*. The results obtained indicated that *trans*-3-hexene-1,5-diyne *(2b)* is present in electric-arc acetylene.

*cis*-3-Hexene-1,5-diyne could not be isolated from crude acetylene. It may occur in traces and be removed with the triacetylene during gas chromatography. / Chem. Ber. *96*, 2504 (1963) / –Ma. [Rd 791/210 IE]



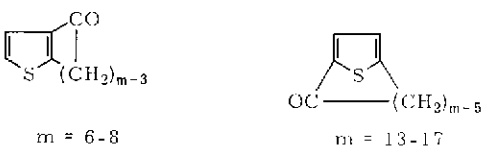
**Five-membered heterocyclics containing Si, Ge, or Sn,** and sulphur in the ring have been synthetized by *M. Wieber* and *M. Schmidt*, who have previously built up the corresponding six-membered rings. Dithioglycol reacts with equivalent quantities of triethylamine and dimethylchloro-silane, -germane, and -stannane in boiling benzene to form 2,2-dimethyl-2-sila-1,3-dithiacyclopentane, b.p. 75–77 °C/12 mm, 2,2-dimethyl-2-germa-1,3-dithiacyclopentane, b.p. 87–93 °C/12 mm, and 2,2-dimethyl-2-stanna-1,3-dithiacyclopentane, b.p. 113–115 °C/5 mm, m.p. 82–83 °C, respectively.

Yields are satisfactory. The compounds have unpleasant odors and are rapidly decomposed by hot water. / Z. Naturforsch. *18b*, 846 (1963) / –Ma. [Rd 789/207 IE]



**A new metalating agent** – **naphthalene magnesium** – is reported by *C. Ivanoff* and *P. Markov*. When Mg powder and naphthalene are stirred together vigorously in liquid $NH_3$, a green color is produced, which is intensified by addition of ether, with simultaneous dissolution of the Mg. The solution is decolorized by the addition of ethanol, and 1,4-dihydronaphthalene, m.p. 24–25 °C, can then be isolated from the mixture. This decomposition reaction suggests the formation of naphthalene magnesium, which can be used as a metalating agent in a manner analogous to naphthalene sodium. It reacts with compounds containing activated methylene groups, such as benzyl cyanide, from which one obtains α-phenylbutyronitrile, b.p. 122–123 °C, on subsequent treatment with ethyl iodide. Metalation of ethyl phenylacetate in absolute benzene instead of in ether leads to the formation of ethyl α,γ-diphenylacetoacetate, m.p. 77.5–78.5 °C, in 61 % yield. / Naturwissenschaften *50*, 688 (1963) / - Ma. [Rd 790/209 IE]

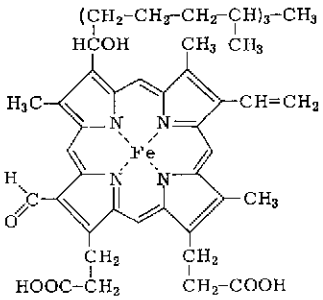
**Syntheses of higher alicyclic systems** were achieved by *Ya. L. Goldfarb, S. Z. Taits*, and *L. I. Belenskii*, starting with thiophene derivatives such as *(1)*. A ring was formed from substituents $R^1$ and $R^2$, *e.g.* by acyloin condensation with Na/K alloy at only 50–60 °C. The sulfur bridge of the resulting bicyclic thiophene derivative was removed with Raney nickel.



*(1)*

2,5-Dialkylthiophenes with ester groups in the 3- or 4-positions of the alkyl chains are particularly suitable for the acyloin condensation. Ring closure of *(1)* is also favored when $R^1$ = $C_2H_5OOCCH_2CO$ and $R^2$ = $(CH_2)_nHal$. Acid chlorides, such as *(2)*, form mono- and diketones as well as polymeric condensation products with Na/K.

*(2)*, n = 3-12 *(3)*, n = 5-9



m = 6-8 m = 13-17

A sulfur-free diketone with 28 carbon atoms was made from *(3)* with n = 9. / Tetrahedron *19*, 1851 (1963) / –Kr. [Rd 846/215 IE]

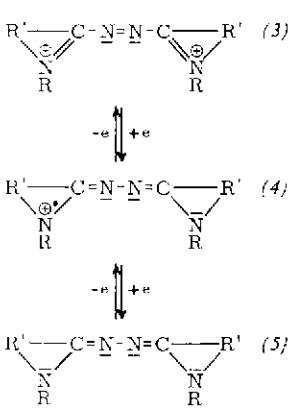
**A new method for identifying substances by gas chromatography** has been developed by *J. Franc* and *S. Michajlova*. The sample for analysis is distributed simultaneously to four columns which are charged with different stationary phases. The gas streams from the four columns pass into a common detector connected to a recorder which prints the elution curves of the four columns in the form of spectra. In the ideal case, *i.e.* when the retention times of the four columns are different, a 'spectrum' is obtained with four maxima. The substance can then be identified by comparison with standard chromatograms. The following stationary phases have proved especially useful: the 3,5-dinitrobenzoyl ester of trimethyleneglycol butyl ether, polyethyleneglycol adipate, Silicone Elastomer E 301 (Griffin & George, London), and distillation residues of methylphenylsilicone oil. / 4th Symp. on Gas Chromatography, Leuna (Germany) 1963, Abstracts p. 32 / –Ko. [Rd 795/211 IE]

**The constitution of cytohaemin,** whose importance in cell respiration has been known for some time, has been elucidated by *M. Grassl, U. Coy, R. Seyffert*, and *F. Lynen*. Cytohaemin *(1)*, was isolated from beef hearts in the form of its hydrochloride and was converted into cytoporphyrin by hydrogenation with $H_2$/Pd in HCOOH. The degradation products resulting from oxidation of cytoporphyrin with $CrO_3$ were haematinic acid, methylethylmaleimide, and a lipophilic maleimide that is identical with recently synthetized methyl-(5,9,13-trimethyltetradecyl)maleimide [b.p. 167–171 °C/ $10^{-5}$ mm (oil bath), $n_D^{20}$ – 1,4835]. Methylethylpyrroledicarboxylic acid is obtained by oxidation of *(1)* with $KMnO_4$.

*(1)*

The nature of the degradation products and the mass-spectrometric and gas-chromatographic determinations carried out on them, together with spectroscopic data and the findings of other authors, indicate that *(1)* is the structural formula for cytohaemin. / Biochem. Z. *338*, 771 (1963) / –De. [Rd 793/213 IE]

**New free radical ions** were obtained by *S. Hünig, H. J. Friedrich, D. Scheutzow*, and *W. Brenninger*. It is known that a substance with an odd number of methine groups between key atoms X *(1)* has maximum delocalization of its π-electrons. This condition is also achieved with an even number of methine groups if the system *(2)* has free-radical character.



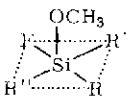
*(1)*

*(2)*

X = –N, –S–, –O–

Application of these facts led to the synthesis of new, stable free radical ions with, for example, 2-benzthiazolyl, 2-pyridyl-, 4-quinolyl, and 9-acridyl substituents according to the general formula *(3)* + *(5)* ⇌ 2 *(4)*.

*(3)*



*(4)*

*(5)*

Some results in recent publications can also be explained by assumption of stable radical ions [1]. / Tetrahedron Letters *1964*, 181 / –Kr. [Rd 847/216 IE]

[1] *M. Fraser* and *D. H. Reid*, J. chem. Soc. (London) *1963*, 1421.

**The racemization of an optically active fluorosilane** was investigated by *L. H. Sommer* and *P. G. Rodewald*. Optically active methyl-α-naphthylphenylfluorosilane ($R_3Si^*F$) is quickly racemized when methanol is added to its solution in pentane or t-butanol. The racemization is not caused by traces of HF, for additions of HF retard the reaction, nor is it due to the formation of $F^\ominus$ ions by ionization of the $R_3Si^*F$, for the racemization is slower in the strongly polar solvent formic acid than in the weakly polar one pentane. The methoxy derivative $R_3Si^*OCH_3$ does not occur as an intermediate, for in a mixture of $R_3Si^*F$ and $R_3Si^*OCH_3$ only the former is racemized. The reaction is of the first order with regard to $R_3Si^*F$, and of about the fourth order with regard to $CH_3OH$. An intermediate that corresponds to these observations is the pentacovalent anion *(1)*, which is

*(1)*

formed by addition of the $CH_3O^\ominus$ ion (present in the methanol owing to dissociation) to $R_3Si^*F$. Displacement of the $CH_3O$ ligand from *(1)* is much faster than the alternative reaction to form $R_3Si^*OCH_3$ by elimination of $F^\ominus$, for after the time required to complete racemization, the methoxy compound could not be found in the reaction mixture. The formation of a hexacovalent intermediate is also possible, though less likely. / J. Amer. chem. Soc. *85*, 3898 (1963) / –Ko. [Rd 851/217 IE]

**Porous glasses as stationary phases in adsorption gas chromatography** were investigated by *Ya. I. Yaschin*, *S. P. Zhdanov*, and *A. V. Kiselev*. The porous glasses obtained by treatment of alkali borosilicate glasses with acids and water are characterized by a uniform pore structure which can be modified by the composition of the starting glass and by the leaching conditions. Moreover, the surface of porous glasses may be easily chemically modified. Glasses with very fine pores (pore diameter ≈ 10 Å) act as molecular sieves and permit the separation of low boiling gases. Glasses of average pore diameter 30 to 100 Å are suitable for the analysis of low boiling gases and vapors, *e.g.* light hydrocarbons. Large-pore glasses (pore diameter 300–500 Å) can be employed for the separation of liquids with boiling points of up to about 200 °C. / 4th Symp. on Gas Chromatography, Leuna (Germany) 1963, Abstracts p. 402 / –Ko. [Rd 796/212 IE]

# BOOK REVIEWS

**Thermodynamische Elektrochemie** (Thermodynamic Electrochemistry). By *Erich Lange* and *H. Göhr*. Alfred Hüthig Verlag GmbH., Heidelberg 1962. 1st Edit., 429 pp., 193 figs., clothbound, DM 39.–.

There are textbooks where the voice of Science herself seems to be heard, and others which make the reader believe, that he is constantly face with the author. The present book is of the latter kind. It was evolved from *E. Lange*'s famous article in Vol. 12 of the Handbuch der Experimentalphysik (Handbook of Experimental Physics). Here we are confronted with the outcome of decades of discussions between the author and his students, in an attempt to put electrochemistry on a firm footing of systematic thermodynamics. The concept thermodynamics is treated generously, irreversible processes being encompassed as well.

The introduction indicates the proper place of electrochemistry in the system of sciences. The text, composed together with his collaborator of many years standing, *H. Göhr*, begins with a discussion of single phases without and with current-flow. This is followed by treatment of the equilibria of simple electrodes and galvanic cells, and a section on thermocouples. An intermediate chapter describes the principles of "concentration" and "activation" overvoltage. The main part of the book is formed by the discourse on double and multiple electrodes, single and twofold protective-layer electrodes, including passivity, and by an additional chapter on scrape effects.

The authors frequently repeat in a generalizing manner the relations they have mentioned earlier, but this can only be welcome to the reader. It offers him a chance to get used to the terminology, which differs considerably from the customary jargon, and gradually to comprehend the rigorous system of symbols given here entwined with indices. In an appendix *E. Lange* has recapitulated his views on several general questions, particularly terminology, but not everybody will agree with this.

The book is not easy to read, but every electrochemist will gain a solid foundation for his science from a tussle with it.

**Atomphysik und menschliche Erkenntnis** (Atomic Physics and Human Understanding), by *Niels Bohr*. Series: Die Wissenschaft (Science), Collections of monographs from all fields of natural science. Edited by W. Westphal. Verlag Friedr. Vieweg & Sohn, Braunschweig 1958. 1st Edit. XIII, 104 pp., 8 figs., bound, DM 9.40 (about $ 2.50).

*Niels Bohr*'s essays from the years 1933–57, which are collected in this volume, serve essentially to define the importance of the concept of complementarity introduced by him into physics, and its applicability to other fields of knowledge such as biology, psychology, sociology, and anthropology. Ontologically the concept of complementarity is founded on the trend towards completeness manifested in several ways by reality, a trend which makes it impossible to draw a permanent sharp distinction between subject and object. In biology the notion of complementarity leads to a balance between the mechanistic and vitalistic attitudes. For its application to psychology, *Bohr* points to the complementarity of thought and feeling, particularly between the conscious deliberation on the motives of an action and the experience of an emotion governed by the will. The complementarity of instinct and reason is a frontier common to all the ultraphysical sciences mentioned. Lastly there is a very general level, on which we find the complementarity between the use of any given concept and attempts to define it precisely. It is in this very connection that *Bohr* manifests his sharp consciousness of the possibilities and limitations of all scientific method.

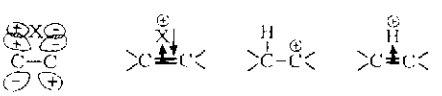
# Polar Addition of Hydrogen Halides onto Olefins [1]

BY PROF. DR. J. S. DEWAR AND DR. R. C. FAHEY [2]

DEPARTMENT OF CHEMISTRY, UNIVERSITY OF TEXAS, AUSTIN, TEXAS (U.S.A.)

*Various structures have been proposed for the intermediates of electrophilic additions onto olefins; these include halonium ions, classical carbonium ions, π-complexes (i.e. non-classical carbonium ions), and π-complexes with back-coordination. It is shown here that it is impossible to use any one of these entities alone to explain all such electrophilic additions; the electrophile itself determines the nature of the transition state formed. Polar addition of hydrogen halides onto olefins appears to proceed via a classical carbonium ion which does not occur as the free ion but as an undissociated ion pair. Various other mechanisms have been excluded by studies reported here of the stereochemical course of such additions.*



Electrophilic addition reactions have long been recognized [3] to proceed via intermediates with the composition of carbonium ions. It is also known that these intermediates, in certain cases at least, are not simple carbonium ions since the reactions are stereospecific, the products being formed by exclusive *trans*-addition onto the olefin. This observation was explained some time ago by *Roberts* and *Kimball* [4] for halogen addition by the assumption that the intermediate is a halonium ion *(1)* rather than a carbonium ion *(2)*; the product is formed by nucleophilic attack on the intermediate with opening of the three-membered ring, and this reaction, in effect an $S_N2$ reaction, takes place by attack of the nucleophile *trans* to the "leaving group", here $X^{\ominus}$.

*(1)* *(2)* *(3)* *(4)* *(5)*

This formulation of the intermediate is, however, open to criticism [5], for it does not explain the orientation of addition onto unsymmetrically substituted olefins (*i.e.* Markownikoff's rule), and one of us accordingly suggested [5] some years ago that the intermediate might be better represented as a π-complex *(3)* in which the filled π-orbital of the olefin is used to form a dative bond by interaction with the empty valence orbital of the acceptor $X^{\oplus}$. This structure is formally analogous to that of an ammonium salt formed by addition of $X^{\oplus}$ to ammonia or an amine; such a complex could be written equivalently as a donor-acceptor complex *(4)* or as an ammonium ion *(5)*.

If the acceptor $X^{\oplus}$ has unshared p- or d-electrons or π-electrons, these can be used to form a reverse dative bond to the olefin by interaction with the empty antibonding π-molecular orbital of the latter *(6)* [6].

*(6)* *(7)* *(8)* *(9)*

The group $X^{\oplus}$ is then attached to the olefin by a double bond composed of two opposed dative bonds involving π-molecular orbitals *(7)*. This structure differs from *(1)* only in the state of hybridization of the olefinic carbon atoms, since the bond between them is only partly double. It is therefore somewhat difficult to distinguish between the two tentative structures *(3)* and *(7)*.

Recent physical evidence [7] indicates that analogous metal complexes, *e.g.* Zeise's salt, are in fact double-bonded π-

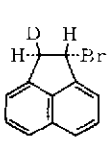
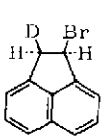
complexes of type *(7)*, the olefinic moiety being coplanar and the carbon atoms multiply linked.

This ambiguity would be avoided if $X^{\oplus}$ were a group without electrons capable of forming a reverse dative bond, for stereospecific *trans*-addition would then indicate very clearly that the intermediate was a π-complex or "non-classical carbonium ion" *(3)*. The study of such reactions is therefore of considerable theoretical interest, both on its own merits and in view of the current controversy concerning the status of such "non-classical carbonium ions" as reaction intermediates. Addition of $X^{\oplus}$ onto an olefin would be expected to give the more stable of the two possible species directly; the course of such reactions should therefore indicate definitely whether or not such "non-classical carbonium ions" or π-complexes *(3)* are more stable than the isomeric classical carbonium ions *(1)*.

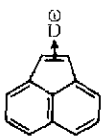


The groups $X^{\oplus}$ that are obviously suitable for this study are carbonium ions or protons; experimental considerations make the latter the more attractive choice. The problem is then to decide whether the electrophilic addition of acids, *e.g.* HBr, onto olefins takes place stereospecifically *trans*; if it does, it may be concluded that classical carbonium ions such as *(8)* are less stable than the isomeric π-complexes such as *(9)*.

It has often been assumed [3] that such additions do take place stereospecifically *trans*, although evidence for this view is somewhat meagre. Hydrogen iodide is known [8] to add *trans* onto certain α,β-unsaturated acids, and *Hammond* and his collaborators [9] have shown that hydrogen bromide adds almost exclusively *trans* onto 1,2-dimethylcyclohexene, and that hydrogen chloride adds predominantly (92 %) *trans* onto 1,2-dimethylcyclopentene. However, these isolated findings cannot be generalized, for there is doubt as to whether the addition reactions of acids are electrophilic in nature, and additions onto cyclic compounds might be subject to conformational effects. We therefore investigated the stereochemistry of the polar addition of hydrogen halides onto olefins where no such complications could arise.

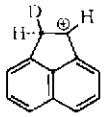


We first examined [10] the addition of hydrogen bromide onto acenaphthylene *(10)*. In order to determine the stereochemistry of the reaction we labelled the atoms isotopically by using deuterium bromide as the reagent.

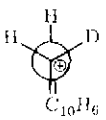


*(10)*

*(11)*



*(12)*



*(13)*

Addition via a π-complex *(13)* should give exclusively *trans*-adduct *(11)*. Addition by a "classical" mechanism would involve a carbonium ion *(14)* which has a plane of symmetry [cf. the Newman projection *(15)*]; if this ion can exist freely in solution, it should combine more or less randomly with bromide ions to give an approximately equimolar mixture of *(11)* and *(12)*. Any difference in the proportions of *(11)* and *(12)* could be due only to secondary isotope effects and would not exceed 10–20 %.

*(14)*

*(15)*

The reaction product was analysed in two different ways, *viz.* by nuclear magnetic resonance, and by elimination. The NMR analysis involved measurement of the splitting of the CHBr proton signal due to interaction with the adjacent CHD proton. The magnitude of this spin-spin splitting should depend on the dihedral angle between the corresponding CH bonds, which is approximately 120° in *(11)* and 0° in *(12)*. The expected splittings, according to *Karplus* [11], are approximately 2 cps and 8 cps, respectively. The difference is thus quite large. The second method of analysis entailed $E_N2$ elimination of HBr or DBr by base (potassium t-butoxide) to regenerate acenaphthylene. Since eliminations from halogenoacenaphthenes are known [12] to take place almost exclusively *trans*, *(11)* should give acenaphthylene free from deuterium, while *(12)* should give acenaphthylene containing one deuterium atom.

The NMR spectrum of the adduct indicated immediately that the reaction was not stereospecific, for the CHBr proton resonance showed four lines, corresponding to the presence of both *cis*- and *trans*-isomers. This interpretation was confirmed by a change in the spectrum with time; the weaker pair of lines increased in intensity at the expense of the stronger, implying gradual conversion of the one isomer into the other. The change was not due to a chemical reaction, for the bromide could be recovered unchanged [*(11)* and *(12)* are of course physically equivalent]. The separations of the pair of lines also corresponded quite closely to *Karplus'* calculations, being 2.7 cps and 6.8 cps, respectively. There seemed therefore little doubt concerning their identification, but much to our surprise it was the pair with $\tau$ – 6.8 cps corresponding to the *cis*-isomer, that was the stronger! Contrary to predictions the reaction had apparently led predominantly to *cis*-adduct. This unexpected conclusion was confirmed by the data from elimination; the recovered acenaphthylene contained nearly one atom of deuterium, showing that the bromide must have been mainly the *cis*-isomer *(12)*.

The proportions of isomeric adducts formed in various solvents were determined quantitatively, by both NMR and elimination. The results are shown in Table 1, together with data for the addition of deuterium chloride. The results of the two methods of analysis always

agreed within the limits of experimental error; some complications arose in the NMR analysis due to long-range couplings with ring protons [13] but these could be eliminated by spin decoupling techniques.

Table 1. Addition of DBr onto acenaphthylene.

| Reagent | Solvent | Temp. [°C] | *cis*-Adduct [*] [%] |
|---|---|---|---|
| DBr | Pentane | −78 | 87 |
| | Pentane | 0 | 89 |
| | $CH_2Cl_2$ | −78 | 84 |
| | $CH_2Cl_2$ | 0 | 85 |
| | DOAc | 25 | 74 |
| DCl | $CH_2Cl_2$ | 0 | 85 |
| | DOAc | 25 | 85 |

[*] In the reaction product before isomerization begins.

We proved that the reactions under our conditions were of the polar rather than of the free radical type by carrying out the addition with HBr in the presence of styrene; free radical additions of HBr involve intermediate bromine atoms, and these would lead to the formation of phenethyl bromide $C_6H_5CH_2CH_2Br$ from the styrene. No trace of this could be detected in the reaction product although this contained large amounts of the "normal" polar adduct $C_6H_5CHBrCH_3$. We also established that the *trans*-isomer formed was a primary reaction product, and was not formed by secondary isomerization, by allowing the reaction mixture to stand for various lengths of time before work-up. The *trans*- → *cis*-isomerization of the bromide was extremely slow; that of the chloride was faster, but we were able to extrapolate the isomer ratios to zero time to find the proportions of *cis*- and *trans*-isomers formed in the initial reaction. These figures are listed in the last column of Table 1. We also demonstrated that the *trans*-isomer was not formed by a concomitant free radical process, for the proportions of *cis*- and *trans*-adducts remained unchanged when the reaction was run under strong illumination. This would have selectively accelerated any free radical processes.

These results showed unambiguously that the addition of hydrogen halides onto acenaphthylene does not involve intermediate π-complexes. However, acenaphthylene is not a typical olefin, and so we extended our studies to indene [14] and *cis*- and *trans*-1-phenylpropene [15]. The stereochemistry of the addition of deuterium bromide onto indene was studied by NMR only, since we could not reconvert 1-bromoindane into indene quantitatively by elimination. The stereochemistry of the adducts obtained from deuterium bromide and the phenylpropenes could not of course be determined by NMR spectroscopy since their molecular skeletons are not rigid; however elimination with potassium t-butoxide converted them quantitatively into mixtures of olefins from which the predominant isomer (*trans*-1-phenylpropene) was separated by gas chromatography. Estimation of the deuterium in this enabled the proportions of isomers in the adduct to be deduced. The results are shown in Table 2.

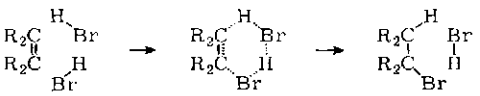

Table 2. Addition of DBr onto indene and *cis*- and *trans*-1-phenylpropene.

| Olefin | Solvent | Temp. [°C] | *cis*-Adduct [%] |
|---|---|---|---|
| Indene | Pentane | −78 | 80 |
| | $CH_2Cl_2$ | −78 | 81 |
| *cis*-1-Phenylpropene | $CH_2Cl_2$ | 0 | 88 |
| *trans*-1-Phenylpropene | $CH_2Cl_2$ | 0 | 88 |

In these experiments it was easy to establish the nature of the addition reactions since the products from radical ("peroxide effect") addition are different from those of polar addition. Indene gave exclusively 1-bromoindane under our conditions, indicating polar addition. The phenylpropenes gave some anti-Markownikoff product (1-phenyl-2-bromopropane) when treated with hydrogen bromide in methylene chloride alone, but this side reaction could be completely suppressed by adding hydroquinone.

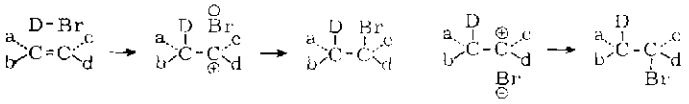
These results show conclusively that the additions of hydrogen halides onto acenaphthylene, indene, and *cis*- and *trans*-1-phenylpropene do not proceed via π-complexes or free carbonium ions as intermediates, for in the former case the products would have been exclusively *trans*-adducts and in the latter case approximately equimolar mixtures of the *cis*- and *trans*-adducts.

One possible mechanism for *cis*-addition would be a Diels-Alder-type mechanism involving a cyclic transition state *(16)*. However this mechanism would be

*(16)*

expected to lead to a second order reaction depending on the concentration of hydrogen halide, whereas the observed order in reactions of this kind is usually three [16]. It would also be impossible to account in this way for the formation of *trans*-adduct as a primary product in proportions which seem to be independent of the concentration of hydrogen halide, because the order with respect to hydrogen halide would certainly differ for *cis*- and *trans*-addition, being necessarily much higher for the latter. The only solution is then to assume different mechanisms for the *cis*- and the *trans*-addition. In this case, the *trans*-addition would have to involve ionic intermediates (*e.g.* π-complexes) and would therefore show a solvent dependence entirely different from that of the non-ionic *cis*-addition. In practice, the proportion of *cis*-adduct was found to change remarkably little with the polarity of the solvent (Table 1), so this mechanism must also be rejected.

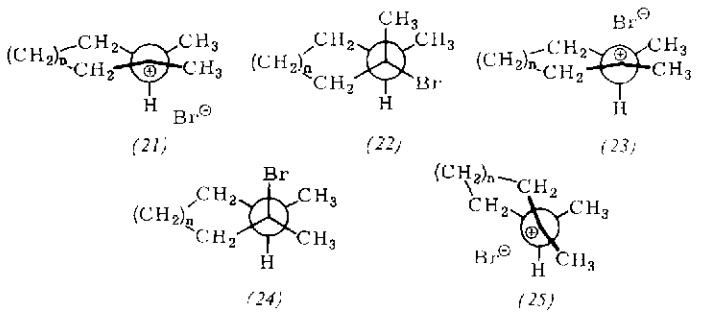
The only remaining possibility is a mechanism in which an intermediate classical carbonium ion is formed, but not as a free ion. This is in fact extremely reasonable;



[13] *M. J. S. Dewar* and *R. C. Fahey*, J. Amer. chem. Soc. *85*, 2704 (1963).

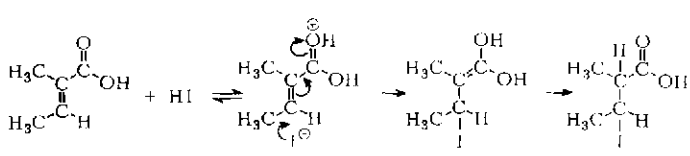
[14] *M. J. S. Dewar* and *R. C. Fahey*, J. Amer. chem. Soc. *85*, 2248 (1963).

[15] *M. J. S. Dewar* and *R. C. Fahey*, J. Amer. chem. Soc. *85*, 3645 (1963).



[16] *F. R. Mayo* and *J. J. Katz*, J. Amer. chem. Soc. *69*, 1339 (1947).

because in the solvents used by us, salts exist mainly as ion pairs, and hydrogen halides are undissociated. The reaction of undissociated deuterium bromide with an olefin should then give first an ion pair in which the bromide ion is retained on the same side of the olefin as the deuterium; collapse of this ion pair *(17)* would give exclusively *cis*-adduct *(18)*. The *trans*-adduct *(20)* is formed only if the ion pair survives long enough for the bromide ion to migrate to the opposite side of the planar carbonium ion *(19)*; if collapse of *(17)* is fast, *cis*-addition will predominate. The probability of isomerization should increase with increasing solvent polarity since this will prolong the life of the intermediate ion pair; the addition of deuterium bromide onto acenaphthylene did infact give increased amounts of *cis*-adduct in less polar solvents (Table 1), but the data for the other reactions were not accurate enough to confirm or refute such a trend. Finally, the high order of the reaction with respect to hydrogen halide can be attributed to solvation; the formation of ions from neutral molecules in a relatively non-polar solvent is a very unfavorable process, and it is very reasonable that solvation of the nascent halide ion by additional molecules of hydrogen halide is needed as a driving force.

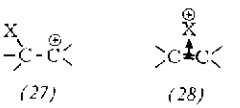


*(17)* *(18)* *(19)* *(20)*

In the reactions studied by us, *cis*-addition predominated; our mechanism can also provide a satisfactory explanation for the *trans*-addition reported by *Hammond* and his collaborators [9] for the additions of hydrogen halides onto 1,2-dimethylcyclohexene and 1,2-dimethylcyclopentene. Here the intermediate carbonium ion is first formed in the conformation represented in Newman projection in *(21)*. Collapse to give the *cis*-adduct *(21)* would then take place through an intermediate configuration in which the methyl groups are

*(21)* *(22)* *(23)* *(24)* *(25)*

eclipsed. This conformational effect should hinder *cis*-addition and encourage isomerization of the primary ion pair to the isomer *(23)*, which can collapse freely to the *trans*-adduct *(24)*. In order to form the *cis*-adduct easily, the initial ion *(21)* would have to isomerize to *(25)*; this isomerization would however be inhibited by the conformational requirements of the remaining carbon atoms in the ring. These requirements are of course less for a five-membered ring than for a six-membered ring; this explains why addition of hydrogen bromide onto 1,2-dimethylcyclohexene gave no detectable trace of *cis*-adduct, whereas 8 % *cis*-adduct was formed in the reaction between hydrogen chloride and 1,2-dimethylcyclopentene. One might also expect *cis*-addition to occur more easily with unsubstituted cyclic olefins, where collapse of the initial ion pair *(26)* involves eclipsing of protons rather than of methyl groups; *Smirnov-Zamkov* and *Piskovitina* [17] reported that the addition of deuterium bromide onto cyclohexene does indeed give large amounts of *cis*-adduct.



*(26)*

The only other example of *trans*-addition of hydrogen halides onto olefins, namely, the reaction of HI and α,β-dimethylacrylic acid, is also easily explained. Hydrogen iodide is a very strong acid, and the carboxyl group has significant basic properties; it therefore seems likely that the addition of hydrogen iodide onto α,β-unsaturated acids is an acid-catalysed Michael (nucleophilic) addition rather than an electrophilic addition. If so, this reaction has no bearing on the mechanism of electrophilic substitution, and the stereochemistry of the product is determined solely by the final prototropic shift. It is easily seen [14] that here steric effects will favor formation of the *trans*-adduct.

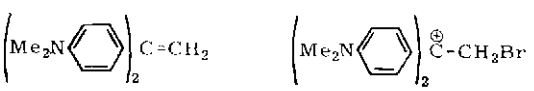
These arguments suggest that the normal course of addition of hydrogen halides onto olefins is a polar electrophilic process involving classical carbonium ions as intermediates and leading mostly, but not exclusively, to *cis*-adducts. A direct corollary would be that classical carbonium ions such as *(8)* are normally more stable than isomeric π-complexes with apical protons *(9)*. The problem is then why some electrophilic additions to olefins take place via π-complexes, while others involve carbonium ions as intermediates.

If we consider the heat of isomerization (ΔH) involved in the transformation of the classical carbonium ion *(27)* to the π-complex *(28)*, we see that in *(27)*, the

*(27)* *(28)*

whole positive charge resides on the carbon; whereas in *(28)*, a part δq of it resides on X. If $E_{C-C}$, $E_{C=C}$, and $E_{C-X}$ are the bond energies of the C–C, C=C, and C–X bonds, $E_\pi$ that of the dative bond in *(28)*, and $I_C$ and $I_X$ the ionization potentials of carbon and X, then:

$$\Delta H = E_{C=C} + E_\pi - E_{C-C} - E_{C-X} + \delta q(I_C - I_X)$$
$$= C + E_\pi - E_{C-C} - E_{C-X} - \delta q \cdot I_X$$



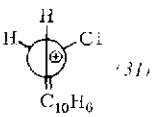
where C is a constant for attack on a given olefin by different reagents X. This equation shows that the π-complex structure will be all the more favored, the

[17] *J. V. Smirnov-Zamkov* and *G. A. Piskovitina*, Ukr. Khim. Zh. *28*, No. 4 (1962), and personal communication from Professor *Smirnav-Zamkov*.

weaker the bond C–X, and the less electronegative X, because the dative bond will be relatively weak, and variations in its (relatively small) bond energy are likely to be relatively unimportant.

To this we must add two further considerations. First, if X has π-electrons, or unshared p- or d-electrons, the π-complex will be selectively stabilized by back-coordination [cf. *(6)* and *(7)*]. Second, the carbonium ion will be selectively stabilized [18] by –E or ±E [18a] substituents, for these will have much smaller effects on the π-complex, as might be expected from their greater charge dispersion and can be demonstrated by molecular orbital calculations.

Now let us consider the experimental facts. Additions involving initial attack by $I^{\oplus}$, $Br^{\ominus}$, or $RS^{\oplus}$ give *trans*-adducts in all the cases that have been studied; the intermediates here are definitely π-complexes or, in the case of $RS^{\oplus}$, the equivalent cyclic structures *(1)*. This is in agreement with evidence [19] from neighboring group participation in solvolytic reactions, which indicates that here the classical ions *(2)* are less stable than *(1)* or *(3)*. The only exceptions appear with molecules in which the carbonium ion is stabilized by strong –E substituents; *e.g.* the olefin *(29)* reacts with bromide to give the ion *(30)* [20].



*(29)* *(30)*

In all these cases, the group X in *(1)* or *(3)* has unshared p-electrons, and the C–X bond is weak (CBr, CI) or X is only weakly electronegative (RS). It is therefore not surprising to find a strong bias in favor of π-complex intermediates.

The situation is different when X is chlorine. While simple olefins, *e.g.* 2-butene [21], seem to add on chlorine stereospecifically *trans*, stilbene gives a mixture of *cis*- and *trans*-dichlorides [22], and acenaphthylene *(10)* adds on chlorine predominantly *cis* [23]. These apparent inconsistencies can be explained if the balance between carbonium ion and π-complex is close, so that a single ±E group (phenyl or α-naphthyl) is enough to displace the balance in favor of the carbonium ion. This conclusion is also supported by solvolytic studies [19] which show that chlorine is a poor neighboring group. The arguments given above would require chlorine to differ in this way from bromine or iodine, for the C–Cl bond is much stronger than that of C–Br or C–I, and chlorine is more electronegative than bromine or iodine.

It is interesting that acenaphthylene *(10)* reacts with iodobenzene dichloride to give mainly *trans*-dichloroacenaphthene [23]; this can again be explained in terms of an intermediate ion pair containing the cation *(31)* and the anion $(C_6H_5ICl)^{\ominus}$. Steric effects due to the bulk of the latter could hinder collapse to *cis*-dichloride and so favor isomerization of the initial ion pair to the *trans*-dichloride.

*(31)*

These considerations suggest that *(1)* should definitely be the more stable form of the ion when X is fluorine. There are no data available for the stereochemistry of the addition of fluorine onto olefins, but fluorine has never been reported to show neighboring group effects.

The position of hydrogen is now intelligible. The C–H bond is extremely strong, and hydrogen possesses no unshared p- or d-electrons and is quite strongly electronegative. It is not surprising to find that π-complexes with apical protons seem to be generally less stable than the isomeric classical carbonium ions.

It appears then that the conventional picture of electrophilic addition is oversimplified. Many such reactions do involve π-complex intermediates, but many others take place by a "classical" mechanism involving intermediate carbonium ions. It will clearly be necessary to reinvestigate many of these reactions in detail in order to delineate the areas where each of the two mechanisms dominates.

One particularly interesting case, which has so far not been studied at all, is that when X in *(1)* or *(3)* is an alkyl group. We know from solvolysis studies [19] that the π-complex is commonly more stable when X is an aryl group with π-electrons; and we know that the π-complex is more stable in certain polycyclic systems in which the carbonium ion is selectively destabilized by ring strain. We do not, however, know the relative stabilities of the π-complex and carbonium ion in simple aliphatic systems. The lack of neighboring group effects throws no light on this problem, for it could well be that the classical carbonium ions and "non-classical" π-complexes are separated by energy barriers. If so, their relative stabilities could be established only by a study of addition reactions where the ion is formed by addition of a carbonium ion to an olefin. The stereochemistry of such reactions has not yet been investigated except in certain cyclizations where conformational effects could have determined the stereochemistry (cf. the cases of dimethylcyclohexene and dimethylcyclopentene discussed above). The evidence concerning addition of protons to olefins allows no speculation on the outcome of such reactions, for alkyl groups are less electronegative than protons, and the C–C bond is much weaker than the C–H linkage. There is dire need for data concerning the stereochemistry of additions to olefins where the primary reagent is a carbonium ion.

# Synthesis of Naturally Occurring Unsaturated Fatty Acids by Sterically Controlled Carbonyl Olefination

BY DR. L. D. BERGELSON AND PROF. DR. M. M. SHEMYAKIN

INSTITUTE FOR THE CHEMISTRY OF NATURAL PRODUCTS,
U.S.S.R. ACADEMY OF SCIENCES, MOSCOW (U.S.S.R.)

*It is shown that carbonyl olefination, i.e. the reaction of carbonyl compounds with alkylidene phosphoranes, can be sterically controlled. In some cases cis-olefins can be obtained by proper choice of the reaction conditions; trans-olefins are formed only in the presence of suitable structural factors. These cis- and trans-olefination reactions have opened new, stereospecific routes to unsaturated and polyunsaturated fatty acids with differing positions and sequences of cis- and trans-double bonds and to ω-hydroxy and branched chain fatty acids.*

I. Introduction

II. Steric control of carbonyl olefination

III. Application of *cis*- and *trans*-olefination to the synthesis of naturally occurring unsaturated fatty acids

1. *cis*-Alkenoic acids $CH_3(CH_2)_mCH=CH(CH_2)_nCOOH$
2. Conjugated polyenoic acids $CH_3(CH_2)_m(CH=CH)_x(CH_2)_nCOOH$
3. Acids of the *cis,cis*-divinylmethane type $CH_3(CH_2)_mCH=CH-CH_2-CH=CH(CH_2)_nCOOH$
4. Polyenes of the divinylethane type
5. Unsaturated ω-hydroxy acids
6. Higher branched-chain carboxylic acids

## I. Introduction

Unsaturated fatty acids are attracting considerable attention of late, mainly in their capacity as constituents of lipids, in particular of the various phospholipids which play an essential part in basic biological processes as the building material of cellular and subcellular membranes. Numerous new acids of this type have been discovered during the last two decades in the lipids of brain, liver, heart, and other mammalian organs, in fish oils, and also in lipids of plant origin [1, 2]. However this period has seen no marked advance in the synthesis of these acids. As a rule, the conventional synthetic methods are complicated, require difficultly available starting materials, and give only minute ultimate yields [3]. For instance, one of the shortest routes to oleic acid [4] involves seven stages and the yield is only 2 % with respect to the starting material pimelic acid. The ways described in the literature for synthetizing polyolefinic acids, *e.g.* the ten-stage synthesis of α-cleostearic acid [5] are even more complicated. Furthermore, most methods for the preparation of unsaturated fatty acids (excepting those starting from acetylenic derivatives) are not stereospecific, the *trans*-isomer usually predominating; natural unsaturated fatty acids usually have the *cis*-configuration. The development of straightforward, stereospecific routes to higher unsaturated fatty acids is therefore a primary objective in lipid chemistry.

Recently new methods have been developed in our institute for the synthesis of the principal types of naturally occurring unsaturated fatty acids. These utilize readily available materials, require only a few stages, and are highly stereospecific. The methods are based on the principles discovered some years ago by the authors and their coworkers [5a] for steric control of the reactions between carbonyl compounds and alkylidenetriphenylphosphoranes [6] or dialkyl phosphonate and diphenylphosphine oxide ions [7] to give olefins.

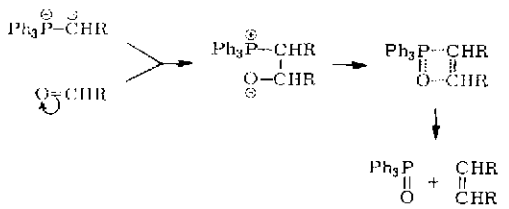
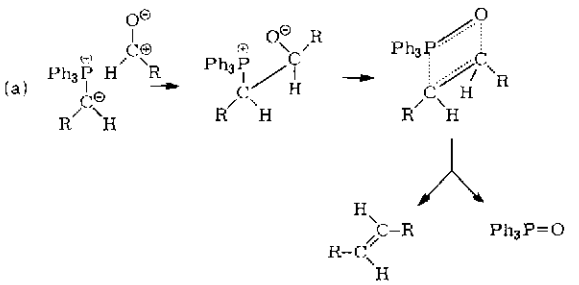
These reactions, which can be designated collectively as carbonyl olefinations, have found widespread use in various fields of organic chemistry as a general means for the synthesis of unsaturated compounds. The newly discovered possibility of their steric control extends their scope even further, especially for the synthesis of natural products.



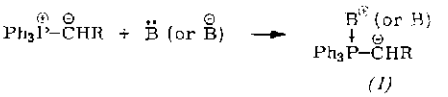
## II. Steric Control of Carbonyl Olefination

The stereochemistry of carbonyl olefination has hitherto received no systematic attention. The reaction of carbonyl compounds with alkylidenetriphenylphosphoranes, *i.e.* the Wittig reaction [8,9], has generally been considered to be non-stereospecific and, since it yields mainly *trans*-olefins, it appeared to be of little promise for the synthesis of naturally occurring unsaturated fatty acids. No data are to be found in the literature regarding the stereochemistry of the reaction between carbonyl compounds and dialkyl phosphonate or diphenylphosphine oxide anions [10, 11].

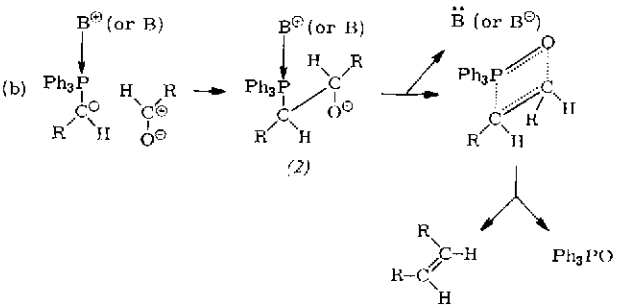


In a systematic investigation of the reaction of aldehydes with alkylidenetriphenylphosphoranes [6], we were able to show that its stereochemistry can be controlled by suitable reaction conditions and structural factors. The following gives a description of the fundamental stereochemical relationships established in the course of this investigation and of how they can be used for the directed stereospecific synthesis of unsaturated compounds.

1. *In the reaction between aldehydes and alkylidenetriphenylphosphoranes, the presence of a sufficiently nucleophilic Lewis base promotes cis-olefin formation.*



The reaction of Wittig reagents with carbonyl compounds is generally assumed to begin with an electrophilic attack of the carbonyl carbon on the negatively polarized phosphorane carbon [8,9] (although nucleophilic attack on the positively polarized phosphorus atom by the carbonyl oxygen cannot be excluded).



In the absence of Lewis bases and in non-polar media, dipole-dipole interaction and mutual repulsion of the substituents R on the reactants lead predominantly to *trans*-olefins (a).

The effect of Lewis bases (B: or $B^{\ominus}$) on the steric course of the reaction is due to their ability to interact with the phosphorus atom, which tends to expand its electronic octet to a decet [6].

The phosphorus is less electrophilic and at the same time sterically less accessible in the resultant complex *(1)* than in the initial alkylidenephosphorane, so that dipole-dipole interaction of the phosphorane with the aldehyde will no longer exert a decisive influence on the orientation of the reactants. These then orientate themselves mainly as in *(2)* and the reaction proceeds with formation of the *cis*-olefin.

This *cis*-directing effect of Lewis bases is observed in the reaction of various aldehydes and alkylidenetriphenylphosphoranes. However, its manifestation may also depend upon the nature of the reactants, in particular upon the stability of the phosphoranes and the branching of the groups R. Efficient Lewis bases are halogenide ions ($Br^{\ominus}$ and especially $I^{\ominus}$) and certain amines. With Lewis bases of the same species, the relative yield of *cis*-isomers is augmented in proportion to their nucleophilicity, *i.e.* in the order Cl < Br < I or ethyl *p*-aminobenzoate < aniline < phenylhydrazine < *N,N*-dimethyl-*p*-phenylenediamine. However, with amines the yield of *cis*-isomer also depends strongly upon steric factors, falling sharply in the order butylamine > diethylamine > triethylamine. It should be noted that, while promoting formation of the *cis*-isomer, Lewis bases retard the overall rate of reaction [6,13,17].

2. *The relative yield of cis-isomer increases when the aldehydes are treated with alkylidenetriphenylphosphoranes in a polar aprotic solvent.*

The *cis*-directing effect increases with the polarity, of the solvent, *e.g.* in the order benzene < ether < tetra-

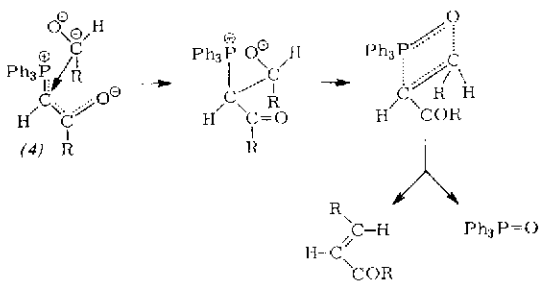
[11] *L. Fieser* and *M. Fieser:* Topics in Organic Chemistry. Reinhold, New York 1963, p. 482.



hydrofuran < dimethylformamide [12, 13]. This effect can be explained by assuming that polar solvents solvate the phosphorus and the carbonyl oxygen, thus facilitating the formation of the intermediate *erythro*-compound *(2)*.

3. *Alkylidenetriphenylphosphoranes with a carbonyl group at the α-carbon atom react with aldehydes to form largely trans-olefins.*

The α-C-atom of such phosphoranes [see *(3)* and *(4)*] has a lower nucleophilicity. Therefore the possibility exists that the carbonyl oxygen attacks the phosphorus atom, although direct evidence for such a mechanism is still lacking.

However, it can readily be seen that a C → C attack in the reaction of *(3)* or *(4)* with aldehydes also leads to *trans*-olefins, formation of the *cis*-isomer being hindered by mutual repulsion of negative groups.

It is noteworthy that the steric course of this reaction depends neither upon the polarity of the solvent nor upon Lewis bases.

Obviously, not only alkylidenetriphenylphosphoranes of type *(3)* but also their vinylogues $Ph_3P{=}CH(CH{-}CH)_n{-}COOR$ [14], as well as β,γ-unsaturated compounds of type $Ph_3P{=}CHCH{-}CHR$ [15] will promote *trans*-olefination.

4. *Alkylidenephosphoranes with sufficiently low positive charge on the phosphorus atom give predominantly trans-olefins with aldehydes, independent of the reaction conditions.*

The positive charge on the phosphorus can be reduced by introducing a substituent of strong −I effect. Compounds of this type, for example dialkyl alkylidenephosphonate and diphenylphosphine oxide anions [7] or alkylidenetricyclohexylphosphoranes [16], cannot form complexes with Lewis bases. They therefore react with aldehydes according to Equation (a) to form predominantly *trans*-olefins, regardless of the polarity of the solvent and the presence of halide ions.

Proper combination of these four principles enables stereoselective syntheses of various unsaturated aliphatic compounds, from simple mono-olefins to complicated polyenic systems, to be carried out. Thus, our study of the influence of environmental factors on the reaction between alkylidenetriphenylphosphoranes and aldehydes led to a stereospecific modification that gives predominantly *cis*-olefins [17]. The reaction is best carried out in a polar aprotic solvent (optimally dimethylformamide) with $I^{\ominus}$ or $Br^{\ominus}$ as Lewis bases. Under such conditions, the amount of *trans*-olefin in the product usually does not exceed 5–6 %. We therefore call this reaction *cis*-olefination.

On the other hand, *trans*-olefination requires favorable structural factors. Thus, dialkyl alkylidenephosphonate or diphenylphosphine oxide anions, react with aldehydes to afford *trans*-olefins, but the relative instability of the dialkyl alkylidenephosphonate anions limits their use for this purpose [11].

Another method of *trans*-olefination takes advantage of the behavior of alkylidenetriphenylphosphoranes with carbonyl groups at the α-carbon atom. For instance, *trans*-α,β-unsaturated acids *(6)* can be prepared by condensation of aldehydes with α-alkoxycarbonylalkylidenetriphenylphosphoranes *(5)* [6].

$$RCHO + Ph_3P{=}CH{-}COOR \longrightarrow \overset{\text{trans}}{RCH{=}CH{-}COOH}$$

*(5)* *(6)*

Use of the corresponding vinylogues *(7)* leads to all-*trans*-polyenoic acids *(8)* [14].

$$RCHO + \overset{\text{trans}}{Ph_3P{=}CH{-}(CH{=}CH)_n{-}COOR} \quad (7)$$

$$\downarrow$$

$$\overset{\text{trans}}{R{-}(CH{=}CH)_{n+1}{-}COOH} \quad (8)$$

Utilizing the principles of sterically controlled carbonyl olefination, it is comparatively easy to carry out directed syntheses of various stereoisomers of 1,4-substituted 1,3-butadienes, RCH−CHCH−CHR. Thus, condensation of saturated aldehydes with *trans*-β-alkenylidenetriphenylphosphoranes *(9)* affords *trans,trans*-dienes [15], whereas condensation with *cis*-β-alkenylidenetriphenylphosphoranes *(9a)* gives *trans,cis*-dienes. Another way to *trans,cis*-dienes is the reaction of *trans*-α,β-

$$RCHO + \overset{\text{trans}}{Ph_3P{=}CH{-}CH{=}CHR} \longrightarrow \overset{\text{trans}}{RCH{=}CH{-}CH{=}CHR}$$

*(9)*

$$RCHO + \overset{\text{cis}}{Ph_3P{=}CH{-}CH{=}CHR} \longrightarrow \overset{\text{trans}}{RCH{=}CH{-}CH{=}CHR}$$

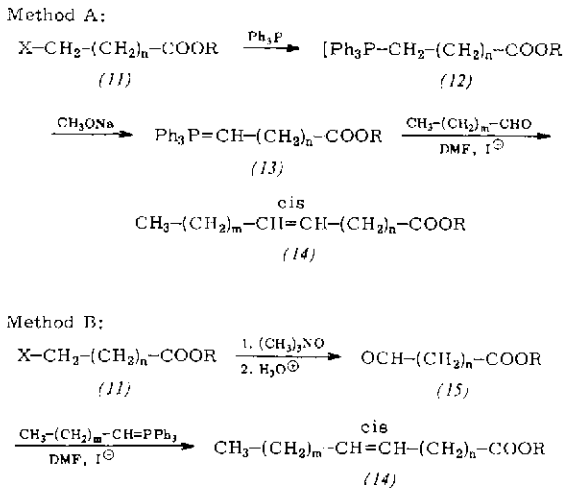
unsaturated aldehydes with alkylidenetriphenylphosphoranes under the conditions of selective *cis*-olefination [18].

*cis,cis*-Dienes should also be available by condensation of alkylidenetriphenylphosphoranes with *cis*-α,β-unsaturated aldehydes; however, owing to the tendency of the latter to isomerize, it is more feasible to start with substituted propiolaldehydes *(10)*.



The following is a brief description of the application of sterically controlled carbonyl olefination to the synthesis of the principal types of naturally occurring unsaturated fatty acids.

## III. Application of cis- and trans-Olefination to the Synthesis of Naturally Occurring Unsaturated Fatty Acids

### 1. cis-Alkenoic Acids

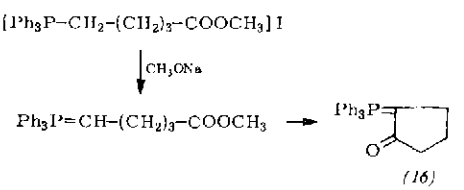
The starting materials for the synthesis of higher *cis*-alkenoic acids $CH_3-(CH_2)_m-CH=CH-(CH_2)_n-COOH$ are aliphatic aldehydes (or alkyl halides) and ω-chloroalkanoic acids $Cl(CH_2)_nCOOH$, which are readily available as industrial products [19]. They are obtained by hydrolysis of the telomerization products of $CCl_4$ and ethylene, so that only acids with an odd number of carbon atoms are commercially available. Acids with even numbers of carbon atoms can be synthetized from the latter by chain extension according to *Arndt* and *Eistert* or by degradation according to *Barbier* and *Wieland*.

Scheme 1. Conversion of ω-chloroalkanoic acids into higher *cis*-alkenoic acids

[18] *L. D. Bergelson, V. D. Solodovnik, E. V. Dyatlovitskaya*, and *M. M. Shemyakin*, Izv. Akad. Nauk SSSR, Otdel. Khim. Nauk *1963*, 683.

[19] *R. Kh. Freidlina* and *E. I. Vasilieva*, Khim. Nauka i Promyshlennost *2*, 2 (1957).

The transformation of ω-chloroalkanoic acids *(11)*, where R=H, X=Cl, into higher *cis*-alkenoic acids is carried out according to one of the two methods shown in Scheme 1.



Method A [20,21]

The ω-chloroalkanoic acids are purified by distillation of their methyl or ethyl esters. ω-Chloroalkanoic esters *(11)*, where R = $CH_3$ or $C_2H_5$, X = Cl, react with triphenylphosphine only on heating in dimethylformamide, whereas the ω-iodo esters, which are readily prepared by refluxing the chloro esters with KI in methyl ethyl ketone, react in benzene. It is better to convert the ω-chloro esters into the iodo derivatives also because the ω-alkoxycarbonylalkyltriphenylphosphonium chlorides *(12)*, where X=Cl, have a greater tendency than the corresponding iodides to undergo partial decomposition to triphenylphosphine during their conversion into the phosphoranes *(13)* with sodium alkoxide. Finally, $I^{\ominus}$ is the Lewis base required for the formation of the *cis*-isomer.

ω-Alkoxycarbonylalkyltriphenylphosphonium iodides *(12)*, where X = I, are comparatively inert. Unlike the α-alkoxycarbonylalkyltriphenylphosphonium salts [8], they do not pass over to the corresponding phosphoranes with alkoxides or sodamide in ether or benzene, but do react quite readily in tetrahydrofuran, diglyme, or dimethylformamide. The latter proved to be most suitable; the phosphorane *(12)* is formed and subsequently reacts with aldehydes in DMF at room temperature.

Studies of the reaction conditions showed that satisfactory yields of unsaturated esters *(14)* are obtained only when the phosphonium salt is in large excess, because it is partially decomposed by the alkoxide with formation of triphenylphosphine. Separation of *(14)* from the latter can be achieved by chromatography on low-activity alumina or by conversion of the crude ester into the acid which can then be easily separated from the triphenylphosphine by chromatography on silica gel or by extraction of its sodium salt with ether.

Method A was employed for the preparation of *cis*-alkenoic acids of type *(14)*, where R = H, with n = 6, 7, or 9, which are found in various animal and plant lipids (see Table 1). However, the procedure proved to be unsuitable for acids of type *(14)* with n = 3, because the ω-alkoxycarbonylalkylidenephosphorane *(13)* with n = 3 behaves anomalously [22] and un-

*(16)*

[21] *L. D. Bergelson, V. A. Vaver, L. I. Barsukov*, and *M. M. Shemyakin*, Izv. Akad. Nauk SSSR, Otdel. Khim. Nauk *1963*, 1417.

[22] *H. O. House* and *H. Babad*, J. org. Chemistry *28*, 90 (1963); *L. D. Bergelson, V. A. Vaver, L. I. Barsukov*, and *M. M. Shemyakin*, Izv. Akad. Nauk SSSR, Otdel. Khim. Nauk *1963*, 1135.

dergoes intramolecular acylation to give 2-oxocyclopentylidenetriphenylphosphorane *(16)* immediately after its formation [22a].

### Method B [21]

In order to prepare $\Delta^5$-unsaturated acids *(14)*, where R = H and n = 3, a variant of the stereospecific synthesis of *cis*-alkenoic acids was devised, according to which alkylidenetriphenylphosphoranes are condensed with ω-alkoxycarbonyl aldehydes *(15)*. The latter can be obtained by Rosenmund reduction of ω-alkoxycarbonylalkylcarbonyl chlorides [23] but undesirable impurities that react with the alkylidenephosphoranes are formed as by-products. Since these impurities are difficult to remove, owing to the low stability of the alkoxycarbonyl aldehydes, the latter are secured more conveniently by treating trimethylamine-*N*-oxide with ω-iodoalkanoic esters *(11)*, where X = I, followed by mild acid hydrolysis [24]. After simple distillation, the resultant ω-alkoxycarbonylaldehydes *(15)* are sufficiently pure and can be used directly for olefination.

Method B was found to be useful not only for the synthesis of $\Delta^5$-unsaturated acids but also of higher acids of type *(14)* with m > 11, the higher alkyl bromides being often more readily available than the corresponding aldehydes. Using this method, unsaturated higher fatty acids that are found as minor components in plant seeds and in the lipids of marine sponges have been synthetized (see Table 1).

Methods A and B are somewhat less specific than the only stereospecific synthesis of higher *cis*-alkenoic acids (via acetylenic derivatives) hitherto available. For instance, ethyl oleate prepared by method A contained up to 6 % elaidic ester [20], whereas in an oleic ester sample obtained by hydrogenation of the corresponding acetylenic compound the *trans*-isomer content was only 2 % [25].

### Preparation of the Starting Materials

a) ω-Methoxycarbonylalkyltriphenylphosphonium Iodides *(12)*, R = $CH_3$, X = I [20].

A mixture of 0.15 mole of anhydrous sodium iodide and 150 ml of dry methyl ethyl ketone is heated for 30 min. at 80 °C; 0.1 mole of methyl ω-chloroalkanoate *(11)*, R = $CH_3$, X = Cl, [31] is added, and heating is continued for further 10 hours with periodic shaking. The cooled solution is filtered, and most of the solvent is distilled off. The residue is diluted with 150 ml of benzene, the solution washed with water, 5 % sodium thiosulfate, again with water, and dried over magnesium sulfate. After evaporating the filtered solution to a volume of 100 ml, 0.12 mole of triphenylphosphine is added, and the mixture is heated at 80 °C for 10 hours. The benzene is then distilled off and the residue thoroughly stirred with 100 ml of absolute ether. The phosphonium salt which crystallizes out on addition of the ether is filtered off, washed with absolute ether, and dried *in vacuo*; yield: 80–90 %.

b) ω-Methoxycarbonyl Aldehydes *(15)*, R = $CH_3$ [21].

To a solution of 0.108 mole of anhydrous trimethylamine-*N*-oxide in 50 ml of dry chloroform is added a chloroform solution of methyl ω-iodoalkanoate prepared from the corresponding chloroester as described above. The mixture is refluxed for 2 hours, cooled, and treated consecutively with 2 N hydrochloric acid, 5 % sodium bicarbonate, and water. The ω-methoxycarbonyl aldehyde *(15)* is purified by distillation; yield, 50–60 %.

Table 1. Unsaturated fatty acids of the type $CH_3-(CH_2)_m-CH=CH-(CH_2)_n-COOH$.

| Acid | Prepd. by Method | Yield [%] | Natural Source | M. p. of acids [°C] | |
|---|---|---|---|---|---|

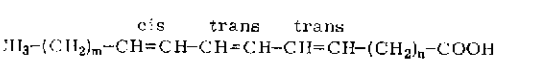
### Synthesis of *cis*-Alkenoic Acids *(14)*, R = H, by Method A [20,31a]

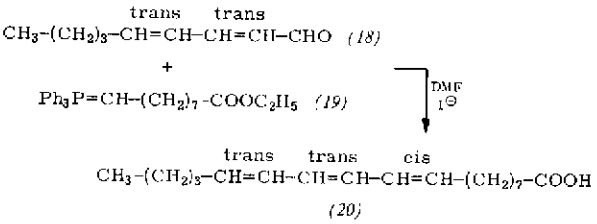


A solution of 25 mmoles of ω-methoxycarbonylalkylidenetriphenylphosphonium iodide *(12)*, where R = $CH_3$ and X = I, in 40 ml of dry dimethylformamide is quickly added to 20 mmoles of dry sodium methoxide and the mixture is stirred for 1 hour at room temperature. The orange-red solution of alkylidenetriphenylphosphorane *(13)* is cooled with ice water, and a solution of 0.15 mmole of aldehyde in 10 ml of dimethylformamide is added, stirring being continued for 2–3 hours. The mixture is then allowed to stand overnight at 20 °C. It is then diluted with water and extracted with hexane. The residue obtained after concentration of the extract is refluxed for 1–1.5 hours with 25 ml of 5 % NaOH in 80 % methanol. After removal of the solvent, the residue is extracted with ether, acidified and chromatographed on a silica-gel column (500 × 15 mm). The triphenylphosphine formed is eluted with hexane and the unsaturated acid *(14)*, R = H, with a 1:1 hexane/ether mixture.

### Synthesis of *cis*-Alkenoic Acids *(14)*, R = H, by Method B [21]

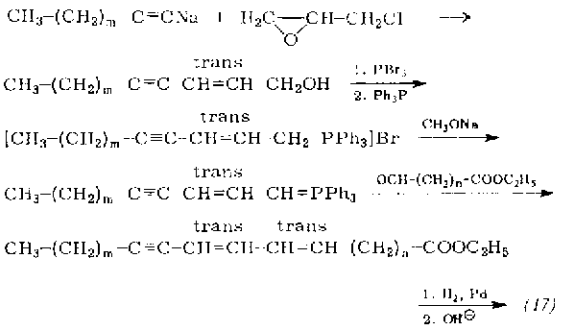
A solution of 12 mmoles of alkyltriphenylphosphonium bromide or iodide in 30 ml of dimethylformamide is added to 10 mmoles of dry sodium methoxide. After 30 min, 7.5 mmoles of the ω-methoxycarbonyl aldehyde *(15)*, R = $CH_3$, are added to the reddish-brown alkylidenetriphenylphosphorane solution formed; the mixture is stirred for 3 hours and left overnight at 20 °C. After evaporation of the solvent, the residue is extracted with hexane, concentrated, and chromatographed in hexane on a column of 250 g neutral alumina (activity grade IV). After separation of the triphenylphosphine, the unsaturated ester *(14)*, R = $CH_3$, is eluted and saponified as described above.

## 2. Conjugated Polyenoic Acids



The lipids of some higher plants contain $C_{18}$-acids with a system of 3 conjugated bonds. These include α-eleostearic acid *(20)*, the principal fatty acid of tung oil [27], catalpa acid *(17)*, where m = 3 and n = 7, isolated from the tree *Catalpa ovata* [32], and its *cis*, *trans*,*cis*-isomer, punicic acid, obtained from the seed oil of the pomegranate *Punica granatum* and of plants of the *Trichosanthes* family [32a]. Closely related to these acids are calendic acid *(17)*, where m = 4 and n = 6, from the marigold *Calendula officinalis* [33], and its *cis*,*trans*,*cis*-isomer, jacaranda acid, isolated from the jacaranda tree *Jacaranda mimosifolia* [34].

*(17)*



Sterically controlled carbonyl olefination makes it possible to carry out directed syntheses of these stereoisomeric alkatrienoic acids. Isomerization is avoided by introducing the *cis*-double bond only at the last stage of the synthesis.

Thus, α-eleostearic acid *(20)* was prepared by condensation of nona-*trans*-2,*trans*-4-dienal *(18)* [35] with 8-ethoxycarbonyloctylidenetriphenylphosphorane *(19)* under conditions leading to selective formation of the *cis*-double bond [36].

*(20)*

Catalpa acid *(17)*, m = 3, n = 7, and calendic acid *(17)*, m = 4, n = 6, were synthetized by means of the *trans*-olefination reaction according to the following scheme [36a]:

### Synthesis of α-Eleostearic Acid [36,36b]

Two grams (4.5 mmoles) of nona-*trans*-2,*trans*-4-dienal [35] are added in the course of 20 min to a solution of 8-ethoxycarbonyloctylidenetriphenylphosphorane *(19)* [prepared from 16.55 g (29 mmoles) of 8-ethoxycarbonyloctyltriphenylphosphonium iodide, see p. 254] in 35 ml of dimethylformamide. The mixture is stirred for 15 hours, and 50 ml of water are added, the whole being then extracted with light petroleum (5 × 50 ml). The extract is dried over magnesium sulfate. After removal of the solvent *in vacuo*, the 4.85 g of oil obtained are chromatographed in hexane on 750 g of neutral alumina (activity grade IV) in a column with a 2:1 hexane/benzene mixture as eluant. The first fractions (90 ml) contain triphenylphosphine; this is followed by ethyl α-eleostearate. The ester is purified by distillation at 135 °C/5 × $10^{-2}$ mm and then saponified with alcoholic sodium hydroxide at 20 °C to give α-eleostearic acid *(20)*, m.p. 46.5–48 °C (from light petroleum).

## 3. Acids of the cis,cis-Divinylmethane Type

The *cis*,*cis*-divinylmethane pattern *(21)* is characteristic of a large group of biologically important unsaturated fatty acids isolated from the phosphatides of various human and animal tissues, as well as from numerous plants [37,38].

[31a] The preparation and reactions of alkylidenetriphenylphosphoranes *(13)* must all be carried out under dry nitrogen.

[38] *J. Asselineau* and *E. Lederer*, Annual Rev. Biochemistry *30*, 71 (1961).

All the syntheses of such acids so far reported are based on the condensation of propargyl halides with acetylenes [39–51].

*(21)*

A fundamentally new way of synthetizing polyunsaturated acids of this type has been developed on the basis of stereospecific *cis*-olefination reactions, starting with either the saturated aldehydic esters *(15)* and γ-alkenylidenetriphenylphosphoranes *(22)* and using Method A, or starting with β,γ-unsaturated aldehydes *(23)* and ω-alkoxycarbonylalkylidenetriphenylphosphoranes *(13)* and using Method B [52].

Linoleic acid and its analogues have been synthetized by these two methods. The methods can also be used for the synthesis of higher fatty acids containing three, four, and more double bonds with alternating methylene groups.

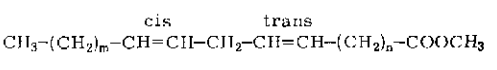
## Method A



The starting materials for the synthesis of divinylmethane-type fatty acids by this method are ω-alkoxycarbonylalkanals *(15)* (cf. p. 254) and *cis*-$\Delta^3$-alkenyl bromides *(27)*, which can be readily prepared from alkylacetylenes and ethylene oxide.

The catalytic hydrogenation of 3-alkyn-1-ols *(25)* to the *cis*-3-alken-1-ols *(26)* is known to be accompanied by the formation of a certain amount of the *trans*-isomer (see *e.g.* [53]). The latter can be conveniently removed at the phosphonium salt *(28)* stage, the salt usually lending itself to purification by simple recrystallization. The phosphonium salts can be prepared by heating $\Delta^3$-alkenyl bromides *(27)* with triphenylphosphine in benzene in a sealed tube. An undesirable side reaction that occurs during the further conversion of these salts *(28)* into the γ-alkenylidenetriphenylphosphoranes *(22)* is the isomerization of the latter to the conjugated β-alkenylidenephosphoranes *(29)*.

This isomerization is promoted by alkaline agents, elevated temperatures, and light, but if sodium methoxide is carefully added to the dimethylformamide solution of the phosphonium salt in the cold and in the dark γ-alkenylidenephosphoranes *(22)* can be obtained that are only little contaminated with the conjugated isomer *(29)*. Condensation of *(22)* with ω-methoxycarbonyl aldehydes *(15)* in the presence of $Br^{\ominus}$ or $I^{\ominus}$ as Lewis bases yields *cis,cis*-divinylmethane-type esters *(24)*, where R = $CH_3$, usually containing less than 10 % of the *trans,cis*-isomer *(30)*.

Separation of the isomers, as well as isolation of the unsaturated ester from triphenylphosphine (see p. 255) can be achieved by chromatography on neutral, low-activity alumina in an atmosphere of nitrogen.

[53] *F. Sondheimer*, J. chem. Soc. (London) *1950*, 877.

Method B

According to this method, the *cis,cis*-divinylmethane-type acids are synthetized by condensation of ω-alkoxycarbonylalkylidenetriphenylphosphoranes *(13)* (cf. p. 255) with *cis*-3-alkenals *(23)*. The latter can be prepared [54] from alkyl halides and the sodium derivative of methoxybutenyne *(31)* according to Scheme 2.

$$CH_3-(CH_2)_m-X + NaC\equiv C-CH=CHOCH_3 \longrightarrow$$
*(31)*

$$CH_3-(CH_2)_m-C\equiv C-CH=CHOCH_3 \xrightarrow{H_2/Pd}$$
*(32)*

$$CH_3-(CH_2)_m-\overset{cis}{CH=CH}-CH=CHOCH_3 \xrightarrow{H_3O^+}$$
*(33)*

$$CH_3-(CH_2)_m-\overset{cis}{CH=CH}-CH_2-CHO$$
*(23)*

Scheme 2. Synthesis of *cis*-3-alkenals *(23)*.

Isomerization of the aldehyde *(23)* to the α,β-unsaturated aldehyde can be avoided if the acid hydrolysis of the methoxydiene *(33)* is carried out under mild, strictly controlled conditions, but a small amount of the conjugated isomer is formed on subsequent condensation of *(23)* with the ω-alkoxycarbonylalkylidenephosphorane *(13)*. Moreover, the *cis,cis*-alkadienoic esters *(24)*, where R = $CH_3$, contain, the *trans,cis*-isomer *(30)* (resulting from the incomplete stereospecificity of the *cis*-olefination) and also the *cis,trans*- *(34)* and the *trans,trans*-isomer *(35)* owing to the small amount of difficultly removable *trans*-isomer invariably present in the *cis*-methoxydiene *(33)* prepared by catalytic hydrogenation. Method B therefore usually leads to less pure products than method A.

$$CH_3-(CH_2)_m-\overset{trans}{CH=CH}-CH_2-\overset{cis}{CH=CH}-(CH_2)_n-COOCH_3$$
*(34)*

$$CH_3-(CH_2)_m-\overset{trans}{CH=CH}-CH_2-\overset{trans}{CH=CH}-(CH_2)_n-COOCH_3$$
*(35)*

Synthesis of Methyl Linoleate by Method A

A mixture of 1.37 g (6.7 mmoles) of *cis*-3-nonenyl bromide *(27)*, m = 4, 2.10 g (8 mmoles) of triphenylphosphine and 20 ml of absolute benzene is heated for 10 hours at 120 °C. The resultant mass is cooled and triturated with 15 ml of absolute ether. The crystalline phosphonium bromide *(28)*, m = 4, is filtered off, washed with absolute ether, and dried *in vacuo*. Yield 2.93 g (94 %), m.p. 111–114 °C.

The phosphonium salt (6.3 mmoles) is dissolved in 15 ml of dimethylformamide and added to a suspension of sodium hydride (5.5 mmoles) in 2.5 ml of dimethylformamide [54a]. The dark red solution of the *cis*-3-nonenylidenetriphenylphosphorane *(22)*, m = 4, formed is stirred for 1 hour at room temperature, and 0.83 g (4.5 mmoles) of ω-methoxycarbonyloctanal *(15)*, n = 7, R = $CH_3$, in 2.5 ml of dimethylformamide is then added. The mixture is allowed to stand for 24 hours at 20 °C, heated for 1 hour at 100 °C, and after evaporation of the solvent *in vacuo*, the residue is extracted with ether. The extract is washed with water, dried over magnesium sulfate, and vacuum distilled. Methyl linoleate is isolated by means of preparative thin-layer chromatography on neutral alumina (activity grade IV) in the system heptane/ether (10:1), 500 mg portions of crude product are applied to 18 × 24 $cm^2$ plates each bearing 100 g of alumina. Yield of methyl linoleate (97 % pure, according to gas chromatography): 0.92 g (71 %).

4. Polyenes of the Divinylethane Type

Substances with the divinylethane pattern $-CH-CHCH_2CH_2CH-CH-$ have frequently been found among various unsaturated naturally occurring compounds. Thus, the leaves of the violet *Viola odorata* contain nona-*trans*-2,*cis*-6-dienal [55], and the corresponding alcohol is one of the odoriferous principles of the flowers of this plant [56]. Some polyunsaturated *N*-butylamides isolated from the pellitory of Spain *Anacyclus pyrethrum*, *Heliopsis longipes*, and other plants also possess the divinylethane structure [1]. Finally, the fats of marine animals contain polyenic acids that yield succinic acid on oxidative degradation; it has thus been concluded that these acids contain a system of double bonds separated by two methylene groups [57–59a]. Sterically controlled carbonyl olefination has provided a new stereospecific route to the *cis,cis*- and *trans,cis*-divinylethane systems.

The synthesis of compounds with the *cis,cis*-divinylethane grouping has been achieved according to Scheme 3 [60].

The principal starting material is the readily available compound 4-bromobutyl acetate [63], which with triphenylphosphine gives a phosphonium salt that is converted into 4-acetoxybutylidene triphenylphosphorane *(36)* in the presence of sodium methoxide. Condensation of *(36)* with an aldehyde under *cis*-olefination conditions (see p. 255) then leads to acetates of $\Delta^4$-unsaturated alcohols *(38)*, usually containing more than 90 % of the *cis*-isomer. Approximately the same stereoisomer ratios result from the condensation of alkylidenetriphenylphosphoranes with 4-acetoxybutanal *(37)*, which is formed by the action of trimethyl-

[54] *H. H. Inhoffen, F. Bohlman*, and *G. Rummert*, Liebigs Ann. Chem. *569*, 226 (1950).

[54a] Beginning with this stage, the synthesis is carried out in an atmosphere of pure nitrogen.

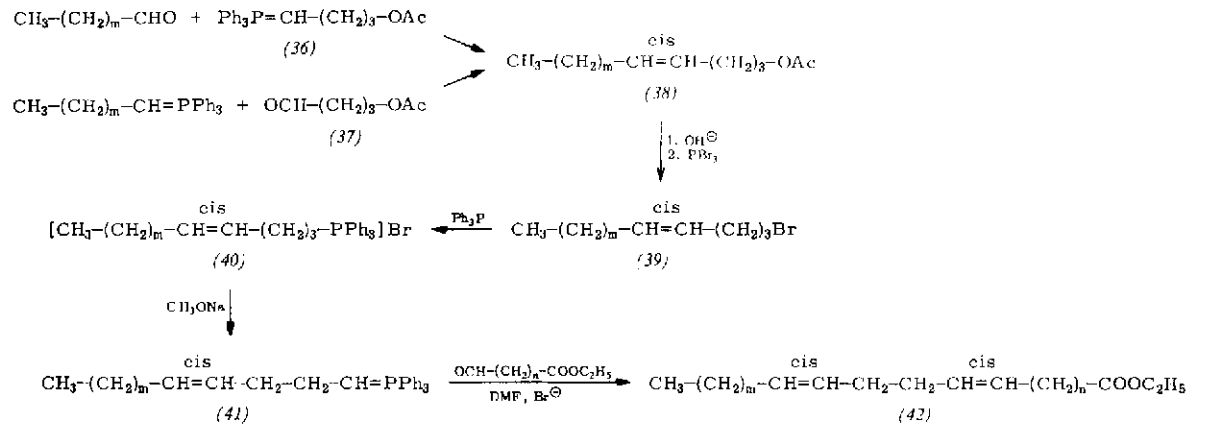
[59] *Y. Toyama* et al., Bull. chem. Soc. Japan *11*, 745, 751 (1936).

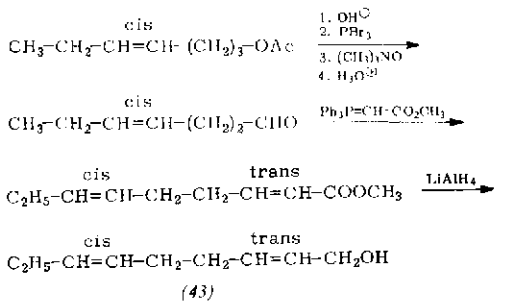
[59a] A more detailed study has shown that at least some of the so-called divinylethane acids are actually of the divinylmethane type [61, 62].



[60] *L. D. Bergelson, V. A. Vaver, A. A. Bezzubov*, and *M. M. Shemyakin*, Izv. Akad. Nauk SSSR, Otdel. Khim. Nauk, in the press.

[61] *Y. Toyama* et al., Fette, Seifen, Anstrichmittel *61*, 846 (1959).

[62] *E. Klenk* and *W. Bongard*, Hoppe-Seylers Z. physiol. Chem. *292*, 51 (1953).

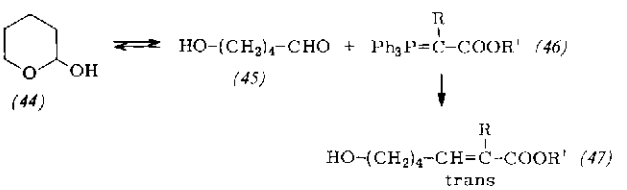


[63] *L. M. Smorgonskii* and *Ya. L. Gol'dfarb*, Zh. Obshchei Khimii *10*, 1113 (1940).

amine-*N*-oxide on 4-acetoxybromobutane [24]. The unsaturated acetates *(38)* and bromides *(39)* are oils, hence the isomers can be best separated at the stage of the crystalline phosphonium salts *(40)*. The *cis*-$\Delta^4$-alkenylidenetriphenylphosphoranes *(41)* obtained from *(40)* condense with ω-ethoxycarbonylalkanals *(15)* (see p. 254) in the presence of $Br^{\ominus}$ in dimethylformamide to give *cis,cis*-divinylethane-type esters *(42)* containing only small amounts of the *trans,cis*-isomers.

Scheme 3. Synthesis of compounds containing the *cis,cis*-divinylethane grouping.

The *trans,cis*-divinylethane system can also be constructed analogously utilizing the *trans*- and *cis*-olefination methods. For instance, a constituent of the odoriferous principle of violets, nona-*trans*-2,*cis*-6-dien-1-ol *(43)*, was synthetized by the short route shown in Scheme 4, starting from *cis*-4-heptenyl acetate *(38)*, m = 1 [64].



Scheme 4. Synthesis of nona-*trans*-2,*cis*-6-dien-1-ol *(43)*.

## 5. Unsaturated ω-Hydroxy Acids

The naturally occurring unsaturated fatty acids include a number of representatives with an ω-hydroxyl group, *e.g.* the 10-hydroxy-*trans*-2-decenoic acid isolated from the royal jelly of the honey-bee [65], the ω-hydroxyoleic acid isolated from the bark of the cork-oak *Quercus suber* [66], the ambrettolic acid $HO(CH_2)_8CH{=}CH(CH_2)_5COOH$ [67] which is found in the seeds of *Hibiscus abelmoschus* as the macrocyclic lactone, and the ω-hydroxy-α-eleostearic (α-camlolenic) acid *(51)* from the seed oil of spurge *Euphorbiaceae* [68,69].

Some of these unsaturated ω-hydroxy acids can be prepared with the aid of the reaction between alkylidenephosphoranes and 2-hydroxytetrahydropyran *(44)* [14,70,71]. This compound is known [72] to react with malonic acid in its tautomeric form, *viz.* 5-hydroxypentanal *(45)*. The results with ω-alkoxycarbonylalkoxyalkylidenetriphenylphosphoranes *(13)* are unsatisfactory, however, because 2-hydroxytetrahydropyran is much less reactive than the aliphatic aldehydes, and the phosphoranes of type *(13)* decompose gradually during the time required for the reaction. However, 2-hydroxytetrahydropyran does condense well with the stabler α-alkoxycarbonylalkylidenetriphenylphosphoranes *(46)*, where R = H or $CH_3$, to give esters of *trans*-α,β-unsaturated ω-hydroxy acids *(47)*, R = H or $CH_3$, although this reaction occurs less readily than the condensation of *(46)* with aliphatic aldehydes [70].

This reaction has been used for the synthesis of lower homologues of 10-hydroxy-*trans*-2-decenoic acid (royal jelly acid), namely *(47)*, R = R′ = H, and *(47)*, where R = $CH_3$ and R′ = H [71].

Steric control of carbonyl olefination has also made it possible to carry out the total synthesis of α-camlolenic acid *(51)* starting from 2-hydroxytetrahydropyran *(44)* [14]. Condensation of *(44)* with 3-methoxycarbonyl-*trans*-$\Delta^2$-propenylidenetriphenylphosphorane *(48)* led

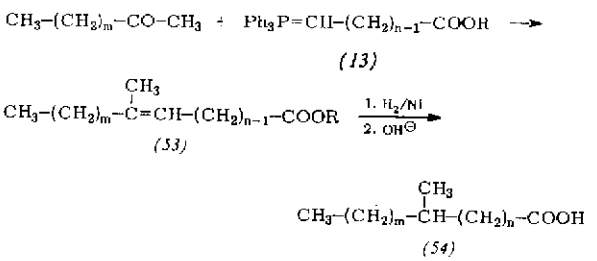
to 9-hydroxynona-*trans*-2,*trans*-4-dienoic ester *(48)*, which was converted into the corresponding aldehyde *(50)*, the acetate of which was condensed under *cis*-olefination conditions with 8-ethoxycarbonyloctylidenetriphenylphosphorane. The resultant α-camlolenic acid *(51)* was then isomerized to β-camlolenic acid *(52)*.



### 6. Higher Branched-Chain Carboxylic Acids

Certain lipids contain not only normal fatty acids but also acids with branched chains. For instance, acids terminated by isopropyl or s-butyl groups (so-called iso- or anteiso-acids) have been isolated from degras and from butter. Branched-chain acids play an important part in the metabolism of some bacteria, particularly mycobacteria. Thus, it has been found that all the known strains of mycobacteria form tuberculostearic acid, *i.e.* D-(−)-10-methylstearic acid. Polymethyl-substituted acids have been isolated from mycobacterial lipids [73].

The specific biological activity and unusual biosynthetic pathways of these compounds have attracted considerable attention. Various methods have been employed for their synthesis [73], but as a rule these involved a large number of stages and gave only small yields of the ultimate product.

The data accumulated during our elaboration of the new carbonyl olefination routes to unsaturated acids pointed out the way for adapting this principle in order to prepare higher branched-chain acids. The synthesis was achieved according to Scheme 5 [74].

In contrast to aldehydes, ketones condense with ω-alkoxycarbonylalkylidenephosphoranes *(13)* only with difficulty, even when the reaction is carried out in dimethylformamide. However, a satisfactory yield (based on the ketone) can usually be obtained with a twofold excess of *(13)*. Hydrogenation and subsequent saponification of the resultant unsaturated esters *(53)* led to the branched acids *(54)* in the yields shown in Table 2.

Scheme 5. Method for synthetizing higher branched-chain acids.

As in the case of aldehydes, reaction of *(13)* with ketones in dimethylformamide is accompanied by the formation of triphenylphosphine, which can best be separated, after hydrolysis of the esters to the sodium salts of the acids, by extraction of their aqueous solution with ether.

Table 2. Branched-chain fatty acids $CH_3-(CH_2)_m-\underset{\displaystyle CH_3}{\underset{|}{CH}}-(CH_2)_n-COOH$

| Acid | m | n | Yield [%] | M.p. of acid [°C] | | M.p. of amide [°C] | |
|---|---|---|---|---|---|---|---|

Synthesis of (±)-Tuberculostearic Acid *(54)*, m = 7, n = 8

A solution of 25 mmoles of methyl octyl ketone in 15 ml of dimethylformamide is added during one hour in an atmosphere of nitrogen to a solution of 8-methoxycarbonyloctylidenetriphenylphosphorane *(13)*, n = 7 (prepared from 0.55 mmole of phosphonium salt; see p. 255) in 40 ml of dimethylformamide. The mixture is stirred for 5 hours and then left to stand for 30 hours at room temperature. The dimethylformamide is distilled off *in vacuo*, and the residue obtained is extracted with ether. The extract is concentrated by evaporation, diluted with 100 ml of hexane, quickly filtered through a column (200 × 15 mm) containing 60 g of $Al_2O_3$ and then washed through with 300 ml of hexane. The unsaturated ester obtained after evaporation of the solvent is saponified by heating with 5 % sodium hydroxide in 80 % methanol; the methanol is then partially distilled off and the residue diluted with water, extracted with ether, and acidified.

Treatment with diazomethane gives the methyl ester *(54)*, where R = $CH_3$, m = 7, n = 8, b.p. 151–155 °C/1.5 mm, $n_D^{20}$ = 1.4557. Hydrogenation of this ester in the presence of Raney nickel at 20 °C followed by saponification with 5 % NaOH in 80 % methanol (refluxing for 2 hours) affords (±)-tuberculostearic acid, m.p. 18 20 °C, which is purified by crystallization from hexane at −20 °C.

# Tetramethylurea as a Solvent and Reagent [1]

BY PROF. DR. A. LÜTTRINGHAUS AND DR. H. W. DIRKSEN

CHEMISCHES LABORATORIUM DER UNIVERSITÄT FREIBURG/BREISGAU (GERMANY)

*Respectfully dedicated to Prof. Karl Ziegler on the occasion of his 65th birthday*

*Tetramethylurea is an excellent solvent for organic substances, particularly aromatic compounds. It is suitable as reaction medium for base-catalysed isomerizations, alkylations, acylations, and other condensation reactions. Being inert toward Grignard compounds, it is a useful solvent for reactions of the latter with compounds that are sparingly soluble in ether. Several industrially feasible syntheses of tetramethylurea are discussed.*

## Introduction

In view of the importance achieved in recent years by solvents such as dimethyl sulfoxide, dimethylformamide, dimethylacetamide, and *N*-methylpyrrolidone it is surprising that tetramethylurea (abbreviated: temur [2]), which is related to the amides cited above, has so far received little attention. Literature references to its use as a solvent are only sporadic. For example, it has been mentioned as a solvent for acetylene [3,4] and for polyacrylonitrile [5]. While studying the accelerating effect of dimethylformamide and similar amides on alkylations, *Zaugg* et al. [6] also compared the effect of tetramethylurea. We first directed our attention to tetramethylurea in the course of systematic studies concerning the dipole moments [7] and infrared spectra [8] of carbonyl compounds and the corresponding thiocarbonyl derivatives. These studies were later extended by *Günthard*, *Béguin*, and *Gäumann* [9]. *Kohlrausch* and *Pongratz* [10] have investigated the Raman spectrum of tetramethylurea.

The aim of our preliminary studies [11,12] was to determine the ability of tetramethylurea to dissolve inorganic, organic, and macromolecular compounds and to establish its value as a medium for alkylations, acetylations, and other coupling reactions, including those involving organometals. To provide a more thorough chemical characterization of tetramethylurea, several reactions were carried out with this compound as a reagent. Finally, we were prompted to work out an industrially feasible process for its synthesis.

## I. Physical Properties

Tetramethylurea is one of the few urea derivatives that are liquid at room temperature. This undoubtedly arises from the fact that the normally strong association of

[1] Communication No. IV "On the Structure of Solutions". – Communication No. III: *A. Lüttringhaus* and *Dagmar Berrer*, Tetrahedron Letters *1959*, No. *10*, 10.

[2] We propose an abbreviation for "tetramethylurea" derived from the English name "TEtraMethylUREa", *viz.* temur; we feel that such mnemonic abbreviations are more desirable than those abominable acronyms consisting of initials, for example TMU. Moreover, TMU has three syllables whereas "temur" has only two. Again, for example, DMS means either "dimethyl sulfoxide" or, in the phrase "DMS Card Index", "Documentation of Molecular Spectroscopy".

amides due to hydrogen bridges involving the hydrogen on the amide nitrogen is lacking here. Tetramethylurea thus acts only as a hydrogen-bond acceptor. However, its boiling point (176.5 °C/760 mm) [13], when compared with that of the isosteric compound diisopropyl ketone (b.p. 125 °C/760 mm), points to strong dipole association, despite the expected hindrance by the four methyl groups. This is in agreement with the relatively high dipole moment, which is of the same order of magnitude as those of the formamides and acetamides, which are shown for comparison in Table 1.

Table 1. Boiling points, dielectric constants, and electric dipole moments of formamides, acetamides, and tetramethylurea.

| | Mol. wt. | B.p. [°C/760 mm] | Dielectric constant | μ [Debye] |
|---|---|---|---|---|
| Formamide | 45 | 210 (decomp.) | 109 | 3.37 |
| Acetamide | 59 | 221 | 74 | 3.6 |
| *N*-Methylformamide | 59 | 185 | 182 | |
| *N*-Methylacetamide | 73 | 206 | 183 | |
| *N*,*N*-Dimethylformamide | 73 | 153 | 36.7 | 3.8 |
| *N*,*N*-Dimethylacetamide | 87 | 165.5 | 37.8 | 3.8 |
| Tetramethylurea | 116 | 176.5 | 23.06 | 3.28–3.66 |

Our measurements show the dipole moment μ of tetramethylurea in benzene to be 3.37 Debye units [7]; recent measurements [14] gave μ = 3.28–3.66 D, depending on the solvent used. These values are high for a trigonal structure in which, because of the amide resonance *(1)* which tends to increase the moment, the three electronegative hetero-atoms are undoubtedly symmetrically

*(1)*

arranged, *i.e.* they do not deviate much from a 120° arrangement around the more positive carbon atom. As in other *N*,*N*-dimethylamides, the dielectric constant of tetramethylurea is markedly lower than that of *N*-unsubstituted amides and, in particular, of *N*-monomethylamides, partly because of the absence of association via hydrogen bridges. We cannot entirely accept the view of *Béguin* [9, 14] and *Zaugg* [6] that the coplanarity of the whole molecule, including the four methyl groups, which is necessary for maximum resonance, is hindered. The Stuart-Briegleb atomic model (Fig. 1) shows no strain, although rotation of both the lower methyl groups is slightly hindered. Moreover, some experimental data indicate that it should be considered that the radius of the hydrogen atoms too large in this type of model by 5 % [17] or 10 % [18]. The resonance energy of tetramethylurea, calculated from

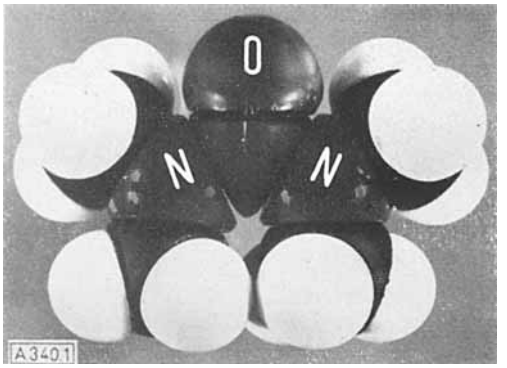

Fig. 1. Stuart-Briegleb atomic model of tetramethylurea.

the calorimetric data given in Table 2, is about 45 kcal/mole [12]; the highest value reported for urea is 41 kcal/mole [21]. However, our value is not to be considered as being very accurate, since we used the heat of formation of ketones for that of the C=O bond and this may introduce additional errors.

are noteworthy. *Béguin* and coworkers find that the Kirkwood-Magat-Bauer theory is only roughly satisfied in this case; they consider that the direct effect and the conformation of the solvent molecules which are the immediate neighbors of the tetramethylurea molecule are more important than the dielectric effect. It has been demonstrated with long-chain paraffins that such solvent effects can have drastic influences on the conformational structure [22,23].

The differences between the infrared spectra of tetramethylurea in the dissolved, liquid, and crystalline state [14] (see Tables 2 and 4) are large. However, these differences do not reflect basic structural differences in the different phases [14]. The strong intermolecular forces existing in the crystal lead to pronounced coupling of the normal internal vibrations, and the resulting mechanical disharmonicity markedly broadens and modulates the band contours. Of the urea derivatives lacking hydrogen bonds investigated by them, *Günthard, Gäumann,* and *Béguin* [9,14] found that only tetramethylurea showed this effect.

Table 4. Solvent dependence of the C=O vibration of tetramethylurea, according to *Béguin* and *Günthard* [9].

| Solvent | $\nu_{C=O}$ [cm$^{-1}$] |
|---|---|
| Heptane | 1668 |
| Cyclohexane | 1666.7 |
| Dioxan | 1650.9 |
| Carbon tetrachloride | 1651.7 |
| *p*-Xylene | 1656.9 |
| Benzene | 1651.8 |
| Chlorobenzene | 1649.1 |
| Methylene chloride | 1639.7 |
| Nitrobenzene | 1648.5 [12] |
| Acetonitrile | 1643.3 |

In the plot of the C=O frequency against the "y" function of the Kirkwood-Magat-Bauer theory, aromatics dissolved in tetramethylurea occupy a special position [12]. Obviously, there is some correlation with the surprisingly high solvent power of tetramethylurea for aromatics (see below). The interaction due to the marked electron delocalization in both species is obviously not so strong as to result in actual charge transfer. Nevertheless, the ultraviolet absorption spectra of simple aromatic hydrocarbons in tetramethylurea show a 3 mμ bathochromic shift of the maxima, compared to corresponding cyclohexane solutions; this is true for both phenanthrene, which is readily soluble, and anthracene, which is exceptionally sparingly soluble [12] (Fig. 2). Analogous shifts toward longer wavelengths amount to 11 mμ for nitrobenzene, 35 mμ for trinitrotoluene, 29 mμ for picric acid, and 20 mμ for *p*-nitrophenol. Tetramethylurea is not sufficiently basic (see below) to promote formation, for example, of the nitrophenoxide ion by accepting a proton.

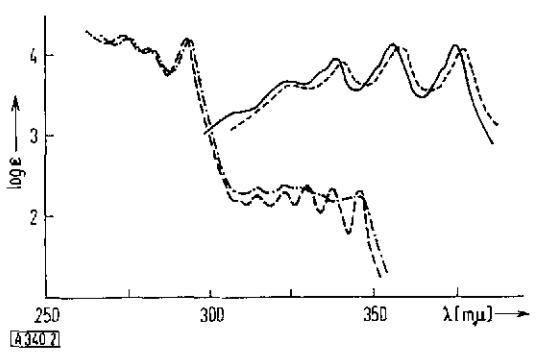

Fig. 2. Effect of the solvent on the ultraviolet absorption spectra of anthracene and phenanthrene.
Anthracene in cyclohexane ———
Anthracene in tetramethylurea — — —
Phenanthrene in cyclohexane ———
Phenanthrene in tetramethylurea —·—·—

For a urea derivative, tetramethylurea has a very high carbonyl absorption maximum (ε = 1940) at λ = 217.5 mμ (π → π*-transition) and a rather broad band (participation of an n → π* transition) (Fig. 3). Hence, measurements of ultraviolet spectra in tetramethylurea at wavelengths below 260 mμ are not accurate.

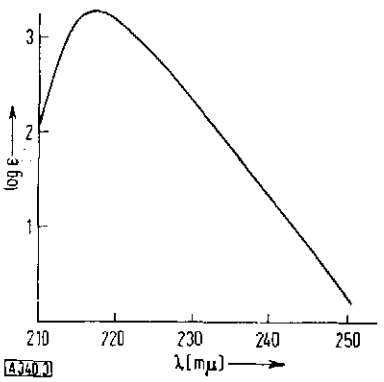

Fig. 3. Ultraviolet absorption spectrum of tetramethylurea in cyclohexane.

The specific conductivity of tetramethylurea is very low, as is to be expected of an aprotic solvent. We determined the density of tetramethylurea/water mixtures and found a maximum ($d_{20}$ = 1.0170 g/cm$^3$) at 86 mole-% water. This corresponds exactly to a water:tetramethylurea molar ratio of 6:1 (Fig. 4), which obviously indicates the optimum hydration number for tetramethylurea.

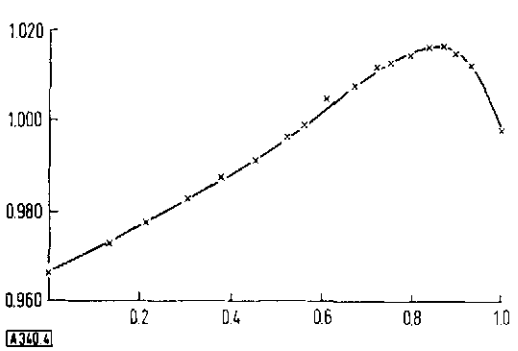

Fig. 4. Density of tetramethylurea/water mixtures at 20 °C.

## II. Dissolving Power

Like pyridine, tetramethylurea is miscible in all proportions not only with water but also with all common organic solvents including petroleum ether. At this point, it is worthwhile mentioning the other (also liquid) lower tetralkylureas. Thus, *N,N*-dimethyl-*N'*,*N'*-diethylurea is still completely miscible with water at 20 °C; at the same temperature, methyltriethylurea is soluble to the extent of 1 g/10 ml of water and 1 g of tetraethylurea (b.p. 94–95 °C/12 mm) dissolves in about 25 ml of water [24].

### 1. For Inorganic Compounds

Since tetramethylurea shows a substantially lower dielectric constant than other simple carboxamides (Table 1) with approximately the same dipole moment, and since the interaction of these two parameters is responsible for ion solvation, it is understandable that the dissolving power for salts of pronounced ionic character is not great, approximating that of acetone. Thus, the dissolving power is poor for alkali and alkaline earth chlorides, moderate for the bromides, and good for the iodides. As usual, the sulfate ion confers only low solubility, whereas many nitrates have surprisingly good solubilities. This indicates that anion solvation, too, affects the dissolving power. The low solubilities of alkali cyanides, cyanates, thiosulfates, and surprisingly, also acetates, are disappointing; on the other hand, many salts of transition metals show good solubilities (Table 5).

Table 5. Solubilities of inorganic compounds in tetramethylurea at 22 °C (g per 100 g of tetramethylurea).

| | [g/100 g] | | [g/100 g] |

| K acetate | 0.21 | *(1)*·HBr [*] | moderate |

[*] Formation of a compound.

To what extent the formation of solvate complexes affects the solubility of inorganic compounds in tetramethylurea remains to be determined. Since such complexes have been found to exist in the case of dimethylformamide [25] and other amides [26], their existence in tetramethylurea is to be expected. This is also indicated by the negative temperature coefficient of the solubility and by the color effects observed with transition metals.

### 2. For Organic Compounds

The miscibility of tetramethylurea with nearly all classes of organic liquids mentioned already points to a good dissolving power. The fact that a polar liquid which is miscible in all proportions with water also shows a high dissolving power for hydrocarbons is not surprising if one considers the tetramethylurea model shown in Figure 1. The surface of this model is formed mainly by the four lipophilic methyl groups which shield the carbonyl oxygen to a large extent. As shown by experience, the ellipsoid form by itself, under equal conditions of polarity, tends to increase the dissolving power. On the other hand, the model shows that the ability of the carbonyl oxygen to accept hydrogen bridges is hardly impaired; this explains the good solubility of uni- and polyvalent hydroxy compounds and carboxylic acids (Table 6).

Even more striking is the generally excellent dissolving power of tetramethylurea for aromatic hydrocarbons and their halogeno and nitro derivatives, phenols, and aromatic carboxylic acids, *etc.* (Table 6). Among the few exceptions are anthracene and anthraquinone,which are also sparingly soluble in other solvents. Anthracene is very soluble in hot tetramethylurea and can be efficiently crystallized from it. All nitro and polynitro compounds show excellent solubilities. We have already discussed (see p. 262) the fact that the spectra of these solutions show bathochromic shifts. However, this fact should not be accepted indiscriminately because the very pronounced color changes which may occur in tetramethylurea solutions of polynitro compounds are due to the presence of dimethylamine admixtures. This phenomenon may even be used as a criterion of purity. The few examples in Table 6 suffice to demonstrate the good solubilities of heterocyclics in tetramethylurea. The probable reasons for the remarkable dissolving power of tetramethylurea for aromatics have already been discussed in Section I. This solvency is probably derived from the van der Waals forces due to the methyl groups, from the interactions between the resonance systems of the solvent and that of the solute, and from a favorable molecular structure of tetramethylurea. The low solubilities of amino acids, even those of aromatic nature, shown in Table 6, are noteworthy. These low solubilities are undoubtedly related to the zwitterionic structure of these compounds, because they increase as this property decreases. Salt formation, for example the formation of cysteine hydrochloride (see Table 6), and especially electronegative substituents (*e.g.* dinitrophenyl residues) on the amino group lower its basicity and increase the solubility of the compound. Amino acids that do not afford zwitterions [27], *e.g.* *p*-aminobenzoic acid or anthranilic acid, show excellent, nearly 1:1 solubilities,

c.m. = completely miscible; v.s. = very soluble
s = soluble; s.s. = sparingly soluble

whereas 2,4-diaminobenzenesulfonic acid, which is zwitterionic, is only sparingly soluble.

The low solvency for zwitterionic amino acids may be explained by the low solvating power of tetramethylurea both for anionized carboxylic groups (low solubility of Na and K acetate, cf. Table 5) and for the ammonium group (ammonium chloride is very sparingly soluble in tetramethylurea; cf. Table 5); the high solubility of ammonium nitrate is obviously due to the nitrate ion, since nitrates generally show remarkably high solubilities (cf. Table 5).

The solubility in tetramethylurea therefore yields useful preliminary information on whether or not acids with basic groups exist preferentially as zwitterions. The remarkable differences in solubility between amino acids and their derivatives suggest the use of tetramethylurea in the analysis of proteins. It has also been used as a component of solvent systems for paper chromatography [28].

[28] We thank Prof. Dr. *O. Westphal*, Freiburg/Breisgau, for having these studies carried out in his Institute.

and nylon-6,6 type are practically insoluble at 22 °C; the polyamides are insoluble even at temperatures exceeding 100 °C. As expected, cellulose esters and poly(vinyl dicyanide) exhibit high solubilities, as do (after swelling) poly(vinyl chlorides) that are chlorinated to various degrees. On the other hand, we found pure polyacrylonitrile to be practically insoluble, in contrast to the observation of *d'Alelio* [5] of solubility. It is possible that his measurements were carried out on copolymers, for example, on copolymers with aromatic components. Good solubility is generally observed for aromatic polymers as polystyrene, polyurethane, Makrolon, and the Novolaks. The highly crosslinked bakelites, on the other hand, are insoluble. Among the polyesters, branched polymethacrylate is soluble, whereas Tergal (Rhodiaceta) is not; the aromatic nature of polyterephthalate accounts for its solubility. It should also be noted that tetramethylurea strongly promotes crystallization of certain polymers, *e.g.* polycarbonate (Makrolon) [29].

## III. Chemical Properties and Reactions

Urea has a $pK_B$ of 13.8. As might be expected, tetramethylurea appears to be more basic. Its behavior toward hexacarbonylchromium(0) and hexacarbonylmolybdenum(0) suggests a $pK_B$ greater than 11 [30]. The half-wave potential (560 mv [31]; 546 mv [32]) for a potentiometric titration of tetramethylurea in acetic anhydride with perchloric acid in glacial acetic acid shows a $pK_B$ of 11.8–12.0 [32], based on a calibration curve [33]. This is in agreement with our value for $pK_B$ of 12.0 (Table 2).

Accordingly, protonation occurs readily in the presence of strong acids. Whether this occurs on the nitrogen or oxygen atom has been the subject of numerous studies involving amides and ureas [34]. Since *O*-protonation has been demonstrated both for *N,N*-dialkylamides [35] and for urea [36], it is assumed that it also occurs with tetramethylurea. However, we were unable to find unequivocal support of *O*-protonation in either the infrared or the NMR spectrum of crystalline tetramethylurea hydrobromide (in dioxan or excess tetramethylurea). The adducts with hydrogen chloride, sulfuric acid, and chlorosulfonic acid could not be obtained in the crystalline form whereas the hydrobromide and hydroiodide could (unfortunately, the latter discolors rapidly). Hexachloroantimonic acid also gives a crystalline adduct. However, this adduct is an "anomalous" basic salt, as indicated by its formula, *viz.* (tetramethylurea)$_2$·$HSbCl_6$. Analogous salts are known with urea [36]. These adducts of urea are the opposite of the "acidic" salts formed with carboxylic acids and other acidic organic substances. The long-suspected proton bridge [37] required for symmetry seems to be characteristic of both series of adducts.

Tetramethylurea hydrobromide, $C_5H_{12}N_2O \cdot HBr$ (197.1) [12], is formed nearly quantitatively when 100 ml each of 0.34 M solutions of HBr and tetramethylurea in absolute ether are simultaneously added dropwise to 50 ml of absolute ether with agitation and external ice cooling, in an atmosphere of dry nitrogen. The salt is extremely hygroscopic [m.p. 130.5–131 °C (decomp.)]. HBr: Calcd. 41.06 %; found 40.99 %.

Tetramethylurea hemihydrohexachloroantimonate, $(C_5H_{12}N_2O)_2$·$HSbCl_6$ (567.8) [12], is obtained by dropwise addition of 5.12 g (0.44 mmole) of tetramethylurea in 5 ml of absolute acetone to 9.46 g (22 millimoles) of $HSbCl_6$·4.5 $H_2O$ in 10 ml of absolute acetone, slow cooling to −15 °C, filtration by suction, and recrystallization from acetone cooled to −70 °C. The compound forms lemon-yellow crystals, m.p. 125–127 °C. Calcd. C 21.15 %, H 4.41 %, Cl 37.6 %; Found C 20.85 %, H 4.66 %, Cl 37.6 %.

Tetramethylurea does not form the sparingly soluble oxalate and nitrate which are characteristic of urea. Nitric acid causes rapid oxidative decomposition of tetramethylurea with formation of dimethylammonium nitrate, carbon dioxide, and dimethylnitramine [15]. The adduct of tetramethylurea with $BF_3$ is a liquid that crystallizes below −15 °C.

As might be expected from their salt character, the adducts with acids show electrical conductivity in excess tetramethylurea. As shown in Figures 5 and 6, these compounds are weak electrolytes.

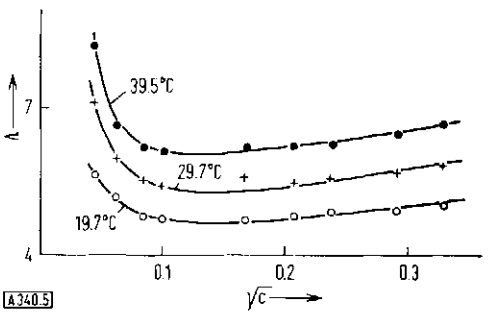

Fig. 5. Equivalent conductivity of HCl in excess tetramethylurea
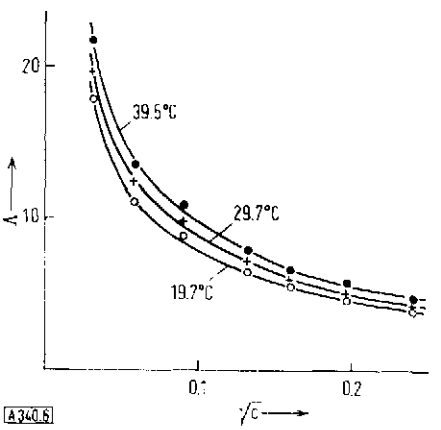
Ordinate: Equivalent conductivity [mho/cm per equiv./ml]
Abscissa: $\sqrt{c}$, with c in equiv./ml

Solutions of carbonyl halides in anhydrous tetramethylurea are also electrically conductive; however, the rate of addition is markedly slower [12] than, for example, for dimethylformamide. This is obviously due to the shielding effect exerted by the methyl groups on the carbonyl oxygen, which in this case is much more pronounced than in additions involving a small proton.



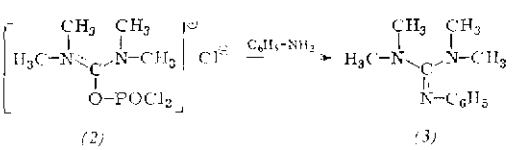


Fig. 6. Equivalent conductivity of HBr in excess tetramethylurea
Ordinate: Equivalent conductivity [mho/cm per equiv./ml]
Abscissa: $\sqrt{c^{-1}}$, with c in equiv./ml

Tetramethylurea gives an adduct with phosphorus oxychloride which is sparingly soluble in ether; to this adduct has been assigned structure *(2)* [38].

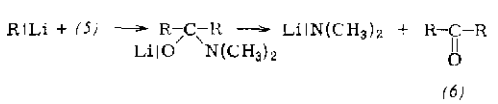
It lends itself well to the preparation of pentasubstituted guanidines. With aniline, for example, *N,N,N',N'*-tetramethyl-*N''*-phenylguanidine *(3)* is obtained.



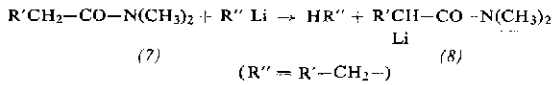
The reaction of tetramethylurea with phosgene results in the replacement of the carbonyl oxygen by two chlorines [39]. This reaction gives high yields of the

$$(CH_3)_2N{-}CO{-}N(CH_3)_2 + COCl_2 \rightarrow CO_2 + (CH_3)_2N{-}CCl_2{-}N(CH_3)_2$$
*(1)* *(4)*

dichloride *(4)*, shown here in its covalent form. Pentasubstituted guanidines are also produced by reaction of tetramethylurea with primary amines. With NaSH, tetramethylthiourea is obtained, while alkoxides yield bis(dimethylamino)dialkoxymethanes, *i.e.* representatives of the interesting group of urea acetals. When a large amount of alkoxide is used, one dimethylamino residue can be replaced with formation of a trialkyl *N*-dimethylorthocarbamate $(CH_3)_2N{-}C(OR)_3$ [39].

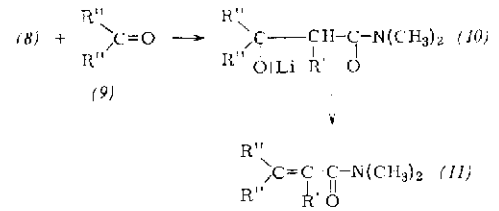
The strong shielding of the carbonyl group is also reflected in the behavior of tetramethylurea towards organometallic compounds. Thus, in the reaction with Grignard compounds, no attack on the carbonyl group takes place even at elevated temperatures. On the other hand, the lithium compounds, which are more reactive, normally afford *(5)* and *(6)*. Thus, depending on the molar ratio of the reactants, a symmetrical ketone *(6)*

or the corresponding dimethylcarboxamide *(5)* may be prepared from an organolithium compound in good yields. The reaction yielding *(5)* has preparative value. When the dimethylcarboxamide is the desired product, this reaction makes it unnecessary to prepare the corresponding carboxylic acid intermediately by carboxylation with $CO_2$. The second step leading to the ketone *(6)* corresponds to the synthesis of ketones from dialkylcarboxamides and organolithium compounds worked out by *Izzo* and *Safir* [40].



For example, *N,N*-dimethylbenzamide is obtained in 80 % yield by dropwise addition of a solution of phenyl-lithium in ether to a six-fold molar excess of tetramethylurea in ether at −30 °C, decomposition of the organometallic complex with a small amount of water, and direct vacuum distillation of the mixture to recover the excess tetramethyurea [12].

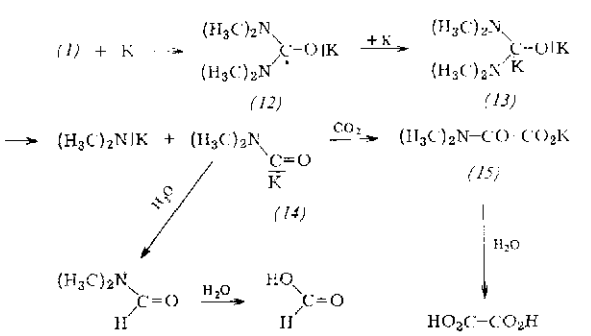
Benzophenone is prepared in 63 % yield by dropwise addition of 175 ml of a 0.36 M solution (0.63 mole) of phenyl-lithium in ether to 36.6 g (0.315 mole) of tetramethylurea in 100 ml of absolute ether over 1 hour, with agitation and external ice-cooling. The mixture is then allowed to stand for additional 4 hours at 0 –15 °C, is decomposed with 20 % sulfuric acid with cooling, is worked up in the usual manner, and distilled *in vacuo* [12].



[39] *H. Eilingsfeld, M. Seefelder*, and *H. Weidinger*, Angew. Chem. *72*, 836 (1960).

[40] *P. T. Izzo* and *S. R. Safir*, J. org. Chemistry *24*, 701 (1959).

Lower yields are obtained when this ketone synthesis is applied to primary or secondary aliphatic lithium compounds. This is because the primary product *(7)* as a result of the



acidifying effect of the carboxamido group, undergoes partial metalation to give *(8)*, which then reacts further with the nascent ketone *(9)* in a manner similar to the modified [41] Reformatsky reaction of esters and affords a β-hydroxy-*N*-dimethylcarboxamide *(10)*. Acid hydrolysis of the latter

followed by distillation then gives the substituted α,β-unsaturated carboxamide *(11)*. Thus, butyl-lithium and tetramethylurea give 40 % 5-nonanone plus *N,N*-dimethyl-2-propyl-3-n-butyl-2-heptenamide (b.p. 158–160 °C/11 mm).

Tetramethylurea also reacts with the still more reactive organosodium compounds, but not with tritylsodium, as indicated by the fact that the red color of this compound remains unaltered in tetramethylurea. This is readily accounted for by steric hindrance in each of the two reactants.

The behavior of tetramethylurea toward alkali metals is noteworthy. Vigorous shaking of this compound with liquid K/Na alloy, in an inert solvent if necessary, produces a dark-blue solution within in a few seconds. Presumably, a system similar to that formed by alkali metals in ammonia and certain ethers is initially formed. At room temperature, this color then rapidly changes to light yellow. Further addition of K to the ketyl radical anion *(12)* yields *(13)*, which undergoes cleavage to give potassium dimethylamide and *(14)*. The formation of *(14)* is demonstrated by its ability to undergo carboxylation to form the oxalic acid derivative *(15)* and hydrolysis to yield formic acid.

The metalating action of K/Na alloy in tetramethylurea on relatively acidic compounds such as triphenylmethane is similar to that of typical radical anion formers, *e.g.* naphthalenesodium [42]; it manifests itself under con-

[41] *P. J. Hamrick* and *Ch. R. Hauser*, J. Amer. chem. Soc. *81*, 2096 (1959).

ditions where no reaction occurs in the absence of tetramethylurea [12]. Tetramethylurea also has a marked accelerating effect on the metalation of triphenylmethane with sodamide. Sodium hydride in tetramethylurea may also he used for metalation reactions [12]; however, according to *Corey* [43], dimethyl sulfoxide is the preferred medium in this case.

The role of tetramethylurea as a source of hydride hydrogen in the reduction of diazonium hexafluorophosphates [45] merits attention. The reaction is carried out hy adding the solid salt in 50 g portions to 200 ml of tetramethylurea at 20 °C and allowing the exothermic reaction and the evolution of nitrogen to take place. The reaction mixture may be warmed slightly without exceeding 65 °C. The replacement of the diazotized amino group with hydrogen by this method is particularly smooth for nitro- and halogenoanilines and *o*- and *p*-aminobenzoic acids; in some cases, this procedure gives better yields than those involving classical reducing agents (alcohol, stannite, alkaline formaldehyde, hypophosphorous acid). The mechanism is obviously ionic, resembling that formulated by *Meerwein* [46] for the reduction of diazonium tetrafluoroborates with dioxan, dioxolans, ethylene glycol dimethyl ether, or tetrahydrofuran.

## IV. Tetramethylurea as a Reaction Medium

*Zaugg* and coworkers [6,32,47] conducted thorough investigations of the accelerating effect of sulfoxides, amine oxides, phosphine oxides, *etc.* and particularly, of *N,N*-dialkylcarboxamides, on *C*-alkylation of alkali enolates. These enolates, *e.g.* ethyl sodioacetoacetate, exist in benzene as highly associated ion pairs. Addition of even a small amount (5–10 %) of dimethylformamide, *N*-methylpyrrolidone, tetramethylurea, *etc.* has an antiassociating and an unusual accelerating effect on the alkylation of enolates, for example of the industrially important monosubstituted sodiomalonate derivatives. These findings and the physical properties of these amides indicate that the high $\pi$-electron density in the amide group, particularly in the $\pi$-orbital of the carbonyl oxygen, accounts for the remarkable solvation of alkali metal ions. On the basis of this concept, tetramethylurea with its two dimethylamino groups should be the most effective agent. The fact that it is not quite as effective as dimethylformamide is explained by *Zaugg* [32] on the basis of the hypothesis of *Günthard* [9,14] (cf. page 261), which assumes that the bulk of the methyl groups hinder the coplanar arrangement of the tetramethylurea molecule and thus prevent it from attaining its full mesomerism. However, it is also conceivable that molecules with a more readily accessible oxygen atom, *e.g.* dimethylformamide, are capable of surrounding an $Na^+$ ion with more molecules and thus form a denser solvation shell than that provided by tetramethylurea.

As a rough guide, the use of dimethylformamide in place of benzene as reaction medium leads to an approximately 1000-fold, [47] and the use of tetramethylurea to a 200-fold [12] increase in the rate of otherwise identical alkylations.

Ethyl α-n-butylacetoacetate [12]: 30 g of a 20 % suspension of NaH in mineral oil (0.25 mole) are added with agitation to 100 ml of tetramethylurea at 0 °C; 32.5 g of ethyl acetoacetate are added dropwise over a period of 20 min, and the mixture is allowed to warm up. Next, 35.5 g of 1-bromobutane are slowly added and agitation continued for 4 hours at 100 °C. Most of the tetramethylurea is distilled off at about 14 mm pressure. Extraction of the residue with ether and working up the extract in the usual manner afford 35 g (75.5 %) of ethyl n-butylacetoacetate (b.p. 121–122 °C/25 mm; $n_D^{23} = 1.4307$). If dimethylformamide is the reaction medium the yield is 60 % [47].

Good yields and particularly high degrees of purity have been achieved also in the alkylation of tertiary heterocyclic amines in tetramethylurea [48]; in this case, too, the high dissolving power of the latter proved to be beneficial. The preparation of mono- and difunctional phosphonium salts from tertiary phosphines can also be advantageously carried out in tetramethylurea [12].

The behavior of tetramethylurea toward carbonyl halides leads to the conclusion that tetramethylurea/carbonyl chloride mixtures are suitable as acylation media. This has been demonstrated in the case of alcohols, phenols, and amines. By following these acylations conductometrically, a high degree of conversion has been demonstrated [12]. Kinetic data indicate that tetramethylurea participates in the reaction by combining with the hydrogen chloride formed.

Pentachlorophenyl acetate, m.p. 150–151 °C, is produced in 83 % yield by adding a mixture of 1 g of acetyl chloride and 10 ml of tetramethylurea to 2.66 g of pentachlorophenol in 15 ml of tetramethylurea, heating the mixture for 30 min at 100 °C, and pouring it into ice water.

Tetramethylurea is also a useful medium for accelerating base-catalysed prototropic double bond shifts, for example that promoted by potassium alkoxides in fatty acids with multiple double bonds [49]. The reason for this is that it combines a solvating power for alkali ions with the ability to combine, via hydrogen bridges, with the interfering free alcohol formed in the reaction [32,50].

It was already mentioned at the end of the preceding section that tetramethylurea is a useful medium for direct metalations with free alkali metals by way of radical ions, with alkali amides or alkali hydrides, or with triphenylmethylsodium. Since it is also inert toward Grignard compounds, it can be used, for example, as the

solvent in determinations of active hydrogen by the Zerewitinoff method. The advantage of tetramethylurea over anisole and amyl ether is its better dissolving power, and over pyridine is its lower vapor pressure. However, direct preparation of Grignard reagents in tetramethylurea is not possible.

Since it boils within the required range, tetramethylurea can also be used as diluent in the Ullmann synthesis of biaryls from aryl halides. Since its boiling point is 23 °C higher than that of dimethylformamide, which is normally used [44], its use is recommended when higher reaction temperatures are needed.

## V. Methods of Preparation

The classical preparation of tetramethylurea from dimethylamine and phosgene [13] proceeds via *N,N*-dimethylcarbamyl chloride *(16)*, which is readily isolable.

$$2\,(CH_3)_2NH + COCl_2 \rightarrow (CH_3)_2NH_2^{\oplus}Cl^{\ominus} + (CH_3)_2N{-}COCl \quad (16)$$

$$(16) + 2(CH_3)_2NH \rightarrow (CH_3)_2NH_2^{\oplus}Cl^{\ominus} + (1)$$

For large-scale preparative purposes, this process has several disadvantages. The considerable heat of reaction is difficult to control in practice. Moreover, since tetramethylurea is miscible with water in all proportions, it is difficult to separate it completely from the salts formed in the process. If this procedure is nevertheless to be used, it is advantageous to isolate the dimethylcarbamyl chloride (b.p. 164–165 °C) first.

The troublesome formation of dimethylammonium chloride is readily circumvented by treating phosgene with trimethylamine [51, 52]:

$$(CH_3)_3N + COCl_2 \rightarrow [(CH_3)_3N{-}COCl]^{\oplus}Cl^{\ominus} \rightarrow CH_3Cl + (16)$$

The primary adduct is readily cleaved into methyl chloride and *(16)*; only a small amount of tetramethylammonium chloride is formed. Trimethylamine can also be used in the second step to produce tetramethylurea and methyl chloride [52]; however, the reaction of trimethylamine with *(16)* is slower than that of phosgene. In contrast, the reaction of *(16)* with dimethylamine is too vigorous. However, 40 % aqueous dimethylamine may be used and the formation of $(CH_3)_2NH_2Cl$ prevented by addition of NaOH. This procedure simultaneously permits complete utilization of the dimethylamine [11].

A 500-ml, four-neck flask equipped with a stirrer and two dropping funnels is charged with 135 g (1.17 moles) of 40 % aqueous dimethylamine, and 107 g (1 mole) of dimethylcarbamyl chloride are added dropwise, with external cooling with a freezing mixture to keep the temperature below −10 °C. After the first 20 ml of the chloride have been added, the addition of 100 ml of 40 % sodium hydroxide is started and is so controlled that the two dropping funnels are emptied at about the same rate. Then, 60 g of sodium hydroxide are added resulting in the formation of two layers. The upper layer is separated and freed from residual salts by vacuum distillation. The lower layer contains about 10–15 % tetramethylurea and is extracted three times with benzene; the benzene extracts are combined with the distillate. The benzene is distilled off, the residual dimethylamine and water being removed azeotropically by this process, and the residue is rectified at 10–20 mm through a short column. The yield, based on acid chloride, lies between 78 and 85 %.

Some potential preparative methods, such as the transamination of urea or the dehydration of dimethylammonium dimethylcarbamate, fail in practice. The oxidative desulfurization of tetramethylthiourea is a possible [53], but probably uneconomical process. The same is true for other methods of preparation [54]. Oxidation of bis(dimethylamino)methane, which is readily prepared from dimethylamine and formaldehyde, with common oxidizing agents to give tetramethylurea shows little promise [12]; catalytic oxidation with air might be better.

Aminolysis of aromatic carbonates such as di-*o*-cresyl carbonate was found to be particularly useful. This reaction is best carried out with diphenyl carbonate, which is used by Farbenfabriken Bayer for the commercial synthesis of Makrolon by the Schnell process [55].

$$(C_6H_5O)_2CO + HN(CH_3)_2 \rightarrow C_6H_5OH + C_6H_5O{-}CO{-}N(CH_3)_2 \quad (17)$$

$$(17) + HN(CH_3)_2 \rightarrow C_6H_5OH + (CH_3)_2N{-}CO{-}N(CH_3)_2$$

The conversion is satisfactory at 200 °C, and the residual urethane *(17)*, which does not react quantitatively, can be reused in the next batch. The phenol formed must be removed in the form of the phenoxide, since it forms a high-boiling azeotrope with tetramethylurea (43 mole-% tetramethylurea [12]).

Gaseous dimethylamine is introduced into 2140 g (10 moles) of diphenyl carbonate (cooled externally with water) until the increase in weight is 1150 g (25 moles). The mixture is then heated for 4 hours at 200 °C in an autoclave (about 20 atm). After cooling, 7 l of 5 N sodium hydroxide are added, and the mixture is extracted with ether for at least 24 hours. The residue is rectified through a short column and the fraction boiling between 60 and 66 °C at 13 mm collected. Yield: 850 g of tetramethylurea. Further distillation of the residue affords 345 g of the urethane, which can be reused [12]

Pure tetramethylurea is obtained by distilling it through a long column. After this distillation, the material is dry and does not react with calcium hydride and should thus be stored over the latter. Amine-free tetramethylurea is obtained if the material is first subjected to azeotropic distillation with benzene/water [12]; it then gives only a weak pink color with trinitrotoluene (see p. 263).

In conclusion, we wish to stress that, in its dissolving power and general miscibility, *tetramethylurea* is closest to *pyridine*. It has the advantage over the latter that it is not accompanied by homologues, a frequent nuisance in the case of pyridine; moreover, it has a more con-

# The Peroxyester Reaction

BY PROF. DR. G. SOSNOVSKY [*]

DEPARTMENT OF CHEMISTRY, ILLINOIS INSTITUTE OF TECHNOLOGY, CHICAGO, ILLINOIS (U.S.A.)

AND LECTURER DR. S.-O. LAWESSON [**]

DEPARTMENT OF ORGANIC CHEMISTRY, CHEMICAL INSTITUTE, UNIVERSITY OF AARHUS (DENMARK)

*The reactions of t-butyl peroxyesters with various classes of compounds in the presence of a catalytic amount of copper ions produce well-defined acyloxy derivatives. This peroxyester reaction, discovered by Kharasch and Sosnovsky, can be used to effect one-step oxidation of saturated and unsaturated hydrocarbons, alcohols, aldehydes, esters, ethers, sulfides, organosilicon compounds, etc. The reaction can be highly selective: in most cases only one specific carbon atom is attacked. However, with some ethers and sulfides the reaction can take a more complex course, other products being formed in addition to the acyloxy derivatives. The mechanism of the reaction has been extensively investigated, and several concerted and chain mechanisms have been proposed.*

## Introduction

In 1956, *Kharasch* and *Sosnovsky* [1] investigated the autooxidation of nitriles catalyzed by metal ions. As an outgrowth of this work, they then studied [2] the reaction of nitriles with t-butyl hydroperoxide and found that the reaction of phenylacetonitrile with t-butyl hydroperoxide in the presence of cobalt or copper ions produces a mixture consisting mainly of oxygen, t-butyl alcohol, hydrogen cyanide, benzoic acid, t-butyl benzoate, and t-butyl peroxybenzoate. The formation of the last three products was interpreted to proceed by reaction of benzoyl cyanide with water, t-butyl alcohol, and t-butyl hydroperoxide.

Another explanation for the formation of t-butyl benzoate, advanced by Sosnovsky [3], is that t-butyl peroxybenzoate is converted into the benzoate by the metal salt catalyst. To test this hypothesis, t-butyl peroxybenzoate was decomposed in boiling benzene in the presence of cuprous bromide. Instead of the t-butyl benzoate expected, methyl benzoate was actually obtained. The formation of this product was later explained by the following chain mechanism [4]:

$$H_5C_6{-}CO{-}O{-}OC(CH_3)_3 + Cu^+ \rightarrow H_5C_6{-}CO{-}OCu^{+(II)} + {\cdot}OC(CH_3)_3$$

$${\cdot}OC(CH_3)_3 \rightarrow {\cdot}CH_3 + H_3C{-}CO{-}CH_3$$

$$H_5C_6{-}CO{-}O{-}OC(CH_3)_3 + {\cdot}CH_3 \rightarrow H_5C_6{-}CO{-}OCH_3 + {\cdot}OC(CH_3)_3$$

Scheme 1. Formation of methyl benzoate from t-butyl peroxybenzoate by a chain reaction.

[*] This work was supported in part by the IIT Research Institute (formerly Armour Research Foundation), Chicago 16, Illinois (U.S.A.).

[**] This work was assisted in part by a grant from the Lucidol Division, Wallace & Tiernan, Inc., 1740 Military Road, Buffalo 5, N.Y. (U.S.A.).

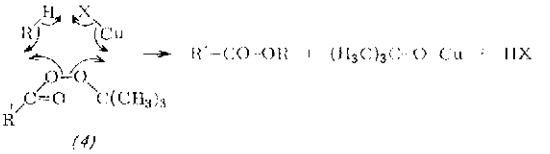
[4] *M. S. Kharasch, G. Sosnovsky*, and *N. C. Yang*, J. Amer. chem. Soc. *81*, 5819 (1959).

These results initiated a series of studies of the decomposition of t-butyl peroxyesters in various substrates [5, 6]. It was found that compounds of the general formula *(1)* react with t-butyl peroxyesters *(2)* in the presence of a catalytic amount of copper ions to give acyloxy derivatives *(3)*.

*(1)*: H = primary, secondary, or tertiary
R = cyclic, acyclic, aromatic, or hetero group
*(2)*: R' = $CH_3$ or $C_6H_5$

The peroxyester reaction can be highly selective: in most cases only one specific carbon atom is oxidized.



Although the metal-catalysed reaction of t-butyl hydroperoxide or α-cumyl hydroperoxide [2, 7, 8] can also be used for selective oxidation of carbon atoms, the peroxyester reaction is more selective, more versatile, and has greater preparative utility. The products of the peroxyester reaction – esters – can be more readily converted into various derivatives than the products of the hydroperoxide reaction – unsymmetrical peroxides. However, the hydroperoxide reaction supplements the peroxyester reaction because it can still be used where the peroxyester reaction fails. For example, diphenylacetonitrile [9] and cyclohexanone [10] undergo no reaction with peroxyesters, but both react [2, 7, 8] with t-butyl or α-cumyl hydroperoxide to yield unsymmetrical peroxides.

## Mechanisms

In the absence of a catalyst, the thermal decomposition of t-butyl peroxyesters in various substrates usually proceeds with multiple-bond cleavage, resulting in a complex mixture of products [4, 11]. In the presence of a copper salt catalyst, however, the reaction is more selective and proceeds at a faster rate.

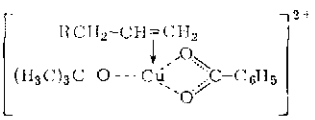
For example, uncatalysed thermal decomposition of a peroxyester in a terminal olefin usually produces ill-defined products plus a large quantity of gases, but the reaction catalysed by copper salts yields mainly 3-acyloxy derivatives with little or no primary allylic esters [4, 5] and little or no gas is evolved. Similarly, the catalysed reaction of peroxyesters with cyclic olefins [4, 5], aralkanes [4, 7], aldehydes [10], and benzylic esters [10], sulfides [12–14], etc. proceeds at a faster rate and often yields products entirely different from those obtained in the conventional uncatalysed free-radical reaction.

These results were previously considered [4–6] as evidence against the occurrence of free radicals or carbonium ions as intermediates. The displacement of hydrogens by the acyloxy radical was postulated by *Kharasch, Sosnovsky,* and *Yang* [6, 10] to occur by a concerted mechanism involving the transition state *(4)*.

*(4)*

At a later stage of their studies [4], these authors favored a chain mechanism involving concerted steps (Scheme 2).

$$H_5C_6{-}CO{-}O{-}OC(CH_3)_3 + Cu^+ \rightarrow H_5C_6{-}CO{-}OCu^{+}(II) + {\cdot}OC(CH_3)_3$$



$${\cdot}OC(CH_3)_3 + RH \rightarrow (H_3C)_3COH + R{\cdot}$$

$$R{\cdot} + H_5C_6{-}CO{-}OCu^{+}(II) \rightarrow H_5C_6{-}CO{-}OR + Cu^+$$

Scheme 2. Chain mechanism for the replacement of hydrogen by acyloxy groups.

*Denney* and coworkers [15] showed that t-butyl [*carbonyl*-$^{18}$O]peroxybenzoate reacts with cyclohexene to give a cyclohexenyl benzoate in which the two oxygen atoms are completely equilibrated. Hence any mechanism which does not permit such an equilibration, such as that via *(4)*, must be excluded. Furthermore, the reaction of t-butyl peroxyester with 3-deuterio-3-phenylpropene showed an isotope effect ($K_H/K_D$) of 4.3 [15]. This value is larger than would be predicted ($K_H/K_D < 2.67$) for a simple hydrogen abstraction from allylbenzene by the t-butoxy radical [15, 15a].

*Denney, Denney,* and *Feig* [15] therefore proposed a mechanism involving a complex between the copper ion and the t-butoxy and acyloxy radicals, which, in turn, coordinates with an olefin to give a π-complex *(5)*.

*(5)*

One of the hydrogen atoms α to the double bond is abstracted by the t-butoxy radical; the acyloxy radical then enters at this position. Complex *(5)* accounts for the isotope effect, since a complexed t-butoxy radical is less reactive than a free t-butoxy radical. In addition, it is harder to abstract a hydrogen from a complexed olefin than from an uncomplexed olefin. This mechanism also explains the equilibration of $^{18}O$ and the lack of $CO_2$ evolution. However, this mechanism does not explain the reaction of peroxyesters with substrates which do not form π-complexes with copper ions.

*Berglund* and *Lawesson* [14] studied the reaction of t-butyl peroxybenzoate with 1,4-dioxane in the presence of $CuCl_2$ and found complex bonded $Cu^{++}$ ion (identified by electron spin resonance) during the reaction and a trace of $Cu^{++}$ ion

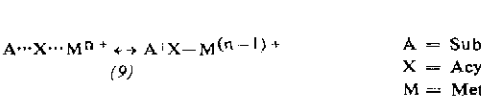
at the end of the reaction. When CuCl was used as catalyst, they found no $Cu^{++}$ at the end of the reaction. They concluded that valence changes occur that cast doubt upon the validity of the $\pi$-complex mechanism *(5)*. A stereochemical study by *Cross* and *Whitham* [16] of the reaction of t-butyl peroxybenzoate with 1-methylene-4-t-butylcyclohexane *(6)* in the presence of CuCl showed that primarily the axial benzoyloxy isomer *(7)* was formed. Although this result can be explained by a free radical mechanism, a mechanism involving a complex explains it better.

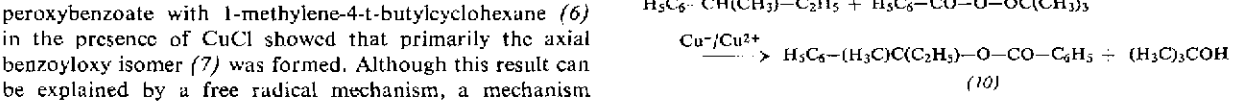


*(6)*: R = H
*(7)*: R = $-O-CO-C_6H_5$
*(8)*: R = OH

The mechanism of metal ion catalysed reactions of peroxides has been thoroughly investigated by *Kochi* [17, 18]. The mechanism he proposed contains essentially the same steps as those shown in Scheme 2.

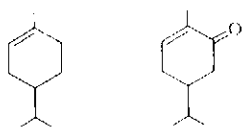
His mechanism also involves a catalyst capable of undergoing rapid redox reactions. In both mechanisms, the first step is reduction of the peroxyester by a cuprous ion, the second is abstraction of the hydrogen atom of a substrate by the alkoxy radical, and the third is oxidation of the substrate radical to the acyloxy derivative with regeneration of $Cu^{+}$. The difference between the two mechanisms is small; *Kochi* believes that the radicals formed are free and that the $Cu^{++}$ is in the form of a true salt, whereas *Kharasch*, *Sosnovsky*, and *Yang* believe that at least some of the radicals form a complex with the metal ion catalyst.

*Kochi*'s hypothesis is based mainly on the reactions of peroxyesters with 1-butene, *cis*- and *trans*-2-butene, or 1-pentene; each reaction produces a mixture consisting of 84–94 % 3-acyloxy derivative and 6–15 % 1-acyloxy derivative in good yield. To explain the effect of the catalytic amount of copper salt, *Kochi* elaborated the last step in his scheme. He proposed that the redox reaction between the substrate radical and the cupric salt proceeds via a resonance hybrid *(9)* which involves contributions from electron-transfer and ligand-transfer processes.



*(9)*

A = Substrate radical
X = Acyloxy radical
M = Metal

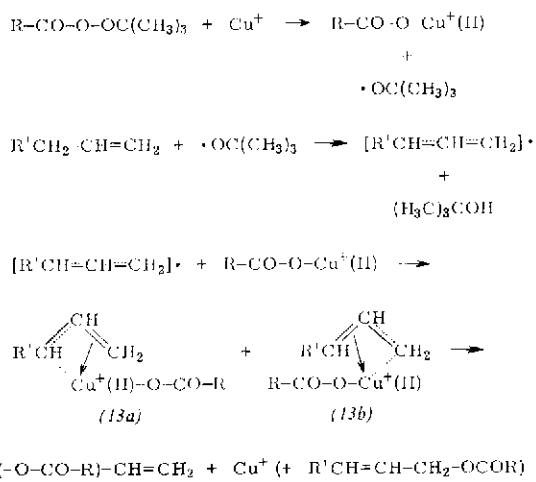


The ligand-transfer and electron-transfer processes are supposed to be extremely rapid; this then precludes the occurrence of the usual chain transfer processes of free radical reactions and confers great selectivity on the peroxyester reaction.

*Hallgarten*, *Wang*, and *Yang* [19, 20] studied the stereochemistry of the rection of t-butyl peroxybenzoate with optically active 2-phenylbutane. Reduction of the reaction product *(10)* with lithium aluminum hydride yielded inactive 2-phenylbutan-2-ol, indicating the occurrence of conventional free radical intermediates during the formation of *(10)*.

*(10)*

A similar conclusion can be made from the result obtained by *Denney* et al. [21] in the reaction of t-butyl peroxyacetate with optically active $\Delta^1$-*p*-menthene *(11)*. In the presence of a copper salt the reaction gave a mixture of acetates, which on hydrolysis and subsequent oxidation yielded the optically inactive ketone *(12)*.



*(11)* *(12)*

*Barnard* and *Yang* [22] found that the rate of the reaction of cyclohexene with t-butyl peroxybenzoate in the presence of cupric ions is of the first order with respect to both peroxyester and olefin. The rate of decomposition of the peroxyester increases with increasing concentration of copper ions at low copper ion concentrations. The rate of the catalysed reaction is several hundred times that of the uncatalysed reaction. These results indicate that the first step of the reaction is reversible or proceeds through a complex. Thus, although free radical species are actually involved in the peroxyester reaction with olefins, a normal free-radical mechanism cannot explain the abnormally high isomer ratio in favor of the allylic ester (see above).

With this consideration in mind, *Yang* and coworkers [19, 20] proposed the mechanism outlined in Scheme 3.

A similar mechanism was considered by *Sosnovsky* in 1958 but was not published because experimental evidence was insufficient at the time.

Scheme 3. Copper-catalysed reaction of olefins with peroxyesters according to *Yang*, *Wang*, and *Hallgarten* [19, 20].

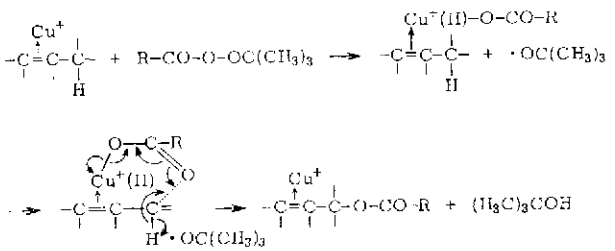
[17] *J. K. Kochi*, Tetrahedron *18*, 483 (1962).

[18] *J. K. Kochi*, J. Amer. chem. Soc. *84*, 774 (1962).

[19] *P. A. Hallgarten*, *T. I. Wang*, and *N. C. Yang*, personal communication, 1963.



[20] *T. I. Wang*, Roles of Metal Salts in Free Radical Reactions, Ph. D. Thesis, University of Chicago, 1962.

[21] *D. Z. Denney*, *A. Appelbaum*, and *D. B. Denney*, J. Amer. chem. Soc. *84*, 4969 (1962).

[22] *P. W. C. Barnard* and *N. C. Yang*, Chem. and Ind. *39*, 1573 (1961).

The first two steps are essentially the same as those of Scheme 2. In the last step, the allylic radical reacts with copper ions to form complex *(13)*. Of the two possible forms *(13a)* and *(13b)* of this intermediate, the one with the double bond in the terminal position *(13a)* ought to be more stable, since copper ions form stronger complexes with less substituted olefins [23]. The complex then collapses to form the product, with regeneration of the cuprous ion.

*Beckwith* and *Evans* [24] expressed the belief that no single mechanism can explain all peroxyester reactions. Under experimental conditions which do not favor formation of a copper ion/olefin complex, *e.g.* high dilution of the olefin or high temperatures, the reaction probably proceeds through an oxidation-reduction sequence to yield rearranged products. However, copper-catalysed reactions of peroxyesters with high concentrations of olefins probably do involve complexes as transition states. On the basis of the products obtained, *Beckwith* and *Evans* therefore proposed the mechanism shown in Scheme 4.

Scheme 4. Mechanism proposed by *Beckwith* and *Evans* for the peroxyester reaction.

Although cupric ion/olefin complexes have not been isolated, there are indications that such complexes exist [24]. Copper(I) forms π-complexes with olefins. Similar mechanisms involving complexes between copper ions and oxygen or sulfur atoms can be written to account for the products of the reactions of peroxyesters with ethers and sulfides.

In summary, it appears that no single mechanism can account for all results of the peroxyester reaction. It is not unreasonable to assume that various mechanisms are operative, depending on the nature of the substrate and on the experimental conditions [*].

[24] *A. L. J. Beckwith* and *G. W. Evans*, Proc. chem. Soc. (London) *1962*, 63.

[*] In this connection two papers [24a, b] are of interest which appeared after this paper was submitted. *Walling* and *Zavitsas* [24a] conducted experiments to test the mechanism of the peroxyester reaction similar to that proposed by *Kochi*. 1-n-Pentene, 2-n-pentene, 1-n-hexene, 1-n-octene, cyclohexene, 1,5-cyclooctadiene, cumene, allylbenzene, and β-methylstyrene were converted with t-butyl peroxyacetate into the corresponding acetates. It was found that the distribution of allylic acetates is in good agreement with *Kochi*'s results. *Walling* and *Zavitsas* favor an electron transfer process with a "free" carbonium ion rather than a ligand transfer process. In another communication [24b] *Sosnovsky* reported the photochemical reactions of peroxyesters in the presence of copper ions. Thus, ethyl ether, dioxan, tetrahydrofuran, dimethylformamide and cyclohexene were converted with peroxyesters at 35 °C to the corresponding acyloxy derivatives. From a preparative viewpoint the photochemical reaction has an advantage over the thermal peroxyester reaction in those cases where thermally unstable acyloxy derivatives are produced. The reactions catalyzed by light only, or copper ions only, proceeded at a much slower rate than the reactions catalyzed by both light and copper ions. The combined effect of light and copper ions on the decomposition of peroxyesters suggests the following interpretation: The first step in the peroxyester reaction is the formation of a complex between the peroxyester and the copper ion. Since less energy is required to dissociate the O-O bond of the complexed peroxyester than that of the uncomplexed peroxyester, the copper-ion catalysed reactions proceed at a faster rate.

## III. Reactions of Peroxyesters with Various Classes of Compounds

### 1. Olefinic Hydrocarbons

Generally, radical reactions of peroxides with olefins result in complex mixtures of products [11], thus rendering the reactions of no preparative value. *Kharasch* and *Sosnovsky* [5,6] found that the reaction of peroxyesters with cyclic and terminal olefins containing allylic hydrogen atoms is modified by a trace of copper ions to give well-defined products with little or no isomerization of the original olefin. For example cyclohexene, 1-hexene, and 1-octene each react with t-butyl peroxybenzoate to give predominantly the corresponding α-acyloxy derivative [*(14)* and *(15)*].

Later other olefins were converted into their acyloxy derivatives in this way [4]. However, the derivatives obtained from 2-octene, 2,4,4-trimethyl-1-pentene, 1-acetoxy-1-cyclohexene, 4-vinylcyclohexene, and α-pinene were not completely characterized.

Since only t-butyl peroxyacetate and t-butyl peroxybenzoate are commercially available, the type of esters which can be readily prepared is limited. However, the scope of the reaction can be increased by adding an excess of an aliphatic acid to the reaction mixture; the allylic ester of this acid is then obtained [4]. For example, the reaction of cyclohexene with t-butyl peroxybenzoate in excess propionic acid yielded 1-cyclohexenyl propionate instead of the benzoate.

The selectivity of the peroxyester reaction observed by *Kharasch* et al. with 1-octene [4–6], cyclohexene [4–6], and allylbenzene [10] was partly confirmed by *Denney* et al. [15] with cyclohexene and allylbenzene, and by *Beckwith* and *Evans* [24] with 1-octene and allylbenzene. However, *Beckwith* and *Evans* found that, in the presence of a solvent, t-butyl peroxybenzoate reacted with allylbenzene to give a small amount of cinnamyl benzoate in addition to the 3-acyloxy derivative.

The stereospecificity of the peroxyester reaction was investigated by *Cross* and *Whitham* [16] using 1-methylene-4-t-butylcyclohexane *(6)*, a cyclic olefin containing a terminal double bond. The reaction of *(6)* with t-butyl peroxybenzoate yielded a benzoyloxy derivative which was hydrolysed to give mainly 2-methylene-*trans*-5-t-butylcyclohexanol *(8)* with an axial hydroxyl group plus only a trace of the corresponding *cis*-isomer, thus confirming the stereospecificity of the reaction.

Working with 1-butene and 1-pentene in solvents, *Kochi* [18] found that exclusive formation of the 3-acyloxy derivative without isomerization is not a general phenomenon of the peroxyester reaction, since he always obtained a small amount of the 1-acyloxy isomer. Furthermore, he found that aliphatic olefins containing an internal double bond and no secondary α-hydrogen atoms undergo the peroxyester reaction with isomerization, yielding predominantly 3-acyloxy derivatives with a terminal double bond. For example, the reaction of 2-butene with either t-butyl peroxyacetate or peroxybenzoate produces a mixture of 84–94 % 3-acyloxy-1-butene *(16)* and 6–15 % crotyl ester *(17)* in high yield.

$$H_3C{-}CH{=}CH{-}CH_3 + R{-}CO{-}O{-}OC(CH_3)_3 \xrightarrow{Cu^+/Cu^{2+}}$$

$$H_3C{-}CH(O{-}CO{-}R){-}CH{=}CH_2 \quad (16)$$

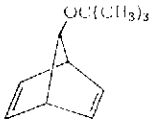
$$+ H_3C{-}CH{=}CH{-}CH_2{-}O{-}CO{-}R + (H_3C)_3COH \quad (17)$$

$R = CH_3, C_6H_5$

A similar rearrangement was observed by *Denney* and coworkers [21] with higher substituted internal olefins. Thus, trimethylethylene and tetramethylethylene each reacted with t-butyl peroxybenzoate to give mainly the benzoyloxy derivative of the rearranged olefin, *viz.* 2-methyl-1-buten-3-yl benzoate *(18)*, and 2,3-dimethyl-3-benzoyloxy-1-butene *(19)*, respectively.

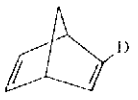
$$H_3C{-}C(CH_3){=}CH{-}CH_3 + H_5C_6{-}CO{-}O{-}OC(CH_3)_3 \xrightarrow{Cu^+/Cu^{2+}}$$

$$H_2C{=}C(CH_3){-}CH(CH_3){-}O{-}CO{-}C_6H_5 \text{ (and isomers)} + (H_3C)_3COH$$



*(18)*

$$(H_3C)_2C{=}C(CH_3)_2 + H_5C_6{-}CO{-}O{-}OC(CH_3)_3$$



$$\xrightarrow{Cu^+/Cu^{2+}} H_2C{=}C(CH_3){-}C(CH_3)_2{-}O{-}CO{-}C_6H_5 \quad (19)$$

The following conclusions can be drawn from these results: The reaction of peroxyesters with cyclic and terminal olefins containing secondary hydrogen atoms in the α-position relative to the double bond yields products with the acyloxy group located either predominantly or exclusively in this position. The reaction of peroxyesters with aliphatic olefins containing internal double bonds with no secondary α-hydrogen atoms, *e.g.* 2-butene, trimethylethylene, and tetramethyl ethylene yields predominantly or exclusively an acyloxy derivative of the rearranged olefin with a terminal double bond.

An interesting deviation from the general pattern of the peroxyester reaction was observed by *Story* [25–27] with norbornadiene. Instead of the expected benzoate, 7-t-butoxynorbornadiene *(20)* was isolated in 26 % yield.

*(20)*

*(21)*

*Story* [25, 26] first proposed a mechanism involving abstraction of a hydrogen atom from C-7 to form a 7-norbornadienyl radical. However, his recent study [27] with [2-D]norbornadiene *(21)* ruled out such a hydrogen abstraction; the reaction of *(21)* with t-butyl peroxybenzoate in the presence of $CuBr_2$ yielded 7-t-butoxynorbornadiene with deuterium at all skeletal positions in approximately statistical distribution. This indicates attack of the t-butoxy radical at all four olefinic carbons, followed by rearrangement of the norbornadiene skeleton. The possible formation of t-butoxy benzoates which eliminate benzoic acid to form the t-butyl ether is unlikely because the yield of the product did not increase with reaction time.

### 2. Non-Olefinic Hydrocarbons

Only hydrocarbons with benzylic hydrogens have been used as substrates. Cumene [7] and optically active 2-phenylbutane [19, 20] each react with t-butyl peroxybenzoate to yield 2-phenyl-2-benzoyloxypropane and inactive 2-phenyl-2-benzoyloxybutane, respectively. 2-Phenyl-2-acetoxypropane (b.p. 93 °C/10 mm, $n_D^{20}$ = 1.4950) was isolated in 36 % yield from the reaction between cumene and t-butyl peroxyacetate [28] [*]. No reaction occurred with triphenylmethane [4] and t-butyl peroxybenzoate. The corresponding reaction of diphenylmethane [14] yielded 1,1,2,2-tetraphenylethane instead of an acyloxy derivative. Tetralin [10] reacts with t-butyl peroxybenzoate to yield 1-benzoyloxytetralin.

### 3. Organosilicon Compounds

Only the following reactions of organosilicon compounds have been investigated [29–31]: in the presence of cuprous bromide, 3-trimethylsilyl-1-propene reacts with t-butyl peroxybenzoate to give the acyloxy derivative *(22)*, 3-trimethylsiloxy-1-propene reacts with t-butyl peroxybenzoate to give the 3-acyloxy derivative *(23a)*, and 1-trimethylsiloxypropane reacts with t-butyl peroxyacetate to give the 1-acyloxy derivative *(23b)*.

$$(H_3C)_3Si{-}CH(-O{-}CO{-}C_6H_5){-}CH{=}CH_2 \quad (22)$$

$$(H_3C)_3Si{-}O{-}CHR{-}O{-}CO{-}R' \quad (23a),\ R = HC{=}CH_2,\ R' = C_6H_5$$

$$(23b),\ R = C_2H_5,\ R' = CH_3$$

## 4. Alcohols

The uncatalyzed reaction of alcohols with t-butoxy radicals yields 1,2-dihydroxy derivatives by dimerization [32–34]; with acyloxy radicals, carbonyl compounds are obtained [35]. t-Butyl peroxybenzoate decomposes slowly in alcohols in the absence of CuCl. Thus, benzyl alcohol yields benzaldehyde and benzoic acid [10, 36] either by fragmentation of the hemiacylal *(24)* or by disproportionation of the benzyl alcohol radical *(25)*.

$$H_5C_6-CHOH-O-CO-C_6H_5 \rightarrow H_5C_6-CHO + H_5C_6-COOH \quad (24)$$

$$2\ H_5C_6-\dot{C}HOH \rightarrow H_5C_6-CHO + H_5C_6-CH_2OH \quad (25)$$

In the presence of CuCl, t-butyl peroxybenzoate decomposes rapidly in primary and secondary alcohols. With n-butyl or benzyl alcohol as substrates, the products are n-butyraldehyde and its di-n-butylacetal, or benzaldehyde and its dibenzylacetal [36]. Secondary alcohols such as s-butanol [36] and α-phenethyl alcohol [36] react with t-butyl peroxybenzoate to give the corresponding ketones but no ketals. The decomposition of t-butyl peroxybenzoate in t-butanol [36] is very slow and only a small amount of methyl benzoate is obtained.

## 5. Aldehydes

By heating t-butyl peroxide and benzaldehyde together in the absence of a catalyst, a high yield of 1,2-diphenylethylene dibenzoate *(26)* is obtained [37]. Compound

$$OC(CH_3)_3 + H_5C_6-CHO \rightarrow (H_3C)_3COH + H_5C_6-\dot{C}=O$$

$$H_5C_6-\dot{C}=O + H_5C_6-CHO \rightarrow$$

$$H_5C_6-CO-O-\dot{C}H-C_6H_5 \rightarrow [H_5C_6-CO-O-CH(C_6H_5)-]_2 \quad (26)$$

*(26)* is also obtained from t-butyl peroxybenzoate and benzaldehyde without a catalyst [10]. In the presence of CuBr, the same reagents yield benzoic anhydride as the main product [10].

$$H_5C_6-CHO + H_5C_6-CO-O-OC(CH_3)_3 \xrightarrow{Cu^+/Cu^{2+}} (C_6H_5-CO)_2O + (H_3C)_3COH \quad (27)$$

With n-butyraldehyde as substrate, no well-defined products are found; it was assumed that disproportionation of an intermediate mixed anhydride occurred [10].

## 6. Ketones, Nitriles, Thiols, Phenols, and Thiophenols

The reactions of ketones or nitriles with t-butyl peroxyesters do not produce well-defined products. Reaction of methyl ethyl ketone [28], cyclohexanone [10], 2-methylcyclohexanone [10], or diphenylacetonitrile [9] with peroxyesters has not been achieved. The reactions of t-butyl peroxyesters with thiols [34] and thiophenols [10] apparently are not modified by copper salt catalysts, since the only products are disulfides. The oxidation of 2,6-di-t-butylphenol to diphenoquinone by t-butyl peroxyesters is accelerated by copper ions [38].

## 7. Esters

Reactions of aliphatic esters such as methyl propionate [28] with t-butyl peroxybenzoate have not been successful. The reaction proceeds slowly, and a complex mixture of products, including a large volume of gas, is obtained. Diethyl malonate [14] and ethyl acetoacetate [14] react with t-butyl peroxybenzoate to form the t-butoxy derivatives *(28)* and *(29)* in 26 % and 22 % yield, respectively. In addition, a 16 % yield of diethyl benzoyloxymalonate is obtained in the reaction of diethyl malonate.

$$(H_3C)_3CO-CH(CO-OC_2H_5)_2 \quad (28)$$

$$H_3C-CO-CH(CO-OC_2H_5)-OC(CH_3)_3 \quad (29)$$

The reaction of t-butyl peroxybenzoate with ethyl i-propylcyanoacetate in the presence of CuCl produces only a small amount of dimer [39]. Cholesteryl benzoate reacts with t-butyl peroxybenzoate to give an equal quantity of 3β,7α-dibenzoyloxy-$\Delta^5$-cholestene and 3β,7β-dibenzoyloxy-$\Delta^5$-cholestene plus a trace of the rearranged product, 3β,6β-dibenzoyloxy-$\Delta^4$-cholestene [24]. This reaction provides a new route to $\Delta^{5,7}$-cholestadien-3β-ol.

Benzylic esters react smoothly with peroxyesters to give the corresponding acylals [10]. Thus, benzyl acetate reacts with t-butyl peroxybenzoate to give α-acetoxybenzyl benzoate *(30)*. The same product is obtained from

$$H_5C_6-CH_2-O-CO-CH_3 + H_5C_6-CO-O-OC(CH_3)_3 \xrightarrow{Cu^+/Cu^{2+}} H_5C_6-CH(O-CO-CH_3)-O-CO-C_6H_5 + (H_3C)_3COH \quad (30)$$

t-butyl peroxyacetate with benzyl benzoate. Correspondingly, benzylidene diacetate [10] can be prepared from benzyl acetate and t-butyl peroxyacetate. Without a copper salt, the reaction takes a typical free-radical course leading to dimers.

## 8. Ethers

### a) Dialkyl and Aryl Alkyl Ethers

Dialkyl ethers react smoothly with t-butyl peroxyesters in the presence of a cuprous salt to give alkyl α-acyloxyalkyl ethers *(31)* [40–43].

$$RCH_2-O-CH_2R + R^1-CO-O-OC(CH_3)_3 \xrightarrow{Cu^+/Cu^{2+}} RCH_2-O-CHR-O-CO-R^1 \quad (31)$$

$R^1 = CH_3, C_6H_5$

[39] *S.-O. Lawesson* and *C. Frisell,* Ark. Kemi *17,* 409 (1961).

[40] *G. Sosnovsky,* J. org. Chemistry *25,* 874 (1960).

[40a] *S.-O. Lawesson* and *C. Berglund,* Acta chem. scand. *14,* 1854 (1960).

[41] *S.-O. Lawesson, C. Berglund,* and *S. Grönwall,* Acta chem. scand. *15,* 249 (1961).

[42] *G. Sosnovsky,* Tetrahedron *13,* 241 (1961).

[43] *S.-O. Lawesson* and *C. Berglund,* Ark. Kemi *17,* 465 (1961).

With excess alcohol, an acetal *(32)* is obtained from *(31)*, thus providing a convenient way of transforming ethers into aldehydes [43].

$$(31) + R^2OH \rightarrow RCH_2-O-CHR-OR^2 \xrightarrow{R^2OH} RCH(OR^2)_2 \quad (32)$$

The reaction of ethers containing one or two tertiary α-hydrogen atoms with peroxyesters does not yield acyloxy derivatives, however [43]. It was assumed that the tertiary hydrogen atom is infact substituted first, but that the acyloxy group is immediately eliminated as the corresponding acid. When excess alcohol is present, the corresponding ketals are formed [43], *i.e.* the acyloxy group is replaced by an alkoxy group.

Aryl alkyl ethers [41] react smoothly with t-butyl peroxybenzoate in the presence of copper ions to yield aryl α-benzoyloxyalkyl ethers *(33)*. Phenyl isopropyl ether

$$H_5C_6-O-CH_2R + H_5C_6-CO-O-OC(CH_3)_3 \xrightarrow{Cu^+/Cu^{2+}} H_5C_6-O-CHR-O-CO-C_6H_5 + (H_3C)_3COH \quad (33)$$

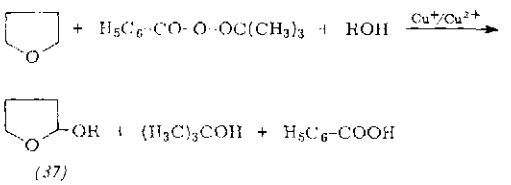
[41] reacts with t-butyl peroxybenzoate, but no benzoate *(33)* is obtained; the course of the reaction is probably the same as that in the case of dialkyl ethers derived from secondary alcohols (see above).

### b) Benzylic Ethers

Benzylic ethers do not undergo dimerization or fragmentation when they react with t-butyl peroxybenzoate in the presence of CuCl; instead, the benzoyloxy group is introduced, giving the acylal *(34)* [14,44].

$$H_5C_6-CH_2-OR + H_5C_6-CO-O-OC(CH_3)_3 \xrightarrow{Cu^+/Cu^{2+}} H_5C_6-CH(OR)-O-CO-C_6H_5 \quad (34)$$

$R = CH_3, C_2H_5, CH(CH_3)_2, C(CH_3)_3, C_6H_5$

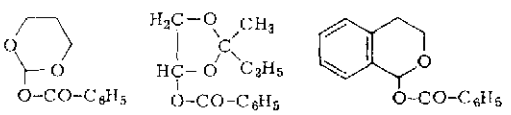


With dibenzyl ether, no acyloxy derivative is isolated, benzaldehyde and its dibenzyl acetal being obtained instead. The first step of this reaction is probably the introduction of the benzoyloxy group into the ether, giving *(35)*. In the following step, t-butanol may react with *(35)* by heterolysis of the alkyl-oxygen bond to give the unsymmetrical acetal *(36a)*, which, by reacetalization, yields the symmetrical acetal *(36b)*.

$$H_5C_6-CH(O-CO-C_6H_5)-O-CH_2-C_6H_5 \quad (35) \xrightarrow{ROH} H_5C_6-CH(OR)-O-CH_2-C_6H_5$$

*(36a)*, $R = C(CH_3)_3$
*(36b)*, $R = CH_2-C_6H_5$

### c) Cyclic Ethers



Decomposition of t-butyl peroxyesters in tetrahydrofuran in the presence of cuprous salt gives 2-t-butoxytetrahydrofuran [40,42,45] as the main product. *Sosnovsky* [40,42] postulated that the product formed first is 2-acyloxytetrahydrofuran, which, by thermal elimination of the corresponding acid, yields 2,3-dihydrofuran; addition of t-butanol onto the 2,3-dihydrofuran would then produce 2-t-butoxytetrahydrofuran. *Lawesson* and *Berglund* [40a,45] offered another explanation: the 2-acyloxytetrahydrofuran undergoes alkyl-oxygen heterolysis with t-butanol to give 2-t-butoxytetrahydrofuran directly. They showed that an excess of an alcohol ROH other than the t-butyl alcohol present in the reaction mixture introduced the alkoxy group of this alcohol *(37)*.

*(37)*

Simular results were obtained with t-butyl peroxyesters in tetrahydropyran [40,40a,42,45].

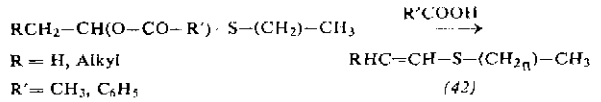
1,4-Dioxan reacts rapidly with t-butyl peroxybenzoate in the presence of a copper salt to give 2-benzoyloxydioxan in good yield [10,14]. Upon prolonged heating, 2-t-butoxydioxan is obtained in poor yield [14,42]. Similarly, 1,4-dioxan reacts with t-butyl peroxyacetate to give 2-acetoxy-1,4-dioxane [28]. The reactions of 1,3-dioxane [14], 2-methyl-2-ethyl-1,3-dioxolan [14], and isochroman [14] with peroxyesters give the products *(38)*, *(39)*, and *(40)* respectively.

*(38)* *(39)* *(40)*

## 9. Sulfides

### a) Straight-Chain Aliphatic and Benzylic Sulfides

Dialkyl sulfides react smoothly with t-butyl peroxyesters in the presence of a copper salt to give α-acyloxyalkyl alkyl sulfides *(41)* [12,13,34,41] without oxidation of the sulfur atom.

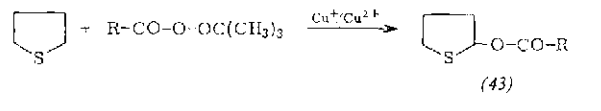


$$RCH_2-S-CH_2R + R'-CO-O-OC(CH_3)_3 \xrightarrow{Cu^+/Cu^{2+}} R-CH(O-CO-R')-S-CH_2R \quad (41)$$

$R' = CH_3, C_6H_5$

In contrast to the α-acyloxy ethers, the α-acyloxy derivatives of straight-chain aliphatic sulfides do not give alkoxy sulfides on heating with an alcohol; instead, mercaptals are isolated [12,46]. For example, the α-acyloxy derivatives of diethyl sulfide, di-n-propyl sulfide, and di-n-butyl sulfide yield acetaldehyde diethylmercaptal, propionaldehyde dipropylmercaptal, and butyraldehyde dibutylmercaptal, respectively. Pyrolysis of the acyloxy derivatives of aliphatic sulfides at temperatures from

[44] *S.-O. Lawesson* and *C. Berglund*, Ark. Kemi *16*, 287 (1960).
[45] *S.-O. Lawesson* and *C. Berglund*, Ark. Kemi *17*, 475 (1961).
[46] *G. Sosnovsky*, Tetrahedron *18*, 903 (1962).

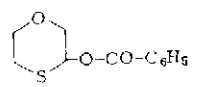


115 to 175 °C produces vinyl sulfides *(42)* and a carboxylic acid [12,41, 47].

*(42)*

b) Cyclic Sulfides

Tetrahydrothiophene [12–14,48] reacts with t-butyl peroxyesters in the presence of a copper salt to give 2-acyloxytetrahydrothiophene *(43)* in good yield. Pyrolysis of *(43)* yields 2,3-dihydrothiophene *(36)* [12,46], which can be isolated if distilled off immediately after its formation; otherwise its dimer *(44)* is obtained [12, 14, 46, 48].



*(43)*

*(44)*

1,4-Thioxan [14] reacts with t-butyl peroxybenzoate in the presence of CuCl to give mainly 3-benzoyloxy-1,4-thioxan *(45)*.

*(45)*

10. Amines and Amides

Attempts [28] to cause peroxyesters to react with aromatic and aliphatic amines have not been successful. The peroxyester decomposes rapidly, with production of the corresponding acid in quantitative yield. However, dimethylaniline undergoes an anomalous reaction which is independent of catalysis to give bis-(*p*-dimethylaminophenyl)methane [10].

Among the amides, only dimethylformamide has been investigated, with CuCl [14] or CuBr [28] as catalyst.

*(46a)*, R = $C_6H_5$
*(46b)*, R = $CH_3$

The reaction with t-butyl peroxybenzoate produces *N*-benzoyloxymethyl-*N*-methylformamide *(46a)* in 35 % yield [14]. The analogous reaction with peroxyacetate produces *N*-acetoxymethyl-*N*-methylformamide *(46b)*, b.p. 66 °C/0.1 mm, $n_D^{25} = 1.4412$, in 25 % yield [28].

[47] *G. Sosnovsky* and *H. J. O'Neill*, J. org. Chemistry *27*, 3469 (1962).

[48] *C. Berglund* and *S.-O. Lawesson*, Acta chem. scand. *16*, 773 (1962).

## General Experimental Procedures for the Peroxyester Reaction

### 1. Reagents

To date, the peroxyester reaction has been carried out only with t-butyl peroxyacetate and t-butyl peroxybenzoate. The peroxyacetate is usually marketed as a 75 % solution in benzene, the peroxybenzoate as the undiluted liquid. Both reagents are stable at room temperature. At 100 °C, the half-life of t-butyl peroxyacetate is 12.5 hours, and that of t-butyl peroxybenzoate is 18 hours. Both compounds can be distilled at reduced pressure; t-butyl peroxyacetate, b.p. 35 °C/8 mm, $n_D^{25} = 1.4022$; t-butyl peroxybenzoate, b.p. 75 -76 °C/0.2 mm, $n_D^{25} = 1.4978$ [9].

### 2. Catalyst

*Kharasch*, *Sosnovsky*, and *Yang* [4] postulated that the peroxyester reaction required as catalyst a metal salt which can undergo rapid redox reactions, and most later investigators agree. Copper salts are the most efficient; either Cu(I) or Cu(II) salts can be used. Cobalt salts are less effective [4], and salts such as $ZnCl_2$ and $MgBr_2$ are ineffective [4].

The reaction is largely independent of the solubility of the catalyst or the nature of the anion [4], although reactions of peroxyesters in the presence of complex copper salts (*e.g.* 1,10-phenanthroline- or α,α-bipyridyl-Cu complexes) show decreased specificity compared with reactions catalysed by simple copper salts [49]. The following catalysts have been used most frequently: CuCl [14], CuBr [4] cupric 2-ethylhexanoate [4], and cupric 3,3,5-trimethylhexanoate [21]. When inorganic salts are used, they are slowly converted during the reaction into organic salts and the reaction proceeds by homogeneous catalysis [4].

### 3. Practical Procedure [4]

The peroxyester is added dropwise to a stirred mixture of the substrate and the copper salt catalyst in a molar ratio of 10:(15 to 40):0.01. A solvent such as benzene can be used if desired. Depending on the nature of the substrate and the stability of the products, the reaction mixture is maintained under an atmosphere of nitrogen at temperatures ranging from 65 to 115 °C [*].

The progress of the reaction can be followed by periodic examination of the infrared spectrum of the mixture ($\nu_{C=O}$ for peroxyacetate = 1785 $cm^{-1}$; $\nu_{C=O}$ for peroxybenzoate = 1775 $cm^{-1}$; acyloxy products usually absorb in the region 1720–1735 $cm^{-1}$) or by titration of the iodine liberated from sodium iodide with a sample of the reaction mixture. If the reaction proceeds according to plan, *i.e.* with formation of an acyloxy product, little or no gas is evolved.

The cooled reaction mixture is washed with a solution of sodium carbonate or sodium hydroxide to remove the carboxylic acid. The remaining organic phase is then washed with water and dried. The excess substrate or solvent or both are removed *in vacuo*, and the product is then purified, usually by distillation.

2. Reactions with electrophilic reagents

V. Summary

## I. Introduction

In contrast to the corresponding aromatic compounds, monomeric aliphatic thioketones *(1)* [2] have been little studied since there were no general methods for their preparation until recently, and some schools have been forced to abandon work they had started because of the foul and penetrating odor of these compounds. One of the greatest difficulties we had to contend with, however,was the extent of contradictory and erroneous information present in the literature.

In this first review, the present state of work in this field will be summarized, the methods of synthesis critically examined, and, as far as is possible at present, mistakes in the literature will be rectified and characteristic properties of aliphatic thioketones described.

## II. Preparation of Aliphatic Thioketones

### 1. From Ketones and Phosphorus Sulfides or Magnesium Bromide Hydrogen Sulfide

A method often used in the past, and proclaimed as a standard procedure for the conversion of C=O into C=S, involved the action of phosphorus sulfides ($P_2S_3$, $P_4S_{10}$) on carbonyl compounds. The reaction was carried out in the presence or absence of solvent, and at high or low temperatures. It is not suitable as a general method for the preparation of monomeric aliphatic thioketones, however, as numerous side reactions occur.

Nevertheless, several authors have claimed to have obtained monomeric thioketones by this method, *e.g.* from dipropyl ketone [3], diisobutyl ketone [3], menthone [4], fenchone [5], and perfluoro-4-heptanone [6]. For a discussion of supposed dimeric thioketones [3,7,8] see [9], and for the action of $P_4S_{10}$ on perfluorocyclobutanone see [10].

MgBrSH was also thought [11] to be a universal reagent for substituting sulfur into carbonyl groups, but as the result of numerous experiments, we were forced to conclude that this method is unsatisfactory for the preparation of unconjugated aliphatic thioketones. Not even traces of thioketones were formed from cyclic ketones.

### 2. From Ketones and Hydrogen Sulfide

Although aldehydes generally react readily with hydrogen sulfide, ketones are almost unaltered [12,13] in the absence of a catalyst. The formation of traces of thio-

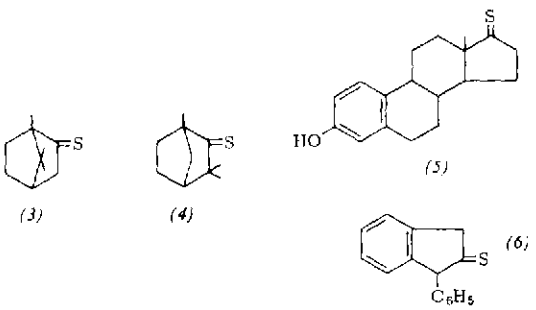
ketones and other sulfur-containing compounds is indicated only by changes in color [12, 14] and by the smell [12, 14, 15] of the thioketones. Reaction occurs only with ketones having electron-attracting substituents [16, 16a], or at pressures of 65 to 8500 atm [17]; thioketones are still not formed even then; only *gem*-olthiols or *gem*-dithiols result.

If catalysts are added, however, thioketones are produced. Apart from the procedure described in an American patent [18], in which hydrogen sulfide reacts with ketones on an alumina catalyst at 450 °C to give thioketones, and which enables diisobutyl ketone, for example, to be converted into diisobutyl thioketone, it is usual to carry out the reaction between hydrogen sulfide and ketones at low temperatures either in an acidic medium (alcohol saturated with hydrogen chloride is so far the preferred solvent) or in the presence of amines.

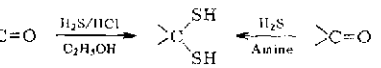
### a) With Acidic Catalysts

This method, introduced by *Fromm* and *Baumann* [8], yields mainly 1,3,5-trithianes *(2)*, *i.e.* trimeric thioketones. In this way, trimeric thioacetone [8, 9, 19–21] is



*(1)* *(2)*

formed from acetone, the presence of monomer being merely presumed [20] from the disgusting smell. We have recently [22] isolated monomeric thioacetone itself for the first time by a different method involving cleavage of acetone diethylketal with $H_2S$. The smell of this unstable red oil [23] is indeed almost indescribable. In our opinion, only traces of this compound or of the *gem*-dithiol could have been obtained in the earlier work, since the monomeric thioketone is unstable under the conditions used.



Methyl ethyl ketone behaves similarly to acetone; the main product is the trimeric thioketone [24, 25].

Higher aliphatic ketones, such as methyl hexyl ketone or methyl pentadecyl ketone, do not appear to be converted into thioketones or their trimers by $H_2S$ in acidic medium [13]; this should, however, be checked, since we were able to obtain similar thiones by other methods [22]. On the other hand, thiocamphor *(3)* [26, 27], thiofenchone *(4)* [28], thioestrone *(5)* [29], 1-phenyl-2-indanethione *(6)* [30], and 1,1,3-triphenylthioacetone [30] are readily obtainable from the corresponding ketones with $H_2S$ and acidic catalysts.

*(3)* *(4)* *(5)* *(6)*

The literature on monocyclic thioketones is contradictory; with cyclopentanone [31], cyclohexanone [31], and 4-methylcyclohexanone [31], the first attempts to prepare thioketones led to trimers. This reaction has also recently been observed with cycloheptanone [30] [*]. According to *Sen* [32, 33] (cf. [26]), however, the action of hydrogen sulfide on cyclopentanone, cyclohexanone, 2-methylcyclohexanone, and menthone in ethanol saturated with hydrogen chloride yields monomeric thioketones, as was confirmed by analysis and the preparation of derivatives. The trimers were mentioned as by-products from ketones with five- and six-membered rings, and dimenthenyl sulfide as a by-product from menthone (cf. [34]). This method of *Sen* has until very recently often been quoted and described as a standard procedure for preparing monomeric thioketones. It is in fact of very limited application for preparing monomeric aliphatic thioketones, since *gem*-dithiols *(7)* are formed preferentially.

*(7)*

We have made an extensive study of the reaction with cyclohexanone. If cyclohexanone is treated with hydrogen sulfide in ethanolic hydrochloric acid in an attempt to prepare cyclohexanethione *(1a)* by the method of *Sen* [33], the main product is a foul-smelling sulfur compound whose infrared spectrum exhibits a strong SH frequency at 2550 $cm^{-1}$ but lacks the C=C and =C–H absorption bands that one would expect for a thioenol. Furthermore, the molecular formula $C_6H_{12}S_2$ of the

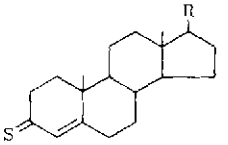
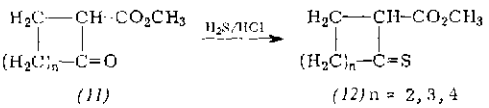
compound contains one mole of $H_2S$ more than is required by the thione *(1a)*. We were able to characterize the product [35] as 1,1-dimercaptocyclohexane *(8)* by comparison with an authentic sample that we obtained by a different method, and also by its reactions.



*(8)*

*(1a)*



Since subsequent reactions of *(8)* and *(1a)* sometimes yield identical products, and in particular, since *(8)* undergoes the reactions used to characterize *(1a)* [36], it is not possible to say whether *Sen* isolated the pure thioketone. Although *Janssen* [37] considers that the spectroscopic data cast doubt on the purity of cyclohexanethione obtained by *Sen*'s method, *Rosengren* regards a lower boiling fraction as the pure thioketone [38].

An acid-catalysed formation of a dithiol had indeed been noted previously [40], but was experimentally confirmed only considerably later by the isolation of 1,3-diphenyl-2,2-propanedithiol [30,39], 1,3-dichloro-2,2-propanedithiol [41], and other dithiols [42]. Although monochloroacetone [9,25,43] and β-diketones [44] react differently, unsaturated thioketones such as $\Delta^4$-cholestene-3-thione *(9)* [45] and 17β-hydroxy-$\Delta^4$-androstene-3-thione *(10)* [46], as well as β-thioxocarboxylic esters [47–55] and β-thioxocarboxamides [56], are accessible by this method.

*(9)*; R = $C_8H_{17}$
*(10)*; R = OH

According to *Mitra* [49], thioacetoacetic ester was obtained in 85 % yield by passing $H_2S$ at 0 °C into a solution of acetoacetic ester in alcohol saturated with hydrogen chloride. Our own research group has recently made a very thorough investigation of the conversion of β-oxocarboxylic esters into β-thioxocarboxylic esters, and has studied the chemistry of the latter. This work is described elsewhere [52,53], and here we only wish to mention that cyclic β-oxocarboxylic esters *(11)* are especially easy to convert into the corresponding thioxocarboxylic esters *(12)* using hydrogen sulfide in an acidic medium.

*(11)* *(12)* n = 2, 3, 4

### b) With Basic Catalysts

An alkaline medium also promotes the formation of *gem*-dithiols *(7)* very strongly [57]. We devised a simple, general synthesis giving good yields of this interesting class of compounds; ketones are treated with hydrogen sulfide in the presence of amines in a polar solvent at 0–20 °C [57,58].

Basic ketones such as *N*-methylpiperidone do not give thioketones with hydrogen sulfide, but react to form *gem*-dithiols [59], whereas cycloheptanone, methyl cyclohexyl ketone, and a few other ketones also give moderate yields of thioketones [57,60]. It has not yet been determined whether the latter should be regarded as primary or secondary products. The action of $H_2S$ on acetylacetone in the presence of morpholine yields monothioacetylacetone, which exists partly as a thioenol [57].

Our experience so far indicates that these base-catalysed reactions are useful for preparing *gem*-dithiols, but not for preparing thiones.

Ammonium polysulfide cannot be used to convert aliphatic ketones into thioketones, not even if excess hydrogen sulfide is passed in; instead, tetrathianes *(13)* and pentathiepanes *(14)* [61] or reduction products [17,62,63] are formed.

Even thiocamphor *(3)*, which is normally formed very readily, is not obtained directly using ammonium polysulfide,

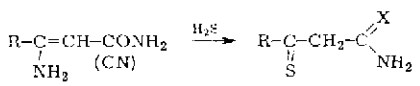
as previously claimed [64], but is produced in a very impure state by secondary pyrolysis [63, 65, 66]. The same applies to thiofenchone *(4)* [66].

*(13)*

*(14)*

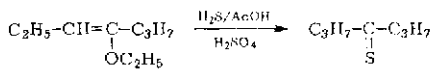


### 3. From Ketone Derivatives and Hydrogen Sulfide

#### a) From Enamines

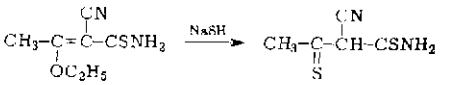
The recently published [67] synthesis of monomeric cyclohexanethione and cyclopentanethione from the corresponding enamines and $H_2S$ could not be repeated [58, 68, 69]. *gem*-Dithiols *(7)* are formed [57], just as with the enamines of other ketones [69].

Thiocarbonyl compounds can, however, be obtained from some α-substituted enamines. Thus, reaction of 1-cyclopentenylmorpholine [70] with acetyl chloride and subsequent treatment with $H_2S$ yielded α-acetylcyclopentanethione, which was characterized by its reactions [36].



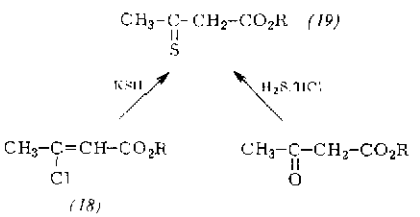
In this connexion, the preparation of β-thioxocarboxylic esters [52], β-thioxocarboxamides *(15a)* [56] and β-thioxothiocarboxamides *(15b)* [71] has also been reported.

*(15a)*; X = O
*(15b)*: X = S



#### b) From Enol Ethers or α,β-Unsaturated Chlorides

Recently we found that enol ethers could be converted into thioketones in the presence of catalytic amounts of sulfuric acid in glacial acetic acid [22]. For example, dipropyl thioketone *(1b)* was obtained in 30 % yield from 4-ethoxy-3-heptene *(16)*.



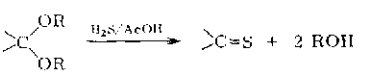
*(16)* *(1b)*

A similar conversion in alkaline medium has so far only been used for the synthesis of an α-cyano-β-thioxothiocarboxamide *(17)* [72].

*(17)*

In contrast to enol ethers, α,β-unsaturated chlorides are not satisfactory starting materials for the synthesis of aliphatic thioketones. The thioacetoacetic esters *(19)* that were prepared from β-chlorocrotonic esters *(18)* and alkali hydrogen sulfides [73–75] can be obtained more conventiently nowadays from β-oxocarboxylic esters by the method of *Mitra* already described [49].

*(18)*



#### c) From Azomethines, Oximes, or Phenylhydrazones

The remarks about enamines apply equally, *mutatis mutandis*, to azomethines. Although diaryl thioketones [76] and thioacetophenone [42] can be prepared from azomethines and hydrogen sulfide, the method fails in the aliphatic series. The ketimines that have so far been examined yielded *gem*-dithiols [42, 77]. Only camphor, the *gem*-dithiol of which is not known, could be converted into thiocamphor by this method [78].

There is still no way known of splitting oximes or phenylhydrazones to get thioketones or *gem*-dithiols, although numerous attempts have been made (cf. [79]).

#### d) From Ketals

We recently discoverd [22] that monomeric thioketones, particularly the lower aliphatic thioketones not previously known in the pure state, can be prepared under mild conditions in average yields of 50 % by cleavage of ketals *(20)*, preferably diethylketals, which are readily accessible from ketones and ethyl orthoformate, with hydrogen sulfide in an acidic medium.

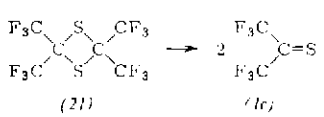
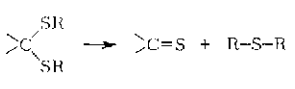
The reaction can be carried out either in the presence of a very small amount of an acidic catalyst ($ZnCl_2$, inorganic acids) with or without solvent, or in an anhydrous organic acid. In either case it is advantageous to add a little hydroquinone as stabilizer.



This method is much superior to any of the others mentioned so far. The alcohol is liberated from the ketal even at room temperature and is removed continuously from the equilibrium by distillation under reduced pressure or, for less sensitive thioketones, under ordinary pressure. Cyclic ketals derived from glycols are less convenient starting materials owing to the high boiling points of glycols.

### 4. Pyrolysis and Photolysis of Compounds Containing Sulfur

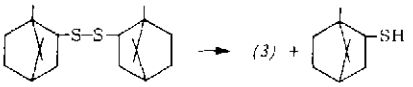
Trithianes *(2)* are readily accessible from thiones, *gem*-dithiols, or ketones and $H_2S$ in an acidic medium, and by analogy with the oxygen derivatives it should be possible to cleave (depolymerize) them to thioketones *(1)*. However, no instance of this is yet known in the aliphatic series, since compounds of type *(2)* are either very stable or decompose only under conditions so drastic that the thiones *(1)* would be unstable or undergo other reactions [8,9,31]. Success was first achieved in the pyrolysis of aryl alkyl thioketones [13]; whereas trimeric thioacetone distils unchanged under reduced pressure [8], trimeric thioacetophenone decomposes above its melting point into the monomer and other products.



Trimeric diaryl thioketones are apparently unknown. *Schönberg* has studied the different stabilities of various trimeric thioketones to pyrolysis [80].

It is interesting that a dimeric thioketone, perfluorotetramethyl-1,3-dithietane *(21)*, can be partly converted into the monomer *(1c)* by pyrolysis at 600 °C [6].

*(21)* *(1c)*

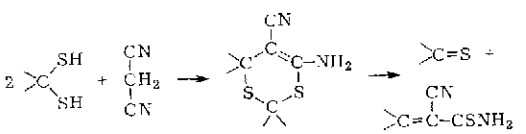


The pyrolysis of simple aliphatic *gem*-bis(alkylthio) compounds *(22)* does not give the desired products [20].

*(22)*

Pyrolysis could sometimes be used to obtain aromatic thioketones, even though side reactions always occurred [81,82]. Aliphatic monosulfides [*], which are relatively stable, have never yet yielded well-defined thioketones on pyrolysis.

Although disulfides are more thermolabile than monosulfides, it has not yet been possible to devise a general method for the preparation of aliphatic thioketones by pyrolysis of disulfides. The only example that works is dibornyl disulfide *(23)*, which is converted into highly impure thiocamphor *(3)* by pyrolysis [63–66,83].

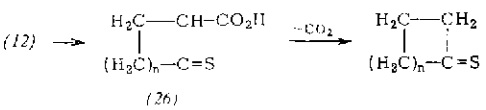


*(23)*

This reaction is evidently a homolytic disulfide fission [84]. Monomeric aliphatic thioaldehydes and thioketones have been detected spectroscopically in the products of photolysis of various disulfides [38,85, cf. 86].

Any pyrolytic process that is to be used for the preparation of aliphatic thioketones must proceed under conditions in which the thiones are stable and will not undergo secondary reactions with other fission products. As we have already seen, this leads to considerable difficulties with trithianes, simple *gem*-bis(alkylthiol) derivatives, monosulfides, and disulfides. The simplest method would be the removal of gaseous hydrogen sulfide from *gem*-dithiols *(7)*, however only fluorinated dithiols (or olthiols) have been converted in this way [16a].

We have therefore chosen an indirect route which has proved to be very successful, and which we use particularly for the preparation of monomeric cyclic thiones in yields of about 60 %: the *gem*-dithiol *(7)* is first treated with malonodinitrile to give an adduct *(24)*, and this



*(7)* *(24)* *(25)*

is then decomposed above its melting point to give the thioketone, which distils off, and a residue of thioamide *(25)* [87].

### 5. Decarboxylation of β-Thioxocarboxylic Acids

As already mentioned, β-thioxocarboxylic esters *(12)* are formed smoothly from β-oxocarboxylic esters *(11)* and hydrogen sulfide in an acidic medium. Careful hydrolysis gives the free acids *(26)*.

*(26)*

Although thioketones had previously been thought to be by-products of this hydrolysis [52,75,88], we were only

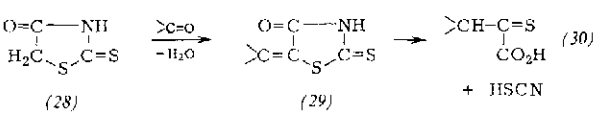
[88] *Z. Reyes* and *R. M. Silverstein*, J. Amer. chem. Soc. *80*, 6367 (1958).

recently [53] able to demonstrate their presence conclusively and to prepare cyclopentanethione, cyclohexanethione, and cycloheptanethione in very pure samples that were, in particular, free from *gem*-dithiols *(7)*, by decarboxylation of the isolated β-thioxocarboxylic acids *(26)*. The thiones thus obtained can be kept for several days as monomers.

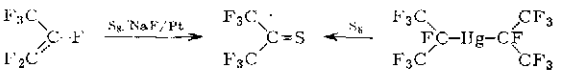
### 6. Special Methods



Certain thiosteroids can be obtained from the corresponding *gem*-bis(benzylthio) derivatives *(27)* by fission with sodium in liquid ammonia [29,89–91].

*(27)* *(1)*

There are no references to similar experiments with *S,S'*-disubstituted *gem*-dithiols leading to simple aliphatic ketones, but a *gem*-dithiol was isolated [92] from the fission of a tetrathiane *(13)* under similar conditions.



Another especially interesting reaction is the alkaline hydrolysis of the compounds *(29)* obtained by condensation of aldehydes or ketones with rhodanine *(28)*, which leads to derivatives of thiopyruvic acid *(30)* [93–96].

*(28)* *(29)* *(30)*

Finally, the action of elementary sulfur on organic compounds may be mentioned, since sulfur should be able to oxidize methylene groups to thiocarbonyl groups. Of course, under the drastic conditions that are necessary, the thiones that are first formed in the main are rapidly dehydrogenated. The reaction can only be used for practical preparative purposes if the thione is not enolizable and hence cannot react further and is to some extent resistent to dehydrogenation. In the aromatic series, for example, diphenylmethane can be converted into thiobenzophenone by elementary sulfur in 30 % yield.

Aliphatic thiones cannot be prepared by this method; however, hexafluorothioacetone *(1c)* was obtained by treatment of hexafluoropropene *(31)* [6] or bis(heptafluoroisopropyl)mercury *(32)* [6,97] with sulfur.

*(31)* *(1c)* *(32)*

## III. Chemical and Physical Properties of Aliphatic Thioketones

All the known thioketones and related compounds are listed in Table 1.

The stability of thiones is very variable; whereas, for instance, dipropyl thioketone [22] and thiocamphor *(3)* [14] will keep for some weeks, thioacetone [22] changes within a few minutes. The other simple thioketones also have only limited stability and polymerize after a time even in the absence of acidic catalysts.

A connection between the instability of thioketones and their photochemical reactivity was noted some time ago [99]. More recently it has been pointed out that photoexcited carbonyl and carbonyl-like groups can be regarded as true biradicals [100,101].

Simple thioketones of low molecular weight are generally red oils with very intensive, unpleasant smells. Only solid thiocamphor and thiofenchone have more pleasant, sulfurous, mint-like odors.

All the thiones we have prepared dissolve readily in nonpolar solvents. Monocyclic thioketones decompose very rapidly in protonating solvents.

If there is at least one hydrogen atom on the carbon atom adjacent to the C=S group, prototropic tautomerism of the thioketone is possible. This can be detected spectroscopically [36]; the thioenol tautomer can

be recognized from infrared bands at 1640 $cm^{-1}$ ($\nu_{C=C}$), 2550 $cm^{-1}$ ($\nu_{SH}$), and 3020 $cm^{-1}$ ($\nu_{=C-H}$), whilst a small amount of the thioketone tautomer is evident from its characteristic color ($\lambda_{max} \approx 500$ mμ). It can be shown in this way that some thioketones exist completely, or nearly so, as the thioenols, *e.g.* β-thioxocycloalkanecarhoxylic acids *(26)* and their esters *(12)* [36], β-thioxothiocarboxamides *(15)* [71,72], derivatives of thiopyruvic acid [93], cyclohexanethione [36], and 1,1,3-triphenylthioacetone *(6)* [30] (in the last compound, the thioenol form was also confirmed by its nuclear magnetic resonance spectrum). On the other hand, some thio-

[*] In 1,1'-bis-thiocamphor two molecules of thiocamphor are joined through the 1 C-atoms.

[**] Note added in proof: for further fluorinated thioketones, see [16a].

ketones, such as dipropyl thioketone, methyl cyclohexyl thioketone, and thiocamphor exist largely as the thiones. It can be shown by means of the infrared and ultraviolet spectra of cycloalkanethiones prepared from ketals, that the concentration of thioketone decreases on standing in favor of that of the thioenol.

The composition of the mixture of tautomers, previously determined iodometrically [33,103], should be checked by a physicochemical method if opportunity occurs.

The dependence of the color of thioketones upon temperature has been related to a shift in the tautomerization equilibrium [33,75], and can still be observed under nitrogen (see, however, [88]). The absorption in the visible part of the spectrum shows that only the intensity of the color alters [37]; it is thus true thermochromism that occurs.

There are considerable difficulties in determining the C=S frequency by infrared spectrometry, since it lies in a very crowded part of the spectrum. Complications also arise from the enolization and instability of some of the compounds. Doubt must be cast on the infrared bands between 1300 and 1550 $cm^{-1}$ cited in the literature [104]. More recent experience indicates that the C=S frequency should be expected to lie between 1100 and 1300 $cm^{-1}$ [*], although only the C–S stretching vibrations of two non-enolizable thioketones are known, *viz.* at 1120 $cm^{-1}$ for di-t-butyl thioketone [105] and at 1180 $cm^{-1}$ for thiofenchone [5]. In spite of spectroscopic comparisons and studies of the influence of the solvent, we have not yet been able to locate the C=S frequency of aliphatic thioketones unequivocally [36].

Aliphatic monothioketones exhibit characteristic absorptions in the visible and ultraviolet regions [106]. Thiofenchone and the enolizable thioketones already mentioned that exist largely in the thioketone form have absorption bands at 488–508 mμ (Type I), 230–244 mμ (Type II), and 214–215 mμ (Type III) in aliphatic hydrocarbon solvents (Fig. 1).

[106] *J. Fabian* and *R. Mayer*, Spektrochim. Acta, in the press.

The figures in italics indicate the strongest absorptions. The positions of the bands depend upon the solvent. The following mean band shifts were observed with four thioketones in passing from cyclohexane to ethanol: Type I: $\Delta \approx 500\ cm^{-1}$ (hypsochromic); Type II: $\Delta \approx 400\ cm^{-1}$ (bathochromic); Type III: $\Delta \approx 500\ cm^{-1}$ (hypsochromic). On the basis of their intensities and solvent dependencies [107] we would assign the bands of Type I to the prohibited transition $n \rightarrow \pi^*$ ($^1U \leftarrow {}^1A$), of Type II to the allowed transition $\pi \rightarrow \pi^*$, and of Type III to the allowed transition $n \rightarrow \sigma^*$ ($^1W \rightarrow {}^1A$) (see [107] for terminology).

The interpretation of the ultraviolet absorption of strongly enolizing monothioketones presents difficulties, since the thioenol configuration exhibits an intense absorption maximum at 220 mμ and hence a superimposed spectrum results [106]. The absorption in the visible region at 500 mμ remains unaffected except for a reduction in its intensity. Substitution of an alkyl residue by an unsaturated residue or by the strongly inductive $CF_3$ group leads to a bathochromic shift (cf. Table 2). Since p-π conjugation of the C=S group causes a marked hypsochromic shift in comparison with dialkyl thioketones, whereas π-π conjugation causes a strong bathochromic shift of the long-wavelength band [108] (Fig. 2), simple aliphatic thioketones can be recognized with some certainty.

## IV. Chemical Properties of Aliphatic Thioketones

### 1. Reactions with Nucleophilic Reagents

Aliphatic thioketones react with nucleophilic compounds by elimination of hydrogen sulfide in close analogy with ketones (Scheme 1); keto-enol tautomerism is of secondary importance here. Some reactions of thioenol ethers that follow a similar course are also known [32, 33, 109].

Scheme 1. Reactions of thioketones with nucleophilic reagents.

It is not yet possible to say to what extent it is advantageous to use thioketones in reactions instead of their oxygen analogues, but since condensations of thioketones proceed without a catalyst, new possibilities are opened up.

Thiones can be characterized as oximes, semicarbazones, and hydrazones, but it should be noted that *gem*-dithiols react similarly. Reduction of sulfur derivatives with sodium borohydride is of special interest in steroid chemistry [29, 89]. As we found [14], particularly with cyclohexanethione, the thione group is hydrolysed to the carbonyl group by hot water, hydrogen sulfide adds onto thiones smoothly to form 1,1-dithiols, and primary aliphatic amines (ammonia) from perhydro-1,3,5-dithiazines.

A remarkable property of aliphatic thioketones is their strong tendency to form polymeric products. In some cases [6, 10], or under certain conditions [14], dimers are observed instead of the more usual trimers [8, 9, 14, 19–21, 24–26, 30–33].

### 2. Reactions with Electrophilic Reagents

Nearly all the thioketones so far examined react at the sulfur atom with electrophilic reagents to give derivatives of the thioenol. This opens up numerous synthetic possibilities. Strongly enolized thioketones undergo the reactions shown in Scheme 2 with particular ease.

Electrophilic attack at the α-carbon atom of the thioketone only occurs occasionally. Because it is only slightly enolized, thiocamphor reacts in this way under the influence of alkaline condensing agents with benzaldehyde

to give α-benzylidenethiocamphor [111, 113] and with isoamyl nitrite to give α-isonitrosothiocamphor [98, 110, 114, 115]. Ester condensations should also be possible at the adjacent methylene group [116], but we have not yet been able to confirm this.

Finally we should mention that the alkali and heavy metal salts that are usually readily obtainable from the thioenolic form of thioketones are important for their detection and purification and for preparative work.

Our research group recently studied the products of further reactions of cyclopentanethione-2-carboxylic ester [52, 53] and of cyclohexanethione [14], but owing to the wealth of information collected we prefer to report these special results elsewhere.

## V. Summary

Although several alternative methods of formation of aliphatic thioketones are known, there is no general method of preparation. Many of the thioketones reported in the literature were found to be impure and some are actually *gem*-dithiols. Well-defined monomeric aliphatic thioketones are nearly always branched at the α-position. Among the stable cyclic thioketones, those ring sizes predominate that are sterically favorable to the formation of trigonal carbon. Neither phosphorus sulfides nor magnesium bromide hydrogen sulfide is satisfactory for the preparation of aliphatic thioketones from ketones.

Thioketones can only occasionally be obtained by the action of hydrogen sulfide on ketones in acidic medium, since trimers or *gem*-dithiols are formed predominantly; the method is only satisfactory for β-thioxocarboxylic esters. Mainly *gem*-dithiols and only occasionally thioketones are also formed in basic medium, even when enamines or ketimines are used as starting materials. On the other hand, ketals and enol ethers are cleaved by hydrogen sulfide in the presence of acidic catalysts to give thioketones; only a few examples yield *gem*-dithiols. Fission of ketals and enol ethers with hydrogen sulfide is the most general and useful method of preparation of aliphatic thioketones yet known.

Most of the methods for preparing aliphatic thioketones by pyrolysis are of doubtful value. Only thermal fission of the adducts of the now readily accessible *gem*-dithiols with malonodinitrile yields thioketones smoothly. Lower alicyclic thioketones are easily obtainable by this method. Very pure thioketones result from decarboxylation of β-thioxocarboxylic acids.

The red color ($\lambda_{max} \approx 500$ mμ) and the very penetrating, unpleasant odor of the lower homologues are characteristic of the unconjugated aliphatic thioketones. Strongly enolized members are almost colorless.

Chemically, thioketones behave like ketones toward nucleophilic reagents and often yield the same products, often even in the absence of catalysts. Nearly all the thioketones so far examined react with electrophilic reagents at the sulfur atom to form thioenol derivatives.

*We wish to record our thanks for generous State support for our work. Special thanks are due to our colleagues, coworkers, and neighbors of the Institute and of our station in Pirna-Copitz for enduring the nuisance of the smell with forbearance.*

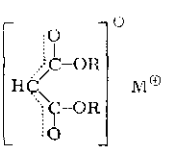
## A. Properties

### 1. Bond and Polarity



The typical organometallic bond links a saturated, non-polar hydrocarbon residue to a strongly electropositive alkali or alkaline earth metal. The limiting structures *(1)* and *(3)* represent the two possible extremes of the state of the bond.

$M{-}CR_3$ $M{\blacktriangleleft}CR_3$ $[:CR_3]^{\ominus}\ M^{\oplus}$.

*(1)* *(2)* *(3)*

The actual state *(2)* of the metal-carbon bond in metal alkyls lies between these two limiting structures. This representation of a covalent, but more or less polarized, bond is intended to indicate that the negative charge is concentrated in the vicinity of the carbon atom.

Two factors contribute to this strong polarization of the bond. One is the high electropositivity of the metal, and the other is the stabilization of the electron pair on the carbon atom which occurs as a result of inductive and mesomeric effects. The mesomeric effects are the more pronounced. Organometallic compounds capable of forming a resonance-stabilized carbanion are mostly present as ion pairs – *e.g.* malonic ester derivatives *(4)* – and thus react only with strong electrophiles. The corresponding hydrogenated compounds behave as Brönstedt acids.

*(4)*

The incompatibility of carbon and an alkali metal as components of a bond is the reason for the extraordinary reactivity and the unusual reactions exhibited by or-

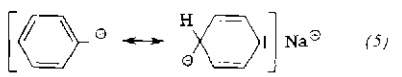
ganoalkali compounds. This incompatibility exists when the organic residue cannot stabilize the negative charge sufficiently. The dependence of the properties of organometallic compounds on the nature of the alkali metal is particularly strong for those with covalent bond character. The increase in electropositivity observed on going from lithium to sodium to potassium is clearly reflected in a striking increase in reactivity. In ionic organometallic compounds, on the other hand, the metal cation does not play an active part [2].

The reactivity is not necessarily directly related to the bond polarity, as indicated by the fact that the electropositivity of the metal, which tends to increase the basicity, and the resonance stabilization of the carbanion, which tends to reduce it, both exert polarizing effects. For example, amylpotassium is more polar and more reactive than amyl-lithium which, in turn, is far more reactive than sodiomalonic ester which is fully ionized.

Although unequivocal, sharp differentiation between true and salt-like organoalkali-metal compounds is not possible, differences in their chemical and physical behavior allow them to be grouped as follows [3]:

Group A: 1. Alkyl-, vinyl-, and aryl-lithium derivatives; 2. Alkyl, vinyl, and aryl derivatives of higher alkali metals.

Group B: 1. Benzylalkali-metal compounds; 2. Alkali-metal derivatives of acidic and highly acidic hydrocarbons; 3. Alkali metal-aromatic complexes and ketyls.

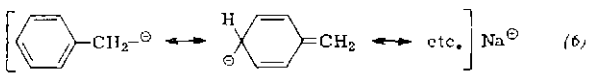


Group C: 1. Metal salts of allylic and cyclopentadienyl compounds; 2. Metal salts of ketones, esters, and nitriles; 3. Metal salts of acetylenes and hydrogen cyanide.

On the basis on this classification, we shall now consider in detail the bond character in organoalkali-metal compounds.

Group A: On passing from organolithium to organic compounds of the higher alkali metals, there are immense changes in properties, even though the electropositivity and the atomic radii increase continuously from lithium to cesium. This unusual behavior is obviously due to the great tendency of lithium compounds to undergo association [4].

Lithium derivatives are colorless, crystallizable substances that are volatile *in vacuo*. Their solutions in ether are stable at 0 °C. Lithium alkyls, with the exception of methyllithium, are readily soluble in hydrocarbons. Derivatives of higher alkali metals are also colorless but are not volatile and possess no definite melting points. They are practically insoluble in hydrocarbons and are rapidly decomposed by ethers.



This diversity in behavior is often interpreted as indicating that the bond between lithium and an alkyl or aryl group is polarized, yet covalent, whereas all organosodium and organopotassium compounds [*e.g.* the ion pair *(5)*] are salt-like [5].

*(5)*

This assumption is not consistent with the observation that amylpotassium is more reactive than amylsodium [6]. Dipole measurements cannot be used to investigate the bond character here, because the lithium alkyls and aryls tend to associate [7], and the corresponding sodium and potassium derivatives are insoluble. It is to be hoped that infrared and nuclear resonance spectroscopy will soon provide further insight into the polarity of the organometallic bond.

Group B: All intensely colored alkali derivatives belong to this group. It is apparent that the benzyl group, sometimes substituted, is a common structural characteristic of these derivatives. The gain in energy due to mesomerism according to *(6)* is so great that the metal-carbon bond is cleaved.

*(6)*

As will be shown below, it appears that all benzylalkali-metal compounds exist as ion pairs. As a result, variation of either the alkali metal (triphenylmethyl-lithium, -sodium, -potassium) or the substituent (benzyl-, dimethylphenyl-, triphenylmethyl-sodium) produces no drastic alterations in properties but rather a series of gradual difference from compound to compound. The decrease in basicity in going from sodium alkyls to benzylsodium is much more pronounced than that resulting from the introduction of a second or third phenyl group capable of resonance. All benzylalkali compounds are soluble and rather stable in ether, although the monophenyl derivatives, in contrast to the polyphenyl compounds [8], are not entirely stable, but cause slow decomposition of the ether [9].

The high dipole moment of triphenylmethylsodium ($\mu = 7.11$ D in dioxan) [10] supports its formulation as an ion pair. The tetramethylammonium salts *(7)* and *(8)* possess completely free anions [11].

$[H_5C_6\text{–}\underline{C}H_2]^{\ominus}[N(CH_3)_4]^{\oplus}$ *(7)*

$[(H_5C_6)_3C]^{\ominus}[N(CH_3)_4]^{\oplus}$ *(8)*

Any enlargement of the resonance system results in further decrease in basic strength of the anions; the acidity of the corresponding acids increases corre-

[2] In its ionic form, the alkali metal can, however, also affect the course of reaction. For example, because of its complex-forming cation, lithium hydroxide is a more effective catalyst of the benzilic acid rearrangement than other alkali hydroxides [*W. H. Puterbaugh* and *W. S. Gaugh*, J. org. Chemistry *26*, 3513 (1961)].

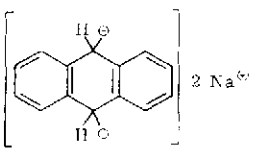
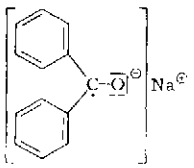
spondingly [12]. Compounds *(9)* [13] and *(10)* [14] are salts of acidic and highly acidic hydrocarbons.



*(9)*



*(10)*

The adducts resulting from the addition of an alkali metal onto aromatic compounds, olefins, carbonyl compounds, or azomethines, *e.g.* anthracenedisodium *(11)* or the sodium ketyl of benzophenone *(12)*, do not possess the reactivity of organometallic compounds [15].

*(11)*

*(12)*

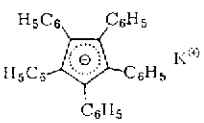
Group C: The members of this group, although colorless, have ionic structures similar to that of the benzylic derivatives. Because of the complete delocalization of its free electron pair, the allylic anion *(13)* shows high resonance stabilization and is similar in this respect to the triphenylmethyl anion.

*(13)*

The anions of enols, esters, and nitriles have considerably less energy because the negative charge encompasses the electronegative hetero-atoms as well. On the other hand, the stability of acetylides and cyanides is not due to mesomerism but to the intrinsic acidity of hydrogens on sp-hybridized carbon atoms. Acetylides and cyanides are too weakly basic to be considered as true organometallic compounds.

## 2. Color and Spectra

No unequivocal correlation has yet been established between the color and the structure of organoalkali compounds. The rule of thumb that benzyl anions are colored is not without exception. Tris-(3,3-dimethyl-1-butynyl)methylpotassium *(14)* [16,17] is bright red; metal derivatives of alkyl-substituted styrenes *(15)* are colorless.

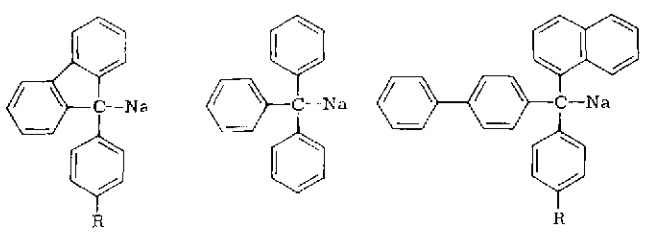


*(14)*

*(15)*

The color phenomena observed are consistent with the following hypothesis: The chromophore is an anion delocalized by resonance. The π-electron system with which the carbanion is in resonance must belong to a hydrocarbon with multiple unsaturation, preferably an aromatic compound. A vinyl group is not sufficient as is indicated by the fact that allylmetal compounds do not absorb in the visible region.

An appreciable portion of the negative charge must be transferred to the resonance system. Compound *(15)* and pentaphenylcyclopentadienylpotassium *(16)* [18] are colorless, because the probability of residence of the free electron pair in the benzene rings is too low.



*(16)*

Any increase in the size of the resonance system causes a shift in absorption toward longer wavelengths. In the case of the polymethine carbanion *(17)* [19], this shift amounts to 33 mμ per vinylene group.

*(17)*

The effect of aryl substituents on color was visually established for derivatives *(18)* through *(22)* [20].

*(18)* (orange-red), R = H
*(19)* (red), R = $OCH_3$

*(20)* (red)

*(21)* (blue-purple), R = H
*(22)* (dark-purple), R = $C_6H_5$

If, as suspected, the color arises from the free resonating carbanion, then the light absorption should be independent of the cation [21]. Identical spectra were in

[12] *G. W. Wheland* [J. chem. Physics 2, 474 (1934)] represents the acidity as a linear function of the difference between the energy of conjugation of the hydrocarbon and that of its carbanion.

[21] The lighter color of benzyl-lithium compared to benzyl sodium and its greater stability towards ether may be due to a partially covalent C—Li bond.

fact obtained for the lithium-, sodium-, and potassium-substituted benzhydryl ethers *(23)*. The Lambert-Beer law is satisfied [22].

*(23)*, M = Li, Na, K

The infrared absorption of allylic anions [23] and the electron-spin resonance of benzophenone ketyls [24] are also independent of the alkali metal. On the other hand, the infrared spectra of phenyl-lithium, phenylsodium, and phenylpotassium show not only common bands but also bands whose positions depend on the alkali metal [25, 26]. One of these groups of bands was tentatively assigned to the carbon-metal bond [26]; for another [25], a linear dependence on the reduced mass of the metal atom was established. These infrared spectroscopic data provide support for the argument that strongly polarized, yet still covalent, organometallic bonds exist in compounds of group A.

## 3. Electrical Conductivity and Electrolysis

Because of their small dielectric constants, ordinary nonpolar solvents do not separate a salt into individual ions. This can be demonstrated, for example, by measurements of the electrical conductivity. Thus, in ether, the carbon-metal bond in group B and group C compounds is fully ionized as the internal ion pair *(24)*, but by no means dissociated into a solvent-separated ion pair *(25)*. In *(24)*, the alkali cation and the carbanion are held together by electrostatic attraction and are surrounded by a common solvent shell. Not even benzophenone ketyls are dissociated in 1,2-dimethoxyethane, as is indicated by ESR measurements [24].

$[M^{\oplus}CR_3^{\ominus}]_{solv}$ *(24)* $\qquad [M(Solv)_m]^{\oplus}[R_3C(Solv)_n]^{\ominus}$ *(25)*

Triphenylmethylsodium has a low conductivity which vanishes with decreasing concentration [20]. A 0.005 M solution of triphenylmethylpotassium in ether is essentially non-conducting [27]. This phenomenon is plausibly explained by the following transport mechanism [20]: Free cations and anions, incapable of existing in ether, add on triphenylmethylsodium affording the complex ions *(26)* and *(27)*. The conductivity of lithium iodide in ether is also very low and that of the sodium salt of acetophenone is immeasurably small [27].

$[Na\{NaC(C_6H_5)_3\}_m]^{\oplus}$ *(26)* $\qquad [\{NaC(C_6H_5)_3\}_nC(C_6H_5)_3]^{\ominus}$ *(27)*

In strongly solvating media such as ammonia, pyridine, or dimethyl sulfoxide, triphenylsodium and triphenylmethylpotassium have identical equivalent conductivities, which are inversely proportional to the concentration, and are as large as those of strong inorganic electrolytes [28].

Organoalkali-metal compounds of group A are apparently all non-conductors [29]. Earlier statements to the contrary are, without exception, based on electrolyses in which a zinc dialkyl was used as solvent. Under these conditions, however, the conductivity is due to the formation of a complex $M(ZnR_3)$ [30].

*Ziegler* [31] recently worked out an industrially interesting synthesis of tetraethyl-lead which is based on the electrolysis of such an $M(ZnR_3)$ complex. Sodium tetraethylaluminate, which behaves chemically as a mixture of ethylsodium and triethylaluminum, is subjected to electrolysis with a mercury cathode and a lead anode, the latter reacting with the ethyl radicals. Tetraethyl-lead distills off along with triethylaluminum. The ethylsodium consumed is regenerated by the reaction of the sodium liberated at the cathode with hydrogen and ethylene; the overall reaction is thus as follows:

$$Pb + 2\,H_2 + 4\,H_2C{=}CH_2 \xrightarrow{\text{electrical energy}} Pb(C_2H_5)_4.$$

## 4. Configurational and Structural Stability

Until now, the studies carried out on optically active lithium alkyls [32], lithium cyclopropyl derivatives [33], and geometrically isomeric vinyl-lithium derivatives [34] have not been extended to the corresponding sodium and potassium derivatives.

Optically active carbanions have been detected as short-lived intermediates in base catalysed deprotonations of hydrocarbons and sulfones, in the cleavage of secondary alkoxides and in the decarboxylation of carboxylic acids. Neutralization proceeds with retention, inversion, or racemization, depending on the protonating solvent applied [35].

Organometallic compounds with $\beta$-hydrogens undergo thermal decomposition with particular ease. Ethylsodium [36] decomposes mainly as follows:

$$Na{-}C_2H_5 \xrightarrow{100\,^{\circ}C} H_2C{=}CH_2 + NaH\ .$$

Higher homologues *e.g.* propylsodium [37] and amylsodium [38], also decompose gradually at room temperature, and rapidly between 50 and 100 °C. In addition to the olefin, this process usually yields the saturated hydrocarbon as a by-product; in some instances it even becomes the major product. An interpretation of this thermal decomposition in terms of a free-radical

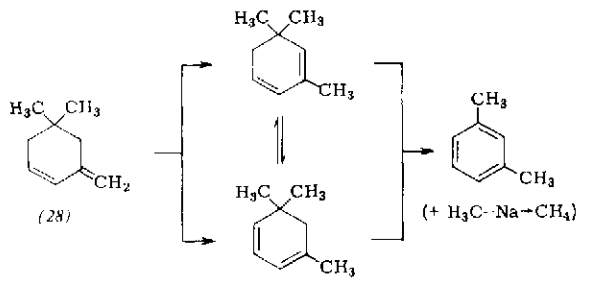
[35] Review: *G. Köbrich*, Angew. Chem. *74*, 453 (1962); Angew. Chem. internat. Edit. *1*, 382 (1962).



[36] *W. H. Carothers* and *D. D. Coffman*, J. Amer. chem. Soc. *51*, 588 (1929); *52*, 1254 (1930).

[37] *R. L. Letsinger* and *D. F. Pollart*, J. Amer. chem. Soc. *78*, 6079 (1956).

reaction [38] was proved by *Bryce-Smith* [39] to be incorrect. For example, decomposition in the presence of cumene affords no 2,3-diphenyl-2,3-dimethylbutane. It is possible that the alkane formation is due to a disproportionating autometalation [36] of the alkylsodium [40]. Methylsodium decomposes at 200 °C into methane, sodium, and sodium carbide. The thermolysis of methylpotassium, although vigorous at 100 °C, goes to completion only at 250 °C. This suggests the formation of thermally more stable intermediates [36,41]:

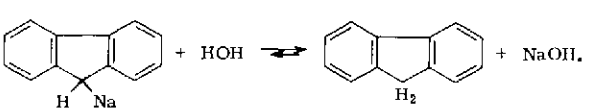
$$K{-}CH_3 \xrightarrow{100\,^\circ C} (K_2CH_2) \rightarrow (K_3CH) \xrightarrow{250\,^\circ C} (K_4C) \rightarrow (K_2C_2)\ .$$

Neopentylsodium is also devoid of β-hydrogens. Its decomposition at 144 °C gives, in addition to resins, 17% neopentane, 8% methane, 45% methylsodium, and 0.5% i-butenylsodium [42]. Obviously, a β-elimination of methylsodium is involved, as was observed for the base-catalysed rearrangement of 1,1,3-trimethylcyclohexadienes *(28)* to *m*-xylene [43].

*(28)*

## B. Replacement of the Metal by Hydrogen

### 1. Neutralization with Compounds Containing Active Hydrogen



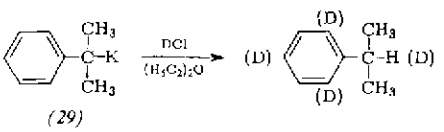
Suitable coreactants for organoalkali compounds, regardless of their bond polarity, are X–Y compounds in which Y can become an anion and X is capable of neutralizing the latent or free carbanion by the formation of a stable, covalent bond.

$$\overset{\delta\oplus\ \ \delta\ominus}{M{-}CR_3} + X{-}Y \rightarrow M^{\oplus} + Y^{\ominus} + X{-}CR_3.$$

In the simplest case, X is hydrogen and Y an acid anion:

$$H_5C_6{-}\underset{(29)}{C(CH_3)_2{-}K} + H{-}Cl \rightarrow H_5C_6{-}CH(CH_3)_2 + KCl;$$

$$H_5C_6{-}Na + H{-}P(C_6H_5)_2 \rightarrow C_6H_6 + Na{-}P(C_6H_5)_2;$$



*(30)*

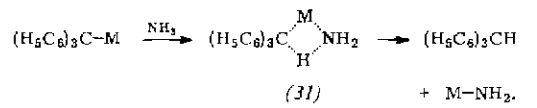
In the third example, the neutralization of a weak organometallic base *(30)* with a weak proton donor ($H_2O$), an equilibrium is observed that is shifted to the right [44].

### 2. Neutralization with Compounds Containing Active Deuterium

On neutralization with heavy water, the metal is replaced by deuterium; thus, a hydrocarbon labelled in a specific position is obtained.

This selectivity is not observed with carbanions with delocalized negative charge. Phenylisopropylpotassium *(29)* reacts with deuterium chloride in ether to afford cumene in which 69% of the α-, 5% of the *ortho*-, and 15% of the *para*-positions are substituted by deuterium. Mass spectrograms indicate that 58% of the product are monodeuterated, 14% dideuterated, and 1% trideuterated; 14% contain no deuterium [45].

*(29)*



Heavy water [45], carbon dioxide, and dimethyl sulfate [46], on the other hand, attack *(29)* exclusively at the α-position. Even deuterium chloride effects only α-substitution when the more polar solvent 1,2-dimethoxyethane or pentane (in heterogeneous phase) is used instead of ether [45].

### 3. Aminolysis

A "reverse" order of reactivity has been established for the reactions of triphenylmethylalkali-metal compounds with ammonia or piperidine yielding triphenylmethane and alkali amide [47,48]:

$$(H_5C_6)_3C{-}Li > (H_5C_6)_3C{-}Na > (H_5C_6)_3C{-}K$$

This may be due to the greater tendency of the lower alkali metals to form complexes, which might promote the formation of an intermediate *(31)* [48].

*(31)*

### 4. Hydrogenolysis

Molecular hydrogen cleaves organometallic compounds into hydrocarbons and metal hydrides. Whereas the hydrogenolysis of organolithium compounds [49] pro-

[39] *D. Bryce-Smith*, J. chem. Soc. (London) *1955*, 1712.

[40] On the other hand, the photolytic decomposition of organoalkali-metal compounds seems to proceed by a radical process [cf. [22] as well as *H. Linschitz, M. G. Berry*, and *D. Schweitzer*, J. Amer. chem. Soc. *76*, 5833 (1954)].

[41] The isolation of methylenedilithium, $Li_2CH_2$, after mild thermolysis of methyl-lithium has been accomplished [*K. Ziegler, K. Nagel*, and *M. Patheiger*, Z. anorg. allg. Chem. *282*, 345 (1955); Chem. Abstr. *52*, 1203 h (1958)].

[42] *R. A. Finnegan*, Chem. and Ind. *1962*, 895.

[45] *G. A. Russell*, J. Amer. chem. Soc. *81*, 2017 (1959).

[46] *K. Ziegler* and *B. Schnell*, Liebigs Ann. Chem. *437*, 227 (1934).

[47] *C. R. Hauser, D. S. Hoffenberg, W. H. Puterbaugh*, and *F. C. Frostick*, J. org. Chemistry *20*, 1531 (1955).

[48] *G. Wittig*, Experientia *14*, 389 (1958).

[49] *H. Gilman, A. L. Jacoby*, and *H. Ludeman*, J. Amer. chem. Soc. *60*, 2336 (1938).

ceeds smoothly only under pressure, potassium derivatives [50] react quite readily even under normal conditions. For example:

$$H_5C_6K + H_2 \rightarrow H_6C_6 + KH\ .$$

## 5. Metalations

Pure hydrocarbons also act as proton donors for organometallic compounds. Reactions in which a new organometallic base is produced by replacement of organic hydrogen with a metal atom from another organometallic base are called "metalations" [51]; the term "anionization" denotes proton abstraction from distinctly acidic reactants such as inorganic acids, alcohols, enols, esters, or nitriles. In metalations, as in other acid-base reactions, the weaker organometallic base and the less acidic hydrocarbon are generally produced:

$$H_5C_6{-}Na + H_3C{-}CH{=}CH_2 \rightarrow H_6C_6 + [H_2C{-}CH{=}CH_2]^{\ominus}Na^{\oplus}$$

For sodium and potassium compounds, the differences in acidity can be rather small. Thus, phenyl-lithium is a poor metalating agent even for triphenylmethane, whereas phenylpotassium reacts readily with toluene.

Table 1 gives a list of several representative hydrocarbons, and Table 2 of a few amines and alcohols, arranged according to their acidic strengths [52a–52d].

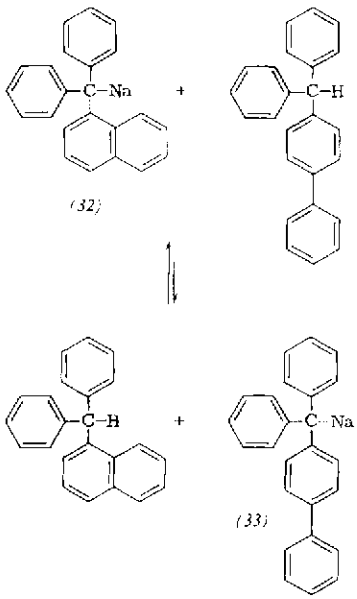
Table 1. Acid strengths of acidic hydrocarbons.

| Proton donor | $pK_a$ |
|---|---|
| $R_3CH$ (R=H, alkyl) | 40 [*] |
| $H_2C{=}CH_2$ | 39 [*] |
| $C_6H_6$ | 39 [*] |
| $H_5C_6{-}CH(CH_3)_2$ | 37 |
| $H_5C_6{-}CH_3$ | 37 |
| $H_2C{=}CH{-}CH_3$ | 37 [*] |
| $(H_5C_2)_2CH_2$ | 35 |
| $(H_5C_6)_3CH$ | 33 |
| Fluorene | 25 |
| Indene | 21 |
| $H_5C_6{-}C{\equiv}C{-}H$ | 21 |

[*] Extrapolated values.

Table 2. Acid strength of amines and alcohols.

| Proton donor | $pK_a$ |
|---|---|
| $NH_3$ | 36 |
| $H_5C_6{-}NH_2$ | 27 |
| $(H_5C_6)_2NH$ | 23 |
| $(H_3C)_3COH$ | 19 |
| $H_3COH$ | 16 |



In accordance with experimental results, the following order of basic strengths for organosodium and organopotassium compounds can be derived from Table 1:

$$\text{alkyl-M} > \text{aryl-M} > \text{benzyl-M} > (H_5C_6)_3C{-}M\ .$$

The more subtle differences established for organolithium compounds are probably also applicable to the higher alkali metals:

$$\text{tert.alkyl-M} > \text{sec.alkyl-M} > \text{prim.alkyl-M} > C_6H_5{-}M > H_3C{-}M\ .$$

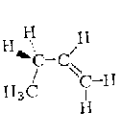
If the hydrocarbons involved in an acid-base reaction are nearly equal in acidity, an equilibrium will result which for potassium derivatives is attained within a few hours and for sodium derivatives [*(32)* ⇌ *(33)*] only after one month [52a].

### a) *Allylic Compounds*

Propylene reacts readily with amylsodium to afford the allyl anion, which can be characterized by carboxylation to give vinylacetic acid *(34)*; in addition, 15 % of a dicarboxylic acid formed by dimetalation is obtained [53].

$$H_2C{=}CH{-}CH_3 \xrightarrow{H_{11}C_5{-}Na} [H_2C{=}CH{-}CH_2]Na$$

$$\xrightarrow[2.\ H_2O]{1.\ CO_2} H_2C{=}CH{-}CH_2{-}COOH\ \textit{(34)},\ 69\ \%$$



The isomerization of olefins discovered by *Morton* [54] is promoted by catalytic amounts of organometallic compounds and proceeds by way of such allylic anions:

1-Pentene → *trans*-2-pentene

1-Octene → *trans*-2-octene

β-Pinene → α-pinene

The double-bond shift can be followed readily in reactions catalyzed with potassium t-butoxide in dimethyl sulfoxide [55]. Thus 1-butene first yields mainly *cis*-2-butene, which then slowly rearranges to the thermodynamically more stable isomer *trans*-2-butene. Apparently, the removal of a proton from a conformation such as *(35)*, resulting in a *cis*-anion and a *cis*-olefin, is particularly easy.

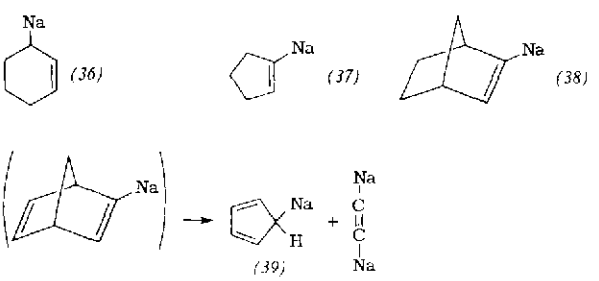
b) *Benzylic Compounds*



Amylsodium metalates toluene instantaneously to give benzylsodium [56]. Phenylsodium is less basic and therefore reacts quantitatively with toluene only on prolonged boiling, whereas the reaction with diphenyl- and triphenylmethane occurs in the cold. The reaction of amylsodium with ethylbenzene is slower than that with toluene. In the reaction of amylsodium with cumene substitution no longer takes place at the sterically protected α-position but instead, preferentially at the more readily available ring hydrogens (55 % *meta*, 42 % *para*). *Benkeser* [57] differentiates between kinetically and thermodynamically controlled reactions. Thus, after 3 hours' treatment with amylpotassium, cumene gives 42 % α-, 39 % *meta*-, and 19 % *para*-metalated product; however, a 20 hour reaction period affords exclusively phenylisopropylpotassium.

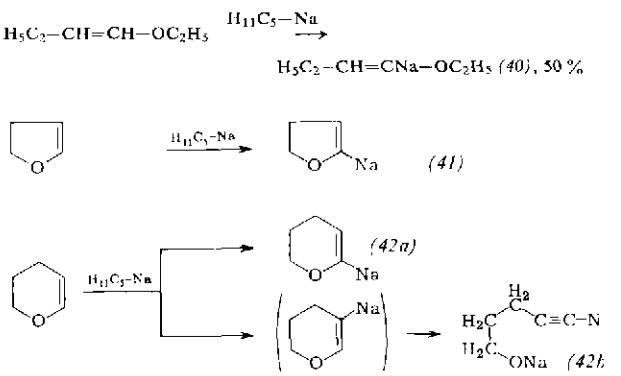
c) *Olefins*

The acidity of a C–H bond increases with increasing s-character ($sp > sp^2 > sp^3$) [58]. Accordingly, alkali alkyls replace an olefinic hydrogen by a metal atom, provided that, as in ethylene [59] or 3,3-dimethyl-1-butene [59], more readily metalated allylic hydrogens are absent.

$$(H_3C)_3C-CH=CH_2 \xrightarrow{H_{11}C_5-Na} (H_3C)_3C-CH=CH-Na \quad (61\,\%).$$

Ring strain also enhances the s-character of exocyclic bonds. Whereas cyclohexene and amylsodium interact to form an allylic anion *(36)*, cyclopentene [60], norbornene [61], and norbornadiene [62] undergo metalation with increasing ease to the derivatives *(37)*, *(38)*, and *(39)*, respectively [63a,63b], with ring opening in the last case.

The olefinic hydrogen in 2,3,3-trimethyl-1-cyclopropene [64] is nearly as active as the hydrogen in acetylene; hence, it is replaced even with methyl-lithium. Cyclopropane [65] reportedly reacts with amylsodium to give cyclopropylsodium [66].



d) *Aromatic Compounds*

Benzene hardly reacts with n-butyl-lithium [67] but is metalated by amylsodium at elevated temperatures to give a 90 % yield of phenylsodium; a small amount of phenylenedisodium is formed as by-product. *m*-Phenylenedisodium is reportedly obtained in 85 % yield if benzene is used in less than the stoichiometric amount [68].

The acidity of polyphenyls and naphthalene differs only slightly from that of benzene. These hydrocarbons, therefore, cannot be metalated at all or only to a slight extent [69,70]. The reaction of naphthalene with amylsodium produces a mixture of the α- and β-isomers of mono-, di-, and trimetalated products [71].

e) *Heterosubstituted Olefins and Heterocycles*

Because of the electron attraction of the hetero-atom, metalation of vinyl ethers involves the alpha rather than the allylic hydrogen, leading for example, to *(40)*, *(41)*, *(42a)*, and *(42b)* [72].

In the case of dihydropyran, the formation of the stable α-metalated derivative is accompanied by a ring opening promoted by β-metalation. The pseudoaromatics furan

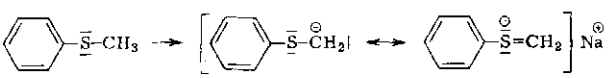
[73, 74] and thiophene [75] undergo substitution of the α-hydrogens by metal with surprising ease. With excess amylsodium, both heterocycles give the 2,5-dimetalated derivatives, thiophene reacting more readily than furan [76].

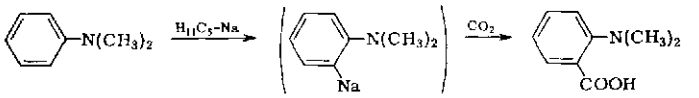


f) *Heterosubstituted Aromatic Compounds*

More remote hydrogens can also be activated by electronegative hetero-atoms, albeit to a lesser extent. This activation accounts for the ease of metalation of *ortho*-hydrogens in aryl halides, aryl ethers, and benzotrifluoride [77].

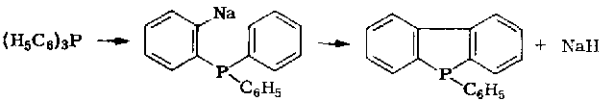
The ability of ring hydrogens to undergo metalation is strongly enhanced by hetero-atoms of the first period which obey the octet rule, indicating inductive effects. Substituents can be arranged in the order of their acidifying effect, as follows:

$$F > F_3C > H_5C_6O > H_3CO > Cl > Br > (H_3C)_2N > H\,.$$



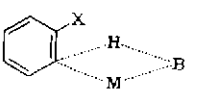
Anisole [56, 70], diphenyl ether [78], and diphenyl sulfide [70] are metalated in the *ortho*-position. With methyl phenyl sulfide, the side chain is more reactive because the d-orbitals of the sulfur participate in the resonance *(43)* [79].

*(43)*



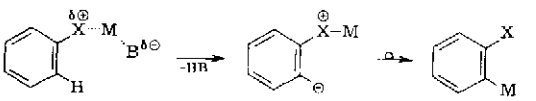
The behavior of dibenzothiophene is similar to that of the acyclic diphenyl sulfide, *i.e.* it is metalated by strong organometallic compounds in one of the two *ortho*-positions [70]. The *ortho*-positions in dibenzofuran are far more activated. This compound is attacked even by methyl-lithium, and benzylsodium, a relatively weak base, converts it into the *o,o'*-disodio derivative in 80 % yield [80].

Aniline [81] and its derivatives [56, 70, 82] are also metalated in the *ortho*-position [*e.g. (44)*].



*(44)*

Under drastic conditions, n-butyl-lithium slowly attacks triphenylamine [83], triphenylphosphine [84], and triphenylarsine [85] at the *meta*-position. At 70 °C, phenylsodium converts triphenylphosphine into diphenylenephenylphosphine *(45b)* [86] presumably by intramolecular elimination of sodium hydride from the *ortho*-metalated form *(45a)*. The *meta*-metalated compound formed undergoes subsequent hydrolytic decomposition.



*(45a)* *(45b)*, 15%

The seeming randomness with which organometallic bases bring about metal-hydrogen exchange – sometimes in the *ortho*- and sometimes in the *meta*-position – has prompted extensive discussions of the underlying mechanism. The interpretation of metalation as an electrophilic reaction [87] or as a free-radical process [88] is obsolete. It is now known that the reaction occurs by a nucleophilic, or more correctly, a protophilic [89], attack by the base. According to the concept developed by *Huisgen* [90], the process has a concerted mechanism (F 2) involving a four-centered transition state *(46)* and does not entail an associated precursor *(47)* [77].

*(46)*

*(47)*

g) *Eliminations Leading to Arynes*

Studies involving trapping and symmetrizing reactions have demonstrated the striking readiness with which *ortho*-metalated aryl halides [91–93] release the oppositely polarized substituent and thus afford arynes such as dehydrobenzene *(48)*, which cannot be isolated as such.

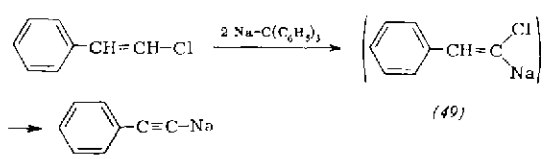
(48)

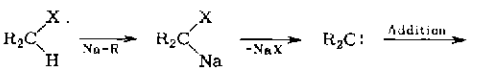
The metalating agents most frequently used in investigations of arynes were organolithium reagents and lithium amide [94]. However, intermediate formation of *o*-phenylene in the reaction of amylsodium with chlorobenzene was already discussed by *Morton* [95] in order to explain the formation of triphenylene and amylbenzene.



*o*-Halogenophenylalkali-metal compounds lose alkali halide even below 50 °C. *ortho*-Metalated diaryle thers eliminate phenoxide ion only on heating, because of the stronger bond between the aryloxy group and the ring. The elimination of this group as an anion is facilitated by a high electron density at the adjacent position. For this reason, *o*-phenoxyphenylsodium decomposes at 60 °C faster than *o*-phenoxyphenyl-lithium [96,97]. The dehydrobenzene *(48)* formed can be trapped *in situ* with triphenylmethylsodium [96].

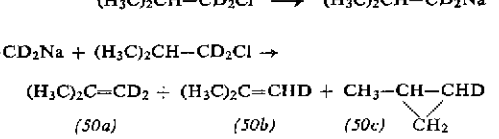
(48)

h) *Eliminations Leading to Acetylenes*



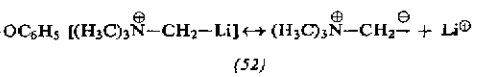
Acyclic acetylenes are lower in energy than the arynes which have a strained triple bond [98]. Accordingly, metalated intermediates could not yet be detected in the dehydrohalogenation of vinyl chlorides with organosodium reagents [99]. The analogous metalation of vinyl ethers and model reactions [100], however, suggest primary attack on the α-hydrogen with formation of *(49)*.

(49)



i) *Eliminations Leading to Carbenes*

The carbenes [101], like the arynes, are short-lived electrophiles that are extremely rich in energy and can hence be detected only by means of trapping reactions. The organometallic precursors of the carbenes are obtained by α-metalation of heterofunctional aliphatics and bear on the same carbon oppositely polarized substituents which are released by α-elimination.



Haloforms [102] and α-chloroalkyl thioethers [103] are sufficiently acidic to be metalated even by alkoxides. On the other hand, the introduction of a metal into α-chloroalkyl ethers [104], dihalogenomethanes [105], and particularly alkyl halides requires the strongest organometallic bases. Thus, methylene is reported to be formed by action of phenylsodium on methyl chloride and to add on in the nascent state to cyclohexene affording norcarane in 1 % yield [106].

*Kirmse* and *Doering* [107] used isotope techniques and collected valuable information concerning the reaction of sodium with primary, secondary, or tertiary butyl halides. Following α-elimination, the carbene is stabilized by either a hydride shift *(50b)* or cyclopropane ring closure *(50c)*; β-elimination to yield *(50a)* also occurs, but no γ-elimination.

α-Elimination increases when potassium is used in place of sodium but is negligibly small with lithium.

Carbene precursors with sodium and chlorine on the same carbon are unstable even at very low temperatures. Replacement of the halogen by a poorer leaving group makes it possible to trap the metalated carbene precursor, for example *(51)* and *(52)*.

In tetrahydrofuran or 1,2-dimethoxyethane, *(51)* undergoes isomerization to triphenylmethoxide (Wittig rearrangement). In ether or petroleum ether, decomposition to diphenylcarbene and phenoxide seems to occur [22,108].

[94] Particular attention is called to the studies of *R. Huisgen* et al., Chem. Ber. *92*, 192 (1959); *93*, 412 (1960).

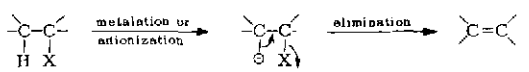
[108] Cf. *U. Schöllkopf* and *M. Eisert*, Angew. Chem. *72*, 349 (1960).

The function of the organometallic bond as an electron reservoir becomes manifest in the cleavage of nitrogen ylides *(52)*. Ylides prepared with phenyl-lithium or in the presence of lithium salts are stable [109]; more electropositive metals, *e.g.* Na *(52a)*, promote cleavage of the ylides into amine and carbene [109a]. Sulfonium ylides are unstable and decompose similarly [110a, 110b].

$$(H_3C)_4N^{\oplus}Br^{\ominus} \xrightarrow{Na-C_6H_5} (H_3C)_3\overset{\oplus}{N}-\overset{\ominus}{C}H_2\cdots Na \rightarrow (H_3C)_3N + :CH_2$$

*(52a)*

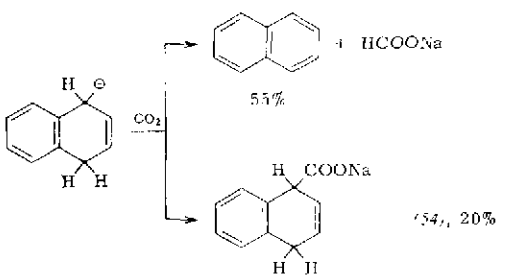
k) *Eliminations Leading to Olefins*



The reaction of organometallic compounds with alkyl halides yields carbenes or, as will be discussed later, results in either halogen-metal exchange or condensations leading to hydrocarbons. If the prerequisites for one of these three types of reaction are not entirely satisfied, concurrent β-elimination occurs and may often become the main reaction, *e.g.* as with *(60)*.

$$n\text{-}H_{13}C_6-Cl + H_5C_2-Na \rightarrow n\text{-}H_9C_4-CH=CH_2 + C_2H_6 + NaCl$$

*(60)*, 46 % [111]

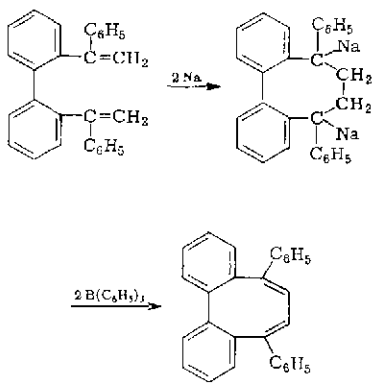


β-Eliminations [112] take place either by the carbanion or the concerted mechanism.

The characteristic of the carbanion mechanism (E 1cB) is an anionic intermediate *(53)* formed by loss of an acidic hydrogen from *(53a)*. The electronegative substituent X is eliminated in a second, rate-determining step.

*(53a)* *(53)*

The elimination of hydrogen chloride from β-chloro sulfones [113] has been explained on the basis of this mechanism. If the substituent to be removed as an anion, *e.g.* a hydride ion, is not a good leaving group, then the anionic intermediate *(53)* can be secured. Thus, 1,4-cyclohexadiene reacts with amylsodium affording a diallyl anion which reacts with carbon dioxide to form

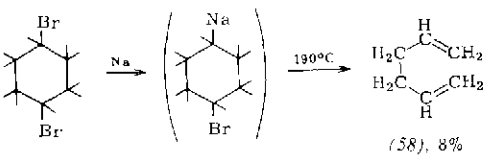


benzene and sodium formate. Carboxylation of the corresponding metalation product obtained from 1,4-dihydronaphthalene affords naphthalene and 1,4-dihydro-1-naphthoic acid *(54)* [114].

If aromatization is precluded, as with *(55)* and *(56)*, elimination of alkali-metal hydride is possible only in the presence of hydride acceptors such as triphenylborane [115].

$$(H_5C_6)_2C-CH_2-H + B(C_6H_5)_3 \rightarrow (H_5C_6)_2C=CH_2 + [HB(C_6H_5)_3]K$$

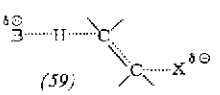
*(55)*, 73 %



*(56)*, 64%

Sometimes the leaving anion is a carbanion. 3,3,3-Triphenyl-n-propylsodium *(57)* [116] evolves ethylene even in liquid ammonia, whereas the analogous decomposition of 3,3-dimethyl-3-phenyl-n-propylpotassium takes

$$(H_5C_6)_3C-CH_2-CH_2I \xrightarrow[NH_3]{Na} \underset{(57)}{(H_5C_6)_3C-CH_2-CH_2Na} \rightarrow$$



$$(H_5C_6)_3C-Na + CH_2=CH_2$$

place only in boiling cyclohexane [117]. The 1,4-elimination leading from 4-bromocyclohexylsodium to diallyl *(58)* must be effected in boiling decalin.

*(58)*, 8%

Eliminations involving a concerted mechanism (E 2) are much more frequent. The simultaneous bond cleavage and formation circumvents the formation of the high-energy intermediate *(53)* and leads directly to the stable olefinic end product via the transition state *(59)* which is similarly favorable as the transition state occurring in $S_N2$ processes [118].

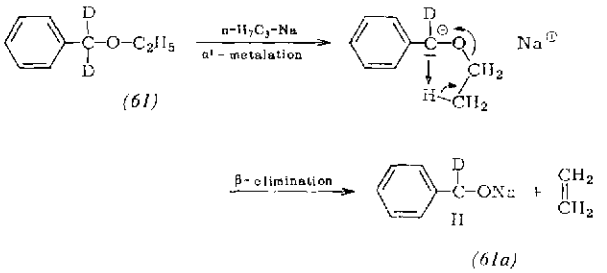
[116] *C. B. Wooster* and *R. A. Morse*, J. Amer. chem. Soc. *56*, 1735 (1934).



[117] *H. Pines* and *L. Schaaf*, J. Amer. chem. Soc. *80*, 4379 (1958).

Strictly speaking, such concerted eliminations should not be considered as metalation reactions, because, in contrast to all the eliminations discussed so far, metalated, even if short-lived, intermediates are no longer formed.

The cleavage of aliphatic ethers by strong organometallic reagents mentioned above also proceeds by β-elimination [119].

$$H_3C-CD_2-OR \xrightarrow{n\text{-}H_7C_3-Na} H_2C=CD_2 + NaOR + n\text{-}C_3H_8 .$$

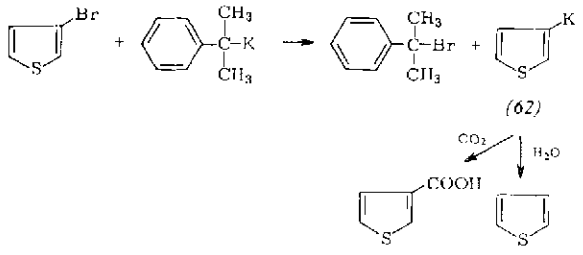
Benzyl ethers *(61)* [119], ammonium salts [120], and sulfonium salts [121] are degraded to olefins via α′,β-elimination. The organometallic base attacks the more acidic α′-hydrogens, and the resulting carbanions then undergo a rapid intramolecular β-elimination to form the more stable end product, *e.g. (61a)*.

*(61)* *(61a)*

## C. Replacement of Metal by Halogen

### 1. Halogenolysis

Donors of positive halogen, like active-proton compounds, are capable of heterolysing the organometallic bond. In the chemistry of organolithium compounds, for example, iodolysis has found wide application in both analysis and synthesis [122]. There are no reports that true organosodium and organopotassium derivatievs undergo analogous reactions, although the reaction of iodine with the sodio derivative of ethyl acetate is known [123]:



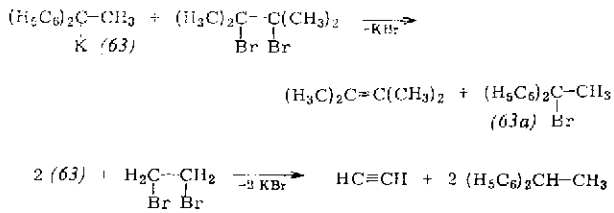
$$H_5C_2OOC-\overset{\ominus}{C}H_2\ Na^{\oplus} \xrightarrow[2.\ \text{Saponification}]{1.\ I_2} I-CH_2-COOH \quad (25\,\%)$$

### 2. Halogen-Metal Interconversion

The reaction of an organic halide with an organometallic compound effecting metathesis of the substituents is referred to as halogen-metal interconversion. If R′H is a stronger acid than RH, the reaction proceeds from left to right:

$$R-M + R'X \rightarrow R-X + R'M .$$

Halogen-metal interconversion is characteristic of organolithium compounds [124] since their associating power is strong enough to give rise to the intermediate complex [125], which is probably responsible for the reaction. Only a few metathesis reactions involving compounds of the higher alkali metals are known; these include n-butylsodium/1-bromonaphthalene [80]; amylsodium/*o*-bromotoluene, bromobenzene, 1-bromonaphthalene [126]; and amylsodium/methyl iodide [95].



*(62)*

*(62b)*, 62% *(62a)*, 93%

The reaction of 3-bromothiophene with phenylisopropylpotassium to give 3-thienylpotassium *(62)* is surprisingly smooth; *(62)* can then be hydrolysed to thiophene *(62a)* or can be carboxylated to 3-thiophenecarboxylic acid; the phenylisopropyl bromide formed as by-product reacts with excess phenylisopropylpotassium to give 2,3-diphenyl-2,3-dimethyl-n-butane [127].

2,3-Dibromo-2,3-dimethylbutane is a very effective brominating agent. It converts 1,1-diphenylethylpotassium *(63)* into the corresponding bromide *(63a)* which, in turn, reacts with excess *(63)*, to yield 70 % 2,2,3,3-tetraphenyl-n-butane. The reaction of *(63)* with 1,2-dibromoethane, on the other hand, occurs predominantly with elimination [46].

*(63)* *(63a)*

## D. Replacement of the Metal by Carbon and Other Non-Metals

### 1. Alkyl and Aryl Halides

#### a) *Condensations* [128]

The organometallic bond reacts not only with acidic hydrogen or positively charged halogen but also with the positive carbon of organic halides. This C–C coupling proceeds satisfactorily only with alkyl deri-

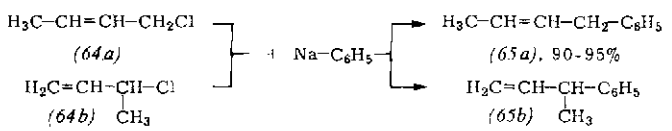
[127] *G. Wittig* and *V. Wahl*, unpublished work.



[128] Condensation generally implies a union of two reactants with loss of an electropositive substituent from the one and of an electronegative substituent from the other. The concept of coupling should be restricted to use in the chemistry of dyes.

vatives which are easily substituted. Compounds that are particularly suitable are alkyl iodides [129] and sulfuric esters, *e.g.* dimethyl sulfate [129a].

$$H_5C_6{-}Na + CH_3I \rightarrow C_6H_5{-}CH_3 + NaI$$

Alkyl bromides and chlorides condense so slowly [130] that side reactions, particularly eliminations, predominate. Phenylsodium and n-octyl bromide yield a mixture of condensation product and olefins. Phenyl-lithium is a milder reagent and reacts more slowly, but without undesirable olefin formation [131].

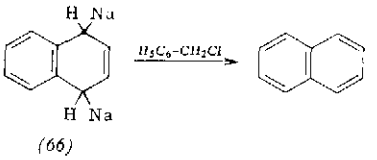
Allyl and benzyl halides are unusually reactive because of the labile halogen they contain. It is noteworthy that the reaction of phenylsodium with the isomeric methylallyl chlorides *(64a)* gave nearly identical mixtures of the two isomeric phenylbutenes *(56a)* and *(56b)* [132].

The extraordinary tendency of alkali-metal derivatives of benzyl, benzhydryl, and triphenylmethyl compounds to give condensation reactions demonstrates that the rate of C–C coupling depends less on basicity than on bond polarity. For example:

$$(H_5C_6)_3C{-}Na + CH_3I \rightarrow (H_5C_6)_3C{-}CH_3 \quad [20, 133]$$

$$(H_5C_6)_2CH{-}Na + CH_2Cl_2 \rightarrow (H_5C_6)_2CH{-}CH_2Cl \quad [134]$$

$$(H_5C_6)_2C(CH_3){-}K + CH_2Cl_2 \rightarrow (H_5C_6)_2C(CH_3){-}CH_2Cl \quad [135]$$



Condensations between benzyl-metal compounds and benzyl halides, *i.e.* between a free carbanion and a labile halogen, are immeasurably fast. The same is true for the following reactions:

$$(H_5C_6)_3C{-}Na + Cl{-}CH_2OCH_3 \rightarrow (H_5C_6)_3C{-}CH_2OCH_3 \quad [136]$$

$$(H_5C_6)_3C{-}Na + Cl{-}COOC_2H_5 \rightarrow (H_5C_6)_3C{-}COOC_2H_5 \quad [137]$$

Steric hindrance sometimes causes elimination to occur rather than condensation. For example, because of its bulk, triphenylmethylsodium only splits off hydrogen chloride from isopropyl chloride [136].

Organometallic derivatives formed by addition of the elemental metal onto unsaturated compounds generally do not undergo condensation; instead, they regenerate the initial hydrocarbon, *e.g. (66)* [138].

*(66)*

b) *The Wurtz-Fittig Reaction*

The Wurtz reaction is a preparative variation of the condensations described under D. 1a). An alkyl halide, preferably an iodide, is treated with metallic sodium to promote C–C coupling of two alkyl radicals. Sodium alkyls are formed [139] which then undergo condensation with unreacted halide.

$$R{-}I \xrightarrow{Na} (R{-}Na) \xrightarrow{R{-}I} R{-}R.$$

With alkyl chlorides, the condensation reaction can be effectively suppressed by applying special conditions; instead, the formation of organosodium compounds is achieved [140].

Intramolecular Wurtz condensations with 1,3- or 1,4-dihalogenoalkanes yield cyclopropanes or cyclobutanes. The scope of intermolecular reactions is restricted, for only symmetrical hydrocarbons can be formed in good yields. If two different alkyl halides, RX and R′X, are used, a mixture of three products, R–R′, R–R, and R′–R′, will result.

The special variant of this condensation discovered by *Fittig* [141], *i.e.* the halogenation of a mixture of aryl and alkyl halides, leads predominantly to unsymmetric products; pure aliphatic derivatives or diaryls are hardly formed [142]. This selectivity arises from pronounced differences in the reactivities of the coreactants. Aryl halides react with sodium faster than alkyl halides. On the other hand, aliphatic halogen can be more easily substituted than aromatic halogen.

c) *Stereochemistry of the Condensations*

When optically active alkyl and benzyl halides were treated with organometallic compounds, sometimes hydrocarbon formation occurred with complete racemization, and sometimes the racemization was accompanied by inversion. Table 3 gives a summary of the stereochemical course of the condensation of various organometallic compounds with ( )-2-bromooctane.

Simple sodium alkyls, *e.g.* n-butylsodium, condense with optically active alkyl bromides with total loss of

[142] For information on the different, but invariably slow, rates of condensation of phenyl halides and phenyl-lithium, see *G. Wittig*, *G. Pieper*, and *G. Fuhrmann*, Ber. dtsch. chem. Ges. *73*, 1193 (1940).

Table 3. Condensation of organometallic compounds R—M with (−)-2-bromooctane (R′—Br).

| R—M | R—R′ [%] | Racemate [%] | Ref. |
|---|---|---|---|
| Benzylmagnesium bromide | | | |
| $H_2C$=CH—$CH_2$—Na | 83 | 13 [*] | [143] |
| $H_2C$=CH—$CH_2$—MgBr | 78 | 13 [*] | [143] |
| $H_5C_6$—$CH_2$—Na | 81 | 30 [*] | [144] |
| $H_5C_6$—$CH_2$—MgBr | 17 | 91 [*] | [143] |
| $H_5C_2$—Na | 25 | 97 [*] | [145] |
| n-Butylsodium | 35 | 100 | [144] |
| 2-Octylsodium | — | 100 | [145] |

[*] The configuration of the remainder of R—R′ is opposite to that of R′—Br.

activity, whereas the latter is preserved in condensations with the analogous alkyl chlorides, although inversion takes place. Thus, the reaction of (+)-2-chlorooctane with ethylsodium affords (+)-3-methylnonane *(67)* with only 20 % racemization.

$\alpha = +26{,}61°$ *(67)*, 6 %; $\alpha = +5{,}16°$

Two hypotheses have been advanced to explain the racemization observed in the case of alkyl bromides. According to the one theory, the sodium ion causes the alkyl bromide to dissociate into a carbonium ion [146a, 146b], while in the other, the racemization is supposed to be preceded by a rapid halogen-metal interconversion and to proceed by way of a carbanion [119].

### 2. Non-Metal Halides

Phenylsodium condenses with boron trichloride to give triphenylborane (50 %) or with silicon tetrachloride at −40 °C to form a mixture of trichlorophenylsilane (38 %), dichlorodiphenylsilane (14 %), and tetraphenylsilane (35 %). Phosphorus trichloride reacts with phenylsodium to give triphenylphosphine, and with benzylsodium to give tribenzylphosphine (84 %) [147]. Silane [148a] and triarylsilanes [148b] condense with organoalkali-metal compounds resulting in elimination of alkali-metal hydride.

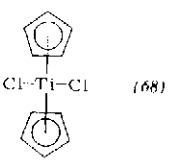
## E. Replacement of the Metal by Another Metal



### 1. Reactions with Metal Halides [149]

The substitution of an alkali-metal atom in an organometallic compound by another less electropositive one occurs quantitatively with inorganic salts. This represents a convenient and effective method for preparing Grignard reagents in hydrocarbon solution [150].

$$MgBr_2 + H_5C_6—Na \rightarrow H_5C_6—MgBr + NaBr$$

Similarly, lithium halides or alkoxides transform phenylsodium into phenyl-lithium, and the reaction of aluminum trichloride with butylsodium yields dibutylaluminum chloride [147].

The synthesis of π-complexes from the weak base cyclopentadienylsodium and transition metal salts falls into the same category as these reactions. Ferrocene can be synthetized in this way [151] from ferrous chloride, and titanocene *(68)* [152] from titanium(IV) chloride, both in 90 % yield.

*(68)*

### 2. Reactions with Metals

When the substituting metal is used in elemental form, the nobler (*i.e.* less electronegative) metal separates out also in elemental form. This phenomenon is applied for the preparation of potassium derivatives from organolithium or organosodium compounds [153].

$$K\cdot + n\text{-}H_9C_4—Li \xrightarrow{-Li\cdot} (n\text{-}H_9C_4—K) \xrightarrow[86\,\%]{H_5C_6} H_5C_6—K\,.$$

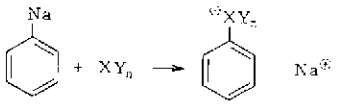
## F. Addition Reactions

In all the reactions discussed so far, the residue Y in polarizable compounds X—Y was displaced by a carbanion (cryptoanion):

$$M—CR_3 + X—Y \rightarrow X—CR_3 + M^{\oplus}Y^{\ominus}.$$

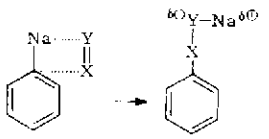
The reactions dealt with in the following all have the common feature that the organoalkali compound adds onto an electron-deficiency site *(69)* or across a multiple bond *(70)*.

[149] These reactions could also be considered as condensations of metal halides with organoalkali-metal compounds.



[150] US.-Pat. 2795626 (June 11th, 1957) and 2914578 (Nov. 24th, 1959) National Distillers and Chem. Corp., inventors: *J. F. Nobis* and *R. E. Robinson*; cf. Chem. Abstr. *54*, 15318h (1960).

[151] *W. F. Little*, *R. C. Koestler*, and *R. Eisenthal*, J. org. Chemistry *25*, 1435 (1960).

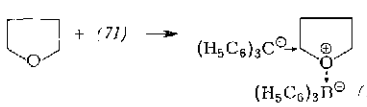


[152] *G. Wilkinson* and *J. M. Birmingham*, J. Amer. chem. Soc. *76*, 4281 (1954).

[153] *D. Bryce-Smith* and *E. E. Turner*, J. chem. Soc. (London) *1953*, 861.

These reactions, too, can be interpreted in terms of the broad concept of charge neutralization. The driving force behind the reaction is provided by the tendency of the carbon to transmit its negative charge to a more electronegative atom or another, less basic, carbon.

*(69)*



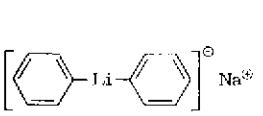
*(70)*

## 1. Lewis Acids

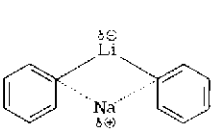
Phenylsodium combines with triphenylborane to form sodium tetraphenylborate (Kalignost®), a useful analytical reagent that is not affected by water or alcohol [154]. Phenylisopropylpotassium also gives a corresponding borate complex [114], and the bulky base triphenylmethylsodium gives adducts *(71)* that are in equilibrium with their components [155].

$$Na{-}C(C_6H_5)_3 + B(C_6H_5)_3 \rightleftarrows [(H_5C_6)_3C{-}B(C_6H_5)_3]Na \qquad (71)$$

Solutions of such antagonist pairs exhibit simultaneous electrophilic and nucleophilic reactivity resulting, for example, in the formation of *(72a)* and *(72b)* [156].



*(72a)*



*(72b)*

Organic derivatives of many elements from different groups of the periodic system (Be, Mg, Zn, B, Al, Si, Sb) undergo addition with organoalkali compounds. Surprisingly, even organolithium bases can act as Lewis acids for other organoalkali compounds. Phenyl-lithium gives a 1:1 complex [*(73a)* or *(73b)*] with phenylsodium which can be crystallized from ether.

*(73a)*

*(73b)*

This complex *(73a)* ↔ *(73b)* reacts vigorously with butyl iodide until the phenylsodium is completely consumed; the residual phenyl-lithium continues to react slowly, with a half-life of 9 hours [157].

The addition of even a few per cent of phenyl-lithium to a suspension of phenylsodium (or phenylpotassium, phenylrubidium, or phenylcesium) stabilizes the latter towards ether [158]. Small amounts of phenyl-lithium are evidently sufficient to complex the entire amount of dissolved phenylsodium. Phenylsodium that is moderated in this manner is less active than the lithium-free reagent prepared in hydrocarbons; however, this loss in activity is compensated by the polarity of the ether (see Table 4).

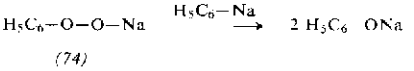


Table 4. Metalation of anisole with phenylalkali-metal compounds at about 20 °C.

| R–M | Solvent | Reaction time [hrs] | Metalation [%] | Ref. |
|---|---|---|---|---|
| $H_5C_6{-}Li + LiBr$ | Ether | 20 | 0 | [159] |
| $H_5C_6{-}Li$ | Ether | 20 | 17 | [159] |
| $[H_5C_6{-}Li \quad C_6H_5]Na$ | Ether | 20 | 71 | [159] |
| $H_5C_6{-}Na$ | Benzene | 24 | 44 | [70] |
| $H_5C_6{-}Na$ | Benzene | 48 | 64 | [70] |

Because of their electron-sextet, carbenes are extremely active Lewis acids. Until now, their reaction with organic derivatives of the higher alkali metals have been reported only sporadically [160]. This reaction is analogous to the frequently observed insertion of carbenes into carbon-lithium bonds [101].

## 2. Oxygen and Sulfur Functions

Molecular oxygen cleaves organoalkali-metal compounds with formation of a peroxide, *e.g. (74)*, which in turn, oxidizes a second molecule of the organometallic

*(74)*

compound [161]. Peroxides of resonance-stabilized organoalkali-metal compounds decompose with elimination of alkali peroxide, for example, to give *(75a)* and *(75b)*.

$$2\,(H_5C_6)_3C{-}Na \xrightarrow{O_2} 2\,(H_5C_6)_3C{-}O{-}O{-}Na \rightarrow (H_5C_6)_3C{-}O{-}O{-}C(C_6H_5)_3 + Na_2O_2 \quad [20, 162]$$

*(75a)*

$$2\,(H_5C_6)_2CH{-}Na \xrightarrow{O_2} (H_5C_6)_2CH{-}CH(C_6H_5)_2 + Na_2O_2 \quad [163]$$

*(75b)*

The reactions of sulfur and sulfur compounds with organoalkali-metal compounds have not yet been systematically studied. The reaction of triphenylmethylsodium with sulfur

[161] *H. Hock* and *H. Kropf*, Angew. Chem. *69*, 315, 317 (1957).

[162] *C. A. Kraus* and *R. Rosen*, J. Amer. chem. Soc. *47*, 2739 (1925).

[163] According to *C. B. Wooster*, Chem. Reviews *11*, 14 (1932).

dioxide affords triphenylmethyl sulfinate [163], and that with diphenyl sulfoxide gives a red-violet adduct [164]. Phenylsodium and diphenyl sulfoxide give diphenylene sulfide [165]. The reaction of sultones with organosodium reagents takes place with ring-opening and leads to sulfonates [166].

### 3. Nitrogen Functions

The N≡N triple bond of molecular nitrogen does not react with organometallic compounds. However, phenylpotassium does add onto the N=N double bond of azobenzene to give *(76)*.

$$H_5C_6-N=N-C_6H_5 \xrightarrow{H_5C_6-K} (C_6H_5)_2N-N(C_6H_5)-K \qquad (76)$$

Phenylcalcium iodide also adds onto azobenzene, whereas phenylsodium, phenyl-lithium, and phenylmagnesium bromide act predominantly as reducing agents yielding, respectively, 25%, 52%, and 62% hydrazobenzene [167].

Nitroso and nitro compounds and most nitrogen oxides react with organometallic compounds so vigorously and give reaction products of such high reactivity that the reaction is uncontrollable; for preparative purposes, less reactive organometallic compounds are therefore used [168]. Nitrous oxide reacts only with organoalkali bases, *e.g.* with triphenylmethylsodium, to yield a diazotate *(77)* which liberates nitrogen on hydrolysis [136].

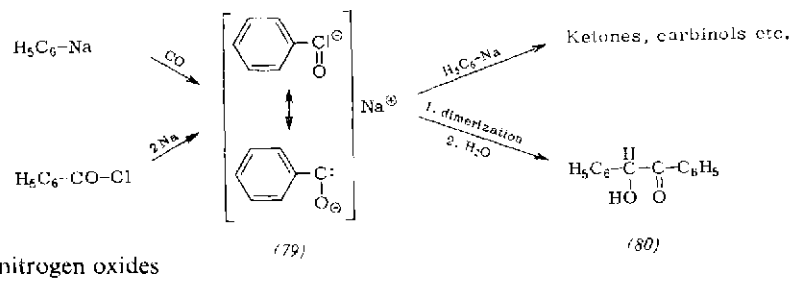
$$(H_5C_6)_3C-Na \xrightarrow{N_2O} (H_5C_6)_3C-N=N-ONa \xrightarrow{ROH}$$

*(77)*

$$(H_5C_6)_3C-OH + N_2 + RONa$$

### 4. Carbon Functions

#### a) *Carbon Oxides*



Carboxylation converts organometallic compounds smoothly into carboxylates *(77)* [169]. However, a local excess of the organometallic compound can cause transmetalation and consequent formation of dicarboxylic acids *(78)* [170]; under suitable conditions, the latter can be obtained in high yields [171].

$$H_5C_6-CH_2-Na \xrightarrow{<1\ CO_2} H_5C_6-CH_2-COONa \quad (77),\ 99\%$$

$$H_5C_6-CH_2-Na \xrightarrow{>1\ CO_2} H_5C_6-CHNa-COONa \longrightarrow H_5C_6-CH(COOH)_2$$

*(78)*, 70%

Prolonged treatment of phenylsodium suspensions with carbon monoxide leads to the acyl anion *(79)* and thence to benzophenone, triphenylmethanol, and benzoic acid [172, 173]. A mechanism involving the same anion *(79)* has been postulated to explain the formation of acyloins *(80)* in the reaction of sodium-aromatic complexes with acid chlorides [174].

*(79)* *(80)*

The lower resonance structure predicts the properties of a nucleophilic carbene for the acyl anion *(79)* [175]; however, it does not add onto olefins or acetylene derivatives [176].

Free triphenylmethylsodium does not react with carbon monoxide [20], but does form a dark-colored adduct with it in the presence of triphenylborane [177].

#### b) *Carbonyl and Carboxylic Compounds*

Sodium alkyls and sodium aryls combine with aldehydes or ketones with extreme rapidity. Triphenylmethylsodium undergoes normal addition onto benzaldehyde [20], phenyl isocyanate [178], and phenyl isothiocyanate

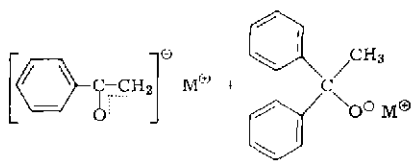
[177] *G. Wittig* and *H. Vogel*; *G. Wittig* and *L. Gonsior*, unpublished work.



[178] *W. Schlenk* and *E. Bergmann*, Liebigs Ann. Chem. *464*, 1 (1928).

[178]; the reaction with benzophenone, however, involves an unusual radical formation [179].

$$(H_5C_6)_3C{-}Na + (H_5C_6)_2C{=}O \rightleftharpoons (H_5C_6)_3C\cdot + (H_5C_6)_2C{-}ONa\,.$$

The attack of organoalkali-metal compounds on enolizable aldehydes and ketones is also influenced by steric factors. Secondary and tertiary alkoxide formation from bulky bases [180], particularly from triphenylmethylsodium [181], is suppressed in favor of enolate formation. The dependence of the enolate/alkoxide ratio on the nature of the metal has been investigated by *Hauser* [182]. Lithium and magnesium, which undergo complex formation, promote addition [→ *(82)*] via a concerted mechanism with a four-centered transition state [183]; sodium and potassium, on the other hand, favor deprotonation [→ *(81)*] (Table 5).

$$H_5C_6{-}CO{-}CH_3 + H_5C_6{-}M \xrightarrow{in\ H_5C_2{-}O{-}C_2H_5}$$

*(81)* *(82)*

Table 5. Effect of the metal in the phenylmetal compound on the formation of *(81)* and *(82)* from acetophenone.

| M | Enolate: carbinolate |
|---|---|
| K | 10:1 |
| Na | 2:1 |
| Li | 1:23 |
| BrMg | 1:∞ |

Nonpolar solvents such as benzene impair metalation and thus promote carbinolate formation [182].

α,β-Unsaturated compounds react as 1,2- or 1,4-dipolar structures with organometallic compounds; the type of addition (1,2- or 1,4-) occurring depends on the metal [182, 184]. Magnesium promotes 1,4-addition via a chelate; other metals give predominantly 1,2-addition (Table 6).

Table 6. 1:1-Addition of $C_6H_5{-}M$ onto β-benzoylstyrene ($H_5C_6CH{=}CHCOC_6H_5$).

| $C_6H_5{-}M$ | 1,2-Adduct [%] | 1,4-Adduct [%] |
|---|---|---|
| + $H_5C_6{-}K$ | 67 | — |
| + $H_5C_6{-}Na$ | 60 | 14 |
| + $H_5C_6{-}Li$ | 75 | 14 |
| + $H_5C_6{-}MgBr$ | — | 94 |

Benzylsodium derivatives *(83)* undergo exclusively 1,4-addition onto α,β-unsaturated esters [185, 186].

$$H_5C_6{-}CH_2{-}COOH \xrightarrow[NH_3]{2\ NaNH_2} H_5C_6{-}\underset{\underset{Na}{|}}{CH}{-}COONa$$

*(83)*

$$(83) + H_5C_6{-}CH{=}CH{-}COOC_2H_5 \xrightarrow{Hydrolysis}$$

$$H_5C_6{-}\underset{\underset{H_5C_6{-}\underset{\underset{COOH}{|}}{CH}}{|}}{CH}{-}CH_2{\cdot}COOC_2H_5$$

(erythro + threo)

The reactions of organoalkali-metal compounds with carboxylic acids [187], carbonyl chlorides, anhydrides, and esters proceed in the manner of a normal Grignard reaction.

### c) *CN Multiple Bonds*

Azomethines (Schiff bases) react with organoalkali compounds in the same way as the isoelectronic carbonyl compounds, and isonitriles behave like carbon monoxide. Heterocyclic compounds containing CN double bonds, *e.g.* pyridine, undergo a variety of organometallic addition and substitution reactions resulting in numerous different products [188]. The reaction of nitriles with organometallic compounds represents a useful ketone synthesis [189]. For practical purposes, the readily available Grignard or organolithium compounds are mostly used. In contrast to phenyl-lithium, phenylsodium does not add onto butyronitrile, but produces the anion instead [189a].

### d) *CC Multiple Bonds*

The highly strained triple bond in arynes and lower cycloalkynes is not the only one capable of undergoing nucleophilic additions [190]. Organometallic compounds also add onto linear acetylenes, although not quite as smoothly.

$$H_5C_6{-}C{\equiv}C{-}C_6H_5 \xrightarrow{H_5C_6{-}C(CH_3)_2K} \underset{H_5C_6{-}C(CH_3)_2\ K}{\overset{H_5C_6}{\overset{|}{C}}{=}\overset{C_6H_5}{\overset{|}{C}}}$$

*(84)*

Methylphenylacetylene behaves like tolane *(84)*. Purely aliphatic acetylenes with a non-terminal triple bond undergo isomerization to 1-alkynes [191] instead.

The addition of organoalkali compounds onto conjugated double bonds was discovered and studied ex-

tensively using phenylisopropylpotassium by *Ziegler* [192a–192c].

$$H_5C_6\text{-}CH{=}CH{-}R + H_5C_6{-}C(CH_3)_2K \rightarrow H_5C_6{-}CHK{-}CHR{-}C(CH_3)_2{-}C_6H_5$$

R = H, $CH_3$, $C_6H_5$ *(85)*

Phenylisopropylpotassium reacts with styrene, β-methylstyrene, stilbene, α-methylstyrene, 1,1-diphenylethylene, and several fulvenes. Other olefins are metalated to allylic derivatives. These include ethylene derivatives with only alkyl substituents, styrenes that are doubly substituted with alkyl groups, α-methylstilbene, and 2-methyl-1,1-diphenylethylene. Monosubstituted styrenes seem to represent the dividing line between predominant addition and predominant metalation. In pentane, the more active reagent amylsodium gives 85 % hydrogen-metal interconversion with α-methylstyrene and 29 % with β-methylstyrene [193]. Substitution of the methyl group with long-chain alkyl groups causes a further increase in metalation at the expense of addition.

A third, free-radical reaction of multiple CC bonds has been observed with phenanthrene *(86)* [192a, 192b].

*(86)*

Although phenylsodium [194] and vinylsodium [59] do not react with 1,1-diphenylethylene in nonpolar solvents, both benzylsodium [194], which is less basic, and the alkali-metal amyls, which are more basic, do (relative reaction rates for amyl-lithium, amylsodium, and amylpotassium = 0.03:1:3 [194]).

Addition of a second molecule of olefin onto the addition product *(87a)* obtained from the olefin and amylsodium affords *(87b)* [194].

$$(H_5C_6)_2C{=}CH_2 \xrightarrow{n\text{-}H_{11}C_5{-}Na} Na{-}C(C_6H_5)_2{-}CH_2{-}(n\text{-}C_5H_{11})$$

*(87a)*

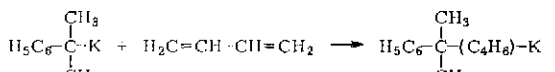
$$(H_5C_6)_2C{=}CH_2 + (87a) \rightarrow Na\text{-}C(C_6H_5)_2{-}CH_2{-}C(C_6H_5)_2{-}CH_2{-}(n\text{-}C_5H_{11})$$

*(87b)*

Additions can often be accomplished with catalytic amounts of organometallic compounds; the resulting adducts, *e.g. (88)*, give rise in turn to new addends by hydrogen-metal interconversion [195].

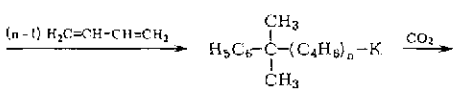
$$H_5C_6{-}CH{=}CH{-}CH_3 \xrightarrow[\text{in } H_5C_6{-}CH_3]{H_5C_6{-}CH_2K} H_5C_6\text{-}CH_2{-}CH(CH_3){-}CH_2{-}C_6H_5 + H_5C_6{-}CH_2{-}K$$

*(88)*



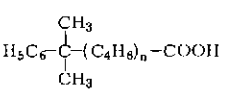
Organoalkali-metal compounds also add onto cycloheptatriene [196] and cyclooctatetraene [197]. Butadiene adds on amylsodium and benzylsodium but not phenylsodium [198]. Phenylpotassium seems to add even onto benzene [198a].

Tri- and tetraarylethylenes do not add on organoalkali compounds. With this exception, obviously due to steric hindrance, additions proceed smoothly whenever a weaker base is formed from a stronger one. For example, the reaction of phenylisopropylpotassium with 1,1-diphenylethylene produces a more highly resonance-stabilized benzhydrylpotassium derivative.



On the other hand, when ethylene reacts with benzylsodium, a stronger base, 3-phenylpropylsodium, results, from which propylbenzene (36 %) and 3-phenyl-n-pentane (37 %) are produced [199]. This reaction requires heat and pressure (100 °C, 200 atm) in contrast to the additions of isopropyllithium or t-butyl-lithium onto ethylene, which take place even at −60 °C, because they lead to weaker bases [200].

### e) *Polymerizations* [201a–203]



The study of addition reactions provided the key to an understanding of anionic polymerization, recognized by *Ziegler* [201a] to be "an organometallic synthesis on the largest scale". In this polymerization, an organometallic compound adds onto a butadiene- or styrene-type olefin giving rise to another organometallic compound which, in turn, can add on further molecules of olefin. Thus, chain growth *(89b)* takes place by recurring additions of butadiene onto the allylpotassium end-group of the butadiene-isopropylpotassium adduct *(89a)*. After all the monomer is consumed, the reactive

[203] *K. Ziegler*, *E. Eimers*, *W. Hechelhammer*, and *H. Wilms*, Liebigs Ann. Chem. *567*, 43 (1949).

chain ends remain intact, provided hydrolytic agents are excluded. Subsequent introduction of dienes results in avid absorption and addition (living polymers).

The reaction can be stopped at an early stage by using low monomer concentrations [202] or scavengers [203] that are inert toward the chain-initiating organoalkali-metal compounds. The products of the initial addition *(89b)* have been isolated and confirm the postulated mode of chain growth.

In the polymerization of butadiene with n-butyl-lithium, *(90a)* and *(90b)* were identified as the products of the second addition step.

$$n\text{-}H_9C_4\text{—}Li + H_2C\text{=}CH\text{—}CH\text{=}CH_2 \xrightarrow[25\,^\circ C]{i\text{-}H_7C_3\text{—}Cl}$$

$$n\text{-}H_9C_4\text{—}CH_2\text{—}CH(i\text{-}C_3H_7)\text{—}CH\text{=}CH_2 \quad (90a)$$

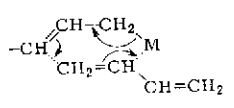
$$+\ n\text{-}H_9C_4\text{—}CH_2\text{—}CH\text{=}CH\ \ CH_2\text{—}(i\text{-}C_3H_7) \quad (90b)$$

The mechanism of the polymerization of butadiene or styrene initiated by phenylsodium or triphenylmethyl-sodium was revealed by an elegant, effective scavenging method using diethylamine and yielding *(91a)* and *(91b)*.

$$(H_5C_6)_3C\text{—}Na + H_2C\text{=}CH\text{—}CH\text{=}CH_2 \xrightarrow{HN(C_2H_5)_2}$$

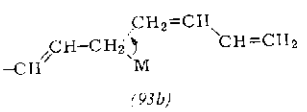
$$(H_5C_6)_3C\text{—}CH_2\text{—}CH\text{=}CH\text{—}CH_3 \quad (91a)$$

$$+\ (H_5C_6)_3C\text{—}CH(CH_3)\text{—}CH\text{=}CH_2 \quad (91b)$$



The initiators appear to act as true catalysts, since they are not detectably consumed; but here, too, organometallic addition is the actual initiating step; however, this process is extremely slow in comparison to the rate of chain growth. Polymers of high molecular weight can be obtained by preventing chain termination [202, 203]. Occasionally the scavenger increases the reactivity of the olefin by complex formation. Thus, 2,3-dimethylbutadiene adds onto triphenylmethylsodium only in the presence of triphenylborane and with exclusive formation of the 1,2-adduct [204].

$$(H_5C_6)_3C\text{—}Na + H_2C\text{=}\underset{\displaystyle H_3C}{\overset{}{C}}\text{—}\underset{\displaystyle CH_3}{\overset{}{C}}\text{=}CH_2 \xrightarrow{B(C_6H_5)_3}$$



$$\left[(H_5C_6)_3C\text{—}CH_2\text{—}\underset{\displaystyle H_3C}{\overset{}{C}}\text{—}\underset{\displaystyle CH_3}{\overset{}{C}}\text{=}CH_2\ \ \ominus B(C_6H_5)_3\right]\ Na^{\oplus}$$

*(92)*

The polymerization of butadiene does not give stereochemically uniform chains. 1,2-Addition predominates at low temperature (90 % at −70 °C) almost independently of the nature of the organometallic initiator and the solvent, whereas at high temperature, 1,4-linked polymers are primarily produced (85 % at 110 °C). These results possibly reflect the competition between abnormal *(93a)* and normal *(93b)* allylic addition [203].

*(93a)*

*(93b)*

[204] *G. Wittig* and *H. Schloeder*, Liebigs Ann. Chem. *592*, 38 (1955).

The stereochemistry of isoprene polymerization depends on both the solvent and the alkali-metal initiator. In polymerizations carried out in hydrocarbons, lithium behaves differently from the other alkali metals. This difference disappears with increasing polarity of the solvent (Table 7) [205].

Table 7. Isoprene polymerization with alkali metals or their organometallic derivatives.

| Solvent | Metal | Polymer [%] | | | |
|---|---|---|---|---|---|
| | | 1,2 | 3,4 | *cis*-1,4 | *trans*-1,4 |
| n-Heptane | Li | — | 6 | 94 | — |
| n-Heptane | Na | 10 | 42 | | 48 |
| n-Heptane | K | 7 | 35 | — | 58 |
| THF | Li | 14 | 52 | — | 34 |
| THF | Na | 15 | 51 | — | 34 |
| THF | K | 17 | 35 | — | 48 |

In practice, it is immaterial whether the metal is used in elemental form or as the alkyl, aryl, or benzyl derivative, since polymerization is effected identically in all cases. Thus, with isoprene, sodium gives the disodium adduct and then isoprenylsodium, which is the actual chain initiator. In the presence of toluene, benzylsodium is the initiator, as indicated by the hydrocarbon *(94)* isolated after premature hydrolysis [206].

$$H_5C_6\ \ CH_2\text{—}(C_5H_8)_n\text{—}H \qquad (94),\ n = 1\ \text{to}\ 5$$

The details of the polymerization of butadiene with sodium are not entirely clarified. In contrast to the known rules of organometallic polymerization, the structure of the Buna rubber polymer is fairly independent of the temperature of polymerization. On the other hand, its structure is quite different from that of the polymer obtained by the free-radical process using azobisbutyronitrile [203].

Polymerizations promoted by alfin catalysts [59, 207] or Ziegler catalysts [208] cannot be discussed here.

## G. Rearrangements

Intramolecular rearrangements provide another route for the conversion of organoalkali-metal compounds into less basic, and hence more stable compounds.

### 1. Charge Transfer to Nitrogen

The Stevens rearrangement *(95)* [209] effectively "short-circuits" the charges condensed in the ylides of nitrogen, arsenic, and antimony. The corresponding high energy

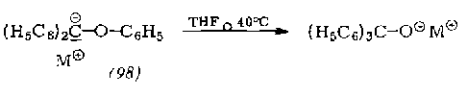
[209] Reviews: *G. Wittig*, Angew. Chem. *63*, 15 (1951); *66*, 10 (1954); Acta chim. Acad. Sci. hung. *12*, 347 (1957); *G. Köbrich*, Angew. Chem. *74*, 453 (1962); Angew. Chem. internat. Edit. *1*, 382 (1962).

gain also promotes the competing Sommelet rearrangement *(96)* [209,210].

In the base-promoted isomerization of tertiary amines *(97)*, also studied by *Stevens* [211], the negative charge is transferred to a previously uncharged nitrogen atom.

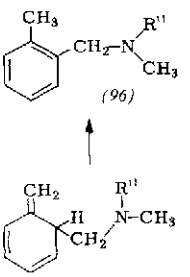


Consequently, here the tendency towards rearrangement is less pronounced, and higher temperatures are required.

Ar = $C_6H_5$; R = $H_5C_6$–$CH_2$; R' = $H_5C_8$–CO

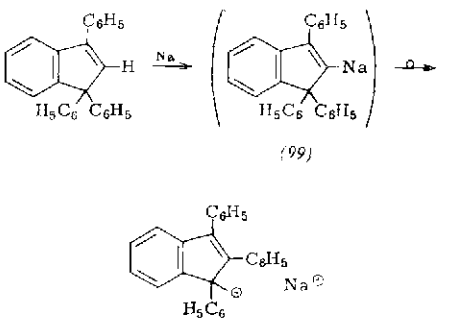
## 2. Charge Transfer to Oxygen

The Wittig rearrangement [22,48,212] of metalated ethers is analogous to the above rearrangement of tertiary amines. This rearrangement generally takes place in the cold; strongly resonance-stabilized metalates, *e.g. (98)*, require slight heating to effect isomerization.



Although the alkali metal M is bound only electrostatically, it exerts an effect on the rate of rearrangement. The kinetic data obtained were measured with relatively concentrated solutions, and, hence, the decrease in reactivity Li > Na, K [22] may be due to a salt effect. The alternative cleavage of metalated ethers in non-polar solvents leading to carbenes has been discussed above.

According to a mechanism postulated by *Schöllkopf* [213a, 213b] for s-alkyl benzyl ethers, the Wittig rearrangement proceeds in two steps, but chiefly by an intramolecular process via an internal ion pair. Competition experiments [213b] show that intermolecular rearrangement is still negligible at −56 °C. t-Alkyl benzyl ethers possibly react according to an $S_Ni$ mechanism [214].



## 3. Charge Transfer to Another Carbon Atom

The isomerization of a metalated hydrocarbon *(99)* was observed thirty-five years ago by both *Schlenk* [215] and *Ziegler* [216].

The rearrangements of β-substituted di- and triarylethylalkali-metal compounds have been investigated recently [135,217,218].

The ease with which the organometallic bond can shift within hydrocarbon molecules is surprising in view of what is known about the nitrogen- and oxygen-containing compounds. The isomerization is initiated by a

weakening of the metal-carbon bond, as indicated by the effect of the metal M on this phenomenon (K > Na > Li ≫ Mg, Hg). When several residues are available for migration, the course of the rearrangement depends more on their tendency to migrate than on the stability of the final product. The following order of decreasing mobility has been observed [217,218]: R = benzyl > phenyl > p-tolyl > methyl.

For example, 2,2-diphenyl-n-propylpotassium [R = $CH_3$; M = K] does not afford the more stable isomer 1,1-

diphenyl-n-propylpotassium *(100a)*; instead, 1,2-diphenylisopropylpotassium *(100b)* is produced [217]. However, these rearrangements, too, reflect the tendency of more strongly basic organoalkali-metal compounds to undergo conversion into less basic ones, thus satisfying a principle established for the chemistry of organosodium and organopotassium compounds.

*The author wishes to express his gratitude to Prof. G. Wittig, Dr. J. Dale, Dr. G. Köbrich, Dr. H. Reimlinger, and Dr. G. Klumpp for discussions and suggestions during the preparation of the manuscript*

## Hindered Internal Rotation in Cyanine Dyes

By Prof. Dr. G. Scheibe, Doz. Dr. C. Jutz, Dr. W. Seiffert, and Dipl.-Chem. D. Grosse

Physikalisch-Chemisches Institut and Organisch-Chemisches Institut der Technischen Hochschule München (Germany)

The proton magnetic resonance of the chain chromophores of *N,N*-dimethylaminoproenylylidene- *(1a)*, *N,N*-dimethylaminopentadienylylidene- *(1b)*, and *N,N*-dimethylaminoheptatrienylylidene-dimethylammonium perchlorates *(1c)* corresponds to the $AX_2$, $A_2X_2Y$, or $AB_2X_2Y_2$ type, respectively. It is the *all-trans*-configuration that occurs in the ground state [1].

$(H_3C)_2N{-}CH(=CH{-}CH)_n{=}\overset{\oplus}{N}(CH_3)_2$

*(1)*

*(1a)*, *(1b)*, *(1c)*: n = 1, 2, or 3

At room temperature in neutral medium, the methyl groups of the auxochromes of *(1a)* and *(1b)* each supply two signals of equal intensity (see Table 1). This splitting of the methyl signals is independent of temperature and is an approximately linear function of the field strength, *e.g.* for *(1a)* in $CHCl_3$: 11.75 cps at 60 Mcps; 4.4 cps at 25 Mcps. It is largely independent of the nature of the solvent in neutral medium. Any external ions added have no influence on the splitting. These results imply that the internal rotation of the *N,N*-dimethylamino groups around the N=C(α) bond is hindered [2, 3], a phenomenon described by *Gutowsky* et al. [4] for carbonyl compounds of the type R-CO-$N(CH_3)_2$. Like all *cis-trans*-rearrangements, the internal rotation is acid-catalysed. When the rotation of the *N,N*-dimethylamino groups is inhibited, the protons of the two freely rotating methyl-groups lie in fields of different intensities. The height of the energy barrier $E_a$ to rotation around the N–C(α) bond was estimated by the method of *Gutowsky* [4] (see Table 1). $E_a$ and $T_{coin}$ (*i.e.* the temperature at which the two methyl signals coincide) decrease with increasing chain length, *e.g.* *(1c)* shows only one methyl-group signal at room temperature (see Table 1).

Table 1. Proton magnetic resonance signals (δ = chemical shift), coupling coostants (J), and activation energies ($E_a$) of dimethylaminopolyenylylidenedimethylammonium perchlorates. External standard: tetramethylsilane.

[*] The carbon atoms of the chain are designated according to their positions relative to the nitrogen atoms as α,β,γ,δ.

[**] $T_2$ is the transverse relaxation time in seconds/radian and is estimated from the linear width $\Delta\omega_{1/2}$.

Addition of acid lowers the activation energy for reorientation, (0.11 % by vol. of $H_2SO_4$ in 0.2 M aqueous solution reduced $E_a$ for *(1a)* from 17 to 8.6 kcal/mole). The NMR spectrum of the protons of the chain carbons remains unchanged, *i.e.* the *trans*-linkage of the cyanine chain is retained. However, proton exchange in β-position of the cyanine chain does take place. In $D_2O$ with addition of about 0.1 % by vol. of $D_2SO_4$ it is slow enough that its kinetics can be examined. The β-position becomes occupied by deuterium; and a singlet replaces the α-doublet. The rate constant in 0.04 N $D_2SO_4$ is $k \approx 2\times10^{-4}$ sec$^{-1}$.

Hindered rotation of *N,N*-dialkylamino groups was also observed in compounds of types *(2)* and *(3)*.

$R_2^1N{-}CH{=}CR^2{-}CH{=}\overset{\oplus}{N}R_2^1$ $R_2^1N{-}CH{=}CR^3{-}CR^2{=}CR^3{-}CH{=}\overset{\oplus}{N}R_2^1$

*(2)* *(3)*

*(2a)*: $R_2^1 = -(CH_2)-$; $R^2 = H$

*(2b)*: $R^1 = CH_3, C_2H_5$; $R^2 = H, CH_3, CH{=}\overset{\oplus}{N}(CH_3)_2$

*(3)*: substituents as in *(2b)*; $R_2^3 = H + H$, $o\text{-}C_6H_4$

## The Furfuryloxycarbonyl Group, an N-Protecting Group for Peptide Syntheses

By Prof. Dr. G. Losse, Dr. H. Jeschkeit, and Dipl.-Chem. E. Willenberg

Institut für Organische Chemie
der Universität Halle-Wittenberg (Germany)

Urethane groups have proved useful as *N*-protecting groups in peptide syntheses: they can be removed under mild conditions.

Systematic studies with new urethane groupings have shown that the furfuryloxycarbonyl (carbofuroxy or Cfo) residue is extremely acid-labile and is removed nearly quantitatively from the amino group at room temperature after 3 min with two equivalents of HBr in glacial acetic acid at a concentration of 85 mg/cm³ (corresponding about to a 6 % solution); cf. Table 1. The fission also proceeds quickly and quantitatively at 0 °C.

Table 1. Acidolysis of Cfo-glycine benzyl ester *(1)*, glycine benzyl ester *(2)*, and Cbo-glycine *(3)* at 20 °C in HBr/AcOH.

| Substance | equiv. of HBr per equiv. of *(1)*, *(2)*, or *(3)* | HBr [mg/cm³] | Proportion [%] of *(1)*, *(2)*, or *(3)* split after 1 | 1.5 | 2 | 3 | 5 | 10 | 15 min |
|---|---|---|---|---|---|---|---|---|---|
| *(1)* | 2 | 450 | 90 | 90 | 90 | 90 | | | |
| *(1)* | 2 | 200 | 87 | 91 | 92 | 91 | | | |
| *(1)* | 2 | 85 | 79 | 85 | 87 | 90 | 92 | 92 | |
| *(1)* | 1 | 85 | 65 | 75 | 79 | 84 | 87 | 90 | 91 |
| *(1)* | 2 | 50 | 21 | 30 | 40 | 54 | 70 | 83 | 85 |
| *(1)* | 1 | 50 | 15 | 24 | 30 | 43 | 59 | 73 | 77 |
| *(2)* | 2 | 85 | <1 | | <1 | | <1 | | <1 |
| *(3)* | 2 | 85 | 0 | | 0 | | 2 | | 4 |

Under these conditions, *N*-Cbo- and *C*-benzyl ester groups remain absolutely intact. In contrast, Cfo and Cbo residues are removed with almost equal rate in neutral solution by hydrogenolysis.

The high speed of acidolysis of the Cfo residue is due to the formation of the strongly mesomerically stabilized furfuryl cation. Being vinylogous acetals, furfuryl esters are just as sensitive to acids as acetals.

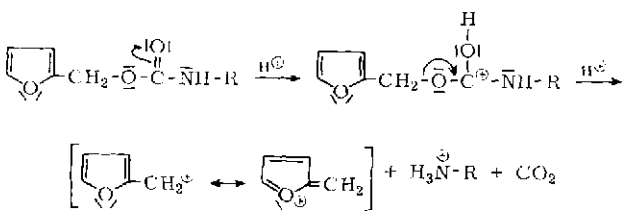

Table 2. Cfo-amino acids, dipeptides, and dipeptide benzyl esters

| Cfo compound [a] | M.p. [°C] |
|---|---|
| Cfo-glycine | 76–77 |
| Cfo-DL-alanine | 82 |
| Cfo-DL-valine | 100–101 |
| Cfo-DL-leucine | 95–96 |
| Cfo-DL-phenylalanine | 100–102 |
| Cfo-glycylglycine | 125 |
| Cfo-glycyl-DL-alanine | 155–156 |
| Cfo-glycyl-DL-valine | 106–107 |
| Cfo-glycyl-DL-phenylalanine | 146–147 |
| Cfo-DL-valylglycine benzyl ester | 132 |
| Cfo-DL-phenylalanyl-glycinebenzyl ester | 118–120 |
| Cfo-DL-leucylglycine benzyl ester | 79–80 |

[a] The Cfo-dipeptides were prepared by the nitrophenyl ester method, the Cfo-dipeptide benzyl esters by the carbodiimide method.

*N*-Cfo-amino acids are formed by the reaction of furfuryl alcohol with the esters of α-isocyanofatty acids and subsequent saponification [1], or directly from amino acids and furfuryl chloroformate, which is produced at −60 °C in toluene from equivalent amounts of furfuryl alcohol, phosgene, and triethylamine. The Cfo compounds are isolated as their dicyclohexylammonium salts. Table 2 shows examples.

## Contribution of an Intermolecular Charge-Transfer Band to the Optical Activity of Electron-Donor/Acceptor Complexes

By Prof. Dr. G. Briegleb and Dipl.-Chem. H. G. Kuball

Institut für Physikalische Chemie
der Universität Würzburg (Germany)

If the electron donor or acceptor in electron-donor/acceptor (EDA) complexes [1] is optically active, the following influences of EDA interaction on rotatory dispersion and circular dichroism may be expected:

1. Change in the partial rotational strength [2] of a given absorption band which is responsible for the optical activity of the optically active component.

2. Rotatory dispersion and circular dichroism should be detectable within the range of the charge-transfer (CT) band.

3. Any absorption band characteristic for the optically inactive component should exhibit circular dichroism as a result of loss of symmetry.

Since the charge transfer is a permissible electrical dipole transfer, the dissymmetry factor $g = \frac{\Delta\varepsilon}{\varepsilon} = \alpha \frac{\mu_m}{\mu_e}$ [*] is very small. On the other hand, since $\mu_e$ is relatively large, the intensity of absorption of the CT band will be correspondingly large. It is therefore necessary for measurements within the range of the CT band to select the product [concentration] × [layer thickness] relatively small, so that the effects measured (difference in optical activity between the components and the EDA complex [3]), are extremely small. The measuring apparatus required has to be particularly sensitive. Furthermore, EDA complexes with as low CT band intensities as possible have to be used.

In practice, a high transmission polarimeter with an accuracy of $\pm 2\times10^{-3}$ degrees was assembled according to an electronic measuring principle described by *Wenking* [4]. For the measurement of circular dichroism, a method based on the principle of *Senarmont* [5] was developed. The ellipticity was measured with an accuracy of $\pm 2\times10^{-5}\times2\pi$.

Seven EDA complexes which have all relatively small charge-transfer moments within the range of the CT band, were examined.

With the first complex, (+)-camphor tetracyanoethylene *(1)*, in heptane, a negative Cotton curve and negative circular dichroism were found for the EDA portion, within the frequency range of the CT band. By way of contrast, the complex (+)-fenchone tetracyanoethylene *(2)* yielded a positive Cotton curve and positive circular dichroism in heptane. The rotational strengths were calculated to be $R_1 = -1.2\times10^{-40}$ [cgs] and $R_2 = 1.1\times10^{-40}$ [cgs], respectively. The dissymmetry factors $g_1 = -3.7\times10^{-4}$ and $g_2 = 4.4\times10^{-4}$ are of the magnitude expected for the charge-transfer moments of EDA complexes [1]. Also, the circular dichroism calculated from the amplitude of the Cotton curve according to an expression given by *Kuhn* [6] is in agreement with the experimental values.

It has thus been proved for the first time with the complexes *(1)* and *(2)* that the EDA-CT band in EDA complexes with an optically active component can develop circular dichroism and contribute to optical activity.

As stated above, the optically active part of a charge transfer is extremely small. Accordingly, this effect could not be detected with another EDA complex, (+)-methylcyclohexanone tetracyanoethylene *(3)*, in heptane.

Plain dispersion curves [2] with a superimposed positive Cotton curve were obtained for the EDA complexes of methyl (−)-α-[2,4,5,7-tetranitrofluorenylideneaminooxy]propionate as optically active acceptor with 2-methylnaphthalene *(4)* or stilbene *(5)* in benzene and carbazole *(6)* in dioxan. Methyl (+)- and (−)-α-[2,4,5,7-tetranitrofluorenylideneaminooxy]propionates with anthracene *(7)* in benzene yielded plain dispersion curves with a superimposed positive or negative Cotton curve, respectively. Circular dichroism could not be observed, within the limits of accuracy, for the EDA complexes *(4)*–*(7)*. The effect referred to under 1. above, *viz.* change in the absorption band of the optically active component responsible for the optical activity, comes into play in the case of complexes *(4)*–*(6)*. This leads to a change in the rotatory dispersion in the appropriate frequency range of the CT band.

As regards complex *(7)*, it is a moot point whether its positive Cotton curve is a result of the effect referred to under 1. above or is due to a partial contribution of the CT band.

While effect 1. is clearly in operation in the case of complexes *(4)*–*(7)*, it is not noticeable, within the limits of experimental accuracy, for *(1)*–*(3)*. This may however be explained by the octant rule [2], since tetracyanoethylene lies in one of the planes of symmetry of the carbonyl orbital and should therefore have only a minor effect on the optical activity of the carbonyl band.

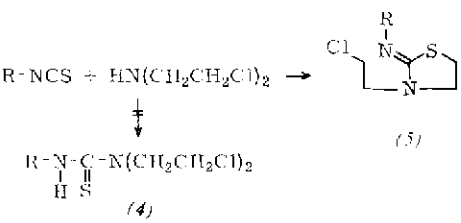
## Formation and Behavior of 2,3,5,6-Tetrahydro-7-arylimidazo[2,1-b]thiazolium Salts [1]

By Dr. H. Dorn



Institut für Organische Chemie der Deutschen Akademie der Wissenschaften zu Berlin, Berlin-Adlershof (Germany)

The bicyclic system imidazo[2,1-*b*]thiazole [2] and 6,7-dihydro-5*H*-imidazo[2,1-*b*]thiazolium salts [3] are accessible from 2-mercaptoimidazole or imidazoline-2-thione and α-halogeno ketones. Aryl isothiocyanates and bis-(β-chloroethyl)amine react in benzene at room temperature to give 2,3,5,6-tetrahydro-7-arylimidazo[2,1-*b*]thiazolium chlorides, which are convertible into other salts, *e.g. (1)*, Ar = $C_6H_5$, X = Cl: m.p. 96–97 °C [*]; *(1)*, Ar = $C_6H_5$, X = $HSO_4$: m.p. 168–169 °C; *(1)*, Ar = $C_6H_5$, X = $ClO_4$: m.p. 145–146 °C. The structure of *(1)* is supported by the absence of non-ionic chlorine, by C=N absorption in the infrared, and by its degradation reactions. The salts *(1)* react with a small excess of alkali on contact with air to yield the thiol *(2)* and, as a by-product, the disulfide *(3)*, *e.g.* Ar = $C_6H_5$: m.p. 157 °C.

*(3)*

Under nitrogen, however, the only product is 1-(β-mercaptoethyl)-3-arylimidazolid-2-one *(2)*, *e.g.* Ar = $C_6H_5$: m.p. 71.5 °C, which is oxidized by air or iodine quantitatively to *(3)*. The disulfide *(3)* is reducible under nitrogen to the thiol *(2)*.

*(4)*

*(5)*

The claim [4] that thioureas *(4)* arise from isothiocyanates and bis-(β-chloroethyl)amine must be treated with reserve. We succeeded in isolating an intermediate of the bicyclic product *(1)*, *viz.* the 2-iminothiazolidine derivative *(5)*, R = 2,3,4,6-tetra-*O*-acetyl-1-β-D-glucosyl, and its salts.

## Cleavage of the f-Amide Bond in Cyanocobalamin Analogues by Propionibacterium shermanii

By Doz. Dr. W. Friedrich and Dr. E. Königk
in collaboration with Waltraud Sandeck

Physiologisch-Chemisches Institut
der Universität Hamburg (Germany)

In the biosynthesis of vitamin $B_{12}$ analogues [1] by *Propionibacterium shermanii* from cobinamide analogues, whose alkanolamine residues are fluorinated, often practically all the starting material is converted into vitamin $B_{12}$ if cobalt-free media are used. This is especially noticeable when the alkanolamine residue is 1-amino-2-hydroxy-2-(*o*-fluorophenyl)ethane, 1-amino-2-hydroxy-2-(*p*-fluorophenyl)ethane, or 1-amino-2-hydroxy-3,3,4,4,5,5,5-heptafluoropentane.

*P. shermanii* obviously produces an amidase, which splits the amide link of the cobinamide analogue giving factor $V_{1a}$ [2] and which then converts this into vitamin $B_{12}$.

The conversion of factor $V_{1a}$ into cobinamide and vitamin $B_{12}$ has already been observed [3]. In order to find out whether the amidase can also convert cobinamide into factor $V_{1a}$, *i.e.* whether Reaction II is reversible, we added factor $V_{1a}$ and [$^{60}$Co]cobinamide to fermentation flasks with *P. shermanii*, and interrupted the experiments at various times. Reversibility of Reaction II should cause factor $V_{1a}$ to become radioactive. The fermentation flasks each contained 7.2 g of corn steep liquor, 10 g of glucose, and ca. 90 ml of tap water. After fermenting for 5 days, 2 mg of factor $V_{1a}$ and 30 nC of [$^{60}$Co]cobinamide were added. After further 12, 24, 36, 48, and 60 h, the fermentation products were worked up; the corrinoids were separated by paper chromatography [4] and their radioactivity measured.

At first the $^{60}$Co appears principally in the vitamin $B_{12}$, *i.e.* Reactions II and III go to the right. Later most of the radioactivity appears in factor $V_{1a}$ [5]; this indicates the reversibility of Reactions II and III. The results show moreover that both [$^{60}$Co]cobinamide and [$^{60}$Co]vitamin $B_{12}$ (and unlabelled factor $V_{1a}$) can serve as precursors for the production of [$^{60}$Co]factor $V_{1a}$ [6].

## Differentiation of Primary, Secondary, and Tertiary Alcohols by Near Infrared Spectroscopy

By Dr. G. Habermehl

Institut für Organische Chemie
der Technischen Hochschule Darmstadt (Germany)

Primary, secondary, and tertiary alcohols are normally distinguished by infrared spectroscopy on the basis of the vibrational band due to C–O valence vibration, which occurs near 1050 cm$^{-1}$ for primary alcohols, near 1100 cm$^{-1}$ for secondary alcohols, and near 1150 cm$^{-1}$ for tertiary alcohols [1]. However, since these bands lie in the same region of the spectrum as the vibrational bands of the carbon skeleton of the molecule, their allocation is sometimes difficult. The range from 7000 to 7080 cm$^{-1}$ has been assigned to the first overtone of the OH valence vibration [2–4], but here primary, secondary, and tertiary alcohols have not previously been differentiated.

Now it was found that primary alcohols absorb in the range from 7090 to 7115 cm$^{-1}$, secondary alcohols from 7067 to 7078 cm$^{-1}$, and tertiary alcohols from 7042 to 7053 cm$^{-1}$, independent of whether the hydroxylated carbon atom is substituted with either methyl or phenyl groups (Table 1). The small frequency differences involved demand very careful recording at low speed in the region of the band, in order to pin-point the correct frequency of the band maximum. The exact value of the band maximum has to be read from the frequency counter, otherwise errors of 5–10 cm$^{-1}$ can occur. The recorded frequencies were measured in 1–5% solution in spectroscopically pure $CCl_4$. The concentration of the solutions had no effect on the recorded position of the bands.

Table 1. Absorption of some alcohols in the near infrared [5].

| | Frequency [cm$^{-1}$] |
|---|---|
| *Primary alcohols* | *7090–7115* |
| Methanol | 7115 |
| Ethanol | 7090 |
| 1-Propanol | 7095 |
| 1-Butanol | 7095 |
| 1-Pentanol | 7095 |
| Isoamyl alcohol | 7105 |
| 2-(*N*-Methylamino)ethan-1-ol | 7100 |
| 2-Amino-2-methylpropanol | 7100 |

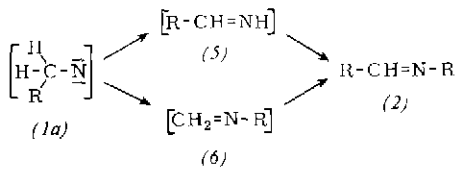
## Pyrolysis of Benzyl Azide in the Gas Phase

By Dr. R. Kreher and Dipl.-Ing. D. Kühling

Institut für Organische Chemie
der Technischen Hochschule Darmstadt (Germany)

The thermal decomposition of azides is significantly affected by the solvent [1]. We have investigated the pyrolysis of benzyl azide *(1)* in the gas phase at 360 °C/0.1 mm with nitrogen as diluent, and have so far succeeded in isolating by chromatography, *N*-benzylideneaniline *(2)*, m.p. 53 to



54 °C, in 20 % yield, 4,5-dihydro-2,4,5-triphenylimidazole *(3)* in 29 % yield (m.p. of picrate 258 °C), and 2,4,5-triphenylimidazole *(4)*, m.p. 274–275 °C, in 12 % yield.

*(1)*

*(2)* *(3)* *(4)*

The formation of *(2)* can be explained by assuming that benzyl azene *(1a)* rearranges to both benzylideneimine *(5)* and *N*-methyleneaniline *(6)*. The azomethines *(5)* and *(6)* interact to form *(2)*, volatile methyleneimine, $[CH_2{-}NH]$, being eliminated.

*(1a)* *(5)* *(6)* *(2)*

It is probable that *(3)* is not produced directly from *(1a)* but is formed from *(5)*, for when benzaldehyde was treated under comparable conditions in an ammonia atmosphere, it gave rise to *(3)* [2], which was characterized as its picrate [3]. Compound *(4)* is presumably formed by dehydrogenation of *(3)*.

According to these preliminary results, benzyl azene is stabilized predominantly by hydrogen migration to give benzylideneimine *(5)*, which reacts further to give *(2)*, *(3)*, and *(4)* [4]. Migration of the phenyl residue to give the unisolable *N*-methyleneaniline *(6)* occurs to only a minor extent; this determines the yield of *(2)*.

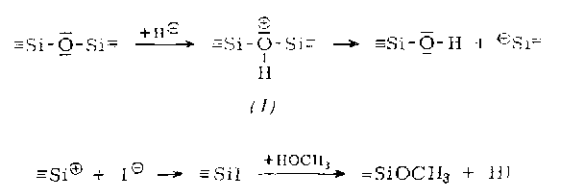
[2] The formation of *(3)* from *(5)* in liquid $NH_3$ has also been observed; cf. *H. Smith:* Organic Reactions in Liquid Ammonia. Interscience, New York, London 1963, Vol. 1/2, p. 286.

[3] *D. Kühling*, Diploma Thesis, Technische Hochschule Darmstadt, 1963.



[4] Thermal decomposition of benzyl azide in diethyl succinate also gave *(4)* together with a compound of m.p. 229 °C [1c]. This compound is not 1-benzyl-2,5-diphenyl-1,3,4-triazole, since an analytically pure sample of this compound which we prepared according to the method given by *R. Stollé* and *K. Thomä*, J. prakt. Chem. *73*, 288 (1906), melted at 219 °C.

## Sensitivity of the Siloxane Linkage towards Acidolytic Cleavage

By Dr. K. Damm, Dr. D. Gölitz, and Prof. Dr. W. Noll

Anorganische Abteilung der Farbenfabriken Bayer AG., Leverkusen (Germany)

Linear and cyclic methyl- and phenylpolysiloxanes with a low degree of polymerization are cleaved in methanol by 0.02 N hydrogen iodide:

*(1)*

The reaction may be followed quantitatively by titration of the silanol groups with Karl Fischer reagent [1]:

$$\equiv Si{-}OH + I_2 + SO_2 + 2\,HOCH_3 + \equiv SiOCH_3 + 2\,HI + CH_3HSO_4$$

Since this titration of the silanol group proceeds much more rapidly than the splitting of the siloxane linkage (cf. Table 1), the rate of cleavage can also be followed quantitatively. It is thus found that acidolytic cleavage of the siloxane bond is a first order reaction, *i.e.* decomposition of the oxonium complex *(1)* is the rate-determining step.

Table 1. Half-lives ($t_{1/2}$) and disintegration constants (k) for the acidic hydrolysis of various organopolysiloxanes.

| Organopolysiloxane | Abbreviation [2] | $t_{1/2}$ [h] | $k \times 10^3$ [$h^{-1}$] |
|---|---|---|---|
| Diphenylsilanediol [a] | — | 0.05 | — |
| Diethylsilanediol [a] | — | 0.05 | — |
| Hexamethylcyclotrisiloxane | $D_3^{Me}$ | 0.44 | 1575 |
| Hexaphenylcyclotrisiloxane | $D_3^{Ph}$ | 21.5 | 32 |
| Hexamethyldisiloxane | $M_2^{Me}$ | 36 | 19 |
| Octamethylcyclotetrasiloxane | $D_4^{Me}$ | 175 | 3.96 |
| Decamethylcyclopentasiloxane | $D_5^{Me}$ | 310 | 2.2 |
| Octamethyltrisiloxane | $MDM^{Me}$ | 780 | 0.9 |
| Dodecamethylcyclohexasiloxane | $D_6^{Me}$ | 1000 | 0.6 |
| Octaphenylcyclotetrasiloxane | $D_4^{Ph}$ | $\infty$ | 0 |

[a] Silanols for comparison.

The considerable differences in the reaction rates indicate pronounced variations in the stabilities of the siloxane bonds. A partial explanation for this may be found in the fact that different substitution of the silicon ($D_3^{Me} \gg D_3^{Ph}$; $D_4^{Me} > D_4^{Ph}$; $M_2^{Me} > MDM^{Me}$) or valence-angle deformations ($D_3^{Me} > D_4^{Me}$; $D_3 \gg D_4^{Ph}$) cause the lone electron pairs on the oxygen to participate in the formation of a $d_\pi$-$p_\pi$ bond:

The greater this effect, the slower the splitting of the siloxanes (*e.g.* $D_6^{Me}$ or $D_4^{Ph}$) on electrophilic attack by a proton.

Reactive siloxane bonds in silicic-acid xerogels can also be determined quantitatively by titration following acidolytic cleavage. Using a xerogel [3] which had been heated at 200 °C for 4 h, it could be shown that practically all the siloxane bonds formed by condensation are so reactive that they are split by acidolysis.

## A Biogenetic-Type Cyclization of a Terpene Phosphate

By J. A. Miller, B.Sc., and Dr. H. C. S. Wood

Chemistry Department, The Royal College of Science and Technology, Glasgow (Scotland)

Unpublished work by *F. R. Atherton* [1] has shown that geranyl diphenyl phosphate *(1)* decomposes on standing to give $C_{10}$ hydrocarbons which were not identified. We have reinvestigated this reaction and have established that the major products obtained by allowing a solution of 8 g of this ester in 1000 ml of ether to stand at 37 °C for several days were the acyclic terpenes, myrcene *(2)* and ocimene *(3)*. Similar treatment of the diphenyl phosphate ester *(4)* of nerol, which has the *cis*-configuration at the allylic double

(1) (2) (3)

(4) (5)

bond, gave limonene *(5)* in 45 % yield. The phosphates were prepared by the conventional method from the alcohols and diphenylphosphorochloridate in pyridine. The terpene hydrocarbons were separated by preparative gas-liquid chromatography, and were identified by spectroscopic methods and comparison with authentic samples.

These experiments simulate the role played by pyrophosphate esters in the formation of carbon-carbon bonds *in vivo* [2]. They also suggest that the stereochemistry at the allylic double bond in the precursor of monoterpene hydrocarbons may determine the nature of the terpene formed.

## Allylbiscyclopentadienyltitanium(III) and -vanadium(III)

By Drs. Hendrik A. Martin and Prof. Dr. F. Jellinek

Laboratorium voor Anorganische Chemie,
Rijksuniversiteit te Groningen (Holland)

No allyl complexes of titanium or vanadium have yet been reported. We have prepared allylbiscyclopentadienyltitanium-(III) *(1)* by the reaction of biscyclopentadienyltitanium(IV) dichloride *(2)* with 2–3 equivalents of allylmagnesium bromide in tetrahydrofuran at room temperature; the original red color of the solution gradually changed into violet. The

*(1)* $(C_5H_5)_2Ti(CH_2{-}CH{=}CH_2)$ $(C_5H_5)_2TiCl_2$ *(2)*

same solution was obtained when *(2)* was first reduced to biscyclopentadienyltitanium(III) monochloride by means of zinc powder [1] and one equivalent of allylmagnesium bromide added to the green solution. The reaction mixture was evaporated *in vacuo*, and the residue extracted with pentane. When the violet pentane solution was concentrated to saturation and cooled to −80 °C, purple crystals of *(1)* precipitated. After two recrystallizations from pentane, pure *(1)*, m.p. 118 °C (decomp.), was obtained in 35 % yield. Reaction of *(1)* with octanol gave propene in 80 % yield.

Allylbiscyclopentadienyltitanium(III) is remarkably stable; the solid compound and its solutions in pentane remained unchanged when kept under nitrogen for several months at room temperature. Solid *(1)* is rapidly oxidized in air, and solutions of *(1)* immediately turn yellow on exposure to air. However, when air is passed through solutions of *(1)* in toluene/HCl, immediate formation of red *(2)* occurs.

The infrared spectrum of *(1)* in KBr has no bands in the 1650–1600 $cm^{-1}$ range, but has a band at 1500 $cm^{-1}$; we conclude, therefore [2], that the allyl group is π-bonded to the metal. Another band at 1435 $cm^{-1}$ is ascribed to the valence vibration of the π-bonded cyclopentadienyl ligands.

Between 400 and 1200 mμ, solutions of *(1)* in hexane show only one rather sharp absorption band at 510 mμ; beyond 400 mμ there is intense absorption. Compound *(1)* is paramagnetic.

The reaction of biscyclopentadienylvanadium(III) monochloride *(3)* with allylmagnesium bromide yielded a brown

*(3)* $(C_5H_5)_2VCl$ $(C_5H_5)_2V(C_3H_5)$ *(4)*

solution. Its absorption spectrum contains bands at 475 mμ and 720 mμ and is similar to that of benzylbiscyclopentadienylvanadium(III) [3]. We assume, therefore, that our reaction product is the analogous allyl compound *(4)*. The compound is unstable and has not yet been isolated. It is also formed, together with *(3)*, by the reaction of biscyclopentadienylvanadium(II) with 0.5 equivalent of allyl chloride. If excess allyl chloride is used, only *(3)* is obtained [4].

## Phenyl Cyanate

By Dr. D. Martin

Institut für Organische Chemie der Deutschen Akademie der Wissenschaften zu Berlin, Berlin-Adlershof (Germany)

Attempts to prepare cyanic esters result mostly in their trimerization products cyanuric esters; thus, cyanogen halides and alkali phenoxides afford cyanuric esters or iminocarbonic esters. Only phenols with bulky *ortho*-substituents and cyanogen chloride have so far yielded cyanates, *e.g.* 2,6-di-t-butylphenyl cyanate, trimerization of which is sterically hindered [1].

It seemed possible to isolate cyanic esters as products of the fission of thermally labile molecules in which the O–C–N grouping is preformed. Interaction of the thiocarbonic ester chloride *(1)* and sodium azide in aqueous acetone at −5 to 0 °C followed by extraction with ether and concentration of the extract at 0 °C gave 5-phenoxy-1,2,3,4-thiatriazole *(2)*, m.p. 33–34 °C from methanol. Compound *(2)* decomposes exothermically in benzene at room-temperature to afford the previously unknown phenyl cyanate *(3)* in 93 % yield as a colorless liquid with a pungent odor, b.p. 74–75 °C/10 mm. Trimerization does not occur under these conditions.

(1) (2) (3)

Phenyl cyanate is partially hydrolysed by dilute sulfuric acid to phenyl carbamate and thence to phenol. Trimerization at 200 °C yields triphenyl cyanurate.

The ultraviolet spectrum of *(3)* contains two absorption bands. The band of longer wavelength has a distinct fine structure; both it and the band of shorter wavelength are displaced by 11 mμ hypsochromically with respect to the bands of phenyl isocyanate. The infrared spectrum of *(3)* includes bands at 2235 and 2280 $cm^{-1}$ ascribed to the C≡N group [2], and a phenyl ether vibration band at 1190 $cm^{-1}$, which is absent in the spectrum of phenyl isocyanate.

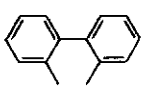
## The Tris(dibenzofulvenyl)methyl Anion, an Extremely Stable Colored Carbanion

By Doz. Dr. C. Jutz and Dipl.-Chem. H. Amschler

Organisch-Chemisches Institut
der Technischen Hochschule München (Germany)

*Dedicated to Professor St. Goldschmidt on the occasion of his 75th birthday.*

We have obtained the deep-blue tris(dibenzofulvenyl)methyl anion *(1)* ($\lambda_{max}$ = 635 mμ) as the Li salt in solution by the action of a) 3 moles of fluorenyl-lithium on 1 mole of the bis-immonium salt *(2)* (colorless crystals, m.p. 220–221 °C from acetonitrile) or b) 1 mole of fluorenyl-lithium on 1 mole of the branched aminofulvene *(3)* (orange-red crystals, m.p. 220–221 °C from benzene/ethanol). The reactants were refluxed under nitrogen in absolute tetrahydrofuran for 30 min. The anion *(1)* is stabilzed by the quasi-aromatic cyclic sextet-conjugation of the five-membered rings and has its charge delocalized over 40 carbon atoms.



*(2)* *(1)*

$(BiphC{=}CH)_2C{=}CH{-}N(CH_3)_2$

*(3)*

Biph =

The blue solutions of the Li salt of *(1)* are stable in air for over 24 h. Oxidation of *(1)* with $K_3[Fe(CN)_6]$ yields the tris(dibenzofulvenyl)methyl radical, which is brownish-yellow and in solution is sensitive to air. On acidifying the solution of the Li salt of *(1)*, the pale yellow, strongly acidic hydrocarbon [1,3] tris(dibenzofulvenyl)methane, m.p. 225–226 °C from benzene/ethanol [yield from a) 30 %, from b) 90 %], is obtained. It can be chromatographed without decomposition with benzene on $Al_2O_3$ (activity grade II) and has the color of the anion *(1)* on the adsorbent. The bis-immonium salt *(2)* was obtained in 80 % yield by formylation of dimethylaminopropenylidenedimethylimmonium perchlorate with dimethylformamide/phosphorus oxychloride or phosgene [2] (the reaction mixture was worked up with $HClO_4$/ethanol). Heating of *(2)* with fluorene and Na methoxide (molar ratio 1:2:2) in pyridine gave a 90 % yield of *(3)* ($\lambda_{max}$ = 457 mμ, log ε = 4.62 in acetonitrile). For optical studies, solutions of salts with anions of type *(1)* were prepared in which 7*H*-benzo[*c*]fluorene or 2,3-diphenylindene replaced one or two fluorene groups.

[3] Note added in proof: In the meantime two communications describing tris(dibenzofulvenyl)methane and the anion *(1)* were published: *R. Kuhn* and *H. Fischer*, Angew. Chem. *76*, 146 (1964); Angew. Chem. internat. Edit. *3*, 137 (1964); *R. Kuhn* and *D. Rewicki*, Tetrahedron Letters *1964*, 383. Accordingly to these, the hydrocarbon is an equilibrium mixture of the protomeric hydrocarbons $C_{43}H_{28}$.

## The Synthesis of Pyrimido[4,5-*e*]-as-triazines (6-Azapteridines) [1]

By Prof. Dr. E. C. Taylor and R. W. Morrison, Jr. [2]

Department of Chemistry, Princeton University, Princeton, N.J. (U.S.A.)

The antibiotics toxoflavin and fervenulin, which have recently been recognized to be derivatives of pyrimido[5,4-*e*]-*as*-triazine (7-azapteridine) [3], are structurally related to the physiologically important pteridines and alloxazines. We have studied analogous systems hoping to find substances with antibiotic, antiviral, and antimitotic properties, and wish

to report two independent synthetic routes to the isomeric ring system of pyrimido[4,5-*e*]-*as*-triazine (6-azapteridine). Reaction of the dibromomalononitrile/KBr complex *(1)* [4] with aminoguanidinium hydrogen carbonate in ethanol furnished *(2)*, which cyclized on heating in water, dimethylformamide, or 2-ethoxyethanol to give 3,5-diamino-6-aminocarbonyl-*as*-triazine *(3)* [5]. Diethyl carbonate and *(3)* condense in ethanolic sodium ethoxide to afford 3-amino-6,8-dioxo-5,6,7,8-tetrahydropyrimido[4,5-*e*]-*as*-triazine *(4)* [6], m.p. >360 °C. Similarly, *(3)* reacts with formamide or with acetamide or ethyl acetate to yield the corresponding 6-unsubstituted and 6-methyl derivatives *(5)* and *(6)*, respectively.

The structure of *(4)* was confirmed by an independent synthesis. Alloxan and aminoguanidinium hydrogen carbonate gave *(7)*, which was cyclized by dilute ammonia to *(4)* [7].

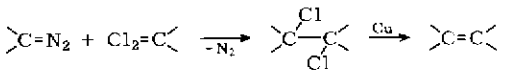
[4] *R. A. Carboni*, Org. Syntheses *39*, 64 (1959).

[5] This compound was previously prepared by a less direct method by *H. M. Taylor* (Ph. D. Thesis, University of North Carolina, 1959; Univ. Microfilms, L. C. card. no MIC 59-5587) but he was unable to utilize it as an intermediate.

[6] The preparation of this compound has been claimed by *L. Heinisch*, *W. Ozegowski*, and *M. Mühlstädt* [Chem. Ber. *97*, 5 (1964)], by the action of ammonia on 3-ethylthio-6,8-dioxo-5,6,7,8-tetrahydropyrimido[4,5-*e*]-*as*-triazine, which was obtained in turn from alloxan and *S*-ethylisothiosemicarbazide hydrochloride. These authors obtained their product only as the hydrate, but we had no difficulty in isolating *(4)* in the anhydrous form. The question of the identity of the two products remains open.



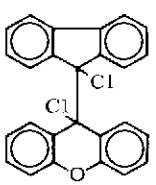
[7] Previous attempts to perform this cyclization with stronger base were reported to result in ring cleavage [5].

## Reactions of Diaryldiazomethanes with Halogeno Compounds [*]

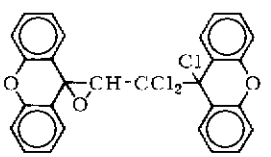
By Prof. Dr. A. Schönberg and Dipl.-Chem. E. Frese

Fakultät für Allgemeine Ingenieurwissenschaften
der Technischen Universität Berlin (Germany)

We have found that diaryldiazomethanes *(1)* in benzene or petroleum ether react briskly at room temperature without irradiation and without decomposition catalysts with some halogeno compounds, *e.g.* diaryldichloromethanes *(2)*.



*(1)* *(2)* *(3)* *(4)*



The 1,2-dichloroethanes *(3)* produced are readily dechlorinated with copper powder in boiling ligroin (100–140 °C) to give the corresponding ethylenes *(4)* in ca. 90 % yield.

For example, starting from diazofluorene and 9,9-dichloroxanthene we obtained a 75 % yield of 9-(*o*-biphenylenechloromethyl)-9-chloroxanthene *(5)*, m.p. 176 °C, which was converted into *o*-biphenylenemethylenexanthene [1]. Again, bis-(4-methoxyphenyl)diazomethane and 9,9-dichloroxanthene gave rise to 9-[bis-(4-methoxyphenyl)chloromethyl]-9-chloroxanthene, m.p. 76 °C (from absolute petroleum ether, b. p. 60–70 °C under nitrogen), in ca. 50 % yield, and thence to 9-bis-(4-methoxyphenyl)methylenexanthene [2], m.p. 179 °C (from chloroform/ethanol). Treatment of the reaction product obtained from diazoxanthene and 9,9-dibromofluorene with copper powder also yielded *o*-biphenylenemethylenexanthene.

Diazoxanthene is very reactive; it reacts exothermally with excess $CCl_4$ at room temperature without irradiation to give 9,9'-dichlorobixanthyl, m.p. 203 °C (from petroleum ether, b. p. 90–100 °C), in ca. 35 % yield. With copper powder it is converted almost quantitatively into the known derivative bixanthylene. Its reaction with excess $CHCl_3$ goes just as easily: the 9-chlorobixanthyl formed is converted by ethanol into 9-ethoxybixanthyl, m.p. 145 °C (from ethanol), in ca. 50 % yield.

*(5)*

*(6)*

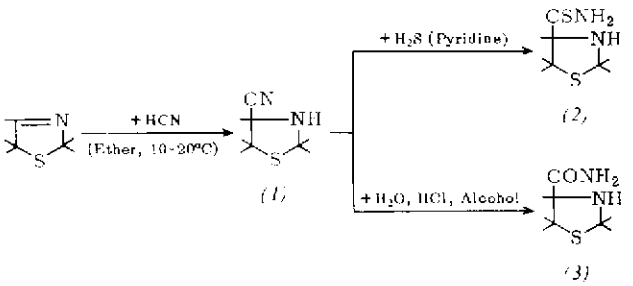
Diazofluorene and diphenyldiazomethane do not react with $CHCl_3$ or $CCl_4$ under the above conditions. Benzylphenyldiazomethane is somewhat more reactive and decomposes to form over 90 % ketazine.

Diazoxanthene and chloral combine in benzene with evolution of nitrogen to yield a compound $C_{28}H_{17}Cl_3O_3$ (decomp. above 180 °C), for which we propose formula *(6)*. The infrared spectrum of *(6)* in Nujol or $CCl_4$ shows no carbonyl band.

Received, February 13th, 1964 [Z 668/496 IE]
German version: Angew. Chem. *76*, 343 (1964)

[*] A recent publication by *H. Reimlinger*, Chem. Ber. *97*, 339 (1964), has induced us to report some of our results.

[1] *A. Schönberg* and *M. M. Sidky*, J. Amer. chem. Soc. *81*, 2262 (1959).



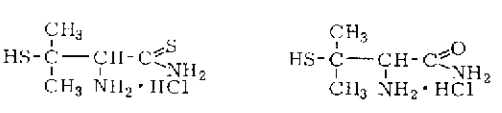
[2] We also obtained 9-bis-(4-methoxyphenyl)methylenexanthene by the reaction of bis-(4-methoxyphenyl)diazomethane with xanthione, the ethylene sulfide formed being desulfurized with copper powder.

## Synthesis of Penicillamine Amide and Penicillamine Thioamide from Thiazolidine-4-carboxamides and -4-thiocarboxamides

By Prof. Dr. F. Asinger, Dr. W. Schäfer, and Dipl.-Chem. E.-Chr. Witte

Institut für Technische Chemie
der Technischen Hochschule Aachen (Germany)

Gaseous hydrogen cyanide adds on smoothly at room temperature to the azomethine bond of many $\Delta^3$-thiazolines [1, 2]. The stability of the resultant novel thiazolidine-4-carbonitriles *(1)* depends both on their purity and the number and type of substituents on the 2- and 4-positions; they are invariably stable in the form of their hydrochlorides (Table 1).



*(1)* *(2)* *(3)*

Table 1. Thiazolidine-4-carbonitriles *(1)*, -thiocarboxamides *(2)*, and -carboxamides *(3)*.

| $\Delta^3$-Thiazoline | *(1)* Yield [%] | *(1)* m.p. [°C] | *(2)* Yield [%] | *(2)* m.p. [°C] | *(3)* Yield [%] | *(3)* m.p. [°C] |
|---|---|---|---|---|---|---|
| 5,5-Dimethyl- | 88 | 57,5 (144)[*] | 79 | 162 | 72 | 177–178 (222) |
| 2,5,5-Trimethyl- | 92 | 58 | 74 | 171 | | |
| 2-Isopropyl-5,5-dimethyl- | 96 | 31 (253) | 62 | 117 | 98 | 97 (236) |
| 2-Phenyl-5,5-dimethyl- | 88 | 109 (167–169) | 25 | 155 | | |
| 2,2,4-Trimethyl- | 93 | 54 | | | 76 | 148 (236) |

| 2,2-Diethyl-5,5-dimethyl- | 97 | 37 | 34 | 174 | | |
| 2,2-Pentamethylene-5,5-dimethyl- | 92 | 54 (185) | 26 | 177 | 74 | 138 (232) |
| 2,2,4-Triethyl-5-methyl- | 94 | 70 | | | | |

[*] In parentheses: m.p. of the hydrochloride.

The nitriles react with $H_2S$ at 0–10 °C to give the previously unknown, colorless thiazolidine-4-thiocarboxamides *(2)*; the yields increase with decreasing substitution at the 2-position (Table 1). $H_2S$ has not yet been added onto 4-substituted nitriles. Treatment of the nitriles with aqueous-alcoholic HCl gives the hydrochlorides of thiazolidine-4-carboxamides *(3)* (cf. Table 1). Hydrolytic ring opening of the thioamides *(2)*

*(4)* *(5)*

with 2N HCl gives high yields of α-amino-β-mercaptothioamides and oxo compounds. Starting from 2,2,5,5-tetramethylthiazolidine-4-thiocarboxamide, we obtained a quantitative yield of the previously inaccessible compound α-

amino-β-mercaptothioisovaleramide as its hydrochloride *(4)* (penicillamine thioamide hydrochloride, m.p. 169 °C). Similarly, hydrolysis of 2,2,5,5-tetramethylthiazolidine-4-carbonitrile hydrochloride led via the 4-carboxamide to the previously unknown derivative α-amino-β-mercaptoisovaleramide hydrochloride *(5)* (penicillamine amide hydrochloride, m.p. 235 °C) in quantitative yield.

## Preparation of Silylgermanes

By Prof. Dr. P. Royen and Dipl.-Chem. C. Rocktäschel

Institut für anorganische Chemie
der Universität Frankfurt/Main (Germany)

Attack by 5–6 N HCl on calcium germanide yields an amorphous lower germanium hydride [1] and a mixture of volatile germanium hydrides. Decomposition of the analogous silicide proceeds correspondingly [2]. The formation of mixed volatile hydrides on decomposing solid solutions of the type $Ca_2(Ge,Si)$ and Ca(Ge,Si) was to be expected.

Homogeneous crystalline solid solutions of germanium and silicon in the ratio 1:1 were produced by melting the elements (Ge: 99.999 % pure, Si: 99.999 % pure from Messrs. Schuchardt) together and tempering at 1050–1100 °C for 30 days [3]. This alloy was mixed with the stoichiometric amount of calcium (99.85 % pure from Messrs. Schuchardt), and the mixture welded into a steel crucible [4], evacuated, and fused by heating briefly to 1200 °C. The X-ray patterns of the mixed crystals thus obtained were in accordance with those of the isotypic phases CaSi and CaGe [5] or $Ca_2Si$ and $Ca_2Ge$ [6]. For the reaction, 5–6 N HCl was slowly dropped onto the solid solution with cooling in an evacuated apparatus.

Examination of the gases developed by mass spectrometry [7] showed that $Ca_2(Ge,Si)$ gave rise to the already known volatile hydrides $SiH_4$, $Si_2H_6$, $Si_3H_8$, $GeH_4$, $Ge_2H_6$, $Ge_3H_8$, and $SiGeH_6$ [8] together with the hitherto unknown mixed hydrides $Si_2GeH_8$ and $SiGe_2H_8$. The same hydrides were obtained together with $Si_4H_{10}$ from Ca(Ge,Si).

## Alcoholysis of Tetraphosphorus Heptasulfide $P_4S_7$

By Dipl.-Chem. H. Petschik and Prof. Dr. E. Steger

Institut für Anorganische und Anorganisch-Technische Chemie und Institut für Spezielle Analytische Chemie der Technischen Universität Dresden (Germany)

The esters $(RO)_2PSSH$, $(RO)_2PSH$, and $(RO)_2PS(SR)$ plus $H_2S$ and some $PH_3$ have been described as the products of alcoholysis of $P_4S_7$ [1]. The NMR spectrum of the reaction mixture of $P_4S_7$ and n-butanol displays 9 signals [2]. We allowed $P_4S_7$ to react in $CS_2$ with ethanol at ≈ 20 °C and analysed the mixture quantitatively by thin-layer chromatography. $(C_2H_5O)_2PS(SC_2H_5)$ *(1)* and $(C_2H_5O)_2PSH$ *(2)* were found to be secondary products. According to our investigations, approximately two atoms of sulfur are split off per $P_4S_7$ as $H_2S$; $(C_2H_5O)_2PS(SH)$ *(3)* is immediately detectable in the infrared spectrum and accounts initially for about half of the phosphorus in solution; hence we consider the main reaction to be:

$$P_4S_7 + 7\,C_2H_5OH \rightarrow \underset{(3)}{2(C_2H_5O)_2PS(SH)} + 2\,H_2S + \underset{(4)}{(C_2H_5O)_2P{-}P(OC_2H_5)SH} \quad (a)$$

*O,O,O'*-Triethyl diphosphonothioate *(4)* is at present only characterized by its position on chromatograms, sensitivity towards water, and strong reducing properties; it decomposes within a few hours. As *(4)* decomposes, the proportion of *(2)* increases until it accounts for nearly one-quarter of the total phosphorus. Ester *(1)* attains this level only after 1–2 days. A substance must therefore be formed by cleavage of *(4)* which alkylates *(3)* to *(1)*, for ethanol does not react with *(1)* under these conditions. From chromatograms and infrared spectra we assume that reactions (b) and (c) occur.

$$\underset{(4)}{(C_2H_5O)_2P{-}P(OC_2H_5)SH} + C_2H_5OH \rightarrow \underset{(2)}{(C_2H_5O)_2PH} + (C_2H_5O)_2PSH \quad (b)$$

$$\underset{(3)}{(C_2H_5O)_2PH} + (C_2H_5O)_2PS(SH) \rightarrow \underset{(1)}{(C_2H_5O)_2PS(SC_2H_5)} + \underset{(5)}{(C_2H_5O)P(O)H_2} \quad (c)$$

$(C_2H_5O)P(O)H_2$ *(5)*, which is unstable at room temperature [3], accounts for the formation of $PH_3$; the proportion of 5–7 % [4] of the total phosphorus found in this form agrees with the maximum amount of 8.33 % to be expected from *(5)*. The other disproportionation product $(C_2H_5O)_2POH$ *(6)* occurs as an impurity that went unrecognized in most of the preparations of *(2)* described, which have $n_D^{20} < 1.4695$ [1, 5] and infrared bands at 550 and 1270 $cm^{-1}$ [6]. It can be isolated from *(2)* by extraction with water; *(2)* and *(6)* are difficult to separate by distillation. In this way, we obtained about 98 % $(C_2H_5S)_2PSH$ *(2)*, b.p. 72.5 °C/13.5 mm, with the refractive index specified. During the alcoholysis, water present converts *(4)* into a more strongly polar substance; the yield of *(2)* falls off correspondingly. This occurs particularly during methanolysis, since the complete esterification of $(CH_3O)_2PS(SH)$ by excess methanol produces water.

The alcoholysis of $P_4S_7$ produces varying yields (≤ 6 %) of a bright yellow, finely powdered substance with P:S = 1:1; this is probably identical with the $(PS)_x$ of *Kuchen* and *Beckers* [7]. This yellow substance, probably mixed with unreacted $P_4S_7$, appears to have been taken for sulfur by several authors [5, 8].

## Synthesis and Crystal Structure of Titanium(III) Tetrametaphosphate and Polyphosphate

By Priv.-Doz. Dr. F. Liebau and H. P. Williams, M. Sc.

Max-Planck-Institut für Silikatforschung,
Würzburg (Germany)

Two phosphates of composition $Ti_2O_3 \cdot 3\,P_2O_5$ have been obtained during investigations of phosphates of trivalent titanium.

Metallic titanium was dissolved with exclusion of oxygen in 85 % phosphoric acid, and the solution was then heated until separation began: tetrameta- or polyphosphates were thus obtained, often together in one and the same charge. On heating metallic titanium in molten $NH_4(H_2PO_4)$, also with exclusion of oxygen, only the polyphosphate was formed.

Under these conditions, titanium(III) tetrametaphosphate forms bright blue tetrahedral and octahedral crystals with a maximum length of edge of 1 mm. X-Ray investigations (Guinier, rotating crystal, and Weissenberg photographs) showed it to be isotypic with the cubic aluminum tetrametaphosphate $Al_4(P_4O_{12})_3$ of known crystal structure [1]. $Ti_4(P_4O_{12})_3$ has cyclic anions containing four $PO_4$ tetrahedra. The crystallographic data of titanium and aluminum tetrametaphosphates are:

| | a [Å] | Z | $\rho_{calc.}$ [g/cm³] | Refractive index |
|---|---|---|---|---|
| $Ti_4(P_4O_{12})_3$ | 13.82 | 4 | 2.84 | $1.584_5$ |
| $Al_4(P_4O_{12})_3$ | 13.71 | 4 | 2.64 | 1.545 [2] |

Titanium(III) polyphosphate was obtained as irregular, oblong, purple-blue crystals of about 0.5 mm maximum length. X-Ray powder patterns showed that this phosphate is isotypic with the monoclinic polyphosphates $Fe(PO_3)_3$ [3], $Cr(PO_3)_3$ [3], and $Mo(PO_3)_3$ [4]. It is a polyphosphate of formula $Ti(PO_3)_3$ with chains of $(PO_3)_\infty^{3-}$ anions. The dimensions of the unit cell and the optical data are similar to those of molybdenum polyphosphate:

| | a sin β [Å] | b [Å] | c [Å] | Z | $\rho_{calc.}$ [g/cm³] | Refractive indices $n_\alpha \approx n_\beta$ | $n_\gamma$ | 2 $V_z$ [5] |
|---|---|---|---|---|---|---|---|---|
| $Ti(PO_3)_3$ | 10.42 | 19.35 | 9.54 | 12 | 2.93 | ≈1.635 | 1.651 | ≈10° |
| $Mo(PO_3)_3$ | 10.67 | 19.48 | 9.55 | 12 | 3.34 | 1.660 | 1.680 | 9.5° |

## Aminoboron Azides [1]

By Dr. P. I. Paetzold and cand. chem. Gert Maier

Institut für Anorganische Chemie
der Universität München (Germany)

*N,N*-Dialkylaminoboron azides are formed in almost quantitative yields from *N,N*-dialkylaminoboron chlorides and lithium azide by stirring for 20 h in boiling benzene. They are isolated by distillation under reduced pressure.

The dialkylaminoboron azides are colorless liquids which are extremely sensitive to hydrolysis but which are more thermostable than diarylboron azides [2] and may be distilled without decomposition. The asymmetric azide valence vibrations ($\nu_1$) lie at higher values than those of diarylboron azides. The B–N valence vibrations of the boron-amine bond ($\nu_2$) lie in the expected region.

$$(R_2N)_{3-n}BCl_n + n\,LiN_3 \rightarrow (R_2N)_{3-n}B(N_3)_n + n\,LiCl$$

| Compound | R | n | B.p. [°C/12 mm] | $\nu_1$ [cm⁻¹] | $\nu_2$ [cm⁻¹] |
|---|---|---|---|---|---|
| *(1)* | $CH_3$ | 1 | 40 | 2151 | 1531 |
| *(2)* | $C_2H_5$ | 1 | 90–93 | 2137 | 1495 |
| *(3)* | $CH_3$ | 2 | 53–55 | 2146 | 1534 |
| *(4)* | $C_2H_5$ | 2 | 75–77 | 2155 | 1504 |

On heating *(1)* for 17 h in a sealed tube at 270 °C, one mole of *(1)* yields 1 mole of nitrogen and 1 mole of dimethylamine, together with insoluble resins; at lower temperatures, the nitrogen is not completely split off. For quantitative decomposition of 1 mole of *(2)* it is necessary to heat it at 280 °C for 18 h; this gives rise to 1 mole of nitrogen plus 0.15 mole of tris(diethylamino)boron and brown products from which no single substance can be isolated. On saponification they yield 10 % 1,1-diethylhydrazine, calculated on the rearrangement:

$$x\,[(C_2H_5)_2N]_2BN_3 \rightarrow x\,N_2 + [(C_2H_5)_2N{-}B{=}N{-}N(C_2H_5)_2]_x$$

in which a diethylamino group moves from boron to the nitrogen atom; analogous reactions of dichloroboron azide [3] and diphenylboron azide [4] led to very high yields of rearrangement products.

On heating the diazides *(3)* and *(4)* to 210 °C, only the nitrogen of one azide group is evolved. Beside tars, salts containing the remaining azide group are formed, namely ammonium azide from *(3)* and diethylammonium azide from *(4)*.

## Preparation of Potassium Hexathiocyanatotitanate(IV) and Its Behavior in Liquid $NH_3$

By Prof. Dr. O. Schmitz-DuMont and Dipl.-Chem. B. Ross

Anorganisch-Chemisches Institut
der Universität Bonn (Germany)

When titanium tetrachloride is added to a solution of potassium thiocyanate in acetonitrile in a molar ratio of 1:6.5, the solution turns orange-yellow and then gradually dark red with concurrent separation of potassium chloride. When the potassium chloride is filtered off with exclusion of moisture, and the filtrate is evaporated to dryness *in vacuo* at room temperature, a reddish-black crystalline residue is obtained, which consists of a thiocyanato salt containing acetonitrile, $K_2[Ti(SCN)_6] \cdot CH_3CN$ *(1)*, and excess potassium thiocyanate. To remove the latter, the solution in acetonitrile is treated with the equivalent amount of silver nitrate dissolved in acetonitrile. Silver thiocyanate and potassium nitrate precipitate out. After evaporating the filtered solution under reduced pressure, the pure coordination complex *(1)* is left. This can be freed from acetonitrile by heating *in vacuo* at 95 °C. Compound *(1)* dissolves in ether to give a red solution and crystallises out on concentrating same. Both *(1)* and the acetonitrile-free compound $K_2[Ti(SCN)_6]$ *(2)* dissolve in water to give colorless solutions from which $TiO_2 \cdot aq$ is deposited only on adding ammonia. Both dissolve in liquid ammonia to give a yellow solution, which becomes brown at higher concentrations. The clear concentrated solution becomes turbid when diluted with liquid ammonia, a behavior suggestive of ammonolysis. The turbidity disappears when the solution is concentrated by evaporating ammonia. After complete evaporation of the ammonia, a product

remains which consists of an ammoniate of titanium(IV) thiocyanate and potassium thiocyanate. On dissolving $K_2[Ti(SCN)_6]$ in liquid $NH_3$ the following reaction occurs:

$$K_2[Ti(SCN)_6] + x\ NH_3 \rightarrow 2\ KSCN + Ti(SCN)_4(NH_3)_x\ (x = 4-5)$$

## Dichloromaleyl Dichloride

By Dr. G. Maahs

Chemische Werke Hüls AG.
Marl, Krs. Recklinghausen (Germany)

Ethyl perchlorocrotonate *(1)* [1] decomposes on boiling into ethyl chloride and 3,4,5,5-tetrachloro-2-oxodihydrofuran *(2)* [2], the latter rearranging to dichloromaleyl dichloride *(3)*, b.p. 192–194 °C. The product is isolated by distillation. On 100% conversion the yield is over 90%. Like the thermal decomposition of 1-ethoxypentachloro-1,3-butadiene [3], the reaction takes place particularly smoothly in the presence of catalytic amounts (≦ 0.01 %) of iron or iron compounds (Fe-powder, iron oxides, iron-containing boiling chips).

*(1)* *(2)* *(3)*

By analogy to the well-known thermal decomposition of γ-bromocarboxylic esters [4], a cyclic onium chloride is probably formed as an intermediate.

## Tristriphenylstannylarsine, -stibine, and -bismuthine

By Dr. H. Schumann and Prof. Dr. Max Schmidt

Institut für Anorganische Chemie
der Universität Marburg/Lahn (Germany)

When stoichiometric quantities of triphenylstannyl-lithium *(1)* [1] dissolved in tetrahydrofuran are added slowly dropwise at room temperature with careful exclusion of air and moisture to vigorously stirred solutions of arsenic trichloride, antimony trichloride, or bismuth trichloride in the same solvent, good yields (ca. 80 %) of tristriphenylstannylarsine *(2)*, tristriphenylstannylstibine *(3)* or tristriphenylstannylbismuthine *(4)* result. These are isolated by evaporation of the solvent and recrystallization from pentane.

$$3\,(C_6H_5)_3SnLi + MCl_3 \rightarrow [(C_6H_5)_3Sn]_3M + 3\,LiCl$$

*(1)*

*(2)*, M = As
*(3)*, M = Sb
*(4)*, M = Bi

Reagent *(1)* must not be present in excess or else secondary cleavage reactions occur. Compounds *(2)*, *(3)*, and *(4)* are colorless solids which are sensitive to air and moisture; m.p. 212–216 °C, 214–215 °C, or 138–142 °C (decomp.), respectively.

By using organo-substituted metal halides instead of the pure trichlorides, other organostanyl derivatives of As, Sb, and Bi are easily obtainable. $(CH_3)_3Sn\ As(C_6H_5)_2$, the first representative of this type, was recently prepared by an alternative, but more complicated, method [2].

## A New Synthesis of Derivatives of Benz[*a*]anthrone and Dibenz[*a*,*d*]anthrone

By Prof. Dr. Ch. Ivanov and L. Mladenova-Orlinova

Institute of Chemical Technology, Sofia (Bulgaria)

As shown previously [1], dehydration of 2,3,4-triaryl-3-hydroxyglutaric acids with conc. sulfuric acid yields 4-aryl-3-hydroxybenzofluorenone. We have found that, in analogous manner, dehydration of the diarylhydroxyglutaric acids *(1a)* and *(1b)*, whose central carbon atom carries an arylmethyl group, yields 4-phenyl-3-hydroxybenz[*a*]anthrone *(2a)* and 4-phenyl-3-hydroxydibenz[*a*,*d*]anthrone *(2b)*, respectively.

*(1)*

*(a)*: with a benzyl group on C-3
*(b)*: with a 1'-naphthylmethyl group on C-3

*(2)*

*(3)*

We obtained the acid *(1b)*, m.p. 167–169 °C (decomp.), in 11.5 % yield by the same method as for *(1a)* [2]; phenylnaphthylacetone, m.p. 58.5–59 °C, was formed simultaneously in 66 % yield.

To carry out the dehydration, *(1a)* is dissolved in conc. sulfuric acid; the solution is then poured into water 15 min later. After washing the precipitate formed to remove sulfonic acids, *(2a)* is obtained in 66 % yield as yellow crystals (from butanol), m.p. 225–225.5 °C (green melt). Its solution in aqueous ethanolic sodium hydroxide is yellow-brown, and turns blue-violet on boiling. Even after prolonged boiling, followed by acidification, a mixture of *(2a)* with orange crystals of 4-phenyl-3-hydroxybenz[*a*]anthranol *(3a)* is always obtained; *(2a)* is not completely rearranged to *(3a)*.

Compound *(2b)* is obtained analogously in 43 % yield as yellow-green crystals, m.p. 216–216.5 °C, which dissolve in aqueous ethanolic sodium hydroxide with an orange-red colour. On prolonged standing or on boiling the alkaline solution, the color turns to blue-violet. On acidification, *(2b)* is reformed, accompanied by orange crystals which are probably those of dibenz[*a*,*d*]anthranol *(3b)*.

## Isothiocyanates of Natural Derivation

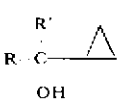
*A. Kjær*, Copenhagen (Denmark)

The isothiocyanate-producing glucosides form a unique and interesting class of natural compounds. Besides the classical representatives, such as sinigrin *(1)* and sinalbin, this class now comprises about 45 glucosides of the same general structure but possessing different side-chains. These can be saturated and unsaturated aliphatic, unbranched ω-methylthioalkyl, unbranched keto-substituted alkyl, aralkyl, aryl, heterocyclic, or β- or γ-hydroxylated alkyl groups.

*(1)* 

The mass-spectra of about 50 individual isothiocyanates, mainly of natural origin, were discussed. Unbranched aliphatic derivatives gave prominent peaks at m/e = 72, attributable to the ion $CH_2NCS^+$ produced by simple β-fission. Strong peaks at m/e = 115 and M-33 obtained with isothiocyanates containing six or more carbon atoms were shown to originate from intramolecular rearrangements. In all methylthioalkyl-substituted derivatives, a strong peak at m/e = 61 was observed due to the ion $CH_3SCH_2^+$. The combination of vapor-phase chromatography and mass spectrometry has proved extremely useful for the rapid and unequivocal identification of small amounts of isothiocyanates of natural origin.

[GDCh-Ortsverband Bonn (Germany), December 12th, 1963]

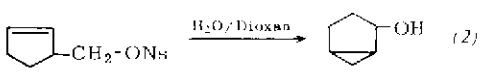


[VB 781/117 IE]

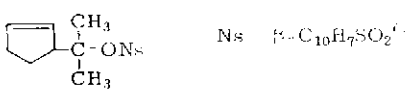
German version: Angew. Chem. *76*, 276 (1964)

## Investigations on Cyclopropane Compounds

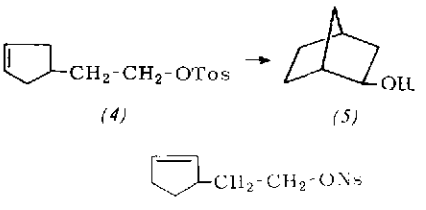
*M. Hanack*, Tübingen (Germany)



As was already shown previously, cyclopropyl carbinols of the general structure



react smoothly with acids and thereby undergo homoallyl rearrangement to the homoallyl halides. If two cyclopropane rings are present in the molecule, the rearrangement proceeds with opening of the substituted cyclopropane ring only. In contrast, halogeno-substituted cyclopropyl carbinols, *e.g.* 2-fluoro-1-cyclopropylethanol, no longer undergo normal homoallyl rearrangement. The fluoro compound is readily obtainable from cyclopropyl diazo ketone via the fluoromethyl cyclopropyl ketone and rearranges with acids to cyclobutane compounds with elimination of fluorine.



The preparative and kinetic aspects of the formation of cyclopropyl carbinols from homoallyl compounds was studied in several solvents. In weakly nucleophilic solvents, the cyclopropyl carbinyl compound is formed almost quantitatively.

The stability of the isomeric carbonium ions that are produced govern the composition of the products formed by cyclization reactions: for example, *(1)* gives 70 % *(2)*, whereas under the same conditions *(3)* does not isomerize to a cyclopropane compound.

*(1)*  *(2)*

*(3)* 

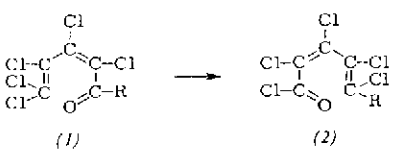
Under solvolytic conditions, *(4)* gives *(5)* [1], whereas *(6)* does not rearrange to the anticipated 7-norborneol.

*(4)* *(5)*

*(6)*

In connection with the formation of *(2)*, the addition of a methylene group onto the double bond of unsaturated cyclic alcohols by treating them with $CH_2I_2$ according to *Simmons* was investigated further. Cyclopropane compounds are only formed if the OH group lies on a carbon atom adjacent to the double bond or if the molecule can assume a conformation in which the OH group comes into the proximity of the double bond.

[GDCh-Ortsverband Wuppertal-Hagen at Wuppertal-Elberfeld (Germany), December 11th, 1963]



[VB 779/121 IE]

German version: Angew. Chem. *76*, 235 (1964)

## Rearrangement of Vinylogous Carbonyl Chlorides

*A. Roedig*, Würzburg (Germany) [2]

Perchloropentadienal *(1a)* [3], perchlorobutadienyl alkyl ketones, *e.g. (1b)*, and perchlorobutadienyl aryl ketones, *e.g. (1c)*, which can be considered as vinylogues of carbonyl chlorides, are converted irreversibly and quantitatively into the isomeric acid chlorides when heated.

*(1)* *(2)*

*(a)*: R = H; *(b)*: R = $CH_3$; *(c)*: R = $C_6H_5$; *(d)*: V = Cl

Starting from *(1a)* labelled with radiocarbon at C-5, it was shown that the oxygen atom and a δ-chlorine atom change places during the rearrangement. Radioactive *(1a)* can be quantitatively converted into radioactive *(2a)* by heating it for three hours in boiling $CCl_4$. Hydrolysis of the acid chloride, thermal cyclization of the resultant acid to 3,4,5-trichloro-2-pyrone, and decarboxylative Diels-Alder condensation of this with maleic anhydride gives a diene adduct containing all the radioactivity; none is found in the $CO_2$.

The rearrangement of *(1a)* is a first oder reaction, and its rate is practically independent of the dielectric constant of the solvent. Radical formers and radical scavengers have no effect. The activation energy (22.8 kcal/mole) and activation entropy (8–11 cal/deg/mole) are independent of the solvent; the latter is negative.

The results indicate a mechanism involving a cyclic intermediate or transition state but do not show whether the rearrangement proceeds via tetrachloropyran *(3a)* (which

[1] *B. D. Bartlett* and *S. Bank*, J. Amer. chem. Soc. *83*, 2591 (1961); *R. G. Lawton*, ibid. *83*, 2399 (1961).

[2] Work carried out in conjunction with *R. Kohlhaupt*, *G. Märkl*, *G. Röbke*, *W. Ruch*, and *M. Schlosser*.

[3] *A. Roedig* and *G. Märkl*, Liebigs Ann. Chem. *659*, 1 (1962).

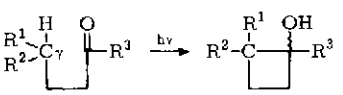
cannot be isolated under the reaction conditions) or concertedly via a four-centred transition state *(4a)*.

*(3)* *(4)*

One prerequisite for the rearrangement is a *cis*-configuration of the double bond adjacent to the carbonyl group of *(1)*. *trans*-Perchlorobutadienyl phenyl ketone *(1c)*, prepared together with the *cis*-isomer by treating *(1d)* with phenylmagnesium bromide, does not rearrange to the acid chloride. Work is in progress to determine whether the halogen substituents on the conjugated chain are important and thus whether the rearrangement is generally applicable.

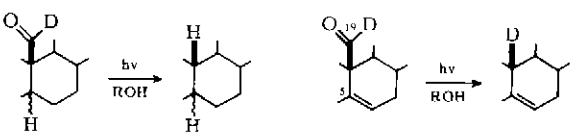
[GDCh-Ortsverband Marl (Germany), December 4th, 1963]

[VB 775/118 IE]



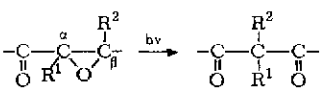
German version: Angew. Chem. *76*, 276 (1964)

## Photochemical Reactions of Steroids

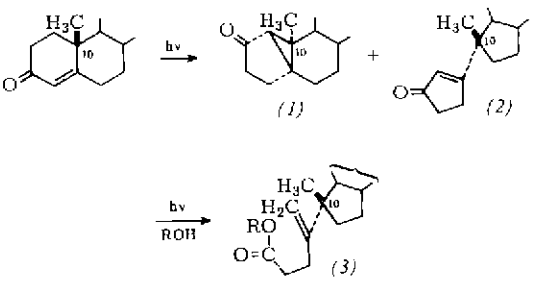


*O. Jeger*, Zürich (Switzerland)

Some novel photochemical reactions of carbonyl compounds were systematically classified according to the structure of the starting compounds and the reaction conditions, using illustrations from the steroid and terpene series.



In the photoreaction involving conversion of saturated aldehydes and ketones with a hydrogen atom in the γ-position into secondary or tertiary cyclobutanol derivatives, intramolecular abstraction of the γ-hydrogen occurs and is accompanied by partial retention of the configuration of the γ-carbon atom.



Photolytic decarbonylation (> 2800 Å) of a deuterated homoallylically conjugated 10-formyl steroid led practically exclusively to stereospecific incorporation of the formyl deuterium (R–CDO → RD + CO). In contrast, CDO is ejected from saturated analogues.

α,β-Epoxy ketones isomerize photochemically to β-dicarbonyl compounds. The 1,2-shift of a β-substituent involved can lead to stereospecific molecular rearrangements. The role of the epoxide oxygen can also be played by the ether oxygen of a lactone.

The diverse behavior of cyclohexenones was discussed, taking testosterone as an example. Molecular rearrangements to compounds of types *(1)* and *(2)* are of special interest. The latter is photochemically unstable and is split with participation of the solvent to give *(3)*.

Some of these reactions give very high yields.

[GDCh-Ortsverband Unterfranken at Würzburg (Germany), November 29th, 1963] [VB 778/120 IE]

German version: Angew. Chem. *76*, 275 (1964)

## Syntheses with N-Metalated Silicon-Nitrogen Compounds

*U. Wannagat*, Graz (Austria)

Sodium bistrimethylsilylamide $NaN(SiR_3)_2$ can be prepared directly from $NaNH_2$ and $R_3SiCl$ (R = $CH_3$) by using special starting conditions (5–6 drops of $R_3SiCl$ are allowed to run into the reaction flask and then the whole amount of $NaNH_2$/benzene suspension is added in one gush; stirring and heating are commenced after the addition of further 40 drops of $R_3SiCl$). The reaction can be modified in such a way that yields of up to 80 % or more of hexamethylsilazane $(R_3Si)_2NH$ or tristrimethylsilylamine $N(SiR_3)_3$ are obtained [1]. For this purpose 8 moles of $NaNH_2$ in benzene are placed in the flask using the starting procedure described above and 6 moles (out of a total of 9 moles) of $R_3SiCl$ are added dropwise and the mixture is then heated for 30 minutes.

$$5\ NaNH_2 + 6\ R_3SiCl \rightarrow 3\ (R_3Si)_2NH + NH_3 + NH_4Cl + 5\ NaCl$$

On heating for several hours under reflux, the $(R_3Si)_2NH$ reacts further:

$$3\ NaNH_2 + 3\ (R_3Si)_2NH \rightarrow 3\ (R_3Si)_2NNa + 3\ NH_3$$

If the remaining 3 moles of $R_3SiCl$ are added and the mixture is heated for 2–3 hours, $(R_3Si)_3N$ is formed.

$$3\ (R_3Si)_2NNa + 3\ R_3SiCl \rightarrow 3\ (R_3Si)_3N + 3\ NaCl$$

Hexamethyldisilazane reacts with $NaNH_2$ and with urea to give off ammonia which, according to the results of studies with $^{15}N$, originates from $NaNH_2$ and $(R_3Si)_2NH$ respectively.

$$(R_3Si)_2{}^{15}NH + NaNH_2 \rightarrow NH_3 + (R_3Si)_2{}^{15}NNa$$
$$(R_3Si)_2{}^{15}NH + CO(NH_2)_2 \rightarrow {}^{15}NH_3 + (R_3SiNH)_2CO$$

$NaN(SiR_3)_2$, m.p. 172 °C, b.p. 202 °C/1–2 mm, crystallizes in the hexagonal system. Its solution in benzene and the melt at 200 °C do not conduct electricity, but its solution in liquid $NH_3$ probably does. Up to the present, the reactions of $NaN(SiR_3)_2$ with halides have given rise *inter alia* to the following compounds.

$FB[N(SiR_3)_2]_2$, b.p. 136 °C/11 mm
$ClPO[N(SiR_3)_2]_2$, b.p. 94 °C/0.1 mm
$Cl_3TiN(SiR_3)_2$, m.p. 75–77 °C
$[(R_3Si)_2N]_2V(OSiR_3)(NSiR_3)$, m.p. 68 °C
$Cr[N(SiR_3)_2]_3$, m.p. 120 °C
$Fe[N(SiR_3)_2]_3$, m.p. 135 °C
$Co[N(SiR_3)_2]_2$, m.p. 73 °C

It reacts with phenoxysilanes to form tris(silyl)amines.

$$R'_3SiOC_6H_5 + NaN(SiR_3)_2 \rightarrow NaOC_6H_5 + (R_3Si)_2NSiR'_3$$

Silicon tetracyanate is converted by it into carbodiimides and polysiloxanes.

$$Si(NCO)_4 + 2\ (R_3Si)_2NNa \rightarrow 2\ NaOCN + R_3SiNCNSiR_3 + 1/x[-OSi(OSiR_3)(NCNSiR_3)-]_x$$

[1] This work will be published in detail soon in Mh. Chem.

The preparation of a tricyanatosilylamine could only be accomplished as shown below.

$$(R_3Si)_2NNa \rightarrow (R_3Si)_2NSiCl_3 \rightarrow (R_3Si)_2NSi(NCO)_3 \text{ (b.p. 81 °C/1 mm)}$$

Carbon monoxide is converted into sodium cyanide, disiloxane being eliminated.

$$CO + NaN(SiR_3)_2 \rightarrow (CN)^-Na^+ + O(SiR_3)_2$$

A five-membered SiN ring *(1)* can be built up.

$$ClSiR_2SiR_2Cl + LiNRSiR_2NRLi \rightarrow 2\ LiCl + \begin{matrix} R_2Si{-}SiR_2 \\ | \quad\quad | \\ RN \quad NR \\ \quad Si \\ \quad R \end{matrix} \quad (1)$$

Octamethyl-1,2,4-trisila-3,5-diazacyclopentane melts at −18 °C and boils at 70 °C/13 mm.

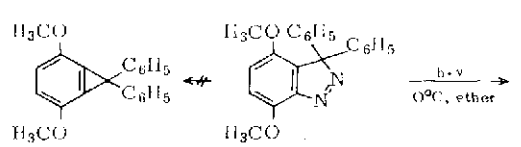
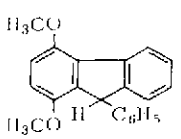
## Investigations on Aromatic Systems

*H. A. Staab*, Heidelberg (Germany)



Hexa-*m*-phenylene *(1)*, which has practically the same geometrical arrangement in its inner ring system as [18]-annulene and probably possesses a practically planar structure, has like that compound π-electrons on all the carbon atoms of its inner ring. However, in view of the *meta*-bonding of the phenylene groups, the cyclic π-conjugation should be suppressed. Compound *(1)* was prepared (with *F. Binnig*) from the Grignard compound of 3,3′-dibromodiphenyl with $CoCl_2$ in tetrahydrofuran. It can be distilled



*(1)*

without decomposition at 650 °C/$10^{-4}$ mm Hg; m.p. 509.5 to 511 °C. Its proton resonance (in view of its low solubility, measurements have so far only been carried out in 1-methylnaphthalene at 180 °C) gave no signals at 3.7–7.7 τ and 8.5–18.0 τ; particularly strong shielding of the six inner protons by an aromatic ring current can thus be excluded, as anticipated. In the ultraviolet, *(1)* absorbs practically at the same wavelength (251.2 mμ, ε = 138000 in $CHCl_3$) as biphenyl (251.5 mμ, ε = 18300).

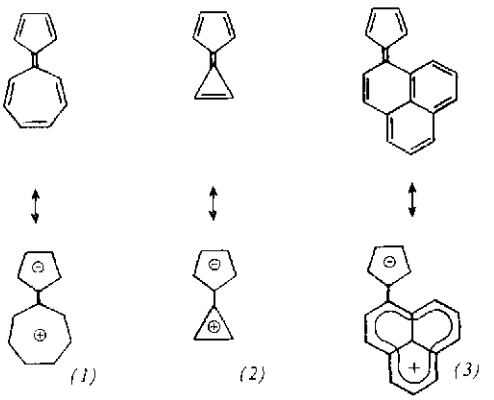
Attempts to prepare the benzocyclopropene *(3)* (with *J. Ipaktschi*) by photochemical elimination of nitrogen from *(2)* did not lead to the desired product. Instead, the 9-phenylfluorene derivative *(4)* was obtained in very good yield.

*(3)* *(2)*

*(4)*

In the course of studies on nine-membered rings containing nitrogen and having 10 π-electrons 1,4,7-dibenzo[*b,h*]triazonines were obtained (with *R. Bader*).

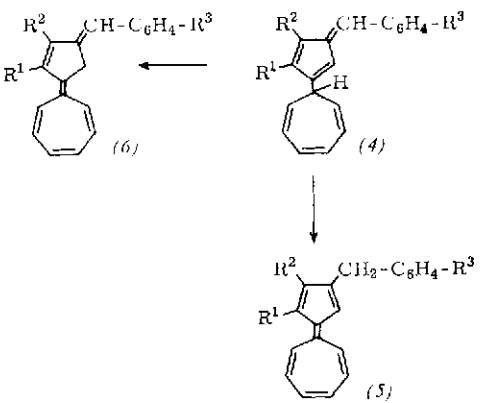
[Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany), January 8th, 1964] [1]



[VB 783/124 IE]

German version: Angew. Chem. 76, 276 (1964)

## New Types of Polyenes with Cyclic Cross-Conjugated Bond Systems



*H. Prinzbach*, Freiburg/Breisgau (Germany)

In the dipolar structural formulae of the hydrocarbons sesquifulvalene *(1)*, calicene *(2)*, and phenafulvalene *(3)*, the central single bond joins, in each case, two relatively stable organic ions.

*(1)* *(2)* *(3)*

Although *(1)* exists only in solution, it may be estimated accurately by spectrophotometry and by its chemical reactions. On the other hand, doubly annellated derivatives of *(1)*, or those containing four phenyl groups on the five-membered ring, are stable. Simple derivatives are obtained by prototropic rearrangement of fulvenes *(4)*. In contrast to the observation in the annellated series *(4a)*, where only a formal 1,5-hydrogen displacement to give *(5a)* is found, a competition reaction occurs in the analogous rearrangement of *(4b)*, and with increasing acceptor-character of $R^3$, progressively more formation of the vinyloguous heptafulvene *(6b)* takes place. The chemical behavior of this class of compounds – including the smooth addition of acids and bases, the site of the electrophilic attack, and adduct formation – is in agreement with the π-electron delocalization favored in the transition state.

*(6)* *(4)* *(5)*

*(a)* $R^1R^2 = -C_4H_4$; $R^3 = -CN, -Cl, -H, -OCH_3, -N(CH_3)_2$

*(b)* $R^1 = R^2 = H$; $R^3 = -CN, -Cl, -H, -OCH_3, -N(CH_3)_2$

[1] Also reported January 10th, 1964, at a meeting of the GDCh-Ortsverband Köln (Germany).

NMR-spectroscopic examination of *(4)*, *(5)*, and *(6)*, and of prototypes of *(2)* and *(3)* showed that the π-bonds are largely localized in these cyclic cross-conjugated systems. On the assumption of changes of bond lengths typical for olefins, molecular-orbital calculations by *Nakajima* on *(1)* gave a value for N-V' excitation [*], that is verified experimentally (calculated: 3.20 eV; found: 3.16 eV).

[GDCh-Ortsverband Ruhr, Mülheim/Ruhr (Germany), December 11th, 1963] [VB 782/123 IE]

## Transport Processes and Equilibria in the Reduction of Oxides

*H. J. Engell*, Clausthal-Zellerfeld (Germany)

In the reduction of metal oxides by gases, a dense layer of the final reaction product can be formed. Then transport processes in this layer can determine the rate of reduction. In the reduction of wustite (FeO) to iron, an outer layer of iron may be formed. The diffusion of oxygen in this layer then determines the rate of reduction, as was shown by comparison of the measured rate with the rate of diffusion of oxygen in iron estimated by other methods. In the reduction of magnetite ($Fe_3O_4$) to wustite (FeO), dense surface layers of wustite are formed. In this case, however, the gas/oxide phase-boundary reaction determines the rate of reaction, since iron diffuses relatively quickly through the wustite layer.

During the reduction of oxide mixed crystals, the oxide phase is decomposed. The extent of this decomposition depends on the equilibrium conditions; its rate depends on transport processes in the oxide, which are controlled by the disorder equilibria. The form of metal precipitation observed here is a result of these equilibria.

## Mechanism of Osazone Formation and of the Amadori Rearrangement

*F. Micheel*, Münster/Westfalen (Germany)

The osazone reaction discovered by *Emil Fischer* in 1884 is not initiated by an Amadori rearrangement of an aldose phenylhydrazone; instead, some phenylhydrazine first decomposes in the acidic solution by partial disproportionation into aniline, ammonia, benzene, nitrogen, *etc.* The phenylhydrazone *(1)* reacts with the aniline produced in this manner by transamination to form a 1-phenylamino derivative *(2)* which is readily converted by further aniline and $H^+$-ions into a 1-deoxy-1-phenylaminoketose derivative *(4)* [1]. The Amadori rearrangement proceeds very rapidly in the presence of excess amine; this also shows that the intermediate product is not a Schiff's base but a 1,1-bis-*N*-acetal *(3)* [2].

Compound *(4)* reacts rapidly with phenylhydrazine to give a 1-deoxy-1-phenylaminoketose phenylhydrazone *(5)*, which in turn can react rapidly with excess phenylhydrazine to form the osazone *(7)*. By using $^{14}C$-phenylhydrazine it can be demonstrated [3] that this step does not involve an intramolecular redox reaction but that *(5)* or *(6)* – as a strongly

reducing enediamine [4] – hydrogenates further phenylhydrazine to ammonia and aniline. Aniline formed in this manner accelerates the osazone formation in accordance with the above equation.

## Complex Formation with Polymolybdate Ions

*K. F. Jahr*, Berlin (Germany)

Telluromolybdates can be detected by conductometric, potentiometric, spectrophotometric, and salt-cryoscopic titrations of acidified $Na_2MoO_4$ solutions (1.0–1.6 $H^+/MoO_4^{2-}$) with solutions of $Te(OH)_6$. With increasing concentrations of $Te(OH)_6$ in solutions with 1.0–1.14 $H^+/MoO_4^{2-}$, telluro-1:12-, telluro-1:7-, and telluro-1:6-molybdates are formed successively; at 1.33 $H^+/MoO_4^{2-}$, the 1:7 and then the 1:6 complex are formed. On titrating the molybdate with solutions of $Al^{3+}$ salts, an alumino-1:7- and then an alumino-1:6-molybdate result; here a 1:12 complex cannot be detected.

The telluro-1:6 complex is the familiar heteropolyanion $TeMo_6O_{24}^{6-}$, which consists of a flat ring of six $MoO_6$ octahedra with $Te^{6+}$ at the center. The new 1:7 complex is thought to be an adduct of $H_4TeO_6^{2-}$ and the "paramolybdate ion" $Mo_7O_{24}^{6-}$, while the new 1:12 complex is a 1-tellurium-2-hexamolybdate ion with $Te^{6+}$ as an octahedrally coordinated central ion sandwiched between two superjacent $Mo_6O_{24}$ rings. The 1-tellurium-1-hexamolybdate was shown by salt-cryoscopic measurements to be the most stable complex at two $H^+/MoO_4^{2-}$ ratios (1.14 and 1.50), since it can be formed from two different hexamolybdate ions which predominate at these ratios. Conductometric titration of an acidic molybdate solution (1.5 $H^+/MoO_4^{2-}$) with free $H_3PO_4$ led to a phospho-1:12-molybdate with consumption of $H^+$. This complex condenses to form the well known 1-phosphorus-2-dodecamolybdate ion only in strongly acidic solution and is thought to be an inclusion compound with a phosphate ion inside a hollow spherical dodecamolybdate ion, which in such acid solutions is in equilibrium with a hexamolybdate ion. The fact that the dodecamolybdate ion has a hollow interior suitable for the formation of inclusion compounds is demonstrated by the formation of a 1-(methyl red)-1-dodecamolybdate ion, which was detected by conductometry and spectrophotometry. On adding methyl red to a molybdate solution with 1.5 $H^+/MoO_4^{2-}$, the initially red solution gradually turns yellow as the indicator is converted into the anion by inclusion inside the hollow space within the dodecamolybdate ion. Even large additions of sulfuric acid do not restore the red color of the solution; however, phosphoric acid, displaces the indicator from the cavities to form the more strongly complexed 1-phosphorus-dodecamolybdate ion and colors the solution red with the liberated indicator. When ammonia is added dropwise to the yellow solution of

[*] N-V' excitation is defined as the transition between the highest MO and the lowest excited singlet state.

[1] *F. Micheel* and *I. Dijong*, Liebigs Ann. Chem. *669* 136 (1963).

the inclusion compound, the dodecamolybdate ion breaks down into the hexamolybdate ion, thus liberating the indicator and coloring the solution – which is still acidic – red. Inclusion compounds can condense to form true heteropolyacids which are purely inorganic chelate complexes. Naturally only such materials are included or complexed which by virtue of their size, structure, and coordinating ability can pass into the hollows within the isopolyanion.

## Adsorption Phenomena at Gas/Solid Interfaces at Low Gas Pressures

*N. Hansen*, Aachen (Germany)

The isotherms for physical adsorption of argon on different adsorbents in ultrahigh vacuum do not yield the proportionality between pressure and amount of gas absorbed predicted for low coverages. Down to a fraction of the monolayer of $10^{-6}$ and at relative equilibrium pressures $p/p_0$ of $10^{-12}$ or $p = 10^{-10}$ mm, a parabolic isotherm is observed, which may be ascribed to thermodynamic heterogeneity of the surface. Experiments suggest that at even lower coverages linear isotherms are obtained and that at very low coverages there are at least $10^4$ units of very sparsely occupied surface for each unit of closely occupied surface.

The chemisorption of gases on pure metallic surfaces takes place very rapidly and cannot be measured in conventional gas-volumetric apparatus. By means of an "open apparatus" (with continuous admission of gas), it was possible to observe the rate of adsorption over many orders of magnitude. For instance, for carbon monoxide on zirconium films obtained by evaporation, it amounts, at low coverage, to about half the maximum possible rate of impact, which may be calculated from gas kinetics. The rate of adsorption of metal powders with relatively pure surfaces – obtainable from some transition metals by heat treatment *in vacuo* – is therefore determined by the Knudsen molecular flow. If a suitable pore structure is generated in these metal powders, they are adequate for the production of compact arrangements that show large adsorptive capacities for gases at very high adsorption rates and may be used as sorption pumps or getters.

## Energetics of the Contraction Cycle in Muscle

*W. F. H. M. Mommaerts*, Los Angeles, Calif. (U.S.A.)

Present day knowledge of the biochemical basis of the energetics of muscle contraction rests mainly upon the experimental possibility of interrupting a muscle contraction at any desired stage by rapid freezing of the specimen and of comparing the chemical composition of the latter with that of an unstimulated control. Technically, this has become possible through methodological developments made in our laboratory during the last decade; the limit of the method is set by statistical fluctuations between the compositions of muscles within a pair. Thus, frog sartorius muscle forms 0.4 µmole of creatine and phosphate in a single tetanic contraction of 400 msec, and the same figure is obtained for the activation metabolism per contraction in a series of brief tetani, extrapolated to conditions of zero work performance, although there are cases where this behavior has not yet been demonstrated. When work is done, more hposphocreatine is broken down.

While these two results, in agreement with work by *Carlson*, account for two categories of energy production, a third, *Hill*'s shortening heat, could not be detected in this way. Since there is good reason to assume the existence of a shortening heat, representing the dissipational heat of a work process under non-ideal conditions, this discrepancy represents one of the urgent problems in this field. The recent observation by *Davies* of the primary breakdown of ATP is in accordance with expectations. One interesting aspect of this work, which we seem able to confirm, is that part of the activation metabolism occurs in the relaxation phase of the contraction cycle, while the activation heat occurs earlier. This finding, too, remains to be explained.

With such fundamental aspects of the energetic balance still incompletely explained, it seems premature to try to account for the energetic problems in molecular terms. However, a discussion was given of some such questions with regard to the energetic effects of binding versus splitting of ATP, of the importance of a specific conformation of myosin-adenosine triphosphatase, of the participation of actin, and of the importance of Curie's theorem in biological energetics.

## Scattering and Absorption Coefficients in Diffuse Reflection of Powdered Materials

*G. Kortüm*, Tübingen (Germany)

In determining "typical color curves" of powdered materials by means of the Kubelka-Munk function

$$F(R_\infty) = (1-R_\infty)^2/2\,R_\infty = K/S$$

it is assumed that the scattering coefficient S is independent of the wavelength, so that the absorption coefficient K becomes proportional to the true absorption coefficient of the absorbing medium. If the multiple scattering of powders is treated generally on the basis of the Mie theory [1] for simple scattering, it is to be expected that, for particle diameters d that are very small in comparison with the wavelength $\lambda$, the scattering coefficient becomes $S \sim \lambda^{-4}$, and for particle diameters that are large in comparison with the wavelength, S becomes independent of $\lambda$. The scattering coefficients of reference standards (Aerosil, MgO, NaCl, $CaF_2$, cracking catalysts, glass powders, *etc.*) were determined, for the limiting conditions indicated, from the reflectance and transmittance of very thin powder layers and from $R_\infty$. For Aerosil samples of varying particle size, for which $d \ll \lambda$, the scattering coefficients ranged from $S \sim \lambda^{-2.6}$ to $S \sim \lambda^{-3.6}$. The exponential –4, characteristic of simple Rayleigh scattering, was thus not reached, while for $d \gg \lambda$, S is in fact independent of the wavelength in the visible and near ultraviolet regions. For application of the Kubelka-Munk theory to the determination of typical color curves of powders, it follows therefore that no particle size below 2–5 µ should be used, if the spectra of adsorbed substances are to be examined. Otherwise, the scattering coefficients of the adsorbent must first be determined.

As an example, the absorption spectrum of graphite on Aerosil was given from 700 to 250 mµ, the scattering coefficients measured being taken into account. It was shown that the scattering coefficients of the adsorbent are not changed by admixture of 0.1 % graphite, so that the true spectrum of the adsorbed substance may actually be obtained in this way with ultrafine adsorbents [*].

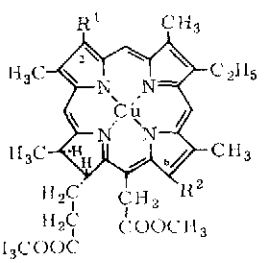
## Bonding in Intermetallic Phases of the Ni-As Type

*H. Wever*, Berlin (Germany)

Among intermetallic phases, the Ni As type represents a transition between mainly metallic and essentially non-metallic phases. The B atoms occupy a close-packed hexagonal unit cell with a c/a ratio of 1.633. Chains of A atoms fit into the octahedral voids. With increasing metallic character of the B partner, both the c/a ratio and the heteropolar forces between the A and B partners decrease. Homopolar forces due to coupling between d-electrons of the A atom are superimposed. The electrical conductivity behavior suggests discrete d-levels for c/a $>$ 1.633, and bands for c/a $<$ 1.633. If the c/a ratio is less than 1.33, then the tetrahedral voids of the hexagonal unit cell can also be filled with A atoms, *i.e.* the structure tends towards $A_2B$. In this way, new coordination and bonding relationships result. Further information can be gained from studies of the electrical and magnetic properties of the phases as well as from electrolytic transport phenomena.

The Ni–Sn and Ni–In systems were also studied. Both phases have a considerable range of homogeneity. Definite compositions ($c_s$) corresponding to the temperature maximum in the phase diagram can be obtained by zone melting. Electrical and magnetic properties are dependent on composition, such that the electrical conductivity of the Ni–Sn phase shows a marked minimum at composition $c_s$. The electrolytic transport shows that for the Ni Sn phase the field force, and for the Ni–In phase the interaction force, is the essential driving force.

A discussion of the experimental results suggests that the d-band is filled increasingly from Ni–In to Ni Sn to Ni Sb. The electrical properties can be understood if an atomic bond between the Ni atoms in the tetrahedral voids and the neighboring B atoms is assumed, for this would lead to a bonding triple band. In the case of the Ni–Sn phase, the band would be completely filled at the composition $c_s$.



[GDCh-Ortsverband Nord-Württemberg, Stuttgart (Germany), January 23rd, 1964] [VB 786/127 1E]

German version: Angew. Chem. *76*, 353 (1964)

## Acetylation Reactions of Chlorins, a Contribution to the Munich Chlorophyll Chemistry

*H. H. Inhoffen*, Braunschweig (Germany)

By heating the Cu complex of 2-devinylisochlorin $e_4$-dimethyl ester *(1a)* with $SnCl_2(\cdot 2H_2O)$ and acetic anhydride at 100 °C for 10 min, *H. Fischer* et al. [1] obtained the corresponding 2,6-diacetyl derivative *(1b)*. When the copper was removed from *(1b)* and the chlorin residue was allowed to stand at room temperature in pyridine with benzoyl chloride, the Cu-free 2-monoacetyl compound *(1c)* was isolated in 5 % yield. From this *Fischer* concluded that partial deacetylation in the 6-position can be achieved. Compound *(1c)* is an important intermediate in *Strell*'s synthetic reactions for chlorophyll a. On checking these reports, it turned out that acetylation of *(1a)* under *Fischer*'s conditions actually gave a mixture of *(1b)* and *(1c)* in the ratio of 4:1. Pure *(1b)*, *i.e.* free of *(1c)*, could not be partially deacetylated in the 6-position by *Fischer*'s method. Moreover, considerably more vigorous conditions, *e.g.* conc. aqueous HCl at room temperature or at 100 °C, were also without effect upon the 6-acetyl group in *(1b)*.

*(1a)*: $R^1 = R^2 = H$
*(1b)*: $R^1 = R^2 = COCH_3$
*(1c)*: $R^1 = COCH_3$; $R^2 = H$
*(1d)*: $R^1 = H$; $R^2 = COCH_3$

If *(1a)* is acetylated at 0 °C (60 min), a new monoacetyl compound can be isolated in 70 % yield. The product obtained from this by removal of its copper with conc. HCl/glacial acetic acid can be regarded on the basis of extensive deuteration experiments together with nuclear magnetic resonance measurements as being the 6-monoacetyl compound *(1d)* (without Cu). Compound *(1d)* is acetylated under Fischer's conditions to give the known mixture of *(1b)* and *(1c)*.

If *(1a)* is acetylated at 100 °C with subsequent addition of water (1 mole of $H_2O$ to 1 mole of $Ac_2O$), *(1c)* is obtained in 90 % yield.

The Cu-free chlorins were also made from *(1b)*, *(1c)*, and *(1d)*.

[GDCh-Ortsverband Braunschweig (Germany), January 27th, 1964] [VB 793/132 1E]

German version: Angew. Chem. *76* (1964), in the press.

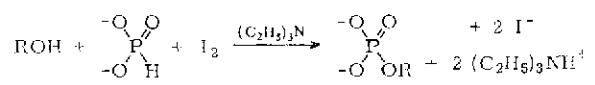
## Methanol/Air Fuel Cells

*W. Vielstich*, Bonn (Germany)

Apart from glycol and glycerin, methanol – including its conversion products – is especially suitable as liquid fuel for galvanic fuel cells. Such cells are particularly useful for maintenance-free energy supplies to signal devices, telegraph stations, emergency power generators, *etc.*

The operating voltage varies between 0.5 and 0.8 V at room temperature. Up to 145 ampere-hours were obtained per mole of methanol (theoretical value for conversion to carbonate about 160 amp.h). It is thus possible to store up to 1000 amp.h per l of fuel/electrolyte mixture. For practical purposes, a "hard discharge curve", *i.e.* a flat curve for the voltage as a function of time or the concentration of methanol, is of importance. This may be attained between –10 and +30 °C by suitable choice of catalysts and electrolyte composition.

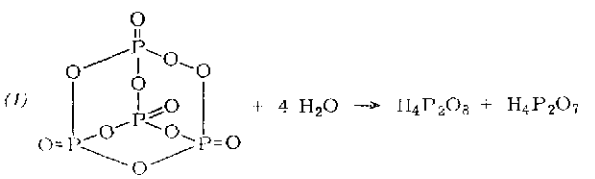
Information about the individual reaction steps was obtained by means of the potentiostatic triangular voltage method. On anodic oxidation of formic acid on platinum (acid electrolyte), formate radicals are formed in the potential range between +300 and +600 mV (relative to hydrogen). They passivate the electrode by adsorption on the surface. It was shown that formation of oxalate or carbon monoxide does not occur.



On passing $CO_2$ over a platinum electrode in the potential range $0 < \varphi < +300$ mV against hydrogen, *Giner* [2] observed deposition of an oxidizable reaction product on the electrode. Now it has been shown that, here again, this product is adsorbed formate radicals and not CO.

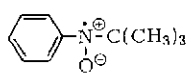
[GDCh-Ortsverband Bonn (Germany), January 28th, 1964] [VB 792/134 1E]

German version: Angew. Chem. *76* (1964), in the press.



[2] *J. Giner*, Electrochim. Acta *8*, 857 (1963); *9*, 63 (1964).

**A new synthesis of monoalkyl phosphates** has been described by *A. J. Kirby*. They are obtained quantitatively by oxidation of phosphite anion with iodine in alcohol.



The reactive intermediate is presumably the $IPO_3^{2-}$ anion, or, less likely, monomeric metaphosphate. Alcohols that are easily oxidized by iodine are unsuitable. To carry out the phosphorylation, crystalline phosphorous acid is dissolved in butene-1,4-diol, for example, and triethylamine, and solid iodine is added; an exothermic reaction takes place. The mixture is then poured into acetone, the monophosphate being precipitated as dicyclohexylammonium-4-hydroxy-2-butenyl phosphate in 100 % yield. The method gives good results with the usual aliphatic alcohols. / Chem. and Ind. *1963*, 1877 / –Ma. [Rd 859/234 IE]

**An improved synthesis of phosphorus peroxide** has been described by *P. W. Schenk* and *H. Vietzke*. Phosphorus and oxygen interact in a glow discharge to form a mixture of $P_2O_5$ with a maximum of 15 % peroxide, which separates as a violet deposit on a cold finger. This violet form of the peroxide is only stable at low temperatures and has free-radical character. It is converted by warming into the colorless peroxide $P_4O_{11}$, which decomposes above 130 °C. $P_4O_{11}$ *(1)* reacts with water to yield only peroxodiphospboric acid and diphosphoric acid.

When nitrogen is added under the conditions for peroxide production, a violet product of composition $P_4O_{11} \cdot 2P_4O_{10} \cdot 3NO$ is formed. Hydrolysis of this leads to the formation of a nitric oxide-tetrametaphosphoric acid which is stable in alkaline media. / Z. anorg. allg. Chem. *326*, 152 (1963) / –Kr. [Rd 840/235 IE]

**Phenyl-t-butylnitroxide, a new free radical,** has been synthetized by *H. Lemaire, A. Radssat*, and *A.-M. Ravet* by the action of t-butylmagnesium chloride on nitrobenzene and also by the reaction of phenylmagnesium bromide with nitro-t-butane. The radical was identified by its paramagnetic

*(1)* 

electron resonance spectrum. The lifetime of the radical is about one week, so that its purification is possible. / Bull. Soc. chim. France *1963*, 1980 / –Ma. [Rd 855/236 IE]

**A localized bond between a substituted benzene and a transition metal** has been demonstrated for the first time with certainty in cyclopentadienyl hexakistrifluoromethyl benzenerhodium. The compound was prepared from hexafluoro-2-butyne and cyclopentadienylrhodium dicarbonyl. According to its infrared and NMR spectra and crystal structure (monoclinic; $C_{2h}^5 hP2_1/c$, a = 9.48, b = 12.59, c = 17.79 Å; $\beta = 114.8°$; Z = 4; $\rho_{20\,°C} = 2.27$ g/cm³) the Rh is octahedrally coordinated. Only four atoms of the benzene ring are coordinated with the rhodium, C-1 and C-4 by covalent σ-bonds, and C-2 and C-3 by a π-bond. The Rh–C distance for C-1 and C-4 is 2.15 Å and for C-2 and C-3 2.04 Å; C-5 and C-6 are 3.0 Å away. The original benzene ring is hinged at an angle of 48 ± 2° across the (C-1)-(C-4) axis. The strained coordinate double bond (C-2)=(C-3) is about 0.13 Å long erthan the uninvolved (C-5)–(C-6) bond. Compared with the benzene ligands in a normal complex, the (C-1)-(C-4) distance is reduced from 2.80 to 2.56 Å. / Proc. chem. Soc. (London) *1963*, 365 / –Jg. [Rd 836/341 IE]

**Salts of xenic acid** have been described by *A. D. Kirschenbaum* and *A. V. Grosse*. Free xenic acid $Xe(OH)_6$ was obtained in 30–40 % yield by hydrolysis of $XeF_4$ or xenon oxide fluorides at 0 °C with water. Solutions free from hydrogen fluoride can be prepared by addition of a small excess of $Ca(OH)_2$ or $CaCO_3$ and separation of the resulting $CaF_2$. Xenic acid can be determined by treating it with iodide and titrating the iodine liberated with thiosulfate.

$$Xe(OH)_6 + 6\,KI + 6\,HCl \rightarrow Xe + 6\,H_2O + 3\,I_2 + 6\,KCl$$

Solutions of this very weak acid can be stored for weeks at –20 to –30 °C. Barium xenate $Ba_3XeO_6$ was obtained in quantitative yield as a white, amorphous, sparingly soluble precipitate from $Ba(OH)_2$ and $Xe(OH)_6$ solutions in a molar ratio of 3:1 at 0 °C. The solubility of $Ba_3XeO_6$ in water at 20 °C is 0.25 g/l. Barium xenate is stable for at least a month at room temperature. At 125 °C, it begins to decompose slowly; at 250 °C, thermal decomposition is complete.

$$Ba_3XeO_6 \rightarrow 3\,BaO + Xe + 1.5O_2$$

The sodium and potassium salts of xenic acid were also prepared. Solutions of these salts at 0 °C and pH 7 appear to be stable. / Science (Washington) *142*, 580 (1963) / Ko. [Rd 849/242 IE]

**Solutions of pure nitrous acid** were obtained by *C. S. Scanley* using ion exchange at low $HNO_2$ concentrations and low temperatures (the decomposition of $HNO_2$ is of the 4th order and is very dependent on temperature). A 3 % solution of sodium nitrite in ethylene glycol dimethyl ether/water (2:1) was run through a column of Dowex 50 W-X4 in its acid form at –30 °C. Analysis of the resulting solution showed that it consisted of almost pure $HNO_2$ (Na content ≤4 ppm). These solutions can be used *inter alia* for the production of nitrites by direct neutralization, for nitrosation, and for diazotization reactions. / J. Amer. chem. Soc. *85*, 3888 (1963) / –Ko. [Rd 850/243 IE]

**For routine measurements of the surface area of finely divided materials,** a simple and rapid method developed by *R. Haul* and *G. Dümbgen* based on low-temperature adsorption of nitrogen can be used. Several samples are degassed simultaneously by heating in a stream of nitrogen. Subsequently, standardized measuring vessels with the samples and a reference vessel of equal volume all filled with nitrogen at atmospheric pressure are cooled with liquid nitrogen. The surface area of the sample can be obtained from the pressure difference read on a differential manometer and the initial (atmospheric) pressure without additional measurements of the equilibrium pressure and the use of empirical calibration factors. Each measurement requires about half an hour, the computation a few minutes. Gases other than nitrogen can also be used [*]. / Chem.-Ing.-Techn. *35*, 586 (1963) / –Hl. [Rd 690/244 IE]

[*] A device based on the above principle is available from Messrs. Ströhlein and Co., Düsseldorf (Germany).

**Über den Ablauf organisch-chemischer Reaktionen** (Organic Reaction Mechanisms). By *S. Hauptmann*. WTB, Science Pocket Books. Akademie-Verlag, Berlin, 1963. 1st edit. 175 pp., paperback, DM 12.50 (about $3.25).

This science pocket book deals with the multiplicity of organic reactions on the basis of 'electronic theory'. From this point of view the booklet is excellent. The arrangement is clear, and the individual reactions are grouped in such a way that their common traits are clearly illustrated by application of electronic theory. One example of this is provided by addition reactions (Section 2.1), almost all of which are induced and influenced by mesomeric and inductive effects. Again, the representation of substitution reactions (Section 2.3), in particular the differentiation between the individual reactions on pp. 86–107, is particularly apt.

How do we know, however, that the molecules do in fact react via the structures shown? Do we arrive at these ideas exclusively as a result of experience, that is, empirically? It seems regrettable to have to read in the preface that the molecular orbital method affords the best means of answering these queries, but that it should be left to the physicist to apply it. In actual fact, however, the book contains such a large number of theoretical fragments which have recently found their way into chemistry almost unnoticed that the more knowledgeable reader will perceive a lack of foundation precisely during more fundamental discussions. The few basic principles which are mentioned frequently and which are said to govern the processes can only be explained on a theoretical basis. The basic concepts mentioned in the section on mesomerism are derived from the field of wave mechanics. This provides the only possibility for explaining the numerous exceptions which are in principle not capable of being treated on the basis of electronic theory.

It is unfortunate that the results of the MO–LCAO method (Hückel method) were not utilized in the treatment of organic reaction mechanisms, as they would make it possible to discuss the position at which the reaction is initiated as well as its likely course, particularly with $\pi$-electron systems. In this connection, mention should also be made here of the LCBO-method and the method of valence structures, the latter in particular with regard to excited states. Only brief mention is made of reaction kinetics, and the concepts of transition states, metastable intermediates, and activation energies are described without much method. No comment is made of molecular vibrations, equilibria are not dealt with. The reader necessarily arrives at the conclusion that there is no basis for the discussion of the reaction processes other than that of electronic theory. The table given on p. 7 is misleading since it shows He with the same number of valence electrons as Be or Mg.

The book could have been made more useful if theoretical concepts developed during the last few years had not been deliberately disregarded, thus introducing an unnecessary limitation to the otherwise excellent treatment of the subject matter. The chemist will profit more from the book if he disregards the statement made in the preface that "classical chemical structural formulae (with additional representation of lone pairs of electrons by dashes and of unpaired electrons by dots) will continue to form the simplest and, generally speaking, completely adequate method of representing the constitution of organic compounds and the course of their reactions."

*H. Preuß* [NB 140/67 IE]

**Kern- und Radiochemie** (Nuclear and Radiochemistry). By *R. Lindner*. Basic principles, practical methods, and technical application. Springer-Verlag, Berlin-Göttingen-Heidelberg 1961. 1st edit., XII, 369 pp., 140 illustrations, linen. DM 49.80 (about $12.50).

The first half of this book, which is the outcome of a series of lectures delivered at the Technical College in Göteborg (Sweden), deals with the basic principles of nuclear physics, measuring techniques, nuclear reactors, and radiation protection. The second half is devoted to radiochemistry and applications of radionuclides in science and technology.

The author presents a wealth of scientific information from this wide field in concise and accurate formulations. The book offers a good review of the whole subject and rapid orientation in the individual topics.

Unfortunately only a brief discussion of the extensive topics of radiochemistry (*e.g.* methods of separation and enrichment; processes of radionuclide production; the chemistry of the radioclements and the fission products of uranium and the transuranic elements; chemical nuclear technology, including the problems of processing nuclear fuels; the chemistry of reactor materials and radioactive wastes) is possible within the framework of such a comprehensive treatment which also includes the basic physical principles involved and borderline subjects.

*G. Schulze-Pillot* [NB 141/70 IE]

**Kunststofftechnisches Wörterbuch** (Dictionary of Plastics Technology). By *A. M. Wittfoht*. Technical terms used in the manufacture, processing, and use of plastics, material testing and mold construction. Vol. 4: German-French. Carl Hanser Verlag, Munich 1962. 1st edit. XV, 534 pp., numerous illustrations, linen, DM 72.- (about $18.-).

This dictionary is of great help to those who deal with plastics, especially if they have to carry out technical correspondence in French or German.

One inestimable advantage of this book is that the individual terms have appended explanations to clarify their exact meaning and the sense in which they are used. It is to be welcomed that a book is now available in which engineers, businessmen, and translators can quickly find the right expression for many a technical term. Illustrations and sketches – many of them in fair detail – are of further help. An appendix of methods of molding, pressing, and pressmolding, in addition to initials and abbreviations, as well as conversion tables is extremely useful.

The author and publisher have created a dictionary that is exemplary in contents and lay-out. It can be warmly recommended to all those interested, especially since no work of this kind has been available up to now.

# Structure and Specificity of Organic Chelating Agents [*]

BY PROF. DR. ERNST BAYER

BASED ON WORK CARRIED OUT IN COLLABORATION WITH DR. H. FIEDLER, DR. K.-L. HOCK, DR. D. OTTERBACH, DR. G. SCHENK, AND DIPL.-CHEM. W. VOELTER

CHEMISCHES INSTITUT DER UNIVERSITÄT TÜBINGEN (GERMANY)

*Macromolecular chelating agents possessing high selectivity for rare metal ions have been synthetized. One of these, with the complexing group of glyoxal bis-2-mercaptoanil, is suitable for selective enrichment of gold from sea-water, while another is suitable for copper and uranium. – The enrichment of metallic ions in nature is discussed, taking hemocyanin as an example. – Both stereochemistry and isomerism, as well as cyclic conjugation during chelate formation, may influence the selectivity of complexing agents. The quasi-aromatic properties of chelates are discussed.*

More than thirty years ago, *Fritz Haber* [1] published a paper entitled "Gold in Sea-Water" in this Journal, and ended it with the words "I have given up my search for this dubious needle in a haystack". With this sentence, the inventor of the ammonia synthesis abandoned his many years' efforts at extracting gold from sea-water. The process proposed by *Haber* failed because the actual gold content of sea-water averages 0.01 $\gamma$/l, a concentration which is several powers of ten lower than previously published values. Despite their lack of commercial success, the methods developed by *Haber* and *Jaenicke* at that time for the determination of the gold content of the ocean are still admired today.

Even the revised determination of the gold content of the sea indicates a reserve of some 70 million tons – a colossal figure when compared with the world production (*e.g.* 1200 tons for 1937). However, the quantities of other elements present in sea-water also exceed those of their known continental deposits. It is estimated, for instance, that the seas contain some $7\times10^9$ tons of copper and $0.5\times10^9$ tons of uranium. Such figures explain the desire to mobilize these supplies and to find methods for their extraction.

Although at present there are no synthetic substances which would selectively concentrate a single rare metal from the multifarious elements present in sea-water, there are certain living organisms which are capable of achieving this result. In addition to the more abundant elements iron and copper, rarer metals such as molybdenum, cobalt, or vanadium are also found in natural chelates.

An extreme example of the concentration of metals by biological organisms is provided by vanadium, which is a million times more concentrated in the blood cells of the tunicate *Phallusia mamillata* than in sea-water [2,3]. A further example is the concentration of copper in the blood of the cuttlefish *Octopus vulgaris*, by a factor of about one hundred thousand [4].

## I. Specificity of Natural Complexing Agents

In nature, the specifically concentrated metal ions are all bound in organic complexes. Thus, the simplest explanation for the selective concentration appeared to be the hypothesis that the organic complexing agents are specific for only one ion. Selectivity for a single metal ion has not yet been achieved with synthetic chelating agents. Most synthetic chelates bind nearly all metal ions, with the exception of the alkali metal and alkaline earth ions, although different ions are held with varying degrees of strength.

The first task was therefore to determine whether natural complexing agents are in fact absolutely specific for a

single ion. Up to now, most of these investigations have failed, either because the complexing agent was altered or destroyed when the metallic ion was removed, or because reintroduction of the metal ion was impossible. For example, the complexing ability of hemovanadine is irreversibly changed when the vanadium is removed. However, hemocyanin, the blue pigment responsible for the transport of oxygen in the blood of molluscs, was an excellent example. Up to 75 % of its complexed copper can be removed without destroying the chelate's complex-forming ability, and the metal can then be reintroduced, with complete restoration of the oxygen-binding capacity [5–7]. This resynthesis of hemocyanin from apohemocyanin can be achieved with cuprous but not with cupric salts [7]. Other metal ions cannot be coordinatively bound to apohemocyanin without denaturing the complexing agent [7]. The complex-forming function is therefore specific for one metal.

It remained to be established whether the specificity applies to monovalent or divalent copper. Resynthesis with cuprous salts does not prove the presence of monovalent copper in hemocyanin and oxyhemocyanin, since oxidation may occur at any time up to the incorporation of oxygen. *Klotz* et al. [8] even suggested the coexistence of monovalent and divalent copper in oxyhemocyanin.

The valence of the central atom cannot be determined by classical magnetic methods, since at a copper content of only 0.24 % any paramagnetism due to copper(II) is masked by the diamagnetism of the organic ligand. The temperature-independence of the magnetic susceptibility was the only indication of the occurence of monovalent copper in both hemocyanin and oxyhemocyanin. A final argument in favor of copper(I) was supplied by electron resonance absorption [7]. Apohemocyanin is therefore a specific complexing agent for copper(I).

The next step consisted in the elucidation of the groups which are responsible for this absolute specificity. Hemocyanin derived from *Octopus vulgaris* has a molecular weight of $2.7 \times 10^6$ [9], and elemental analysis indicates that its composition is that of a protein. Amino acids were the sole product which could be detected in the hydrolysate. Thus, hemocyanin contains no prosthetic groups, *i.e.* no low molecular-weight complexing agent, as is the case with all other natural chelates of known constitution. The complex-forming function is therefore part of the macromolecular protein.

The mercapto groups of the cysteine linked by peptide bonds in the protein are known to be the group capable of binding the copper [6, 7]. In addition, the copper may also be fixed by the imidazole nitrogen of histidine, at least in oxygen-free hemocyanin. Neither simple, low molecular-weight complexing agents which contain mercapto groups, such as cysteine, nor cysteine-histidine dipeptides exhibit absolute specificity for copper, so that the steric arrangement of these groups in the macromolecule must be responsible for their selectivity. Consequently, the naturally occurring selectivity cannot be reproduced in low molecular-weight models, since in addition to the sequence of the links, the secondary structure of the protein is likely to play a part.

## II. Synthetic Complexing Agents

Since the selective concentration observed in nature could not be directly reproduced with synthetic models, it was necessary to find organic ligands which would exhibit specificity during chelation by virtue of their steric structure or special bonding features. Even if these experiments could not be expected to result in specific bonding of a single metal, limitation of the complexing power to a few metals would represent a great step forward. Recognized chelating agents such as ethylenediaminetetraacetic acid, 8-hydroxyquinoline, *N,N'*-bis-(*o*-hydroxybenzylidene)ethylenediimine (salicylaldehyde-ethylenediimine), or 1,3-diketo compounds were immediately rejected, since these yield complexes with almost all metallic ions. This behavior is clear from the results of experiments with complexing agents of low molecular weight, and from unsuccessful attempts to enhance the specificity of such groups by incorporating them into ion-exchangers [10, 11].

In attempts to synthetize suitable complexing agents for the concentration of metal ions from sea-water, attention must be paid to their practicability. The complex-forming entity should be built into a macromolecule, so as to obtain compounds which are sufficiently insoluble for column filtration or suspension processes. Furthermore, it should be possible to remove the metal bound by the chelating agent reversibly without destroying the macromolecule, so that the latter can be used again. Only for valuable metals such as gold, could this requirement perhaps be sacrificed. Agents in which hydrogen is replaced by metallic ions when complexing occurs are suitable, since these can be regenerated by treatment with an acid:

$$\text{Complexing agent}-H_2 + M^{2+} \rightleftharpoons \text{Complexing agent}-M + 2H^+$$

The stability constants should be such that the metal is displaced even by dilute acids.

The complex bonding of numerous organic ligands has been studied in detail. In many instances, this study revealed new facts regarding the bonding relationships which have helped to define our practical aim and which will be discussed in connection with the complex-forming groups involved in the concentration of uranium, copper, and gold from sea-water.

### Complexing Agents Prepared from o-Aminophenol and Glyoxal

Condensation of *o*-aminophenols with α,β-dicarbonyl compounds gives rise to complexing agents such as glyoxal bis-2-hydroxyanil *(1b)*, which are particularly suitable for sequestering copper and uranyl ions [12–14].

[14] *E. Bayer* and *G. Schenk*, Chem. Ber. *93*, 1184 (1960).

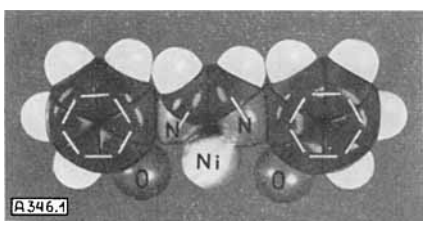
Nickel, uranyl, and copper ions are smoothly and rapidly bound in weakly acidic media at room temperature. Complexes are also formed in weakly alkaline media with $Co^{2+}$, $Zn^{2+}$, and $Cd^{2+}$, and even with the alkaline earth ions. This unusual preference for a few metals at pH less than 7 is connected with the special steric structure and the isomerism of glyoxal bis-2-hydroxyanil.

In the condensation of *o*-aminophenol and glyoxal, the initial product is not the open-chain Schiff base *(1b)*, but principally the isomeric bis-2-benzoxazolinyl *(1a)* [14]. In weakly alkaline media, this ring form *(1a)*, which is incapable of forming complexes, rearranges to form the open-chain form *(1b)*, which is the true complexing agent. In the presence of the most strongly complexing ions $Cu^{2+}$, $UO_2^{2+}$, and $Ni^{2+}$, this rearrangement can occur even in acidic to neutral media. The open-chain isomer, traces of which are present in equilibrium even in acidic media, is removed in the form of the complex *(2)*. Less stable complexes are formed only in weakly alkaline media, in which the complexing agent exists predominantly or exclusively as the double Schiff base *(1b)*. In

*(1a)* *(1b)*

*(2)*

the acidic pH range, these complexes can be completely redissociated to give back the metal ion and the ligand. A Stuart-Briegleb model of the nickel(II) chelate of glyoxal bis-2-hydroxyanil (Fig. 1) shows that its phenolic oxygens cannot approach the metal atom sufficiently closely. Consequently, formation of neither a covalent



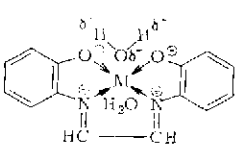


Fig. 1. Stuart-Briegleb model of (glyoxal bis-2-hydroxyanilato)nickel(II).

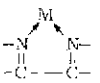


oxygen-metal bond nor a firm electrostatic bond is possible. On the other hand, the arrangement of the nitrogen atoms is exceptionally favorable for covalent bonding. The chelates can therefore be regarded as zwitterions which depend for their stability on the metal-nitrogen bond. This zwitterionic strucutre *(3)* is supported

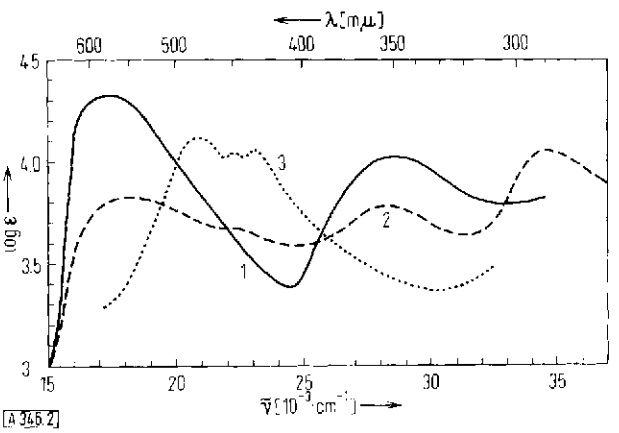
*(3)*

further by the very firm binding of two molecules of water to the fifth and sixth coordination sites. The polar water molecule is fixed not only by its oxygen to the central atom, but also by its hydrogen to the phenoxide groups. This dual electrostatic bonding also explains the unusual fact that water cannot be removed from (glyoxal bis-2-hydroxyanilato)copper(II) *(2)* by heating without decomposing the molecule. Here the coordination number 6 is therefore preferred to the coordination number 4 which is otherwise formed almost exclusively by copper(II) [15].

Complex formation is thus determined exclusively by the metal-nitrogen bond. If the latter is regarded as being covalent, a formally heterocyclic N–M–N–C–C five-membered ring *(3a)* is obtained, which according to Figure 1 can have a planar structure similar to that of other five-membered heterocyclic rings. Cyclic conjugation seems then possible.

*(3a)*

Many of the properties exhibited by the chelates must be ascribed to this five-membered ring. These include the deep color of the glyoxal bis-2-hydroxyanil complexes, which is due to a new absorption maximum between 550 and 580 mμ and which is not exhibited by the alkali metal salts or the free complexing agent. This maximum lies in the same region for all of the complexes of *(1b)* irrespective of the nature of the central metal atom [12]. For example, the zinc(II) complex shows the same deep color (cf. Fig. 2), and since the d-shell is filled in zinc(II)



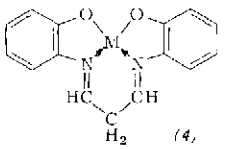


Fig. 2. Absorption spectra (in methanol at 20 °C)
1. (Glyoxal bis-2-hydroxyanilato)nickel(II)
2. (Glyoxal bis-2-hydroxyanilato)zinc(II)
3. (Malonaldehyde bis-2-hydroxyanilato)nickel(II).

the band between 550 and 580 mμ cannot be attributed to d-electron transfer in the single metal ion. Instead, this band is considered to be characteristic of the heterocyclic five-membered ring, as evidenced by arguments given below. The copper, uranium, and nickel complexes exhibit the highest extinctions, since the cyclic conjugation is apparently developed most strongly in these substances. The decisive part played in the absorption mechanism by the cyclic conjugation, and not by the metal

[15] *J. Bjerrum*, Chem. Reviews *46*, 381 (1950).

ion or by the metal-nitrogen bond alone, is demonstrated by comparing the spectra of glyoxal bis-2-hydroxyanil complexes with those of the malonaldehyde bis-2-hydroxyanil complexes *(4)*. Conjugation ist not possible in *(4)*, because of the methylene group and the non-planar structure. Accordingly, no new absorption maximum appears in this case, but the bands – shown by even the sodium salt – are slightly displaced (see Fig. 2) [16].

*(4)*

Another property which can be traced back to the cyclic conjugation is the chemical and spectroscopic behavior of the C=N double bond. Normally Schiff bases can be smoothly hydrogenated by palladium/activated carbon to form secondary amines. In exceptional cases, the hydrogenation can even lead to cleavage of the C=N bond with the formation of primary amines and hydrocarbons. This cleavage proceeds particularly readily with Schiff bases containing *o*-aminophenol components, providing a very mild procedure for the reduction of carbonyl compounds to hydrocarbons [17]. Both C=N bonds in the sodium salt of *(1b)* are readily hydrogenated to give secondary amines.

No hydrogenation could be observed with the stable Cu, Ni, and $UO_2$ complexes of glyoxal bis-2-hydroxyanil. The other metal complexes are catalytically hydrogenated with Pd/activated carbon, although the reaction is slower than that with the sodium salt. However, it can be seen from Figure 3 that even in this case, the rate of

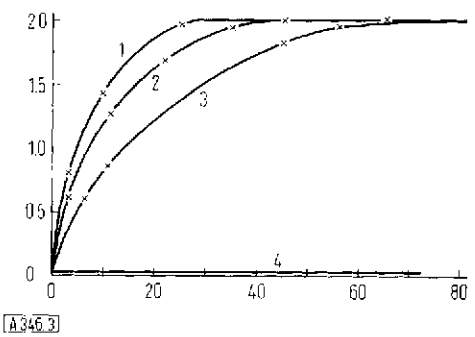

Fig. 3. The rate of hydrogenation of glyoxal bis-2-hydroxyanil complexes (Pd/activated carbon catalyst at 20 °C)

1. Disodium salt
2. Cadmium(II) complex
3. Cobalt(II) complex
4. Nickel(II) complex

hydrogenation decreases with increasing stability of the complex. These experiments show that the C=N double bond in the stable complexes of glyoxal bis-2-hydroxyanil no longer exhibits normal reactivity. In contrast, the complexes of malonaldehyde bis-2-hydroxyanil *(4)* can be hydrogenated in exactly the same manner as the free complexing agent.

[16] *E. Bayer* in *K. Issleib:* Anomalien bei Ionenaustausch-Vorgängen. Akademie-Verlag, Berlin 1962, pp. 305 et seq.

[17] *G. Schenk*, Ph. D. Thesis, Technische Hochschule Karlsruhe. 1961.

The behavior of (glyoxal bis-2-hydroxyanilato)nickel(II), particularly with respect to its lack of susceptibility to hydrogenation, is that of a quasi-aromatic heterocyclic structure. Incidentally, this difference in susceptibility to hydrogenation can be used as the basis of a quantitative determination of nickel in the presence of cobalt. The deeply colored nickel and cobalt complexes *(3)* are formed, the total extinction is measured, and the cobalt complex is selectively hydrogenated with Pd/activated carbon. Since the cobalt compound of the resulting secondary amine is colorless, the nickel content can be determined by remeasuring the extinction (at 556 mμ) after hydrogenation. The difference of the two values obtained is a measure of the absorption due to the cobalt compound.

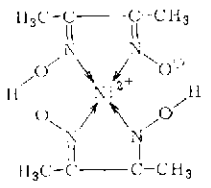
The change in reactivity of the C=N double bond after chelation can be explained as being due to its acquisition of certain characteristics of a C–N single bond, as would also be expected in the case of cyclic conjugation. A corresponding displacement of the C=N band can in fact be detected in the infrared spectra; again the displacement is greatest for the stable complexes (Table 1).

Table 1. Infrared bands of the C=N bond of various complexes of glyoxal bis-2-hydroxyanil and malonaldehyde bis-2-hydroxyanil.

| Compound | ν [cm⁻¹] |
|---|---|
| GBHA–$Na_2$ [a] | 1635 |
| GBHA–Cd(II) | 1550 |
| GBHA–Co(II) | 1550 |
| GBHA–Ni(II) | 1540 |
| GBHA–Cu(II) | 1535 |
| GBHA–U(VI)$O_2$ | 1515 |
| MBHA–$H_2$ [b] | 1618 |
| MBHA–Ni(II) | 1615 |

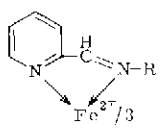
[a] GBHA = divalent anion of glyoxal bis-2-hydroxyanil [cf. *(1b)*].
[b] MBHA = divalent anion of malonaldehyde bis-2-hydroxyanil [cf. *(4)*].

With regard to the infrared bands, it can be shown that cyclic conjugation is a prerequisite for the displacement, since, as can be seen from Table 1, the C=N band lies in the usual region in the case of the malonaldehyde bis-2-hydroxyanil complexes.



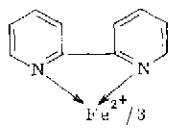
These properties have led us to the working hypothesis that the heterocyclic N–M–N–C–C five-membered ring *(3a)* is not merely formally analogous to quasi-aromatic five-membered heterocyclic structures such as pyrrole, thiophene *etc.*, but actually represents a non-benzenoid, non-classical aromatic system.

## III. Metal Chelates with Quasi-Aromatic Five-Membered Rings

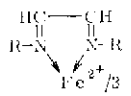


Since the glyoxal bis-2-hydroxyanil complexes are relatively complicated molecules, the properties described cannot be attributed with absolute certainty solely to the N–M–N–C–C five-membered ring *(3a)*. To confirm the quasi-aromatic character of these chelates, simpler complexes had to be studied.

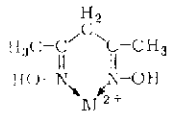
Examination of the known complexing agents reveals that a large number of complexes, which are known from analytical reactions to be specific, can be related to such five-membered rings. These include the red (dimethylglyoxime)nickel complex *(5)* and the red iron(II) complexes of pyridine-2-carboxaldimine *(6)*, α,α′-dipyridyl *(7)*, and 1,2-diketimines and glyoxaldimines *(8)*.



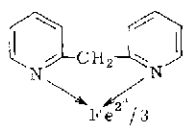
The exceptional stability of these chelates, their specific metal-sequestering ability, and their extraordinarily deep colors have long been among the unsolved mysteries of the chemistry of complexes. The existence of a cyclically conjugated ring provides at least a qualitative explanation.



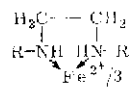
(5)



(6)



(7)

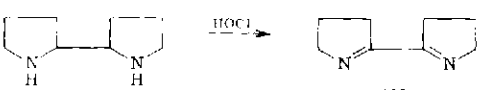


(8)

(9)

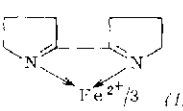
(10)

(11)



The deep color, high stability, and specificity disappear if structures *(5)* to *(8)* are modified so that cyclic conjugation is no longer possible. The complexes of the saturated ring system analogous to *(8)* that is derived from ethylenediamine are colorless and less stable. Interruption of the conjugation by insertion of a methylene group also produces a reduction in color and stability. In contrast to (dimethylglyoxime)nickel *(5)*, which is deeply colored, and to the α,α′-bipyridyliron complex *(7)*, the corresponding chelates of acetylacetonedioxime *(9)* and dipyridylmethane *(10)* are rather unstable [18]. The deep red complex tris(glyoxal bis-*N*-methylimine)iron(II) chloride *(8)*, where R = $CH_3$ [19], which can be easily prepared from glyoxal, methylamine, and iron(II) salts, can be used for comparative tests. This complex contains no groups capable of resonance other than the five-membered ring.

The great stability of *(8)* is noteworthy. As in the case of (glyoxal bis-2-hydroxyanilato)nickel(II), the C=N bond in *(8)* cannot be hydrogenated. Oxidizing agents attack the complex only under drastic conditions. Bromine oxidizes neither the chelate nor its ferrous iron constituent. The properties of the latter are masked to such an extent in this ring that it cannot be oxidized to ferric iron, for example, without destroying the complex. Even dilute mineral acids do not destroy the complex. These properties are all the more remarkable because the metal-free ligand cannot be prepared – an instructive example of stabilization by chelation.



The infrared spectrum *(8)* again shows displacement towards longer wavelengths of the band due to the C=N double bond. The visible light absorption characteristics are surprising (cf. Fig. 4). The longest wavelength band is at 550 mμ, *i.e.* in the same region as that of the glyoxal-bis-2-hydroxyanil complex, which was ascribed to the N–M–N–C–C five-membered ring *(3a)*. There can no longer be any doubt that, in tris-(glyoxal bis-2-methylimine)iron(II) iodide, this band must be associated with the five-membered ring.

It has long been known that alicyclic Schiff bases are considerably more stable than purely aliphatic ones. In the course of our syntheses in the pyrroline series [20], we therefore prepared alicyclic Schiff bases, including α,α′-bipyrrolinyl *(12)*.

As expected, *(12)* forms red iron(II) complexes *(13)* with visible light absorption characteristics similar to that of *(8)*. Comparison of the spectra of the complexing agent and the iron(II) complex (Fig. 4) shows the appearance of a new maximum at 560 mμ after complex formation. The infrared band due to the C=N double bond is again displaced here (Fig. 5).

2. α,α′-Bipyrrolinyl *(12)*
3. Tris-(α,α′-bipyrrolinyl)iron(II) chloride *(13)*

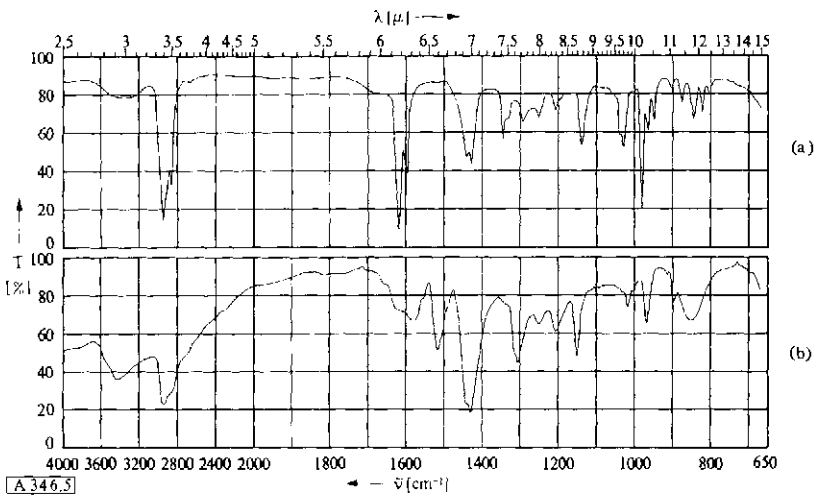
[18] *K. L. Hock*, Ph. D. Thesis, Technische Hochschule Karlsruhe, 1962.

[19] *P. Krumholz*, J. Amer. chem. Soc. *75*, 2163 (1953).

[20] *D. Otterbach*, Ph. D. Thesis, Technische Hochschule Karlsruhe, 1963.

Up to now, it has been assumed that the tris-(α,α′-bipyridyl)iron(II) complex *(7)* can also be regarded as one of these quasi-aromatic chelates. This would mean that two double bonds per pyridine nucleus are not required for complex formation.

each five-membered ring contains a π-electron sextet. Four electrons in each ring are contributed by the two C=N double bonds. The remaining two electrons can only be supplied by the metal ion. The total of six d-electrons in iron(II) is just sufficient for the formation of three π-electron sextets in the three five-membered rings of tris-(α,α′-bipyridyl)iron(II)



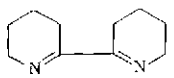


Fig. 5. Infrared spectra of (a) α,α′-bipyrrolinyl *(12)* and (b) its iron(II) complex *(13)* in KBr.

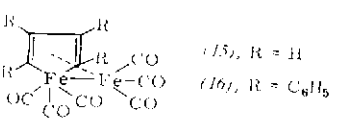
α,α′-Bipiperideinyl *(14)* should therefore form iron(II) complexes with the same properties. α,α′-Bipiperideinyl *(14)* was synthetized by the method given for bipyrrolinyl and yielded the expected red iron(II) complexes. This

*(14)*



behavior indicates a close generic relationship between these complexes and the iron chelates of α,α′-bipyridyl and phenanthroline. In addition to the characteristic absorption maximum, the infrared spectra of all of these compounds show displacements towards longer wavelengths of the C=N band, corresponding to linkages intermediate between a single and a double bond. Moreover, the susceptibility of the C=N bond to reduction is lost, and the iron(II) chelate cannot be oxidized to an iron(III) chelate.

This stabilization of ferrous iron has long been known for the tris-(α,α′-bipyridyl)iron(II), (phenanthroline)iron(II), and (pyridinecarboxaldimine)iron(II) complexes, and had been attributed to the well-known concept of a filled krypton shell. Some doubt regarding the validity of this explanation had already been expressed by *Bezier* [21], who showed that the redox potential of the hexacyanoiron(II) complex ($E_0$ = + 0.36 V), which is also diamagnetic, is displaced in the expected direction, *i.e.* towards that of iron(II) salts ($E_0$ = + 0.771 V), whilst that of the phenanthroline complex ($E_0$ = + 1.14 V) is displaced in the opposite direction. Enhancement of the stability of the iron(II) is therefore observed only with the phenanthroline complex. Analogous results are obtained with the bipyridyl compound.

This resistance to oxidation can be readily explained by recourse to the concept of the formation of cyclically conjugated quasi-aromatic rings, and by the assumption that

iodide or the tris(glyoxal bis-*N*-alkylimine)iron(II) complexes. Only five d-electrons are available in iron(III), so that not all the rings can be "aromatized". Such non-aromatic complexes should automatically be less stable and this does in fact correspond to the experimental results. The observation that three ligands are preferentially added, the absence of intermediate stages with one or two ligands, and the stabilization of lower valency states of the metal ions which are isoelectronic with divalent iron [22], can also be explained in this way.

There is no reason that a quasi-aromatic five-membered ring should be limited to the N–M–N–C–C structure [cf. *(3a)*]. It should also be possible to replace the nitrogen atoms by carbon, so that the hetero-ring contains only a metal atom. Quasi-aromatic C–C–Fe–C–C five-membered rings would be named ferroles, by analogy with the azoles. *Hübel* et al. [23] and *Stone* et al. [24] treated acetylenes and thiophene with dodecacarbonyltriiron and obtained compounds which can be regarded as complexes of structures *(15)* and *(16)*. These compounds would represent aromatic π-complexes containing the quasi-aromatic ferrole system. Reactions of

*(15)*, R = H
*(16)*, R = $C_6H_5$

2,5-dichloromuconic esters with sodium iron carbonyl yields the ferrole system *(17)* which does not contain the additional tricarbonyliron group present in *(15)* and *(16)* [25]. Compound *(17)* has merely carbon monoxide added on coordinately. Nuclear resonance

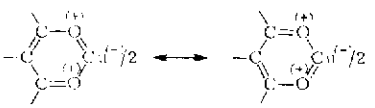
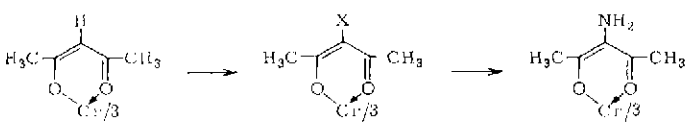
studies show that the signals for the β-protons lie in the normal region for heterocyclically bound protons.



Comparison with cyclobutadiene-nickel complexes [26, 27] shows that *(17)* does not contain a cyclobutadiene system and is therefore intermediate between organometallic compounds, chelates, and quasi-aromatic heterocyclic systems.

*(17)*



By analogy with ferrole, other metal ions with partially filled d-electron shells from the first long period of the periodic table should also be able to give such five-membered rings. According to studies on models, similar complexes with metals of the second and third long period are no longer planar. Cyclic conjugation is therefore reduced or becomes impossible.

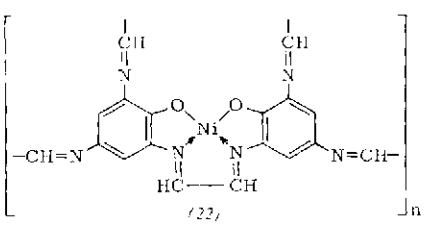
It should also be possible for six-membered rings to exhibit aromatic behavior. *Calvin* et al. [28] postulated quasi-aromatic rings for acetylacetonates and proposed the mesomeric structures *(18a)* ↔ *(18b)*.

*(18a)* *(18b)*

*Collman* et al. [29] succeeded in obtaining confirmation for this view by electrophilic substitution of acetylacetonates. For example, tris(acetylacetonato)chromium *(19)* can be readily halogenated and nitrated [28–31]. The nitro compound *(20a)* can even be catalytically hydrogenated to yield an aminoacetylacetonate chelate [32, 33].

*(19)* *(20a)*, X = $NO_2$ *(21)*

*(20b)*, X = Halogen



*Collman* and *Yamada* [33] recently succeeded in diazotizing the amino group to a stable diazonium salt.

Since beryllium acetylacetonates also exhibit the properties mentioned for the chromium complex [33a], the d-electrons are not essential for the formation of a quasi-aromatic six-membered ring. For this reason, no specificity associated with a definite number of electrons in the metal ion can be expected from these complexes. This is in agreement with the observation that acetylacetone forms complexes with all metallic ions; even the sodium compound may be regarded as a complex.

## IV. Concentration of Copper and Uranium from Sea-Water

Let us now return to the practical application of complexing agents to the selective concentration of metal ions. According to the foregoing discussion, complexing agents which react with metal ions to yield chelate rings such as that in *(3a)* appear to be particularly promising. The glyoxal bis-2-hydroxyanil grouping can be grafted onto macromolecules by condensing di- and triaminophenols with glyoxal.

The transition from low molecular-weight model substances to macromolecular complexing agents possessing adequate chemical and mechanical stability was a difficult task. The polycondensation is carried out in a weakly alkaline solution with a several-fold excess of glyoxal [34]. For large charges, condensation in the presence of nickel salts, has proved successful; this yields the polymeric nickel complex *(22)* in which the complexing group is protected. The nickel can then be eluted with hydrochloric acid at pH 1–1.5.

*(22)*

These macromolecular complexing agents are used in column or suspension processes, with particle sizes ranging from 0.2 to 0.8 mm. The substances [13] are suitable for selective sequestration of uranium and copper, and can take up as much as 5 % by weight of copper and 20 % by weight of uranium. The sequestered metal ions can be eluted with dilute hydrochloric acid at pH 1–2 without decomposing the complexing agent, which can be regenerated repeatedly.

Despite encouraging results with concentrated solutions, it was not certain whether these substances would actually concentrate the extremely low uranium and copper contents in sea-water. It was not known whether uranium and copper are held in sea-water (pH ≈ 7) in colloidal form, as a dissolved complex, or within microorganisms. Samples of water from the Gulf of Naples contained 4.5–5.0 γ/l of dissolved copper and 0.5 γ/l of dissolved uranium [35]. It was found that it was a simple matter to concentrate the copper and uranium in yields of up to 100 % [35] by passing the sea-water, at the rate of 1.5 l/cm²/hr, through a column packed with the ma-

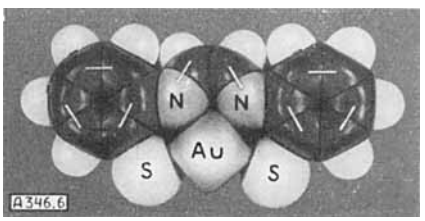
cromolecular complexing agent. To the best of our knowledge, this was the first time that rare metals had been concentrated from sea-water by a simple process.

## V. Concentration of Gold

Replacement of both the hydroxyl groups in glyoxal bis-2-hydroxyanil by mercapto groups results in a complexing agent in which covalent coordination between the sulfur and the metal ions is conceivable.

A Stuart-Briegleb model (Fig. 6) indicates that, in addition to nitrogen-metal bonds, sulfur-metal bonds are also sterically possible owing to the larger atomic volume of sulfur. Overlapping of the electron orbits of the sulfur and the metal should be exceptionally favorable



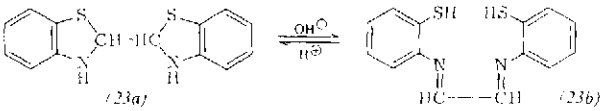


Fig. 6. Stuart-Briegleb model of the (glyoxal bis-2-mercaptoanilato)-gold(III) complex.

with metals possessing larger ionic radii, *e.g.* the transition elements of the second and third long periods. For this reason, and because of the well-known preferential coordination of ligands containing sulfur to metals of the first and second transition groups, it was possible to predict that glyoxal bis-2-mercaptoanil *(23a)* ⇌ *(23b)* would be specific for silver, gold, and mercury ions.

[36] *E. Bayer*, Angew. Chem. *73*, 659 (1961).

Condensation of aminothiophenol and glyoxal first produces bis-2-benzothiazolinyl *(23a)*, which is rearranged by alkalis to the oxidizable form glyoxal bis-2-mercaptoanil *(23b)* [36]. Deep red to violet complexes are formed with gold(III), mercury(II), and silver salts at pH > 1, whilst other metal complexes are formed only

in weakly alkaline media. For practical application, it seems particularly favorable that, owing to the tautomeric ring form *(23a)*, oxidation of the SH groups of the chelating agent cannot occur in preference to the bonding of the metal ions.

Judging from the selectivity of the low molecular-weight model, incorporation of the complex-forming glyoxal bis-2-mercaptoanil group into macromolecular complexing agents should produce substances capable of concentrating gold from sea-water, and so of finding the "needle in the haystack" which *Haber* sought in vain.

Polycondensation of di- and triaminotbiophenols with glyoxal does in fact give macromolecules, by means of which it is possible to concentrate gold specifically from dilute solutions, whithout interference from other metals. It was thus found possible to extract gold from the water of the Gulf of Naples in quantities of 1.4 γ/100 l, corresponding to the gold content determined analytically.

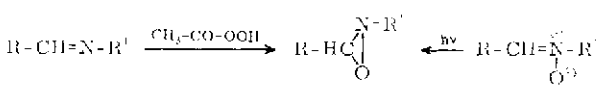
# Three-Membered Rings Containing Two Hetero-Atoms



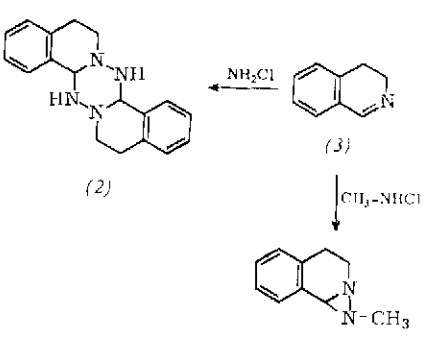
BY PROF. DR. ERNST SCHMITZ [*]

INSTITUT FÜR ORGANISCHE CHEMIE DER DEUTSCHEN AKADEMIE DER WISSENSCHAFTEN
BERLIN-ADLERSHOF (GERMANY)

*Since their discovery five years ago, the diaziridines have become an extensive and easily accessible class of compounds. Hydrolysis of these compounds effects a simple synthesis of hydrazine, alkylhydrazines, and N,N'-dialkylhydrazines. They are also powerful oxidizing agents. The rigidity of the three-membered ring gives rise to a few stereoelectronic peculiarities. Investigations on the mechanism of formation of the three-membered rings led to a new synthesis of oxaziranes and to discovery of the isomeric oximes with a three-membered ring structure. The latter decompose readily to form diimide. Diazirines are cyclic isomers of the aliphatic diazo compounds and are surprisingly easy to obtain by dehydrogenation of suitable diaziridines; they are chemically much more stable than the linear isomers. Grignard reagents add onto the N–N double bond without destruction of the three-membered ring. Thermal decomposition yields carbenes.*

The ease of formation of three-membered rings containing one hetero-atom often led to erroneous postulations of structural formulae with two hetero-atoms in a three-membered ring. Hydrazones, nitrones, and aliphatic diazo compounds were for a long time formulated as three-membered rings. However, we now know that no three-membered rings containing two hetero-atoms had ever been prepared prior to 1950 [1].

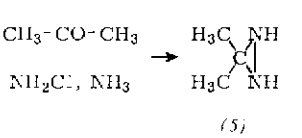
The first compounds which proved to be true three-membered rings of this type were the oxaziranes *(1)* prepared in 1952 by *H. Krimm* from Schiff bases and peroxy acids. These were first described in patents [2], but were later discovered independently by *Emmons* [3] and by *Horner* and *Jürgens* [4]. Oxaziranes *(1)* may also be prepared by exposing nitrones to light [5].



*(1)*

The diaziridines (C–N–N three-membered rings) were discovered independently by three research groups a few years later [6–8].

## Diaziridines



### a) Synthesis of Diaziridines

In 1958, *Schmitz* described the synthesis of a hexahydrotetrazine derivative *(2)* from 3,4-dihydroisoquinoline *(3)* and chloramine [9]. A similar experiment with *N*-chloromethylamine did not yield the expected tetrazine derivative [*(2)* with $N-CH_3$ in place of NH], but instead a compound of the same empirical formula but with only half of the molecular weight. This was formulated as a diaziridine derivative *(4)* [6].

*(2)* *(3)* *(4)*

In an attempt to carry out the Raschig hydrazine synthesis in the gas phase and to trap the hydrazine formed with acetone, *Abendroth* and *Henrich* [7] obtained an isomer of acetone hydrazone, to which they assigned a C–N–N three-membered ring structure *(5)*. In a patent, *Paulsen* reported corresponding compounds from diethyl ketone and from methyl ethyl ketone [8].

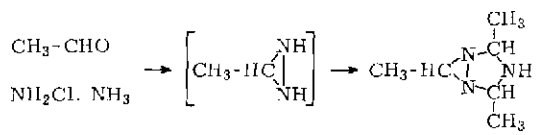
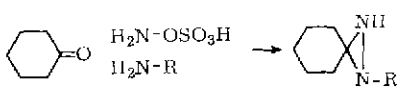
[9] *E. Schmitz*, Chem. Ber. *91*, 1495 (1958).

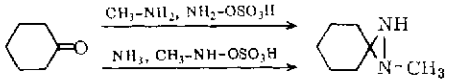
The three-membered ring structure postulated by the discoverers of this new class of compounds was confirmed by extensive synthetic work carried out between 1959 and 1962. In this work, the smoothness of formation of the C–N–N three-membered ring proved to be just as surprising as the general applicability of the synthesis [10].



The reaction discovered with the Schiff base 3,4-dihydroisoquinoline *(3)* is quite generally applicable to aliphatic Schiff bases. In all the cases investigated, chloramine in ether transferred its NH residue to the Schiff bases, immaterial whether the latter were derived from aldehydes, ketones, or cyclic ketones [11, 12].

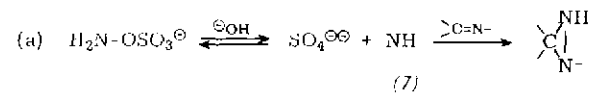


Formation of the three-membered ring also proceeded smoothly if chloramine was replaced by *N*-chloromethylamine or the *N*-chloro derivatives of other primary aliphatic amines [11, 13].



In the reaction of aliphatic aldehydes with ammonia and chloramine, the formation of diaziridines was accompanied by a further condensation leading to a triazolidine ring [14]. This reaction also occurred with benzaldehyde.

Both ketone/ammonia mixtures and Schiff bases react with hydroxylamine-*O*-sulfonic acid to form diaziridines [15, 16]; a mixture of a carbonyl compound and a primary amine may also be used in place of the Schiff base:



About 50 diaziridines have been prepared by this method [10], generally in yields ranging from 50 to 80 %. During these syntheses a simple proof of the three-membered ring structure was obtained. The reaction of cyclohexanone with methylamine and hydroxylamine-*O*-sulfonic acid leads to the same diaziridine *(6)* as the reaction with ammonia and methylhydroxylamine-*O*-sulfonic acid. The classical method of labelling with methyl groups proved the equivalence of the two nitrogen atoms [17]:

*(6)*

### b) Mechanism of the Formation of Diaziridines

Both the synthesis of cyclopropanes from olefins and carbenes [18] and the old view of the mechanism of the Raschig hydrazine synthesis [19] tempt one to formulate the formation of diaziridines as the addition of an imene *(7)* or alkylimene to a C=N double bond:

*(7)*

This view has often been expressed [20] and appears so plausible that it must be refuted all the more vehemently. The formation of an imene *(7)* with an electron sextet on the nitrogen is impossible during the synthesis of diaziridines. Hydroxylamine-*O*-sulfonic acid in alkaline solution is not in equilibrium with imene and sulfate [Equation (a)], for it does not incorporate radioactive sulfur from a solution of active sulfate by isotope exchange [21]. There is still the possibility that irreversible decomposition of the hydroxylamine-*O*-sulfonic acid into imene and sulfate occurs. If this were so, the formation of diaziridine, in a subsequent reaction should not be rate-determining, but should proceed at the same rate as the decomposition of hydroxylamine-*O*-sulfonic acid in the absence of a Schiff base. However, it is in fact appreciably faster. The formation of diaziridine from cyclohexanone, ammonia, and hydroxylamine-*O*-sulfonic acid is complete within about one hour at 0 °C, whereas only about half of a given amount of the sulfonic acid is decomposed in 0.1 N sodium hydroxide solution after about 20 hours at 20 °C [22]. Thus, the Schiff base does not wait for the irreversible decomposition of the hydroxylamine-*O*-sulfonic acid to occur before reacting with one of the decomposition products, the imene, to form the three-membered ring, but attacks the sulfonic acid as such.

The same is true in the case of chloramine. $^{36}Cl$ is not incorporated: hence there is no equilibrium between the chloramine and imene [23]. Since the rate of formation

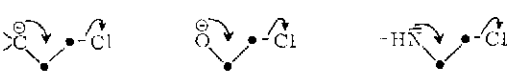
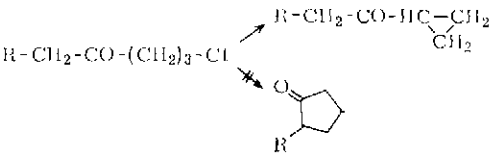
of diaziridine is again faster by several powers of ten than the rate of decomposition of chloramine, the reaction must be due to attack of the Schiff base on the chloramine.

The closure of the three-membered ring is probably preceded by the formation of a geminal compound *(8)*, which can arise from hydroxylamine-*O*-sulfonic acid either by addition to a Schiff base or by aminoalkylation with a carbonyl compound and an amine.



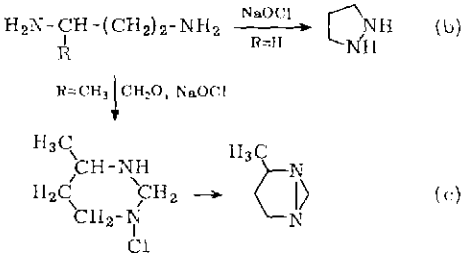
*(8)* *(9)*

The ring closure to form the diaziridine *(9)* is then an intramolecular $S_N2$ reaction. The following observations indicate the intermediate occurrence of the geminal compound *(8)*:



1. The tendency towards opening of the double bond in the series of cyclic ketones passes through a maximum at the six-membered ring [24]. The occurrence of *(8)* as an intermediate in the formation of diaziridine suggests that the optimum should occur with cyclohexanone, as is indeed the case. Cyclopentanone and cycloheptanone react less smoothly than cyclohexanone [25].

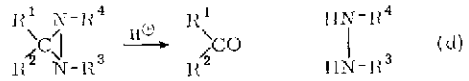
2. The majority of the reactions leading to three-membered rings proceed by intramolecular attack of a nucleophilic center on an atom bearing a labile group, generally a halogen. Thus, carbanions [26], alkoxides [27], or amino groups [28] react by rear-side attack on a carbon-halogen bond to form three-membered rings.



The formation of diaziridine from *(8)* fits into this scheme. A fact which can be inferred from this mechanism, namely that the diaziridine ring-closure should not require a basic catalyst, is in fact realized in practice.

3. The analogy between the formation of cyclopropane by 1,3-elimination and the mode of formation of diaziridine is accentuated by the predominance of the two reactions over the closure of larger rings. Hydrogen halide is eliminated from γ-halogeno ketones by bases to form only three-membered rings; the completely analogous formation of five-membered rings, though conceivable, is not observed in practice [26].

An intramolecular hydrazine synthesis resulting in a five-membered ring [Equation (b)] proceeds with only a moderate yield [29]. However, if the two nitrogen atoms are also linked by formaldehyde, the reaction proceeds in 98 % yield, but this time with formation [Equation (c)] of a three-membered ring [30].



What is the reason for this preferential formation of three-membered rings? In $S_N2$ reactions, nucleophiles react particularly rapidly if they can penetrate their solvation shell easily [31]. However, the latter cannot be of considerable magnitude between the ends of a three-membered chain, for example in *(8)*, so that the chief obstacle to an $S_N2$ reaction is simply avoided.

### c) Reactions of Diaziridines

Diaziridines are weak bases. After their preparation, they are extracted from organic solvents with dilute mineral acids, and are recovered practically without loss by means of alkali [12]. There are at present no quantitative data on their basicities. The pH-dependence of the rate of hydrolysis of 1-methyl-3,3-pentamethylene-diaziridine *(6)* indicates that the compound is almost completely protonated at pH 3, *i.e.* its basicity corresponds roughly to that of aniline (pK of the anilinium ion: 4.58) [32].

Stable salts with the three-membered ring intact have been obtained from some 1,3-dialkyldiaziridines and oxalic acid [12].

When heated with aqueous mineral acids, diaziridines are cleaved to form a carbonyl compound and a substituted hydrazine [Equation (d)]. Some yields are shown in Table 1. Side reactions occur only with the extremely stable diaziridines derived from formaldehyde [33].

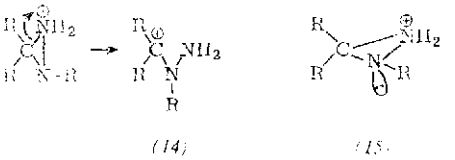
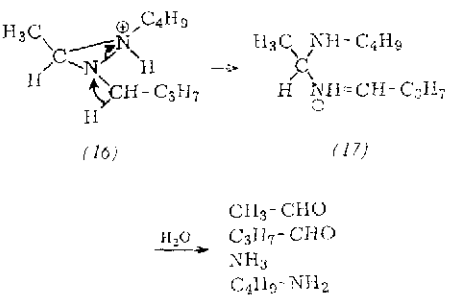
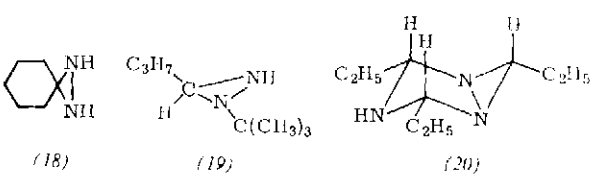
Synthesis of a diaziridine and its cleavage to the alkylated hydrazine corresponds in effect to the direct reaction of an amine with chloramine [36] or hydroxylamine-*O*-sulfonic acid [37, 38]. The carbonyl compound introduced with the Schiff base is recovered on cleavage of the diaziridine. However, the detour via the diaziridine is richly repaid. A considerable excess of amine must always be used in the direct reaction in order to suppress further interaction of the alkylhydrazine formed with the aminating agent.



The diaziridines, on the other hand, are insensitive to the aminating agent. Furthermore, the range of application of the hydrazine synthesis via diaziridines is considerably wider: *N*-chlorinated primary amines react just as readily as chloramine itself to form diaziridines, while all attempts to react *N*-chlorinated primary amines with ammonia or amines to form hydrazines have so far proved unsuccessful [29]. An efficient and generally applicable method is thus now available for the synthesis of alkylhydrazines and *N*,*N'*-dialkylhydrazines.



Hydrolysis of diaziridines with acid requires much more vigorous conditions than was expected from experience with open-chain compounds or larger rings. It is well known that open-chain 1,1-diamines *(10)* are decomposed instantaneously by dilute acids [39]. In contrast, diaziridines *(11)* derived from ketones have a half-life of about one hour in mineral acids at room temperature [33]; those *(12)* derived from aldehydes have half-lives of a few days, and those *(13)* derived from formaldehyde of a few weeks. Thus increasing alkyl substitution strongly accelerates the rate of hydrolysis. The magnitude and direction of this substituent effect are characteristic of an $S_N1$ reaction.



The rate-determining step must therefore be the ionization of a protonated diaziridine to the carbonium ion *(14)*. It can be seen from the spatial representation *(15)* that this ionization receives no help from the lone pair of electrons on the unprotonated nitrogen: the diaziridine molecule is perfectly rigid, and the orbital of this electron pair lies at an angle of about 60° to the plane of the ring; this configuration prevents any synchronous electron displacements.

Hydrolysis to the hydrazine derivative in a strongly solvating solvent is an $S_N1$ reaction. The reaction follows a different path in a weakly solvating solvent; with HCl in carbon tetrachloride, the N–N bond is broken. However, since the formation of an electron sextet on the nitrogen is impossible, the N–N bond can only break if a hydride ion simultaneously migrates over from the adjacent carbon atom [*i.e.* *(16)* → *(17)*]. Thus, one nitrogen atom is also dealkylated, the alkyl residue split off being recovered as the corresponding aldehyde [13].

The possibility of the migration of a hydride ion is a prerequisite for this N–N cleavage. Diaziridines which do not contain a suitable C–H bond do not undergo N–N fission. For example, pentamethylenediaziridine *(18)* is stable to HCl/carbon tetrachloride.

Once again, owing to the rigidity of the three-membered ring, the N–N cleavage is stereoelectronically very demanding. Simultaneous N–N cleavage and hydride migration requires that the two bonds involved be almost parallel. The C–H bond on the ring carbon atom in *(19)* and the axial C–H bonds in *(20)* form such large angles with the N–N bond that they cannot assist N–N cleavage: both compounds are stable to HCl/carbon tetrachloride [13].

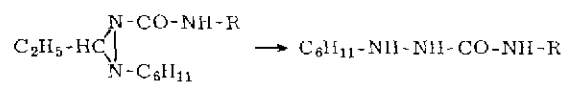
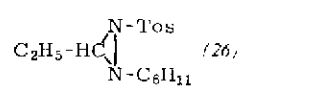
The role of the hydride ion in assisting the N–N cleavage of the protonated diaziridine can also be taken over by nucleophilic reagents. Iodide ions cleave the N–N bond quantitatively in acidic solutions [7, 10]. The liberation of two equivalents of iodine in this reaction provides a simple analytical method for the determination of diaziridines.

Evolution of chlorine was observed on heating diaziridines with concentrated hydrochloric acid [20a]. The attack of halide ions on the protonated diaziridine to cleave the N–N bond appears to be the exact reversal of the diaziridine ring closure.

The relatively high stability of diaziridines enables them to undergo reactions in which the three-membered ring remains intact. Benzoylation of 3-methyldiaziridine *(21)* proceeds smoothly to give a dibenzoyl derivative *(22)*, R = $CH_3$, with an undamaged three-membered ring, as shown by its ability to oxidize iodide [35].



*(21)* *(22)*



This oxidizing character disproves an earlier, supposed diaziridine synthesis. The diaziridine structure *(22)* had repeatedly been assigned to the product of the reaction between aliphatic diazo compounds and azodicarbonyl compounds *(23)* [40]. However, in contrast to 1,2-dibenzoyl-3-methyldiaziridine *(22)*, R = $CH_3$, these products are not oxidizing, and are thus no diaziridines. The suspected oxadiazoline structure *(24)* [41] has recently been proved by nuclear magnetic resonance [42] and infrared spectroscopy [43].

*(23)* *(24)*

Other acylating agents also react smoothly with diaziridines. Reaction with nitrourea or phenyl isocyanate yields three-membered ring compounds *(25)* which are isomeric with semicarbazones, and toluenesulfonyl chloride gives *(26)*. Hydrolysis of these derivatives

*(25)*, R = H, $C_8H_5$

*(26)*

provides a simple method for the preparation of *N*-alkyl-*N'*-acylhydrazines, which are otherwise difficult to obtain [35].

## Oxaziranes

### a) New Synthesis of Oxaziranes

The same is true of the majority of amination reactions of hydroxylamine-*O*-sulfonic acid as of the diaziridine synthesis: the compounds that are aminated attack the aminating agent; an imene does not occur as an intermediate stage [44]. The reaction with methylamine, for example [Equation (e)], is about ten times as fast as the reaction with hydroxyl ions (Fig. 1). This is also true of the amination of hydroxylamine [diimide formation, Equation (f)] [45].

$$CH_3-NH_2 + NH_2-OSO_3H \rightarrow CH_3-NHNH_2 \quad \text{(e)} \quad [38]$$

$$NH_2OH + NH_2-OSO_3H \rightarrow NH_2-NH-OH \rightarrow HN=NH \quad \text{(f)} \quad [45]$$

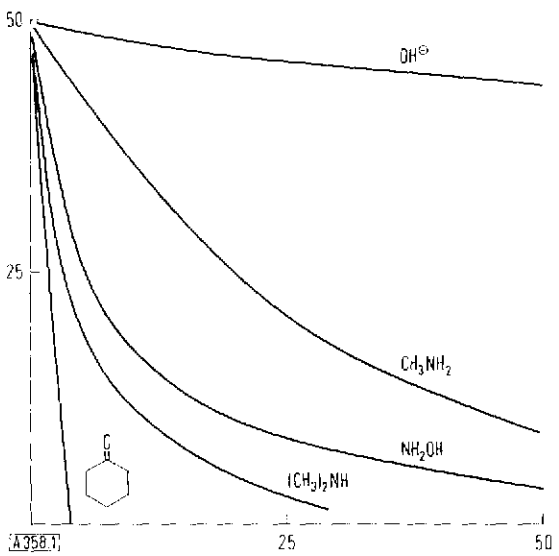


Fig. 1. Rates of some amination reactions with hydroxylamine-*O*-sulfonic acid (0.05 M solution in 0.5 N NaOH at 20 °C; reactants in equivalent quantities) [46].

Ordinates: Initial concentration [mmoles/l].
Abscissae: Time [min]

It was difficult at first to understand why cyclohexanone consumes the hydroxylamine-*O*-sulfonic acid about ten times as rapidly as the other compounds. A detailed investigation showed that this is also due to three-membered ring formation.

When methylhydroxylamine-*O*-sulfonic acid in dilute sodium hydroxide is allowed to act on cyclohexanone, a strongly oxidizing, ether-soluble substance is formed within a few minutes. This was found to be the oxazirane *(28)* [47]. Its properties are analogous to those of oxaziranes prepared by known methods [2–4]. Oxa-

ziranes are also formed from other carbonyl compounds, *e.g.* benzaldehyde. However, the reaction rapidly reaches a limit with increasing size of the *N*-alkyl residue. With cyclohexanone, the yield falls off from 60 % for the *N*-methyl compound *(28)* to 10 % for the *N*-ethyl compound. No oxaziran is formed with *N*-t-butylhydroxylamine-*O*-sulfonic acid. The reason for this behavior becomes clear if the oxaziran ring closure is formulated similarly to the formation of diaziridine.

*(27)* *(28)*, R = $CH_3$

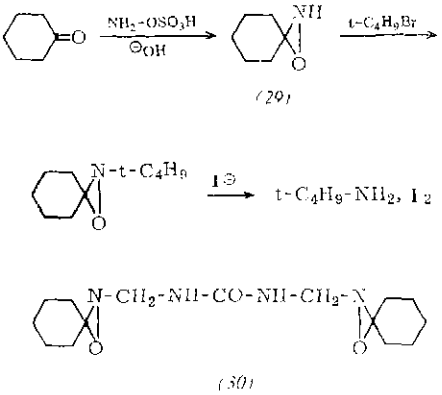
The rear-side attack of the alkoxide oxygen in *(27)* is sterically hindered as the size of the *N*-alkyl residue increases. Thus when R = t-butyl, the leaving group is in the particularly strongly sterically hindered neopentyl position.

The similarity repeatedly observed between the *N*-halogenoamines and the *O*-sulfonic acids of the hydroxylamines suggests that *N*-chloromethylamine should also form oxaziranes with aldehydes. This conjecture was opposed by the observation that benzaldehyde reacts with *N*-chloromethylamine to give *N*-methylbenzamide in 80 % yield [41]. Repetition of this experiment showed that, in addition to the amide, an oxazirane was indeed formed in 15 % yield. Thus, 1,3-elimination to form the oxazirane [Equation (g)] competes with the 1,2-elimination [Equation (h)] to form the amide [47].

(g)

(h)

The yield of oxazirane is tripled on *ortho*-substitution of the benzaldehyde (Table 2). It is possible that the 1,2-elimination is repressed by steric hindrance.

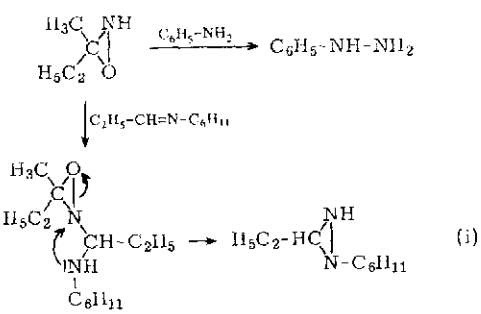


Ketones are more suitable starting materials than aldehydes, since the competition of amide formation is suppressed. Some yields are shown in Table 2. Unfortunately, the synthesis is adversely affected by the sensitivity of the oxazirans to alkalis [3]; the yields with cyclopentanone and simple aliphatic ketones do not exceed 30 %. Once again, the maximum yield is obtained with cyclohexanone. Replacement of *N*-methyl by *N*-ethyl again appreciably reduces the yields.

Table 2. Oxaziranes from carbonyl compounds and *N*-chloroalkylamines

| Carbonyl compound | *N*-Alkyl | Oxazirane yield [%] |
|---|---|---|
| Cyclohexanone | Methyl | 85 |
| 4-Methylcyclohexanone | Methyl | 65 |
| Cyclopentanone | Methyl | 22 |
| Methyl ethyl ketone | Methyl | 30 |
| Acetone | Methyl | 30 |
| Cyclohexanone | Ethyl | 10 |
| Benzaldehyde | Methyl | 15 |
| *o*-Chlorobenzaldehyde | Methyl | 48 |
| *o*-Nitrobenzaldehyde | Methyl | 43 |

### b) Isomeric Oximes with Three-Membered Ring Structures

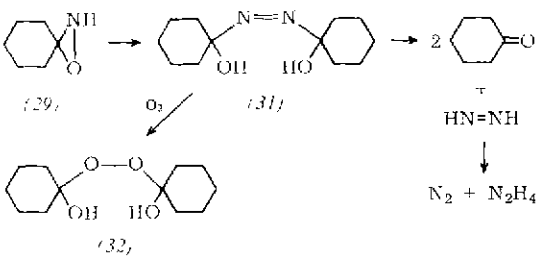


Since alkyl substituents on the nitrogen make oxazirane formation more difficult, it seemed worthwhile to try to omit the alkyl residue completely, and to treat hydroxylamine-*O*-sulfonic acid itself with carbonyl compounds. It was infact possible, with very rapid work, to obtain from cyclohexanone an oxazirane *(29)* unsubstituted on the nitrogen. This is an isomer of cyclohexanone oxime, and is extremely unstable. It yields a crystalline derivative *(30)* with dihydroxymethylurea; its relation to the known oxaziranes is shown by *N*-alkylation with t-butyl bromide.

*(29)*

*(30)*

The isomeric oxime partly duplicates the oxaziranes in its chemical behavior; it oxidizes iodide to iodine; acid hydrolysis yields hydroxylamine. In contrast to the *N*-alkylated compounds, however, the isomeric oximes are strong aminating agents, *e.g.* they convert aniline into phenylhydrazine [48]. The NH group is transferred to Schiff bases to form diaziridines [Equation (i)]. This is an interesting reaction, since the opening of one three-membered ring supplies the energy for closure of a new three-membered ring.

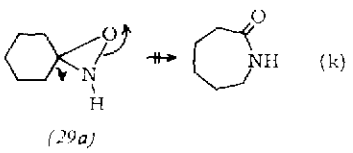


(i)

Pentamethyleneoxazirane *(29)* decomposes almost instantaneously in the presence of alkali, even at room temperature, to cyclohexanone, nitrogen, and hydrazine. Since the three bonds of the nitrogen molecule can hardly be formed in a single reaction step, an intermediate product must occur. This intermediate was isolated in the form of the crystalline azo compound *(31)* [49]. As expected, the azo compound was even less

[48] *E. Schmitz, R. Ohme,* and *S. Schramm,* Z. Chem. *3*, 190 (1963).

[49] *E. Schmitz, R. Ohme,* and *S. Schramm,* Angew. Chem. *75*, 208 (1963); Angew. Chem. internat. Edit. *2*, 157 (1963).



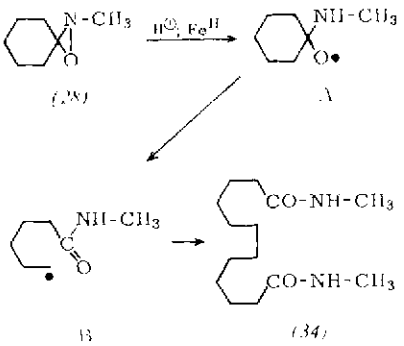
stable than the three-membered ring, for it contains the diimide in a weak hemiacetal like bond. Diimide is liberated from *(31)* even by traces of acid or base, its presence being demonstrated by its hydrogenating action on azobenzene, and by its disproportionation to hydrazine and nitrogen [50].

*(29)* *(31)* *(32)*

Free radical reactions of the azo compound *(31)* have also been observed. A solution of *(31)* in carbon tetrachloride becomes opaque within a few seconds and hydrazine hydrochloride separates. Introduction of oxygen into a solution of *(31)* in benzene results in formation of the peroxide *(32)*, in 80 % yield. The peroxide is obtained in the same yield if crystalline *(31)* is stored for a few days at −15 °C in air.

It was particularly surprising that caprolactam was not formed, even in traces, on thermal decomposition of pentamethyleneoxaziranc *(29)* [Equation (k)]. Attempts to find amides revealed only caproamide *(33)* in about 1 % yield.

(k)



*(29a)*

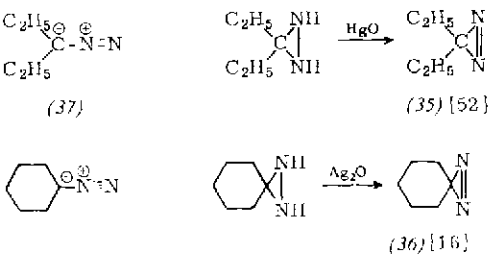
$CH_3$-$(CH_2)_4$-$CONH_2$

*(33)*

This may again be due to stereoelectronic factors. The three-membered ring in *(29a)* and the two bonds projecting outwards from its carbon atom lie in mutually perpendicular planes. There is thus no possibility of mutual assistance of O–N bond cleavage and migration of the bond from the carbon to the nitrogen [arrows in *(29a)*]. The formation of *(33)*, which probably occurs by way of free radicals, shows very clearly the reluctance of *(29a)* to undergo the stereoelectronically unfavorable rearrangement to caprolactam.

The view that the formation of *(33)* involves opening of the three-membered ring by a one-electron reduction, followed by opening of the six-membered ring, also by a free radical mechanism, is supported by the following experiment: If 2-methyl-3,3-pentamethyleneoxaziranc *(28)* is treated with an iron(II) salt, the bis-*N*-methylamide of a $C_{12}$-dicarboxylic acid *(34)* is obtained in 50 % yield. By analogy with the modes of decomposition of simple oxaziranes [3] and of cyclohexanone peroxides [51], it is probable that the radicals A and B take part in this reaction.

*(28)* A B *(34)*



Since *(28)* can be obtained in 85 % yield from cyclohexanone, methylamine, and chlorine, this points to a simple route for the preparation of the $C_{12}$-dicarboxylic acid.

## Cyclic Diazo Compounds (Diazirines)

In the last three years, cyclic diazo compounds with three-membered rings (diazirines) have been added to the ranks of the well-known aliphatic diazo compounds. These became available before their existence was even suspected. Although the three-membered ring structure had previously been widely discussed, it was only in its capacity as a tentative structure for the known diazo compounds. The idea that, in addition to the linear aliphatic diazo compounds, cyclic isomers might exist as a distinct class of compounds had never arisen. The first publications on the existence of cyclic diazo compounds [16,52,57a] were therefore received with some doubt.

Within a year, not only had the three-membered ring structure been proved [17,53], but it has also been shown that the cyclic isomers *(35)* and *(36)* were often more readily available than the linear aliphatic diazo compounds. Whereas, for example, 3-diazopentane *(37)* has never been described, and diazocyclohexane is only known in solution [54], the cyclic isomers are obtained in good yield within a few minutes by dehydrogenation of the saturated three-membered rings. This new class of compounds, in the form of these two examples, was discovered by *Paulsen* [52] and by *Schmitz* and *Ohme* [16,55].

Other members of the class were prepared from acetone, methyl ethyl ketone, 4-heptanone, acetophenone, cyclo-

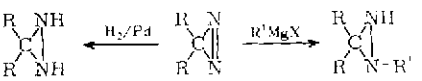
pentanone, and cycloheptanone [10]. Cyclic diazo compounds with primary alkyl residues can be prepared from aldehydes by a two-stage procedure [56]. Intermediates in this process are the bicyclic diaziridines *(38)*, whose five-membered rings can be easily split off by hydrolysis, without damage to the three-membered ring. Hydrolysis in the presence of dichromate yields the cyclic diazo compounds *(39)* directly in 70–95 % yield.

*(38)* *(39)*

The parent compound of this class [57b] is prepared by adding methylenediammonium sulfate *(40)* [58] to hypochlorite solution. This results in neutralization, *N*-chlorination, ring-closure, and dehydrogenation to cyclodiazomethane. The yield is about 30 %.

*(40)* *(41)*

A second synthesis of *(41)* was discovered recently; in it difluoramine is treated with t-butylazomethine [59].



$$CH_2{=}N{-}t.C_4H_9 + HNF_2 \rightarrow (41)$$

A few months after the discovery of diazirine *(41)*, measurements of its bond lengths and bond angles were already available, so that there is no doubt about its three-membered ring structure [53b], particularly since the two nitrogen atoms have been shown to be equivalent by labelling with $^{15}N$ [17].

The preparation of cyclodiazomethane puts an end to the discussions regarding the three-membered ring structure of the "classical" aliphatic diazo compounds. The cyclic diazo compounds differ so markedly from the linear compounds that confusion between the two types is impossible. In certain respects the cyclic diazo compounds do in fact appear to be the exact opposites of their linear isomers.

For instance, the linear aliphatic diazo compounds absorb in the visible region, but the cyclic compounds are colorless. The latter absorb only below 360 mμ [60]. Aliphatic diazo compounds are extremely sensitive to acids, whereas the cyclic isomers are resistent to even strong mineral acids, and are only decomposed by 80–90 % sulfuric acid. The greater part of the nitrogen then appears in molecular form, but considerable quantities of hydrazine also occur, *e.g.* about 0.15 mole in the decomposition of pentamethylenediazirine *(36)* [61].

In the reactions of diazomethane, almost without exception a new bond is attached to the carbon atom. With the cyclic compounds, on the other hand, the view of *Thiele* [62] has been confirmed. He disputed the three-membered ring form of diazomethane on the grounds that addition to the N=N double bond would be expected in the case of a cyclic diazomethane molecule. In fact, both catalytically activated hydrogen [16] and Grignard reagents [34] add onto the double bond. Both reactions give rise to diaziridines, thus providing proof of the three-membered ring structure of diazirines.

The linear aliphatic diazo compounds are among the most reactive substances known in organic chemistry. They mostly behave as nucleophilic reagents. The cyclic isomers, on the other hand, are surprisingly inert. In the few reactions which are known at present, they exhibit electrophilic character. The reaction with Grignard reagents mentioned above, together with hydrolysis of the resulting 1-alkyldiaziridines, provides an efficient synthesis for alkylhydrazines.

Linear aliphatic diazo compounds are stabilized by substituents which can assume a partial negative charge from their α-carbon atom: thus, diazoketones are more stable than unsubstituted aliphatic diazo compounds. Attempts to synthetize a diazoketone with a three-membered ring structure [63] indicated that the cyclic diazo group is destabilized by an adjacent keto group.

However, the two types of diazo compounds have one property in common: they both explode violently on overheating. The diazirines appear to be rather more stable than the linear isomers; the activation energy for the decomposition of dimethyldiazirine was found to be 33.165 kcal/mole [64].

The elimination of nitrogen from diazirine should lead to carbene [65], and from substituted diazirines to alkylcarbenes [66, 67]. The formation of carbenes can be easily demonstrated. Carbenes are characterized by their tendency to attack a β-C-H bond and form cyclopropanes. Cyclodiazoneopentane *(42)* was thermally decomposed to give 80 % dimethylcyclopropane, and cyclodiazoisobutane yielded 40 % methylcyclopropane. Hexamethylenediazirine *(43)* gave norcarane *(44)* plus cycloheptene [67]. The yields correspond to those of the

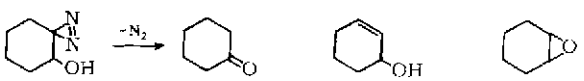
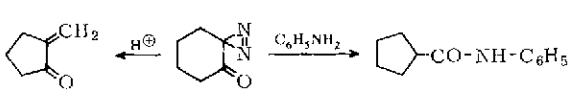
best known sources of carbenes [68]. The inertness of the diazirines may be advantageously applied in reactions requiring carbenes. Thus, for example, in the presence of compounds which react with diazomethane,



*(42)*

*(43)* *(44)*

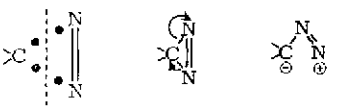
the latter cannot be used as a source of carbene but diazirine can. Carbenes are also formed from diazirines in the absence of strong bases, but these must be present in most other reactions yielding carbenes.



The thermal decomposition of α-hydroxypentamethylenediazirine *(45)* can be formulated to proceed via an α-hydroxycarbene. Cyclohexanone, cyclohexenol, and cyclohexene epoxide were found as the stable end-products [63].

*(45)* 75% 20% 5%

The appreciable sensitivity of *(45)* towards acid was remarkable; 2N sulfuric acid was sufficient to split off its nitrogen quantitatively within a few minutes at 80 °C. The only reaction product was cyclohexanone.



A compound *(46)*, prepared from hydroxydiazirine *(45)* by oxidation with t-butyl hypochlorite, is even more sensitive to acids. Nitrogen is eliminated by dilute acid within a few seconds, even at room temperature. A suspicion that this is actually a linear diazo compound could not be confirmed: its reaction with Grignard reagent yielded a diaziridine, recognized by its ability to oxidize iodide [63].

*(47)* *(46)* *(48)*

Decomposition of the cyclic diazo ketone *(46)* with acid results in ring contraction, with formation of methylenecyclopentanone *(47)*; the dinitrophenylhydrazone of *(47)* was identical with an authentic sample [69]. Thermal elimination of nitrogen from *(46)* takes place even at 40 °C and results a Wolf rearrangement: in the presence of aniline, cyclopentanecarboxanilide *(48)* is formed.

It appears to be interesting for the mechanism of the elimination of nitrogen that the introduction of electron-attracting groups reduces the stability of the diazirines by several orders of magnitude. The α-ketodiazirine *(46)* decomposes in solvents whose protonating capacity is at least $10^6$ times smaller than that of the 80% sulfuric acid required to decompose pentamethylenediazirine *(36)*. Compound *(46)* undergoes thermal decomposition slightly above room temperature, whereas diazirines without additional substituents are only appreciably decomposed above 150 °C. Assuming that a general principle holds good in these cases, some of the possible mechanisms can be neglected.

*(49)* *(50)* *(51)*

If the two C–N bonds are broken homolytically *(49)* as in the case of the aliphatic azo compounds [70], the electron distribution on the carbon atom in the transition state must tend towards a sextet. However, an electron deficiency cannot be stabilized by a withdrawal of electrons.

A simultaneous shift of two electron pairs in the directions of the arrows drawn in *(50)* is equally improbable. Substituent effects of the order of magnitude mentioned above point to a transition state with extensive charge separation. A transition state with a negative charge accumulation on the carbon atom would be stabilized, and hence more easily achieved, as a result of withdrawal of electrons. Thus, the two electron displacements shown by the arrows in *(50)* must be non-synchronous, the first step being the displacement of a pair of bonding electrons to the carbon. This gives rise to *(51)*, the carbanionic limiting structure of an aliphatic diazo compound, which however lacks the linear arrangement of atoms necessary for resonance stabilization.

Further investigations may possibly lead to the discovery of a "no-man's-land" between the two distinct classes of aliphatic diazo compounds known today [71].

*I am sincerely grateful to my colleagues Dr. R. Ohme, D. Murawski, D. Habisch, R. D. Schmidt, S. Schramm, K. Schinkowski, and A. Stark for their contributions to these results; particular attention should be drawn to Dr. Ohme's share. My appreciation is also due to my technical assistants E. Beyer, Ch. Kuck, I. Kapsch, and U. Pieper. I would also like to thank Prof. A. Rieche for his interest and for his assistance in the present study.*

## Introduction

Sodium hydrazide is a pale yellow crystalline compound that explodes violently on reaction with oxygen or on heating above 100 °C. It was first prepared in pure form in 1915 by *Schlenk* and *Weichselfelder* [1], but was then neglected for more than four decades. Since the hydrazide ion is much more nucleophilic than hydrazine, it seemed likely to have interesting synthetic possibilities; we have been studying the reactions of sodium hydrazide with organic compounds since 1958, and have discovered many that were completely unexpected.

The reactions described below were carried out in a well-screened splinter-proof apparatus [2]. The sodium hydrazide was not isolated, but was used as a suspension in ether, diisopropyl ether, or benzene; it was prepared by the action of sodamide [3] or sodium hydride [4] on anhydrous hydrazine in an atmosphere of nitrogen [5] at 20 °C, according to the equation

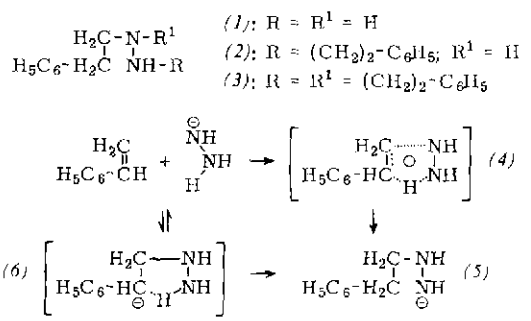
$$NaR + H_2N{-}NH_2 \rightarrow NaNH{-}NH_2 + HR \qquad (R = NH_2 \text{ or } H)$$

[1] *W. Schlenk* and *Th. Weichselfelder*, Ber. dtsch. chem. Ges. *48*, 669 (1915).

[2] *Th. Kauffmann*, *Ch. Kosel*, and *D. Wolf*, Chem. Ber. *95*, 1540 (1962).

[3] *T. W. B. Welsh*, J. Amer. chem. Soc. *37*, 497 (1915).

[4] *Ch. Kosel*, Ph. D. Thesis, Technische Hochschule, Darmstadt 1962.



[5] The method of preparation used by *Schlenk* and *Weichselfelder* ($Na + H_2N{-}NH_2$) [1] often leads to explosions even when oxygen is strictly excluded.

## 1. Addition Reactions

### a) With Alkenes

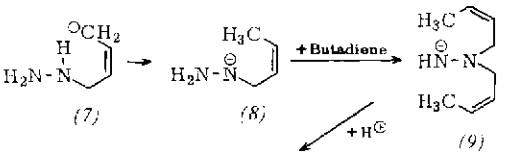
Sodium hydrazide does not attack isolated double bonds, apart from those in which the bond angle is strained [6]. On the other hand, it adds onto C=C double bonds that are conjugated with a phenyl residue or another C=C double bond.

Styrene adds on sodium hydrazide in ether very rapidly even at 0 °C. The sodium derivatives of the bases *(1)* to *(3)* are formed in successive stages; of these, *(1)* can be isolated as the main product by carrying out the reaction in the presence of much free hydrazine, and *(2)* by the use of excess styrene [2] (cf. Table 1).

[6] Bicyclo[2,2,1]hepta-1,5-diene adds on sodium hydrazide slowly at 40 °C [7]. Other olefins with strained double bonds have not yet been investigated.

We ascribe the surprising [8] ease of hydrazide addition and the complete lack of anionic polymerization of styrene to a one-stage mechanism via transition state *(4)* or a two-stage mechanism via intermediate *(6)* in which a hydrogen atom from the uncharged nitrogen atom of the hydrazide ion participates. In conformity with this mechanism, sodium methylhydrazide (probably a mixture of sodium *N'*-methylhydrazide and sodium *N*-methylhydrazide, cf. Section 4a) and sodium *N,N'*-dimethylhydrazide, whose anions, like that of sodium hydrazide, have a hydrogen atom on the uncharged nitrogen atom, also add onto styrene rapidly at 0 °C, whereas sodium *N,N*-dimethylhydrazide and sodium trimethylhydrazide, which have no hydrogen atom on the uncharged nitrogen atom, do not react in this way [2, 9].

Only a catalytic amount of sodium hydrazide need be present for the reaction of styrene with sodium hydrazide plus hydrazine to give phenethylhydrazine *(1)*. Apparently it is continually reformed by metal-hydrogen exchange between the sodium derivative of *(5)* and hydrazine.



The styrene derivatives numbered 2 to 6 in Table 1 also add on sodium hydrazide in ether at 0 °C but α-benzylstyrene (metalation) and α,α-dimethylstyrene do not. In experiments 2–6, reaction almost ceases after formation of the monosubstituted hydrazine under conditions [2] under which styrene itself gives a mixture of the bases *(1)–(3)*. Like styrene, alkenes that have a double bond allylic to an aromatic ring (allylbenzene, 1,4-dihydronaphthalene) add on the hydrazide ion in the α-position. Probably the strongly basic hydrazide displaces the double bond into conjugation with the ring before addition occurs.

Table 1. Addition of hydrazide onto olefins in ether [a].

| Expt. | Olefin | Product | Yield [%] |
|---|---|---|---|
| 1 | Styrene | Phenethylhydrazine *(1)* | 61 |
| | | or *N,N'*-diphenethylhydrazine *(2)* | 83 |
| 2 | β-Methylstyrene | 1-Hydrazino-2-phenylpropane | 52 |
| 3 | α-Methylstyrene | 2-Hydrazino-1-phenylpropane | 62 |
| 4 | Anethole | 2-Hydrazino-1-(4-methoxyphenyl)propane | 65 |
| 5 | Isoeugenol | 2-Hydrazino-(4-hydroxy-3-methoxyphenyl)propane | 34 |
| 6 | 1,2-Dihydronaphthalene | 2-Hydrazino-1,2,3,4-tetrahydronaphthalene | 82 |
| 7 | 1,4-Dihydronaphthalene | | 81 |
| 8 | Allylbenzene | 2-Hydrazino-1-phenylpropane | 59 |

[a] Experiments 4 and 5 were carried out at 35 °C, the others at about 0 °C.

Butadiene also adds on sodium hydrazide in ether at 0 °C. In addition to nitrogenous polymeric products, up to 50 % *N,N*-di-*trans*-crotylhydrazine *(10)* can be isolated [4] from the reaction mixture after hydrolysis with water. The fact that the disubstituted hydrazine that is formed is unsymmetrical and not, as in the case of styrene (see above), symmetrical may be due to prototropic rearrangement of the mesomeric primary adduct *(7)* via a six-membered ring to the hydrazide ion *(8)*, which reacts with more butadiene to give *(9)*. The *trans*-configuration (infrared spectrum) of *(10)*, which is contrary to this explanation, may occur on subsequent isomerization.

*(7)* *(8)* *(9)*

*(10)* $H_2N\text{-}N(CH_2\text{-}CH{=}CH\text{-}CH_3)_2$

The other 1,3-dienes studied [10] react with sodium hydrazide in ether or benzene only in the presence of free hydrazine, but here, as will be shown in Section 5, hydrazide addition is always accompanied by dehydrogenation.

### b) With Alkynes

Reactions between sodium hydrazide and alkynes have been little studied. As might be expected, compounds with terminal triple bonds are merely metalated. The isolated triple bond of stearolic acid does not add on sodium hydrazide [11]. On the other hand, tolane takes up hydrazide smoothly in ether at 0 °C [9]. The hydrazone *(11)* is formed in 78 % yield after hydrolysis. One hydrogen atom on the uncharged nitrogen atom of the hydrazide ion apparently also plays an important part in this addition, since sodium methylhydrazide and sodium *N,N'*-dimethylhydrazide also add onto tolane in benzene/ether at 0 °C, whereas sodium *N,N*-dimethylhydrazide and sodium trimethylhydrazide, which do not have a hydrogen atom on the uncharged nitrogen, do not add on even at 50 °C [12].

$$\begin{matrix} & & N\text{-}NH_2 \\ & & \| \\ H_5C_6\text{-} & C & \text{-}CH_2\text{-}C_6H_5 \end{matrix} \quad (11)$$

### c) With Nitriles

The successive action of sodium hydrazide (at 0–20 °C) and water on nitriles produces amidrazones *(12)* [13] in good yields. These compounds are extremely useful for the synthesis of heterocyclic systems but have been

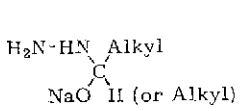
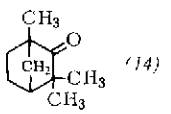
comparatively inaccessible [14] until recently, as is evidenced by the fact that in the aliphatic series only acemidtarazone [15] has been described.



*(12)*



The following were prepared: acetamidrazone (63 %), capramidrazone (87 %), lauramidrazone (85 %), myristamidrazone (100 %), hexadecanecarboxamidrazone (93 %), stearamidrazone (74 %), phenylacetamidrazone (78 %), benzamidrazone (99 %), *o*-hydroxybenzamidrazone (100 %), α-naphthoamidrazone (57 %), and β-naphthoamidrazone (88 %).

### d) With Carbonyl Compounds

Reaction between aliphatic aldehydes or unbranched aliphatic ketones and sodium hydrazide in ether at 20 °C gives colorless precipitates, presumably containing the adducts *(13)*, which when hydrolysed with water with ice cooling give hydrazones [7, 16] in good yield. There is practically no formation of azines, as in the corresponding reactions with hydrazine.

*(13)*

*(14)*

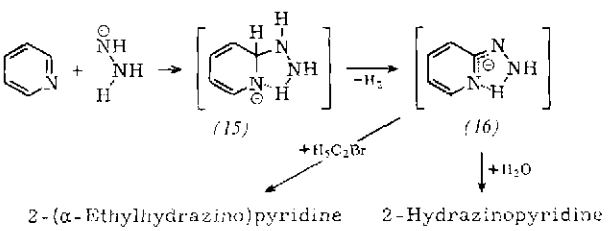
It was not found possible to convert ketones, such as those listed below – which react with hydrazine only at elevated temperatures or not at all – smoothly into their hydrazones using sodium hydrazide, a reaction that would have been of interest in connexion with the *Wolff-Kishner* reduction. The major part of the starting materials were recovered unchanged in the reactions of sodium hydrazide with acetophenone [17] (1 h at 22 °C), t-butyl phenyl ketone (1 h at 60 °C), camphor (1 h at 50 °C), and fenchone *(14)* (4 h at 35 °C); there was little or no evidence for the formation of an intermediate [7].

In the case of enolizable ketones (acetophenone, camphor), an enolate could be formed. With non-enolizable ketones (t-butyl phenyl ketone, fenchone), the failure to form hydrazones can be attributed to steric hindrance of hydrazide addition or to the elimination of hydrazine instead of water during hydrolysis of the adduct.

[14] The best method of preparation hitherto involved the reaction of imido esters (imino ethers) with hydrazine; cf. *A. Pinner*, Liebigs Ann. Chem. *297*, 221 (1897), and [15].

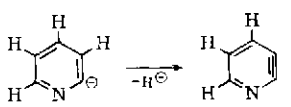
[15] *W. Oberhummer*, Monatsh. Chem. *63*, 285 (1933).

[16] *G. Ruckelshauss*, Diploma Thesis, Technische Hochschule Darmstadt 1964. Hydrazones of aliphatic aldehydes dimerize to 3,6-dialkylhexahydro-*sym*-tetrazines: *Th. Kauffmann, G. Ruckelshauss*, and *J. Schulz*, Angew. Chem. *75*, 1204 (1963); Angew. Chem. internat. Edit. *3*, 63 (1964).



[17] To obtain the corresponding hydrazones, acetophenone must be heated with hydrazine hydrate at 80–100 °C for 3 days, and benzophenone (mentioned in Section 6) in an autoclave at 150 °C for 6 h; cf. *Th. Curtius* et al., J. prakt. Chem. [2] *44*, 540, 194 (1891); *H. Staudinger* et al., Ber. dtsch. chem. Ges. *49*, 1932 (1916).

## 2. Substitution Reactions



### a) With Aromatic Nitrogen Heterocycles

#### α) *Preparation of Hydrazino Compounds*

Pyridine can be converted directly into 2-hydrazinopyridine by treatment with sodium hydrazide/hydrazine and subsequent hydrolysis with water [18]. Two stages can be clearly distinguished in the hydrazination reaction at room temperature: a rapid first phase, characterized by evolution of heat and the formation of a brown coloration, is succeeded by a second, slow phase, which can be followed by means of the evolution of hydrogen that continues for several hours. The mechanism of this substitution is thus probably analogous to that suggested by *Ziegler* and *Zeiser* [19] for Tschitschibabin amination via the adduct *(15)*:

The aryne mechanism involving the deprotonated pyridine *(17)* and 2,3-dehydropyridine *(18)* [20] recently postulated [21] for the Tschitschibabin amination is highly unlikely. This mechanism demands that, owing to the lower proton affinities of their anions, sodium hydrazide and sodium methylhydrazide should substitute pyridine less readily than sodium *N,N*-dimethylhydrazide or sodamide. The reverse is in fact the case: sodium hydrazide and sodium methylhydrazide react in benzene even at 10–20 °C, whereas sodium *N,N*-dimethylhydrazide and sodamide react only at about 80 °C. If, however, one assumes that the preliminary step in the substitution reaction is adduct formation, the higher reactivities of sodium hydrazide and sodium methylhydrazide are readily understood, since these hydrazides are also characterized by their great tendency to form adducts with styrene, tolane, and *p*-fluorotoluene [cf. Sections 1a), 1b), and 2b)].

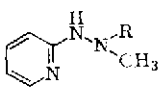
*(17)* *(18)*

As can be seen from Table 2, substitution of pyridine by methyl in the 4-position (4-methyl-, 2,4-dimethylpyridine) has a favorable effect on the yield of hydrazination product. This is even more marked in the quinoline series. Almost no 2-hydrazinoquinoline is

[18] *Th. Kauffmann, J. Hansen, Ch. Kosel*, and *W. Schoeneck*, Liebigs Ann. Chem. *656*, 103 (1962).

[19] *K. Ziegler* and *H. Zeiser*, Ber. dtsch. chem. Ges. *63*, 1848 (1930).

[20] It is not certain whether 2,3-dehydropyridine [*R. J. Martens* and *H. J. den Hertog*, Tetrahedron Letters *1962*, 643] adds on bases preferentially at C-2 or C-3; cf. also *Th. Kauffmann* and *F.-P. Boettcher*, Chem. Ber. *95*, 1529 (1962).



[21] *L. S. Levitt* and *B. W. Levitt*, Chem. and Ind. *1963*, 1621.

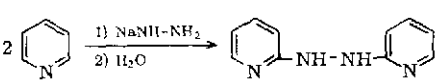
formed in the reaction between unsubstituted quinoline and sodium hydrazide/hydrazine, owing to reduction reactions [22] that are apparently initiated by addition of the hydrazide ion in the γ-position [cf. the reduction of quinaldine, Section 3a)]. Isoquinoline, in which the position *para* to the nitrogen is occupied, gives the 1-hydrazino compound in the expected good yield.

Table 2. Hydrazination to give hydrazino compounds.

| Heterocycle | α-Hydrazino compound Yield [%] |
|---|---|
| Pyridine | 36 |
| 2-Methylpyridine | 25 |
| 4-Methylpyridine | 62 |
| 2,4-Dimethylpyridine | 58 |
| Quinoline | 0.5 |
| 4-Methylquinoline | 76 |
| Isoquinoline | 69 (1-hydrazinoisoquinoline) |

Similar hydrazination of pyridine with sodium methylhydrazide gives *(19)*, and with sodium *N,N*-dimethylhydrazide gives *(20)* and *(21)* [18,23].

*(19)*: R = H (26%)
*(20)*: R = $CH_3$ (33%)

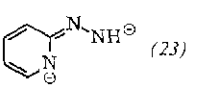


*(21)* (2%)

Compounds of the 2-hydrazinopyridine type are of interest, since they react with a large number of reagents to undergo ring-closure reactions similar to those of *o*-phenylenediamine [24].

### β) *Preparation of Hydrazino Compounds*

If no free hydrazine is present, the reaction of sodium hydrazide with aromatic nitrogenous heterocycles produces hydrazo compounds [11,25], as shown below for pyridine.



*(22)*

The yields (Table 3) generally correspond to those obtained in the synthesis of hydrazino compounds. Quinoline can be hydrazinated to the hydrazo derivative in far better yield than to the hydrazino compound; this is probably due to the much weaker reducing properties of sodium hydrazide compared with the sodium hydrazide/hydrazine system [cf. Section 2a.α)].

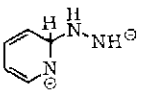


Table 3. Hydrazination to give hydrazo compounds.

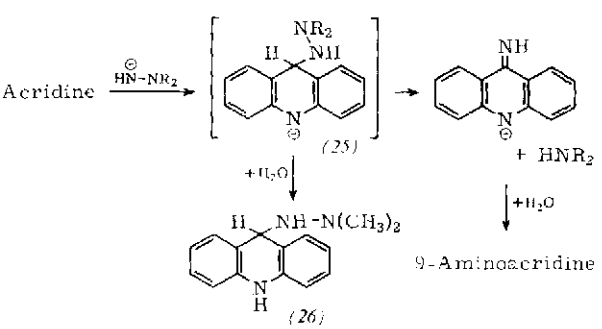
| Heterocycle | α,α'-Hydrazo compound Yield [%] |
|---|---|
| Pyridine | 20 |
| 4-Methylpyridine | 64 |
| Quinoline | 45 |
| 4-Methylquinoline | 62 |
| Isoquinoline | 64 (1,1'-hydrazodiisoquinoline) |

It is not clear how the pyridine residue becomes attached during the synthesis of 2,2'-hydrazodipyridine (*N,N'*-di-α-pyridylhydrazine) *(22)*. The anion *(16)*, which can be obtained from 2-hydrazinopyridine and 1 mole of sodamide, and which is presumably the primary product of the reaction of pyridine with sodium hydrazide, does not react with pyridine. If, on the other hand, 2-hydrazinopyridine is treated with 2 moles of sodamide, and then heated with pyridine at 80 °C for 7 h, 2,2'-hydrazodipyridine is formed in 19 % yield [4]. The latter might therefore be formed in the reaction of sodium hydrazide with pyridine through the dianion *(23)*. Linking of the two pyridine rings via the deprotonated intermediate *(24)* formed from the adduct *(15)* is a further possibility.



*(23)*

*(24)*

### γ) *Preparation of Amino Compounds*

Although sodamide converts acridine smoothly into 9-aminoacridine [26], corresponding hydrazinations with sodium hydrazide/hydrazine or with sodium hydrazide alone to give 9-hydrazinoacridine or 9,9'-hydrazodiacridine do not occur. 9,10-Dihydroacridine is formed almost quantitatively with sodium hydrazide/hydrazine [27], whereas with sodium hydrazide in the absence of hydrazine, 9-aminoacridine is formed with evolution of ammonia [28]. The formation of 9-aminoacridine must be assumed to proceed via *(25)*, R=H, since 9-aminoacridine (89 %) is also formed, with elimination of dimethylamine, by the action of sodium *N,N*-dimethylhydrazide on acridine. The fact that the adduct *(25)* is an intermediate in this reaction is confirmed by the isolation of the hydrolysis product *(26)*, which in this series is surprisingly stable [28].

In the hydrazinations described above, the adducts are stabilized by dehydrogenation, whereas in this case the

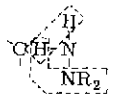
[24] Cf. *Th. Kauffmann* and *H. Marhan*, Chem. Ber. *96*, 2519 (1963); *K. Vogt*, Ph. D. Thesis, Technische Hochschule Darmstadt 1961.



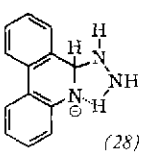
[25] *Th. Kauffmann, H. Hacker*, and *Ch. Kosel*, Z. Naturforsch. *14b*, 602 (1959).

[26] *K. Bauer*, Chem. Ber. *83*, 10 (1950).

[27] *Th. Kauffmann, H. Hacker, Ch. Kosel*, and *W. Schoeneck*, Angew. Chem. *72*, 918 (1960).

[28] *Th. Kauffmann* and *H. Hacker*, Chem. Ber. *95*, 2485 (1962).

second mode of stabilization *(27)* is realized, namely loss of $NH_3$ or dimethylamine [29].



*(27)*, R = H or $CH_3$

It will be seen from Table 4 that amino compounds are also formed on interaction of sodium hydrazide or *N,N*-dimethylhydrazide and other heterocycles; with quinazoline, both an amino group and a hydrazino group are introduced into the molecule [30].

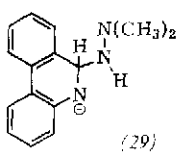


Table 4. Amination of heterocycles with sodium hydrazide and with sodium *N,N*-dimethylhydrazide (yields in parentheses)

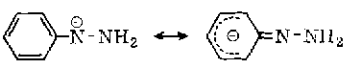
| Heterocycle | Amination product | Yield [%] |
|---|---|---|
| Acridine | 9-aminoacridine | 65 (89) |
| Phenanthridine | 9-aminophenanthridine | 2 (85) |
| Quinazoline | 4-amino-2-hydrazinoquinazoline | 16 |
| 2-Methylquinazoline | 4-amino-2-methylquinazoline | 25 |

The yield of 9-amino compound from the reaction between phenanthridine and sodium hydrazide is low (Table 4) because at the temperature of the reaction (60 °C) the adduct *(28)*, in contrast to the adduct *(29)* from sodium *N,N*-dimethylhydrazide, is quite stable. This difference in stabilities indicates that, like most thermal eliminations [31], the elimination of $NH_3$ or amine here is a *cis*-elimination, and therefore occurs only when the β-nitrogen of the hydrazine can approach very close to the hydrogen atom linked to the hydrazinated C atom. In *(28)* this approach may be hindered by the formation of a hydrogen bond with the ring nitrogen.

*(28)*

*(29)*

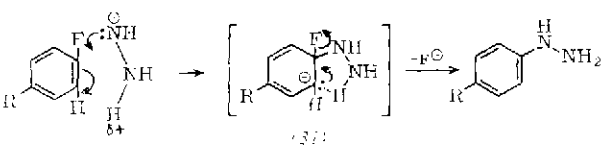


### b) With Aryl Halides

Nearly all the halogeno compounds that have been treated with sodium hydrazide are aromatic, and with these the halogen is replaced either by a hydrazino group or by hydrogen. The latter reaction is discussed in Section 3c).

#### α) *Substitution by an Aryne Mechanism*

*p*-Bromotoluene in ether reacts rapidly with sodium hydrazide/hydrazine even at 0 °C, whereas *p*-chlorotoluene does not react until about 30 °C. Since *m*-tolylhydrazine is always formed alongside *p*-tolylhydrazine, the reaction proceeds via 3,4-dehydrotoluene. The formation of ditolylhydrazines (see below) is further evidence for this. Under similar conditions (molar ratios of halogeno compound:sodium hydrazide:hydrazine = 1:2:4 in ether at 35 °C for 90 min), the ratios of *p*-: *m*-tolylhydrazines are 42:58 and 40:60, respectively [11,32], *i.e.* close to the ratio (38:62) of *p*-: *m*-toluidines produced in the reaction between *p*-chlorotoluene and sodamide in liquid ammonia [33].



The reactions of bromo- and chlorobenzene with sodium hydrazide/hydrazine (molecular ratios 1:3:15 in ether at 35 °C for 90 min) give not only phenylhydrazine (*ca.* 65 %) but also a mixture of *N,N*- and *N,N'*-diphenylhydrazine (*ca.* 25 %). Since sodium phenylhydrazide [34] does not react with chloro- or bromobenzene [35] under the conditions used, the two diphenylhydrazines can only arise by addition of sodium phenylhydrazide onto dehydrobenzene (benzyne) produced by *o*-metalation of the halides and subsequent elimination of sodium halide. The ratio of *N,N*- to *N,N'*-diphenylhydrazine is about 2.3:1 [11,32]. Thus, the negatively charged α-nitrogen atom (adjacent to the benzene ring) is the more successful of the two nitrogens of the phenylhydrazide ion *(30)* in competing for the extra bond of benzyne.

*(30)*

#### β) *Substitution by an Addition-Elimination Mechanism*

*p*-Fluorotoluene and fluorobenzene also react with sodium hydrazide in ether or benzene containing hydrazine even at only 30 °C. As *p*-tolylhydrazine or phenylhydrazine is formed exclusively [cf. Section 2b.α)], there is no doubt that the reactions proceed entirely by an addition-elimination mechanism [36]. This observation is surprising, since *p*-fluorotoluene reacts with the comparable lithium piperidide/piperidine system entirely by the aryne mechanism [37]; however, it is probably due [36] to the ease of the single-stage process (see formulae below) [38] by which the hydrazine ion attaches itself, aided by a hydrogen atom on the uncharged nitrogen, to the phenyl residue, which is activated by the fluorine atom. The adduct *(31)*, R–$CH_3$ or H, is then stabilized by elimination of fluoride.

*(31)*

[29] For a discussion of why stabilization of the adduct occurs in some cases by elimination of hydrogen and in others by elimination of ammonia or amine, see [28].
