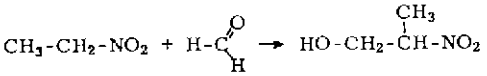
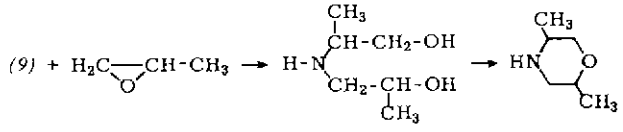
For the introduction of only one substituent at position 3, or only two substituents at positions 3 and 5 of tetrahydro-1,4-oxazine, the starting material must be a 1-amino-2-hydroxyethane *(9)* that is substituted on the carbon atom adjacent to the nitrogen. These 1,2-amino alcohols are prepared by base-catalysed addition of nitroalkanes containing acidic hydrogen atoms to carbonyl compounds such as formaldehyde, acetaldehyde, or acetone, and catalytic hydrogenation of the resultant 1,2-nitroalcohols, *e.g. (9a)* [7]. 1,2-Alkylene oxides convert the 1,2-amino alcohols, *via* bis-(2-hydroxyalkyl)amines, into 2- and/or 5-substituted tetrahydro-1,4-oxazines, for example *(10)*.



(9a)

(9)



(10)

If the amine to be cyclized carries two substituents on different carbon atoms, two sterically different products are obtained on ring closure in about equal amounts. They can be detected by gas chromatography as, for example, in the case of the 2,6-dialkylmorpholines.

3. Introduction of Substituents at the Nitrogen Atom

Alkylation of the nitrogen atom in tetrahydro-1,4-oxazines by means of alkyl halides is successful with aliphatic compounds, but it is frequently unsuccessful with alicyclic halides which are dehydrohalogenated to cycloalkenes. It is therefore practical, particularly in the alicyclic series, to synthesize by hydroxyalkylation with epoxides *N*-substituted amines which are then cyclized (cf. Section II.2), or to react a cyclic ketone with the tetrahydro-1,4-oxazine, which is unsubstitued on the nitrogen atom, and hydrogenate the resulting enamine.

The primary alicyclic amines *(11)* and *(12)* needed for the first procedure were prepared by the usual methods

[8], mainly by complete hydrogenation of the easily available alkylphenols, followed by dehydrogenation of the resulting alcohols to yield ketones *(11a)*, and reductive amination of the latter. Alternatively, carbonyl compounds were condensed with cycloalkanones, followed by hydrogenation and reductive amination of the resulting cycloalkylidenealkanones *(12a)*.

Some tetrahydro-1,4-oxazines, particularly those carrying large alicyclic substituents, behave as sterically hindered strong bases ("Hünig bases"), and are difficult to peralkylate with the usual reagents [*].

III. Relations between the Chemical Constitution and the Fungicidal Action of Tetrahydro-1,4-oxazines, Their Precursors, and Analogues

For the sake of clarity, the following Tables list only the results obtained on treating *Erysiphe graminis* (powdery mildew of barley).

Most morpholines are active against powdery mildews (such as the mildews of cereals, cucumbers, roses, gooseberries, scorzonera, and apples), against fungi causing plant rusts such as grain rust, against *Sigatoka*, a fungus disease of banana leaves, and also against the molds attacking citrus fruits. Some morpholines are also active against downy mildew fungi such as *Peronospora* and *Phytophthora*. The compounds included in the Tables represent only a small fraction of the large number of substances examined.

Table 1 shows that the fungicidal action is generally stronger for tetrahydro-1,4-oxazines than for the corresponding amino alcohols. It is immaterial whether the amino alcohol contains one or two OH-groups. The great influence of the *N*-substituent of the tetrahydro-1,4-oxazine upon the fungicidal action is shown in Table 2.

Table 3. Variation of the fungicidal action with the *C*-substituents at the tetrahydro-1,4-oxazine ring.

contains 12 to 18 carbon atoms. With alicyclic *N*-substituents, the fungicidal properties are considerable even when the alicyclic group contains only 7–8 carbon atoms. Alkylated cyclohexyl groups or bicyclic substituents usually do not lead to the same activity as larger ring systems (*e.g.* the cyclododecyl group). Tetrahydro-1,4-oxazines with aromatic *N*-substituents generally do not exhibit good fungicidal properties. However, when the aromatic group is linked to the nitrogen atom by an aliphatic residue, the fungicidal action will be strongly increased, particularly if the aromatic group is further substituted with a fairly large aliphatic residue (cf. Table 2).

Table 3 shows that the fungicidal activity of tetrahydro-1,4-oxazines is enhanced (relative to unsubstituted or aromatically substituted compounds of the same type) by lower alkyl substituents on the C-atoms. Particularly good fungicidal properties, coupled with low phytotoxicity, are observed when the carbon atoms in positions 2 and 6 of the tetrahydro-1,4-oxazine ring carry hydrogen atoms and lower alkyl groups. The fungicidal activity changes only slightly when the free electron pair on the nitrogen atom of the morpholine ring is blocked (see Table 4). However, the anion of the resulting quaternary salt may exert a greater influence.

It can also be seen from Tables 1–4 that compounds containing alicyclic *N*-substituents generally have a lower phytotoxicity than derivatives of comparable or somewhat better fungicidal action which carry an open-chain aliphatic substituent. This applies in particular to the *N*-tridecyltetrahydro-1,4-oxazines. The tridecyl group clearly is exceptional among aliphatic substituents, since many tridecylamine derivatives are good fungicides; in this respect it is of minor importance whether the nitrogen atom is further substituted. This is shown in Table 5 which lists ring systems differing from tetrahydro-1,4-oxazine.

In conclusion it can be said that substitution of the nitrogen in tetrahydro-1,4-oxazine by an alicyclic group containing more than 7–8 carbon atoms frequently results in good fungicidal properties. A further increase in the fungicidal activity is caused by aliphatic or alicyclic *N*-substituents containing 12–18 carbons, and by one or two lower alkyl substituents, preferably in positions 2 and 6 of the tetrahydro-1,4-oxazine ring.

The Function of the Promotors in the Technical Ammonia Catalyst

BY DR. R. KRABETZ AND DR. CL. PETERS

BADISCHE ANILIN- & SODA-FABRIK AG., LUDWIGSHAFEN/RHEIN (GERMANY)

Published on the occasion of the 100th anniversary of the establishment of Badische Anilin- & Soda-Fabrik AG., on April 6th, 1965.

An attempt is made to give a phenomenological description of the relationships between the catalytic activity and the distribution of the promotors in the reduced ammonia catalyst. Investigations were carried out on series of catalysts whose compositions were gradually brought closer to that of technical ammonia catalysts by the addition to iron of one new activator (Al_2O_3, K_2O, CaO, MgO, SiO_2) at a time.

Following the elucidation of the composition of a catalyst suitable for the technical synthesis of ammonia by *Mittasch* [1], numerous investigations were carried out on the function of the activators. Publications on this topic up to 1955 are reviewed in monographs by *Frankenburg* [2], *Bokhoven*, *van Heerden*, *Westrik*, and *Zwietering* [3], and *Nielsen* [4]. More recent papers have dealt with the kinetics of the reaction over singly and multiply promoted catalysts [5–7d], the mechanism of reversible poisoning [8], and the reaction kinetics in the

presence of catalysts poisoned with sulfur [9,10]. A more detailed picture of the influence of alumina on the surface structure of the reduced catalysts has been obtained [11]. Attempts have been made to explain the action of potassium in the light of current views on heterogeneous catalysis [8,12].

As the requirements placed upon the ammonia catalyst became increasingly stringent, its composition became more and more complex. The first BASF technical catalyst consisted essentially of iron and two promotors (alumina and potassium oxide); calcium oxide was later added to give a triply promoted catalyst. Recently, quadruply and quintuply promoted catalysts containing magnesium or beryllium and silica as well as alumina, potassium oxide, and calcium oxide, have gained technical importance.

1. Experimental

a) Preparation

The catalysts were prepared by oxidative melting [1], using iron carbonyl and analytically pure additives.

b) Reduction and Activity Testing

The catalysts were both reduced and tested for activity with a stoichiometric nitrogen/hydrogen mixture at atmospheric pressure. The gases were so pure that the activity of an unpromoted catalyst remained unaltered for several weeks of use. The catalyst samples were reduced at 450 °C and subsequently at 480 °C until the concentration of ammonia in the final gas showed no increase (about 80 h). The catalytic activity was tested with 4 g samples of sieve fractions between 0.4 and 0.6 mm mesh size, at a space velocity of 10000 l of gas per liter of catalyst per hour. The quantity of ammonia in moles-% of the total gas formed under these conditions at 370 °C was taken as a measure of the catalytic activity.

c) Determination of the Total Surface Area

The total surface area was determined from the quantity of nitrogen adsorbed at −195 °C, using the method described by *Brunauer*, *Emmett*, and *Teller* [13]. The value taken for the area occupied by an adsorbed molecule of nitrogen was that reported by *Livingstone* [14], *viz.* 15.4 Å^2.

d) Distribution of the Promotors in the Catalyst Surface

The proportions of "free-iron surface area" and "free-potassium surface area" to the total surface area of the catalyst were determined by the method of *Brunauer* and *Emmett* [15].

The proportion of "free-iron surface area" to the total surface area is defined as the ratio of the quantity of carbon monoxide chemisorbed at −183 °C to the quantity of physically adsorbed carbon monoxide. Similarly, the proportion of "free-potassium surface area" to the total surface area is given by the ratio of the quantities of carbon dioxide chemisorbed and physically adsorbed at −78 °C. Although carbon dioxide is also chemisorbed on calcium and magnesium oxides under these conditions, we shall retain the term "free-potassium surface area" for catalysts which contain alkaline earth oxides as well.

e) Pore Size Distribution

The pore size distribution for very small pore sizes (10–500 Å in diameter) was determined from the capillary condensation, using the method proposed by *Barret*, *Joyner*, and *Halenda* [16]. The size distribution of pores with diameters between 150 and 300000 Å was determined by impregnation with mercury (at pressures of up to 1100 atm), as described by *Drake* and *Ritter* [17].

f) Water-Soluble Potassium

The water-soluble portion of the potassium oxide in the unreduced catalyst samples was determined by extraction with water for 24 hours, using uniform sieve fractions (900 to 1600 meshes/cm^2).

2. Results

a) Fe—Al_2O_3 Catalysts

We have dealt in detail with the influence of alumina in an earlier paper [11]. The catalytic activity reaches a maximum at 3% alumina. The total surface area increases rapidly with alumina contents of up to 3%, but beyond this concentration, the increase becomes slower, and the proportion of free iron in the surface decreases. Like the activity, the free-iron surface area reaches a maximum at an alumina content of 3%.

The principal function of the alumina is to stabilize a porous iron structure with a large surface area. The 3 to 4% alumina is probably the quantity which is dissolved in the magnetite lattice and which separates out at the surface on reduction as an intimate mixture with the iron atoms. A further portion of the Al_2O_3 separates out together with magnetite between the iron regions, in the form of mixed spinels which are difficult to reduce. This portion makes no substantial contribution to the formation of the surface, but simply decreases the proportion of free iron in the surface.

Stabenow [17a] has carried out electron-microscopic studies on ultrathin sections of catalysts which were singly promoted with various quantities of alumina. The samples were prepared by oxidative melting and were reduced at 500 °C. They exhibited a structure intermediate between the two extremes [3,4] of a continuous solid iron phase with many pores (sponge structure) and a loose packing of iron particles in which the interstitial

spaces form the "pores". The dimensions of the irregular, continuous cavities were found to vary from less than 100 to over 1000 Å, in agreement with the values obtained from pore size distribution curves. The sizes of the iron particles are similar to those of the pores.

Another function of the alumina is probably to prevent the thermal transformation of particularly active crystal faces, *e.g.* the (111) face. When magnetite is carefully reduced at about 300 °C, the reduced iron chemisorbs roughly one molecule of carbon monoxide per atom of iron, when it is assumed that the exposed crystal face is the (111) face [18]. If the catalyst is then heated to 600 °C, the quantity of carbon monoxide chemisorbed per atom of iron decreases by 50%, which indicates that the iron surface has been sintered to more closely packed crystal faces. The quantity of carbon monoxide chemisorbed on the sample containing 3% alumina was the same before and after heating at 600 °C.

The sensitivity of the catalyst towards inactivation by sulfur or chlorine decreases with increasing alumina content [18a].

b) Fe—Al_2O_3—K_2O Catalysts

Small quantities of a potassium compound are added during the preparation of the catalyst by the melting method. This leads to an increase in activity, but only in catalysts which contain difficultly reducible oxides of metals of Groups III and IV. The catalytic activity of pure iron is reduced on introduction of potassium oxide. The change in the activity of catalysts containing alumina depends on the quantity of potassium oxide added (see Fig. 1).

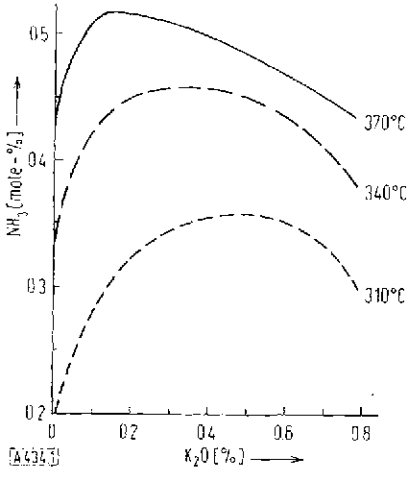

Fig. 1. Influence of the potassium content on the yield of ammonia obtained over an Fe—Al_2O_3—K_2O catalyst containing 2.5% Al_2O_3, after reduction at 480 °C.

In contrast to the situation with singly promoted catalysts, here the action of the promotor is not related to the total surface area or to the free-iron surface area, both of which decrease with increasing potassium content (see Fig. 2). Any increase in the potassium content simply leads to an increase in the concentration of potassium at the surface. This quantity again bears no direct relationship to the catalytic activity, since the activity falls off again when the surface concentration of potassium exceeds 30%, corresponding to a potassium oxide content of 0.78%.

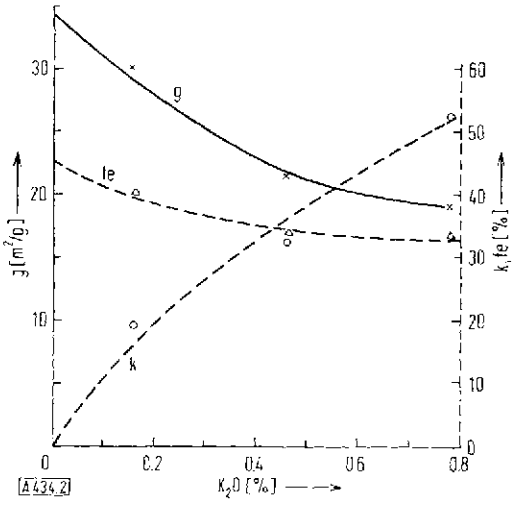

Fig. 2. Influence of the potassium content on the total surface area (g), the percentage of free-potassium surface area (k), and the percentage of free-iron surface area (fe) for Fe—Al_2O_3—K_2O catalysts.

The observation that samples containing potassium have smaller internal surface areas than those without it indicates that potassium promotes recrystallization of the iron crystallites. This effect is particularly noticeable when the reducing or synthesis gas contains oxygen compounds. Table 1 shows the ammonia yields at 370 °C and the total surface areas for catalysts with increasing potassium content immediately after reduction (I), after ageing in extremely pure gas at 600 °C (II), and after ageing at 600 °C in a gas containing oxygen (III). In addition to the acceleration of the decrease in surface area in the presence of small quantities of oxygen, this table clearly shows that high potassium contents decrease the stability of the catalysts towards overheating.

Table 1. Resistance of catalysts containing potassium and 2.2% of Al_2O_3 towards sintering, after various pretreatments (cf. text).

Total K_2O [%]	Total surface area [m^2/g]			NH_3 yield at 370 °C [%]			K_2O in the surface [%]
	I	II	III	I	II	III	I
0.18	30.1	22.3	20.5	0.518	0.510	0.456	19.3
0.46	(21.6)	18.9	15.3	0.486	0.425	0.401	32.3
0.78	19.2	18.1	14.6	0.433	0.361	0.336	52.3

The pore structure also undergoes a typical change during recrystallization. Figure 3 shows the distribution of pore size for a sample containing no potassium, a second with a low potassium content, and a third with a high potassium content after heating at 600 °C.

The fine pores (100–400 Å) of the potassium-free catalyst are replaced by larger pores (400–1600 Å) on addition of potassium. The mean pore diameter was calculated from the inner surface area O [*] and the pore

[*] Determined by the method of *Brunauer*, *Emmett*, and *Teller*.

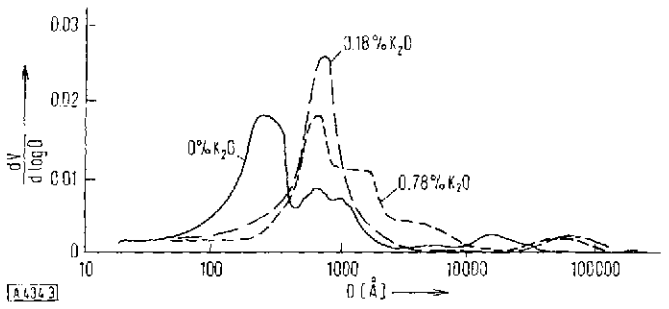

Fig. 3. Influence of the potassium content on the pore size distribution in $Fe-Al_2O_3-K_2O$ catalysts.

Abscissa: Pore diameter D [Å].

Ordinate: $\frac{dV}{d \log D}$, *i.e.* the distribution of pore volumes V corresponding to the various pore diameters D.

volume V_p [*] of a catalyst sample, using the formula $\overline{D} = 4V_p/O$. The values obtained were 284 Å for the sample containing no potassium, 364 Å for the catalyst with the low potassium content, and 484 Å for that with the high potassium content. The total pore volume is practically the same for all the catalysts (0.15 cm^3/g).

The fact that the ammonia yield is maximum at a certain potassium content can be explained by the opposing influences of the potassium increasing the catalytic activity on the one hand, and decreasing the free-iron surface area by accelerating recrystallization on the other.

However, the optimum potassium content varies from one type of catalyst to another, and also according to production conditions, since the properties of the potassium-activated catalysts are governed not only by the concentration of the activator, but also by its distribution in the surface. The close relationship between structure and properties of the reduced catalyst and the distribution of the potassium in the unreduced sample can be seen from the following experiment.

Fused magnetite containing 2.5% alumina and 0.5% potassium oxide was cooled at three different rates in tubes of different diameters. The sample which was cooled slowest (Fig. 4a) had a more homogeneous structure than the other two, which solidified faster. Since only the potassium was dissolved out at the dark patches in the polished surfaces, photomicrographs give a first indication of the distribution of the potassium.

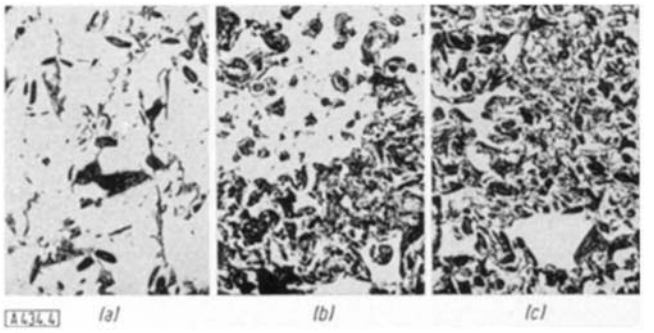

Fig. 4. Photomicrographs (magnification 100×) of $Fe-Al_2O_3-K_2O$ catalyst melts solidified at various rates, after surface polishing and etching with dilute HCl.

[*] V_p is found from the true and the apparent densities of the catalyst. The true density was determined by gas pycnometry using helium and the apparent density by liquid pycnometry using mercury.

A further indication is given by the quantity of potassium which can be extracted with water. The "water-soluble potassium" [19] occurs as a separate phase at the boundaries between the secondary particles which can be seen under the light microscope and the primary particles which can be recognized in the electron microscope and is partly responsible for the structure obtained on etching. According to *Wykoff* and *Crittenden* [20], the "water-insoluble potassium" probably forms a solid solution as aluminate or ferrite with the magnetite, without mixed crystal formation. It is therefore relatively well distributed inside the particles. On reduction, it separates out as finely divided aluminate on the surface of the iron crystallites [21]. As can be seen from Column 4 in Table 2, the proportion of water-insoluble potassium is greater in the samples cooled slowly, which have more homogeneous structures.

Table 2. Analysis of unreduced $Fe-Al_2O_3-K_2O$ catalysts (Al_2O_3 = 2.8%) cooled at various rates, and the surface properties of the reduced samples.

Relative cooling time	FeO/Fe_2O_3	K_2O insoluble [%]	K_2O total [%]	Total surface area [m^2/g]	Free-iron surface area [m^2/g]	K_2O coating [% of total surface area]	NH_3 yield at 370 °C [%]
2.86	0.93	0.18	0.54	16.25	3.75	21.4	0.46
2.50	1.05	0.20	0.66	16.7	3.75	21.9	0.475
1.67	1.09	0.31	0.53	17.4	4.58	24.7	0.496
1.25	1.11	0.29	0.56	20.7	4.91	24.5	0.506
1.00	1.1	0.28	0.51	19.35	5.48	27.3	0.514

According to Table 2, these samples have a higher potassium concentration in the surface and a greater free-iron surface area after reduction than the samples with lower proportions of water-insoluble potassium. The catalytic activity and the proportion of insoluble potassium fall off again if the melt is cooled slowly [22].

Potassium also changes the resistance of the catalysts toward poisons. We found that catalysts containing potassium adsorb more hydrogen sulfide per unit area, and are poisoned to a lesser degree by a given surface coating of sulfur than samples activated with alumina alone [9]. Conversely, potassium increases the sensitivity of the catalysts toward gaseous oxygen compounds.

c) $Fe-Al_2O_3-K_2O-CaO(MgO)$ Catalysts

Catalysts activated with calcium or magnesium alone have smaller surface areas and poorer catalytic activity than samples activated with alumina ($CaO < MgO < Al_2O_3$).

[22] *H. Uchida* and *N. Todo*, Bull. chem. Soc. Japan *29*, 20 (1956).

However, alkaline earth oxides in combination with Al_2O_3 and K_2O have gained some technical importance. Three catalysts with constant alumina and potassium-oxide contents, but containing increasing quantities of calcium oxide, were reduced at 500 °C and then aged at 600 °C in synthesis gas containing oxygen. Table 3 shows the total surface areas after ageing and the ammonia yields before and after ageing. It can be seen from these data that the sample with the highest calcium content was the least damaged by heat treatment.

Catalysts containing calcium are also less sensitive toward irreversible poisoning by hydrogen sulfide or chlorine compounds [18a].

Table 3. Resistance of catalysts (Al_2O_3 = 2.2 %; K_2O = 0.42–0.5 %) containing calcium towards sintering.

CaO [%]	Total surface area after aging [m²/g]	NH_3 yield before aging [%]	NH_3 yield after aging [%]
0.14	11.7	0.506	0.410
0.53	13.9	0.492	0.460
1.95	16.0	0.505	0.484

Magnesium did not have the same effect as calcium in catalysts containing alumina and potassium. This is remarkable, since according to our results magnesium stabilizes an iron structure with a large surface area more efficiently than calcium, in the absence of other activators. On the other hand, if part of the calcium in a catalyst activated with 2.5% alumina, 0.5% potassium oxide, and 2.0% calcium oxide, is replaced by magnesium, the activity is increased. The ammonia yield reaches a maximum when about half of the calcium has been replaced by magnesium. This "mutual reinforcement" of calcium and magnesium is illustrated in Figure 5.

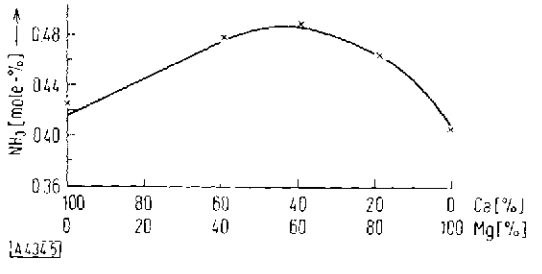

Fig. 5. Influence of the calcium/magnesium ratio on the catalytic activity of Fe–Al_2O_3–K_2O–CaO(MgO) catalysts at 370 °C.

d) Fe—Al_2O_3—K_2O—CaO(MgO)—SiO_2 Catalysts

Catalysts containing silica together with the usual activators alumina, potassium oxide, and calcium oxide have recently become technically important. Moreover, the technical Fe–Al_2O_3–K_2O–CaO catalyst contains about 0.5% silica as an impurity.

As can be seen from Table 4, the proportion of water-soluble potassium in the unreduced catalyst decreases with increasing silica content. The silica evidently leads to a more uniform distribution of the potassium inside the secondary particles, probably by formation of potassium alkaline earth silicates. The properties of catalysts containing silica are listed in Table 4. The total surface area (Column 5) increases with the silica content (Column 3), but the percentage of the total surface covered with free potassium and alkaline earth metals (Column 4) decreases. The catalytic activity (Column 6) passes through a maximum.

Table 4. Analysis of unreduced catalysts containing silica (Al_2O_3 = 2.6 %; CaO = 1.2 %; MgO = 1.5 %) and surface properties of the reduced samples.

Total K_2O [%]	Water-soluble K_2O [%]	SiO_2 [%]	K_2O(+ CaO) coverage [% of total surface area]	Total surface area [m²/g]	NH_3 yield at 340 °C [%]
0.74	0.32	0.35	41	21.3	0.320
0.69	0.17	0.55	27	23.3	0.395
0.99	0.03	2.23	17	29.7	0.374
0.83	0.03	2.72	9	30.9	0.344

Thus, a better distribution of the potassium, the alumina, and the silica during the reduction stabilizes reduced iron structures with larger surface areas. However, the catalytic activity depends not only on the total surface area, but probably also on the concentration of free potassium in the surface, which is greatly reduced by silica. This assumption was initially rather hypothetical but is supported by the following experiment.

Three series of catalysts were prepared containing respectively 0, 2.2, and 4.2% silica. The potassium content was varied over a wide range within each series. The upper part of Figure 6 shows a plot of the ammonia yield at 370 °C against the percent by weight of potassium oxide in the unreduced samples. As with the simpler Fe–Al_2O_3–K_2O catalysts, the catalytic activity passes through a maximum at a certain potassium content, which increases with the silica content. Thus, while only

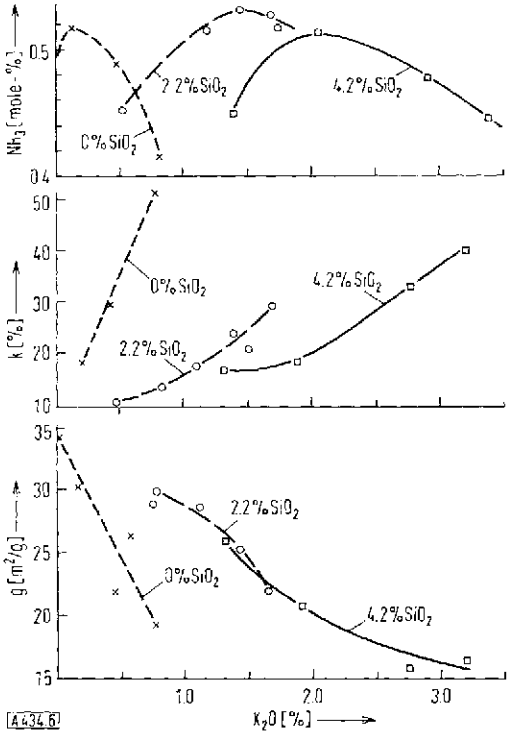

Fig. 6. Influence of the potassium content on the catalytic activity, percentage free-potassium surface area (k), and total surface area (g) for Fe–Al_2O_3–K_2O–CaO–(MgO)SiO_2 catalysts with various SiO_2 contents.

0.4% potassium oxide is required for maximum conversium with a catalyst containing no silica, 2% potassium oxide is necessary in the presence of 4.2% silica. The lower part of Figure 6 shows that the total surface area (g) within each series (*i.e.* at constant silica contents) decreases with increasing potassium content, whereas the concentration of potassium in the surface increases (Fig. 6, middle).

Figure 7 shows the ammonia yields not as a function of the potassium content of the unreduced catalyst but as a function of the percentage of potassium at the surface of the reduced sample. It is now possible to correlate the catalytic activities of the various series of catalysts in Figure 6. In Figure 7 it is shown that the best catalysts always have a potassium concentration of 25 to 30% in the surface, irrespective of the absolute quantities of silica and potassium oxide present.

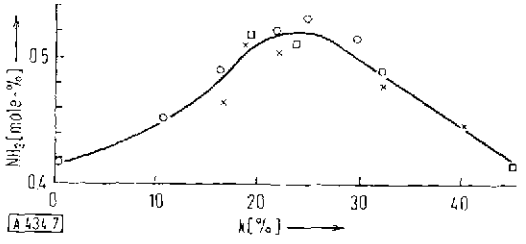

Fig. 7. Dependence of the catalytic activity on the percentage of free-potassium surface area (k) with respect to the total surface area (surface concentration of free potassium) for
Fe–Al_2O_3–K_2O–CaO(MgO)–SiO_2 catalysts.

○: with 2.2% by weight of SiO_2.
×: with 4.2% by weight of SiO_2.

3. Discussion

The metal oxides added to magnetite as activators can be grouped according to their influence on the surface structure and on the catalytic action of the reduced ammonia catalyst. Acidic and amphoteric oxides such as silica and alumina stabilize a fine-pored iron structure with a large surface area during reduction and use, and prevent the sintering of high-energy crystal faces which are particularly active catalytically or which are geometrically favorable to adsorption. The differences in the activities of the oxides are partly caused by different solubilities and distributions in the magnetite. The advantageous effect of alumina on technical ammonia catalysts is undoubtedly due to the ease with which the relatively small trivalent aluminum ion can replace the trivalent iron ions in the magnetite lattice or can occupy vacant interstitial sites without altering the crystal structure [3].

The alkaline earth oxides have a similar stabilizing effect, particularly when used in combination with acidic or amphoteric oxides. The divalent alkaline earth ions can replace ferrous ions in the magnetite lattice, the smaller magnesium ion being more easily accommodated than the calcium ion. The resultant ease of distribution of magnesium in the magnetite may explain the fact that magnesium has a more efficient stabilizing action than calcium in the absence of other promotors.

The mutually reinforcing effects of calcium and aluminum or of calcium and magnesium may be related to the effect described by *Nielsen* [4], *viz.* that the introduction of larger cations into the magnetite lattice is facilitated by the presence of smaller ions already dissolved therein. This picture is undoubtedly still too incomplete to explain all the differences in the stabilizing actions, *e.g.* of magnesium and aluminum. Magnesium inhibits recrystallization to a lesser extent than aluminum, although it can enter the magnetite lattice without difficulty. It may be possible to interpret differences of this kind on the basis of a theory of recrystallization advanced by *Kummer* [*].

Investigations on tungsten and nickel with the aid of the field-emission microscope suggest that the surface layer of the ammonia catalyst is constantly reorganized during the course of the synthesis as a result of chemisorption and desorption. Certain crystal faces have a stronger tendency to grow than others, and smaller crystallites tend to coalesce to larger ones. This coalescence can obviously be hindered by a surface barrier of promotors. The effect will increase with decreasing permeability of the barrier, *i.e.* with decreasing diffusion coefficient of the iron atoms or iron ions in the lattice of the promoting oxide. This will depend both on the crystal structure of the oxide and on the lattice disorder. For example, our investigations have shown that in the presence of traces of gaseous oxygen compounds, catalysts promoted with alumina alone probably form mixed spinels between magnetite or γ-alumina and the iron-alumina spinel. These mixed spinels are probably more permeable to diffusing iron atoms than the pure γ-alumina spinel, which is presumably the material of which the barrier is formed when the synthesis gas does not contain oxygen. This explains the acceleration of the recrystallization caused by oxygen compounds.

The alkali metal oxides have quite a different effect. Although these compounds accelerate rather than inhibit the recrystallization, they increase the ammonia output per unit of total surface area, particularly at high pressures. Singly promoted catalysts containing acidic or amphoteric oxides and the catalysts containing potassium also show fundamental differences in their effect on the decomposition and synthesis of ammonia, the rate of hydrogen-deuterium exchange, or the adsorption capacity for nitrogen and hydrogen. Table 7 contains a list of the various effects compiled by *Frankenburg* [2] and supplemented by ourselves on the basis of more recent work.

Frankenburg believes that the surface of the reduced catalyst stabilized by metal oxides such as alumina consists of atoms of metallic iron, intimately mixed with weakly acidic oxide centers. Proton acidity may be due to the adsorption of water, which is always present in traces in the synthesis gas. This view is in agreement with both the greater capacity of singly promoted catalysts for the chemisorption of hydrogen at −195 °C, and the ability of the catalysts containing no alkali to catalyse hydrogen-deuterium exchange at this temperature, if these properties are attributed to acidic centers (as in cracking catalysts). A further argument for the acidic character of the alkali-free catalysts is the formation of

[*] Quoted by *A. Nielsen* [4].

Table 5. Comparison of singly promoted Fe—Al_2O_3 catalysts with doubly promoted catalysts containing potassium.

Properties of the catalysts	Singly promoted with Al_2O_3	Doubly promoted with Al_2O_3 and potassium	Ref.
Chemisorption of hydrogen at −195 °C	Occurs	Extremely slight	[2]
Rate of H_2/D_2 exchange at −195 °C	half-life = 0.06 sec	half-life = 6000 sec	[2]
Influence of preadsorbed N_2 on the chemisorption of H_2 at −195 °C	Increase in chemisorption indicates formation of NH and NH_2 groups in the adsorption layer	Decrease in chemisorption	[2]
Kinetics of the decomposition of ammonia	Anomalous kinetics between 400 and 420 °C: rate of reaction decreases with pNH_3 and increases with pH_2	Rate of reaction increases uniformly with pNH_3 and decreases with pH_2 over the entire temperature range	[2]
Kinetics of the synthesis of ammonia	Satisfies a rate equation deduced on the assumption that the surface is covered with NH radicals; the rate-determining step is the adsorption of nitrogen[*]	Satisfies the Temkin rate equation deduced on the assumption that the surface is preferentially covered with adsorbed nitrogen atoms; the rate-determining step is the chemisorption of N_2. On partial poisoning with O_2, the kinetics are as for potassium-free catalysts[*]	[5-7d, 23]
Adsorption of H_2S at 400—500 °C	The potassium-activated catalyst adsorbs more sulfur per unit of area than catalysts activated by alumina alone		[9]
Specific catalytic activity	The specific catalytic activity of potassium-activated catalysts is greater than that of catalysts activated by alumina alone, particularly at high pressures		[3]

[*] It has repeatedly been assumed [7c, 7d] that a step following the adsorption of nitrogen is rate-determining. However, it has also been doubted [23] that a rate-determining step exists at all.

stable NH and NH_2 radicals on the catalyst surface during the decomposition and synthesis of ammonia; this may be compared to the poisoning of cracking catalysts by nitrogen bases. The lower adsorption capacity of the singly promoted iron-alumina catalysts for hydrogen sulfide points in the same direction.

Neutralization of the surface with alkali or more strongly basic alkaline earth oxides leads to the disappearance of these effects, but gives rise to a new type of catalyst. This is the simplest explanation for the fact that the activity of catalysts containing potassium is not related to the total content of potassium oxide, but to the basicity of the surface of the reduced catalyst. The promoting action of potassium can thus be explained from a more chemical point of view: potassium eliminates the inhibition of the ammonia synthesis caused on potassium-free catalysts by adsorbed NH, NH_2, and NH_3 particles, by accelerating further reactions of the radicals or desorption of the ammonia formed.

Mechanization of Chemical Documentation

BY DR. ERNST MEYER

BADISCHE ANILIN- & SODA-FABRIK AG., LUDWIGSHAFEN/RHEIN (GERMANY)

Published on the occasion of the 100th anniversary of the establishment of Badische Anilin- & Soda-Fabrik AG., on April 6th, 1965.

The principal reasons for the failure of mechanized documentation to gain wide acceptance in chemistry are the inflexibility of the systems used and the difficulties encountered in precisely formulating all search questions. The present paper describes documentation methods for structural formulae, reaction types, and other data; these methods are more flexible than those commonly used. To avoid the use of electronic computers for simple enquiries, it is suggested that small card files should be supplied ready-encoded from a central store, and mechanically sorted in accordance with the code which best suits the particular case

Chemistry, more than any other branch of science, is founded upon innumerable experimental experiences, which may be repeated at any time, and which are described in the technical literature. It is therefore particularly important to make this literature readily accessible; consequently, chemical documentation has become highly developed.

In his search for literature references, the chemist is aided by the well-known reference books (*e.g.* "Gmelin", "Beilstein", "Houben-Weyl", *etc.*) and by the indexes of the abstracting

journals (Chemisches Zentralblatt, Chemical Abstracts). As the technical literature increases in volume, however, queries must be fitted more closely to the problem at hand, with the result that these traditional aids are becoming increasingly inadequate. For this reason, individual card files have been compiled. These files are growing at an alarming rate, and a great deal of work is involved in the classification and filing of newly published material. The obvious solution is to make use of mechanical aids and data processing equipment.

The great difficulty in documentation lies in the volume of the material to be processed and in the wide variety of possible questions. A good documentation system should be sufficiently flexible to permit the storage and retrieval of information of an entirely new nature without changing the code book. Also the store should be able to answer questions which were not foreseen when it was compiled. It must be possible to formulate questions to the store so precisely that a minimum of irrelevant material is retrieved, while at the same time no important information is missed. And finally the costs of encoding, storage, and retrieval must not be excessively high.

It is only when these requirements are met that mechanized documentation systems will be satisfactory even for very large quantities of data. The development of methods and equipment in this field is still in its infancy. The first objective, therefore, is to evolve sufficiently flexible systems. Two methods of coding are described in the present paper, neither of which has yet fully proved its value in practice. They are nevertheless published at this stage in order to promote the exchange and progress of ideas.

1. Documentation of Structural Formulae

One aspect of chemical documentation is concerned with information which can be conveyed by structural formulae. This information consists of "hard" data, *i.e.* of data the meaning of which is unambiguous and sharply defined. On the other hand, the number of criteria involved here and of their possible combinations is particularly large. This justifies the application of methods other than those used in dealing with information which cannot be represented by formulae. Nevertheless, both documentation systems must be capable of combination, since many questions relate to structures as well as to other criteria.

The chemist must be able to ask for any desired structure or partial structure. As early as 1951, *C. N. Mooers* [1] pointed out that queries regarding partial structures are possible if a topological coding system [2] is used. In this system, the atoms of a molecule are numbered, in any order; the code for each atom includes, in addition to its number and symbol, the numbers of the atoms to which it is attached (Fig. 1). Multiple bonds and other special features can be denoted by additional code numbers, together with the numbers of the atoms involved.

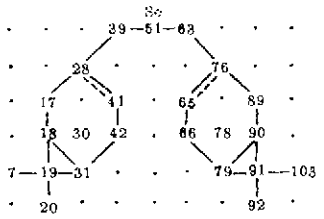

Fig. 3. Topological representation (top, read horizontally from left to right) and formula, showing the numbering of the grid positions.

The punched tape is then passed to an electronic data processor, which prepares the topological representation (Fig. 3, top) and simultaneously prints out the formula (Fig. 4, top), so providing a check on the coding

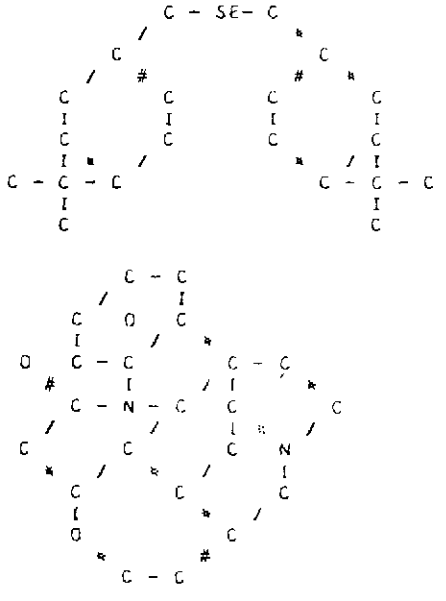

Fig. 4. Structural formulae reconstructed by the computer from topological representations (bottom: strychnine).

The topological method is complicated by the need to store and enquire about incompletely defined structural formulae (*e.g.* with substituents at undefined locations in a ring), formulae with variable substituents (Markush formulae [4]), and even chemical reaction schemes. However, these problems can be solved. For example, reactions are encoded [4a] by superimposing transparent gridded sheets containing the formulae of the starting materials and the final products in such a way that identical atoms obtain the same grid point numbers.

As an example, Figure 5 shows the reaction of a bromo compound (sheet A) with acetoacetic ester (sheet B) to yield a ketone (sheet C). Ethanol and carbon dioxide, which are also formed, are trivial in this connection and are therefore omitted. Later, queries can be largely varied: it is possible to enquire about syntheses using acetoacetic ester in general, or about syntheses with acetoacetic ester and α,β-unsaturated bromo compounds. Even more specific, reactions involving α,β-unsaturated β-branched or α,β:ε,ζ-unsaturated bromo compounds can be searched for. To this end, the reaction scheme must be keyed onto the tape together with the index numbers of the individual gridded sheets (A, B, and C in the case of Figure 5). It is then possible at a later date to enquire not only about any conceivable partial structure, but also about any type of reaction which can be represented by a series of partial structures. This is an important feature, since most of the queries from preparative chemists are basically concerned with reactions.

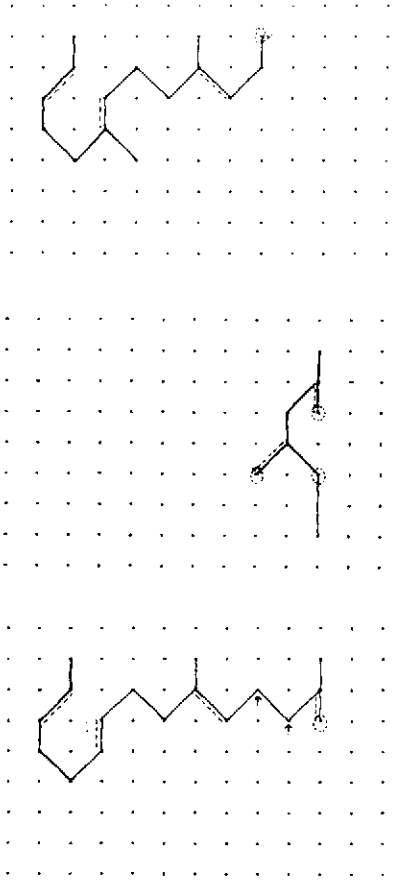

Fig. 5. Encoding of chemical reactions (cf. text). Partial structures of various sizes in the starting materials and products can later be searched for. If equivalent atoms in these structures are topographically identical, *i.e.* occupy equivalent positions on the gridded sheets, all reactions are obtained which can be described by the given scheme of partial structures.

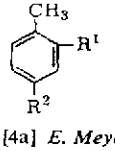
[4] *Markush* established the permissibility, in U.S. Patent law, of claims which protect groups of substances. For this reason, the term "Markush formula" is given to a formula which represents several definite compounds by the use of variable substituents, *e.g.*



$R^1 = NH_2, NHCH_3, OCH_3;$

$R^2 = NO_2, CF_3.$

[4a] *E. Meyer*, Nachr. Dokumentat. *13*, 144 (1962); ADI Annual Meeting 1963, Short Papers, Part 2, p. 131.

Thus satisfactory solutions to the problem of topological coding had been found [5]. There remained the question whether searches could be carried out at acceptable costs. Preliminary tests with an IBM 704 showed that the time required for comparing a structural formula, atom by atom, with all the formulae in the store is too long by at least one order of magnitude. Therefore, the number of comparisons required for each query must be reduced to comprise only about one percent of the formulae in the store.

In searches for single compounds, this would present no difficulties. The machine would first check the empirical formula, the number of rings, double bonds, *etc.*, and would then have only a small number of isomers to examine for topological equivalence with the formula in question. However, a search of this type can be more easily accomplished by the old method, using a formula index. The problem becomes more severe when searching for classes of compounds which can be described only by partial structures. Here it is necessary to use other criteria for the preliminary examination of the structures in the store. For example, the topological representations may be prefixed by code signs indicating characteristic groupings in the compounds. This would double the work involved in coding, however, and would be acceptable only if the code for preliminary examination could be produced mechanically and automatically from the topological representations of the compounds. Work is being carried out at present on machine programs for transcoding operations of this type. In addition, new methods of topological comparison have been developed at Harvard University [9] which seem to be less time-consuming than those used by us. It can therefore be expected that topological systems will soon find practical application.

2. Documentation of Other Information

Data regarding processing, applications and other topics should also be stored in such a form, that they can be searched for by machine and from as many viewpoints as possible. At present, these data are coded by pure classification: key words or criteria relating to a given document (*i.e.* to a literature reference) are selected from a questionnaire or code book, and are punched and stored. This procedure has the disadvantage that concepts which do not fit accurately into the scheme of the code (in particular those which are new) cannot be satisfactorily characterized. The code must be modified and supplemented at regular intervals, with the result that the store becomes increasingly heterogeneous, and search becomes increasingly difficult.

In the case of large stores, the documents must be very thoroughly analysed. Not only must the code book include a very large number of terms, but a very large number of criteria must also be recorded for each document. This makes coding more difficult and increases the volume of unwanted material retrieved by multiplying the number of spurious combinations of code terms which do not, in fact, relate to the document in question.

Is was therefore attempted to move away from pure classification and, as in language, to establish syntactical relationships between the code terms, which can be searched mechanically. At the same time this would make possible the synthesis of composite terms, thus permitting a considerable reduction in the size of the vocabulary or code. The "links" and "role indicators" [9a] which are occasionally used may be regarded as first steps in this direction. Since the store is only intended to supply sufficient information for reliable retrieval, the vocabulary and syntax of "machine language" can be much more limited than in natural language. In order to keep the costs of searching as low as possible, the vocabulary and syntactical relationships must be standardized. Moreover, the code for chemical compounds (even the topological code) must be compatible with this system, to permit the inclusion of structural features and reaction types in a complex statement of facts. The most important requirement, however, is that there should be no significant increase in the work involved in coding. All these requirements are largely satisfied by the following procedure.

The first step in coding is to select the various key concepts from the document and to list these in any order in the form of their notations [9b], or in the case of chemical compounds, in the form of their topological representations. The notations used should be such that the machine can recognize the broader concept to which any subconcept belongs; this condition is automatically satisfied by the topological representations.

Each concept on the list is assigned an identification number, which relates only to the particular document in question. The operator pencils these numbers against the appropriate key words or formulae in the document. The next step is to build up "sentences", which give an unambiguous representation of the essential information contained in the document. These "sentences" consist of the appropriate identification numbers syntactically linked by functional signs (Table 1), just as the individual quantities in a mathematical expression are linked by operators.

[5] In the meantime, two methods involving acceptable costs have been developed in the U.S.A. However, one of these [6] seems not to permit the coding of reactions; the other [7] requires considerably more manual work, although it does not involve the use of a special machine. A method [8] of optical scanning using a commercially available device (television camera) is also under development, but the cost of data processing by this method will probably be rather high.

[9a] "Links" are code signs which are attached to two or more key words or notations, and which represent a particularly close relationship between these. "Role indicators" show the sense or connection in which the concepts are used, *i.e.* the role played by a concept in a statement.

[9b] "Notation" here means a sign, preferably an alphanumeric code, representing a concept.

Table 1. Syntactical operators.

Symbol and transcription	Explanation
A "as"	adjectival relationship, physical state, *e.g.* "oxidation *in* the gas phase", "azeotropic mixture". The number corresponding to the broader concept precedes, that corresponding to the explanatory concept follows operator A.
C "with"	equivalent substances or agents, *e.g.* reaction of "carboxylic acids *with* olefins"
E "with or without"	substances or agents which should or may be present, but are not necessarily so, *e.g.* dyeing of "polyester fibers *with or without* added wool".
G "of"	relationship between process and substrate, *e.g.* "esterification *of* carboxylic acids".
I "from"	relationship between end product and starting material, *e.g.* "aromatic compounds *from* alicyclic compounds".
L "by"	"in the presence of" (auxiliary substances, apparatus), *e.g.* "hydrogenation *with* Raney nickel", "atomization *by* a nozzle"
N "for"	use, application, purpose, *e.g.* "phenols *as* stabilizers".
P "at"	quantitative statement of reaction conditions, *e.g.* "decarboxylation *at* 120 to 150 °C".
R "then", "before"	chronological order, *e.g.* distillation *followed* by drying.
v "or"	disjunction, links alternatives, *e.g.* "with phosgene *or* thionyl chloride".
– "not"	"in the absence of" (negation); precedes the identification number in question and is used together with one of the signs A through R.
( )	brackets are used as in mathematics to indicate a closer connection or to form subgroups in a sentence.
"period"	(end of sentence); terminates a proposition which completely describes a state of affairs.

The machine program can be designed in such a way that concepts associated with certain operators (*e.g.* v, A, E, N, P, and R) can be retrieved, even when the operators are not named in the question, whereas other operators must be specifically requested or allowed for. As a result, the machine will retrieve those documents, too, in which things are described and encoded in greater detail than in the question.

The use of brackets and disjunction operators ("v") permits the expression of complex relationships and affords the analyst considerable freedom in representing them, so that he is not too much restricted by the need to choose the correct formulation. The machine resolves these composite expressions during the search (or even during the storage operation) in accordance with the rules of Boolean algebra [10]. To avoid the need for large numbers of brackets in establishing unambiguous relationships, an order of precedence is set up for the operators: an earlier letter of the alphabet represents a closer relationship than a later one (just as the multiplication sign takes precedence over the addition sign in algebra).

[10] Boolean algebra is a method of expressing logical relationships ("and", "or", "not") by matematically exact formulae. These formulae can be manipulated in accordance with certain rules, just as equations are used to carry out calculations in ordinary algebra.

As an example, we shall now illustrate the procedure for encoding the following abstract [10a]:

"Catalytic ⑥ alkylation ⑤ of an isoparaffin ② with an olefin ③. An excess ① of the isoparaffin, *e.g.* isobutane ②, is brought into contact with the olefin ③ in a reaction zone, in the presence of an acidic ⑬ catalyst ⑥ such as sulfuric acid ④. The mixture consisting of the catalyst, the excess isoparaffin, and the reaction product is removed from the reaction zone. The catalyst ⑥ is almost completely eliminated ⑫ from the mixture, and the residual hydrocarbon phase is led into a fractionating zone. The improved procedure consists in subjecting at least the greater part of the hydrocarbon phase to flash ⑦ evaporation ⑧ before it enters the fractionating zone. The isoparaffin ② vapor released during the flash evaporation is condensed ⑨, and the condensate is returned ⑩ to the reaction zone".

The list of concepts used for coding here is as follows:

1 ..... (notation for "excess")
2 ..... (notation or topological representation for "isobutane", which is a sub-class of the class of "isoparaffins")
3 ..... (notation or topological representation for "olefins")
4 ..... (notation or topological representation for "sulfuric acid")
5 ..... (notation for "alkylation")
6 ..... (notation for "catalyst, catalysis")
7 ..... (notation for "rapid")
8 ..... (notation for "evaporation")
9 ..... (notation for "condensation")
10 ..... (notation for "recycling")
11 ..... (notation for "fractionation")
12 ..... (notation for "removal, separation")
13 ..... (notation for "acid, acidic")

Using the operators of Table 1, the following sentences are obtained:

5 A 6 G 2 C 3.

2 A 1 C 3 L (4 v 6 A 13) R 12 G (4 v 6) R 8 A 7 R 11 R 9 G 2 R 10 G 2.

From these sentences the abstract can be reconstructed, just as a structural formula can be reconstructed from its topological representation (although somewhat less accurately): "Catalytic alkylation of isobutane with olefins. Excess isobutane (reacts) with olefin in the presence of sulfuric acid or an (other) acidic catalyst; then separation of the sulfuric acid (or) of the catalyst; then rapid evaporation; then fractionation; then condensation of isobutane; then recycling of isobutane."

As has already been mentioned, the notations should show a "hierarchy" of concepts. For example, if the concept "acids" was assigned the notation "47", "mineral acids" could be represented by "47.1", and "sulfuric acid" by "47.1.1". Then if the machine is questioned about "47", *i.e.* about acids in general, the references in which sulfuric acid is named will automatically be included in the documents selected. The same applies to the series: isobutane – isoparaffins – paraffins. If the store gives no answer to a query, the question can be generalized step by step until suitable references are obtained.

The code sentence thus contains the essential facts completely and unambiguously, so that any piece of information which is implicit in the coded abstract can be sought out mechanically, just as partial structures can be retrieved from a topological representation. Admittedly, the length of the machine program required for this search will be considerable; however, the computer time needed will not be as long, since the notations specified in the question are first checked

[10a] The numbers to the key words were not present in the original abstract but were inserted by the analyst.

against the list of concepts, so that it is unnecessary in the majority of cases to recheck the sentences printed by the machine.

3. Supplying Other Card Indexes

A great disadvantage of the methods described, as in all mechanized documentation with very large stores, is that they require the use of punched-card machines or electronic data processing equipment. This makes it difficult for these methods to gain acceptance, since even simple queries must first be translated into machine language and punched on tape or cards. The answer will then be obtained after the next machine run at the earliest. Owing to these difficulties, many questions which could be answered immediately by a card index, undoubtedly would remain unasked.

Card indexes become too large unless they are confined to selected fields. They are useful only if the code book used is specially designed for that particular field, and this is the main reason why it has not so far been possible to coordinate them and provide them with ready-coded material from a central supply. However, electronic data processing may also provide a solution to this problem. Thus if all the criteria used by a customer in his code book can be retreived individually from a large electronic store, then the document numbers supplied by the machine can be punched into IBM cards each containing *e.g.* 500 punching positions. One card per set is provided for each criterion, with holes in the positions corresponding to the documents which exhibit this criterion.

At first, these punched cards are used as peephole cards, *i.e.* the cards corresponding to the criteria in question are placed on top of one another and held up to the light. The punch positions of the documents containing all the criteria requested then shine through. When 5000 documents (*i.e.* ten sets of punched cards) have been processed, the cards are transferred to a single set of normal peephole cards to facilitate handling during further enquiry; this operation can be carried out with special machines.

It may be possible in this way to reduce the high cost of independent handling and encoding of the same technical literature in many small card indexes. However, a prerequisite (apart from the existence of suitable machine programs) is a large mechanized information store permitting great flexibility in the formulation of queries.

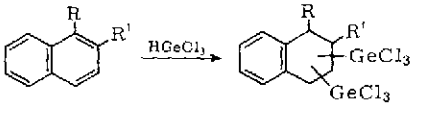
Hydrogermylation of Aromatic Compounds

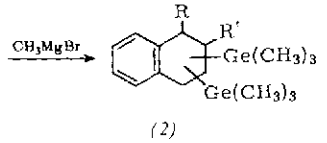
By S. P. Kolesnikov and Dr. O. M. Nefedov

N. D. Zelinskii Institute of Organic Chemistry of the Academy of Sciences of the U.S.S.R., Moscow (U.S.S.R.)

When 0.05 mole of naphthalene is heated for 10–15 min at 110–130 °C with 0.05 mole of $HGeCl_3$ and the mixture is subsequently methylated with excess methylmagnesium bromide in ether, a 52.5 % yield of 1,3-bis(trimethylgermyl)-1,2,3,4-tetrahydronaphthalene *(2)*, R = R′ = H, b.p. 100 to 102 °C/0.2 mm, is obtained.



(1)



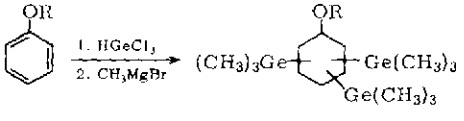
(2)

The structure of this product was proved by its infrared spectrum. Its NMR spectrum at 60 Mc with tetramethylsilane as internal standard contains signals at 0.06 and 0.12 ppm for the methyl groups on the germanium, at 2.75 and 2.49 to 2.60 ppm for non-aromatic methine protons, and at 6.86 and 6.94 ppm for aromatic protons, plus two multiplets at 1.90 and 2.58 ppm for the methylene groups. Dehydrogenation of the new compound *(2)* with selenium for 3 h at 290–300 °C or by refluxing it with chloranil in xylene for 10 h yields naphthalene in 65–80 % yield.

Apart from *(1)*, R = R′ = H, pentakis(trichlorogermyl)decahydronaphthalene is formed in 10–20 % yield during the reaction of naphthalene with $HGeCl_3$.

Hydrogermylation of 1-methylnaphthalene under identical conditions leads within 5 min to a bistrichlorogermyl derivative, which on methylation affords a 1-methylbis(trimethylgermyl)-1,2,3,4-tetrahydronaphthalene, b.p. 101 to 104 °C, in an overall yield of 62 %. The addition of $HGeCl_3$ onto dimethylnaphthalenes or anthracene, phenanthrene, and their derivatives proceeds with equal ease.

$HGeCl_3$ does not react with benzene, toluene, or the xylenes under these conditions. Alkoxybenzenes, on the other hand, do yield adducts. For example, when anisole is heated for 8.5 h with an equimolar amount of $HGeCl_3$ at 110 °C and the product is then methylated, a mixture of isomeric methoxytris(trimethylgermyl)cyclohexanes *(3)*, R = CH_3, is produced.



(3)

1-Methoxy-1,3,5-tris(trimethyl)cyclohexane, m.p. 66 °C, b.p. 105–107 °C/0.6 mm, can be isolated in 32 % yield from this mixture by distillation. The infrared spectrum of this compound contains bands characteristic of its methylgermyl and methoxy groups. Its NMR spectrum contains two singlets at 0.07 and 0.13 ppm (intensity ratio 2:1) due to the methyl groups on the germanium atoms, a multiplet at

1.0–2.0 ppm due to the methylene and methine protons, and a singlet at 3.14 ppm due to the methoxy group.

Heating of ethoxybenzene with $HGeCl_3$ for 0.5 h at 110 to 130 °C and subsequent methylation lead to the ethoxy derivatives corresponding to *(3)*.

It is remarkable that the reaction of alkoxybenzenes and $HGeCl_3$ does not give rise to trichlorogermylbenzene, since refluxing of dialkyl ethers with $HGeCl_3$ produces alkyltrichlorogermanes in yields of 35–40 % [1].

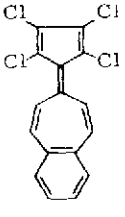
1,2,3,4-Tetrachlorobenzo[g]sesquifulvalene [1]

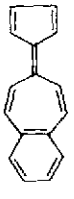
By Prof. Dr. Y. Kitahara, Dr. I. Murata, and Dr. S. Katagiri

Department of Chemistry, Tohoku University, Sendai (Japan)

We have found that the reaction of tropone with 1,2,3,4-tetrachlorocyclopentadiene in methanol affords a mixture of 1,2,3-trichloro-6-(*o*-methoxyphenyl)fulvene and the corresponding *p*-isomer [2]. The formation of fulvene derivatives can be avoided by using benzo[*d*]tropone. Thus, treatment of 3.12 g (0.02 mole) of benzo[*d*]tropone with 4.08 g (0.02 mole) of 1,2,3,4-tetrachlorocyclopentadiene in 150 ml of methanol at room temperature leads within about 44 h to 1,2,34,-tetrachlorobenzo[*g*]sesquifulvalene *(1)* in a maximum yield of 15 % (0.51 g).



(1)



(2)

The structure *(1)* was confirmed by X-ray crystallography [3]. The new compound crystallizes in violet needles, m.p. 234 °C (decomp.), λ_{max} in methanol at 241 mμ (log ε = 4.38), 320 mμ (3.95), and 480 mμ (4.44). The dipole moment in benzene at 25 °C is 5.20 D. This implies a strong π-electron displacement from the seven-membered ring into the five-membered ring, leading to a highly polar structure. If the dipole moment of the four chlorine atoms is subtracted (−1.1 D) [4], a dipole moment of 4.1 D results for benzo[g]-sesquifulvalene *(2)*. This (theoretical) dipole moment is the highest ever calculated for a hydrocarbon.

Uvanite, a Swelling Uranyl Vanadate with a Layer Structure

By Prof. Dr. Armin Weiss and Dipl.-Chem. K. J. Hilke

Anorganisch-Chemisches Institut
der Universität Heidelberg (Germany)

Uvanite [1] is a rare, earth-like, brownish-yellow mineral, whose structural formula should be written as follows:

$$\underbrace{M^{\oplus}(H_2O)_x}_{\text{exchangeable cations and swelling liquid}} \quad \underbrace{[UO_2 V_3O_9]^{\ominus}}_{\text{anionic layer lattice}}$$

So far we have been unable to decide with certainty whether part of the water is attached to the trimetavanadate ion. In the formula given for the mineral in the literature [2], the exchangeable cations are neglected as impurities. The anionic layer lattice has a trigonal structure with a = 6.87 Å. It is decomposed by aqueous alkaline solutions. The unit cell contains only one formula unit.

The cations $M^{\oplus}$ can be interchanged with other cations, including primary or quaternary alkylammonium cations. The exchange capacity is about 177 mval per 100 g of mineral after drying at 110 °C. The water content and basal plane spacing depend on the atmospheric humidity and the nature of the exchangeable cations in the sample. When alkylammonium ions are present, swelling also occurs with numerous polar organic compounds (see Table). The basal cell edge remains unaltered.

The X-ray diffraction pattern contains only (hk) bands, which tail off toward larger angles (cross-lattice interferences), and (001) reflexes.

Redox Potentials of Phenol-Phenoxyl Systems

By Priv.-Doz. Dr. H. Mauser and Dipl.-Chem. B. Nickel

Institut für Physikalische Chemie der Universität Tübingen (Germany)

Up to the present, redox potentials of phenoxyl radicals could not be measured directly. Platinum is unsuitable as electrode material because it catalyses electrolytic oxidation of the solvent too strongly at high electrode potentials.

We have found that sintered boron carbide electrodes [1, 2] react reversibly to the redox equilibrium

$$C_6H_5OH \rightleftharpoons C_6H_5O\cdot + H^{\oplus} + e_0^{\ominus}$$

in acetate-buffered ethanolic solution (but not in 0.01 N HCl in ethanol). The e.m.f. of the cells

$$Pt/Hg/[Hg_2Ac_2]\ldots/\ldots C_6H_5OH,\ C_6H_5O\cdot/B_4C/Hg/Pt$$

and

$$Pt/Hg/[Hg_2Ac_2]\ldots/\ldots/H_2,\ Pt$$

(electrolyte: $C_2H_5OH/[NaAc]$, $[HAc] \leq 0.1$ mole/l)

was measured at 15.0 °C. The difference E between the two e.m.f.'s is independent of the pH, provided the electrolyte composition is the same in both cells.

$$E = E_0^h + \frac{RT}{F} \ln \frac{[C_6H_5O\cdot]}{[C_6H_5OH]} + \frac{RT}{2F} \ln p_{H_2}$$

E_0^h is the redox potential.

Substance [a]	λ_{max} [mμ]	ε_{max} [l/mole/cm]	10^4 K [mole/l]	E^h_{redox} [mv]	100 k [h]
(1)	694 ± 5	712 ± 20	1.07	1203.6 ± 0.5	52
(2)	694 ± 5	795 ± 40	0.50	1203.4 ± 0.5	54
(3)	629 ± 5	411 ± 10	∞	1023.2 ± 1.0	0.6
(4)	496 ± 2	2780 ± 50	∞	1008.8 ± 1.0	0.23

[a] *(1)* = 2,6-Di-t-butyl-4-methoxycarbonylphenoxyl; *(2)* = 2,6-di-t-butyl-4-ethoxycarbonylphenoxyl; *(3)* = 2,4,6-tri-t-butylphenoxyl; and *(4)* = 2,6-di-t-butyl-4-phenylphenoxyl.

The dimeric phenoxyls *(1)* and *(2)* were prepared according to [3] and recrystallized under nitrogen at −40 °C from petroleum ether/benzene (10:1). In solution, the blue-green monomeric phenoxyl radicals are present in equilibrium with their colorless dimers. The dissociation constants $K = [C_6H_5O\cdot]^2/[(C_6H_5O\cdot)_2]$ and the molar extinction coefficient ε_{max} were determined from the concentration dependence of the optical density $A = d\cdot\varepsilon_{max}\cdot[C_6H_5O\cdot]$ at the maximum of the long-wave absorption band. The phenoxyls *(3)* and *(4)* were prepared by partial electrolytic oxidation of solutions of the corresponding phenols directly within the spectroscopy cell.

The gradation of the redox potentials (see Table) cannot be expressed using the Hammett σ constants.

The decomposition of the phenoxyls is a first order reaction (rate constant k) relative to the concentration of the monomeric phenoxyl.

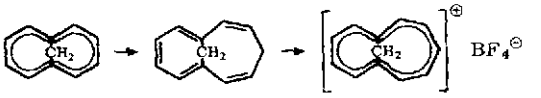
Synthesis of the Bicyclo[5,4,1]dodecapentaenylium Cation — a Carbonium Ion with 10 π-Electrons

By Dr. W. Grimme, Dipl.-Chem. H. Hoffmann, and Prof. Dr. E. Vogel

Institut für Organische Chemie der Universität Köln (Germany)

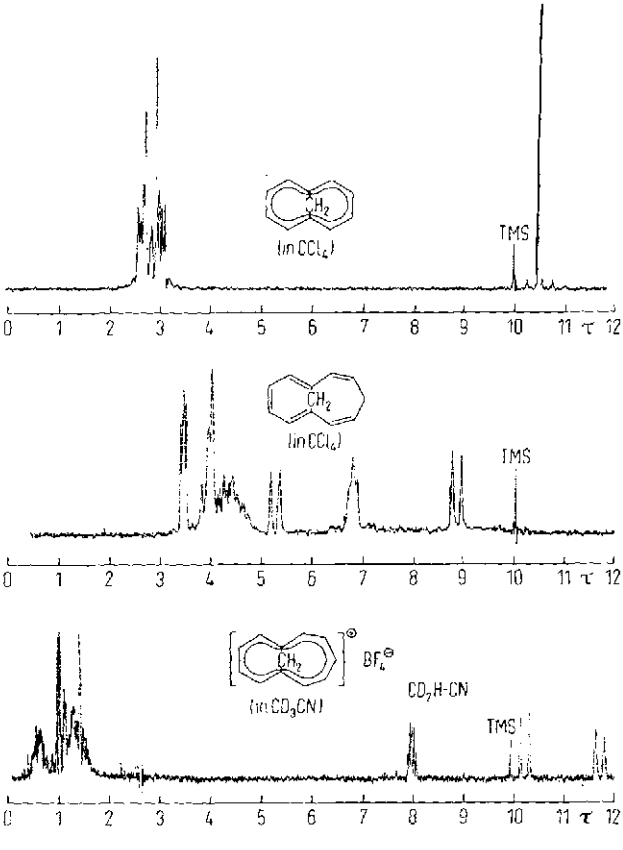
The fact that 1,6-methanocyclodecapentaene *(1)* [1] has a largely delocalized 10 π-electron system made it appear likely that the carbonium ion *(3)* [2] is capable of existence. The conversion of benzene *via* norcaradiene and cycloheptatriene into the tropylium cation served as a guide for the synthesis of *(3)*.



(1) *(2)* *(3)*

When *(1)* is treated with diazomethane in the presence of CuCl, the bright yellow olefin *(2)* is obtained, possibly in admixture with other isomers; *(2)* has a b.p. of 98 °C/1 mm, $n_D^{20} = 1.6375$, and λ_{max} in cyclohexane at 215 mμ (ε = 17500), 250 (13300), and 335 (3500). The conversion of *(1)* into *(2)* is clearly shown by NMR spectroscopy (see Figure): owing to the loss of the cyclic conjugation, the resonance signals for the vinylic protons shift from 2.3–3.2 τ for *(1)* to 3.3–4.7 τ for *(2)*, and the signal for the bridge protons, originally a singlet at 10.5 τ, splits into an AB system at 5.3 and 8.8 τ with J = 11 cps. The remaining signal group in the NMR spectrum of *(2)* at 6.2–7.2 τ is due to the methylene protons in the C_{11}-perimeter.

Reaction of *(2)* and triphenylmethyl fluoroborate [3] in acetonitrile gives rise by hydride transfer to a stable salt of formula $[C_{12}H_{11}]^{\oplus}BF_4^{\ominus}$ [4], yellow-orange needles from acetic acid, m.p. 185 °C (decomp.); this product has λ_{max} in 60% sulfuric acid at 272 mμ (ε = 31600), 302 (51800), 320 (14100), 385 (2300), and 423 (4000). The aromatic structure *(3)* ascribed



to this compound is again based largely on its NMR spectrum (see Figure), in which the signals for the ring- and bridge protons exhibit the expected large shifts to lower (0.4–1.7 τ) and higher fields (10.3 and 11.8 τ, $J = 10$ cps), respectively, relative to the signals in the spectrum of *(2)*. Compound *(2)* and the salt *(3)* must have the same carbon skeleton, for on catalytic hydrogenation both give the same saturated hydrocarbon $C_{12}H_{22}$, which we consider to be bicyclo[5,4,1]dodecane.

The NMR and ultraviolet spectra of *(3)* resemble those of the benzotropylium cation [5].

Reaction of Triphenylaluminum with Cyclohexyl Isonitrile

By Prof. Dr. G. Hesse, Dr. H. Witte, and cand. chem. P. Mischke [*]

Institut für Organische Chemie
der Universität Erlangen-Nürnberg (Germany)

When triphenylaluminum and cyclohexyl isonitrile are heated in xylene at 50–60 °C, compound *(1)* – the first representative of a new class of organoaluminum derivatives – is formed; it crystallizes out of the solution at −20 °C after removal of most of the xylene and addition of anhydrous petroleum ether.

$$(C_6\text{–}\overset{\ominus}{C}H_5)_3Al{=}\overset{\ominus}{N}\text{–}C_6H_{11} \qquad (1)$$

The product is colorless and is stable under pure nitrogen. It dissolves readily in benzene, ether, or carbon tetrachloride but is only slightly soluble in petroleum ether. It decomposes in air with liberation of cyclohexyl isonitrile. When heated, it begins to soften and to decompose slowly above 75 °C. Its structure was verified by its elemental analysis and infrared spectrum (sharp band due to the $-C{\equiv}\overset{\oplus}{N}$ group at 2215 cm^{-1}; $\tilde{\nu}_{-N\equiv C}$ for cyclohexyl isonitrile is at 2125 cm^{-1}).

The same compound was obtained by the following quantitative metathesis reaction:

$$(C_6H_5)_3\overset{\ominus}{B}\text{–}C\text{–}\overset{\ominus}{N}{\equiv}C_6H_{11}\ [1] + Al(C_2H_5)_3 \rightarrow (C_6H_5)_3\overset{\ominus}{Al}\text{–}C{\equiv}\overset{\oplus}{N}\text{–}C_6H_{11} + B(C_2H_5)_3$$

Here the method described by *Köster* [2] for the preparation of triethylboron from boric esters was used; the reaction product was crystallized and purified with petroleum ether.

Isolation of Benzoyl Radicals [1]

By Prof. Dr. Ulrich Schmidt, Dr. K. H. Kabitzke, and Dipl.-Chem. K. Markau

Chemisches Laboratorium der Universität Freiburg/Brsg. and Institut für Elektrowerkstoffe der Frauenhofer-Gesellschaft, Freiburg/Brsg. (Germany)

The formation of aldehydes, diketones, and numerous acyl compounds on irradiation of acyl chlorides and acyl bromides in solution [1,2] can be explained only by the photochemical formation of free acyl radicals. We have now succeeded in capturing the free acyl radicals formed on irradiation of aromatic acyl bromides *in vacuo* by condensation in a cold trap behind the site of exposure.

Despite its extremely low resonance energy (about 10 kcal/mole), the orange-red free benzoyl radical is stable at 70 °K and combines only above 140 °K with a bromine radical to yield benzoyl bromide within a few minutes. The free-radical nature of the condensate was proved by measurement of its strong electron spin resonance signal. The color and ESR signal disappear simultaneously on warming. The benzoyl radical was also detected and captured following photolysis of benzaldehyde. Homolytic cleavage of the C-H bond in aldehydes resulting from attack by a radical former has previously been assumed in order to explain the course of radical additions of aldehydes onto olefinic double bonds [3]. The ESR signals for the benzoyl radicals made from benzoyl bromide or from benzaldehyde were identical.

When *p*-chlorobenzoyl bromide and *p*-methoxybenzoyl bromide were photolysed, red-brown *p*-chlorobenzoyl and green *p*-methoxybenzoyl radicals, respectively, were caught in the cold trap. The ESR signals have a width (peak-peak) of about 15 gauss and exhibit slight anisotropy. The average g factors are about 2.006.

Thermolysis of Cycloalkyl Esters Yielding Cycloalkanones

By Ing. Hansdieter Hofman [*]

Forschungslaboratorien der H. J. Zimmer AG., Frankfurt/Main (Germany)

Cycloalkyl esters are cleaved at 330–450 °C on dehydrogenating catalysts to produce good yields of the corresponding cycloalkanones; cycloalkanols and cycloalkenes are formed as by-products. The rate of the reaction depends mainly upon the nature of the acyl group and decreases in the order formyl ≫ acetyl > propionyl > butyryl, valeryl. In the presence of hydrogen, the yield of cycloalkanone is 8–20 % higher. The catalyst used was zinc oxide containing 6.7 % CaO, 4.5 % Al_2O_3, and 1.6 % Cr_2O_3.

Cyclohexanol/cyclohexanone mixtures containing cyclohexyl esters such as are obtained by oxidation of cyclohexane with air can also be dehydrogenated to cyclohexanone by this procedure. For example, a mixture consisting of 64.3 % cyclohexanol, 28.3 % cyclohexanone, and 2.7 % cyclohexyl esters (calculated as acetate) were pyrolysed at 370 °C. The conversion of cyclohexanol and cyclohexyl ester was 80.3 %. The yield of cyclohexanone based on the amount of mixture

Cycloalkyl ester	Temp. [°C]	Conversion [%]	Cycloalkanone (yield [%])	Cycloalkene (yield [%])
Cyclopentyl acetate	400	76.1	cyclopentanone (65.5)	cyclopentene ([a])
Cyclohexyl formate	400	99.7	cyclohexanone (77.4)	cyclohexene (0.8)
Cyclohexyl acetate	400	82.6	cyclohexanone (50.3)	cyclohexene (20.8)
Cyclohexyl valerate	420	76.6	cyclohexanone (42.9)	cyclohexene (50.7)
Cycloheptyl acetate	410	94.6	cycloheptanone (49.2)	cycloheptene (33)
Cyclododecyl formate	420	97.2	cyclododecanone (71.6)	cyclododecene ([a])
Cyclohexyl formate [b]	400	100	cyclohexanone (trace)	cyclohexene (97.3)
Cyclohexyl formate [c]	410	5		cyclohexene (2.5)

[a] Yield not determined.

[b] Catalyst: γ-Al_2O_3.

[c] Catalyst: glass Raschig rings.

charged was around 97.8 mole-%. About 0.36 mole-% cyclohexene was formed as a by-product. The residual content of cyclohexyl esters (calculated as acetate) was only 0.3 %.

Synthesis of Cyclotri-L-prolyl, a Cyclotripeptide Having a Nine-Membered Ring [1]

By Priv.-Doz. Dr. M. Rothe and Dipl.-Chem. K.-D. Steffen, in collaboration with Dr. Ilse Rothe

Organisch-Chemisches Institut
der Universität Mainz (Germany)

No synthesis of cyclotripeptides has hitherto been achieved because linear tripeptides normally undergo dimerization during ring closure to give cyclohexapeptides with an unstrained 18-membered ring.

On cyclization of tri-L-proline [hemihydrate, m.p. 125 to 130 °C (decomp.)] using either the *p*-nitrophenyl ester or the phosphite method [2] and simultaneously applying the dilution principle, we obtained an 88 % yield of readily crystallizable, sublimable cyclotri-L-prolyl in thin-layer chromatographic and analytical purity [m.p. 338 °C (decomp.), $[\alpha]_D^{25} = +48.5°$ (c = 0.48 in methanol)]. The size of the ring is indicated by the partial hydrolysis of the compound with 0.1 N $Ba(OH)_2$ [5 min at 100 °C] to give proline, diproline, and triproline, and by the results of molecular-weight estimations (calc. 291; found by the method of Rast in 1,4-cyclohexanecarbolactam: 293; by mass spectrometry: 291 [3]).

L-Prolyl-L-prolylglycine, on the other hand, yields only the cyclohexapeptide [trihydrate, m.p. 242 °C (decomp.); $[\alpha]_D^{25} = -140.0°$ (c = 0.57 in water)] in 21 % yield by both ring closure methods. Here the infrared spectrum contains an amide II band at 1550 cm^{-1}, indicating *trans*-amide configuration of the 18-membered ring. Partial hydrolysis here gives rise to linear hexapeptides of molecular weight 502 (determined by mass spectrometry; calc.: 502).

Optically Active Trisbiphenylenephosphates

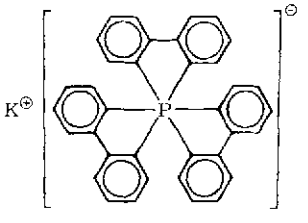
By Dr. D. Hellwinkel

Institut für Organische Chemie
der Universität Heidelberg (Germany)

The formal resemblance between the trisbiphenylenephosphate anion [1] and the chelate complexes of hexacoordinated transition metals [2] made it appear likely that this ate-complex *(1)* of pentavalent phosphorus would have an octahedral structure and should therefore be separable into optically active antipodes.

Treatment of lithium trisbiphenylenephosphate with an equivalent amount of *N*-methylbrucinium iodide in methanol results in quantitative precipitation of a mixture of the two diastereoisomeric *N*-methylbrucinium trisbiphenylenephosphates. Several recrystallizations from acetone led to a 25 % yield of pure (−)-methylbrucinium (−)-trisbiphenylenephosphate, m.p. 234–236 °C, $[\alpha]_{578}^{24.5} = 1250 \pm 15°$ (c = 0.8–1.0 in CH_2Cl_2). After removal of all crystalline fractions from the mother liquors, (−)-methylbrucinium (+)-trisbiphenylenephosphate, which does not crystallize out, can be precipitated with methanol; m.p. 230–234 °C. Here the highest rotations measured were $[\alpha]_{578}^{24.5} = 950 \pm 50°$ (c = 0.8–1.0 in CH_2Cl_2).

The diastereoisomeric salts react smoothly with potassium iodide in acetone to give *N*-methylbrucinium iodide and colorless potassium trisbiphenylenephosphates *(1)*, which have the remarkably high specific rotations $[\alpha]_{578}^{24.5} = \mp 1930 \pm 20°$ (c = 0.4–0.7 in acetone); $[M]_{578}^{24.5} = \mp 10150 \pm 100°$; m.p. 295–298 °C (decomp.).



(1)

When the optically active potassium or sodium salts *(1)* were treated with bisbiphenylenephosphonium iodide [1] in methanol, the two stereoisomeric yellow phosphonium phosphate complexes *(2)*, $[\alpha]_{578}^{24.5} = \mp 1265 \pm 15°$ (c = 0.7–1.0 in dimethylformamide), $[M]_{578}^{24.5} = \mp 10\,410 \pm 120°$, m.p. 247 to 250 °C (decomp.), were obtained.

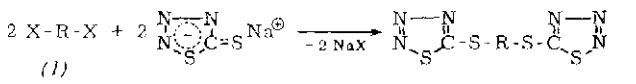
Bis-(1,2,3,4-thiatriazol-5-yl)thio Compounds with High-Explosive Properties

By Dr. K. Pilgram and Prof. Dr. F. Korte

Shell Grundlagenforschungs-Gesellschaft m.b.H.,
Schloß Birlinghoven/Siegkreis (Germany)

Sodium 1,2,3,4-thiatriazol-5-thiolate *(2)*, which can be prepared readily from sodium azide and carbon disulfide [1], reacts with α,ω-dihalogenoalkanes *(1)* in acetone/water (3:1 v/v) within several hours at about 10 °C to form α,ω-bis-[(1,2,3,4-thiatriazol-5-yl)thio]alkanes *(3)*.



(1) *(2)* *(3)*, R = $-(CH_2)_n-$, n = 1–4

X = Br, I

(4), R = 
(5), R = 
n	*(3)* Yield [%]	M.p. [°C] [a]
1	89.0	82 [b], 99
2	28.3	92
3	22.6	85
4	20.9	75

[a] With decomposition.

[b] Nitrogen is evolved without melting of the sample.

1,4-Bisiodomethylcyclohexane, m.p. 76–77 °C, reacts analogously with *(2)* to form *(4)* [2], m.p. 92 °C (decomp.), in 39.9 % yield. Dichloromaleimide reacts with *(2)* at only −15 to −10 °C in aqueous acetone to afford 58 % *(5)*, m.p. 92 °C (decomp.). The structures of *(3)*, *(4)*, and *(5)* were confirmed by elemental analysis, infrared spectroscopy, and thermoanalysis. Thermolysis of *(3)* between 50 and 75 °C in inert solvents affords nitrogen, sulfur, and α,ω-bisthiocyanatoalkanes *(7)*, which absorb in the infrared at 4.6 μ. The formation of isothiocyanates was not observed.

$$N\equiv C-S-(CH_2)_n-S-C\equiv N \quad (7)$$

Compounds *(3)* and *(5)* are stable at room temperature, but decompose when struck with a loud clear report. During melting-point determinations in a Büchi apparatus, the temperature of decomposition also was often indicated by a clear report.

Resolution of the Silicon Complex with 2-Hydroxypyridine N-Oxide into Its Enantiomers – Evidence for Octahedrally Coordinated Silicon

By Dr. D. R. Harvey and Prof. Dr. Armin Weiss

Anorganisch-Chemisches Institut
der Universität Heidelberg (Germany)

Partial resolution of the complex of silicon with 2-hydroxypyridine *N*-oxide (HPNO) [1] into its optical enantiomers by treatment with disodium (−)-dibenzoyl-L-tartrate (Na_2BT) confirms that silicon is 6-coordinated in this compound. The diastereoisomer (−)-$[Si(PNO)_3]HBT$ is less soluble than the other and precipitates preferentially from aqueous solution. A saturated aqueous solution of this precipitate gave a negative rotation which decreased with time (became more positive) as the asymmetric silicon complex decomposed, and finally reached a constant negative value due to the monohydrogen (−)-dibenzoyl-(L)-tartrate anion. The filtrate from the precipitation reaction gave a high positive rotation, which decayed according to first order kinetics at pH 1.8–1.9 and 25 °C with a half-life of about 70 minutes.

2-Hydroxypyridine *N*-oxide thus resembles acetylacetone in forming a cationic complex with silicon, in which the central silicon atom is octahedrally surrounded by six oxygen atoms [2]. However, whereas HPNO forms a complex with silicic acid even in aqueous solution, acetylacetone does not react under the same conditions.

HPNO also forms complexes analogous to those already known for acetylacetone with other elements, *e.g.* $Al(PNO)_3$, $Fe(PNO)_3$ or $[Sn(PNO)_3]_2SnCl_6$ (cf. also [3,4]).

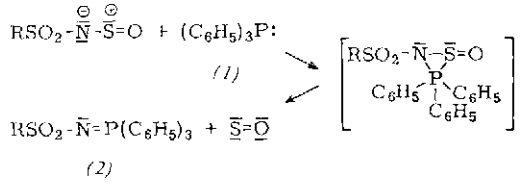
Reactions of *N*-Sulfinylsulfonamides with Organophosphorus Compounds

By fil. lic. A. Senning

Kemisk Institut, Aarhus Universitet, Aarhus (Denmark)

A new type of reaction was discovered when *N*-sulfinyl compounds were treated with triphenylphosphine *(1)*. Reaction of *N*-sulfinylmethanesulfonamide and *(1)* in a molar ratio of 1:1 in refluxing benzene affords 95 % methanesulfonyliminotriphenylphosphorane *(2)*, R = CH_3; analogously, *N*-sulfinyl-*p*-toluenesulfonamide and *(1)* give rise to 50 % of the corresponding iminophosphorane *(2)* with R = *p*-$CH_3C_6H_4$.



(1) *(2)*

The reaction can be interpreted in terms of attack by the coordinately unsaturated phosphorus atom (with expansion of its valence shell) at the semipolar nitrogen-sulfur bond. With triphenylphosphine sulfide, a quasi-Wittig reaction takes place [1]. Here, too, *p*-toluenesulfonyliminotriphenylphosphorane *(2)*, R = *p*-$CH_3C_6H_5$, is formed in about 50 % yield from *N*-sulfinyl-*p*-toluenesulfonamide.

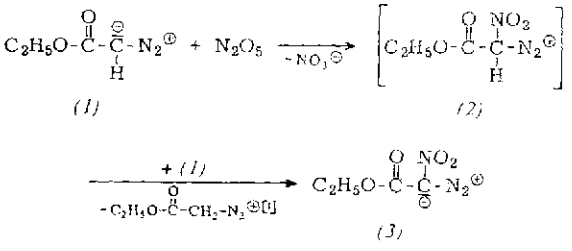
Synthesis of Ethyl Nitrodiazoacetate

By Prof. Dr. U. Schöllkopf and Dr. H. Schäfer

Organisch-Chemisches Institut
der Universität Göttingen (Germany)

Ethyl nitrodiazoacetate *(3)* is formed in 35 % yield as a yellow oil (absorptions at 2140, 1730, and 1500 cm^{-1}; m.p. of triphenylphosphazine deriv. 133–134 °C) when 1 mole of an approx. 1 M solution of dinitrogen pentoxide in carbon tetrachloride is added dropwise at −20 °C to a solution of 2 moles of ethyl diazoacetate *(1)* in CCl_4. After removal of the solvent and the nitric acid ester of ethyl glycollate (b.p. 41–42 °C/0.1 mm), the nitro derivative *(3)* is isolated by chromatography on silica gel (petroleum ether/ether 3 : 1).



(1) *(2)* *(3)*

Probably the diazonium ion *(2)* is an intermediate and is deprotonated by the second mole of *(1)*. Compound *(3)* is the first diazoalkane derivative with a nitro group on the diazo-substituted carbon atom.

The Crystal Structure of Lithium Silicide Li_2Si

By Dipl.-Chem. H. Axel, Dr. Herbert Schäfer,
and Prof. Dr. Armin Weiss

Anorganisch-Chemisches Institut
der Universität Heidelberg (Germany)

The silicon sublattices in the silicides of the Group I and II metals investigated to date exhibit a great variety of forms. In addition to three-dimensional networks ($SrSi_2$) [1], structures with Si layers ($CaSi_2$) [2], Si chains (CaSi [3], SrSi [4], and BaSi [5]), isolated Si_4 tetrahedra (NaSi [6], KSi, RbSi, CsSi [7], and $BaSi_2$ [8]), and isolated silicon atoms (Ca_2Si [9] and Mg_2Si [10]) have been reported.

We have now found a new structural group in Li_2Si, namely Si_2 dumbbells. The Si–Si distance is 2.37 Å and is thus in the same order of magnitude as the Si–Si bonds in elemental silicon. The shortest Si–Si distance between neighboring dumbbells is 4.41 Å. Each silicon atom of a Si_2 dumbbell has 7 lithium atoms as nearest neighbors at distances of 2.58_5 to 2.77_1 Å.

Crystallographic data for Li_2Si:

Monoclinic; space group $C2/m - C_{2h}^3$
$a = 7.70$ Å; $b = 4.41$ Å; $c = 6.56$ Å; $\beta = 113.4°$
$d_{exp} = 1.38_5$ g/cm³; $d_x = 1.36$ g/cm³; $Z = 4$

Equivalent positions:

4 Si in (4i) $x,0,z$; $\bar{x},0,\bar{z}$; $1/2+x, 1/2, z$; $1/2-x, 1/2, \bar{z}$ with $x = 0.067$ and $z = 0.197$
4 Li_I in (4i) with $x = 0.375$ and $z = 0.120$
4 Li_{II} in (4i) with $x = 0.788$ and $z = 0.365$

The discrepancy indices R obtained for a series of planes were: (h0l): $R = 0.10_7$; (0kl): $R = 0.09_0$; (1kl): $R = 0.12_9$; (2kl): $R = 0.12_4$; (3kl): $R = 0.10_7$.

In order to obtain Li_2Si single crystals, a stoichiometric mixture of lithium and silicon was heated in an iron crucible for 3.5 h at 800 °C in an atmosphere of argon and then cooled slowly.

α-Formyl Ketones from Aminoalkenes by Vilsmeier Formylation

By Dr. W. Ziegenbein

Wissenschaftliche Abteilung der Chemische Werke Hüls AG.,
Marl/Westfalen (Germany)

α-Hydroxymethylene ketones, which are tautomers of α-formyl ketones, were hitherto usually prepared by formylation of ketones with ethyl formate in the presence of sodium. α-Alkoxyformylalkenes or α-alkoxyformylcycloalkenes and the corresponding α-chloro compounds have been synthesized from ketals or ketones or from acetylenic compounds using Vilsmeier complexes prepared from *N*-substituted formamides and acid chlorides, *e.g.* $POCl_3$ or $COCl_2$ [1, 2].

We have observed that α-formyl ketones *(2)* can be obtained with Vilsmeier complexes from the aminoalkenes *(1)* [3].

The unstable β-dicarbonyls *(2)*, of which the formyl group is largely enolized if $R^1 + R^2$ are cyclic, generally can be characterized as monoanils or *o*-phenylenediamine derivatives [4].

(2)

(1), $R^2{-}C{=}CH{-}R^1$	Yield [%] [a]	*(2)* B.p. [°C/mm] or m.p. [°C]
Cyclopentenyl	ca. 20	71–72
Cyclohexenyl	52 [b]	40–42/1
Cycloheptenyl	48	58–60/1.5
3,4-Dihydronaphthyl	92	123–125/2
Cyclododecenyl	59	115–116/1

[a] Based on *(1)*.
[b] With 1-piperidinocyclohexene, the yield is 50 %.

α-Formylcyclohexanone: A solution of 73 g of dimethylformamide in 300 g of dichloromethane is stirred with exclusion of moisture at 5–10 °C, and a solution of 100 g of phosgene in 300 g of dichloromethane is added dropwise. The mixture is left standing for 3 h, and then 167 g of 1-morpholinocyclohexene are added gradually with stirring at room temperature. The solution is heated for 30 min at about 40 °C under reflux; 400 g of ice water are then added, and the whole is left standing overnight. The products are extracted with ether, the ether extract is washed several times with water, dried with sodium sulfate, and concentrated *in vacuo*. The residue is vacuum distilled over a Vigreux column 30 cm long, yielding 65 g of α-formylcyclohexanone as an oil ($n_D^{20} = 1.5128$) which rapidly turns brown. It reacts exothermally with aniline in dimethylformamide to yield the anil, m.p. 151 °C from dimethylformamide.

Synthesis of Phosphoryl and Thiophosphoryl Compounds from Sulfur Dioxide and Phosphorus Compounds with a Coordination Number of Three

By Doz. Dr. E. Fluck and H. Binder

Anorganisch-Chemisches Institut
der Universität Heidelberg (Germany)

During attempts to prepare phosphorus triisocyanate from PCl_3 and KOCN in liquid SO_2, we obtained after a reaction time of several months a quantitative yield of $OPCl_3$ instead of the expected product.

We then found that any compound containing phosphorus with a coordination number of three reacts with sulfur dioxide. The reactions are generally straightforward and run to completion within a short time at about 50 °C (in a sealed tube or an autoclave) and in the presence of catalytic amounts of PBr_3, $OPBr_3$, or $OPCl_3$; they can therefore be used for the synthesis under mild conditions of phosphoryl and thiophosphoryl compounds.

Depending on the nature of the original phosphorus compound and on the excess of sulfur dioxide the reactions proceed according to Equation (a) or Equation (b):

$$2\ P(XYZ) + SO_2 \rightarrow 2\ OP(XYZ) + {}^1/_8\ S_8 \quad (a)$$

$$3\ P(XYZ) + SO_2 \rightarrow 2\ OP(XYZ) + SP(XYX) \quad (b)$$

where X, Y, and Z = alkyl, aryl, alkoxyl, aroxyl, Cl, Br, NCS, or NCO; X and Y or X, Y, and Z may be identical. When a large excess of SO_2 is used, the reaction according to Equation (b) is followed by a reaction according to Equation (c).

$$2\ SP(XYZ) + SO_2 \rightarrow 2\ OP(XYZ) + {}^3/_8\ S_8 \quad (c)$$

Mixtures of phosphoryl and thiophosphoryl compounds can generally be separated making use of the differences in boiling points or solubilities.

Compound	Reacts according to Eq.	Products	Catalyst	Reaction time [a]
PBr_3	(b)	$OPBr_3$, $SPBr_3$	–	72 h
$P(NCS)_3$	(b)	$OP(NCS)_3$ + $SP(NCS)_3$ (≈2:1)	–	24 h
$P(C_6H_5)Cl_2$	(b)	$OP(C_6H_5)Cl_2$, $SP(C_6H_5)Cl_2$	–	42 days
	(b)	$OP(C_6H_5)Cl_2$, $SP(C_6H_5)Cl_2$ [b]	PBr_3	10 days
$P(C_6H_5)_2Cl$	(a)	$OP(C_6H_5)_2Cl$, S_8	–	24 h
$P(C_6H_5)_3$	(a)	$OP(C_6H_5)_3$, S_8	PBr_3 or $OPBr_3$	24 h
$P(C_6H_5)_3$	(b)	$OP(C_6H_5)_3$, $SP(C_6H_5)_3$	–	42 days
$P(OC_6H_5)_3$	(b)	$OP(OC_6H_5)_3$, $SP(OC_6H_5)_3$	–	35 days
$SP(C_6H_5)Cl_2$	(c)	$OP(C_6H_5)Cl_2$	PBr_3	42 days

[a] Complete consumption of the original phosphorus compound determined by ^{31}P-NMR spectroscopy; reaction temperature 50 °C; molar ratio of starting material to liquid $SO_2 \approx 1:10$.

[b] After 42 days, all the $SP(C_6H_5)Cl_2$ had been transformed into $OP(C_6H_5)Cl_2$.

CONFERENCE REPORTS

Symposium on Coordination Chemistry

A Symposium on Coordination Chemistry organized by the Hungarian Chemical Society was held between September 14th and 17th, 1964. About 120 scientists met at Tihany (Hungary).

R. S. Nyholm, London (England), reported on complexes such as $(C_6H_5)_3PAu\text{-}V(CO_6)$, $(TA)Cu\text{-}Co(CO)_4$, (TA = $H_3CAs[o\text{-}C_6H_4As(CH_3)_2]_2$), and $[(TA)Ag]_2Fe(CO)_4$. The last complex has octahedrally coordinated iron. The CO absorption band of these and similar carbonyl compounds is shifted to smaller wave numbers as the difference in the electronegativities of the metals decreases.

In his lecture on "Assumptions and Facts about Polyions", *L. G. Sillén*, Stockholm (Sweden), showed that the composition of polyions in aqueous solution frequently differs from the composition of the solid products that can be separated from these solutions. Values determined in solution (mostly by e.m.f. measurements) can be used to attain a "best" description of the state of polyions in solution. If a quantity U is defined as a measure for the discrepancy between the calculated and experimental values, then the best approximation for the real states can be found using the relationship U(BE) = U[DA-EQ(BE)] in combination with a computation program

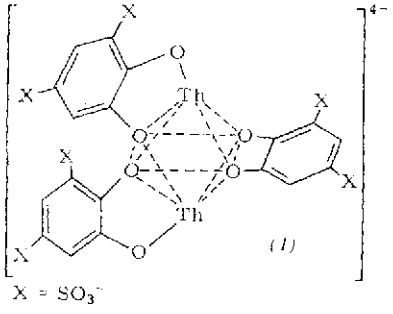
[EQ(BE) is a set of equations for the best description, DA is a set of experimental data]. For the complexes in the system $Be^{2\oplus}/OH^{\ominus}$, the formation constants β_{pm} for the equilibria

$$p\ Be^{2\oplus} + m\ H_2O \rightleftharpoons Be_p(OH)_m^{(2p-m)\oplus} + m\ H^{\oplus}$$

were found to be $\log\beta_{33} = -8.66$ and $\log\beta_{21} = -3.22$. In addition, small amounts of $Be(OH)_2$ must be taken into account; no indications were found for the occurrence of $[Be_4(OH)_4]^{4\oplus}$. Evaluation of the experimental results for a minimum in U led to the following formation constants: $10^4\cdot\beta_{12} = 6.73 \pm 0.07$, $10^9\cdot\beta_{33} = 2.068 \pm 0.013$, and $10^{10}\cdot\beta_{21} = 1.56 \pm 0.6$. Negative formation constants were obtained for 2:2, 4:4, and 1:1 complexes.

The relationships between the light absorption and the electronic configurations of complexes were discussed by *C. J. Jorgensen*, Cologny (Switzerland). To a first approximation, the wave-number of the electron-transfer band is proportional to the difference in electronegativity between the central atom and the most strongly reducing ligand. The position of this band is at higher wave numbers for complexes with two ligand spheres (*e. g.* $[Cr(OH_2)_6SO_4]^{\oplus}$) than for those with only one ligand sphere (*e. g.* $[Cr(OH_2)_4SO_4]^{\oplus}$) and can therefore be used to distinguish complex types. The reason for this shift is a charge-separation effect which is connected with the interelectronic repulsion caused by the second-order density matrix. Examination of anisotropic Cu(II) and U(VI) complexes, ion pairs, and complexes with two ligand spheres of the ions $Sm^{3\oplus}$, $Eu^{3\oplus}$, $Y^{3\oplus}$, and $Np^{4\oplus}$ showed that it was sometimes possible to differentiate by spectroscopy between normal anion complexes, anisotropic complexes, and complexes with two ligand spheres and to show that participation of 5f orbitals in the complex formation probably occurred. This finding was confirmed by *B. Jezowska-Trzebiatowska*, Warsaw (Poland), for complexes of $U^{4\oplus}$ and $U^{6\oplus}$. The spectroscopic series ROH<tributyl phosphate<$Cl^{\ominus}$<RCN<H_2O<tetrahydrofuran was found for $U^{4\oplus}$, and the series $F^{\ominus}$<$Cl^{\ominus}$<$NO_3^{\ominus}$<acetate<$SO_4^{2\ominus}$<acetylacetonate for $UO_2^{2\oplus}$ in non-aqueous systems. The series for $U^{4\oplus}$ applies for the $^3P_2$-$^3P_1$ electronic transition with reference to the quantity $\vartheta_{3P} = \Delta\nu/(J+1)$, where $\Delta\nu = \nu_{3P2} - \nu_{3P1}$ and $J + 1 = 2$. For the $UO_2^{2\oplus}$ complexes, either ν_1' in the electronic spectra or the position of the ν_1'' and ν_3'' vibrations in the infrared spectra was taken as criterion.

Numerous other lectures were devoted to complex formation, equilibria and exchange reactions in solution. For example, *P. Szarvas*, Debrecen (Hungary) found that the formation of dodecatungstate upon acidification of tungstate solutions is strongly suppressed by tartaric acid or malic acid, owing to the formation of 1:1 complexes. The formation of dodecatungstate begins only below pH 3.2. A proton is split off readily from the tartrato and malato complexes.



(*I*)

X = SO_3^-

The formation of binuclear and higher complexes of $Fe^{3\oplus}$, $Th^{4\oplus}$, $Zr^{4\oplus}$, $VO^{3\oplus}$, and $UO_2^{2\oplus}$ involving hydroxyl bridges can be blocked by the addition of chelating agents (catechol-3,5-disulfonate), according to *A. E. Martell*, Chicago, Ill. (U.S.A.). Several complexes can be prepared from $UO_2^{2\oplus}$; while $Th^{4\oplus}$ gives a 2:3 complex, probably of structure (*I*). On the other hand, the formation of a binuclear complex from uranyl citrate, which is present only in dilute solution, is non-specific. *A. Gergely*, Debrecen (Hungary), found that $Nd^{3\oplus}$ and D-glucosaminic acid (= G) forms an equilibrium mixture of four complexes: $Nd(H_3G)^{2\oplus}$, $Nd(H_3G)OH^{\oplus}$, $Nd_2(H_3G)(OH)_4^{2\oplus}$, and $Nd_2(H_3G)(OH)_2^{4\oplus}$.

Their equilibrium constants are:

$K_1 = 1.54 \times 10^{-7}$ for $Nd^{3\oplus} + H_4G \rightleftharpoons Nd(H_3G)^{2\oplus} + H^{\oplus}$

$K_2 = 3.86 \times 10^{-5}$ for $Nd^{3\oplus} + H_3G^{\ominus} + H_2O \rightleftharpoons Nd(H_3G)(OH)^{\oplus} + H^{\oplus}$

$K_3 = 5.92 \times 10^{-8}$ for $2\ Nd(H_3G)(OH)^{\oplus} + H^{\oplus} \rightleftharpoons Nd_2(H_3G)(OH)_2^{3\oplus} + H_4G$

K_4 for the equilibrium

$$Nd_2(H_3G)(OH)_2^{3\oplus} + 2\ H_2O \rightleftharpoons Nd_2(H_3G)(OH)_4^{\oplus} + 2\ H^{\oplus}$$

was not determined.

V. Gutmann, Vienna (Austria), reported that triethylammonium azide in non-aqueous solvents, *e. g.* acetonitrile, is a better azide-ion donor than alkali azides. Triethylammonium azide reacts in acetonitrile with $Co^{2\oplus}$ to yield $CoN_3^{\oplus}$, $Co(N_3)_2$, and $Co(N_3)_3^{\ominus}$, and with $Cu^{2\oplus}$ to give $CuN_3^{\oplus}$, $Cu(N_3)_2$, $Cu(N_3)_3^{\ominus}$, and $Cu(N_3)_4^{2\ominus}$. It does not react with $Ni^{2\oplus}$, but $V^{3\oplus}$ affords $V(N_3)_3$.

The attainment of the equilibrium

$$cis\text{-}[Cr(ox)_2(H_2O)_2]^{\ominus} + 2H_3O^{\oplus} \rightleftharpoons [Cr(ox)(H_2O)_4]^{\oplus} + H_2C_2O_4$$

was followed spectrophotometrically by *H. L. Schläfer*, Frankfurt/Main (Germany). The rate-determining step was found to be

$$[Cr(ox)(H_2O)_3oxH] \rightarrow [Cr(ox)(H_2O)_4]^{\oplus} + H_2C_2O_4$$

It follows a fast protonation of *cis*-$[Cr(ox)_2(H_2O)_2]^{\ominus}$ (ox = oxalate).

Optical rotatory dispersion was used by *S. Kirschner*, Detroit, Mich. (U.S.A.), to differentiate between bidentate, monodentate, and non-coordinated tartrate in the complexes $[Co(NH_3)_4(D\text{-tart})]^{\oplus}$, $[Co(NH_3)_5(D\text{-tart})]^{2\oplus}$, and $[Co(NH_3)_6](D\text{-tart})_3$. The last compound shows no Cotton effect in the visible region of the spectrum. The existence of complexes in which the thiosulfato and salicylato groups are in the outer sphere was demonstrated by *R. Larsson*, Lund (Sweden) in the systems $[Co(en)_3]^{3\oplus}/S_2O_3^{2\ominus}$ and $[Co(en)_3]^{3\oplus}$/salicylate using optical rotatory dispersion spectroscopy (en = ethylene diamine). The complex formation constants were given relative to the concentration of $[Co(en)_3]^{3\oplus}$. With thiosulfate, four complexes MA_n are formed (where n = 1,2,3, or 4, M = $[Co(en)_3]^{3\oplus}$, and A = anion). Their complex formation constants are $\beta_1 = 150\ M^{-1}$, $\beta_2 = 7.5 \times 10^3\ M^{-2}$, $\beta_3 = 1.5 \times 10^4\ M^{-3}$, and $\beta_4 = 1.5 \times 10^5\ M^{-3}$. Correspondingly, for salicylate complexes, $\beta_1 = 22\ M^{-1}$, $\beta_2 = 46\ M^{-2}$, and $\beta_3 = 3\ M^{-3}$.

The fact that the stability of mixed complexes MA_nB_m is higher than that of compounds MA_{n+m} and MB_{n+m} was explained by *Y. Marcus*, Rehovot (Israel), using essentially polarization effects due to ion-ion, ion-dipole, and dipole-dipole interactions. The enthalpies of formation calculated for mercury halides agree well with those found by experiment.

Since $F_3CCOO^{\ominus}$ and $(NH_3)_5Co(OH)^{2\oplus}$ do not exchange oxygen with $^{18}OH_2$, *H. Taube*, Stanford, Calif. (U.S.A.), was able to determine whether water attacks the Co-O bond or the C-O bond in $(NH_3)_5Co(OCOCF_3)^{2\oplus}$ by examining the concentration of ^{18}O in the hydrolysis products. At high $OH^{\ominus}$ concentrations and low temperatures, only the C-O bond is hydrolysed, whereas at low alkalinity and high temperature, the Co-O bond is cleaved preferentially. Addition of $^{18}OH^{\ominus}$ to the complex and competition between proton and cobalt transfer in the intermediate complex are suggested to occur during the reaction.

The exchange reaction of $U^{4\oplus}$ with $UO_2^{2\oplus}$ in $NaClO_4/HClO_4$ at an ion strength of 2.0 M is accelerated in the series malonic acid<maleic acid<malic acid<tartaric acid. *C. H. Brubaker*, East Lansing, Mich. (U.S.A.), found that the rate law

$$R = F + k_2C + k_3C[UO_2^{2\oplus}]$$

applies, where $k_2 = 7.3 \times 10^{-4}$ min^{-1}, $k_3 = 1.2 \times 10^{-3}$ min^{-1}, $C = [U^{4\oplus}]\,[H_2tart]/[H^{\oplus}]^2$, and $F = [U^{4\oplus}]^2[UO_2^{2\oplus}]/[H^{\oplus}]^4$. Uranium(V) may be formed as an intermediate.

G. N. Nord-Waind, Copenhagen (Denmark), found that the slow exchange of Tl in the system $Tl^{\oplus}/Tl3^{\oplus}/Cl^{\ominus}$ at low chloride concentrations is due to the low rate of exchange of the $Tl^{3\oplus}$, which is present as a complex. On the other hand, the faster Tl exchange observed with increasing $Cl^{\ominus}$ concentration can be explained by an increase in the rates of exchange of both oxidation states of the Tl.

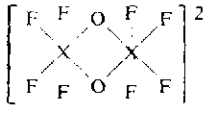
Condensed fluoro-oxo complexes were obtained from monomeric fluoro-oxo complexes by *L. Kolditz*, Berlin (Germany), by thermal condensation. The condensation may be caused either by dehydration

$$n\ K_2[SnF_4(OH)_2] \rightarrow K_{2n}[HO(SnF_4{-}O)_{n-1}{\cdots}SnF_4OH] + n-1\ H_2O$$

or by elimination of HF

$$n\ KAsF_5OH \rightarrow K_n[HO(AsF_4{-}O)_{n-1}{\cdots}AsF_4OH] + n-1\ HF$$

The binuclear complexes $(C_2H_5)_4N[F_5Sb\text{-}O\text{-}SbF_5]$, $(C_2H_5)_4N[Sb_2O_2F_8]$ *(2a)*, and $K_2[As_2O_2F_8]$ *(2b)* probably contain oxygen-bridged octahedra.



(2a): X = Sb
(2b): X = As

F. Majdik, Veszprem (Hungary), reported on the products of pyrolysis of alkoxides and aroxides of Al and Ti. Olefins and alcohols are split off and products with oxo bridges are obtained; these sometimes still contain free hydroxyl groups. Thermolysis of compounds of the type $Al(OC_4H_9)_2(OC_6H_5)$ yields polymeric products which contain the phenoxy group. Analogous investigations of $VO(OCH_3)_3$ were reported by *Gy. Pfeiffer*, Veszprem (Hungary). Here methanol and water are eliminated leading *via* $V_4O_7(OH)_4(OCH_3)_2$ to V_2O_5.

Investigations of gold complexes of the type $K[Au(CN)_2X_2]$ by infrared and Raman spectroscopy were carried out by *L. H. Jones*, Los Alamos, Calif. (U.S.A.), who showed that the force constant for the Au-C bonds decreases from 3.16 to 2.92 mdynes/Å in the series X = $CN^{\ominus}$, $Cl^{\ominus}$, $Br^{\ominus}$, $I^{\ominus}$. These values imply a strong σ- but only a weak π-interaction in the Au-C bonds.

Catalytic hydrogenation was studied by *P. J. Halpern*, Chicago, Ill. (U.S.A.), *V. A. Tulupov*, Moscow (U.S.S.R.), *J. C. Bailar*, Chicago, Ill. (U.S.A.), and *L. Simandi*, Budapest (Hungary). Metals, metal ions, and coordination compounds of the d^5-d^{10} elements have catalytic activity. The hydrogen appears to be activated either heterogeneously (*e. g.* by $RuCl_6^{3\ominus}$ or $Cu^{2\oplus}$) or homogeneously (*e. g.* by $Co(CN)_5^{3}$ or $Ag^{\oplus}$) or by addition (*e. g.* with $IrCl(CO)\,[C_6H_5)_3]_2$). During the hydrogenation of olefins, generally a metal-olefin complex is formed first and is then hydrogenated, probably *via* intermediate formation of an olefin-hydrido complex. *Bailar* showed that Pt-Sn compounds can be used for selective hydrogenation, *e. g.* of soya oil. The configuration of dienes is altered in the presence of these catalyst systems above 30 °C. Halogenoalkanes, particularly CCl_4 and $CHCl_3$, can be reduced catalytically by $NaBH_4$ in the presence of $Co^{\oplus}(trispy)_3$; *D. Konrad*, Prague (Czechoslovakia), found that the reaction

$$[Co(trispy)_3]^{\oplus} + CHCl_3 \rightarrow [Co(trispy)_3]^{2\oplus} + CHCl_3^{\ominus}$$

occurs first and that the $CHCl_3^{\ominus}$ reacts further rapidly. The Co(II) complex is reduced again to the Co(I) complex by the $NaBH_4$ (trispy = trispyridyl).

Hydroformylation and hydrogenation using $Co_2(CO)_8$ as a catalyst are inhibited by C_2H_5SH, $(C_2H_5)_2S_2$, and CS_2, but not by thiophene and $(C_2H_5)_2S$, according to *K. Markó*, Veszprem (Hungary). CoS is formed first and then reacts further in the presence of the organosulfur compounds to form $Co_3(CO)_9S$ or $Co_3(CO)_9S(SR)$, so that the reaction comes to a standstill.

W. Langenbeck, Rostock (Germany), observed a structural specificity in the catalytic action of tridentate $Cu^{2\oplus}$, $Co^{2\oplus}$, and $Zn^{2\oplus}$ chelates and of the chelates of these ions with Schiff bases in the oxidative activity of the imidazole/parahematin and benzoyldihydronicotinamide/9-phenylflavin systems. Stereochemical specificity was found with the parahematin of L-histidine and with its Cu complex with D- and L-DOPA as substrates; L-DOPA was oxidized 43% faster than D-DOPA (DOPA = dihydroxyphenylalanine). *E. Thilo*, Berlin (Germany), found that metal ions catalyse the hydrolytic degradation of condensed phosphates and of the $S_2O_7^{2\ominus}$ ion. The catalytic activity is approximately proportional to the stability of the metal-ion EDTA complexes. The concentration dependence of the effect on the reaction with the $S_2O_7^{2\ominus}$ ion indicated that complex formation (chelating) occurs prior to the hydrolysis of the S-O-S bond.

Theory and Technique of Precipitation Crystallization

From November 10th to 12th, 1964, the Mineralogy Section of the Geological Society of the German Democratic Republic held a symposium on "Theory and Technique of Precipitation Crystallization".

From the lectures:

R. F. Strickland-Constable (London, England) described four methods for increasing the number of nuclei in supersaturated solutions and supercooled melts: (1) On addition of a crystal to a supersaturated solution or melt, the small particles, adhering to the crystal, turn into fresh seeds. This may be prevented by first placing the crystal into a solution slightly below the saturation point. The small particles on the crystal surface are then rapidly dissolved, while the large crystal remains almost undamaged and continues to grow in a supersaturated solution. (2) New seeds are formed when crystalline needles are broken or crushed. (3) The fragments of polycrystals, which frequently show poor cohesion, yield fresh seeds. Cases (2) and (3) commonly occur in mass crystallization. Depending on the type of crystal, the degree of supersaturation and the nature of foreign compounds present in the solution, crystalline needles and polycrystals are formed instead of ideal crystals with plane surfaces. (4) If ideal crystals are required, the number of nuclei can only be increased by disintegration of the crystals already formed on impact with one another or with the stirrer and the wall.

These types of seed increase are the only possible ones on crystallization in the metastable zone (moderately supersaturated solution). Fundamentally, these types of seed increase are to be distinguished from seed formation, the rate of which markedly increases only at higher degrees of supersaturation.

$$I = C\exp[-A_k/kT] = C\cdot\exp[-U\cdot\sigma^3/T^3\,(\ln\alpha)^2]\ \text{seeds/cm}^3\text{sec}$$

I = rate of seed formation
C = frequency factor
A_k = work of seed formation
k = Boltzmann constant
T = temperature [°K]
σ = surface tension
α = degree of supersaturation, *i.e.* effective concentration/saturated concentration
U = constant

J. Myl (Pardubice, Czechoslovakia) discussed the stability of supercooled liquids. Within the metastable zone, *i.e.* within the range between saturation and supersaturation curves in the solubility *vs.* temperature diagram, crystal seeds do not form spontaneously. The width of the metastable zone of aqueous solutions increases with their purity and viscosity, with the duration and degree of superheating, and with the rate of saturation, *i.e.* with the increase in saturation per unit time. This may be proportional to the rate of cooling. Complete degradation of the aggregates of water molecules may be assumed to take place on prolonged and strong heating, while their recombination is retarded on rapid cooling.

According to *U. Steinicke* (Berlin, Germany) aluminum hydroxide may be prepared by a channel process: the solutions of aluminum salt and ammonia are mixed in a jet and directly sprayed into the internal tube (a few cm in diameter) of a double-walled glass tube (the "channel"). The basic idea of this continuous process is to mix the original solutions in the absence of a wall, with subsequent ageing of the precipitate in a channel system. Ageing is controlled by the rate of flow (slope of the channel), the pH-value and the temperature profile. The dried and calcined final product has a high catalytic activity and a sharp maximum in the particle size distribution curve (particle size can be varied from about 10 to 100 μ).

M. J. Koslovski (Tiraspol, U.S.S.R.) examined the influence of spark discharges on the formation of seeds in aqueous electrolyte solutions. The rate of seed formation at the surface of a supersaturated solution is proportional to the square of the field strength and to the degree of supersaturation. The spark flashes over from the electrode to the surface of the solution. Seed formation largely depends on which pole of the power supply the solution is connected to. In the case of KCl, spark discharge with the solution as the negative pole produced a marked crystallization, while crystallization was low with the solution being the positive pole. The crystallization of halides, sulfates, nitrates, phosphates, and carbonates of the alkali metals and alkaline earths was investigated. The rate of seed formation decreases with increasing viscosity and purity of the solution.

According to *H. J. Meyer* (Bonn, Germany) vaterite ($CaCO_3$) is preferentially formed during rapid precipitation from aqueous solutions, especially in the presence of electrolytes. The proportion of the $CaCO_3$-modifications (calcite, aragonite, vaterite) at 50 °C and in the presence of uni-univalent electrolytes (*e.g.* NaCl, NH_4NO_3) depends on the concentration and nature of the latter. Other solutes present and high degrees of supersaturation favor the formation of somatoids [*].

As *R. Boistelle* and *R. Kern* (Nancy, France) showed, clumping of sodium chloride crystals can be prevented by spraying the crystalline powder, *e.g.* with $K_4[Fe(CN)_6]$ solution. On evaporation, the $K_4[Fe(CN)_6]$ forms small sharp points on smooth sodium chloride surfaces. These probably prevent a close fit of the crystal planes and, therefore, the clumping of the crystals. From a more than 23% supersaturated solution, sodium chloride does not crystallize in cubes, but in octahedra. Other solutes present (Cd^{2+}, $CO(NH_2)_2$, $Fe(CN)_6^{4-}$, $Fe(CN)_6^{3-}$) lower the critical concentration and may lead to further changes in form and habit (*e.g.* rhomboid dodecahedra and dendrites are formed).

M. Hille (Berlin, Germany) prepared small NaCl and KCl crystals of definite form and size for flotation studies. Cubes of NaCl and KCl as well as octahedra of NaCl (size about 50 to 60 μ) are formed by precipitation with methanol/ethanol/acetone mixtures from aqueous solutions of these salts, saturated at 20 °C. The organic solvents added must be miscible with the solution. Formamide (20%) is required for precipitating octahedra of NaCl. Octahedra of KCl crystallize from an aqueous solution of KCl, which is saturated at 50 °C, contains urea (50%), and is supercooled down to 30 °C. The flotability of minerals may be improved or made at all possible by a definite crystal form.

Ch. Jentsch (Berlin, Germany) carried out adsorption measurements on alkali halide crystals of different forms. The crystals, 5 to 10 μ in size, were obtained by precipitation with methanol/ethanol/acetone mixtures. The crystal size varies with the ratio of the organic solvents. The solution contained $PbCl_2$ for the precipitation of KCl octahedra, glycine for the precipitation of NaCl rhomboid dodecahedra. No adsorption of the solutes affecting crystal form was noted, but water was adsorbed in several layers.

M. Kahlweit (Göttingen, Germany) dealt with growth studies. A temperature jump was used to produce super- or subsaturation in a saturated solution within about 10^{-5} sec. Growth and dissolution of the crystals were traced by conductivity measurements. It is concluded that growth is controlled by surface reactions (*e.g.* dehydration) at lower degrees of supersaturation, and by diffusion at higher degrees of supersaturation (above 1%).

H. Neels and *S. Aslajan* (Leipzig, Germany) studied the formation of spherolites of sodium hydrogen carbonate from an aqueous solution by addition of methanol. The size of the spherolites decreased from 8 to 4 μ with increasing degree of supersaturation (70–100%). The crystalline needles of the spherolites showed a step-wise growth. *H.* Neels and *A. Felbinger* (Leipzig, Germany) observed that the rate of formation of sodium hydrogen carbonate seeds on carbonization of an ammoniacal sodium chloride solution, is related by an exponential function to the degree of supersaturation. *Todes* (U.S.S.R.) used the rate of seed formation to determine the interfacial energy of $CaSO_4$ in aqueous solution as 12 erg/cm², and *A. E. Nielsen* (Copenhagen, Denmark) determined that of $BaSO_4$ as 130 ± 10 erg/cm². *R. Piwonka*, *H. Ortmann*, and *H. Hartmann* (Lübenwalde, Germany) precipitated cadmium sulfide, in the presence of halide ions, in the stable hexagonal modification, while sulfate ions led to the metastable cubic modification. *St. Zagrodski* and *Z. Niedzielski* (Lodz, Poland) observed increased seed formation on ultrasonic irradiation of supersaturated saccharose solutions, reaching a maximum at a sound frequency of 7.2 kc. [VB 881/212 IE]

German version: Angew. Chem. 77, 351 (1965)

[*] Somatoids are small crystals with uneven planes, which, depending on the conditions of precipitation, are spindle-shaped, spherical, lenticular, sheaf-like, dumbbell-shaped or snow-textured.

Chemical Effects Associated with Nuclear Reactions and Radioactive Transformations

About 130 scientists from 28 countries attended this symposium which was arranged by the International Atomic Energy Agency and the I.U.P.A.C. Joint Commission on Applied Radioactivity and was held in Vienna (Austria) on December 7th–11th, 1964. Some 60 papers, which are to be published soon, were presented.

Investigations Using Mass Spectrometry

The chemical effects of internally converted isomeric transitions with subsequent Auger effect [1] could previously be measured only with compounds of a few nuclides. Due to the occurence of recoil the results were uncertain to an unknown

extent. Molecular disintegrations following the Auger effect were now brought about with non-radioactive molecules, using X-rays to produce an electron deficiency at one of the atoms. The resultant positive charge is rapidly distributed throughout the molecule, which then disintegrates due to internal Coulombic repulsion. The charges and kinetic energies of the fragments were measured about 10^{-5} sec after the energy absorption. After excitation of the L-shell, CH_3I splits into C^{2+}, $3\,H^+$, and I^{5+}, while HI decomposes into H^+ and I^{7+}, and Xe yields Xe^{8+}. Molecular ions and neutral fragments are not formed. The recoil energy measured for the products of the disintegration of CH_3I corresponds to that calculated with the assumption that $C^{2+}H^+{}_3I^{5+}$ with the atomic parameters of CH_3I appears as an intermediate (*R. M. White*, U.S.A.). For the Wilzbach labelling of CH_4, the Pratt-Wolfgang mechanism was confirmed by detection of the $C_2H_4T^+$ ion. The

$$T_2 \xrightarrow{\beta^-} T^3He^+ \xrightarrow[-{}^3He]{+\,CH_4} CH_4T^{+*} \xrightarrow[10^{-11}\,sec]{-H_2} CH_2T^+$$

$$\xrightarrow[-H_2]{+\,CH_4} C_2H_4T^+ \xrightarrow[>10^{-5}\,sec]{+\,e^-,\,-CH_2} CH_2T \xrightarrow{+\,CH_4} CH_3T + CH_3$$

radiochemical portion of the reaction, which is due to β-radiation, was determined separately by addition of D_2 to the CH_4/T_2 mixture; deuterated molecules can only be formed in this way and not *via* T^3He^+ (*S. Wexler*, U.S.A.).

Gases

Radioactive carbon from the reaction $^{12}C(\gamma,n)^{11}C$ reacts mainly as such, or as methine after addition of a hydrogen atom. ^{11}C reacts with hydrocarbons to form $CH\equiv{}^{11}CH$, and ^{11}CH forms $CH_2={}^{11}CH_2$; oxygen reacts only with ^{11}C to yield ^{11}CO. The formation of ^{11}CO is six times more probable than that of a labelled hydrocarbon (*G. Stöcklin*, Germany). The reaction of ^{11}C with hydrocarbons proceeds by insertion into a C–H bond. A primary C–H bond is preferred to a secondary by a factor of 1.26. In hydrocarbon/N_2 mixtures, labelled hydrocarbons and $H^{11}CN$ result, but labelled amines are not observed. The ratio of the cross-sections in these mixtures with reference to the formation of ^{11}CO, $CH\equiv{}^{11}CH$, and $H^{11}CN$ from energy-rich carbon atoms, is 9:4.5:1. Further informations on the reaction mechanisms are to be expected from investigations of the isotopic effect (*A. P. Wolf*, U.S.A.). Isotopic effects of hot T-atoms from the reaction $^3He(n,p)T$ are also being investigated. Recently it has become possible to separate olefines in which only one H is replaced by D. With CH_3CD_3 as starting material, the reaction

$$T^* + C_2H_6 \xrightarrow{-H} C_2H_5T^* \longrightarrow C_2H_3T + H_2 \text{ or } C_2H_4 + HT$$

yields C_2H_2DT and C_2HD_2T in the ratio 1:1.6. Correspondingly, replacement of H in the first stage of the reaction is preferred to the replacement of D by a factor of about 1.3, and disintegration of $CH_2TCD_3{}^*$ is more frequent than that of $CH_3CD_2T^*$ by the same factor (*F. S. Rowland*, U.S.A.). The β-decay of T in $C_2H_4T_2$ *via* $C_2H_4T^3He^+$ as an intermediate yields 11 % HT, 2.5 % CH_3T, 5.5 % C_2H_3T, 1 % C_3H_7T, and 3–4 % C_4H_9T (*F. Cacace*, Italy). This result agrees with mass-spectrometric observations of the ions resulting from $C_2H_4T^3He^+$. Calculations of bond conservation in tritiated alkanes and $^{14}CO_2$ during β-decay gave values of ca. 1 and 80 %, respectively, in agreement with experimental results (*A. A. Gordus*, U.S.A.).

[1] An isomeric transition is called internally converted if the energy of the γ-ray quantum is transferred to an inner-shell electron which is then emitted. Filling of the vacancy by electrons from higher shells may result in further loss of electrons by similar conversion of the X-ray quanta. The latter process is termed the Auger effect and yields multiply positively charged atoms.

Liquids

In organic halides a considerable proportion of activated atoms is found incorporated into the starting material. This is not due to retention, *i.e.* to lack of bond-breaking, (*J. E. Willard*, U.S.A.) but to substitution according to:

$$*X + RX \rightarrow R*X + X$$

To clarify the reaction mechanism, the following reactions were carried out:

1. meso- or (±)-2,3-dichlorobutane$(n,\gamma)^{38}Cl \rightarrow$ dichlorobutanes

2. as 1. but with the addition of $Br_2(n,\gamma)^{80m}Br \rightarrow$ 2-^{80m}Br-3-Cl-butane

3. 2-chlorobutane$(n,\gamma^{38}Cl \rightarrow$ dichlorobutanes.

The isomeric products were separated. It was shown that the replacement of Cl by Cl or Br proceeds partly with retention of configuration and partly with racemization, and that the time of reaction is comparable with the duration of the radical transformation. The replacement of H by Cl is mainly statistical; nevertheless differences due to the different C–H bonds are perceptible. Radicals are not formed (*F. S. Rowland*, U.S.A.). Although frequently investigated, the chemical effects of the nuclear reaction $^{81}Br(n,\gamma)^{82}Br$ in liquids and solids need further discussion, since it has recently become clear that the major part of the 36h-^{82}Br in a strongly internally converted isomeric transition originates from 6 min-^{82m}Br.

Solids

Products from the nuclear reaction $^{14}N(n,p)^{14}C$ in carefully purified NH_4Cl were investigated. After dissolution the radioactivity was found in the form of 75 % CH_3NH_2, 8 % gases ($CO + CO_2 + CH_4$), 3 % HCOOH, 3 % HCHO, and 4 % CH_3OH. While CH_4 and CH_3NH_2 are probably present immediately after irradiation, the oxygen-containing compounds apparently result from precursors on dissolution in water. Surprisingly, the distribution of products is unaltered if, after irradiation, the substance is sublimed in vacuum, or at 1 mm of H_2 or NH_3; thus the precursors survive destruction of the lattice. Two possibly simultaneous mechanisms were discussed in explanation: 1. during sublimation the concentrations of NH_3 and HCl are so small and the contact times so brief, that the precursors do not react; 2. the precursors are less reactive or more stable in the lattice than was so far assumed (*P. E. Yankwich*, U.S.A.). While in normal alkali-metal halides the nuclear reaction $^{35}Cl(n,p)^{35}S$ yields 100 % $^{35}SO_4^{2-}$ after dissolution, ca. 50 % of the activity produced in vacuum-sublimed material or in single crystals can be captured as $^{35}S^{2-}$ after dissolution in sulfide- or sulfite-containing dilute alkali. The precursor may be atomic, neutral sulfur S^0, or perhaps S^- or S^+. Its behavior depends on the structure of its surroundings. From powdered CsCl, ^{35}S can be extracted with carbon disulfide. The lifetime of the fragment in solution must be at least 10^{-6} sec, since, due to the low sulfide concentration, only 1 in 10^6 collisions leads to exchange according to

$$^{35}S^0 + S^{2-} \rightleftharpoons {}^{35}S^{2-} + S^0$$

The numerical values varied within wide limits from experiment to experiment even when using different parts of the same single crystal; they could also be considerably influenced by doping (with Ca^{2+} or Cd^{2+}), γ-irradiation (before or after activation), heating, optical bleaching, or crushing. In pure solvents S^0 is oxidized by water mainly to sulfate (*J. E. Willard*, U.S.A.; *A. G. Maddock*, England).

The change in proportion of the different recoil fragments, caused by heating or irradiation, took up a considerable part of the discussions. It was suggested that migrating electrons

transfer energy to the recoil atoms and thus activate the process or that they alter the environment of the recoil atoms so that a lesser energy of activation is required. Moreover, these electrons interact with defects in the crystal matrix, which explains the complicated annealing behavior. Electrons, as well as defects, can be produced by additional γ-irradiation. The structure of the surroundings of the recoil atom is no longer regarded as controlling the course of annealing (*K. E. Collins*, U.S.A.). The importance of crystal defects is seen from the different annealing behavior of cobalt acetylacetonate/aluminum acetylacetonate mixed crystals, which were prepared by two methods (*J. I. Vargas*, Brazil). For neutron-activated potassium chromate, a parallelism has been found between thermoluminescence, electrical conductivity and isochronous thermal annealing. All these properties or processes show maxima at 160, 250, and 340 °C. The product was found to be predominantly $^{51}Cr^{2+}$ and not Cr^{3+} as previously assumed (*T. Andersen*, Denmark). The old theory by Libby, which explained the recoil behavior of central atoms in complexes in terms of a successive loss of ligands (CrO_3, CrO_2^{2+}, CrO^{4+}, Cr^{6+}) was thereby finally disproved (*G. Harbottle*, U.S.A.). In cobalt nitroammine complexes, annealing proceeds directly from $^{60}Co^{2+}$ to the end product with no intermediate stages. It is not stereospecific (*A. Todesco*, Brazil).

Recoil reactions are accomplished in a small area without greater disturbance of the atomic arrangement and lead to specific changes. The triphosphate fraction isolated from phosphates is preferentially labelled in the middle (P–O–^{32}P–O–P), which can be explained in terms of the insertion of a recoil atom between two PO_4 etrahedra. Triphosphate formed from diphosphates is preferentially labelled at the end (^{32}P–O–P–O–P), the triphosphate resulting from addition and not insertion (*L. Lindner*, Netherlands). Analogous conclusions came from the non-statistical distribution of $ReCl_nBr_{6-n}^{2-}$ ions on activation of K_2ReBr_6–K_2SnCl_6 mixed crystals. Generalization of these conclusions led to a "disorder model" for the mechanism of recoil processes. The region in which the recoil atom originates and in which its fate is decided, includes no more than 20 atoms (*H. Müller*, Germany). Further evidence for the small size of this region was obtained during investigation of alkyl-bromide/bromine mixtures (*R. Hahne*, U.S.A.) and from the annealing behavior of compounds such as $[Rh(NH_3)_5{}^{80m}Br]Br_2$ after the nuclear isomeric transition $^{80m}Br \rightarrow {}^{80}Br$ (*G. B. Schmidt*, Germany).

Considerable isotope effects are found with tetraphenylporphin complexes of Zn, Pd, and Pt (*H. E. Rosenburg*, U.S.A.). Isotope effects of similar magnitude and retentions of less than 1 % were found with ruthenocene. In general, retention seems to be mainly due to reformation (*G. Harbottle*, U.S.A.). In contrast with earlier assumptions, reformation seems also to be possible in complicated organic molecules. Thus, ^{35}S-methionine can be obtained directly from methionine by neutron-irradiation (*B. G. Dzantiev*, U.S.S.R.). Interesting commercial applications can be expected.

Mössbauer Effect

^{129}I and ^{131}I disintegrate with β-radiation into excited ^{129}Xe and ^{131}Xe, respectively, which are converted to the ground state after about 10^{-9} sec. With the aid of the Mössbauer effect information can be obtained about the chemical state of the xenon at the instant of disintegration, *i.e.* 10^{-9} sec after its formation. At this time all changes in the electron shells are completed. The following chemical changes occur due to β-decay:

NaI	→	Xe^0
$NaIO_3$	→	XeO_3
KIO_4	→	XeO_4
$Na_3H_2IO_6$	→	6 O octahedrally around Xe, perhaps XeO_6^{4-}
I_2	→	Xe^0, no Xe^+, no XeI
$KICl_4 \cdot H_2O$	→	$XeCl_4$
$KICl_2 \cdot H_2O$	→	probably $XeCl_2$

These experiments show that the hitherto unknown xenon compounds XeO_4, $XeCl_4$, and $XeCl_2$ are stable at least for a short time (*G. Perlow*, U.S.A.). [VB 892/203 IE]

Tenth Aniversary of the Institute for Organic Chemistry of the German Academy of Sciences

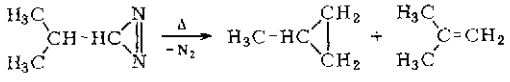
The tenth anniversary of the Institut für Organische Chemie der Deutschen Akademie der Wissenschaften in Berlin-Adlershof (Germany) was celebrated by a Colloquium on November 26th, 1964. Three lectures were delivered: *H. Bredereck* (Stuttgart, Germany) reported on "Complexes of Acid Amides with Acid Chlorides or Dialkyl Sulfates", *J. Rudinger* (Prague, Czechoslovakia) on "Oxytocin: Organic Synthesis as a Means for Investigating the Effects of Hormones", and *H. A. Staab* (Heidelberg, Germany) on: "Investigations on New Aromatic Ring Systems". During the afternoon session, members of the Institute reviewed current work of the Institute in the course of 10 short communications. Abstracts of some of these papers are given below [1].

[1] Other papers, which have in part already been published, were the following: *M. Schulz*, Angew. Chem. *75*, 918 (1963); Angew. Chem. internat. Edit. *2*, 623 (1963); Z. Naturforsch. *19b* 263 (1964); *M. Lorenz*, Mber. dtsch. Akad. Wiss. Berlin *6*, 578 (1964); *H. Dorn*, Angew. Chem. *76*, 920 (1964); Angew. Chem. internat. Edit. *2*, 748 (1964).

Ring Opening of Cyclic Diazo Compounds

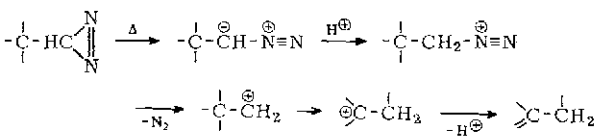
E. Schmitz, R. Ohme, D. Habisch, S. Schramm, A. Stark, and *Ch. Hörig*

Cyclic diazo compounds *(1)* split off nitrogen at temperatures above 150 °C. Cyclopropanes *(2)* and olefines *(3)* are formed *via* intermediary carbenes.

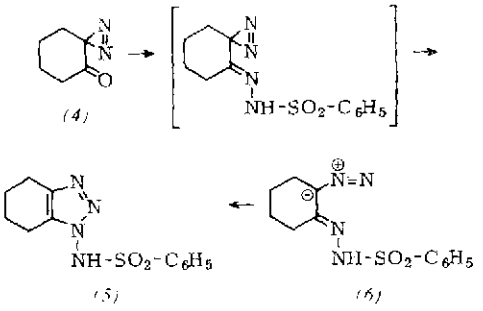


(1) *(2)* *(3)*

The formation of some of the olefines can only be explained by the assumption that a linear diazo compound is formed as an intermediate:



The same is indicated by the fact that the cyclic diazo compound *(4)* of cyclohexanone yields the same triazole *(5)* on reaction with benzenesulfonylhydrazine as is obtained from the linear diazo compound *(6)*.



(4)

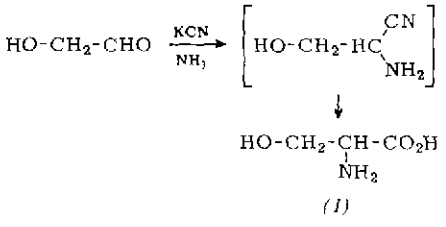
(5) *(6)*

Compound *(5)* is the first derivative which has been obtained from a cyclic as well as from a linear diazo compound.

New Syntheses of β-Hydroxy-α-amino Acids

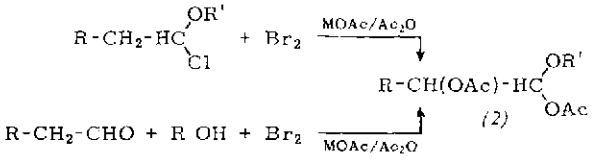
H. Gross, H. Geipel, J. Gloede, and *K.-P. Hilgetag*

In the case of β-hydroxyamino acids the Strecker synthesis has, so far, only been used to prepare serine *(1)*. Glycolaldehyde was the starting material, and the yield was below 10 %.



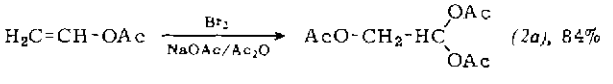
(1)

Higher hydroxy aldehydes have not been used, since they may tautomerize to the hydroxy ketones. Instead of the free hydroxy aldehydes, however, their acylal esters *(2)* can be used for the Strecker synthesis. Compounds of this type are obtained in high yields in the following manner:



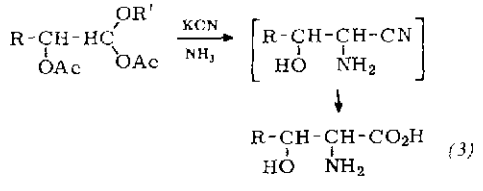
(2)

M = Na up to R = C_3; Ag with R > C_3



(2a), 84%

Strecker syntheses using compounds of type *(2)* afford β-hydroxyamino acids *(3)* in yields of 60 to 80 % with R = CH_3 up to C_4H_9. With R = C_5H_{11} up to $C_{10}H_{21}$, yields of 45 to 60 % are obtained. Thus, yields are generally higher than in the usual Strecker synthesis.



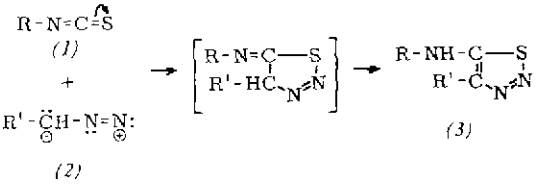
(3)

Compound *(2a)* yields serine in 87 % yield. When using primary amines instead of ammonia, *N*-alkylated serines are obtained, but here yields are lower.

Synthesis of Heterocycles Containing Sulfur and Ring Opening with Formation of Esters of Cyanic Acid

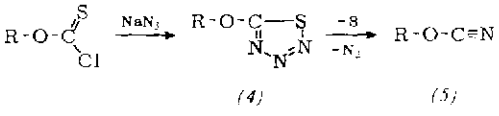
D. Martin and *W. Mucke*

The reaction of isothiocyanates *(1)* with diazo compounds *(2)* yields 5-alkylamino-1,2,3-thiadiazoles *(3)*. According to kinetic studies, this reaction is a 1,3-dipolar cycloaddition proceeding in one step. The rate of addition increases with increasing electrophilic character of the C-atom in *(1)* and is decreased by electron attracting groups R' in *(2)*.



(1) *(2)* *(3)*

The thiadiazoles *(3)* possess considerable thermal stability. On the other hand, the structurally similar 1,2,3,4-thiatriazoles *(4)*, which can be prepared from thiocarbonic ester chlorides and sodium azide, decompose by an exothermic reaction even at 0 °C.



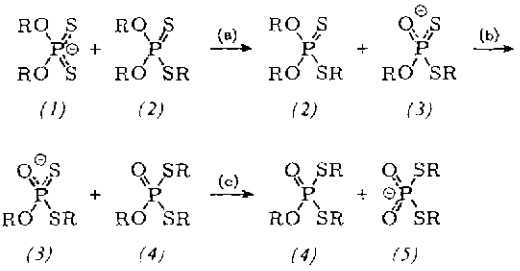
(4) *(5)*

Fractionated distillation of the reaction products yields esters of cyanic acid with about 85 % yield. The aryl esters *(5)*, R = aryl, trimerize on heating at 200 °C to form esters of cyanuric acid. Friedel-Crafts catalysts or sodium alkoxides accelerate this reaction. The alkyl esters of cyanic acid *(5)*, R = alkyl, on the other hand, isomerise on heating to yield alkyl isocyanates [1].

Alkylation and Isomerization Reactions of Dithiophosphates

H. Teichmann

In order to study the side reactions occuring during the technical syntheses of dithiophosphate insecticides, a simple model system was investigated using thin-layer chromatography. Equimolar amounts of *(1)* and *(2)*, R = CH_3, react



(1) *(2)* *(2)* *(3)*

(3) *(4)* *(4)* *(5)*

in methanol at 65 °C within only a few minutes to form *(3)*; after 1.5 h, equal concentrations of *(1)* and *(3)* are present; after about 7 h, *(1)* has completely disappeared. The species *(5)* begins to appear after about 1.5 h and is the only anion left after 25 h. About 50 % of the ester *(2)* has been converted when *(1)* is used up. The alkylation of *(3)* according to Reaction (b) is therefore overlapped by Reaction (c). The final products are *(5)* plus about equal amounts of *(2)* and *(4)*. It follows from the course of reaction that *(4)* is a stronger alkylating reagent than *(2)* and that the nucleophilicity of the anions decreases rapidly in the series *(1)* > *(3)* > *(5)*.

[1] For further reactions of esters of cyanic acid, see *D. Martin*, Angew. Chem. 77, 96 (1965); Angew. Chem. internat. Edit. 4, 73 (1965).

During syntheses of dithiophosphates $(RO)_2P(S)SR'$ from *(1)* and R'Hal, side reactions of types (a)–(c) can be largely suppressed by using low temperatures: the half-life for Reaction (a) at 20 °C is about 6 days.

Catalytic Cleavage and Formation of C—C Bonds in Aromatic Compounds in the Gas Phase

H. Seeboth

Linkages between carbon atoms in aromatic compounds can be split under relatively mild conditions with a nickel catalyst (Ni/NiO on γ-Al_2O_3, Leuna catalyst 6524) which is used for the hydrogenation of phenol. Benzyl alcohol is converted at 200 °C into benzaldehyde and this loses carbon monoxide to form benzene quantitatively.

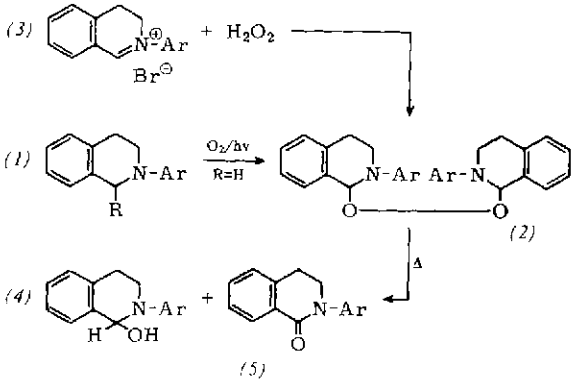
The hydrodemethylation of toluene at normal pressure can be carried out at 300–350 °C. Methane is formed; its amount increases with temperature and with the hydrogen:toluene ratio, but is decreased by the presence of water. Similarly, ethylbenzene and cumene are converted with successive loss of methyl groups into benzene. The demethylation occurs by a radical mechanism. Cycloaliphatic compounds are not formed as intermediates, since methylcyclohexane yields toluene from which benzene is subsequently formed.

Benzene and methane react to form toluene. The yield of toluene increases when the process is carried out in the presence of hydrogen. It is about 10% at 350 °C, a molar ratio of $C_6H_6:CH_4:H_2 = 1:2:2$, and a throughput of benzene of 0.15/hour. Toluene is formed by the reaction of benzene with methyl or methylene radicals which originate from benzene or methane. This is confirmed by the observation that [^{14}C]-toluene is formed when $^{14}CH_4$ and toluene are reacted at 350 °C.

Formation of Peroxides from Heterocyclic Compounds Containing Nitrogen

E. Höft and *H. Schultze*

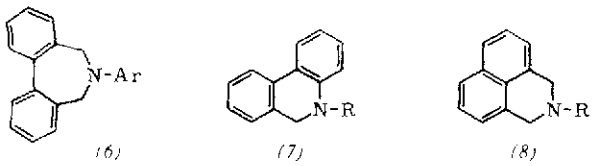
When *N*-aryl-1,2,3,4-tetrahydroisoquinoline *(1)*, R=H, is shaken in benzene with oxygen under ultraviolet irradiation, a peroxide of structure *(2)* is formed which crystallizes on addition of isopropyl alcohol.



It is of interest that a hydrogen peroxide intermediate could not be detected in this reaction.

Peroxides of type *(2)* are colorless stable compounds which revert to the starting material *(1)* on hydrogenation. They can also be prepared from the immonium salts *(3)* and H_2O_2. On heating they decompose into the pseudobases *(4)* and the lactams *(5)*.

In analogy to *(1)*, compounds *(6)* and *(7)* yield peroxides with a structure similar to that of *(2)*. On the other hand, 1,2-disubstituted tetrahydroisoquinolines *(1)*, R = alkyl or aryl, and *N*-aryl-2,3-dihydro-1*H*-benz[*de*]isoquinolines *(8)* do not form peroxides.



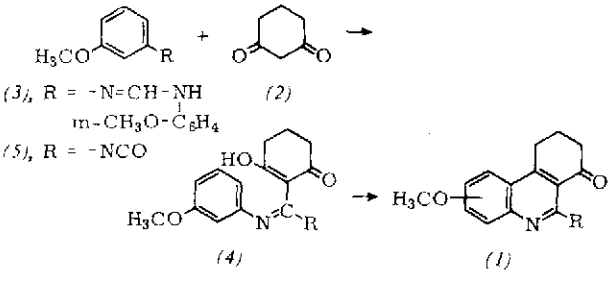
(6) *(7)* *(8)*

Syntheses with Dihydroresorcinol

G. Lehmann

None of the usual quinoline syntheses can be used for the preparation of phenanthridine derivatives *(1)*, R = H. Such syntheses either do not give the desired products or they require starting materials which in turn can only be synthesized in several steps.

A synthesis of *(1)*, R = H, was developed which starts with the addition of dihydroresorcinol *(2)* onto the amidine *(3)*. The Schiff base *(4)* thus formed was cyclized with polyphosphoric acid above 100 °C, to yield a mixture of the 1- and 3-methoxy derivatives *(1)*, R = H.



(3), R = -N=CH-NH *(2)*

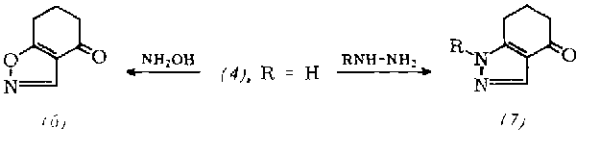
m-CH_3O-C_6H_4

(5), R = -NCO

(4) *(1)*

Starting from dihydroresorcinol and the isocyanate *(5)*, the compounds *(4)*, R = OH, and *(1)*, R = OH, were obtained.

The arylimino group in *(4)*, R = H, can be replaced easily by other amine derivatives. Reaction with hydroxylamine leads to the oxime which is readily cyclized to tetrahydrobenzisoxazolone *(6)*. Reaction with hydrazines, followed by cyclization, yields tetrahydroindazolones *(7)*.



(6) *(4)*, R = H *(7)*

[VB 898/206 IE]
German version: Angew. Chem. 77, 381 (1965)

Complex Acetylides of Transition Metals

R. Nast, Hamburg (Germany)

In liquid ammonia, cadmium and mercury form diamagnetic anionic complexes of the type $Ba[M(C{\equiv}CR)_4]$. Protolytic decomposition of diphenylzinc and diphenylcadmium with phenylacetylene in ether/tetrahydrofuran according to

$$M(C_6H_5)_2 + 2\ HC{\equiv}C{-}C_6H_5 \rightarrow 2\ C_6H_6 + M(C{\equiv}C{-}C_6H_5)_2$$
M = Zn or Cd *(1)*,

leads to the crystalline bisphenylacetylides *(1)*, which are nonelectrolytes and dissolve readily in liquid ammonia. Unsymmetrical phenylacetylides of the type C_6H_5-M-C≡C-C_6H_5, where M = Zn or Hg, were also obtained.

Complex dialkynylmetalates *(2)* of silver and gold are readily obtained in liquid ammonia according to

$$MC{\equiv}CR + KC{\equiv}CR \rightarrow K[M(C{\equiv}CR)_2]$$
(2), M = Ag or Au

These anionic complexes are diamagnetic, sensitive to light, and strong electrolytes in liquid ammonia. Analogous reactions with Ag_2C_2 and Au_2C_2 produced the polynuclear acetylides $[KC{\equiv}CAg]_\infty$ and $K_2[HC{\equiv}C\text{-}Au\text{-}C{\equiv}C\text{-}Au\text{-}C{\equiv}CH]$.

The ligands in $K_2[Pd(CN)_4]$ and $K_2[Pt(SCN)_4]$ can be partly or completely replaced by acetylide ions in liquid ammonia, giving the diamagnetic complexes *cis*-$Ba[Pd(CN)_2(C{\equiv}CR)_2]$ and $K_2[Pt(C{\equiv}CR)_4]$, which are presumably planar.

From theoretical considerations stabilization of the lower oxidation states of central atoms by acetylide ions would be expected. This was confirmed by the preparation of complex acetylides of Cr(0), Mo(0), W(0), Pd(0), Pt(0), and Cu(0). For example the reaction

$$[M(CO)_3(NH_3)_3] + 3\ KC{\equiv}CR \rightarrow 3\ NH_3 + K_3[M(CO)_3(C{\equiv}CR)_3]$$

(3), M = Cr, Mo, or W

in liq. ammonia lead to the tricarbonyltrialkynylmetalates (0) *(3)*. With potassium in liquid ammonia as reducing agent, diamagnetic, pyrophoric, probably polynuclear acetylides*(4)* of Pt(0) and Pd(0) are obtained as follows:

$$K_2[M(CN)_4] + 2\ KC{\equiv}CR + 2\ K \rightarrow 4\ KCN + K_2M(C{\equiv}CR)_2$$

(4), M = Pd or Pt

Finally, an orange-brown, pyrophoric, crystalline phenylacetylide complex *(5)* of formally zero-valent copper is produced by the reaction

$$2\ K_2[\overset{\oplus 1}{Cu}(C{\equiv}C\text{-}C_6H_5)_3] + 2\ Li + 3\ Ba^{2\oplus} \rightarrow \overset{0}{Ba_3}[Cu(C{\equiv}C\text{-}C_6H_5)_3]_2 + 4\ K^{\oplus} + 2\ Li^{\oplus}$$

(5)

The diamagnetism of *(5)* and the position of its C≡C band in the infrared give evidence for a binuclear complex with a Cu-Cu bond.

The infrared spectra of the complex acetylides of metals of the Cr, Ni, Cu, and Zn groups indicate some double-bond character of the carbon-metal bonds, which decreases with increasing electronegativity of the central metal atom of the complex. In the mixed alkynyl complexes of the Pd and Cr groups, the carbonyl and cyano ligands can form much stronger d_π-p_π bonds to the metal than the acetylide ions.

Association of Isomeric Hydroxyalkane Derivatives

G. Geiseler, Leipzig (Germany)

The tendency of isomeric alcohols, oximes, hydroperoxides, and carboxylic acids derived from n-heptane and n-octane to associate was studied in carbon tetrachloride by infrared spectroscopy and thermodynamic methods. For the alcohols, the degree of association decreases when the hydroxyl group is shifted from a terminal position toward the middle of the molecule. The heats of association for the different associates (maximum multiplicity: 8–10 [1]) indicate that cyclic structures are present (at least for tri- and tetrameric associates) in addition to chains and three-dimensional aggregates.

The oximes are much more strongly associated and behave contrarily. The degree of association increases as the hydroximino group approaches the center of the molecule, but the influence of the position of the NOH group is less marked than that of the OH group in the alcohols. The reason obviously is the bifunctional character of the oxime group. Only two- and three-dimensional associates are formed, and these have probably cyclic structures.

The hydroperoxides are intermediate between the alcohols and oximes. Like primary alcohols, primary hydroperoxides are more strongly associated than the secondary isomers; these, however, are more similar to the corresponding oximes, *i.e.* their degree of association increases as the hydroperoxy group approaches the center of the molecule. Here again only dimers and trimers are formed and hence it can be concluded that hydroperoxides also associate bifunctionally and probably form cyclic structures.

No differences (within the accuracy of the methods) were observed for isomeric carboxylic acids; they form only dimeric associates, which are most stable.

These results suggest that molecules which associate bifunctionally tend to form aggregates of only a few molecules, *i.e.* mainly dimers and trimers; moreover, the dimers are all the more dominant, the stronger the hydrogen bonds. In contrast, molecules which associate monofunctionally form mainly chains and three-dimensional networks containing many molecules. The thermodynamic excess functions for the isomeric alcohols and oximes indicate that the position of the functional group in the chain has a considerable influence on the short-range order. Polar and unsaturated solvents not only suppress the association but also reduce the maximum multiplicity and alter the compositions of the associates.

The Importance of Canal Inclusion Compounds for Polymerization Research

H. Clasen, Frankfurt/Main (Germany)

2,3-Dimethylbutadiene forms a canal inclusion compound with thiourea; the dimethylbutadiene molecules lie head-to-tail in tube-like lattice interstices. Although dimethylbutadiene does not polymerize without a catalyst outside these canals, here it polymerizes spontaneously to form an unbranched, highmelting polymer which gives a crystalline X-ray diffraction pattern. This "canal polymerization" is accelerated by X-rays.

After this and the canal inclusion compound of butadiene became known [1], numerous monomers were examined for their ability to undergo canal polymerization under the influence of high-energy β- and γ-rays [2]. Cyclooctatetraene will not form homopolymers, but will copolymerize with dichlorobutadiene. – So far, stereoregular polymers could be produced by irradiation only via canal inclusion compounds. Following recrystallization, their structures and melting points are the same as those of stereoregular Ziegler-Natta polymers. The yields increase with the duration of irradiation, but it is not yet known for certain whether the decrease in average molecular weight with increasing duration of radiation and with increasing impurities can be explained quantitatively by a monoradical reaction mechanism [3].

[1] The term multiplicity denotes the number of monomers in an associate.

Uniform polymers would be expected in ideal single crystals from purest monomers if the mechanism were a biradical one.

Perhydrotriphenylene functions as host not only for small molecules, but also for unbranched macromolecules, which form highly stable, even fusable canal inclusion compounds [4]. This affords a method of separating branched molecules even in the macromolecular range and provides a means of shielding macromolecular substances in order to prevent undesired reactions. Graft polymerization in canals has not yet been observed. Radioactive host substances which can be regenerated are economically important.

Valence Tautomerism of Unsaturated Ring Systems

R. Huisgen, F. Mietzsch, G. Boche, and *H. Seidl*, München (Germany)

The same kinetic method [5] which was used to prove the presence of 0.01 % bicyclo[4,2,0]octa-2,4,7-triene in equilibrium with cyclooctatetraene by valence tautomerism was applied in the cyclooctatriene series. Kinetic investigations of the Diels-Alder additions of pure cycloocta-1,3,5-triene and of bicyclo[4,2,0]octadiene afforded all the parameters of the free-energy diagram; the free energy of tautomerism is 1.5 kcal/mole, and the activation energy for conversion into the bicyclic compound is 27.1 kcal/mole.

With substituted cycloocta-1,3,5-trienes the equilibrium concentration of the bicyclic tautomer at 20 °C strongly depends on the nature of the substituents: It is 0.007 % for 7,8-epoxycycloocta-1,3,5-triene, 5 % for cycloocta-2,4,6-trien-1-one, 9 % for cycloocta-1,3,5-triene, and 100 % for 7,8-dibromocycloocta-1,3,5-triene.

The kinetics of the Diels-Alder reaction also indicate a valence tautomerism between *trans*-1,2-diphenylbenzocyclobutene and *trans,trans*-5,6-dibenzylidenecyclohexadiene (α,α'-diphenyl-*o*-quinodimethane), activation energy: 20.6 kcal/mole. Analogous ring opening of *cis*-1,2-diphenylbenzocyclobutene at 50 °C to give *trans,cis*-5,6-dibenzylidenecyclohexadiene proceeds seventy times as slow.

Fluorosulfonic Acid as a Reaction Medium and a Fluorinating Agent

A. Engelbrecht, Innsbruck (Austria)

Fluorosulfonic acid is probably the most strongly proton-donating solvent. The conductivities observed for solutions of sulfuric acid, perchlorid acid, and hydrogen fluoride in fluorosulfonic acid can best be interpreted by assuming that these substances behave as bases. Only a few fluorides (SbF_5, BF_3, PtF_4, TaF_5, and AuF_3) behave as Lewis acids in fluorosulfonic acid. Correspondingly, many salts, particularly salts of oxyacids, are solvolysed completely in FSO_2OH. In most cases fluorides are subsequently formed, sometimes immediately in strongly exothermic reactions (*e.g.* $FMnO_3$, F_2CrO_2, F_3PO, and F_5TeOH), sometimes only on prolonged heating (*e.g.* $FClO_3$, F_2SeO_2, AsF_5, and AsF_3). In addition to the fluorides, fluorosulfates or fluorosulfate-fluorides may occur as more or less stable intermediates, which in turn undergo thermal decomposition to give either fluoride and SO_3 or mostly oxide and pyrosulfurylfluoride (the anhydride of fluorosulfonic acid).

Characteristic reactions of fluorosulfonic acid are illustrated by its reaction with telluric acid (in the form of BaH_4TeO_6) which leads to new compounds containing the F_5Te group. The most interesting product is undoubtedly F_5TeOH, m.p. 40 °C, b.p. 60 °C, a strong acid which can be used to produce salts with the anion $F_5TeO^{\ominus}$ and other derivatives with the F_5Te group.

Hydrolysis of Metal Alkoxides – a New Method for Studying Polyacids

K. F. Jahr, Berlin (Germany)

If an ester of a metallic acid, *e.g.* $Nb(OC_2H_5)_5$ or $WO(OC_2H_5)_4$, is hydrolysed in an organic solvent with less than the equivalent amount of water in the presence of an anhydro base, a polyanion is formed which precipitates as the salt of the base. The degrees of condensation and protonation of the polyanion are determined mainly by the pK of the base.

Advantages of this new method are:

1. The products are pure salts of the polyacids, without any water of crystallization [1]; in organic solvents, the water only causes hydrolysis and not hydration. Any water contained in the salts is exclusively part of the molecular structure.

2. It is possible to estimate quantitatively the amounts of the metallic acid ester and of the anhydro base which react with a given amount of water to form the salt of a polyacid. The reactions leading to the various anionic species of the polyacid can then be formulated precisely. In particular, the ratio of oxygen to metal atoms (*e.g.* Nb or W) can be determined for each polyanion, a factor which is indispensible for structure determination.

3. Salts of polyacids can be obtained which would be completely hydrolysed in aqueous solution.

4. Salts can be obtained of polyacids which are intermediates in the hydrolysis reaction but which cannot be isolated from aqueous solutions. During the hydrolysis of $WO(OC_2H_5)_4$ in ethanol, the ammonium salt of hexameric "paratungstic acid A" was isolated for the first time [2]. In contrast to the ammonium salt of dodecameric "paratungstic acid Z" (the ammonium paratungstate which crystallizes from aqueous solution in a highly hydrated form) the new salt is readily soluble in water and exhibits all reactions characteristic of the paratungstate A ion, which was hitherto known only in solution; these reactions serve to distinguish it from the paratungstate Z ion.

Oxyacids which condense with metallic acids also react with the esters of metallic acids to give heteropolyacids [3]. Thus, acidolysis of t-butyl orthovanadate $VO(OC_4H_9)_3$ with phosphoric acid in anhydrous organic solvents leads to linear chains of alkoxyvanadatophosphoric acids, $H-(HPO_3-VO_2-OR)_n-PO_4H_2$, in which the vanadate and phosphate groups alternate. The alkoxyl groups are hydrolysed with a little water, giving short-chain vanadatophosphoric acids $H-(HPO_3-HVO_3)_n-PO_4H_2$ *(1)*. The solubilities of *(1)* in organic solvents decrease as the length of the chains increases, and hence the chain extension ceases as soon as the solubility becomes zero. The greater the hydrophilicity of the solvent, the higher is the solu-

bility of the vanadatophosphoric acids, and the degree of polymerization (n) of the products which separate out increases correspondingly. In ethanol and water $n > 100$, so that formula *(1)* becomes practically $(-HPO_3-HVO_3-)_n$ *(2)*. The long-chain polyvanadatophosphoric acids *(2)* produced in water are identical with the "luteophosphorovanadic acids" $P_2O_5 \cdot V_2O_5 \cdot xH_2O$ known since the time of *Berzelius*; like these, *(2)* form polybasic salts $[(-PO_3-HVO_3-)_n]^{n\ominus}M_n^{\oplus}$. The structures of these salts correspond to those of the polyarsenatophosphates which were prepared from molten arsenate/phosphate mixtures and studied extensively by *Thilo* and *Kolditz* [4].

Thermal Decomposition of Hydrazine

K. W. Michel, Göttingen (Germany) [*]

The thermal decomposition of anhydrous hydrazine was induced by shock waves and was studied using an ultraviolet-absorption method [1]. By increasing the temperature and by diluting the hydrazine/argon mixture (to 0.03 % N_2H_4), bimolecular chain reactions were suppressed to such an extent that the decomposition of hydrazine was virtually determined by the unimolecular dissociation reaction $N_2H_4 \rightarrow 2 \cdot NH_2$. The rate of this reaction is a function of pressure; for a molar density (predominantly argon) of $\varrho_T = 7.5 \times 10^{-5}$ moles/cm³, $k_1 = 10^{12.8} \exp(-\frac{52\ \text{kcal/mole}}{RT})$ sec⁻¹; for $\varrho_T = 2.5 \times 10^{-5}$ moles/cm³, $k_1 = 10^{12.0} \exp(-\frac{48\ \text{kcal/mole}}{RT})$ sec⁻¹. Thus for the rate-determining radical reaction

$$NH_2 + N_2H_4 \rightarrow NH_3 + \cdot N_2H_3,$$

$$k_2 = 10^{13.5} \exp(-\frac{17\ \text{kcal/mole}}{RT})\ \text{cm}^3\ \text{mole}^{-1}\ \text{sec}^{-1}.$$

Quantitative study of the decomposition products was extended to the range from 1100 to 2000 °K. NH_3 was determined from its ultraviolet absorption behind reflected waves. At 1100 °K, about 1 molecule of NH_3 is formed per molecule of N_2H_4. The rate of the unimolecular reaction

$$Ar + NH_3 \rightarrow \cdot NH_2 + \cdot H + Ar$$

is proportional to the molar density of Ar between 10^{-5} and 8×10^{-5} moles of Ar/cm³ and between 2000 and 3000 °K:

$$-d[NH_3]/dt = k[NH_3][Ar]$$

with $k = 10^{15.6} \exp(-\frac{79.5\ \text{kcal/mole}}{RT})\ \text{cm}^3\ \text{mole}^{-1}\ \text{sec}^{-1}$

It follows from this that NH_3 is stable under the conditions of the decomposition of N_2H_4. Nevertheless only $^1/_2$ mole of NH_3 is formed per mole of N_2H_4 at 1600 °K, and less than $^1/_{10}$ mole of NH_3 at 2000 °K.

From these molar ratios, from the fact that only small quantities of NH-radical are formed [2] (in contrast to the decomposition of NH_3), and from the presence of large quantities of N_2H_2 in hydrazine decomposition flames [3], it can be concluded that the reaction

$$2 \cdot NH_2 \rightarrow NH_3 + :NH$$

is less important than the reaction

$$2 \cdot NH_2 \rightarrow N_2H_2 + H_2.$$

Introduction of Tertiary Alkyl Groups into Aliphatic Compounds

P. Boldt and *Lothar Schulz*, Göttingen (Germany)

The direct introduction of tertiary alkyl groups into compounds containing active methylene groups did so far not proceed with good yields. When it was attempted to achieve this reaction by mixing t-butyl bromide, the bromo derivative of a CH-acidic compound (*e.g.* bromomalononitrile), and cyclohexene, only isobutene and malonitrile were obtained in addition to 1,2-dibromocyclohexane. The addition of bromomalononitrile to isobutene also failed to afford compound *(1)*, from which t-butylmalononitrile should have been obtainable, but instead gave the new compound *(2)* in good yield.

(1) $(CH_3)_2C(CH_2Br)-CH(CN)_2$ $\qquad$ $(CH_3)_2C(CH_2CH(CN)_2)-Br$ *(2)*

The first experiment showed that reaction conditions must be observed, under which t-alkylcarbonium ions are stable until alkylation has taken place; an attempt was therefore made to alkylate CH-acidic compounds under the conditions of the Friedel-Crafts reaction. It had been demonstrated in the case of acetoacetic ester [1], that only low yields of products containing the t-alkyl group are obtainable, and that CH-acidic compounds decompose readily [2]. We found, however, that these difficulties can be circumvented.

t-Butyl-malononitrile and -malonic ester [3], as well as t-amylmalononitrile were accessible in good yields using Lewis acids as catalysts. CH-Acidic compounds containing activating keto groups were particularly readily alkylated by employing silver cations or protonic acids as catalysts. The previously unknown ethyl t-butylacetoacetate is formed on treatment of t-butyl bromide and ethyl acetoacetate with equivalent quantities of silver perchlorate, or on passing isobutene into a solution of ethyl acetoacetate in nitromethane containing catalytic quantities of perchloric acid. In both cases, the yield did not exceed 60 %, because the formation of ethyl t-butylacetoacetate is reversible.

The Steric Course of Catalytic Hydrogenations

F. Zymalkowski, Bonn (Germany)

The widespread opinion that catalytic hydrogenations always yield the stereoisomer of highest energy which is stable under the conditions used is at variance with the following findings:

1) Hydrogenation of *o*-, *m*-, or *p*-cresol with Rh/Al_2O_3 in aqueous NaOH at 20 °C and 1 atm of hydrogen always leads to the *cis*-methylcyclohexanols as the major products, *i.e.* *m*-cresol yields the isomer of lower energy under the same conditions as *o*- and *p*-cresol yield the isomer of higher energy. Here the relative positions of two substitutents is there-

[4] *E. Thilo* and *L. Kolditz*, Z. anorg. allg. Chem. *278*, 122 (1955).

[*] Present address: Esso AG., Hamburg (Germany).

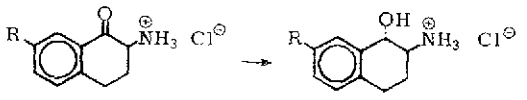
[2] *W. J. Monacelli* and *G. F. Hennion*, J. Amer. chem. Soc. *63*, 1722 (1941).

[3] *P. Boldt* and *L. Schulz*, Naturwissenschaften *51*, 288 (1964).

fore more important for the steric course of the reaction than the energy content of the hydrogenation products.

2) Hydrogenation as above with Pt instead of Rh/Al_2O_3 gives rise to the *trans*-methylcyclohexanols as the major products [1]. The catalyst, too, can therefore influence the steric course of the hydrogenation more decisively than the energy content of the hydrogenation products.

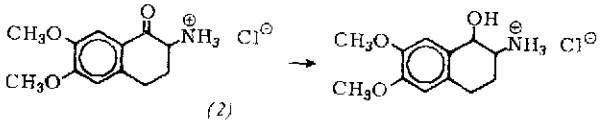


(1a): R = H

(1b): R = OCH_3

(1c): R = OH

3) Hydrogenation of *(1a)*, *(1b)*, or *(1c)* in aqueous-ethanolic hydrochloric acid produces a *trans*-aminotetralol from each. However, under the same conditions, *(2)* gives rise to the *cis*-aminotetralol. Here the nature of the substituent determines the steric results.

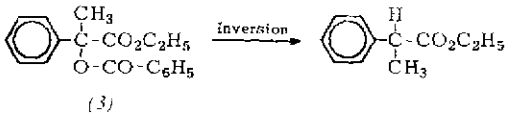


(2)

4) When *m*-cresol is hydrogenated in acetic acid at room temperature with Pt/Rh [2], 55–60% *trans*-3-methylcyclohexanol is obtained at atmospheric pressure, but 60% of the *cis*-isomer is obtained at 5 atm pressure. Similar results are found for resorcinol. This means that a relatively slight alteration in pressure can influence the steric course of a hydrogenation.

Since isomerization of the products certainly does not occur under the conditions used for these hydrogenations, it appears that the energy content of the stereoisomers formed is only one of the factors – and by no means always the dominating one – which influence the steric course of catalytic hydrogenations.

Hydrogenolysis of ethyl D-benzoylatrolactate *(3)* over Pd/$BaSO_4$ in 10% ethanolic triethylamine causes inversion of the configuration to give ethyl L-α-phenylpropionate in 70% optical purity.



(3)

Since the reaction occurs only in this strongly polar solvent, it can be concluded that a polar mechanism and not a radical mechanism is involved, and that a benzoyloxy group is displaced in an S_N reaction by a hydride anion.

The Photolysis of Ammonia in the Vacuum-Ultraviolet

W. Groth, Bonn (Germany)

The photolysis of ammonia was studied at 1849 Å (Hg), 1470 Å (Xe), 1236 Å and 1165 Å (Kr), both in stationary and flowing systems. At 1849 Å, the primary process is

(a) $NH_3 + h\nu \rightarrow NH_2 + H$;

at 1470 Å, 12 to 13% of the NH_3 molecules decompose according to

(b) $NH_3 + h\nu \rightarrow NH + H_2$,

87 to 88% according to (a), while at 1236 Å and 1165 Å, 14% of the NH_3 molecules decompose according to (b), 86% according to (a) and/or according to

(c) $NH_3 + h\nu \rightarrow NH + H + H$.

Addition of molecular hydrogen has no influence on the quantum yield of the NH_3 decomposition. The stationary H-atom concentration is about 3.5 times higher at 1236 Å and 1165 Å than at 1470 Å.

The pressure dependence of the quantum yield was measured in all three cases. The quantum yield is the larger, the shorter the wavelengths used. Reaction mechanisms were derived, which, in the case of (b) and (c) correctly describe the nature and the ratio of the products if reactions of the NH radicals are taken into account.

The photochemical transformation of flowing ammonia to hydrazine is achieved at 1849 Å with a relative yield of up to 86%. It is much smaller at shorter wavelengths, due to the primary formation of NH radicals.

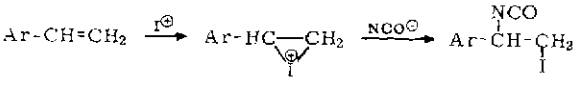
[GDCh-Ortsverband Karlsruhe (Germany), January 7th, 1965] [VB 901/205 IE]

German version: Angew. Chem. 77, 387 (1965)

SELECTED ABSTRACTS

High-melting metal oxides were obtained in crystalline form by *K.-Th. Wilke* from solutions in melts of metal compounds which decompose at high temperatures (*e.g.* oxalates, nitrates, or sulfates). Suitable media for the decomposition include alkali salts which can be dissolved away with water after the reaction. The oxides are obtained mainly as dendritic or skeleton-like crystal clusters. Platelets with a maximum diameter of 5 mm and needles up to 15 mm long were produced. Thus, CeO_2 was prepared from $Ce(SO_4)_2$ in NaCl as glistening white crystals in the form of hairs or needles, Fe_2O_3 from $FeSO_4$ in Na_2SO_4 as dark red platelets or from $FeSO_4$ in LiCl as green-black platelets, and TiO_2 from $TiOSO_4$ as a yellowish crystalline powder. / Z. anorg. allg. Chem. *330*, 164 (1964) / –Kr. [Rd 125/312 IE]

New syntheses of aziridines, carbamates, oxazolidones, and cis- or trans-2-amino alcohols were achieved by *A. Hassner* by addition of pseudohalogens such as INCO and INO_2 onto olefins. INCO adds on exclusively *trans* to open-chain and cyclic olefins and *trans*-diaxially to steroid olefins.



This permits steroespecific introduction of nitrogen functions into organic compounds. The additions proceed *via* an iodonium ion as intermediate. / 148th Meeting Amer. chem. Soc. 1964, Abstracts p. 29S / –Ma. [Rd 129/316 IE]

The synthesis of FSO_2NF_2 and $(FSO_2)_2NF$ has been carried out by *W. Lustig, C. L. Bumgardner* et al. Thus two further N–F compounds containing S–N single bonds have become known in addition to F_5S-NF_2. FSO_2NF_2 is formed from SO_2 and N_2F_4 either by heating at 100 °C at 100 atm pressure or by irradiation with ultraviolet light ($\lambda = 2537$ Å); the yield is 60 % (based on the SO_2). It is a colorless gas, m.p. −110 °C, b.p. −18 °C, with a Trouton constant of 21.29. $(FSO_2)_2NF$ is formed by fluorination of imidodisulfuryl fluoride $(FSO_2)_2NH$ at 25 °C with a 1:9 mixture of fluorine and helium. It is a colorless gas, m.p. −79.9 °C, b.p. −60.8 °C, and has a Trouton constant of 23.3. / Inorg. Chem. *3*, 1165 1964) / −La. [Rd 185/394 IE]

The synthesis of alkali fluoroxenates(VI) has been carried out by *R. D. Peacock, H. Selig,* and *I. Scheft*. Molten XeF_6 (m.p. 46 °C) reacts with MF (where M = Cs or Rb) to give $MXeF_7$; these heptafluoroxenates(VI) decompose above 50 °C (M = Cs) and above 20 °C (M = Rb), respectively, to yield XeF_6 and octafluoroxenates(VI) M_2XeF_8, which are stable up to 400 °C. KF and NaF are also absorbed by XeF_6, but here there are probably no compounds formed that are stable at room temperature apart from the octafluoroxenates(VI). The sodium derivative decomposes below 100 °C and can be used to purify XeF_6. LiF does not react with XeF_6. $CsXeF_7$ and molten XeF_6 are both yellow; the other fluoroxenates(VI) and solid XeF_6 are colorless. The infrared spectra of XeF_6, $MXeF_7$, and M'_2XeF_8 (M' = Cs, Rb, K, or Na) are quite different. $CsXeF_7$ is pseudotetragonal; Cs_2XeF_8 and Rb_2XeF_8 are considered to be the most stable compounds of Xe. / Proc. chem. Soc. (London) *1964*, 285 / −Gn. [Rd 195/404 IE]

Charge-transfer complexes of biochemically important substances have been investigated by *L. D. Wright* and *D. B. McCormick*. L-Tryptophan, *p*-aminobenzoic acid, flavianic acid, and picric acid, for example, form strong π-complexes with a twofold amount of D-riboflavin, as indicated by the 56 % reduction in the extinction of these substances on addition of riboflavin. 1,1,3-Tricyano-2-aminoprop-1-ene forms stronger complexes with D-riboflavin, flavin mononucleotide, flavin adenine dinucleotide, and diphosphopyridine nucleotide than with pyrimidine compounds. It is probably complexes between pyrimidine and flavin coenzymes which are involved in hydrogen and electron transport in biological systems, for 1,1,3-tricyano-2-aminoprop-1-ene is a strong inhibitor of oxidative phosphorylation. / Experientia *20*, 501 (1964) / −Re. [Rd 167/376 IE]

A synthesis of lactones by hydroformylation of unsaturated esters is reported by *J. Falbe, N. Huppes,* and *F. Korte*. Aliphatic and alicyclic α,β- or β,γ-unsaturated carboxylic esters react with CO/H_2 (synthesis gas) at 200–300 atm pressure and 200–250 °C in the presence of 1–2 % $Co_2(CO)_8$ as catalyst to give mono- or bicyclic lactones. Long-chain α,β-unsaturated esters yield both γ- and δ-lactones owing to isomerizations which occur during the reaction. The lactone formation proceeds in three steps:

$$RHC{=}CR\text{-}CO_2R + CO/H_2 \rightarrow OHC\text{-}CHR\text{-}CHR\text{-}CO_2R$$

$$\xrightarrow{CO/H_2} HOH_2C\text{-}CHR\text{-}CHR\text{-}CO_2R$$

$$\rightarrow \text{(lactone)} + ROH$$

Thus, for example, ethyl acrylate gives 88 % γ-butyrolactone, ethyl crotonate gives 67 % δ-valerolactone plus 23 % β-methyl-γ-butyrolactone, ethyl β,β-dimethylacrylate gives 88 % β-methyl-δ-valerolactone, ethyl sorbate gives 33 % 3-propyl-γ-butyrolactone and 49 % γ-ethyl-δ-valerolactone. / Chem. Ber. *97*, 863 (1964) / −Ma. [Rd 130/317 IE]

A filter solution for the mercury resonance line at 1849 Å is described by *C. M. Wolff* and *R. Pertel*. This spectral line can normally be disregarded in photochemical experiments for both ordinary quartz and atmospheric oxygen absorb strongly at this wavelength. (In order to work at this wavelength, a specially purified quartz, *e.g.* Suprasil, must be used for all optical parts, and the light beam must pass through a vacuum or a nitrogen atmosphere.) A 3.2×10^{-4} M solution of 9,10-dimethylanthracene in cyclohexane with a light path of 1 mm absorbs 99.9 % of the next Hg resonance line at 2537 Å but transmits about 20 % of the intensity at 1849 Å. / J. opt. Soc. America *54*, 1168 (1964) / −Hz. [Rd 168/377 IE]

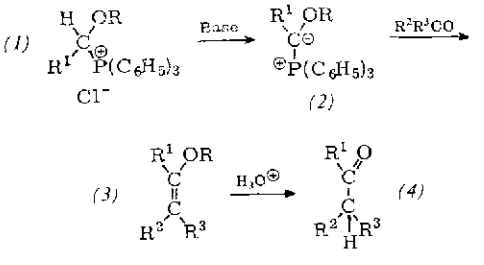
Potentiometric "acid-base" titrations in fused salts were carried out by *A. M. Shams el Din* and *A. A. El Hosary*. Following a proposal by *H. Lux*, acids and bases in fused salts are defined by the equation:

$$\text{acid} + O^{2-} \rightarrow \text{base},$$

i.e. the O^{2-} activity must be measured. Electrodes made of silver, nickel, copper, iron, or tungsten are suitable for this purpose. These electrodes differ in their standard potentials, and thus the determination of the equivalence point during titrations becomes possible by measuring the potential difference (maximum ΔE at the equivalence point) between any two of the above indicator electrodes. In this way, the difficult task of preparing reference electrodes of constant potential is avoided. The titration of the "acids" $NaPO_3$, NaH_2PO_4, and $K_2Cr_2O_7$, for example, with the "base" Na_2O_2 in molten $NaNO_3$ is described. / J. electroanalyt. Chem. *8*, 139 (1964) / −Hz. [Rd 170/379 IE]

***N*-Fluoro compounds of the types RNF_2, HNF–COOR, and RFN–CO–NHR** have been synthesized from amides, urethanes, and *N*-substituted ureas by *R. E. Banks, R. N. Haszeldine,* and *J. P. Lalu* by passing a stream of fluorine diluted with nitrogen through 5–16 % aqueous solutions of the organic compounds at 0–5 °C. The reactions carried out included: $H_3C-CO-NH-CH_3 \rightarrow H_3CNF_2$ (7 % yield); $H_2N-CO-OC_2H_5 \rightarrow FHN-CO-OC_2H_5$ (30 % yield, b.p. 56 °C/5 mm) + $H_3C-NF-CO-NH-CH_3$ (27 % yield, b.p. 74 °C/19mm) + H_3CNF_2(4 % yield); $H_5C_2-NH-CO-NH-C_2H_5 \rightarrow H_5C_2-NF-CO-NH-C_2H_5$ (9 % yield, b.p. 56 °C/1 mm) + $H_5C_2-NF_2$ (5 % yield, b.p. 15 °C). Disubstituted compounds RNF–CO–NFR were not isolated. The *N*-fluoro compounds are strong oxidizing agents. / Chem. and Ind. *1964*, 1803 / −Ma. [Rd 171/380 IE]

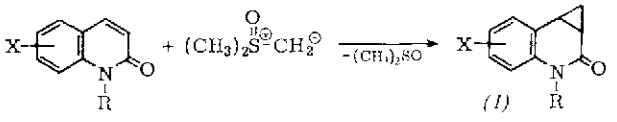
A new synthesis of methyl ketones applying the Wittig olefin synthesis is described by *D. R. Coulson*. α-Halogenoethyl methyl ether reacts with triphenylphosphine to give the phosphonium salt *(1)*, which on treatment with potassium t-butoxide in glycol monomethyl ether yields the unstable ylide *(2)*. This ylide reacts with aldehydes and ketones to form the enol ethers *(3)*, which are separated off by distillation and hydrolysed with aqueous methanolic HCl to give



the ketones *(4)*. Thus, for example, benzaldehyde → 3-phenylpropan-2-one in 88 % yield, cinnamaldehyde → 3-styrylpropan-2-one in 82 % yield, n-heptanal → 2-nonanone (57 %), pelargonaldehyde → 2-undecanone (51 %), cyclohexanone → cyclohexyl methyl ketone (45 %), and 2-octanone → 3-methylnonan-2-one (15 %). / Tetrahedron Letters *1964*, 3323; cf. Angew. Chem. *71*, 260 (1959) / −Ma. [Rd 175/384 IE]

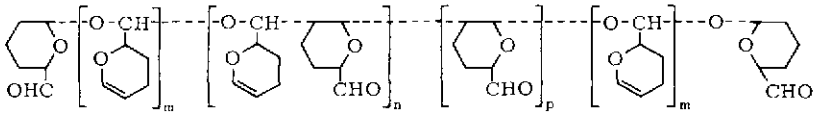
Aliphatic carboxylic acids formed by a Friedel-Crafts synthesis from pentane and carbon dioxide in the presence of $AlCl_3$ were detected for the first time by gas chromatography by *H. Hopff* and *Th. Zimmermann*. At 90–100 °C and a CO_2 pressure of 100–144 atm, a 1 % yield (based on $AlCl_3$) of the following acids is obtained: $C_nH_{2n-1}COOH$ (n = 2, 4, or 5), α-methylbutyric acid, and an isomeric acid $H_5H_{11}COOH$. – The synthesis of a small amount of benzoic acid using this method was achieved by *Friedel* and *Crafts* in 1888; later *Meyer* and *Hopff* obtained much higher yields of benzoic acid (German patent 524186). / Helv. chim. Acta *47*, 1293 (1964) / –Re. [Rd 166/375 IE]

***N*-Alkyl-3,4-dihydro-3,4-methylenequinol-2-ones, derivatives of a new ring system,** were obtained by *B. Loev, M. F. Kormendy*, and *K. M. Snader* from dimethylsulfoxonium methylide and *N*-alkylquinol-2-ones. For example, the reaction of *N*-methylquinol-2-one in dry dimethyl sulfoxide with excess ylide (prepared from trimethylsulfoxonium iodide and NaH) followed by hydrolysis and distillation leads to the derivative

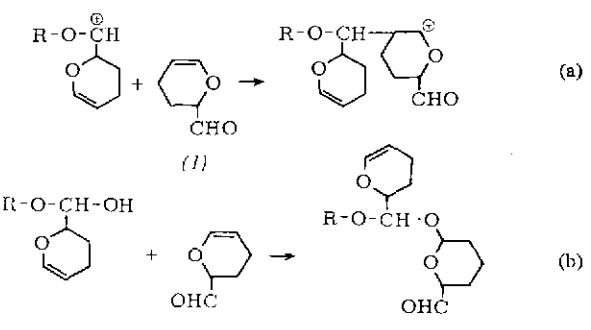


(1), R = CH_3, b.p. 100–104 °C/0.005 mm, n_D^{25} = 1.6100, in 43 % yield. Further derivatives prepared include *(1)*, X = 6-CF_3, R = CH_3, m.p. 82.5–84 °C (78 % yield); *(1)*, X = 6-CF_3, R = C_2H_5, m.p. 60.5–62 °C (56 % yield); and *(1)*, X = 7-CF_3, R = CH_3, m.p. 50 °C (66 % yield). / Chem. and Ind. *1964*, 1710 / –Ma. [Rd 172/381 IE]

High molecular-weight soluble polymers were made from 2*H*-3,4-dihydropyran-2-carboxaldehyde *(1)* ["dimeric acrolein"] by *H. Ohse, H. Cherdron*, and *F. Korte* by polymerization with diethylaluminum chloride at 25 °C/760 mm. The polymers formed by working below 0 °C are insoluble. The average conversion was 67 %. In solvents with high dielectric constants, the products have significantly higher molecular weights, *e.g.* in dichloroethane (ε = 10.65, 69.4 % conversion), $\eta_{sp}/c \cdot 10^2$ = 3.0; in chloroform (ε = 4.81, 61.8 % conversion), $\eta_{sp}/c \cdot 10^2$ = 1.8 (c = 10 g/l in pyridine). The polymers dissolve in pyridine, and some in $CHCl_3$, tetrahydrofuran, or aromatic hydrocarbons. When the solutions of the polymers are not stabilized by addition of a basic substance, *e.g.* β-naphthylamine, the polymers soon precipitate out quantitatively. From the results of infrared spectroscopic examination, the authors propose the following structure for the polymers:



(2)



which are formed by steps (a) and (b). / Makromolekulare Chem. *76*, 147 (1964) / –Hl. [Rd 183/392 IE]

The thiazolo[3,2-*a*]pyridinium ion, a new aromatic heterocyclic system, has been prepared by *C. K. Bradsher* and *D. F. Lohr*. Its salts are readily obtained by dehydration of pyridyl sulfides *(1)* containing a carbonyl group in β-position to the sulfide bridge. The sulfides are prepared from the sodium salt of 2-mercaptopyridine and an α-acylalkyl halide. The parent ion *(2)* is obtained from the dimethylacetal of chloro-

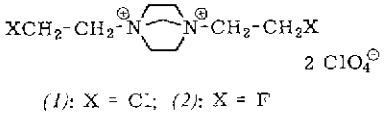
acetaldehyde *via* an acetal of b.p. 100–103 °C/0.2 mm (32 % yield), which is hydrolysed with concentrated sulfuric acid and isolated as its perchlorate, m.p. 281–283 °C (85 % yield). Bromoacetone affords the analogous compound *(3)*, m.p. 177–178.5 °C, and phenacyl bromide yields *(4)*, m.p. 201–202 °C. / Chem. and Ind. *1964*, 1801 / –Ma. [Rd 173/382 IE]

The condensation of formaldehyde with bis-(2-halogenoethyl)-amines in alcohol at room temperature was investigated by *G. R. Pettit* and *J. A. Settepani*. The derivative *(1)* of a new ring system 1,4-diazabicyclo[2,2,1]heptane is obtained from bis-(2-chloroethyl)amine in 76 % yield as its diperchlorate, m.p. 222–223 °C (decomp.). A dose of 23 mg/kg completely inhibits the growth of Walker 256 carcinoma in rats. An ethanolic solution of bis[di-(2-fluoroethyl)amino]methane,

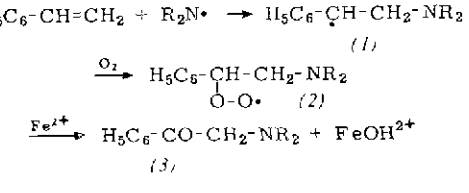


(1): X = Cl; *(2)*: X = F

$CH_2[N(CH_2CH_2F)_2]_2$, obtained from formaldehyde and bis-(2-fluoroethyl)amine, gave the same quaternary ammonium salt *(2)*, m.p. 223.5–225 °C (decomp.), as an ethanolic solution of bis-(2-fluoroethyl)amine and formaline. The results of NMR studies and the chemical properties of the products are in agreement with the structures assumed. / Chem and Ind. *1964*, 1805 / –Ma. [Rd 174/383 IE]

A new synthesis of α-amino ketones from olefins has been reported by *F. Minisci* and *R. Galli*. Amino radicals are generated by the redox system *N*-chloroamine/Fe^{2+} or Cu^+ salt. They add onto olefinic double bonds. The alkyl radical *(1)* thus formed reacts with oxygen to give a peroxy radical *(2)*, which is then reduced to the α-amino ketone.

The reactivity of the amino radical depends on its charge distribution and on steric factors. Products prepared include the amino ketones from styrene and dibutylamine (76 % yield); from styrene and morpholine (41.5 %); from *trans*-stilbene and dibutylamine (21.7 %); from *trans*-stilbene and



(1)

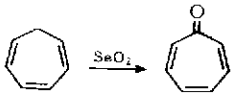
hexamethylbenzene *(1)*, yield cyclohexadienones. The reagent is capable of removing hydrogen from reactive methylene groups in the form of hydride ion, so that diphenylmethane derivatives *(2)* result. / Abstracts, 148th Meeting Amer. chem. Soc. *1964*, 20U / –Ma. [Rd 152/339 IE]

A one-stage synthesis of tropone *(1)* has been discovered by *P. Radlick*. A mixture of 0.1 mole of KH_2PO_4 in 33 ml of water, 330 ml of dioxane, 0.46 mole of 1,3,5-cycloheptatriene *(2)*, and 0.48 mole of selenium dioxide are heated at 90 °C for 15 h.



(2) *(1)*

After cooling, the mixture is filtered and poured into 750 ml of ice water; the aqueous solution is extracted thrice with 250 ml of methylene chloride each. The extract is washed with 10 % $NaHCO_3$ solution, dried over magnesium sulfate, filtered, and concentrated *in vacuo*. Vacuum distillation of the liquid residue affords about a 25 % yield of tropone, b. p. 91–92 °C/4 mm, $n_D^{23} = 1.6152$. / J. org. Chemistry *29*, 960 (1964) / –Bi. [Rd 153/340 IE]

Organic solvents alter the coding properties of synthetic messenger RNA. This was observed by *A. G. So* and *E. W. Davie* when they added alcohols, acetone, dioxane, or ethylene glycol to protein-synthesizing cell-free systems of *Escherichia coli*. For example, ethanol suppresses the incorporation of phenylalanine into acid-insoluble material normally observed in the presence of polyuridylic acid but stimulates the incorporation of leucine and isoleucine. The incorporation of proline into acid-insoluble protein in the presence of polycytidylic acid is increased twentyfold by ethanol, but the amino acids leucine and threonine are also incorporated, although they are normally not coded by polycytidylic acid. The dependence of the incorporation on the presence of organic solvents and on the magnesium ion concentration, and the striking parallel between these phenomena and the effects of streptomycin [1] will probably make it necessary to revise the code assignments made to date. It is possible that the keto-enol tautomerism equilibria in the bases of the transfer RNAs become displaced because of the lower polarity of the organic solvents and that this alters their coding properties. / Biochemistry *3*, 1165 (1964) / –Sch. [Rd 181/390 IE]

[1] *J. Davies, W. Gilbert*, and *L. Gorini*, Proc. nat. Acad. Sci. U.S.A. *51*, 883 (1964).

The acid-catalysed oxidative solvolysis of diphenyl ketene *(1)* and its *N*-(*p*-tolyl)imine *(2)* in dimethyl sulfoxide (DMSO) is described by *I. Lillien*. Benzilic acid is formed in 88 % yield from *(1)* in DMSO containing a few drops of concentrated HCl or $HClO_4$, while *(2)* gives rise to 91.5 *N*-(*p*-tolyl)-α-hydroxydiphenylacetamide *(3)*. When a solution of *(2)* in DMSO is mixed with an equal volume of methanol and acidified with a few drops of conc. HCl, 71 % *N*-(*p*-tolyl)-α-methoxydiphenylacetamide *(4)* can be isolated. In the absence of water (gaseous HCl in ether/DMSO), *(2)* affords only 66 % *N*-(*p*-tolyl)diphenylacetamide *(5)*, which arises by hydrolysis of the primary keteneimine/HCl adduct during work-up. All the reactions proceed at room temperature.

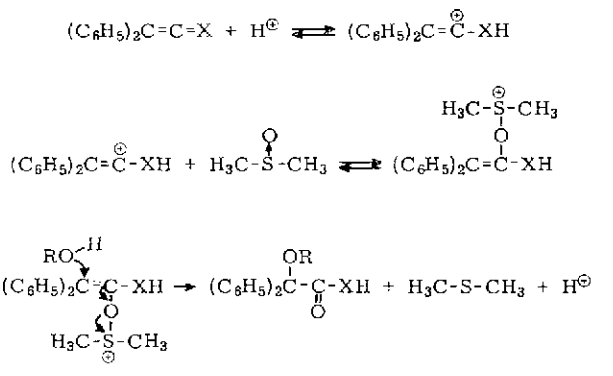
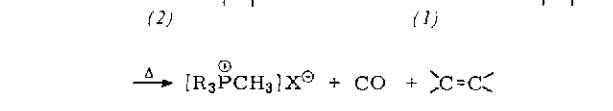
The following course of reaction is probable (X = $-N-C_6H_4-CH_3(p)$ or $=O$; R = H or CH_3):



/ J. org. Chemistry *29*, 1631 (1964) / –Bi. [Rd 154/341 IE]

A new synthesis of olefins has been discovered by *D. B. Denney, C. J. Rossi*, and *J. J. Vill*. Pyrolysis of the phosphonium salts *(1)* at 130–225 °C produces high yields of olefins derived from the alcoholic component of the ester *(2)*.

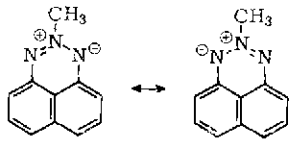


(2) *(1)*

R = C_4H_9, C_6H_5; X = Cl, Br

The salts *(1)* are prepared by mixing α-halogeno esters *(2)* with tributyl- or triphenylphosphine and can be used without previous isolation. Thus, for example, pyrolysis of the salt obtained from n-octyl bromoacetate and tributylphosphine at 170 °C/14 mm for 4 h afforded 72 % pure 1-octene (based on salt). Secondary butyl esters pyrolysed at 160 °C gave 33 % 1-butene, 48 % *trans*-2-butene, and 19 % *cis*-2-butene (overall yield: "excellent"). Cyclohexyl esters give 57 % cyclohexene; *cis*-2-phenylcyclohexyl esters give (at 195 °C/0.5 mm) 83 % 1- and 17 % 3-phenylcyclohexene; the *trans*-isomer gives 65 % 1- and 35 % 3-phenylcyclohexene. t-Amyl esters give rise to 32 % 2-methyl-1-butene and 68 % 2-methyl-2-butene (total yield 60 %). In general, primary alcohols yield terminal olefins, secondary and tertiary alcohols yield approximately thermodynamic equilibrium mixtures of isomeric olefins (in contrast to the pyrolysis of the esters or xanthates of the alcohols). Sometimes rearrangements occur; for example, cyclopropylmethanol yields butadiene instead of methylenecyclopropane. / J. org. Chemistry *29*, 1003 (1964) / –Bi. [Rd 155/342 IE]

2-Methyl-2 *H*-naphtho[1,8-*de*]triazine, a blue triazine, has now been recognized to be the first representative of a new class of heterocyclic compounds. Although the compound *(I)* was first obtained by *Sachs* [1] in 1909, its structure has only now been elucidated by *M.J.Perkins*. It is produced by methylation of 1*H*-naphtho[1,8-*de*]triazine (prepared by diazotization of



(I)

1,8-diaminonaphthalene in acetic acid) using dimethyl sulfate in caustic soda and crystallizes from petroleum ether as blue-black needles, m.p. 132 °C; the yield is 30 %. The isomeric 1-methyl derivative is also obtained in 30 % yield as a by-product; it forms red prisms, m.p. 91–92 °C from CCl_4. The unusual triazine *(I)* forms a 1:1 adduct with 1,3,5-trinitrobenzene of m.p. 154 °C, and can be converted into a tetrabromo derivative, m.p. 212–213 °C. Its methyl group reacts with aromatic aldehydes to give 2-(β-styryl)-2*H*-naphtho-[1,8-*de*]triazines. / J. chem. Soc. (London) *1964*, 3005 / –De.
[Rd 180/389 IE]

Two molecular-weight ranges in poly-(4-vinylpyridine) were found by *P. P. Spiegelman* and *G. Parravano*, who polymerized 4-vinylpyridine by initiation with butyl-lithium in toluene or heptane at temperatures between –30 and + 30 °C. The polyvinylpyridine precipitates out. The conversion to polymer was measured by dilatometry and was found to be proportional to the monomer concentration, *i.e.* to $[H_2C{-}C{-}C_5H_4N]^1$, and to $[n\text{-}C_4H_9Li]^{1/2}$; the activation energy is 12.7 kcal/mole. These results suggest the formation of an equilibrium complex by the growing polymer anions. It was concluded from the conversion data that one chain end is activated by each molecule of initiator and that no chain transfer occurs. Fractionation of the polymer by elution chromatography divided it into two quite sharp molecular-weight ranges (3.2×10^4 and $1.0–3.0\times10^6$). When the limit of solubility of the growing polymer is exceeded, the precipitating polymer apparently encloses active chain ends which then cannot grow further. Active ends that lie exposed, however, continue to grow to higher molecular-weight polymers. / J. Polymer Sci. *A 2*, 2245 (1964) / –Hl.
[Rd 182/391 IE]

The amino-acid sequence around the active site in liver alcohol dehydrogenase from horses has been elucidated by *T. K. Li* and *B. L. Vallee*. Of the 28 molecules of cystein in the enzyme, only two can be carboxymethylated with [^{14}C]iodoacetate at pH 7.5 and 22 °C within 165 min. This reaction completely inactivates the enzyme. The labelled protein was then hydrolysed with succinyltrypsin yielding 36–38 different peptides, although from its content of 80 lysine and arginine residues about twice this number was to be expected. Two-dimensional electrophoresis and chromatographic purification of the peptides showed that only one was radioactive. This peptide contained the sequence Met–Val–Ala–Thr–Gly–Ileu–Cys–Arg. These results suggest that the enzyme consists of two similar or identical peptide chains. / Biochemistry *3*, 869 (1964) / –Hö.
[Rd 189/398 IE]

The diphenylphosphide anion, $(C_6H_5)_2P^{\ominus}$, can be prepared from diphenylphosphine using either lithium aluminum hydride or butyl-lithium, and according to studies by *F. G. Mann* and *M. J. Pragnell* has the ability to cleave not only anisole, but also benzyl phenyl ether (88 % phenol, 82 % benzyldiphenylphosphine), allyl phenyl ether (78 % phenol, 76 % allyldiphenylphosphine), and benzyl *p*-hydroxyphenyl ether (46 % hydroquinone, 43 % benzyldiphenylphosphine). The cleavage occurs in boiling tetrahydrofuran. When $(C_6H_5)_2P^{\ominus}$ is heated alone in tetrahydrofuran, 22 % 4-hydroxybutyldiphenylphosphine is formed after 7 h. *O,O'*-Methylenecatechol affords 18 % catechol and 31 % *o*-hydroxymethyldiphenylphosphine after 10 h under these conditions. Ethyl ethers such as phenetole are hardly attacked, so that demethylation of ethoxymethoxy compounds can be effected without appreciable de-ethylation. / Chem. and Ind. *1964*, 1386 / –Ma.
[Rd 127/314 IE]

An adduct of triphenylphosphine and hydrogen peroxide has been discovered by *D. B. Copley*, *F. Fairbrother*, *J. R. Miller*, and *A. Thompson*. During the preparation of $(C_6H_5)_3PO$ from triphenylphosphine and H_2O_2 in methanol, the solvent was distilled off *in vacuo* at room temperature and the adduct $[(C_6H_5)_3PO]_2{\cdot}H_2O_2$ was obtained as a white solid, m.p. 131 °C, which dissolves in chloroform, methanol, and acetone. The adduct decomposes *in vacuo* at 160 °C but is reformed from its components in methanol. The infrared spectrum of the adduct contains a band at 1180 cm^{-1} which is not due to an H–O deformation vibration, for it is also present in the same position in the spectrum of $[(C_6H_5)_3PO]_2{\cdot}H_2O_2$. This band was assigned to a P=O vibration which is also observed in the spectrum of $(C_6H_5)_3PO$, where it lies 15 cm^{-1} higher. The shift in wave numbers indicates that the H_2O_2 links pairs of $(C_6H_5)_3PO$ molecules together via hydrogen bridges. The absence of absorptions between 1600 and 1700 cm^{-1} proves that the adduct is not a hydrate. / Proc. chem. Soc. (London) *1964*, 300 / –Gn.

BOOK REVIEWS

Massenspektrometrie (Mass Spectrometry). By *C. Brunnée* and *H. Voshage*. Part I: Physikalische und apparative Grundlagen (Physical Fundamentals and Basic Equipment); Part II: Anwendungen (Applications). Karl Thiemig KG., Munich 1964. 1st Edit., XII + 316 pp., numerous illustrations, several tables, linen, DM 54.– (about $ 13.75).

It is about ten years since the book by *H. Ewald* and *H. Hintenberger* on the methods and applications of mass spectroscopy was published. Since then, no monograph on mass spectroscopy has appeared in the German language. The book by *Brunnée* and *Voshage* is written by two first-class capacities in this field and reports on the theoretical fundamentals, the instrumentation and equipment, and the practical applications of mass spectrometry. Following an introductory section, chapters are devoted to mass separation, sample introduction, and ion detection. A rigorous but thoroughly comprehensible treatment is given to the physical fundamentals of the subject, and the apparatus required are well explained; the text is clear and goes into sufficient detail. The second part of the book deals with the applications of mass spectrometry, with the determination of the relative abundances of isotopes, precision mass determinations, quantitative analyses, qualitative analyses, physicochemical investigations, and studies of the interactions of ions with materials.

It is understandable and excusable that the authors have given a preferential treatment to their own field of research. For this reason, the section on the determination of the relative abundances of isotopes seems to be overaccentuated in comparison

with the other chapters, and the Atlas-Werke in Bremen is given too strong preference by frequent mention in the text and in the figures compared with other instrument manufacturers.

However, on the whole, this book can be recommended as an introduction to and a review of the complete field of mass spectrometry for a broad range of readers, including physicists, chemists, and engineers, as well as geologists and mineralogists, and even clinical physicians and biologists.

H. Kienitz [NB 335/193 IE]

Anleitung zum Messen von Absorptionsspektren im Ultraviolett und Sichtbaren (Directions for Measuring Absorption Spectra in the Ultraviolet and Visible Regions). By *M. Pestemer*. Georg Thieme Verlag, Stuttgart 1964. 1st edit., viii + 78 pp., 7 figs., paperback DM 7.80 (about $ 2.00).

This little pocketbook attempts to give foolproof instructions for the measurement of absorption curves for purposes of structural investigations or for determining concentrations. In the first section (26 pages), the fundamental aspects of optical absorption are introduced, and the most important structural elements of spectral photometers are described. This is followed by a discussion of sources of errors (14 pages), including information on the measurement of fluorescence spectra and on the determination of the direction of transition moments. There follow some practical procedures for the purification of samples and solvents, and then several tables are given containing a variety of data.

The book contains a number of useful tips, but for more detailed information and discussions, recourse will still have to be made to more comprehensive works. More precise specifications are desirable occasionally, *e.g.* in the description of the prerequisites for the validity of Beer's law (p. 10). In the discussion of methods for determining the direction of transition moments (p. 38), the expressions "direction of photoexcitation" or "orientation of electronic excitation" are used, but the correct term "transition moment" does not appear. Moreover, magnetically induced dichroism of molecules in solution has probably never been used to evaluate the direction of transition moments (p. 39). The concept of the transition moment or transition probability is also not utilized in the discussion of the Beer-Lambert equation; instead, an absorption equation is derived on the basis of the absorption cross-section – a concept no longer used in molecular spectroscopy (p. 8). *W. Liptay* [NB 265/123 IE]

Biochemie der Mineral- und Spurenelemente (Biochemistry of Mineral and Trace Elements). By *Th. Bersin*. Akademische Verlagsgesellschaft, Frankfurt/Main 1963. 1st Edit., XVI + 695 pp., 99 figures, 1 color plate, linen, DM 68.– (about $ 17.25).

The importance of trace elements (*i. e.* elements required in only minute concentrations by living organisms) in both biochemistry and medicine has become more and more apparent within recent years. Since no monograph had hitherto been published on this rapidly developing field, the attempt to give a comprehensive survey is worthy of recognition. *Bersin* has divided his book into three main sections, which can be characterized as follows: theoretical fundamentals and general importance; descriptions of individual trace elements; practical applications.

The second part of the book is the longest and completest (pp. 238–554); here the importance of the individual trace elements is recorded, almost in the form of a handbook. The value of this compilation is evident from the fact that, in the reviewer's estimation, over 90% of the numerous publications cited appeared within the past ten years. A list of references as complete as this is hard to find anywhere else. Probably due to the compactness of this review of a field which is still in rapid development, important papers with well-founded results are often given just as little space as work of poorer quality. Critical appraisal of the contents of the book is thus left to the reader.

Before the individual trace elements are discussed, the ligands with which they are associated are dealt with. It would have been better to have coupled this discussion with that of the individual elements in order to avoid frequent repetition of the same data in various parts of the book. Thus, for example, relatively long descriptions of transferrin are found on pp. 178–180. and again on pp, 320–321. The same applies to ferritin, chlorophyll, vitamin B_{12}, and most of the other naturally occurring metal chelates whose structures are known. It is particularly redundant to repeat complicated structural formulae, when a cross-reference would have sufficed.

The applications of chelates recounted in the final section (pp. 555–631) impressive by demonstrate how deeply coordination chemistry has penetrated into biology, medicine, therapy, and agronomy.

The introductory section (pp. 5–136) must be criticized more strongly. The fundamentals required for an understanding of the subject are to be disclosed here, but the arrangement of the material is didactically inadequate. For example, the reader is confronted with the concept of hybridization on p. 11, whereas the discussion of the chemical bond only starts on p. 36. The gap between is filled with such variegated topics as chelates, polynuclear complexes, inclusion compounds, association colloids, and exchange reactions. Obviously such an array of different themes condensed into such little space must occasionally fall short of a correct deductive treatment. Experimental methods should have been discussed more fully.

Despite these reservations, the book ought to prove useful for research workers in this field. It provides a key to the literature on the subject and serves as an introduction to special problems. The book is intended for use by chemists, physicians, biologists, and agronomists.

Ernst Bayer [NB 339/197 IE]

Schmelzpunkttabellen organischer Verbindungen (Tables of the Melting Points of Organic Compounds). By *W. Utermark* and *W. Schicke*. Friedrich Vieweg & Sohn, Braunschweig 1963. 2nd Edit., XXXII + 715 pp., linen DM 75.– (about $ 19.–).

In this second edition, in accordance with the title of the book, the melting point – as the essential criterion for identifying organic compounds – has been maintained as the ordering principle. Over 3200 of the most important organic compounds with melting points between −189.9 °C and +500 °C are tabulated for rapid checking by analysts for purposes of identification or purity control.

The good formula and trivial name indices given provide helpful keys to the use of the complete tables. An important plus for this book is its inclusion – contrary to the usage of handbooks and pocketbooks, which often list more substances – of not only columns for the molecular weight, density, refractive index, melting point, boiling point, solubilities, color, crystal form, and a reference of each compound, but also of columns for "structural formula", "physical constants and properties", and "typical reactions and derivatives".

It is unfortunate that the authors have not succeeded in finding specific reactions for every compound, and it would be profitable if they could fill up the space allotted to "physical constants and properties", for this is sometimes yawningly vacant. For most of the substances, it is a very old reference to the original volumes of Beilsteins Handbuch that is given, and for 10 or 20% of the compounds there is no literature reference at all (*e.g.* for lupolone, p. 238, 7-dehydrocholesterol, p. 362, or sulfathiourea, p. 436). Current usage in nomenclature has not been applied throughout; for example, tetraethyltin would have been better than tin tetraethyl (p. 12), and the names of substituents in compounds should have been placed in alphabetical order. However, these and other

minor errors such as the diazirine structure given for diazomethane (p. 2) have little effect upon the prime purpose of the tables.

The introductions, indices of technical terms, and interchangeable table headings are in four languages (German, English, French, and Russian) and increase the value of the book. These features ought to contribute to its broad dissemination among chemists, and its success is confirmed by the appearance of an English edition.

W. Jung [NB 317/176 IE]

Fachwörterbuch der Chemie (einschließlich Verfahrenstechnik und den Grundlagen der verwandten Wissenschaften) / Dictionary of Chemistry (Including Chemical Engineering and Fundamentals of Allied Sciences), Vol. II: English-German. By *Richard Ernst* and *Ingeborg Ernst-von Morgenstern*. Brandstätter Verlag, Wiesbaden 1963. 1st Edit., 1056 pp., linen DM 48.– (about $ 12.00).

It is a remarkable phenomenon that the present generation, which is by no means inexperienced in scientific exchange – in particular with the Anglo-American countries – seems to be incapable of producing a German-English chemical dictionary which is at least free from drastic language or chemical errors. The present volume too does not completely satisfy all the demands which must be placed upon a dictionary of this kind. Although it does explain that "allenolic acid" is 2-hydroxy-6-naphthylpropionic acid and does contain a lot of interesting information on the German meanings of English trivial names – an aid which should not be underestimated when it comes to doing translations – the experienced bilingual chemist cannot suppress a feeling of pity when he sets the book a less severe test, and places himself in the position of a foreigner, for example, who wants to know what the German is for "alumium (!) potassium sulphate", for the book recommends the translation "Alumen[ustum]", whatever that may be. The results are not much better for "aluminium sulphate", for which the only German translation given is "schwefelsaure Tonerde". Carbenes are only known in the plural – and here the explicatory remark "(Asphaltteile)" is appended! And for a "carbethoxyl group", in German one is supposed to say "Cathylgruppe" and nothing else. These examples can be multiplied.

The complete title of the book reads "Dictionary of Chemistry Including Chemical Engineering and Fundamentals of Allied Sciences". Even when applying a rather free interpretation of the fundamentals of allied sciences, the reviewer is still unable to see any justification for the inclusion of entries such as "ammi visnaga" (= Zahnstocherdolde), "blank-cartridge fire" (indicated as a verb (!) and translated accordingly as "mit Platzpatronen schießen"), "eleven marker drill" (= elfreihige Drillmaschine), or "psilosis" (= weiße Diarrhöe) in a chemical technical dictionary. Even the term "Panzerfaust" – an anti-tank gun – is included.

Some of the omissions are "electrophilic", "thin-layer chromatography", and "exocyclic", but fortunately the number of these lapses is few. The word "fragmentation" appears with the abbreviated description "(biol.)". Paper chromatography is called "paper strip chromatography" in the English section, and "enzymatical" is found instead of enzymic or enzymatic; antiquated key-words such as d-[pri-act]amyl bromide (= optically active amyl bromide) are also encountered. In addition, the spelling of German terms, *e.g.* Zyklohexan, Zystin, Karbonat, does not correspond to modern practice.

If the reviewer may be allowed to give a word of advice, it is: if a second edition of this dictionary should become necessary, the services of a competent chemist should be engaged in order to effect drastic modernization of the English and German vocabulary and to reduce it to such terms as really belong to chemistry.

H. Grünewald [NB 316/175 IE]

Einführung in die Elektronentheorie organisch-chemischer Reaktionen (Introduction to the Electronic Theory of Organic Reactions). By *Heinz Becker*. VEB Deutscher Verlag der Wissenschaften, Berlin 1964. 2nd edit., 501 pp., numerous illustrations and tables, linen DM 56.– (about $14.25).

This is the second edition of this book by *H. Becker*; the first edition appeared in 1961. The earlier chapters are devoted to the theory of the chemical bond, the distribution of electrons in organic molecules, and general discussion on the course of chemical reactions. The following chapters contain descriptions of nucleophilic substitution at saturated carbon atoms, eliminations, nucleophilic reactions at polarized double bonds and electrophilic reactions at olefinic and aromatic double bonds. The two concluding sections deal with electronsextet rearrangements and freeradical reactions. Each chapter includes references to important monographs or to surveys in manuals or review journals. In parts the literature has been reviewed up to 1962. The author's intention has not been to give as exhaustive a treatment as possible of all chemical reactions. Instead he has attempted to give an intelligible presentation of the mechanisms of the most important reaction types both by considering the interaction between substrate and reagent and by discussing the factors which influence the course of the reaction. He has thereby tried to draw attention to general principles in order to make it easier to understand and survey the entire subject. *Becker*'s book is not only very suitable as an introduction to the theory of organic reactions, but also it offers a great deal of inspiration to the practical organic chemist by showing him how to apply his theory usefully to the selection of suitable reaction conditions. It can therefore be heartily recommended to every student who wishes to acquire deeper insight into the theory of organic reactions.

H. Zimmermann [NB 271/128 IE]

Fortschritte der Arzneimittelforschung (Progress in Drug Research), Vol. 7. Edited by *E. Jucker*. Birkhäuser Verlag, Basel-Stuttgart 1964. 1st Edit., 477 pp., numerous illustrs. and tables, linen DM 96.– (about $ 24.00).

This most recent volume of the series again brings a number of monographs on current problems of pharmaceutical research.

D. R. H. Gourlay deals with the "Basic Mechanisms of Drug Action" (44 pp.) and attempts with data from 157 references to summarize modern concepts concerning the point of attack and mode of action of pharmaceutical preparations. Although most of these ideas are purely hypothetical, they nevertheless provide incentives for further research. – "The Application of Radioactive Isotopes in Pharmaceutical Research" is discussed in 68 pp. (in German) by *K. E. Schulte* and *I. Mleinek*. First they deal with the use of radioactive isotopes in research related to the various modes of application of drugs and then with their use as an analytical tool; finally they report on the sterilization of pharmaceutical products with high-energy radiation (100 references). The essay by *H. Jackson* on "The Development of Antifertility Substances" evaluates information from 231 publications and gives a lucid 53-page review of this subject. *F. Trendelenburg* reports (in German) on "Antibacterial Chemotherapy of Tuberculosis" on 100 pp. After an introduction to the definition of the concept and to the methods for evaluating an antituberculous chemotherapy, he describes individual tuberculostatics, summarizing the characteristic features of each preparation. Following a discussion of the biological basis of tuberculosis chemotherapy, his article closes with a practical clinical section and a list of 380 references – all in all an excellent contribution. – A review of "The Pharmacology of Homologous Series" is given on 32 pp. with 55 references by *H. R. Ing*, who again calls attention to the problems involved in correlating structure and activity. – A monograph (in German) on "Amino Nucleoside Nephrosis", in which *U. C. Dubach* has made an exhaustive appraisal of the pertinent literature, concludes the volume.

"Amino nucleoside" is the designation given to the basic nucleoside obtained from the antibiotic puromycin after the elimination of *p*-methoxyphenylalanine; in it, 6-dimethylaminopurine is attached by a glycosidic linkage to 3-aminoribose. A typical nephrotic syndrome can be produced experimentally in rats by this amino nucleoside, and the present article (112 pp., 245 references) is intended to contribute to an understanding of nephrotic syndromes in humans.

A subject index for this volume and an author index and article index for Vols. 1–7 of the series close the book, whose outlay and appearance are excellent.

O. Schaumann [NB 308/167 IE]

Analytical Methods for Pesticides, Plant Growth Regulators, and Food Additives (in 4 Vols.). Edited by *G. Zweig*. Vol. I: Principles, Methods, and General Applications. Academic Press, New York-London 1963. 1st edit., xiv + 637 pp., numerous illustrations and tables, linen $24.00.

The current nutritional laws have caused an ever increasing demand for reliable methods for routine control of agricultural products and foodstuffs for their content of residues of pesticides, growth regulators, and other similar chemicals which are added to perishable nutritional goods during their commercial and industrial production and handling.

In this first volume of the series, edited by *G. Zweig*, on the analyses of such residues, twenty-seven notable American authors from universities, and from industrial and government laboratories have combined to give numerous practical examples illustrating the methods of formulation analysis, residue analysis, analysis of food additives, extraction and purification procedures, and toxicological tests. Further sections are allotted to the fitting-out of laboratories for residue analysis, to special procedures, *e.g.* spectrophotometry, gas and paper chromatography, total halogen analysis, isotopic methods and bioassays, to the statistical evaluation of results, and to special problems of interest in individual branches of food industry.

The forthcoming volumes will contain discussion of the analysis of residues of insecticides (Vol. II), of fungicides, nematicides, soil fumigants, rodenticides, and food and feed additives (Vol. III), and of herbicides (Vol. IV). There has long been a pressing need for a reliable modern laboratory manual of toxic residue analysis, and hence each of these volumes will undoubtedly be eagerly awaited and welcomed by workers in this field.

H. Maier-Bode [NB 273/130 IE]

Chemical Applications of Infrared Spectroscopy. By *C.N.R. Rao*. Academic Press, New York-London 1963. 1st edit., xiii + 683 pp., numerous illustrations and tables, linen $19.50.

It is amazing that, with the exception of the world-renowned book by *Bellamy*, it has taken so long for monographs on infrared spectroscopy to appear in English, although the British and Americans have had undoubtedly the greatest share in the development and application of this subject. For about two years now a glut of books in English on this theme has appeared on the market; the book by *Rao* holds a spezial position among them. It deals mainly with the chemical applications of infrared spectroscopy. It is only in the first chapter that a very brief survey of the theory of spectra, some experimental influences on the appearance of spectra, instrumentation and sample preparation, and the fundamental applications of infrared spectroscopy are given. Chapters 2–7 contain discussions of the spectra of individual classes of compounds. Frequently, despite the brevity of the text, the treatment goes into considerable detail. The next three chapters – two of them by collaborators – are devoted to special applications of infrared spectroscopy in organic chemistry and biochemistry and in the field of high polymers. In conclusion, there are chapters on quantitative analysis and other subjects which do not fit well into the general scheme of presentation selected. An appendix is given which includes a short proposal for a course of instruction in infrared spectroscopy, tables for band assignments, and commendably extensive author and subject indexes.

It is only natural to compare this volume with *Bellamy*'s book. The scope of the topics dealt with is the same, and the arrangement of material is largely the same. However, the presentation in *Rao*'s book seems to be more fluent. The inclusion of numerous illustrations and tables provides an aid to simple comprehension and speedy orientation. The abundance of references given for each chapter are also collected together here and are more readily surveyed and easier to use. The reviewer does not agree with *Rao* on one point, *viz.* the divison between the "middle" and "far" infrared at 650 cm^{-1}. The so-called KBr region at least – because of the techniques required for measurement therein and because of the information it conveys – and perhaps even the whole of the spectral region that can be measured with prism instruments belongs to the middle infrared, so that the division should be drawn at 200–250 cm^{-1}.

W. Brügel [NB 280/137 IE]

Behavior of Electrons in Atoms. Structure, Spectra, and Photochemistry of Atoms. By *R. M. Hochstrasser*. The General Chemistry Monograph Series, edited by *R. Johnson*. W. A. Benjamin, Inc., New York-Amsterdam 1964, 1st edit., xi + 162 pp., numerous illustrations, linen $4.50. paperback $2.15.

The electronic theory of the atom forms the basis of all modern instruction in chemistry. It is therefore desirable to familiarize the student of chemistry as early as possible with the most important concepts of quantum mechanics. In this book, *R. M. Hochstrasser* attempts to give a simple presentation of the theory of the atom for the beginner in chemistry. The author strives to explain the fundamentals of the theory without recourse to the mathematical formalism of quantum mechanics. The starting point for his discussion takes the form of experimental phenomena which can be easily interpreted.

In the earlier chapters atomic spectra, the interaction between atoms and electrons (the Franck-Hertz experiment), the wave nature of particles, the electron shells of atoms, electron spin, the Pauli principle, and the periodic system of the elements are considered. Finally, the Zeeman effect, interatomic transfer of excitation energy (sensitized fluorescence), and the formation and properties of excimers are discussed. However, the material covered does include the theory of the chemical bond.

In accordance with its purpose, the book is written in a rather elementary way and does not demand any specialized knowledge on the part of its readers. An understanding of the text is made quite easy by numerous explanatory diagrams. Thus the book seems ideal for giving the beginner in chemistry a first impression of the electronic structure of the atom.

H. Zimmermann [NB 270/127 IE]

The Inorganic Chemistry of Nitrogen. By *W. L. Jolly*. The Physical Inorganic Chemistry Series. Edited by *R. A. Plane* and *M. J. Sienko*. W. A. Benjamin, Inc., New York-Amsterdam 1964. 1st edit., xi + 124 pp., numerous illustrations and tables, linen $5.75.

The present volume in this series is intended to give a survey of nitrogen and its inorganic compounds with particular emphasis on their physical and physico-chemical properties. Following a comparison of nitrogen with the elements carbon phosphorus, and oxygen, elemental nitrogen as such is discussed, with particular attention to the nature of the bonding in the N_2 molecule. This is followed by a chapter on ammonia, including the use of liquid NH_3 as a medium for reactions,

on metal amides, imides, and nitrides and ammonium salts, and on metal amine complexes (metal-salt ammoniates). In the next seven chapters a systematic survey is given of data on nitrogen-halogen compounds, on further H–N and HO–N compounds, on *N*-oxides and the corresponding acids, and on S–N, P–N, C–N, and B–N compounds. In conclusion, a chapter on the thermodynamics of nitrogen compounds is given.

It is naturally a gigantic task to try to reproduce even only the essential aspects of this expansive field on 124 pages with an acceptable degree of coverage without creating the impression of only a very superficial treatment. It is therefore not surprising that on reading through the book, one notices a number of unfortunate omissions. For example, it is not enough to characterize the nitrides of the transition metals simply by the expression "interstitial or metallic nitrides". Again in the treatment of the synthesis of NaN_3, the reader misses even a short discussion of the reaction mechanism (use of ^{15}N to elucidate it). Furthermore, although many physical properties have been gathered together into tables, some of these are absolutely without explanation. This applies, for example, to the table of successive formation constants for metal amine complexes in aqueous solution. Without some discussion, such a table is of little value, especially since the book is not intended to be simply a work of reference. However, it must be emphasized that there are many interesting new results to be found in the book which is characterized by its lucidity in the presentation of the material and in the mode of expression in the text. Nevertheless, in the reviewer's opinion, the present volume falls somewhat short of its aim in filling an existing gap in the literature in this field.

O. Schmitz-Du Mont [NB 275/132 IE]

Steroid Chromatography. By *R. Neher*. Elsevier Publishing Company, Amsterdam-London-New York 1964. 2nd revised and extended edition, xiii + 389 pp., 31 figs., 78 tables, linen DM 33.50 (about $8.50).

In this second considerably enlarged edition of his monograph, *Neher* surveys column chromatography (77 pp.), paper chromatography (152 pp.), thin-layer chromatography (41 pp.), and gas chromatography (36 pp.) of steroids. Following a short introduction to the individual methods, the conventional adsorbents, solvents for elution, and spray reagents, *etc.* are described, and then the chromatographic behavior of the various classes of steroids is described, frequently in readily surveyable tabular form. The examples taken from the extensive literature in this field have been critically chosen – no attempt has been made to reproduce a comprehensive collection of references – and in the appendix more important publications which have appeared this year are given, by title at least. The book provides, particularly in the first two sections, so many facts that it is a pity that not all are to be found by using the extensive subject index. Thanks to its detailed description of representative separations and the many practical hints that it includes, derived from the experience of its competent author, this book should be of value even to the experimental worker who is already well versed in this field.

The layout of the book is excellent, printing errors and incorrect references are few (the solvent systems from Table 63 and the table on page 210 are confused in the text). The formulation of digoxigenin with a 3α-hydroxyl group and the use of ζ instead of ξ to indicate unknown configurations are in error throughout; the general remarks made on pages 56 and 57 contradict in part the data given in the tables.

Neher's book can be highly recommended to all (chemists, biologists, and medical practitioners) who are concerned with the separation or detection of steroids. The time spent in careful scrutiny of this monograph will soon be repaid many times by following the instructions given by its author when running chromatograms.

G. Snatzke [NB 276/133 IE]

Physical Methods in Organic Chemistry. Edited by *J. C. P. Schwarz*. Oliver & Boyd, Edinburgh-London 1964. 1st edit., xi + 350 pp., several illustrations and tables, linen £2.10.0 (about $7.00).

This book is intended to appeal principally to students and to those chemists who did not have the good fortune to come into contact with the latest physical methods for determining structures during their student days. After an introductory section (*J. C. P. Schwarz*, 21 pages) which includes *inter alia* extensive tables indicating various problems and their methods of solution, there follows a review of the principles common to both ultraviolet and infrared spectroscopy (*P. Bladon* and *G. Eglinton*, 13 pages). Next come chapters on infrared and Raman spectroscopy (*G. Eglinton*, 91 pages), electron-jump spectroscopy (*P. Bladon*, 42 pages), nuclear and electron spin resonance spectroscopy (*L. M. Jackman*, 42 pages), optical rotation [optical rotatory dispersion, circular dichroism, and the correlation of $[\alpha]_D$ values] (*J. C. P. Schwarz*, 34 pages), molecular-weight estimations (*C. T. Greenwood*, 32 pages), X-ray diffraction methods (*G. A. Sim*, 30 pages), mass spectrometry (*R. I. Reed*, 17 pages), and dipole moments (*B. L. Shaw*, 15 pages). The best chapters are those on infrared and ultraviolet spectroscopy in which the positions of the bands are explained in detail by recourse to effects that are completely familiar to every organic chemist. The results summarized in the tables here represent a valuable supplement to larger monographs on the subject for those familiar with the uses of infrared spectroscopy. Numerous examples are used to demonstrate its applications, particular attention being paid to the possibilities of erroneous interpretations. The section on NMR spectroscopy is also excellent, apart from the fact that the difference between the coupling constant J and spin-spin splitting – a point that is especially difficult for the beginner – is unfortunately not made clear enough. A review of the methods of ORD and CD, which are constantly finding more and more applications, especially in the field of natural products, such as that given in the chapter on "optical rotation" has so far never appeared in a monograph in German. On the other hand, in the chapter on mass spectrometry by *Reed*, it is astonishing that no mention is made of the present rapid trend towards application of this technique to the elucidation of the structures of even the most complex molecules.

This book can be warmly recommended not only to every student, but also to every older practitioner; this is one of the monographs that the reviewer would have liked to have available during his graduate research work.

G. Snatzke [NB 277/134 IE]

Encyclopedia of Chemical Technology. Edited by *R. E. Kirk* and *D. F. Othmer*. New edition edited by *A. Standen*. Interscience Publishers, a division of John Wiley & Sons, New-York-London-Sydney 1963. 2nd revised edit., Vol. 2: Aluminum Compounds – Azo Dyes. xv + 910 pp., numerous illustrations and tables, price for the single volume $45.–. Vol. 3: B – Calcium. xvi + 927 pp., numerous illustrations and tables, price for the single volume $45.–.

The two new volumes contain a total of 82 articles each with an average length of 22.5 pages arranged under alphabetical key-words. The longer articles include "Boron compounds" (131 pp.), "Batteries and electric cells, primary" (161 pp.), "Aluminum compounds" (66 pp.), "Anthraquinone derivatives" (63 pp.), "Amines" (57 pp.), "Amino acids" (57 pp.), "Ammonia" (55 pp.), "Antiseptics and disinfectants" (45 pp.), "Asphalt" (44 pp.), "Ammonolysis" (42 pp.), "Azo dyes" (42 pp.), "Beer and brewing" (42 pp.), "Bacterial, ricketsial, and mycotis infections, chemotherapy" (35 pp.), "Butylenes" (35 pp.), "Amino resins and plastics" (35 pp.), and "Bioassay" (29 pp.).

The authors of the two volumes comprise 116 collaborators, 32 from technical colleges and 84 from the chemical industry. In contrast to the first edition, here the results of efforts to secure non-American authors as contributors can be seen: 6

of the experts come from Switzerland, 5 from France, 2 from the Netherlands, and one each from England, Denmark, and Israel. This new edition has really been completely revised, as can be seen, for example, from the fact that only 20 of its 116 coauthors participated in the first edition 15 years ago, but principally from the significant increase in size of the new edition. The material covered in 1091 pages in the first edition requires 1836 pages in the new edition. In order to maintain the usefulness and handiness of the book, it is to be hoped that it will not try to cover new material through an increase in length but rather through abridgement by clever editorial organization.

The new edition contains many valuable improvements on its predecessor. A 15-page section on organo-aluminum compounds has been added under the heading of aluminum compounds. One innovation is the instructive article (25 pp.) which reports the facts about automobile exhaust and offers measures for controlling and avoiding it. The technology of azeotropic distillation has increased so much that entirely new article written by *D. F. Othmer* is devoted to it; this covers 20 pages in contrast to the mere 4 pages allocated previously to the whole subject of distillation. An important section on antistatic agents (24 pp.) gives reliable information about both the theoretical and practical aspects of this problem, which is of such great significance to the textile industry. In the section on "Aquametry", all the methods for estimating water contents are given in summary – an interesting review of modern analytical technique collected together under the common denominator of one special estimation. The section on "Bioassay" (29 pp.) indicates the general regularities of biological assay methods and explains the mathematical manipulations required for carrying out biological tests quantitatively. The treatment of "Boron compounds" (131 pp.) has been extended and now includes the contributions from the first edition (34 pp.), from the first supplement (26 pp.), and from the second supplement (35 pp.). The U.S. Borax Research Corporation is largely responsible for compiling this article, which has been completely rewritten, which is excellently composed, and which presents a first-class survey of this new field which is of equally great importance for inorganic and organic chemistry and for atomic energy technology. The articles on the production of electrical current in galvanic elements (primary batteries or cells) and on the storage of current in accumulators (secondary batteries) have also been considerably lengthened. These cells have acquired immense importance in the U.S.A. in information and rocket technology, so that this review is highly welcome.

With regard to the other sections, the question arises whether the progressive development could not have been adequately discussed without an increase in the number of pages. The extensions of the sections on "Ammonia" (from 38 to 55 pp.), "Ammonolysis" (from 18 to 42 pp.), "Asphalt" (from 34 to 44 pp.), and "Beer and brewing" (from 30 to 42 pp.) could perhaps have been avoided. In contrast, the sections on "Analgetics and antipyretics" (14 pp.) and on "Anaesthetics" (18 pp.) do not contain enough information. However, these paragraphs might have been omitted altogether, since the encyclopaedia includes the key phrase "Stimulants and depressants of the nervous system" under which the same facts about these pharmaceuticals are considered in a broader connection. It also appears somewhat irregular when analgetics, antipyretics, and anaesthetics are allocated individual key-word articles, whereas analeptics, antidiabetics, and antiphlogistics, *etc.* are not. In the condensed form that is required in a reference book of this kind, it is unnecessary to include an alphabetically arranged article for every individual technical concept; instead, this calls for systematic, intensively edited collective articles. The encyclopedia would be more valuable if the editor tried to divide up the material better among his collaborators and to achieve more active coordination among them.

The encyclopaedia has the advantage of being backed by the greatest and most highly differentiated chemical industry in the world, and the American chemical industry is renowned for its liberal policy in revealing the results of its development work for general publication. The work is of particular interest to German readers because they can find in it information on technical fields which are sadly neglected in Germany. The extensive reviews of the literature given at the end of each section are also an admirable feature. Every contributor to these volumes is to be congratulated, and it is to be hoped that the publication will have much success in the future.

H. Sachsse [NB 283/141 IE]

Comprehensive Biochemistry. Edited by *H. Florkin* and *E. H. Stotz*. Volume 13: Report of the Commission on Enzymes of the International Union of Biochemistry. Elsevier Publishing Co., Amsterdam-London-New York 1964. 1st Edit., XII + 164 pp., price of single volume DM 22.80 (about $ 5.75).

Section III of this handbook, which is appearing in the form of numerous small volumes, has as its general theme "Biochemical Reaction Mechanisms" and is to deal mainly with enzymes. It may at first appear surprising that a whole volume of this section, which is to consist of only five volumes in all, is devoted to the reproduction of the new proposals of the International Union of Biochemistry for the nomenclature of enzymes. However, perusal of this volume soon places its usefulness beyond doubt. The editors have not restricted the text to the 1961 nomenclature report, but have worked in amendments and corrections which have become necessary in the meantime. Enzyme units, symbols for describing enzyme kinetics, a list of enzymes almost one hundred pages long which gives information on the systematic names, the trivial names, the reaction catalysed, and the specificity of each enzyme, and a long subject index form the main sections of the book, which can be recommended as a work of reference. The orderly arrangement of the text and the particularly clean print deserve special mention.

H. Grünewald [NB 345/202 IE]

A History of Chemistry. By *J. R. Partington*. Vol IV. McMillan & Co. Ltd., London; St. Martin's Press, New York 1964. 1st Edit., XXXI + 1007 pp., 91 illustrs., linen £10.10.0 (about $ 29.00).

This volume of "A History of Chemistry" deals with the development of chemistry in the 19th and partly in the 20th century. Volumes II and III have already appeared, and volume I will be published last.

Although it appears to be relatively easy from our present-day perspective to appraise the value of results from earlier centuries with regard to their importance for the progress of chemical science, any such evaluation becomes more and more difficult, the closer one approaches to the present. For this reason, the order of presentation used in the previous volumes (*i. e.* arranging the material mainly according to the personality of prominent historical figures) is maintained only for the time up to about 1865. In the present volume the period from *Davy* (first electrochemical investigations) up to the time of *Kekulé* (theoretical considerations on the structures of organic compounds which culminated in the cyclic formula for benzene) is presented in this fashion. Thereafter, like *Paul Walden* in his "Geschichte der Organischen Chemie seit 1880" (History of OrganicChemistry since 1880), *Partington* switches over to a non-personalized presentation of the general trends in the fields of physical, organic, and inorganic chemistry; here, for example, thermochemistry and thermodynamics are described up to the time of *Nernst* and *Haber*, organic chemistry up to *Willstätter*, *H. Wieland*, *Diels*, and *Wallach*, and inorganic chemistry up to *Ruff*, *Stock*, and *K. A. Hofmann*. The final chapter deals with radioactivity and atomic structure and ends with a description of the preparation of the transuranic elements, thus leading right into the present.

The reader is amazed at the author's exquisite command of the data on the evolution of chemistry. Anyone who has ever taken the trouble to trace back the development of an idea or the repercussions of an original discovery by recourse to the original publications will appreciate the vast effort that has been expended by a single author here in order to produce this excellent "History of Chemistry".

W. Ruske [NB 321/179 IE]

Crystallographic Data on Metal and Alloy Structures. Compiled by *A. Taylor* and *B. J. Kagle*. Dover Publications Inc., New York; Constable & Co. Ltd., London 1963. 1st Edit., 263 pp., paperback $ 2.25.

This book of tables was prepared, according to statements by the authors, from original literature, the ASTM data file, Pearson's Handbook of Lattice Spacings and Structures of Metals and Alloys, Structure Reports, Strukturberichte, and "Landolt-Börnstein". The columns in the tables contain in series: chemical formula (in alphabetical order), occasionally the mineral name/crystal system, indications of the structural type, and, if known, ASTM index data/space group/lattice constants/number of formula units per unit cell. The contents are arranged in three parts: Table 1 contains about 2300 "Alloys and Intermetallic Compounds" – where, however, a large number of halides (!), sulfides, and selenides are included; Table 2 contains borides (about 95), carbides (about 105), hydrides (about 45), nitrides (about 110), and oxides (about 350) together with a number of silicates and a few carbonates; Table 3 contains data on elements.

Judging from the title, more detailed and more comprehensive data on the crystal structures proper might have been expected; partly it would be sufficient to include an additional column of "references" and to reduce, for example, the abundant space allotted to lattice constants. It is difficult to understand – in view of the title – why the authors have augmented their data by an apparently random selection of information on non-metallic compounds, *e.g.* halides and oxides. It is also not clear why the data given for silicates are so incomplete, why (occasionally erroneous) mineral names are given for oxides but mostly none for sulfides, arsenides, *etc.* Moreover, the ASTM index data, *i.e.* d-values and relative intensities of the three strongest X-ray reflexes, can only seldom be used for purposes of identification, when recourse cannot be had to the complete X-ray diffraction diagram.

The booklet may occasionally be of value as a supplement to other literature, especially for getting a first information. Its low price is attractive.

H. J. Meyer [NB 306/165 IE]

Oxidation Mechanisms. Applications to Organic Chemistry. By *R. Stewart*. Frontiers in Chemistry, edited by *R. Breslow* and *M. Karplus*. W. A. Benjamin, Inc., New York-Amsterdam 1964. 1st edit., xi + 179 pp., 2 figs., several tables, linen $ 7.50.

Mechanisms of Oxydation of Organic Compounds. By *W. A. Waters*. Methuen's Monographs on Chemical Subjects. Series edited by *H. J. Emeléus*, *D. W. G. Style*, and *R. P. Bell*. Methuen & Co., Ltd., London; John Wiley & Sons, Inc., New York 1964. 1st. edit., vii + 152 pp., 2 figs., linen £1.5.0 (about $ 3.50).

Most mechanistic investigations carried out during the past thirty years were concerned with substitution, addition, elimination, and rearrangement reactions, and only these were dealt with in textbooks. However, the simultaneous appearance of these two monographs shows that there is also a wide interest in oxidation (and reduction) reactions and their mechanisms. Both books cover the material to an extent that would fill out a course of a one-hour lecture per week for a semester. *Stewart* arranges his presentation mainly according to oxidizing reagents, whereas the arrangement by *Waters* is based (albeit none too strictly) on the type of substrate being oxidized. Neither book attempts to achieve exhaustive coverage; in *Stewart*'s treatment some aspects (*e.g.* ozonolysis) are omitted altogether, because they have been reviewed within recent years. Instead, he gives a detailed discussion particularly of chromic acid and permanganate oxidations. *Waters* emphasis mainly oxidations which involve a one-electron transfer, for he himself has participated significantly in the elucidation of the course of these reactions. His book is intended principally for students, and hence he gives only a few references to original publications and does not include an author index. *Stewart*, on the other hand, cites about 400 articles, which will help his readers to find easier access to more specialized aspects of the subject. Biochemical oxidations are discussed in a separate chapter by *Stewart*, but *Waters* only touches upon this subject.

The reviewer is reluctant to recommend either book more than the other, for both are stimulating and are critically written. Organic chemistry institutions should acquire both of them, for they complement each other to a certain degree.

R. Criegee [NB 293/151 IE]

Azeotropy and Polyazeotropy. By *W. Swietoslawski*. A translation from the Polish edited by *K. Ridgway*. Pergamon Press, Oxford-London-New York-Paris 1963. 1st edit., 226 pp., numerous illustrs. and tables, linen £3.10.0 (about $ 9.75).

This monograph is a new edition of the book which appeared in 1957 in Polish.

In part I (pp. 13–146), individual azeotropic mixtures and series of azeotropic mixtures are dealt with, with particular attention to the azeotropic boiling range even for ternary and quaternary mixtures. An especially long chapter is devoted to interesting azeotropic mixtures with a saddle-like temperature profile. The concept of polyazeotropy is introduced in the second part (pp. 147–160) and illustrated with the example of coal-tar distillation. Part III (pp. 161–192) deals with special polyazeotropic systems, with the dehydration of ethanol, and with experimental methods for determining azeotropic distillation ranges. In part IV (pp. 193–205), a short discussion is given of the methods for thermochemical investigation of azeotropic mixtures, particularly the estimation of enthalpies of evaporation and of mixing.

The book contains numerous illustrations and is intended primarily for the use of the practical experimenter. The author's highly condensed description of ebulliometry and its use in practice for examining azeotropic mixtures is excellent. Experimental difficulties are not passed over without comment.

The monograph makes no demands on the theoretical knowledge of the reader, and is thus readily understandable even for beginners, although the overall clarity suffers somewhat because of the vast amount of experimental material included. It should also be mentioned that a clear distinction is not always drawn between rules that have been derived empirically and regularities that have been derived by calculation from thermodynamics.

The layout of the book is satisfactory, although the print is sometimes smudged or broken and although there are several misprints. The book contains numerous references to literature sources (312 in all) and can be recommended to anyone who wishes to be come acquainted with the problems and applications of azeotropic distillation. Moreover, the book will go a long way to alleviate the lack of coordination that is frequently extant between research and applied work. This intention of the author has been well achieved in the reviewer's opinion, for the book offers interesting incentives to workers in both fields.

M. Rehse [NB 296/154 IE]

Technique of Organic Chemistry. Edited by *A. Weissberger*. Vol. XI: Elucidation of Structures by Physical and Chemical Methods. Part I. Edited by *K. W. Bentley*. Interscience Publishers, a Division of John Wiley & Sons, New York-London 1963. 1st edit., ix + 642, 23 pp., numerous illustrations and tables, linen £6.5.0 (about $17.50).

Methods for the elucidation of structures are of interest not only to the natural-products chemist, but also to the organic chemist engaged in synthetic work, for he often encounters new and unexpected reaction products. The present volume of this series will therefore appeal to a wide variety of readers. A chapter on "Isolation, purification and preliminary observations" by *K. H. Overton* forms the introduction here; this includes very valuable tables of data on color and precipitation reactions for use in determining roughly what class of compound is being examined. This is followed by contributions on ultraviolet spectroscopy (*J. C. D. Brand* and *A. I. Scott*), infrared spectroscopy (*A. R. H. Cole*), nuclear magnetic resonance spectroscopy (*J. B. Stothers*), mass spectrometry (*K. Biemann*), and dissociation constants and optical activity (*J. F. King*). These topics are discussed in greater detail in Vol. I of the same series (Physical Methods of Organic Chemistry, four parts). In this book, descriptions of the appropriate practical procedures and theoretical fundamentals have been almost completely disregarded; instead, only an appraisal of the value of the methods for purposes of elucidating structures is given. In each section a description of the general principles involved is followed by illustrations with examples from the chemistry of natural produtes. These chapters are wonderfully adapted to the needs of the organic chemist engaged in empirical evaluation of physical measurements conducted with commercial instruments.

Working hypotheses on the structures of certain natural products are often developed using biogenetic principles. The general background for such an approach is given by *E. Leete* in chapter VII, who reminds readers to consider theories before applying them. An essay by *G. A. Swan* on the "Detection and protection of functional groups" introduces chemical methods. Of the latter, Part I contains discussion on "Reduction and hydrogenation" by *F. J. McQuillin* and on "Dehydrogenation" by *Z. Valenta*. The material collected together in this volume can be obtained only with considerable effort from other sources, and it gives terse but reliable information on the applicability and drawbacks of the reactions discussed. We can look forward to the forthcoming "chemical" chapters with great interest.

The whole volume has been very carefully edited; errors are seldom found (the position of the $\rangle C-H$ nuclear resonance in Fig. 4, page 212 is incorrect, an equation on page 460 is printed upside down). The layout, *e.g.* the appearance of the steric formulae, is excellent. However, this has been attained at the expense of the time required for publication: the literature reviewed in the individual contributions does not go beyond 1960 (copyright 1963).

This small book contains so much information that it can be recommended to even those who are undecided about buying the complete series.

W. Kirmse [NB 266/124 IE]

Noble Gases and their Compounds. By *G. J. Moody* and *J. D. R. Thomas*. Pergamon Press, Oxford-London-Edinburgh-New York-Paris-Frankfurt 1964. 1st edit., vii + 62 pp., 11 tables, linen 12s. 6d. (about $1.75).

This little book gives on the whole an excellent survey of the title subject. In the first chapter, the history of the discovery of the noble gases is recounted briefly. The second chapter is devoted to early attempts to produce inert gas compounds and deals with helides, MHe_2, clathrates, and the particularly interesting older studies on the preparation of inert gas halides. In the third chapter, the authors give a reasonably detailed report on the "present" status of the chemistry of the noble gases; this begins with *Bartlett*'s compound $XePtF_6$, the discovery of which initiated numerous investigations in the U.S.A., and then describes the xenon fluorides XeF_2, XeF_4, and XeF_6, together with their properties, crystal structure, and the nature of their bonds, and finally the oxyfluorides XeO_xF_y. The discussion then proceeds to XeO_3 and the salts of the acids H_6XeO_6 and H_4XeO_6, the krypton fluorides KrF_2 and KrF_4, and attempts to prepare compounds of radon. The compound $BaKrO_4$ recently obtained by *von Grosse* and the recent determination of the structure of $Na_4XeO_6 \cdot 8H_2O$, for instance, could not yet be fully considered. In the fourth chapter a survey of future prospects for developments in this field is given. The cursory reader will miss the presence of tables summarizing the most important physical properties of the compounds.

The book is well arranged, and is easy to read; the latter stattement applies especially the discussion of the chemical bonds of these compounds. As in almost every account in English of the discovery of the first genuine valence compounds of the noble gases in 1962, here too there is no mention, of the fact that the first binary noble gas fluorides were prepared independently and almost simultaneously in Germany (XeF_2, July 1962) and in the U.S.A. (XeF_4, early August 1962). Purchase of this little volume can be recommended without reservation.

R. Hoppe [NB 278/135 IE]

Treatise on Analytical Chemistry. Edited by *I. M. Kolthoff* and *P. J. Elving*. Part I: Theory and Practice. Vol. 5: Section D.3: Optical Methods of Analysis. Interscience Publishers, a Division of John Wiley & Sons, New York-London-Sidney 1964. 1st edit., xx + 639 pp., numerous illustrations and tables, linen £6.0.0 (about $16.75).

The constantly increasing number of publications appearing nowadays in every field of science lends increasing importance to the various multivolume series which contain comprehensive surveys of extensive, but specialized, topics. This series edited by *Kolthoff* and *Elving* is intended to give a complete appraisal of the entire field of analytical chemistry. Volumes 5 and 6 of Part I are devoted to optical analytical methods. The concept "optical methods" is assumed to be very wide in scope, and hence includes all techniques employing absorption or emmison, optical rotation, or diffraction or scattering over the whole range of the electromagnetic spectrum, from X-rays up to microwaves. Diffraction and absorption of electrons and neutrons are also discussed in these volumes.

In Vol. 5, *E. J. Meehan* reviews the general principles pertaining to all optical investigations in the first three introductory chapters of Volume I (optical methods, the fundamentals of spectrophotometry, spectroscopic apparatus and measurements). Detailed discussions are given by *F. W. Billmeyer* of the fundamentals of light scattering, by *D. B. Judd* and *I. Nimeroff* of the specification and designation of color, by *A. A. Schilt* and *B. Jaselskis* of ultraviolet and visible spectrophotometry, by *A. L. Conrad* of fluorescence methods, by *H. A. Liebhafsky*, *H. G. Pfeiffer*, and *E. H. Winslow* of the absorption, emission, and diffraction of X-rays, by *D. B. Wittry* of X-ray microanalysis, by *J. H. Goldstein* of microwave spectrophotometry, and by *F. P. Hochgesang* of light scattering and turbidity measurements.

In every chapter the theoretical basis of the phenomenon in question is first discussed to an extent required for a complete understanding of its analytical applications. Instrumentation and measurement problems are considered by using simple illustrations, and the most important properties of commercial or even "home-made" apparatus are reviewed. Practical examples are used to give a critical survey of methods of evaluation; a detailed treatment of possible sources of errors is also always given. Each chapter closes with a list of references which, however, seldom contains mention of continental European monographs.

Despite the large number of contributors, the volume conveys an impression of completeness; in the more specialized

chapters the fundamentals discussed in the introductory chapters are considered in more detail; repetitions have largely been avoided, and the symbols used have all been standardized throughout the text.

This volume makes it possible to secure rapid familiarity with the methods of optical analysis and to obtain reliable information on the scope and limitations of their application. The complete work promises to become the standard handbook of analytical chemistry, and probably will be soon found in every chemical library.

W. Liptay [NB 264/122 IE]

Structure Elucidation of Natural Products by Mass Spectrometry. Vol. I: Alkaloids. By *H. Budzikiewicz, C. Djerassi,* and *D. H. Williams.* Holden-Day Series in Physical Techniques in Chemistry. Holden-Day Inc., San Francisco-London-Amsterdam 1964. 1st edit., xi + 233 pp., numerous illustrations, linen $10.50.

The present volume contains a detailed discussion of the mass spectrometry of alkaloids, especially of those of the indole and isoquinoline series. Although the book has therefore a highly specialized character, it is of general significance since it contains a chapter on deuteration procedures. In this remarkable section, a comprehensive collection of methods for marking organic compounds with deuterium is given with numerous examples. In their later discussion on the mass-spectrometric degradation of alkaloids, the authors presume that the charge on the molecule ion – *e.g.* on a nitrogen atom – is localized. All the degradation mechanisms are formulated according to this principle in the present volume, although this approach sometimes leads to structural formulae for the degradation products, which are unacceptable from the energy standpoint. Thus, for example, the fragment p from a pyrrolizidine alkaloid shown on p. 223 is formulated as a diradical cation, and the energetically much more favorable, and thus more probable simple cation is not even considered.

A few careless errors probably result from the rapid appearance of the book (only three months after completion of the general first part), but these will be certainly corrected in any future edition.

Despite these faults, the book can be recommended as being the first detailed review of the mass-spectroscopy of the alkaloids, and it well deserves a place in every laboratory devoted to mass-spectroscopic investigations of these compounds.

G. Spiteller [NB 289/147 IE]

The Mitochondrion. Molecular Basis of its Structure and Function. By *A. L. Lehninger.* W. A. Benjamin, Inc., New York-Amsterdam 1964. 1st edit., xx + 263 pp., numerous illustrations, and some tables, linen $9.90.

Although classical cell research was in a position to define mitochondria both morphologically and functionally at the beginning of this century, research proper on these subcellular particles which are responsible for energy metabolism in the cell only began with the development of modern biochemical and biophysical methods after the Second World War. Today the beginnings of the elucidation of the molecular function and structure of mitochondria are recognizable. A decisive contribution to this development was made by *A. L. Lehninger* with his discovery of the participation of mitochondria in the oxidation of fats and in oxidative phosphorylation. In the present volume he presents the first summary of the current state of research and of the molecular basis of mitochondrial structure and function. The subject matter is discussed in detail, and comprises mitochondria in the intact cell, the oxidative cycles and the respiratory chain, the components of the oxidative system and of oxidative phosphorylation, problems of control, compartmentation, and integration, as well as further questions related to active ion-transport, water balance, and biogenesis. The book is well illustrated and contains much unabridged material taken directly from representative authors in this field, and abundant references to review articles and important journal publications are also included. It forms an excellent introduction for those who wish to acquaint themselves with the problems involved in this field, and should also be welcome as a work of reference for the expert on this subject.

Relationships between Structures and Mass Spectra of Organic Compounds [*]

BY DOZENT DR. G. SPITELLER [**] AND DR. MARGOT SPITELLER-FRIEDMANN
INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT, VIENNA (AUSTRIA)

Our knowledge concerning the relationships between the structure and mass spectra of organic compounds has widened immensely during the past few years. It has become possible to alter the course of fragmentation in the mass spectrometer by changing certain substituents using simple chemical reactions. The fragmentation products formed are then entirely different from those of the starting material. A combination of controlled mass-spectrometric decomposition with chemical microreactions often permits the solution of complicated structural problems with a minimum expenditure of time and material. One example for the alteration of the fragmentation pattern by a simple chemical reaction is discussed in connection with the elucidation of the structure of pleiocarpamine.

I. Introduction

The qualitative analysis of organic compounds by means of mass spectrometry is a method of very recent origin. During the initial period between 1950 and 1959, *Beynon* [1], *Stenhagen* and *Ryhage* [2, 3], *Meyerson* [4] and particularly *McLafferty* [5] investigated the characteristic fragmentation reactions of simple classes of compounds. The general laws of fragmentation determined in this way then allowed the elucidation of the structures of unknown compounds, mainly natural products. This second stage of development was initiated by the elucidation of the structure of phthiocerol, a wax-like constituent of the capsule of the tubercle bacillus [6]. The tremendous possibilities opened up by the new method were demonstrated by *Biemann* [7] and also by *Djerassi* and *Budzikiewicz* [8] by solving complicated structural problems in the fields of amino acids and alkaloids.

II. Mass-Spectrometric Investigations of Organic Compounds

In the ionization chamber of the mass spectrometer, the molecules of the gaseous sample are bombarded with electrons, generally with an energy of 70 eV. On collision the electron transfers energy to the molecule. The quantity of energy transferred is not exactly known and probably depends on whether the impact is central or glancing. The energy is generally sufficient to eject an electron from the molecule, and is also sufficient to split the molecular ion formed into fragments. In this way an organic compound is cleaved by the reagent

"electron" inside the ionization chamber, and is irrecoverably destroyed.

In the course of degradation, positively and negatively charged ions, neutral molecules, and radicals are formed. The charged particles can be separated by physical means, *i.e.* by electrical and magnetic fields (according to their mass and charge), and their mass spectrum can be determined photographically or with the aid of a recording device (Fig. 1). In general, only the positively charged ions, whose formation is more probable than that of the negative ions by a factor of 10^4, are measured. The spectra of negative ions, which are more difficult to record and which have mainly been studied by *von Ardenne* [9], can supplement the spectra of positive ions, especially in the case of compounds of higher molecular weight containing hydroxy groups [10].

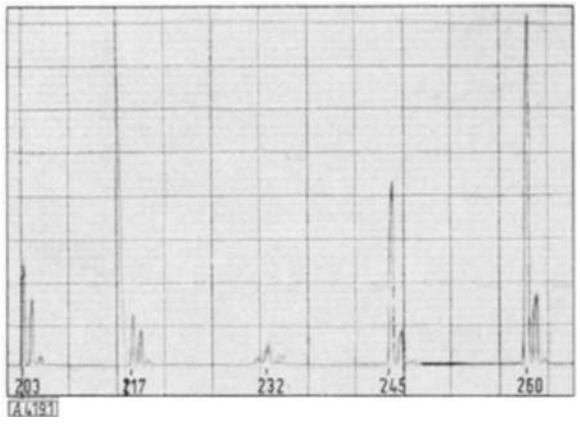

Fig. 1. Section from the mass spectrum of androstane, $C_{19}H_{32}$, reduced to half-size, taken with an Atlas Model CH-4 Mass Spectrometer; temperature of the TO-4 ion source approximately 60 °C. The mass/charge ratios m/e were inserted to facilitate interpretation. The molecular-ion peak is at 260. The entire spectrum from m/e = 29 to m/e = 262 is 79.5 cm long.

Except for compounds which contain numerous π-electrons, electrons of the energy normally used (70 eV) form singly charged particles almost exclusively, so that the peaks of a mass spectrum indicate the mass numbers (molecular weights) of the decomposition products. The quantity of ions having the same mass number is proportional to the height of the peak.

In this sense, mass spectrometry differs fundamentally from other techniques such as infrared or ultraviolet spectroscopy; in the latter two methods a molecule is excited by electromagnetic waves but is not altered chemically, so that the sample used can be recovered unchanged. In contrast, a molecule hit by an electron in the ionization chamber of the mass spectrometer generally undergoes cleavage. In infrared and ultraviolet spectroscopy, wavelengths are measured, *i.e.* the quantities of energy absorbed which are characteristic for certain structural elements. In the mass spectrometer, the quantity of energy transferred on collision with the electron varies (when electrons are used whose energy lies above the ionization potential of the compound investigated) and can therefore be neither measured nor related to the structure of the investigated compound. On the other hand, the quantity and molecular weight of the fragmentation products can be derived from the mass spectrum. Chemical and mass-spectrometric decomposition processes exhibit many parallel characteristics.

A. Prerequisites for the Investigation of Organic Compounds by Mass Spectrometry

1. *Volatility*

In contrast to ultraviolet and infrared spectroscopy, where a substance is generally investigated in solution or as a solid, mass spectra can be obtained from substances only if these are present as a gas. This does not mean that gases or easily volatile liquids and solids alone are appropriate. Rather, the minimum vapor pressure required (about 10^{-6} mm Hg) is so small that even compounds such as amino acids can be investigated [11]. Difficultly volatile substances cannot, however, be evaporated into the gas reservoir of the mass spectrometer in the normal manner, and introduced through a nozzle into the ion source [7a], but must be carefully volatilized in the ion source itself [12–14]. With the exception of a few classes of compounds, nearly all organic substances can be studied by mass spectrometry in this way. Admittedly, strongly polar compounds which contain numerous OH or NH groups must be converted into more volatile derivatives, *e.g.* by acetylation, in order to make them suitable for mass spectrometric investigation [7b].

2. *Resolving Power of the Instruments*

The applicability of mass spectrometry is also limited by the resolving power of the instrument, *i.e.* by its ability to record ions of different masses as two separate peaks. The maximum resolving power of currently available single-focusing instruments is between 1000 and 1500. A resolving power of 1000 means that ions with a mass of 999 and 1000 can just be separated.

Double-focusing instruments achieve a resolving power which is approximately twentyfold. However, this increase in resolving power to 20000 does not necessarily mean that it is possible to obtain spectra of compounds with molecular weights up to 20000, since most substances with molecular weights above 1000 do not possess the required vapor pressure.

The advantage of using double-focusing mass spectrometers is mainly that the empirical formula of an ion can be determined by an accurate measurement of its

[14] *J. F. Lynch, J. M. Wilson, H. Budzikiewicz,* and *C. Djerassi,* Experientia *19,* 211 (1963).

mass [15]. For example, it is possible to decide whether an ion with a mass of 44 has the empirical formula C_2H_4O (exact molecular weight 44.0403) or C_3H_8 (exact molecular weight 44.0767) simply by comparison with a standard sample (peak-matching). However, this method is still very expensive, so that single-focusing instruments are preferable for routine measurements.

3. *Amount of Sample*

The quantity of sample required to record a mass spectrum depends on the method of introduction and on the type of recording device used. With photographic recording and direct evaporation of the sample inside the ion source, approximately 10^{-3} mg is sufficient, while 1 mg may be required if the compound is introduced into the ion source *via* the gas reservoir.

4. *Purity*

In general, the interpretation of a mass spectrum is not seriously affected by small quantities of impurities. Since a mass spectrum is composed additively of the contributions of the individual components, it is often possible to recognize impurities in the sample from the appearance of additional or more intense peaks. However, it is very difficult to detect a compound which is stereoisomeric with the main component, as in general such isomers afford similar mass spectra.

[15] Review: *R. A. Saunders* and *A. E. Williams* in [3], pp. 343 to 398.

B. Reproducibility of the Mass Spectra

The ratio of the intensities of the fragment peaks to the intensity of the molecular-ion peak is strongly influenced by instrumental factors; when mass scanning is achieved by altering the electric field, the focusing quality decreases with increasing molecular weight of the ions, so that the intensity ratio recorded in the spectrum is displaced in favor of particles having a low molecular weight (massdiscrimination effect).

In addition, as in chemical processes, the experimental conditions are of considerable importance; with increasing electron energy the intensity ratios of fragment to molecular-ion peaks increases appreciably, but reaches a limiting value at about 30 eV. Between 50 and 100 eV the spectra are more or less independent of the electron energy. For this reason, an energy of 70 eV is generally selected.

A decisive factor affecting the relative abundance of fragments and the molecular ion produced, is the temperature of the substance undergoing cleavage in the mass spectrometer [16]. Molecules which possess more kinetic energy require less energy for decomposition, as they are already thermally excited and more easily cleaved than "cold" ones [17]. In the spectra of compounds which have been evaporated in cold ion sources at relatively low temperatures, the peaks of the molecular ions are more intense than those of the fragments. This is less so when the same compounds are evaporated in hot ion sources.

The upper part of Figure 2 shows the mass spectrum of n-triacontane, taken with a CEC instrument (scanned by variation of the electric field) at an ion-source temperature of 340 °C. The lower part of the figure shows the spectrum of the same compound taken with an Atlas CH-4 instrument (scanned by variation of the magnetic field) at an ion-source temperature of approximately 70 °C. The differences in the inten-

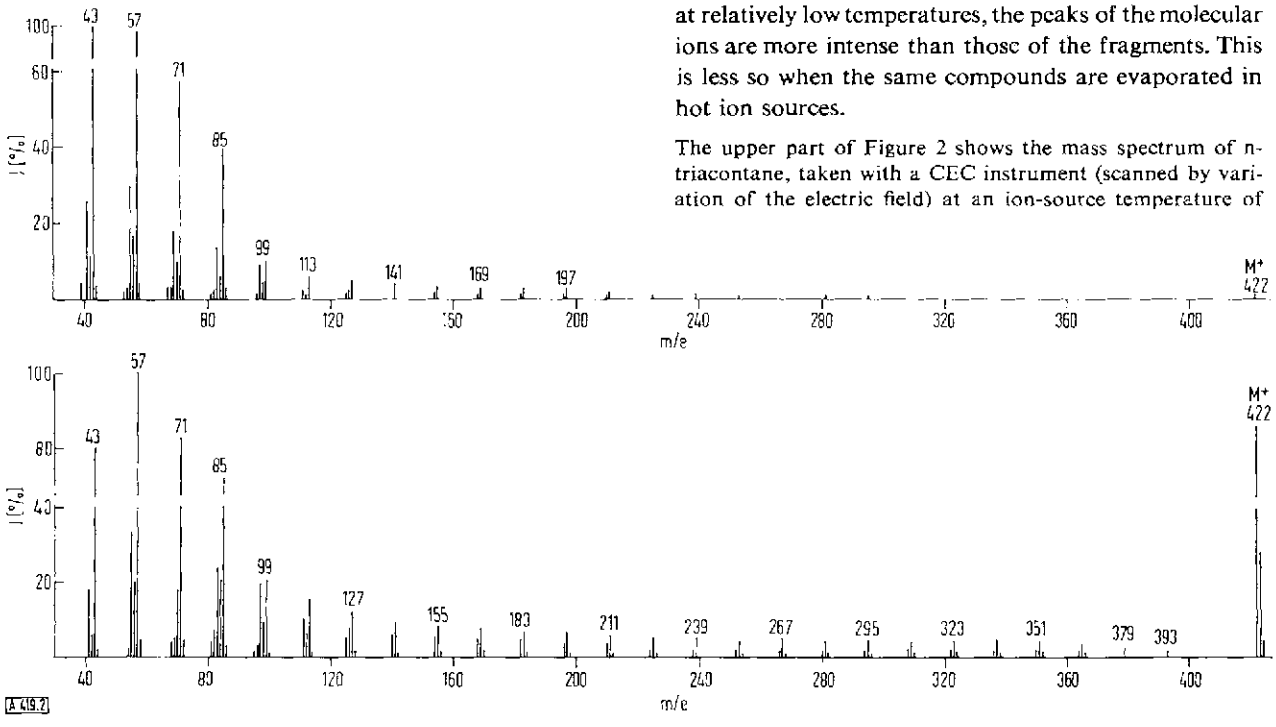

Fig. 2. Top: mass spectrum of n-triacontane $H_3C-(CH_2)_{28}-CH_3$ (A.P.I. no. 1316 [*]) taken with a CEC instrument; ion source at 340 °C. Bottom: mass spectrum of the same substance taken with an Atlas CH-4 instrument; TO-4 ion source at about 70 °C.
Ordinate: Intensity I [%].

[*] The A.P.I. number refers to the "Catalogue of Mass Spectral Data", issued by the American Petroleum Institute (A.P.I.) as Research Project 44.

sity ratios of the ions can be ascribed principally to the difference in temperature. (These and all following diagrams are line spectra derived from original spectra.)

The reaction conditions and the type of instrument influence the intensity ratio of the ions, but have no effect on the main fragmentation reactions. The same fragments are therefore formed from a particular substance irrespective of the nature of the instrument and conditions, and a qualitative analysis of the spectrum becomes possible. Using identical reaction conditions and the same instrument, the mass spectra are exactly reproducible and perfectly suitable for quantitative analysis (*e.g.* hydrocarbon mixtures in the petroleum industry).

C. The Course of Decomposition Reactions in the Mass Spectrometer

While in a chemical reaction the reagent attacks a particular group or bond, the electronic attack in the mass spectrometer is directed towards no particular site of the molecule. Whereas a chemical reaction owing to the relative sizes of the reaction partners takes place only on the surface of the molecules, it must be assumed that the much smaller electron can penetrate a molecule at any point, transferring part of its energy to the bonding and non-bonding electrons of the molecular orbitals penetrated and leading to the excitation of different centers. Within about 10^{-13} seconds [18], an electron is ejected from the excited molecule leaving behind a positively charged molecular ion. According to the "statistical theory of mass spectra" [18], the energy in excess of the ionization potential is assumed to distribute itself uniformly over all bonds, and fragmentation of the molecular ion then occurs. Numerous examples have shown that, with a few exceptions, this theory is at least qualitatively valid; in larger molecules, however, only partial distribution of the transferred energy takes place before fragmentation occurs [19].

D. Fragment Formation

Fragments are formed preferentially with a minimum expenditure of energy. It follows that the intensity of an ion peak will be the greater the less energy is required for ion formation and the more is needed for its further cleavage. The intensity of an ion peak therefore depends on both the probability of formation and the probability of decomposition of the ion.

The ionization of an unsubstituted aromatic hydrocarbon requires a relatively small amount of energy owing to the abundance of π-electrons, while cleavage of the resultant molecular ion, in which the positive charge is stabilized by the residual π-electrons, requires a considerable amount of additional energy. For this reason, fragment formation is not very probable and the molecular-ion peaks of such compounds exhibit a very high intensity (Fig. 3).

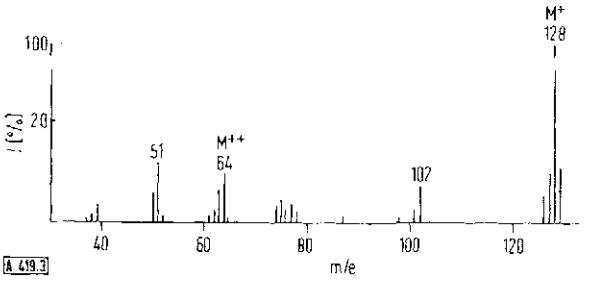

Fig. 3. Mass spectrum of naphthalene (A.P.I. no. 41).
Ordinate: intensity I [%].
Abscissa: m/e.

In a saturated aliphatic hydrocarbon, electrons can be removed only from σ-bonds. Since these are more stable than π-bonds, appreciably more energy is necessary to bring about ionization. Stabilization of the charge in the molecular ion is not possible. The latter must contain a single-electron bond, so that the difference between the energy required to form the ion and that required to decompose it is relatively small. This means that the fragment peaks have a very high intensity compared to the molecular-ion peak (Fig. 2).

It was frequently attempted to solve stereochemical problems with the aid of mass spectrometry. Normally, however, stereoisomeric compounds have similar mass spectra, due to the fact that the main fragmentation reactions do not involve the center of stereoisomerism. Thus, stereoisomeric differences lead to only slight variations in peak intensity, particularly when the center of stereoisomerism is remote from the bonds which are preferentially cleaved. It is only when bonds participating in the center of stereoisomerism are broken in the main fragmentation reactions that the mass spectra differ sufficiently for stereochemical conclusions to be drawn.

1. *Single Bond Cleavage*

Since fragmentation occurs preferentially with minimum energy expenditure, weaker bonds are ruptured rather than stronger ones, and cleavage reactions in which stable fragments are formed are preferred, because here the energy required for rupture is at least partially balanced by the gain in stabilization energy.

In saturated aliphatic hydrocarbons, for example, the weaker C–C bonds are therefore split more readily than the stronger C–H bonds, the main fragments being ions with the general formula C_nH_{2n+1} and masses 15, 29, 43, 57, *etc.*

By cleavage of a C–C bond in a straight-chain saturated hydrocarbon, primary carbonium ions of approximately equal stability are formed (subsequent rearrangement leading to secondary and tertiary carbonium ions may then occur). All C–C bonds in such a hydrocarbon therefore have an equal probability of being ruptured. The continuous decrease in peak intensity with increasing molecular weight of the fragments (Fig. 2) is due to the fact, that ions of higher molecular weight undergo secondary cleavage reactions more readily (see Section II.D.2a), which lead to the accumulation of low molecular-weight ions as final degradation products.

a) Influence of an Alkyl Substituent on the Course of Fragmentation

The C–C bonds in a branched saturated hydrocarbon are likewise approximately equal in strength. By fission of bonds at branching points, however, secondary and tertiary carbonium ions are formed. Because of the inductive electron donor effect of alkyl groups, a positive charge is better stabilized in such intermediates than in primary carbonium ions. For this reason, less energy is required to split branched saturated hydrocarbons than their straight-chain isomers. The molecular-ion peaks of branched hydrocarbons therefore exhibit a lower intensity than those of their straight-chain isomers (Fig. 4). The preferential splitting of bonds at branching points is demonstrated by the relatively high intensities of the peaks of ions formed by such reactions. However, it must be remembered that secondary decomposition reactions are less favored because of the greater stability of secondary and tertiary

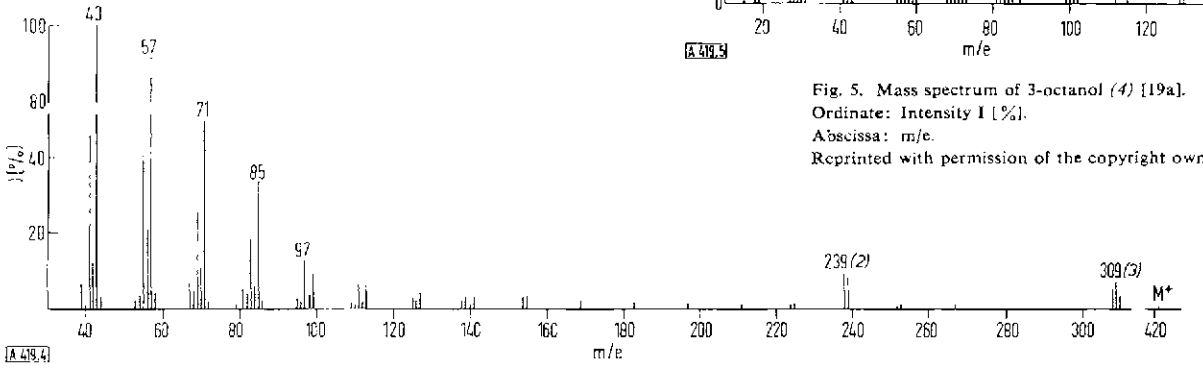

Fig. 4. Mass spectrum of 9-octyldocosane *(1)* (A.P.I. no. 866).
Ordinate: Intensity I [%].
Abscissa: m/e.

carbonium ions. It is therefore possible, in the absence of functional groups, to deduce the position of branching from the mass spectrum (Fig. 4). For example, 9-octyldocosane *(1)* is decomposed into the carbonium ions *(2)* and *(3)*.

$H_3C-(CH_2)_7-\overset{\oplus}{C}H-(CH_2)_{12}-CH_3$ *(3)*, mass number 309

$\overset{1}{\uparrow}\,{}^{-e}_{-H_3C-(CH_2)_7\cdot}$

$H_3C-(CH_2)_7-\overset{1}{C}H-(CH_2)_{12}-CH_3$ *(1)*

$\overset{2}{\downarrow}\,{}^{-e}_{-H_3C-(CH_2)_{12}\cdot}$

$H_3C-(CH_2)_7-\overset{\oplus}{C}H-(CH_2)_7-CH_3$ *(2)*, mass number 239

b) The Influence of a Substituent Containing a Singly Bonded Hetero-Atom with a Lone Electron Pair

Functional groups containing a singly bonded hetero-atom with a lone pair of electrons (first-order substituents) have a much stronger effect on fragmentation than alkyl groups. Such compounds are cleaved with high probability at one of the C–C bonds adjacent to the hetero-atom, since in this way stabilized ions can be formed.

X = NH_2, NHR, NR_2, OH, OR, SH, SR, Halogen

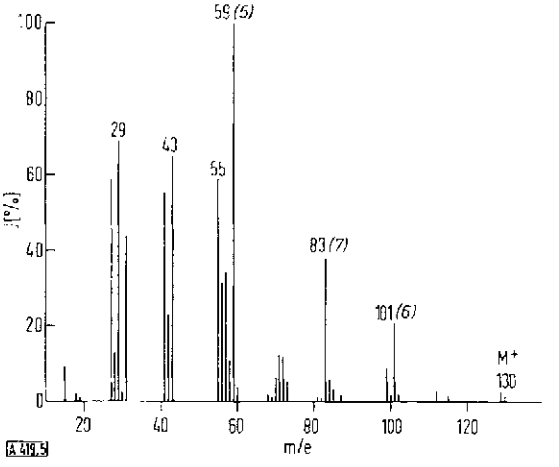

Fig. 5. Mass spectrum of 3-octanol *(4)* [19a].
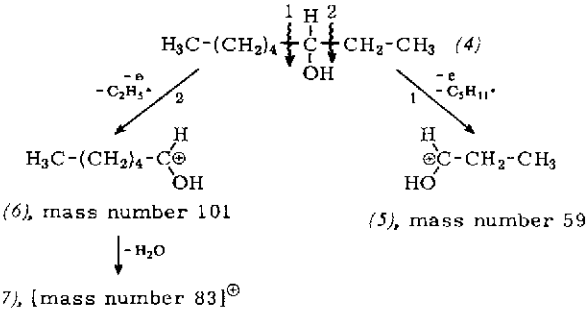
Ordinate: Intensity I [%].
Abscissa: m/e.
Reprinted with permission of the copyright owner.

For example, the mass spectrum of 3-octanol *(4)* (Fig. 5) contains two characteristic fragments with mass numbers 59 *(5)* and 101 *(6)*, formed by cleavage of a C–C bond on either side of the functional group.



The low intensity of the peak of fragment *(6)* compared to that of fragment *(5)* can be attributed at least in part to the greater tendency of heavier ions to undergo further decomposition reactions. For example, *(6)* decomposes very readily to form *(7)* with the elimination of one molecule of water.

In general, molecular ions of alcohols and amines show a lower intensity than those of straight-chain saturated hydrocarbons with the same number of carbon atoms, in spite of the fact that ionization occurs more readily due to the lone pair of electrons at the hetero-atom. The reason is that the probability of decomposition of the molecular ions is greater (because of the high stability of the fragments $[>\overset{\oplus}{C}-X:]$) than their probability of

formation, so that the energy required to form the fragments is smaller than in the case of hydrocarbons.

An increase in the tendency of the hetero-atom to supply a negative charge to stabilize a positive charge on an adjacent carbon atom leads to increased fragmentation probability. The fragments of amines formed in such reactions therefore produce a much higher intensity in the mass spectrum than those of alcohols of comparable constitution. The ability of halogens to supply a negative charge is so small that such fissions are hardly ever observed, especially since the lower bond strength of the carbon-halogen bond (compared to that of the C–C bond) strongly favors release of the halogen over other possible decomposition reactions.

The ability to stabilize charges decreases from nitrogen to the halogens *via* sulfur and oxygen. It does not run parallel to the electronegativity [20] (which refers to the ease of displacement of the electrons of a σ-bond) but is a measure of nucleophilic properties (*i.e* of the availability of a lone π- or p-electron pair). Although bimolecular nucleophilic reactions in solution and monomolecular decomposition reactions in the gas phase (such as take place in the mass spectrometer) cannot be directly compared, it is in some cases possible to carry out comparative basicity measurements by mass spectrometry; for example in methoxyethanol *(8)* the negative charge density and hence the basicity of the ether oxygen is greater than that of the alcoholic hydroxy group because of the inductive electron-donating effect of the methyl group. When the compound is decomposed in the mass spectrometer, formation of fragment *(9)* is much more likely than that of *(10)* (Figure 6).

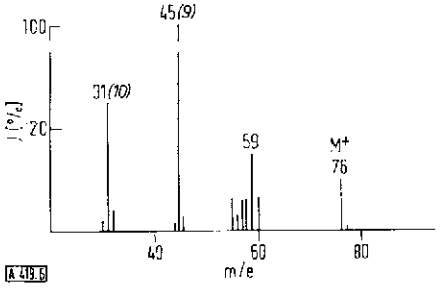

Fig. 6. Mass spectrum of methoxyethanol *(8)* taken with an Atlas CH-4 instrument; temperature of the TO-4 ion source approximately 50 °C.
Ordinate: Intensity I [%].
Abscissa: m/e.

A comparative determination of basicity by mass spectrometry has the advantage over wet chemical processes that interfering effects of the solvent are eliminated. For example, tertiary amines in aqueous solution exhibit a lower basicity than secondary ones, although an increase could be expected from the additional alkyl group and the consequent increase of electron density on the nitrogen [21]. The decrease actually observed is due entirely to the water, since with chloroform as solvent the basicity rises on passing from secondary to tertiary amines. Similarly, mass-spectrometric studies show that tertiary amines [$>\overset{\oplus}{C}-\ddot{N}R_2$] form fragments much more frequently than secondary [$>C-\overset{\oplus}{\ddot{N}}HR$] or primary [$>\overset{\oplus}{C}-\ddot{N}H_2$] ones [22].

[20] Cf. [7b], p. 88.

2. *Multiple Bond Cleavage*

So far we have considered only the stability of positively charged fragments. No allowance has been made for the simultaneously formation of uncharged particles. Since however the total energy balance determines the course of a decomposition reaction, this consideration is valid only when fissions are compared in which particles of roughly equal stability are formed, *e.g.* alkyl radicals. Very often, neutral molecules may be split off during decomposition reactions. They are much more stable than radicals and therefore can no longer be disregarded.

Uncharged particles, *i.e.* neutral molecules and radicals, cannot be observed directly in the mass spectrum, but their mass can be obtained from the mass difference between peaks of positively charged ions. For example, a mass difference of 28 could be due to the loss of a molecule of carbon monoxide or one of ethylene.

A decision whether a neutral molecule or a radical has been eliminated can readily be made in many cases; compounds which consist only of C, H and O must have an even-numbered molecular weight. If a radical is eliminated from such a compound by single bond cleavage, an ion of odd mass number is formed, and the difference in mass between the molecular ion and the fragment must likewise be an odd number. In contrast, release of a neutral molecule from such a compound can be recognized by an even difference in mass. The formation of a neutral molecule from nitrogen-containing compounds, which do not necessarily possess an even-numbered molecular weight, cannot be so easily recognized from their mass spectra, since nitrogen-containing neutral molecules of uneven mass as well as nitrogen-free neutral molecules of even mass or with an even number of nitrogen atoms can be eliminated.

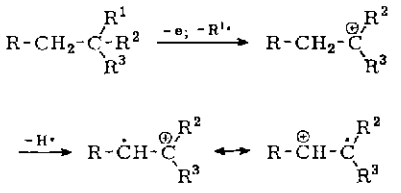
a) Multistage Decomposition Reactions

Uncharged particles, *e.g.* H_2O, CH_3, and CO, are generally eliminated in stages. Normally, almost any number of stable neutral molecules but only a single radical can be eliminated. Multiple homolytic bond cleavage would lead to radical-ions of low stability, so that such processes do not occur for energetic reasons if other fissions can take place. Although this rule is not always valid, its application may frequently help to exclude erroneous interpretations of fission mechanisms. For example, a mass difference of 30 might be interpreted as the loss of two methyl groups, but much more likely represents the release of one molecule of CH_2O or NO.

[21] *H. A. Staab*: Einführung in die theoretische organische Chemie. 2nd Edit., Verlag Chemie, Weinheim, 1960, p. 631, where further references are given.

[22] *L. Dolejš, V. Hanuš, V. Černý*, and *F. Šorm*, Collect. czechoslov. chem. Commun. *28*, 1586 (1963); *N. Neuner-Jehle, H. Nesvadba*, and *G. Spiteller*, Mh. Chem. *95*, 687 (1964); Cf. [8b], p. 77; [8c], p. 167.

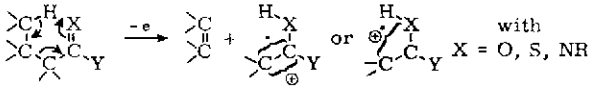
An exception to this rule is, for example, the decomposition of an ion which is formed by the homolytic fission of a saturated, branched hydrocarbon at the branching point.



This ion decomposes with the elimination of a hydrogen radical from one of the CH groups adjacent to the positive charge center, as the radical cation formed is more stable than the primary ion (see Figure 4).

b) Rearrangement Reactions

McLafferty [23] was the first to show that neutral molecules are frequently split off during rearrangement reactions, *via* a six-centered intermediate. For example, the elimination of an olefin is characteristic for compounds containing a double bond and a γ-CH group. If X = O, S, or NR, the free p-electrons may contribute considerably to the stabilization of the rearranged fragment.



X = CH_2, CHR, O, S, NR
Y = H, R, OR, OH, NH_2

The positive charge may reside in the olefin or in the rearranged fragment, depending on the degree of stabilization. In the mass spectra of aliphatic carboxylic acids (X = O, Y = OH), for example n-butyric acid [23a], the rearranged fragment has a mass number of 60. The intensity of the peak of the rearranged fragment is particularly marked in the case of low-molecular compounds

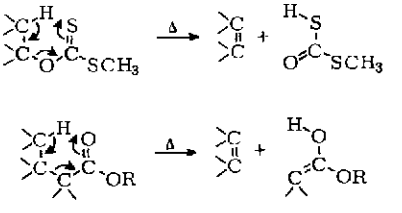
The exclusive participation of γ-hydrogen atoms in the rearrangement reaction was demonstrated by using a carboxylic acid in which the CH_2 groups had been successively replaced by CD_2 groups. While in the mass spectrum of the α-labelled compound the rearranged fragment had the mass number 62, a fragment of mass number 60 occurred in the case of the β-labelled compound, and the spectrum of the γ-labelled compound showed the rearrangement peak at mass number 61. It was concluded that the rearranged fragment contains the α-CH_2 group and one γ-H atom [24], in agreement with *McLafferty*'s postulate [23].

The labelling of carbon atoms in a molecule by hydrogen-deuterium exchange [25] is frequently used in mass spectrometry to explore decomposition mechanisms. However, a particular hydrogen atom is not always shifted to a precisely defined site in the molecule, as in the above-mentioned McLafferty rearrangement (which, for this reason, is designated as a "specific" rearrangement [23]). It is frequently observed that labelled atoms are more or less uniformly distributed over all the fission fragments. Such "random rearrangements", which occur predominantly in hydrocarbons, generally lead to fragments of low peak intensities and are often only of secondary importance in the interpretation of a spectrum.

While the origin of the hydrogen atom in the McLafferty rearrangement has been clarified, there is still no agreement as to whether the hydrogen migrates in the form of a radical [8b, 8c] or as a proton [26]. A proton migration is supported by the fact that an increase in electron density at the atom X facilitates the reaction. The rearrangement probability decreases in the order X = NR > O > CH_2.

The main argument for a radical migration comes from measurements of the ionization potentials of simple molecules, which indicate that the positive charge of the molecule-ion is located at the atom X. This argument, however, does not appear to be conclusive, since no allowance has been made for the fact that in recording mass spectra of organic compounds the electron energy is not maintained in the region of the ionizing potential but at 70 eV, so that initially any electron can be eliminated from the molecule. In addition, it has been demonstrated that the course of the rearrangement is independent of the site of the positive charge [26].

The "McLafferty rearragement", which in many cases strongly influences the decomposition of compounds with second-order substituents, finds parallels in certain chemical decomposition reactions, for example in the preparation of olefins by *Tschugaeff*'s method or in the thermal decomposition of esters.



Other decomposition processes occurring in the mass spectrometer cannot be compared with chemical reactions and cannot be interpreted by a simple displacement of pairs of electrons. One example is the decomposition of *o*-anisidine *(11)*. Here the mass spectrum shows that the molecular ion releases a methyl group and then decomposes to form a pyridinium ion *(12)* with the elimination of one molecule of CO [27]. These fission products have a particularly low energy content, so that alternative fragmentation routes

are not available in this and similar decomposition reactions [28] because of the stability of the original compound.

c) Decomposition Reactions which Proceed via Radical Ions

The interpretation of the cleavage of alicyclic compounds is appreciably more difficult. Except when fragments are formed by hydrogen abstraction, at least two carbon-carbon bonds must be broken, and naturally more energy is required for this purpose than for the rupture of a single bond. Therefore, the molecular-ion peaks of unsubstituted alicyclic compounds are much more intense than those of open-chain saturated compounds with the same number of carbon atoms (Fig. 7).

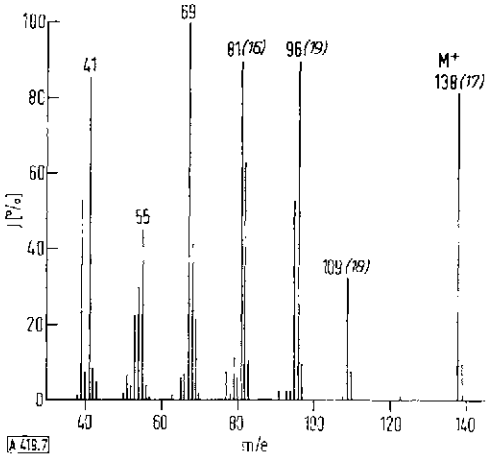

Fig. 7. Mass spectrum of *cis*-decalin *(13)* (A.P.I. no. 992).
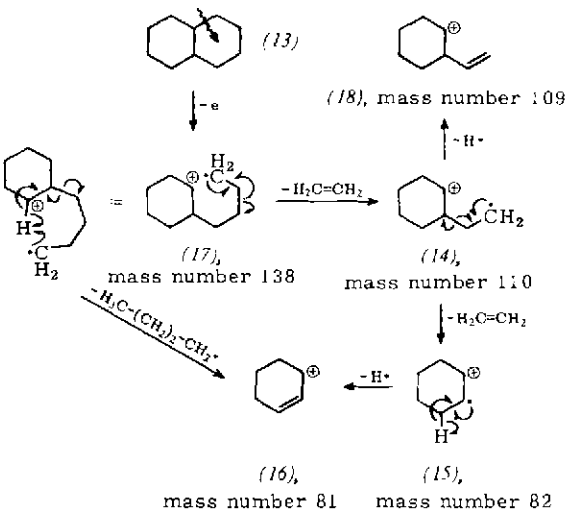
Ordinate: Intensity I [%].
Abscissa: m/e.

As the mass spectrum of *cis*-decalin *(13)* shows, alicyclic hydrocarbons decompose to give numerous fragments which are, however, not particularly characteristic. Their formation can proceed along various routes, so that relationships between structure and mass spectrum are not readily apparent. The primary cleavage occurs preferentially at a ring junction; in this way relatively stable carbonium ions can be formed. The primary decomposition product is a radical ion *(17)* in which the center of positive charge is separated from the radical site by several saturated carbon atoms; stabilization of the decomposition product is therefore insignificant. Formation of such radical ions makes the decomposition of alicyclic hydrocarbons fundamentally different from that of aliphatic hydrocarbons, which form simple ions.

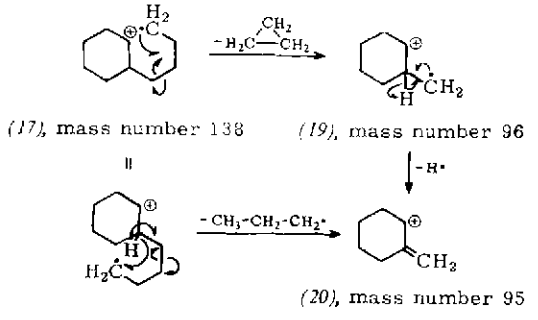
For the decomposition of such radical ions, the radical character of the particles appears to be of decisive significance. The elimination of one molecule of ethylene from *(17)* [29] leads to the formation of the radical ion *(14)* with mass 110, which can decompose further with the elimination of a hydrogen atom or a molecule of ethylene. The fragment *(15)* formed by the twofold elimination of ethylene can be stabilized by the loss of a hydrogen radical to form an allyl cation *(16)* with mass 81.

[28] *J. H. Beynon, G. R. Lester*, and *A. E. Williams*, J. physic. Chem. *31*, 1861 (1959).

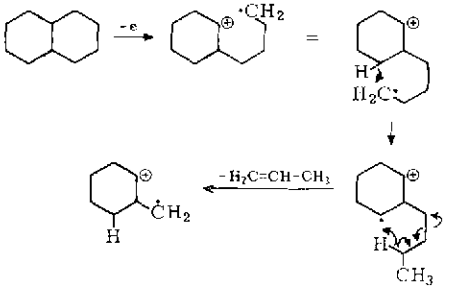
[29] Following a suggestion of *Budzikiewicz, Djerassi*, and *Williams* [8b], the displacement of a pair of electrons is symbolized by an arrow and that of a single electron by a small hook. However, unlike these authors, we are indicating each electron to avoid errors.



The decomposition of the primary fission product *(17)* by elimination of a butyl radical in the course of rearrangement may explain the formation of *(16)* in a different manner. Probably, both reactions occur simultaneously. The loss of one molecule of cyclopropane from *(17)* leads to an ion *(19)* from which, once again, a hydrogen atom can be eliminated. However, fragment *(20)* can also be formed in a single step from *(17)* by rearrangement.



In analogy with observations by *N. Neuner-Jehle* with quinolizidines, it seems that C_3H_6 can also be eliminated as propylene in the course of a twofold hydrogen shift:



Although the formation of only a small proportion of the fragments appearing in the spectrum of *cis*-decalin has thus been interpreted, and only a few ways of formation of the individual ions have been discussed, this example does show the many possible decomposition reactions of cyclic compounds and hence the difficulties encountered in the interpretation of their spectra. If functional groups are present, however, they may exert a specific influence on the mode of fragmentation.

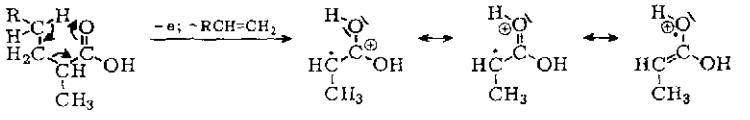
III. General Rules for the Interpretation of Mass Spectra

A. The Formation of Key Fragments

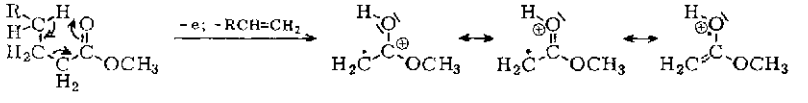
The rules derived so far for the decomposition of organic molecules in the mass spectrometer allow us to formulate some principles governing the interpretation of mass spectra.

A relationship between the structure and the mass spectrum of a compound will be apparent if some decomposition reactions require much less energy than all others, so that spectra are formed which contain few, but intense peaks. Such characteristic peaks frequently represent the key to the elucidation of the structure of an unknown compound, and may be designated as peaks of "key fragments".

Key fragments differ from others which occur in nearly every spectrum by their particularly high intensity and/or their unusual mass number. For example, an ion of mass number 41, in general an allyl cation, cannot be designated as a key fragment since, owing to its great stability, it arises from many organic compounds with different structures. The same is true for other hydrocarbon fragments unless their peaks are distinguished by abnormally high intensities (see Fig. 4).



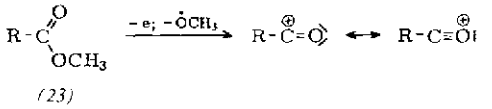
(21) mass number 74



(22) mass number 74

It is self-evident that a single key fragment is not sufficient to postulate the existence of a certain group in the compound studied, since ions of the same empirical formula may have different structures. For example, the spectra of α-methylcarboxylic acids *(21)* and of unbranched methyl esters *(22)* show a key fragment with mass number 74, which in both cases is formed in the course of a McLafferty rearrangement.

However, in simple methyl esters *(23)*, release of an $\cdot OCH_3$ radical is also favored, since a stable ion can be formed in this manner, too. Consequently, the spectra of simple methyl esters exhibit a fragment with mass number M minus 31 (M = molecular ion) corresponding to the loss of a methoxyl radical, in addition to the rearrangement fragment with mass number 74. On the other hand, carboxylic acids cannot yield fragments of 31 mass units (M.U.), provided that substituents



(23)

such as CH_2OH are absent, since to achieve this both an OH group and a CH_2 group (in the form of a carbene) must be eliminated, which is impossible for energetic reasons. The simultaneous presence of peaks at mass numbers 74 and M minus 31 therefore indicates a methyl ester rather than an α-methylcarboxylic acid.

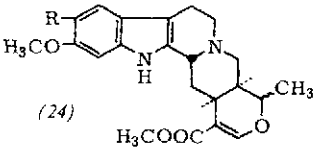
While individual key fragments normally indicate only the group to which a compound belongs, they may provide conclusive evidence of the presence of certain structural elements when taken together. Hence they can make a substantial contribution to the elucidation of the structure of an unknown compound.

Key fragments are formed above all from compounds containing basic nitrogen atoms or aromatic ring systems, since stabilized ions can be derived from these with particular ease. It is therefore not surprising to find, for example, that in alkaloid chemistry mass spectrometry has been widely employed to determine structures.

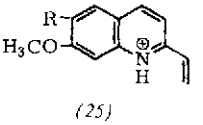
B. Spectrum-Comparison Technique

The use of mass spectrometry in the elucidation of alkaloid structures depends to a significant extent on the ability of many plants to produce several alkaloids which differ only by the presence or absence of functional groups but contain the same carbon skeleton. If these functional groups do not substantially influence the course of fragmentation, then the same main cleavage reactions ensue on decomposition of all these alkaloids in the mass spectrometer. According to the masses and positions of the substituents, the positions of the key-fragment peaks differ merely by a certain number of mass units, so that the carbon skeleton can be identified simply by comparison of the spectra (Figure 8). For example, the positions of the key-fragment peaks of isoreserpinine *(24a)* and reserpiline *(24b)* differ by 30 mass units (1 CH_3O minus 1 H).

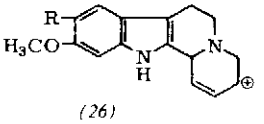
This spectrum-comparison technique was initially used by *Biemann* [30]. It permits a structure determination only when spectra of compounds with known structure



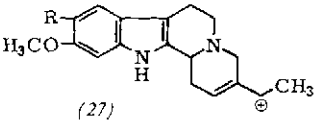
(24)



(25)



(26)



(27)

(a): R = H; *(b)*: R = OCH_3

are available for comparison, or when the key fragments give some indication of the groups present so that reference compounds can be selected.

Ordinate: Intensity I [%].

Abscissa: m/e.

IV. Combination of Chemical and Mass-Spectrometric Decomposition Reactions

Even when a structure cannot be derived directly, *e.g.* for lack of reference material, the mass spectrum almost invariably gives some indication of the structural elements present. These indications can be confirmed or disproved by chemical degradation reactions. Samples of 2–5 mg are sufficient when the reaction products are also studied by mass spectrometry. Their purification is generally unnecessary, since impurities do not adversely affect the recognition of the usually intense key-fragment peaks, although they do increase the number of low-intensity peaks. In addition, volatile constituents originating from impurities can be removed within the ion source by gradual heating.

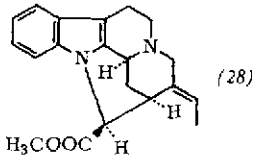
Frequently, the course of a reaction can be deduced merely from the change in molecular weight. Simple chemical reactions frequently alter the basicity of key atoms and thus influence the course of fragment formation in such a way that the spectra exhibit characteristic cleavage products first for one and then for the other part of the molecule.

A. Elucidation of the Structure of Pleiocarpamine

The structure of the alkaloid pleiocarpamine *(28)* was determined by combining small-scale chemical reactions with mass spectrometry and NMR measurements [31]. Elementary analysis gave the empirical formula $C_{21}H_{24}O_2N_2$ and showed the presence of OCH_3 and $C{-}CH_3$ groups as well as the absence of an $N{-}CH_3$ group [32]. Its ultraviolet spectrum indicated the presence of a methoxyindole chromophore and the infrared spectrum the absence of NH and OH groups as well as the presence (possibly) of a five-membered cyclic ketone [32]. The NMR spectrum showed an ethylidene side-chain, and methylation revealed that the second nitrogen atom also was tertiary [32].

The small amount of substance available made the elucidation of structure by chemical means very difficult, and resort was made to mass spectrometry.

The mass spectrum of pleiocarpamine *(28)* (Fig. 9) contained the molecular-ion peak at mass number 322. This led to a correction of the empirical formula from $C_{21}H_{24}O_2N_2$ to $C_{20}H_{22}O_2N_2$ [31]. A key fragment at mass number 263 corresponded to the loss of a particle with mass 59, presumably a methoxycarbonyl group.



(28)

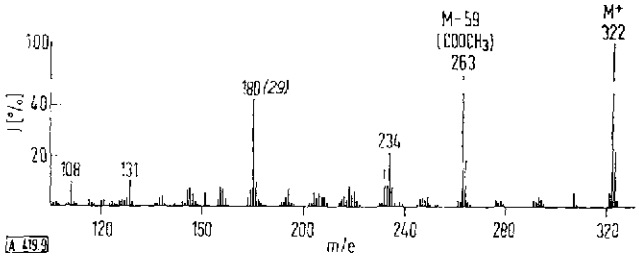


Fig. 9. Mass spectrum of pleiocarpamine *(28)* [31].

Ordinate: Intensity I [%].

Abscissa: m/e.

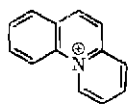
This finding was in contradiction to previous results [32] but could be confirmed by a reinterpretation of the infrared and ultraviolet spectra. In order to fully clarify this point, pleiocarpamine was reduced with $LiAlH_4$, giving a product with a molecular weight of 294 (determined by mass spectrometry). This corresponds to the loss in mass accompanying the reduction of a $COOCH_3$ group to a CH_2OH group (28 M.U.). At the same time, the unchanged position of the key fragment at mass number 263 demonstrated that a CH_2OH group had been eliminated in place of a $COOCH_3$ group. In this way the presence not only of a methoxycarbonyl group in pleiocarpamine was demonstrated, but also that of an unsubstituted indole chromophore, since the molecule could not contain more than two oxygen atoms.

The structure of the important key fragment with mass number 180 in the spectrum of pleiocarpamine was elucidated in the following manner. Since this ion is formed not only from pleiocarpamine but also from the product of reduction with $LiAlH_4$, it could not contain the functional group, since in this case replacement of $COOCH_3$ by CH_2OH would have caused a displacement of the peak by 28 mass units. Removal of parts of the stable indole system is impossible for energetic reasons. A fragment which is formed by loss of both the functional group (59 mass units) and the indole part (115 mass units) from pleiocarpamine (molecular weight 322) will have a maximum molecular weight of $322 - (59 + 115) = 148$. Since the key fragment had a molecular weight of 180, it must still contain the indole system, and so the only possible empirical formula for the fragment with molecular weight 180 is $C_{13}H_{10}N$. If in addition it is considered that the indole nitrogen is substituted, then this ion must be a quinolinium ion (rearrangements of 3-substituted indoles to quinolinium ions are frequently observed in mass-spectrometric decomposition reactions).

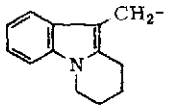
[30] *K. Biemann*, Tetrahedron Letters *1960*, No. 15, 9.

[31] *M. Hesse, W. v. Philipsborn, D. Schumann, G. Spiteller, M. Spiteller-Friedmann, W. I. Taylor, H. Schmid*, and *P. Karrer*, Helv. chim. Acta *47*, 878 (1964).

[32] *W. G. Kump* and *H. Schmid*, Helv. chim. Acta *44*, 1503 (1961).



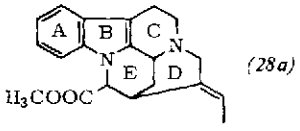
(29), mass number 180



(30)

These findings suggested a six-membered ring [structure *(30)*] which links the indole nitrogen with the neighboring carbon-atom.

These results together with evidence obtained from spectra and chemical decomposition reactions, led *Schmid* et al. to postulate a provisional structural formula *(28a)* for pleiocarpamine [31].



(28a)

This formula has been confirmed by a detailed analysis of the 100 Mc ^1H-NMR spectrum and by a combined chemical and mass-spectrometric degradation in which many of the reaction products were not characterized by elementary analysis but by their mass spectra.

The mass spectrum of pleiocarpamine (Fig. 9) contains no fragments indicating the presence of a piperidine ring. Evidently such fragments are absent because stabilization of a positive charge is far better in the indole system than in the piperidine part of the molecule. Reduction of the indole to the indoline system greatly reduces stabilization of the positive charge in the aromatic part of the molecule, so that the mass spectrum of dihydropleiocarpamine *(31)* (Fig. 10) is entirely different.

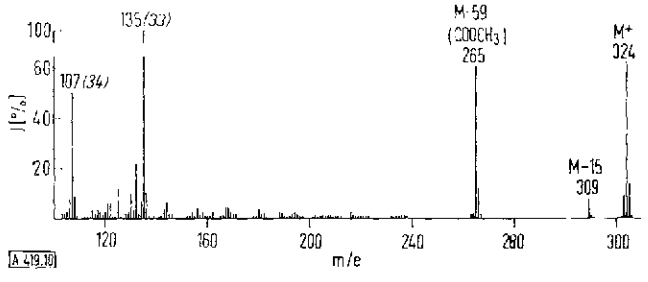


Fig. 10. Mass spectrum of 2,7-dihydropleiocarpamine *(31)* [31].
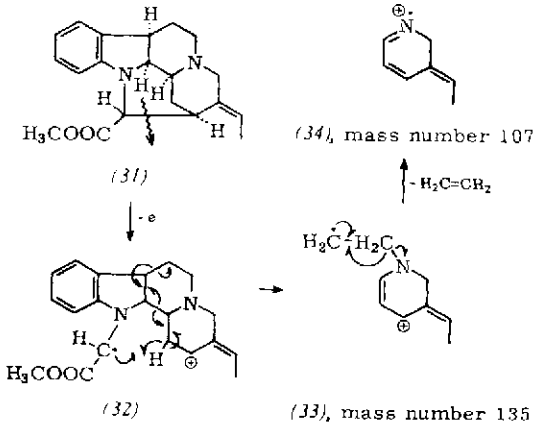
Ordinate: Intensity I [%].
Abscissa: m/e.

During decomposition of the dihydro derivative *(31)*, an allyl cation *(32)* seems to be formed initially, which then undergoes rearrangement with displacement of a hydrogen radical to form the key fragment *(33)*. The elimination of one molecule of ethylene from *(33)* finally leads to formation of the fragment *(34)*.

In this way, the existence of a tryptamine bridge linking the piperidine part with the indole ring was made probable in addition to the presence of a piperidine ring. Besides, the decomposition reaction indicated that the methoxycarbonyl group must be located in ring E.



V. Elucidation of the Structures of Compounds in Mixtures without Isolation of the Components

Isolation in pure form is not always necessary for the mass-spectrometric elucidation of the structure of an unknown compound. By fractional evaporation of the sample into the reservoir of the mass spectrometer [7a] or better by continuous gradual volatilization of the substance in the ion source, a mixture of substances can be partly or even completely separated. From the alterations in the intensities of ion peaks it is then possible to recognize which fragments are formed from the components of the mixture.

In mixtures of very similar compounds, it is possible under certain conditions to derive the structures of the individual components (without isolation of pure substances) by chemical reactions on a microscale followed by a mass-spectrometric study of the mixture of reaction products. One example is the structural elucidation of eight alkaloids from only 30 mg of material [33].

VI. Summary

The principal rules governing the fragmentation of organic compounds in the mass spectrometer have been discussed; whether a mass spectrum can be successfully interpreted depends to a large extent on the magnitude of the energy difference between the possible decomposition paths of the compound studied. In general, spectra characterized by the presence of few key fragments can be expected only from compounds which decompose preferentially in a few directions. This is the case when stable fragments can be formed, as in the decomposition of aromatic or heterocyclic derivatives or of compounds with substituents releasing negatively charged portions, since in all these substances a positive charge may become stabilized.

Simple chemical reactions alter the ability of various substituents to stabilize charges. Thus the course of mass-spectrometric degradations can be varied to some extent, with consequent formation of key fragments from either one or the other part of a molecule.

A particular advantage is that all reactions can be carried out on a microscale, since impurities usually do not interfere with the subsequent mass-spectrometric investigation of the reaction products.

We should like to thank Prof. F. Wessely and our collaborators R. Kaschnitz, N. Neuner-Jehle, and Dr. S. Eggers for numerous stimulating discussions and the Österreichischer Forschungsrat for the provision of a mass spectrometer.

Sequence Distribution in Copolymers

Chemical Studies [*]

BY PROF. DR. H. JAMES HARWOOD

INSTITUTE OF RUBBER RESEARCH, UNIVERSITY OF AKRON, AKRON, OHIO (U.S.A.)

Various chemical procedures are available for studying the sequence distribution in copolymers, but none can be applied routinely. The run-number approach permits the results of such studies to be treated with ease; all results obtained to date are consistent with classical copolymerization theory.

A. Introduction

Copolymerization of two monomers can lead to a variety of copolymers differing in composition and in the arrangement of the monomer units. The monomer units may be randomly distributed, may tend to alternate, or may tend to cluster in blocks of like units.

	~~ABAABBAABB~~~	Random type
A + B →	~~~ABABABABAB~~~	Alternating type
	~~AAAAABBBBB~~~	Block type

Knowledge of the composition and sequence distribution [1–3] of copolymers is necessary for investigating copolymerization mechanisms and the properties of copolymers. Unfortunately, only information on copolymer composition is easy to obtain.

Chemical studies on sequence distribution in copolymers will be reviewed here, physical approaches will be discussed in a later article. Studies on the characterization of tacticity in homopolymers will be mentioned only when they involve techniques which can be applied to determine the sequence distribution in copolymers as well.

B. Theory and Principles Governing the Determination of Sequence Distribution

In principle, the experimental determination of the sequence distribution in copolymers is very simple. It is only necessary to determine the extent of any single recurring structural feature. In most chemical approaches the percentage of A–A, A–B, or B–B linkages is determined, whereas most physical or spectroscopic approaches yield the percentage of A or B units present in the middle of various triads, pentads, or heptads. For example, in copolymer *(1)*, the percentage of A–A linkages (indicated by arrows) or the fraction of A units in the middle of triads of the type A–A–B (indicated by asterisks) might be determined.

The results obtained by various approaches can be compared using the concept of run numbers [4]. The run number R of a copolymer is defined as the average number of uninterrupted monomer sequences (or runs) which occur in a copolymer chain per 100 monomer units. There are twelve runs (underlined) in the twenty-unit copolymer *(1)*; this chain therefore has a run number of 60 (*i.e.* 12 runs/20 monomer units = 60/100).

(1)

Equations (a)–(f) are examples relating the run number R to the molar composition of the copolymer (% A and % B) and to measurable aspects of the copolymer structure. The symbol f in Equations (d)–(f) denotes the fraction of A monomers to be found in the middle of the triads AAA, BAA (and AAB), and BAB.

% A–B linkages (including B–A linkages)	R	(a)
% A–A linkages	$-\%\ A\ (R/2)$	(b)
% B–B linkages	$-\%\ B\ (R/2)$	(c)
AAA triads (f_{AAA})	$\frac{[\%\ A-(R/2)]^2}{(\%\ A)^2}$	(d)
BAA (and AAB) triads (f_{BAA})	$\frac{R[\%\ A-(R/2)]}{(\%\ A)^2}$	(e)
BAB triads (f_{BAB})	$\frac{R^2}{4(\%\ A)^2}$	(f)

These expressions, in conjunction with analogous expressions for B-centered triads, will usually be adequate for most sequence-distribution studies; however, sometimes A or B units in pentads or larger sequences must be considered. Equation (g) expresses the fraction f of A monomers in the middle of the pentad ABABA.

$$f^{*}_{ABABA} \quad \frac{R^2}{4(\%\ A)^2} \quad \frac{R^2}{4(\%\ B)^2} \quad \frac{R^4}{16(\%\ A)^2(\%\ B)^2} \qquad (g)$$

In general, the extent of any measurable feature of the copolymer structure that is related to sequence distribution can be expressed as a function of the run number R and the composition of the copolymer.

[*] An article on physical investigations of the sequence distribution in copolymers will appear shortly in this journal.

[4] *H. J. Harwood* and *W. M. Ritchey*, Polymer Letters *2*, 601 (1964).

Run numbers R can also be predicted for copolymers when the mechanism of polymerization is known. For example, Equation (h) expresses the run number of a copolymer with a random structure.

$$R_{random} \quad \frac{2\,(\%\ A)\,(\%\ B)}{100} \qquad (h)$$

Run numbers for vinyl copolymers may be predicted from monomer reactivity ratios (r_A and r_B) and the molar percentages of monomers (A_x and B_x) in the polymerization mixtures using Equation (i).

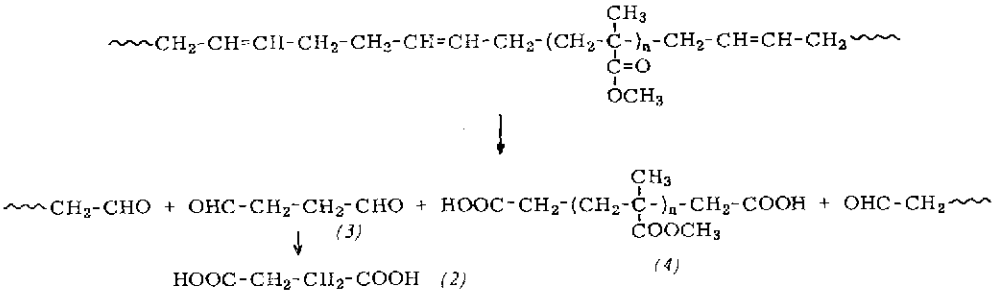
$$R \quad \frac{200}{2 + r_A A_x/B_x + r_B B_x/A_x} \qquad (i)$$

Many theoretical treatments of tacticity and sequence distribution have been published [1–3, 5–12], and methods [13] or parameters [5–8] for characterizing such distributions have been proposed. However, the run-number approach is used exclusively in this review.

C. Chemical Methods for Determining Sequence Distributions

1. Oxidative Degradation

In one of the earliest studies on copolymer structure, *Hill, Lewis,* and *Simonsen* [14] investigated the ozonolysis of a 50:50 butadiene (B)/methyl methacrylate (M) copolymer. The principal products were succinic acid *(2)*, succindialdehyde *(3)*, and dicarboxylic acids containing several methyl methacrylate residues *(4)*, [isolated as their methyl esters].



The percentage of butadiene (9.2%) recovered as succinic acid and succindialdehyde provided a measure of the 1,4-butadiene-1,4-butadiene linkages in the copolymers, and the percentage of methyl methacrylate units (> 51%) recovered as trimethyl 2-methylbutane-1,2,4-tricarboxylate *(4)*, n = 1, provided a measure of the methyl methacrylate units in the middle of BMB triads. Applying these results, the run number of the copolymer is found to be between 71 [value obtained from the content of methylbutane tricarboxylate using Equation (f)] and 91 [value obtained from the content of succinic acid and succindialdehyde using Equation (b)].

These values are considerably larger than the value of 50 expected for a random 50:50 copolymer. This work provided the earliest chemical evidence for the strong alternation tendency exhibited by many vinyl copolymerization systems.

Marder and *Schuerch* [15] utilized another procedure of selective oxidation for studying the sequence distribution of hydrolysed vinyl acetate/vinylene carbonate copolymers. The hydrolysed copolymers were degraded with periodic acid, and the amount of formic acid produced was measured. Here, the amount of periodic acid consumed (M_{HIO_4}) should provide a measure of copolymer composition, and comparison of this with the amount of formic acid liberated (M_{HCOOH}) should indicate the number of vinylene glycol sequences present. The run number of a copolymer is related to these quantities and the molar percentage of vinylene glycol

$$R \quad 4 \cdot \%\ VG \cdot (1 - M_{HOOCH}/M_{HIO_4}) \qquad (k)$$

(%VG) present according to Equation (k). Unfortunately, products formed by oxidation of the polymer also consumed periodic acid and liberated formic acid. *Marder* and *Schuerch* managed to predict the approximate amount of overoxidation. In Table 1, the experimentally determined M_{HCOOH}/M_{HIO_4} ratios are compared with those predicted from calculated sequence distributions, taking the effects of overoxidation into account.

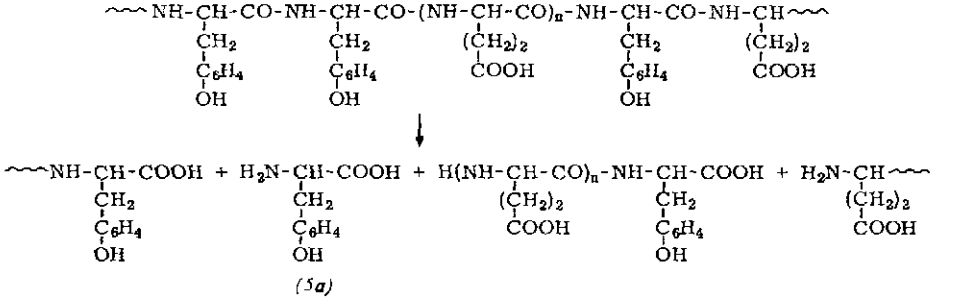
Table 1. Degradation of hydrolyzed vinylene carbonate-vinyl acetate copolymers with periodic acid [15] [a].

VG in copolymer [mole %]	M_{HIO_4} [moles/g] × 10^3		M_{HCOOH} [moles/g] × 10^3		M_{HCOOH}/M_{HIO_4}	
	calc.	obs.	calc.	obs.	calc.	obs.
30.0	22	18	11.8	8.7	0.54	0.49
25.7	17.5	15	9.3	7.8	0.53	0.51
20.9	13.3	13	7.0	5.6	0.52	0.43

[a] VG = vinylene glycol; M = amount.

2. Enzymatic Degradation

Kanakkanatt [16] investigated the degradation of L-glutamic acid/L-tyrosine copolymers with chymotrypsin. Chymotrypsin effects selective hydrolysis of *C*-tyrosyl peptide linkages in the copolymers, so that free tyrosine and a series of glutamic acid peptides containing *C*-tyrosine end groups are formed during hydrolysis. The amount of free tyrosine *(5a)* obtained provides a measure of the number of tyrosine-tyrosine linkages present in the copolymers. The fraction F of tyrosine which was



(5a)

recovered as free tyrosine was related in a simple manner to the run number R and the molar percentage of tyrosine %T in the copolymer (cf. Equation b).

$$\%\ \text{T–T linkages} = F\ \%\ T + \%\ T - (R/2) \qquad (l)$$

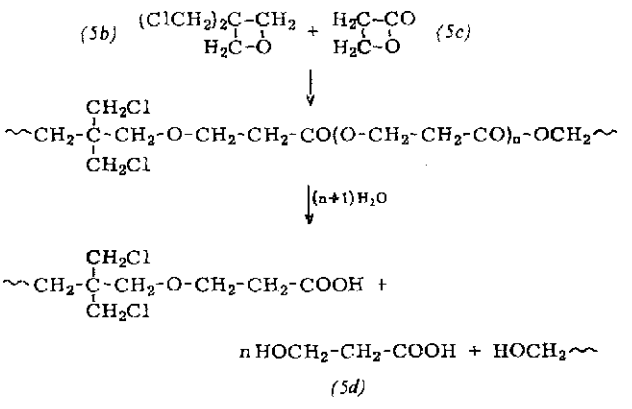
$$F = 1 - [R/(2 \cdot \%\ T)]$$

Kanakkanatt studied the degradation of a supposedly random 5:95 L-tyrosine/L-glutamic acid copolymer. Since R_{random} for such a copolymer would be 9.5, only a very small fraction (F = 0.05) of the tyrosine in the copolymer was expected to be liberated by digestion with chymotrypsin. However, tyrosine was recovered from the hydrolysis mixture in over 90% yield, and dialysis of the hydrolysate afforded high molecular-weight poly-L-glutamic acid in 53% yield. These results indicate that the copolymer was block-polyblend in structure, and did not have the random structure expected. Consequently, current ideas about the copolymerization behavior of *N*-carboxy anhydrides should be modified. Although these materials were formerly assumed to copolymerize randomly, it now appears that some of them do not copolymerize readily.

[16] *A. T. Kanakkanatt*, Ph. D. Thesis, University of Akron, 1963; to be published.

3. Selective Hydrolysis

An approach similar to that taken by *Kanakkanatt* was used to study the sequence distribution in copolymers derived from 3,3-bischloromethyloxacyclobutane *(5b)* plus β-propiolactone *(5c)* [17]. The amount of β-hydroxypropionic acid *(5d)* liberated on hydrolysis of such copolymers provided a measure of the number of ester-ester linkages present and indicated the copolymers to have block-polyblend structures.



(5d)

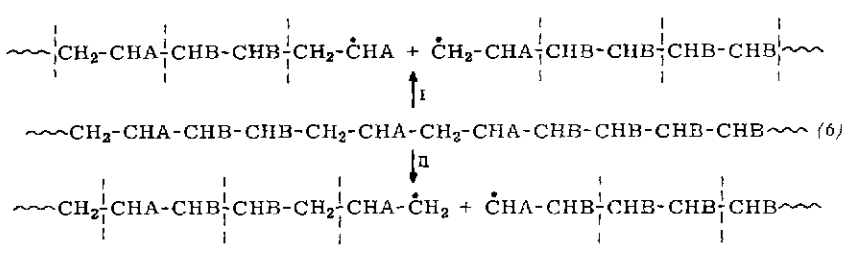
4. Thermal Degradation

Thermal degradation of copolymers often regenerates large amounts of monomer. Such degradations generally occur by depropagation or unzipping mechanisms. Depending on how the depropagation chains are initiated, the regenerated monomers may contain either only original atoms or atoms initially associated with neighboring monomer units as well.

The copolymer chain *(6)* may be considered to have resulted from polymerization of monomers CH_2=CHA and CHB=CHB. Depropagations initiated by homolysis of CHA–CHB bonds (intermonomer or external bonds; Reaction I) regenerate the original monomers, whereas depropagations initiated by homolysis of CH_2–CHA or CHB–CHB bonds (intramonomer or internal

[17] *K. Tada, T. Saegusa*, and *J. Furukawa*, Makromolekulare Chem. *71*, 71 (1964).

bonds; Reaction II) produce the hybrid monomers, CH_2=CHB and CHA=CHB. Similar effects may be observed in the pyrolysis of copolymers derived from CH_2=CHA and CH_2=CHB monomers provided that one of the monomers contains labelled methylene groups.



(6)

Wall [18] has suggested that the quantity $\Theta/2$ be used to represent the fraction of internal monomer bonds broken during a copolymer pyrolysis. Random degradation of a copolymer would then be characterized by $\Theta = 1$, and the yields Y of regenerated and hybrid monomers can be expressed in terms of the copolymer composition, R, and Θ [Equations (m)–(o)].

$$Y_{CH_2\cdot CHB} \quad Y_{CHA\cdot CHB} = R\cdot\Theta/4 \qquad (m)$$

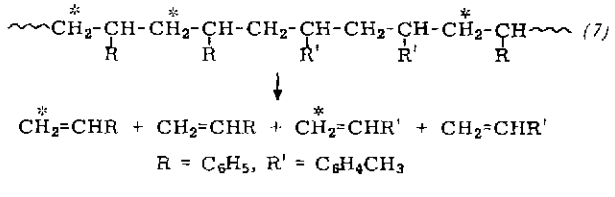
$$Y_{CH_2\cdot CHA} \quad \%\,(CH_2\cdot CHA) = R\cdot\Theta/4 \qquad (n)$$

$$Y_{CHB\cdot CHB} \quad \%\,(CHB\cdot CHB) = R\cdot\Theta/4 \qquad (o)$$

Since few polymers are degraded to give exclusively monomer units, *Wall* attempted to correct for oligomer formation by comparing the yield of regenerated monomer obtained during copolymer degradation with that obtained on pyrolysis of the corresponding homopolymer. This approach is sometimes helpful, but occasionally leads to bizarre results, especially with copolymers derived from dienes.

On pyrolysis of β-deuteriostyrene/methyl methacrylate and styrene/dimethyl fumarate copolymers, *Wall* succeeded in correlating the amounts of products formed with the expected sequence distribution, utilizing values of about 1.0 and 1.25, respectively, for Θ for the two systems. Deuteriostyrene/methyl methacrylate copolymers thus appeared to undergo random degradation, whereas styrene/dimethyl fumarate copolymers exhibited a slight preference for cleavage of internal monomer bonds.

Morthland and *Brown* [19] prepared copolymers *(7)* of [β-^{14}C]-styrene with *m*- and *p*-methylstyrene and pyrolysed films of the copolymers at 300–400 °C. The radioactivity of the styrene recovered was less than that of the original monomer owing to dilution with "hybrid" styrene units formed during the degradation; the regenerated methylstyrene was also radioactive.



(7)

$$\overset{*}{CH_2}{=}CHR + CH_2{=}CHR + \overset{*}{CH_2}{=}CHR' + CH_2{=}CHR'$$

$$R = C_6H_5,\ R' = C_6H_4CH_3$$

Assuming complete regeneration of monomers, the activity a_S of the recovered styrene (S) would be proportional to the fraction of styrene units regenerated in original form, and the activity a_{MeS} of the recovered methylstyrene units (MeS) to the fraction of such units obtained as hybrids.

$$a_S \quad \frac{(\%\ S) - R\ \Theta/4}{(\%\ S)}\ a_S^0 \qquad (p)$$

$$a_{MeS} \quad \frac{R\ \Theta}{4\ (\%\ MeS)}\ a_S^0 \qquad (q)$$

$$\frac{a_S}{a_{MeS}} \quad \frac{(\%\ MeS)}{(\%\ S)}\ \frac{(\%\ S) - R\Theta/4}{R\Theta/4} \qquad (r)$$

a_S^0 = activity of the original styrene monomer.

Brown and *Morthland* predicted a_S/a_{MeS} values for several [β-^{14}C]-styrene/methylstyrene copolymers, assuming the degradations to occur randomly (Θ=1), and assuming the copolymers to have random distributions of monomer units [R = (%S)·(%MeS)/50]. The results given in Table 2 support these assumptions.

Table 2. Pyrolysis of [β-^{14}C-styrene (S)/methylstyreoe (MeS) copolymers [19].

Vapor-phase chromatography and mass speetrometry are powerful tools for the study of copolymer pyrolysis products. *Shibasaki* and *Kambe* [20,21] used vapor-phase chromatography to determine the monomer yields obtained on pyrolysis of styrene/acrylonitrile and styrene/methyl methacrylate copolymers. Their results were interpreted in terms of "boundary-effect" parameters β_A and β_B for the monomers A and B. These parameters are mathematically equivalent to *Wall*'s $\Theta_A/2$ and $\Theta_B/2$ values but have a different physical significance. The parameter β_A, for example, is a function of the probability P_{AB} of obtaining monomer A from ~~BA-radicals relative to that P_{AA} of obtaining A from ~~AA-radicals.

$$\beta_A = \frac{P_{AA} - P_{AB}}{P_{AA}} \qquad (s)$$

Boundary-effect parameters obtained from experimental results by using relationships similar to Equations (m) to (o), for example, were reasonably constant for a given copolymer over a wide range of composition, provided that the experimental conditions were kept constant. The constancy obtained indicates that this approach has pro-

mise as a method for determining sequence distributions. *Shibasaki* used experimentally determined β-values for styrene (S) and acrylonitrile (AN) to determine the percentages S–AN and AN–S linkages present in several commercial styrene/acrylonitrile copolymers.

Pyrolysis plus vapor-phase chromatography in which copolymer decomposition and product analysis are combined in essentially a single operation are likely to be valuable in future studies, especially when only approximate or relative information on sequence-distribution is required. In the first such study, *Bombaugh, Cook*, and *Clampitt* [22] reported that the amount of methanol formed on pyrolysis of ethylene/methyl acrylate copolymers increases with the block character of the copolymers. The relative amounts of methanol and methyl acrylate formed on pyrolysis proved useful for distinguishing copolymers from homopolymer blends. Copolymers indicated by this technique as having block structures were shown to be partly crystalline by differential thermal analysis; random copolymers of the same composition were non-crystalline.

Furthermore, the amount of methyl methacrylate regenerated when ethylene/methyl methacrylate copolymers were pyrolysed decreased as the number of ethylene/methyl methacrylate junctions in the copolymers increased. The results obtained in this study are presented in Figure 1

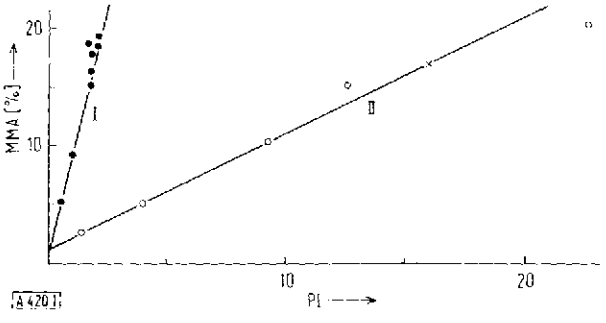

Fig. 1. Pyrolysis and vapor-phase chromatography of ethylene/methyl methacrylate copolymers [22].

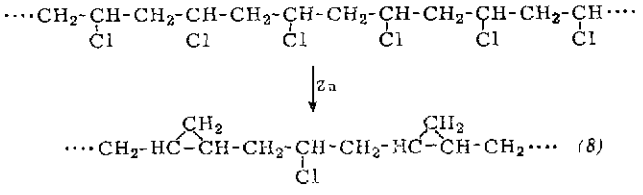
D. Copolymer Alteration Studies

1. Intrasequence Cyclization Reactions

The monomer units in many homopolymers can be made to cyclize. Examples of such reactions are the dechlorination of poly(vinyl chloride) with zinc [23], the self-condensation of methyl vinyl ketone [24], and the cyclizations observed in poly(α-halogenoacrylic acids) or their esters [25–27].

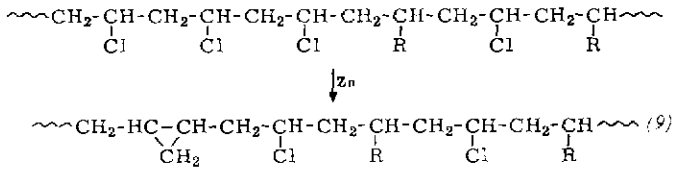
Such cyclizations are usually incomplete because reactive groupings become isolated between cyclized structures as the cyclization proceeds, *e.g.* as in *(8)* from poly(vinyl chloride).

The maximum extent of cyclization has been calculated for several reactions [28,29] assuming the cyclizations to occur randomly; experimental results [23,30] have been in excellent agreement with these calculations.



(8)

In copolymers, cyclizable monomer units may become isolated between comonomer units or between comonomer units and cyclized portions, as in *(9)* from a vinyl chloride copolymer.



(9)

Thus, the maximum extent of cyclization occurring in a copolymer should be less than that possible in the corresponding homopolymer and should be strongly influenced by sequence distribution. This problem has been treated by statistics for vinyl chloride copolymers [31,32] and random methyl vinyl ketone copolymers [29], but only vinyl chloride/vinyl acetate copolymers have been studied experimentally. The results of early studies [33] on such copolymers seemed in reasonable agreement with statistical expectations, but later results indicated that about 87% of the chlorine atoms in such copolymers can be removed with zinc, regardless of copolymer composition [34]. The early results were therefore a reflection only of the relative rates of degradation, rather than a measure of the amounts of isolated vinyl chloride units in the copolymer structure.

2. Intersequence Cyclization Reactions

Cyclization reactions which can occur only at intersequence (run) junctions can provide information about sequence distribution. Lactonization of hydrolysed vinyl acetate/maleic anhydride copolymers *(10)* is a good

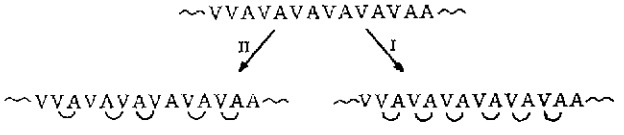
(10)

example. For example, *Minsk*, *Waugh*, and *Kenyon* [35] noted that a hydrolysed 1:1 vinyl acetate/maleic anhydride copolymer could be converted into material having 46.8% of its carboxyl groups lactonized. This indicates that the copolymer had an almost completely alternating structure, in agreement with the copolymerization characteristics of the vinyl acetate/maleic anhydride system.

The possibility, first suggested by *Price*, that the extent of lactone formation in hydrolysed vinyl acetate/acrylate ester copolymers could provide a measure of their sequence distribution, was discussed in one of the early theoretical papers on copolymerization [1].

Two independent research groups [36,37] derived expressions predicting, in terms of monomer reactivity ratios and copolymerization mixture compositions, the extent of lactone formation to be expected for low-conversion copolymers prepared from given monomer mixtures. Both treatments assume that lactone formation occurs randomly in alternating portions of the copolymer chains but only at vinyl alcohol (V) –acrylic acid (A) junctions. Assumptions of this kind should not be made indiscriminately, however. When very stable rings can be formed reversibly, maximum cyclization (Path I) rather than random cyclization (Path II) may occur.



In calculating the amount of lactone formation expected for a given copolymer, *Sakurada* and *Kawashima* [37] considered the behavior of carboxylic acid units in the middle of the ten possible pentads towards alcohol units. Obviously, acid units $\overset{*}{A}$ centered in AA$\overset{*}{A}$AA, AA$\overset{*}{A}$AV, or VA$\overset{*}{A}$AV pentads cannot form lactones. Acid units $\overset{*}{A}$ in VV$\overset{*}{A}$VV, VV$\overset{*}{A}$VA, VV$\overset{*}{A}$AA, or VV$\overset{*}{A}$AV are almost certain to lactonize since they have sole access to at least one neighboring alcohol (V) group. Acid units centered in AA$\overset{*}{A}$VA and in VA$\overset{*}{A}$VA pentads have approximately a 50:50 chance of being converted in to lactone. Finally, all acid units centered in AV$\overset{*}{A}$VA type pentads were assumed to be converted into lactone; although this assumption was recognized to be incorrect (only about 80% can be cyclized), it simplified the treatment, and the error it introduced was fairly small. In order to calculate the expected number of lactone linkages, *Sakurada* and *Kawashima* added up the number of acid groups in a 100-unit copolymer which could be converted into lactone. In our terminology, this number would be given by Equation (t) [cf. Equations (d) to (g)]:

$$\text{Lactone units/100 monomer units} = \%\,A\,(f_{VVAVV} + f_{VVAVA} + f_{VVAAA} + f_{VVAAV} + f_{AVAVA} + {}^1/_2\,f_{AAAVA} + {}^1/_2\,f_{VAAVA}) \qquad (t)$$

% A = the percentage of monomers with acid groups;
f_{VVAVV} = the fraction of A units centered in VVAVV pentads.

Using a conductometric technique developed by *Matsumoto* [38], *Sakurada* and *Kawashima* [37] determined the compositions and lactone contents of a series of hydrolysed vinyl acetate/methyl acrylate copolymers. The copolymers were prepared in various yields from several monomer mixtures. The hydrolysed copolymers lactonized spontaneously in acidic solution.

Graphical methods were used to calculate the average composition and amount of lactone formation expected for each sample; in Table 3, the experimental results are compared with those calculated by *Sakurada* and *Kawashima*.

Table 3. Lactone content of hydrolyzed vinyl acetate/methyl acrylate copolymers [37].

Methyl acrylate in polymerization mixture [mole%]	Yield of copolymer [%]	Acrylic acid in hydrolysed copolymer [mole%]		Lactone content in hydrolysed copolymer [mole%]	
		found	calc.	found	calc.

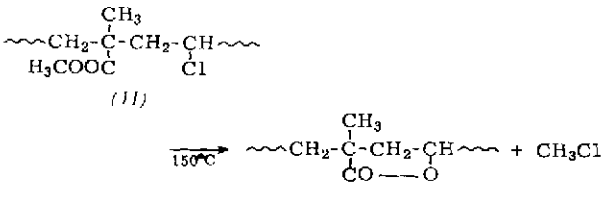
20	37.2	46.4	42.4	22.2	29.3
20	87.0	22.3	23.0	13.4	17.1
50	87.0	53.9	57.0	22.9	21.7

Zutty and *Welch* [39] recently reported another promising example of intersequence cyclization. They observed that vinyl halide/methyl methacrylate copolymers can lactonize on heating, liberating methyl halide and forming rigid foams of good compressive strengths. It was shown that this reaction occurred only intramolecularly



(11)

and presumably only at intersequence junctions [as in *(11)*]. *Smets* [40] called attention to other cyclizations observed in polymers, *e.g.* imide, lactam, α-tetralone,

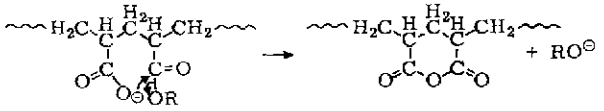
and indane ring formation. It is therefore possible that cyclization techniques may be used in other sequence distribution studies.

Little use has so far been made of cyclizations to characterize tacticity in homopolymers, but acetals based on isotactic and syndiotactic poly(vinyl alcohol) differ in stability [41]. Equilibrium constants for acetal formation differ for various stereoregular poly(vinyl alcohols), and the corresponding acetals are hydrolyzed at different rates [42].

3. Reactivity of Copolymers

Neighboring group effects [43] may play an important role in the reactions of copolymers, and it is possible that the reactivity of monomer units in copolymers will be affected by their immediate or sequential environment. The autocatalysis or autoinhibition noted in the hydrolysis [44,45] or pyrolysis [46] of polymeric esters has been traced to such effects [47-49].

Most studies have involved copolymers in which reactive groups were isolated, so that their environments were easily specified. *Morawetz* and *Zimmering* [50] studied the alkaline hydrolysis and methanolysis of acrylic acid/*p*-nitrophenyl methacrylate copolymers. Ester groups in the copolymers *(12)* were hydrolyzed up to 10^6 times as fast as comparable monomeric models (*p*-nitrophenyltrimethylacetate). Since the rates of hydrolysis of the copolymers increase with the extent of carboxyl ionization, the rapid hydrolysis rates observed were attributed to the participation of neighboring carboxylate groups.



(12)

Results reported somewhat later by *Cooper* [51] supported this suggestion; autocatalysis was observed in the alkaline hydrolysis of poly(ethyl acrylate), but not in the alkaline hydrolysis of a 70:30 butadiene/ethyl acrylate copolymer, where the ester groups are probably almost entirely isolated.

Subsequent work [52] has shown that such neighboring group effects are very sensitive to chain configuration or tacticity. Measurements of hydrolysis rates are often used to characterize tacticity in ester or amide homopolymers [53,54]. Isotactic polymers have been found to be more reactive than syndiotactic or atactic polymers.

In studies involving hydrolysis of ester or amide groups in copolymers, it is very difficult to differentiate between effects due to sequence distribution and those due to tacticity. *Smets* and *Van Humbeeck* [55] recently reported that the rate of alkaline hydrolysis of acrylic acid/ethyl ethacrylate copolymers is directly proportional to the fraction of ester units in the middle of acid-ester-acid triads, but is independent of the fraction of ester units centered in acid-ester-ester triads (Figure 2). However, only about 60% of such ester groups were hydrolyzable;

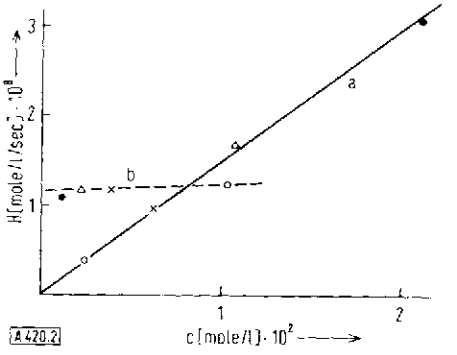


Fig. 2. Rates of hydrolysis of acrylic acid/ethyl ethacrylate copolymers containing a constant concentration of acid-ester-ester triads (0.32×10^{-2} mole/l, Curve a), or of acid-ester-acid triads (0.77×10^{-2} mole/l, Curve b), and varying concentrations of acid-ester-acid and acid-ester-ester triads, respectively.

o: Copolymer with 50 mole% acid groups [55]
x: Copolymer with 67 mole% acid groups
Δ: Copolymer with 77 mole% acid groups
•: Copolymer with 85 mole% acid groups

Abscissa: Concentration c of the acid-ester-acid triads (Curve a) and acid-ester-ester triads (Curve b) [mole/l]$\times10^2$ [55].

Ordinate: Rate of hydrolysis H [mole/l/sec]$\times10^8$.

the resistance of the unreacted ester groups to hydrolysis was explained on stereochemical (tacticity) grounds. In this connection, *Smets* and *von Humbeeck* noted that isotactic acrylic acid/metbyl acrylate copolymers could be hydrolyzed 3–5 times faster and to greater extents than conventional copolymers with the same compositions. Similar results had been obtained earlier with methacrylic acid/methyl methacrylate copolymers.

Arcus [56] observed that alkaline hydrolysis of polymethacrylamide ceased after 70% conversion. He suggested that the hydrolysis-resistant amide groups were stabilized by hydrogen bonding with two neighboring acid groups. *Pinner* [57] tested this suggestion by examining the behavior of methacrylic acid/methacrylami-

de copolymers on hydrolysis. He assumed that the copolymers have random structures, that amide hydrolysis occurs randomly, and that isolated amide groups are unreactive, and thus predicted the extent of hydrolysis. The predictions agreed well with experimental results, as shown in Table 4.

Table 4. Extent of hydrolysis of methacrylic acid/methacrylamide copolymers [57].

Methacrylamide [mole %]		Polymerization [%]	Amide units hydrolysed [% of total]		
polymerization mixture	copolymer		found	calc. [a]	calc. [b]
80	54.5	7	46.3	44	52
60	37.7	12	34.5	34	36
50	30.0	10	31.5	27.7	31
20	8.97	18	13.5	8.9	8.2
10	4.18	35	4.3	4.2	–

[a] Values taken from *Pinner* [57].

[b] Values calculated by *Harwood* (see text).

Although random hydrolysis of amide groups was assumed by *Pinner*, this is not compatible with the autoacceleration observed. It is interesting that the experimental results also agree with those calculated on the assumption that one amide group in each amide sequence becomes resistant to hydrolysis. Such a result would be

~~~acid-amide-amide-amide-acid~~~
↓
~~~acid-acid-amide-amide-acid~~~
↓
~~~acid-acid-amide-acid-acid~~~
↓
no further reaction

obtained if only amide groups having a single acid neighbor hydrolyse rapidly; the proportion of unaccessible amide groups then equals the ratio of amide runs to amide units in the copolymer, or R/[2(% Amide)].

Results predicted from this relationship using reactivity ratios determined by *Pinner* (random structure not assumed), are also included in Table 4.

In a novel chemical study of sequence distribution, *Rodriguez* [58] investigated the photochemical bromination of styrene (S)/fumaronitrile (F) copolymers. The bromination was shown to occur exclusively by substitution at aliphatic (presumably benzylic) sites. Since free-radical bromination is relatively selective and occurs at sites of high electron density [59], styrene units in the middle of SSS type triads should be more easily brominated than those in the middle of triads of the types FSF or FSS. *Rodriguez* noted that the copolymers could be brominated only partially. By studying the kinetics of the bromination, he determined the bromine content of copolymers at infinite reaction time.

For copolymers containing less than 60 mole% styrene, such bromine contents correlate very well with those expected if only styrene units in the middle of SSS type triads can be brominated. However, as shown in Table 5, this correlation does not apply when the copolymers contain more than 60% styrene; not all styrene units in the middle of triads of SSS type can be brominated in such polymers.

Table 5. Bromination of styrene/fumaronitrile copolymers [58].

Styrene [mole %]		Polymerization [%]	Bromine in copolymer		
polymerization mixture	copolymer		found	calc. [a]	calc. [b]
12.5	51.3	2.5	0.125	0.123	0.122
25.0	54.5	3.1	1.30	1.56	1.14
58.2	55.8	13.4	2.05	2.05	1.64
58.2	57.5	12.8	2.59	3.24	2.42
75.0	64.4	10.5	6.35	12.1	5.65
76.9	66.7	1.7	8.35	12.9	6.52
–	72.0	–	11.2	18.3	9.63

[a] Calculated assuming that only styrene units in the middle of triads of the SSS type can be brominated (R = 2% F).

[b] Calculated, assuming that only one bromine atom is incorporated into each styrene run in the copolymers (R = 2% F), where each run has 3 or more styrene units.

Rodriguez obtained a better correlation with the experimental results by assuming that only one bromine atom was introduced into each styrene run of three or more units [60]. Such a correlation might be expected for copolymers of relatively low styrene content if styrene units adjacent to brominated styrene units do not react with bromine. Thus, only one of the two styrene units of SSS type marked with asterisks in the sequence *(13)* should be brominated.

~~~F-S-F-S-S*-S*-S-F-S-F-S-S-F~~~ *(13)*
↓ Br_2
~~~F-S-F-S-S(Br)-S-S-F-S-F-S-S-F~~~

This correlation applies to copolymers containing less than *65 mole% styrene* (see Table 5). As might be expected, the correlation does not hold for copolymers where the average styrene runs are relatively long.

New Findings in the Chemistry of the Lower Oxides of Sulfur [1]

BY PROF. DR. P. W. SCHENK AND DIPL.-CHEM. R. STEUDEL

ANORGANISCH-CHEMISCHES INSTITUT DER TECHNISCHEN UNIVERSITÄT BERLIN (GERMANY)

Dedicated to Professor Erika Cremer on the occasion of her 65th birthday

Important advances have recently been made in the chemistry of the lower oxides of sulfur, both in the preparative sphere and by the application of modern physical methods of investigation. In this paper the knowledge gained to date on the compounds SO, S_2O_2, S_2O, S_2O_3, and the polysulfur oxides is reviewed and critically appraised.

Definition

In the present paper, the term "lower oxides of sulfur" refers to oxides in which the oxidation number z of sulfur is $\leqslant 2$. Thus, although S_2O_3 is discussed briefly, it does not belong to this group, particularly since the sulfur in this compound is evidently present in two very different oxidation states. However, the term does encompass the oxides SO, S_2O_2, S_2O, and the polysulfur oxides of general formula $(S_nO)_x$ in which $n > 2$. According to their properties, compounds containing hydrogen in addition to sulfur and oxygen should be grouped together with the polysulfur oxides. These compounds will be referred to as polysulfane oxides.

A. Sulfur Monoxide SO

I. Stability

The ultraviolet and microwave spectra of SO show that the electronic ground state of this molecule, like that of O_2 and S_2, is a $^3\Sigma$ state [2–5]. Unlike O_2, however, SO is thermodynamically unstable, with regard to both its theoretical dissociation into the elements and its actual dissociation into sulfur and SO_2. The enthalpy of formation at 0 °K of SO from its elements in the standard state is not yet known with certainty, but is approximately zero ($\Delta H_0^0 = +1.6$ kcal/mole [6]).

The enthalpy of its decomposition [Equation (a)] is $\Delta H_0^0 = -36.8$ kcal/mole. This agrees with the fact that

$$SO \rightarrow {}^1/_2\, S_{rhomb.} + {}^1/_2\, SO_2 \qquad (a)$$

SO (like S_2) is present in an appreciable concentration only at high temperatures. The enthalpy of formation of sulfur monoxide is found by investigation of equilibria such as those shown in Equations (b) and (c) [9, 10].

$$2\, SO_2 \rightleftarrows SO + SO_3 \text{ at } 1500\,^\circ C \qquad (b)$$
$$\Delta H_0^0 = +48.6 \text{ kcal/mole of SO}$$

$$SO_2 + {}^1/_2\, S_2 \rightleftarrows 2\, SO \text{ at } 1250\,^\circ C \qquad (c)$$
$$\Delta H_0^0 = +58.3 \text{ kcal/mole of } SO_2$$

A thermodynamic treatment of the Equilibria (c)–(e) is given in the literature [1], but this calculation is based

$${}^1/_2\, S_2 + {}^1/_2\, O_2 \rightleftarrows SO \qquad (d)$$
$$\Delta H_0^0 = -13.8 \text{ kcal/mole of SO}$$

$$SO_2 \rightleftarrows SO + {}^1/_2\, O_2 \qquad (e)$$
$$\Delta H_0^0 = +72.0 \text{ kcal/mole of SO}$$

on earlier values for the enthalpies of the reactions. The results indicate that appreciable dissociation of SO_2 into $S_2 + O_2$ and into $SO + O_2$ occurs only at very high temperatures. Only Equilibrium (d) is entirely displaced to the right at room temperature [1]. More recent calculations [8] have indicated that there is 16% SO present in Equilibrium (c) at 1500 °C and 7.6 mm pressure.

Sulfur monoxide is found to be a true biradical which is extremely reactive and decomposes immediately into sulfur or S_2O and SO_2. In order to detect its occurrence as an intermediate, it is therefore necessary to use mild reaction conditions (vapor phase, low pressure) and sensitive physical methods of measurement (see Table 1).

It is often possible to recognize the formation of SO indirectly by the detection of S_2O as a subsequent product.

Polysulfur oxides and polysulfane oxides	thermolysis	S_2O	[40–42]

[a] Ultraviolet photolysis at 10–100 mm. γ-Photolysis of liquid SO_2 yields sulfur and SO_3 as endproducts [14].

[b] Electric discharges in SO_2 at 0.01–1.0 mm. Particularly high SO concentrations (up to 100 %) are obtained if sulfur is also present in the discharge tube, in accordance with Equilibrium (c) [17].

[c] Thermal dissociation of SO_2 either at a Nernst rod or in a luminous arc in the presence of sulfur vapor.

[d] The decomposition temperatures of the thionyl halides and pseudohalides decrase in the order $SOCl_2 > SOBr_2 > SO(CN)_2 > SO(SCN)_2$ [22].

[e] Detection of S_2O by formation of sulfide with $Ag^{\oplus}$ solution [25].

[f] At temperatures of up to 435 °C and oxygen pressures of 0.1–4.0 mm, pyrites and zinc sulfide yield only SO_2 and metal oxide on roasting. S_2O is obtained in small quantities only from Ag_2S [23].

[g] Detectinn of S_2O by its oltraviolet spectrum.

[h] With pure oxygen at 10–40 mm.

[i] The formation of SO may be quantitative. The gas obtained consists of a stoichiometric (1:1) mixture of S_2O and SO_2 [15, 19, 27, 36, 37, 40].

II. Formation of SO

Ways in which sulfur monoxide is formed as an intermediate are listed in Table 1, together with methods for its detection.

SO is formed from SO_2 in accordance with Equation (f).

$$SO_2 \rightarrow SO + O \qquad (f)$$

This reaction requires about 131 kcal/mole [7], *i.e.* it is effected only by high-energy radiation, an electric discharge, or high temperatures. After the activation process $SO_2 \rightarrow SO_2^*$, Reactions (g) and (h) are possible [11].

$$SO_2^* \rightarrow SO + O \qquad (g)$$

$$SO_2^* + SO_2 \rightarrow SO + SO_3 \qquad (h)$$

SO is formed from $SOCl_2$, $SOBr_2$, $SO(CN)_2$, and $SO(SCN)_2$ by thermal decomposition in accordance with Equation (i), or by dehalogenation of thionyl chloride or bromide with silver or antimony [*e.g.* Equation (k)] at 100–400 °C and about 1 mm pressure.

$$SOX_2 \rightarrow SO + X_2 \qquad (i)$$

$$SOCl_2 + 2\,Ag \rightarrow SO + 2\,AgCl \qquad (k)$$

SO and SO_2 are formed on decomposition of the sulfites (MSO_3) of Sc, Y, La, *etc.* in a current of nitrogen at 300–800 °C:

$$SO_2 + MSO_3 \rightarrow SO + MSO_4 \quad (l)$$

$$2\,SO_2 + 3\,MSO_3 \rightarrow S_2O + 3\,MSO_4 \quad (m)$$

Roasting of sulfides at 700–1000 °C in a current of nitrogen containing oxygen also yields S_2O [26], which is undoubtedly derived from SO formed as an intermediate.

When a mixture of metal oxides is heated with sulfur *in vacuo*, disulfur monoxide is formed *via* sulfur monoxide:

$$2\,CuO + S \rightarrow CuS + SO \quad (n)$$

The disulfur monoxide can be detected as such [35].

High concentration of SO are obtained in mixtures of sulfur vapor and SO_2 at a Nernst rod, in a glow disharge, or in a high-voltage luminous arc at pressures of 0.1 to 100 mm. The SO can be detected as its subsequent reaction product S_2O.

SO is evolved from solid polysulfur oxides and polysulfane oxides on dry distillation *in vacuo*, possibly in accordance with Equation (o).

$$-S-\underset{\underset{O}{\|}}{S}-S- \longrightarrow SO + 2\,S_{rhomb.} \quad (o)$$

III. Properties of SO

In order to investigate the decomposition of SO, the compound was prepared by the following methods: photolysis of SO_2 [12], photolysis of an H_2S/O_2 mixture [27,28], combustion of CS_2 and COS with O_2 or atomic oxygen [3,27,32,34]. The reaction conditions entailed temperatures between 20 and 3000 °C and total pressures of 0.1 to 100 mm. The SO could no longer be detected after about 1–10 msec.

Sulfur monoxide decomposes spontaneously in accordance with Equation (a) to form sulfur and sulfur dioxide. At temperatures below 100 °C and pressures below 100 mm, however, it is possible to detect several intermediate products. Thus, an equimolar mixture of S_2O and SO_2, which was long thought to be SO itself, is formed directly by disproportionation of SO [Equation (p)].

$$3\,SO \rightarrow S_2O + SO_2 \quad (p)$$

Disulfur monoxide S_2O was first prepared as a mixture with SO_2 in 1933 [15,24,36]. On the basis of the methods of synthesis (action of glow discharge on SO_2; dehalogenation of SOX_2) and the composition of the gas mixture (S:O = 1:1), the new oxide was assigned the formula SO. However, molecular-weight determinations in the vapor phase gave a value of about 70 [42] instead of 48, as expected for SO, and the ratio of the original to the final volume on decomposition of the gas into sulfur and SO_2 [Equation (a)] was not 2:1, but 4:3 [18,42,43]. These results could not be reconciled with the simple formula SO and led to the assumption that part of the gas was either irreversibly dimerized ($2\,SO \rightarrow S_2O_2$) or disproportionated in accordance with Equation (p) [42,44].

There was no preparative method available around 1940 to solve this question. Although several publications suggested that the product was probably S_2O_2 [29,45,47a] (cf. the criticism by *Schenk* [46,47b]), *Meschi* and *Myers* later showed by mass spectroscopy that it was in fact an equimolar mixture of S_2O and SO_2 [48].

Thus, data given in the earlier literature on the preparation, isolation, and properties of a stable gas SO or S_2O_2 are erroneous, and actually apply to the S_2O/SO_2 mixture [49].

Owing to the rapidity of the decomposition of sulfur monoxide, practically nothing is known of its chemical properties, apart from a few facts regarding the decomposition itself. The reaction is known to proceed in accordance with the overall Equation (p) because of the constant composition of the gas (S:O = 1:1) [17], the mean molecular weight of about 70 (calculated value = 72) [42], and the fact that the intensities of the S_2O and SO_2 peaks in the mass spectrum are equal [31].

The disproportionation of SO proceeds extremely rapidly, even at pressures under 1 mm; the half-life of the compound is about 2 msec [34]. Attempts to freeze out SO immediately after its formation have so far led only to the S_2O/SO_2 mixture [49a].

IV. Mechanism of the Decomposition of SO

The high rate of decomposition of SO rules out a three-body collision [Equation (p)]. The first step is probably a dimerization:

$$2\,SO \rightarrow (SO)_2 \quad (q)$$

This assumption is supported by the detection of $(SO)_2$. Because of the low heat of reaction involved, this first step can proceed by a two-body collision (see Section B).

In considering possible mechanisms for the rapid decomposition of $(SO)_2$, the Reactions (r) and (s) occasionally proposed can be rejected, since both are endothermic. The only other possibility would be Reaction (t).

$$(SO)_2 \rightarrow S_2O + O \quad (r)$$
$$\Delta H_0^0 = +33.0\ \text{kcal/mole}$$

$$(SO)_2 \rightarrow S_2 + O_2 \quad (s)$$
$$\Delta H_0^0 = +27.5\ \text{kcal/mol}$$

$$(SO)_2 \rightarrow SO_2 + S \quad (t)$$

The enthalpy of Reaction (t) is practically zero. However, even if this reaction were feasible on energetic grounds, it does not lead to an S_2O/SO_2 mixture unless

[45] *A. Yakovleva* and *V. Kondratyev*, Acta physicochim. SSSR *2*, 241 (1940); *Y. Kondratyeva* and *W. Kondratyev*, Zhur. fiz. Khim. *14*, 1528 (1940).

[46] *P. W. Schenk*, Z. physik. Chem. B *52*, 295 (1942).

[47a] *A. V. Jones*, J. chem. Physics *18*, 1263 (1950).

[47b] *P. W. Schenk*, Z. anorg. allg. Chem. *270*, 301 (1952).

[48] *D. J. Meschi* and *R. J. Myers*, J. Amer. chem. Soc. *78*, 6220 (1956).

[49] The publications in question include: [1], [3], [15], [18], [19], [24], [26], [29], [33], [36], [37], [38], [40], [42], [43], [45], [46], [47a], [47h], [56], [59], [61], [62], [64], [65], [91].

[49a] Recently a yellow substance has been isolated at low temperatures which is probably condensed SO (*R. Steudel*, Ph. D. Thesis, Technische Universität Berlin, 1965).

the sulfur reacts quantitatively in accordance with Equation (u). This is however improbable. Reaction (u) is

$$S + SO \rightarrow S_2O \qquad (u)$$
$$\Delta H_0^0 \quad 90.5 \text{ kcal/mole}$$

only conceivable as a wall reaction or as a three-body collision reaction. Thus, Reaction (t) can also be ruled out.

There is therefore no alternative but to assume that $(SO)_2$ in equilibrium with monomeric SO has a sufficiently long life time to enable it to react in accordance with Equation (v).

$$(SO)_2 + SO \rightarrow S_2O + SO_2 \qquad (v)$$
$$\Delta H_0^0 \quad 97.8 \text{ kcal/mole}$$

This reaction is supported by the observation that, if an excess of sulfur vapor is present during the decomposition of sulfur monoxide, the disproportionation is partially suppressed in favor of Reaction (w):

$$(SO)_2 + S_2 \rightarrow 2\,S_2O \qquad (w)$$
$$\Delta H_0^0 = -79.4 \text{ kcal/mole}$$

Here the S_2O is obtained in 85% purity [17].

Comparison of the dissociation energies D_0 [7] (Table 2) shows that the bond strength in sulfur monoxide is greater than that in O_2 and in S_2. Table 2 also includes the interatomic distances r, the force constants k, and the bond orders n calculated from these data.

Table 2. Dissociation energies D_0, bond lengths r, force constants k, and bond orders n in O_2, SO, and S_2.

	D_0 [kcal/mole]	r [Å]	k [mdyne/Å]	n	Ref.
O–O	118.0	1.208	11.39	1.45	[50]
S–O	123.5	1.481	7.94	1.98	[39, 51]
S–S	101.5	1.893	4.99	2.00	[52]

B. Dimeric Sulfur Monoxide $(SO)_2$

It is only recently that a molecule S_2O_2 has been discovered in mass-spectroscopic studies on the reaction of atomic oxygen with sulfur, H_2S, and COS. In addition to the SO band, the mass spectrum of the reaction product also contains peaks due to S_2O, SO_2, and S_2O_2 in intensity ratios of 1:1:0.04. The peak at mass 96 is assigned to S_2O_2 because another peak is observed at mass 98, and these peaks correspond in their intensity ratio to half the natural $^{32}S/^{34}S$ ratio [31].

Although no details are available regarding the nature of the new compound, it can be assumed to be a molecule similar to dimeric O_2, *i.e.* O_4. It is therefore preferable to use the formula $(SO)_2$. Owing to the low enthalpy of formation (from the monomers) of such dimers ($\Delta H_0^0 = -0.13$ kcal/mole for O_4), they can result from two-body collisions [Equation (x)], if the excess energy is stored in internal degrees of freedom.

$$2\,SO \rightleftharpoons (SO)_2 \qquad (x)$$

[50] *H. Siebert*, Z. anorg. allg. Chem. *273*, 170 (1953).

[51] *W. Moffitt*, Proc. Roy. Soc. (London), Sect. A *200*, 409 (1950).

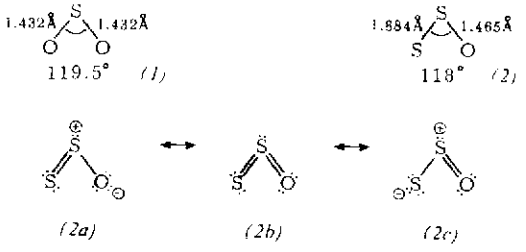
[52] *A. F. Wells*: Structural Inorganic Chemistry. Clarendon Press, Oxford 1962, p. 414.

According to Equilibrium (x), $(SO)_2$ can be expected to appear only in the mass spectrum of nascent SO, since one second is long enough for complete decomposition of the SO [8, 48].

C. Disulfur Monoxide S_2O

I. Stability of S_2O

The microwave spectrum of S_2O *(2)* indicates that this molecule has a structure similar to that of SO_2 *(1)* [53].



(2a) (2b) (2c)

The dipole moments of the bonds were calculated to be $\mu_{SS} = 0.30$ D and $\mu_{SO} = 1.58$ D; the resultant molecular moment is $\mu_{S_2O} = 1.47$ D, the individual moments being opposite in sign [53]. The resonance structure *(2c)* can therefore contribute little to the ground state, and the bond order n of the S–S bond should be close to 2. Using *Moffitt*'s formulae [51], *Giguère* [54] obtained a value of n = 1.80 for the S–O bond.

The standard enthalpy of formation of S_2O is calculated from the sharp predissociation limit to be $\Delta H_0^0 = -22.7$ kcal/mole. The dissociation energy of the S–S bond is $D_0(OS-S) = 90.5$ kcal/mole; that of the S–O bond is $D_0(SS-O) = 112.5$ kcal/mole [7]. Recently, the enthalpy of formation of S_2O was calculated from the appearance potential of $SO^{\oplus}$ from S_2O and from equilibrium measurements on sulfur vapor/SO_2 mixtures to be $\Delta H_0^0 = -9.6$ kcal/mole [8]. Thus, S_2O is thermodynamically stable, although it tends to polymerize.

On heating, disulfur monoxide decomposes into sulfur and SO_2 [Equation (y)]. Gravimetric determination of the sulfur formed is used for quantitative analysis of

$$2\,S_2O \rightarrow 3\,S_{\text{rhomb.}} + SO_2 \qquad (y)$$
$$\Delta H_0^0 = -12.5 \text{ kcal/mole of } S_2O$$

S_2O (polysulfur oxide is formed first, but is completely decomposed by heating above 100 °C) [40].

In the vapor phase disulfur monoxide is stable for a few hours to a few days, but only at pressures of about 1 mm [40]. Its molecular weight corresponds to the simple formula S_2O [42]. Its decomposition is accelerated by heating and proceeds quantitatively in one minute at 180 °C [36]. Free S_2O is not stable in the condensed phase; polysulfur oxides are always formed.

Very sensitive methods are available for qualitative detection of S_2O. When gas containing S_2O is cooled to

[53] *D. J. Meschi* and *R. J. Myers*, J. molecular Spectroscopy *3*, 405 (1959).

[54] *P. A. Giguère*, J. physic. Chem. *64*, 190 (1960).

−195.8 °C (liquid nitrogen), an orange to deep red condensate is obtained. In this way it is possible to detect as little as 5–10% S_2O in a gas mixture; the color deepens with increasing S_2O content. The red condensate undergoes a characteristic color change to yellow on warming to between −150 °C and −100 °C [23,55]; at room temperature a solid, deep yellow residue of polysulfur oxide, together with SO_2, is all that remains. When the quantity of S_2O present is small, the polysulfur oxide is found in the cold trap as a yellow to whitish-yellow ring; this provides a very sensitive indication of the presence of S_2O if a large quantity of gas has been condensed [19].

An unambiguous and extremely sensitive method of detection involves ultraviolet spectroscopy, which permits the detection of S_2O at partial pressures as low as 10^{-3} mm in a cell 100 cm long. The most intense bands lie between 2800 and 3200 Å [15,40,47a,56].

Jones [47a] discovered two absorption regions at 679 and 1165 cm^{-1} in the infrared spectrum of S_2O (which he thought to be S_2O_2). These absorptions can be assigned to the S–S and S–O valence vibrations, respectively. The deformation vibration absorbs at 387 cm^{-1} [53].

II. Formation of S_2O

Disulfur monoxide can be obtained by two routes:

1. From sulfur monoxide, by disproportionation or by treatment with sulfur [Equations (z) and (α), respectively].

$$(SO)_2 + SO \rightarrow S_2O + SO_2 \quad (z)$$

$$(SO)_2 + S_2 \rightarrow 2\,S_2O \quad (\alpha)$$

2. By direct synthesis [Equations (β)–(ε)].

$$SOCl_2 + H_2S \rightarrow S_2O + 2\,HCl \quad (\beta)\ [57]$$

$$SOCl_2 + MS \rightarrow S_2O + MCl_2 \quad (\gamma)\ [58]$$

$$S_2Cl_2 + H_2O \rightarrow S_2O + 2\,HCl \quad (\delta)\ [57]$$

$$S_2Cl_2 + MO \rightarrow S_2O + MCl_2 \quad (\varepsilon)\ [57]$$

In Syntheses (γ) and (ε), the gaseous component (thionyl chloride or disulfur dichloride) is passed at about 1 mm over the heated metal sulfides (*e.g.* Ag_2S or Sb_2S_3) or oxides (*e.g.* Ag_2O, Sb_2O_3, or CdO). Some of the S_2O decomposes on the metal sulfide to form SO_2 [59]. If both of the reactants are gaseous, the gas mixture is allowed to pass rapidly at about 1 mm through a furnace and is subsequently condensed in a cold trap.

Reactions (β), (δ), and (ε) do not proceed to completion. Disulfur monoxide has so far been obtained only together with SO_2, but according to Reaction (γ) at a purity of up to 97% [58].

III. Properties of S_2O

The most striking property of disulfur monoxide is its ease of polymerization, which prevents the establishment of phase equilibria, and hence also the characterization of the compound by its melting or boiling point. The deep red condensate described above (Section C. I) probably owes its color to congealed monomeric S_2O. Like SO_2, which has a similar structure, disulfur monoxide reacts with trimethylamine to form a crystalline donor-acceptor complex *(3)*, which is in equilibrium with its components [60]. The yellow solid *(3)* condenses out

$$(CH_3)_3N: + S_2O \rightleftharpoons (CH_3)_3\overset{\oplus}{N}\text{-}\underset{\ddot{O}:}{\overset{:\ddot{S}:}{\ddot{S}}}\text{=}\ddot{O} \longleftrightarrow (CH_3)_3\overset{\oplus}{N}\text{-}\underset{:\ddot{S}:}{\overset{\ddot{S}}{\ddot{S}}}\text{-}\ddot{O}:^{\ominus}$$

(3)

from a mixture of the components at 1 mm and −30 °C and is stable at this temperature for a few days. It can be sublimed *in vacuo* above −27 °C. Spectroscopic evidence shows the presence of free S_2O in the vapor; the complex therefore represents S_2O which is "stabilized" in the solid state. The complex *(3)* gives an intensely yellow solution in anhydrous inert organic solvents ($CHCl_3$ or CS_2) but decomposes at room temperature to yield sulfur, SO_2, and trimethylamine, owing to the cleavage of the S–S bonds by amine nitrogen [23]. Disulfur monoxide also appears to form a stable solid complex with triphenylphosphine [61]. BF_3 and S_2O (like BF_3 and SO_2) yield only very unstable adducts [60].

Disulfur monoxide does not react with nitrogen [18], and reacts with oxygen only after ignition or at elevated temperatures [37,62]; however, it reacts immediately with chlorine to form $SOCl_2$ and S_2Cl_2 [1].

Water vapor decomposes S_2O with deposition of sulfur and formation of H_2S; however, the decomposition is not so fast as to prevent the detection of S_2O in any reaction in which it is formed together with H_2O [23,24, 28,63].

Introduction of an S_2O/SO_2 mixture into ice-water leads to the formation of sulfur, hydrogen sulfide, and sulfur dioxide, while sulfide, sulfite, and thiosulfate are formed in alkaline solutions. Surprisingly, no polythionic acids can be detected [64].

Potassium iodide solutions are oxidized by S_2O to iodine with simultaneous formation of sulfur and hydrogen sulfide [64].

D. Polysulfur Oxides and Polysulfane Oxides

These names are used to denote products which always contain sulfur and oxygen, but which may also contain hydrogen, depending on their mode of preparation. They are generally mixtures of more or less polymeric compounds, which have not yet been extensively studied.

I. Polysulfur Oxides

"Pure" polysulfur oxides are formed during the polymerization of disulfur monoxide, which is always associated with partial disproportionation ("degradative polymerization") [40].

$$S_2O \rightarrow (S_nO)_x + SO_2 \quad n \geq 2 \qquad (\xi)$$

This decomposition reaction always occurs when the S_2O concentration is raised above a critical value by condensation of the gas at −196 °C and subsequent thawing, by introduction of the gas into organic solvents, or by raising the pressure in the vapor phase.

It may be assumed that polymerization proceeds by opening of the S–S double bonds, and that SO_2 is eliminated when the OS groups of two S_2O molecules come together, *e.g.* as shown in Equation (η).

$$(\eta)$$

However, owing to the polarity of the S_2O molecule, polymerization is also possible with similarly oriented molecules [Equation (ϑ)]. Thus Reaction (ϑ) can yield

$$(\vartheta)$$

polysulfur oxides with the composition S:O = 2:1 (cf. the composition S:O = 3:1 calculated on the basis of Equation (η) [40,42,55]). The remaining S–S double bond in the polysulfur oxides is probably delocalized, as in π-sulfur [67].

A characteristic feature with all polysulfur oxides is the course of their thermal decomposition *in vacuo*, which results in regeneration of disulfur monoxide (maximum 50 mole% S_2O) [40], probably in accordance with Equations ($\varkappa$) and (p).

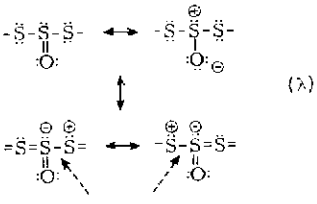
$$(S_nO)_x \rightarrow xSO + (n-1)xS \qquad (\varkappa)$$

In compounds containing sulfur chains, the S atoms are not simply linked by single bonds; instead, the "lone" electron pairs also participate, with occupation of the bonding d-orbitals [52,68–71]. This can be expressed by the formulae *(4a)* and *(4b)*.

(4a) *(4b)*

Sulfur chains, such as those in π-sulfur [67], and S_2 and S_2O, with almost pure S–S double bonds and electron deficiencies [68] at the terminal sulfur atoms, exhibit a strong tendency to polymerize.

In the polysulfur oxides, the uniformity of the bond order along the sulfur chain is upset. The triply bonded sulfur atoms attain a stable configuration with 12 valence electrons which prevents the formation of two double bonds to the two adjacent sulfur atoms. This explains the ease of thermolysis of polysulfur oxides; the reaction probably involves elimination of SO [cf. Scheme (λ)].



$$(\lambda)$$

1. Preparation of Polysulfur Oxides by Freezing out S_2O

On thawing, the red condensate of disulfur monoxide (cf. Section C. I) becomes deep yellow between −150 and −100 °C. This color change is regarded as a sign of polymerization. At room temperature, a solid, yellow polysulfur oxide is obtained, the gas phase then consisting of SO_2 together with some S_2O [23,40]. Thus, condensed S_2O cannot be vaporized without decomposition. After the gas has been pumped off, the stoichiometric composition of the polysulfur oxide is found to be approximately S_3O [42,65]. The substance is amorphous to X-rays [1], and its molecular weight is unknown. Only a small portion dissolves in carbon disulfide, giving a deep yellow solution [1,72].

Murthy [65] claims that warming condensed S_2O to −30 °C leads to pure, orange-red S_2O, if the sulfur dioxide which is still present from the preparation of the S_2O is removed by purging with nitrogen. However, this color could not be reproduced at −30 °C [23,55]. It is doubtful whether the SO_2 could be completely removed from the yellow polymer in this way. The composition S:O = 2:1 is probably merely fortuitous [66] and furnishes no proof of the presence of pure disulfur monoxide.

2. Preparation of Polysulfur Oxides by Dissolution of S_2O

When a mixture of S_2O and SO_2 is led into cooled (−20 °C) chloroform or methyl phenyl ether, the S_2O immediately polymerizes. The yellow solution can be freed from SO_2 by purging with nitrogen. The dissolved material has a molecular weight of 210–380 or higher and a composition S:O = 2.2:1–5.6:1; it is therefore a polysulfur oxide [42,44,73].

Nevertheless *Murthy* described the reactions of these solutions with water and piperidine as "reactions of S_2O" [74,75].

Solutions of polysulfur oxides oxidize hydrogen iodide stoichiometrically to iodine, in accordance with Equation (μ). This provides a convenient titrimetric method

$$(S_nO)_x + 2xHI \rightarrow nxS + xI_2 + xH_2O \qquad (\mu)$$

for the volumetric determination of the oxidation state [73 76].

3. *Preparation of Polysulfur Oxides by Compression of Gaseous S_2O*

Gaseous disulfur monoxide is stable for a few hours to a few days, but only at about 1 mm [40]; on compression of the gas to about 40 mm, polysulfur oxide separates out as an aerosol and as a film on the wall of the vessel [36]. However, gaseous S_2O can be handled at higher pressures when diluted with nitrogen or sulfur dioxide, provided its partial pressure remains low [1].

II. Polysulfane Oxides (Polysulfur Oxides Containing Hydrogen)

1. *Preparation of Polysulfane Oxides from SO_2 and H_2S*

H_2S and SO_2 react at room temperature and below in the presence of traces of water to form polysulfane oxides. When the moist gases are mixed, the polysulfane oxide is deposited on the walls of the vessel [64]; if the gases are led into cooled organic solvents, they form solutions of polysulfane oxides, from which the latter can be precipitated [73].

The most important of these polymers is "Wackenroder's sulfur"; it is precipitated when a vigorous current of H_2S is led into ice-water saturated with SO_2. After filtration, washing, and drying at 10^{-2} mm and 0 °C, the approximate composition of the yellow, plastic product is $S:O:H \approx 5:1:1.1$ [41,63]. The substance can be stored at −20 °C for several days without decomposing. On thermolysis *in vacuo*, SO_2, S_2O, and H_2O are liberated, possibly with some H_2S, leaving a residue of sulfur. It is not improbable that some of the hydrogen here is bound in the form of occluded water [63,77].

The yellow solutions obtained by dissolving H_2S and SO_2 in organic solvents tend to become turbid and to fluorescence, and must be stabilized by drying over phosphorus pentoxide, since they otherwise decompose to form SO_2 and sulfur. After removal of residual synthesis gases with a filter pump, the composition was $S:O = 4:1-8:1$. The molecular weight of one product was found to be 360 [73]. As expected, the dissolved polysulfane oxide disproportionates on heating to form sulfur and SO_2 [73]. The yellow solutions oxidize hydrazoic acid to nitrogen and liberate an equivalent amount of iodine from a solution of hydrogen iodide in formic acid [73].

The reaction of H_2S and SO_2 in CCl_4 at −10 to −15 °C yields a polysulfane oxide with a particularly high oxygen content. This product is obtained as an intensely yellow precipitate with a composition corresponding closely to the formula $H(S_2O)_nSH$; this formula can be derived from Equations (ν) and (π) [78].

[76] *H. Stamm* and *K.-D. Wiebusch*, Naturwissenschaften *32*, 42 (1944).

[77] *W. Kretschmer*, Diploma Thesis, Freie Universität Berlin, 1962.

[78] *R. Ludwig*, Diploma Thesis, Technische Universität Berlin, 1965.

In our opinion, the initial product of the Wackenroder reaction is (as has long been thought [79]) thiosulfurous acid, which exists in equilibrium with H_2S and H_2SO_3 [24,41,64,80]. The unsymmetrical form of thiosulfurous

$$H_2S + H_2SO_3 \rightleftarrows H_2S_2O_2 + H_2O \qquad (\nu)$$

acid, HO–SO–SH, is initially formed and slowly rearranges to the symmetrical form HO–SS–OH. This then condenses with sulfurous acid to form tetrathionic acid *(5)*, which is the first and principal product of the Wackenroder reaction [81].

$$HO{-}SS{-}OH + 2\ H_2SO_3 \rightarrow \underset{(5)}{H_2S_4O_6} + 2\ H_2O \qquad (\xi)$$

When H_2S is led rapidly into the SO_2 solution, some of the unsymmetrical thiosulfurous acid condenses to form the deep yellow polysulfane oxide, which precipitates out (Wackenroder's sulfur) [see Scheme π].

$$HSH + HO{-}\overset{\overset{O}{\|}}{S}{-}OH + HSH + HO{-}\overset{\overset{O}{\|}}{S}{-}OH \qquad (\pi)$$

$$\rightarrow HS{-}\overset{\overset{O}{\|}}{S}{-}OH + HS{-}\overset{\overset{O}{\|}}{S}{-}OH + 2\ H_2O$$

$$\xrightarrow{H_2S} HS{-}\overset{\overset{O}{\|}}{S}{-}S{-}\overset{\overset{O}{\|}}{S}{-}SH + 2\ H_2O$$

The ideal composition of polysulfane oxide, $H(S_2O)_nSH$, is never quite attained because of the sensitivity of the substance towards water. The oxygen content of polysulfane oxide increases as the quantity of water present decreases. The fluffy powder is stable for several days at −20 °C. No monomeric S_2O can be detected during the Wackenroder reaction [24].

2. *Preparation of Polysulfane Oxides from $SOCl_2$ and H_2S*

Liquid thionyl chloride reacts with H_2S at room temperature in accordance with Scheme *(ρ)*.

$$HSH + Cl{-}\overset{\overset{O}{\|}}{S}{-}Cl + HSH + Cl{-}\overset{\overset{O}{\|}}{S}{-}Cl + HSH \qquad (\rho)$$

$$\xrightarrow[-4\ HCl]{} H{-}S{-}\overset{\overset{O}{\|}}{S}{-}S{-}\overset{\overset{O}{\|}}{S}{-}S{-}H$$

The yellow, plastic reaction product was formerly thought to be sulfur, but has been identified as a polysulfane oxide by thermolysis *in vacuo* and spectroscopic detection of the S_2O formed [57]. If H_2S is passed into a solution of $SOCl_2$ in absolute ether at −10 °C, polysulfane oxide again precipitates out as a light powder. After drying *in vacuo*, the composition of a product obtained in this manner was found to correspond approximately to the formula $H_2S_{14}O_5$. Thus the terminal atoms of the chains are hydrogen, and not chlorine [78].

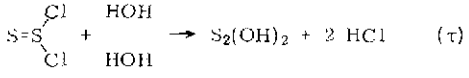
[81] *R. Krämer*, Ph. D. Thesis, Technische Universität Berlin, 1964.

3. Preparation of Polysulfane Oxides from S_2Cl_2 and H_2O

When S_2Cl_2, preferably dissolved in CCl_4, is hydrolysed with ice-water, polysulfane oxide is formed, probably *via* thiosulfurous acid [Equation (σ)], as in the Wackenroder reaction [57,63].

$$S_2Cl_2 + 2\ H_2O \rightarrow H_2S_2O_2 + 2\ HCl \qquad (\sigma)$$

The analogy with the Wackenroder reaction would be particularly striking if the disulfur dichloride could react as thiothionyl chloride *(6)*, as shown in Equation (τ).



$$(\tau)$$

(6)

The syntheses of S_2O from S_2Cl_2 vapor suggest that the isomer *(6)* does perhaps exist in equilibrium with the dichlorodisulfane Cl–S–S–Cl detected. This is also supported by other reactions of S_2Cl_2 [82]. In the case of S_2F_2, both isomers are actually obtained and have been characterized by their infrared and microwave spectra [83,84].

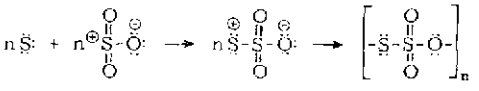
E. Disulfur Trioxide S_2O_3

I. Formation of S_2O_3

Disulfur trioxide is a blue-green solid formed in a vigorous reaction when sulfur is introduced into liquid sulfur trioxide. After a few hours, the product can be separated from the excess SO_3 by decantation; residual traces of SO_3 are removed in a current of CO_2 [85] or with a filter pump, care being taken to exclude moisture [77].

II. Constitution of S_2O_3

Disulfur trioxide is thought to exist as a polymeric substance *(7)* [85] formed by insertion of sulfur into the electron deficiencies of the Lewis acid SO_3.



(7)

The sulfur acts here as an electron donor and can consequently be displaced by stronger donors. For example, S_2O_3 is decomposed by pyridine, with formation of the adduct pyridine·SO_3 and sulfur; the sulfur is extremely reactive [85]. This reaction and the discovery that S_2O_3 synthesized from radioactive elemental sulfur and SO_3 yields only inactive SO_3 on degradation support the structural formula *(7)* [86].

III. Properties of S_2O_3

Disulfur trioxide gradually assumes a light brown color and is stable only at −80 °C under CO_2, and even then for only a few hours [85]. It is insoluble in liquid sulfur trioxide, but dissolves in fuming sulfuric acid to give a deep blue solution. Similar blue solutions are also obtained on direct addition of sulfur to fuming sulfuric acid.

Depending on the SO_3 content of these solutions, the ESR spectrum shows the presence of one of two different free sulfur radicals, namely a blue compound at high SO_3 contents and a brown substance at low SO_3 contents [87]. It has been concluded from comparison of the visible, ultraviolet, and ESR spectra of the solutions of sulfur in oleum that the blue paramagnetic substance is monomeric S_2O_3, which slowly polymerizes to colorless $(S_2O_3)_x$. The solutions do become colorless on standing, but the blue color can be regenerated by gentle warming [88].

The brown radical present in solutions with low SO_3 contents is thought to be similar to the radicals present in molten sulfur [89], being a stage intermediate between S_2O_3 and the sulfur precipitated on dilution of sulfur-oleum solutions.

The only products of hydrolysis of S_2O_3, apart from sulfur, are H_2SO_4 and H_2SO_3 in a ratio of about 5:1. The sulfurous acid results from reduction of SO_3 by elemental sulfur [85].

Decomposition of solid disulfur trioxide at temperatures of up to 150 °C yields sulfur, SO_2, and SO_3 [85]. It was thought earlier that SO was formed as an intermediate, and decomposed in accordance with Equation (a) [90]. However, attempts to detect SO by ultraviolet spectroscopy as its derivative S_2O yielded no experimental evidence for the intermediate formation of lower oxides of sulfur [24]. The earlier results were confirmed recently after evidence had meanwhile been given to the contrary [91]; the S_2O spectrum was not observed, and no polymeric sulfur oxide residue was found on evaporation of the condensed gases [77].

It may therefore be assumed that the decomposition proceeds according to Equation (φ), and that the extremely reactive sulfur produced reduces some of the S_2O_3 to SO_2 [Reaction (χ)].

$$S_2O_3 \rightarrow S + SO_3 \qquad (\varphi)$$

$$2\ S_2O_3 \rightarrow S + 3\ SO_2 \qquad (\chi)$$

The Prostaglandins

BY DR. B. SAMUELSSON

DEPARTMENT OF CHEMISTRY, KAROLINSKA INSTITUTET STOCKHOLM (SWEDEN)

Prostaglandins occur in many animal species and tissues. They are C_{20}-carboxylic acids containing one five-membered ring, one keto group, two or three hydroxy groups, and one to three C=C double bonds. Their structures were elucidated by chemical, radiochemical, and physical methods in combination with gas chromatography and mass spectrometry. The prostaglandins are biosynthesized from essential fatty acids. By their action smooth muscles are stimulated and lipid metabolism is affected.

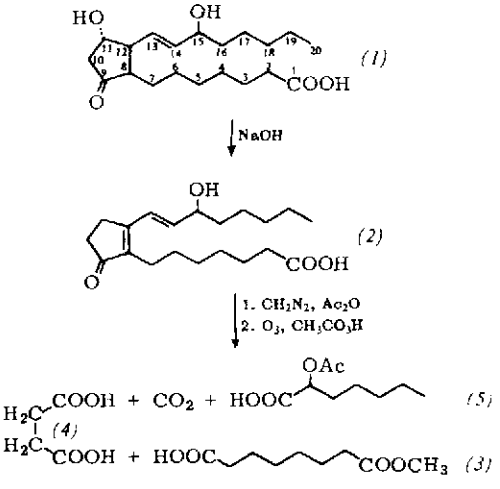
Introduction

In 1933–1934 *Goldblatt* [1,2] and *von Euler* [3] independently demonstrated the presence of vasodepressor and smooth muscle stimulating material in extracts of human seminal plasma and of vesicular glands of sheep. *Von Euler* also showed that the biological activity was due to lipid soluble material with acidic properties, and named the factor prostaglandin [4–7].

In 1957, *Bergström* and *Sjövall* reported the isolation of two biologically active crystalline compounds, PGE_1 and $PGF_{1\alpha}$, from vesicular gland of sheep [8–10]. PGE_1 was a very potent vasodepressor and smooth muscle stimulant, whereas $PGF_{1\alpha}$ only possessed smooth muscle stimulating activity. Later, additional compounds having similar biological activity, *i.e.* PGE_2 and PGE_3, were isolated from the same tissue [11]. However, investigations which will be described in more detail below have demonstrated that the prostaglandins are more widely distributed in animal tissues. These findings and the recent experiments demonstrating that the prostaglandins are biosynthesized from essential fatty acids have provided a new impetus for studies of the physiological role of the prostaglandins.

I. Chemistry

It was demonstrated with different physical methods that PGE_1 is a C_{20}-carhoxylic acid ($C_{20}H_{34}O_5$) containing two hydroxy groups, one keto group in a five-membered ring and one *trans*-double bond. Treatment of PGE_1 *(1)* with alkali gave a compound (PGE_1–278) *(2)* with λ_{max} at 278 mμ [12,13]. On oxidative ozonolysis, the acetylated methyl ester of this derivative gave monomethyl suberate *(3)*, succinic acid *(4)*, and α-acetoxyheptanoic acid *(5)*, *i.e.* all but one of the carbon atoms of PGE_1 – 278 were accounted for. The degradation products were



separated by gas-liquid chromatography and identified by mass spectrometry. The isolation of succinic acid, which must originate in the ring, showed that two vicinal methylene groups were present in the five-membered ring and that, accordingly, the three carbon atoms carrying the side chains and the keto group must be adjacent. Furthermore, the isolation of monomethyl suberate, produced by oxidation of the vicinal diketone originally formed, indicated that the carboxyl side chain must be attached to the carbon atom that is in α-position relative to the keto group. The proposed structure of PGE_1–278 was also supported by the infrared data.

Another derivative was prepared by treatment of hydrogenated PGE_1 *(6)* with 0.5 N NaOH at 100 °C. This compound, PGE_1–237 *(7)* [λ_{max} = 237 mμ in ethanol], was degraded by oxidative ozonolysis after conversion to the methyl ester and acetate. Only two products were formed, *i.e.* monomethyl suberate *(3)* and 7-acetoxy-4-oxododecanoic acid *(8)*. The structure of the latter compound was deduced from mass-spectrometric and gas-

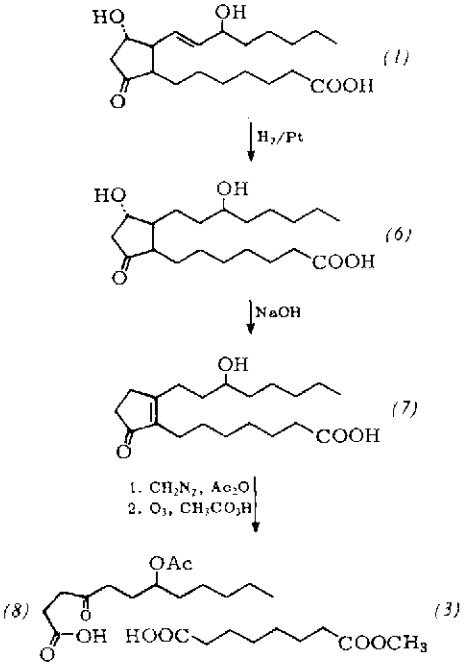
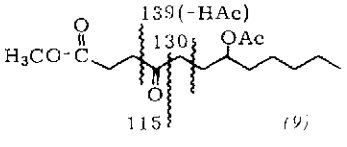
chromatographic data. In the mass spectrum of methyl 7-acetoxy-4-oxododecanoate *(9)* no molecular ion could be observed but peaks at m/e=226 (elimination of acetic acid) and at m/e=195, (subsequent loss of a methoxy



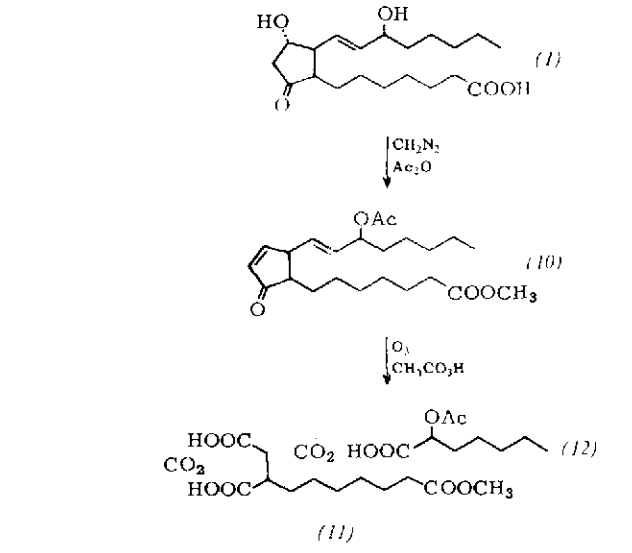
group) are seen. The position of the keto group in *(9)* was determined from the peaks at m/e=115, 139 and 130. The ion at m/e=130 is formed by cleavage of the

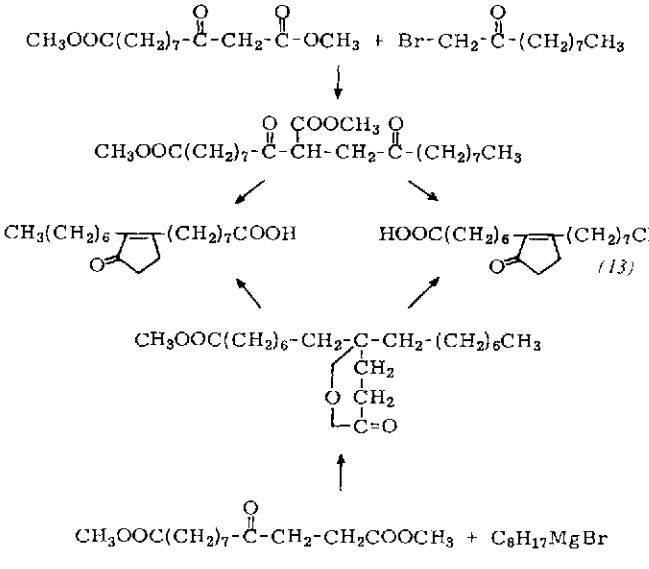


C(5)–C(6) bond and transfer of a hydrogen atom from C–7 to the oxygen of the keto group. The presence of the acetoxy group at C–7 was indicated by a peak at m/e=155, probably formed by cleavage of *(9)* between C–7 and C–8 and elimination of acetic acid. All of the 20 carbon atoms of the prostaglandin molecule were thus identified.

The formation of the two degradation products *(3)* and *(8)* has been visualized as follows: Initial attack on the tetrasubstituted double bond in *(7)* results in formation of two keto groups, one of which is vicinal to the original one. Oxidative cleavage of the C–C bond between the vicinal keto groups by peracetic acid affords the two carboxyl groups of monomethyl suberate *(3)* and of 7-acetoxy-4-oxododecanoic acid *(8)*. The ultraviolet absorption of PGE_1–237 *(7)* was in accordance with the values reported for a number of trisubstituted α,β-unsaturated cyclopentenones and the tetrasubstitution of the double bond was confirmed by the absence of signals for olefinic protons in the NMR spectrum of *(7)*. Treatment of PGE_1 *(1)* with acetic anhydride yielded a derivative *(10)* with λ_{max} = 218 mμ in ethanol. Oxidative ozonolysis of the methyl ester acetate of this compound gave 1,2,8-octanetricarboxylic acid *(11)*, α-acetoxyheptanoic acid *(12)*, and CO_2. The formation of these degradation products provided firm support for the proposed structure of PGE_1–218 *(10)*.

The physical data of the derivatives of PGE_1 [PGE_1–278 *(2)*, PGE_1–237 *(7)*, and PGE_1–218 *(10)*] and the identification of their degradation products rigorously established their structures. From this work followed the structures of the side chains of PGE_1 *(1)* as well as their positions on the ring and the position of the keto group. The position of the hydroxy group was derived from indirect evidence. Acylation experiments as well as NMR data ruled out that the hydroxy group was attached to a tertiary carbon atom and the remaining two positions could easily be differentiated. A hydroxy group at the secondary carbon atom α to the keto group was excluded by the finding that neither PGE_1 *(1)* nor $PGF_{1\alpha}$ or $PGF_{1\beta}$ (see Section II) were oxidized by periodate or lead tetraacetate. However, the presence of the hydroxy group at the secondary carbon atom β to the keto group was in agreement with the facile elimination of water with formation of a monosubstituted α,β-unsaturated ketone on treatment of PGE_1 *(1)* with acetic anhydride. Finally, the carbon skeleton of PGE_1 was established by comparing the derivative *(13)* with a synthetic specimen prepared by two different procedures [14]. The structure of PGE_1 was confirmed by a three-dimensional single crystal X-ray analysis of the tris-*p*-bromobenzoate of the





[14] *B. Samuelsson* and *G. Ställberg*, Acta chem. scand. *17*, 810 (1963).

methyl ester of $PGF_{1\beta}$ [15–17]. In addition, this investigation provided the stereochemical features of the molecule which are shown in Figure 1.

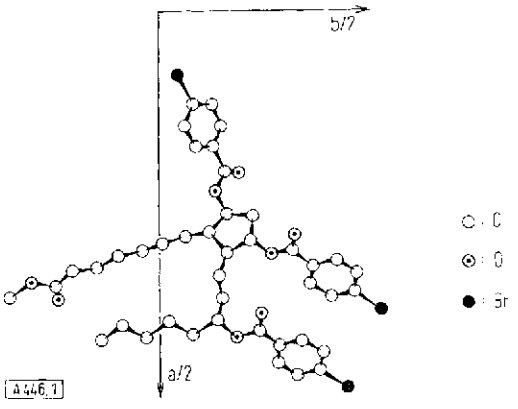


Fig. 1. Molecular model of the methyl ester of prostaglandin $PGF_{1\beta}$ (in the form of its tris-*p*-bromobenzoate) as derived from X-ray analysis.

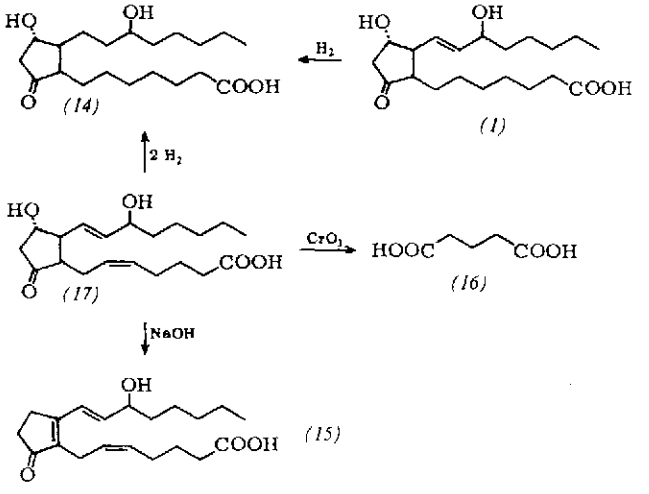
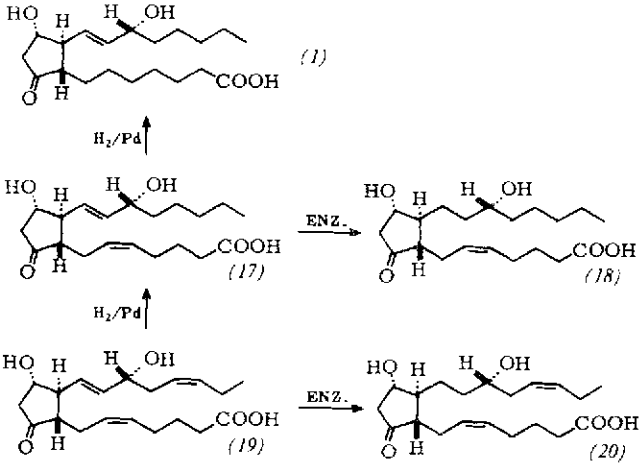
The structures of PGE_2 *(17)* and PGE_3 *(19)* were partly elucidated by mass spectrometry, which showed that the molecular weight of PGE_3 was two units less than that of PGE_2 and four units less than that of PGE_1 [11]. That the parent structure was the same for all three compounds followed from their conversion by catalytic reduction into the same derivative *(14)* as judged by mass-spectrometric analysis. Since all three compounds were



transformed into chromophores *(15)* with the same λ_{max} on treatment with alkali, it was evident that they all had the Δ^{13}-double bond demonstrated for PGE_1 *(1)*. The location of the additional double bond of PGE_2 *(17)* in the carboxyl side chain was indicated by mass spectrometry and its position was established by the identification of glutaric acid *(16)* as a product of chromic acid oxidation. Using the same methods it could also be established that PGE_3 *(19)* only differed from PGE_2 *(17)* by having an additional double bond.

The final elucidation of the structure of PGE_3 was achieved by NMR spectroscopy [18]. The NMR spectrum of PGE_3 showed six olefinic protons between 4.25 and 4.8 τ. Two of these protons appeared at low frequencies (4.25 to 4.5 τ) and in the same region as the two olefinic protons in PGE_1 due to the deshielding by the allylic hydroxy group at C–15. The other four olefinic protons in PGE_3 *(19)* had the same chemical shift as the olefinic protons in the carboxyl side chain of PGE_2 *(17)*. Of particular interest for the structure determination was the absorption due to the protons of the methyl group in PGE_3, appearing as a clear triplet at 9.04 τ. The spin-spin splitting and chemical shift of the methyl protons in PGE_3 demonstrated that the double bond in the terminal pentyl group was located between C–17 and C–18.

That the stereochemical features of PGE_1 *(1)*, PGE_2 *(17)* and PGE_3 *(19)* are identical was recently demonstrated through conversions of PGE_2 into PGE_1 and of PGE_3 into PGE_2 by selective catalytic hydrogenation of the Δ^{17}-and Δ^{5}-double bonds, respectively [19, 20].



With regard to the stereochemistry of the double bonds, it was observed that PGE_1 *(1)* exhibits infrared absorption at 10.3 μ, demonstrating that the Δ^{13}-double bond has the *trans* configuration. PGE_2 *(17)* and PGE_3 *(19)* also show absorptions at this wavelength but it could not be decided wether the absorption was due to the Δ^{5}-and Δ^{17}-double bonds in addition to the Δ^{13}-double bond. This question has recently been solved by selective reduction of the Δ^{13}-double bond of PGE_2 and PGE_3 by enzymes from lung tissue [21]. The reduction products *(18)* and *(20)* do not show any absorption at 10.3 μ, demonstrating that the Δ^{5}-and the Δ^{17}-double bonds of PGE_2 and PGE_3 have the *cis* configuration.

Chemical reduction of PGE_1 *(1)* results in formation of two trihydroxy acids epimeric at C–9. These have been designated $PGF_{1\alpha}$ and $PGF_{1\beta}$ [15]. Similarly, PGE_2 gives $PGF_{2\alpha}$ and $PGF_{2\beta}$, and PGE_3 gives $PGF_{3\alpha}$ and $PGF_{3\beta}$ [11]. Only the PGF compounds with the hydroxy group at C–9 in α-position occur naturally. Recently, a systematic nomenclature based on the trivial name prostanoic acid for the parent C_{20}-acid has been introduced (see Table 1).

Table 1. Systematic names of prostaglandins.

(1)	PGE_1	11α,15-Dihydroxy-9-oxo-13-prostenoic acid
(17)	PGE_2	11α,15-Dihydroxy-9-oxo-5,13-prostadienoic acid
(19)	PGE_3	11α,15-Dihydroxy-9-oxo-5,13,17-prostatrienoic acid
	$PGF_{1\alpha}$	9α,11α,15-Trihydroxy-13-prostenoic acid
	$PGF_{2\alpha}$	9α,11α,15-Trihydroxy-5,13-prostadienoic acid
	$PGF_{3\alpha}$	9α,11α,15-Trihydroxy-5,13,17-prostatrienoic acid

II. Occurrence

PGE_1 and $PGF_{1\alpha}$ were isolated in pure form for the first time from the vesicular gland of sheep in 1957 [8–10]. A few years later two additional compounds, *i.e.* PGE_2 and PGE_3 were isolated from the same source [11]. Seminal plasma of the sheep has been shown to contain PGE_1 and one other smooth muscle stimulating component [22]. No reinvestigation has been performed after PGE_2 and PGE_3 were recognized.

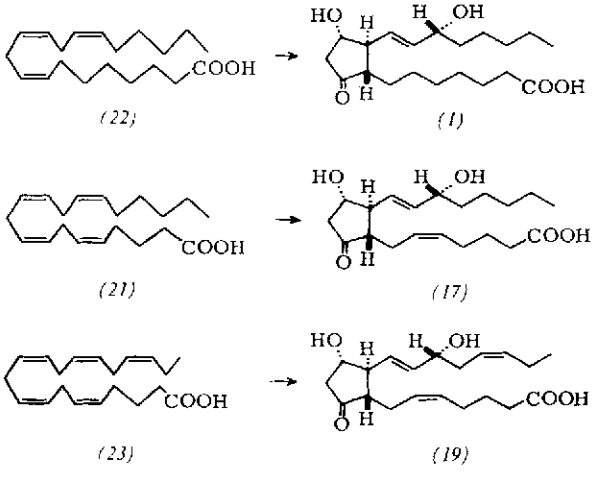
Human seminal plasma, which has been investigated in more detail recently, was shown to contain five different prostaglandins, *viz.* PGE_1, PGE_2, PGE_3, $PGF_{1\alpha}$, and $PGF_{2\alpha}$ [23]. The concentrations of these compounds have been determined in single samples of seminal plasma by a method which was recently developed [24]: After group separation of the prostaglandins into PGE and PGF compounds by chromatography on silicic acid, the PGE group was further separated by thin-layer chromatography using silica gel impregnated with silver nitrate. The PGE compounds were eluted from the plates and determined quantitatively by measuring the absorption at 278 mμ, which develops on treatment of the eluates with alkali. The chromophore with λ_{max} at 278 mμ is due to a dienone formed by dehydration of the β-ketol system and isomerization of the introduced double bond. The PGF compounds, $PGF_{1\alpha}$ and $PGF_{2\alpha}$, were converted into their methyl esters and treated with hexamethyldisilazane in tetrahydrofuran with trimethylchlorosilane as catalyst. The resulting trimethylsilyl ether derivatives were separated and determined quantitatively by gas-liquid chromatography. The concentrations of prostaglandins in seminal plasma of normal males were: PGE_1: 25 μg/ml, PGE_2: 23 μg/ml, PGE_3: 6 μg/ml, $PGF_{1\alpha}$: 3 μg/ml and $PGF_{2\alpha}$: 4 μg/ml.

Recent experiments demonstrated that the prostaglandins are present in a variety of tissues and species. $PGF_{2\alpha}$ was thus first isolated from lung tissue of sheep and pig [25] and has more recently also been demonstrated in lungs of guineapig, monkey, and man [26]. The concentration of $PGF_{2\alpha}$ in lung tissue of sheep was determined to be about 0.5 μg/g tissue (fresh weight) by use of isotope dilution [27]. PGE_2 has recently also been identified in sheep lung [27] and $PGF_{3\alpha}$ in bovine lung [28]. In calf thymus only PGE_1 could be detected [29].

The presence of smooth muscle stimulating material in extracts of iris and brain tissue from various species has been reported [30,31]. Since the properties of these substances to some extent agreed with those of the prostaglandins, the material was further investigated. Sheep iris contained several lipid soluble and smooth muscle stimulating compounds which could be separated by chromatography on silicic acid. One of these components was identified as $PGF_{2\alpha}$ [32]. The same compound could be identified in extracts of bovine brain and was present in a concentration of about 0.3 μg/g tissue (fresh weight) [33]. PGE_2 and $PGF_{2\alpha}$ have also been detected in menstrual fluid [34].

III. Biosynthesis

It was recently demonstrated [35,36] that [^{3}H]-arachidonic acid *(21)* [all-*cis*-eicosa-5,8,11,14-tetraeonic acid] is converted into labelled PGE_2 *(17)* by homogenates of the vesicular gland of sheep and it was also predicted that homo-γ-linolenic acid *(22)* [all-*cis*-8,11,14-trienoic acid] and all-*cis*-eicosa-5,8,11,14,17-pentaenoic acid *(23)* would be precursors of PGE_1 and PGE_3, respectively. The conversion of homo-γ-linolenic acid *(22)* into PGE_1



(1) has been demonstrated experimentally with the ^{14}C-labelled precursor [37,38]. It could also be shown that the net formation of PGE_3 *(19)* increased after addition of all-*cis*-eicosa-5,8,11,14,17-pentaenoic acid *(23)* [37]. This conversion has been confirmed with [14c]-

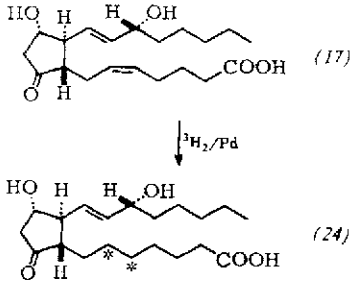
pentaenoic acid *(23)*, prepared biosynthetically in *Euglena gracilis* [39].

The specificity of the enzyme system for the substrate in the formation of prostaglandin-type compounds has been studied with precursors of different chain lengths. It was thus demonstrated that [4-^{14}C]-all-*cis*-docosa-10,13,16,-trienoic acid is converted into a product with properties expected for "bishomo"-PGE_1 [37] and that nor-PGE_1 and nor-PGE_2 were formed from all-*cis*-nonadeca-7,10,13-trienoic acid and all-*cis*-nonadeca-4,7,10,13-tetraenoic acid, respectively [38]. However, a C_{18}-trienoic acid, *i.e.*, all-*cis*-octadeca-6,9,12-trienoic acid, did not appear to be a substrate for this enzyme system.

IV. Metabolism

[5,6-$^3H_2$]-prostaglandin E_1 *(24)* with high specific activity has recently been prepared by selective reduction of the Δ^5-double bond of PGE_2 *(17)* with carrier-free tritium gas using palladium as catalyst [19]. When *(24)* was administered to rats, about 50% of the tritium was recovered in the urine and about 10% in feces within 20 hours. Administration of labelled PGE_1 to a rat with cannulated bile duct gave similar recoveries in the urine and the bile, respectively [19].

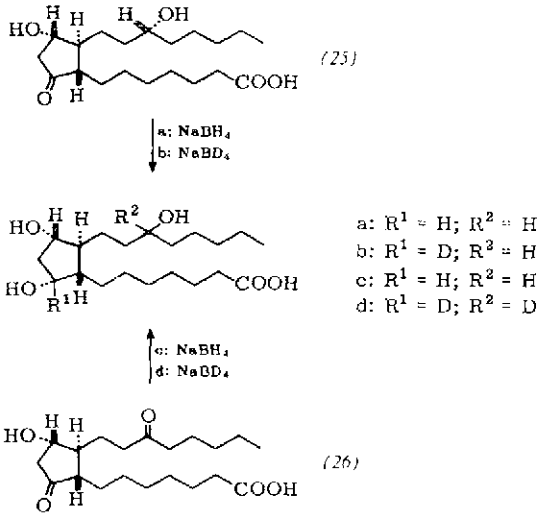


Fractionation of the labelled products excreted in the urine of rats after administration of labelled PGE_1 demonstrated that PGE_1 is completely metabolized to more polar derivatives. This is also the case in man. As yet none of these metabolites have been identified.

Studies of the distribution of radioactivity in various organs of the rat following administration of small amounts (0.2 μg) of labelled PGE_1 showed high concentrations of tritium in the kidneys and the liver [19]. In the lungs, pituitary gland, adrenals, ovaries, and uterus the tritium concentrations were slightly above the blood level, whereas brain, adipose tissue, muscle and thymus had very low concentrations of tritium.

The distribution of tritium after administration of labelled PGE_1 to sheep has also been investigated. This species has been shown to have prostaglandin in the seminal plasma and the uptake in the reproductive organs was therefore of particular interest. Significant concentrations of tritium were found in the fallopian tubes, uterus and ovaries of the female and in the vesicular gland of the male [40]. The distribution of tritium in the other organs of the sheep was similar to that found in the rat.

The metabolism of prostaglandins has also been studied *in vitro* in lung tissue [41]. These experiments demonstrated that PGE_1 was transformed into two less polar metabolites in homogenates of guinea-pig lung. The enzymes responsible for these transformations resided in the particle-free fraction of a lung homogenate. One of the metabolites was identified as 11α,15-dihydroxy-9-oxoprostanoic acid *(25)* and is formed by reduction of the double bond of PGE_1. The other metabolite *(26)* was less polar than the first one, and its infrared data demonstrated that here, too, the double bond was reduced. In



order to determine the number of keto groups in the limited amounts (0.5 mg) of material available, a combination of isotope labelling and mass spectrometry was used. The isolated metabolites were reduced with sodium borohydride and sodium borodeuteride. The products were converted to the methyl esters and acetylated prior to the mass spectrometric analyses. 11α,15-Dihydroxy-9-oxoprostanoic acid *(25)* was used as reference and subjected to the same sequence of reactions. After reduction of the reference compound with sodium borodeuteride, the m/e-values for the major fragments [M-59, M-(2×60), M-(3×60)] were *1 unit* higher than those obtained after reduction with sodium borohydride. However, the increment observed on reduction of the metabolite *(26)* with sodium borodeuteride as compared with sodium borohydride was *2 units*. After reduction with sodium borohydride the metabolite *(26)* gave essentially the same mass spectrum as the reduced reference compound *(25)*. These experiments therefore demonstrated that the metabolite *(26)* contained two keto groups. Their location followed from the infrared data, which excluded a 1,3-diketone in the five-membered ring (no absorption at 6.4 μ), and the metabolite *(26)* was therefore most likely 11α-hydroxy-9,15-dioxoprostanoic acid. Unequivocal proof for this structure was obtained by comparison with a sample prepared through partial synthesis from PGE_1 *(1)* via *(27)*.

The formation of the two metabolites *(25)* and *(26)* has been demonstrated in lung tissue of man, sheep, rabbit and rat [42]. A survey of different organs and tissues of the guinea-pig has shown that the same transformations take place in the kidney and the small intestine [42]. The formation of these metabolites *in vivo* has also been de-

[39] *E. Änggård* and *B. Samuelsson*, unpublished work.

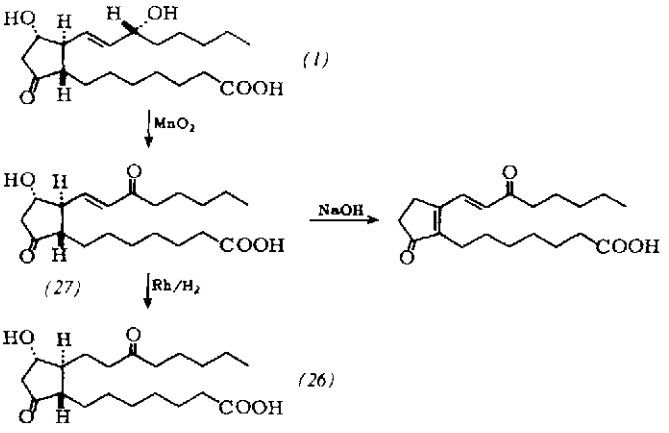
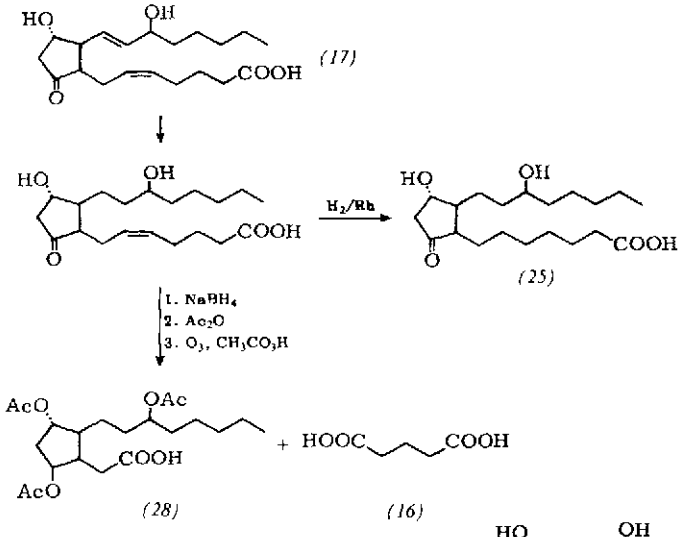
[42] *E. Änggård* and *B. Samuelsson*, unpublished work.

monstrated in the rat: they could be identified in the blood 15 minutes after administration of labelled PGE_1 [19]. However, their absence in the urine indicates that they are further metabolized before being excreted.

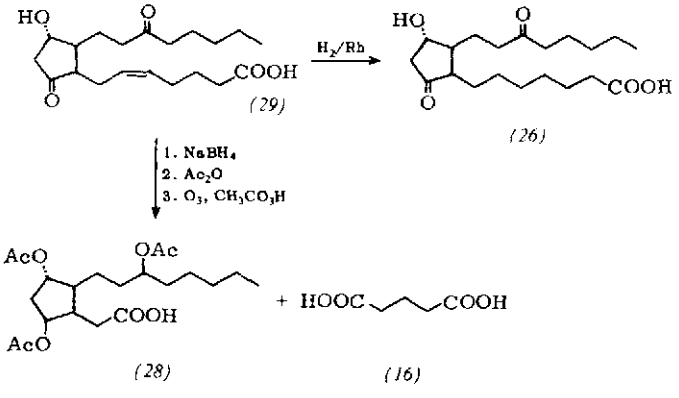


The metabolism of PGE_2 *(17)* in lung tissue of the guinea-pig was also recently studied. Two weakly polar metabolites were isolated and characterized. Catalytic reduction converted one of these into 11α,15-dihydroxy-9-oxoprostanoic acid *(25)*, and oxidative ozonolysis after reduction with borohydride and acetylation gave a C_{15}-fragment *(28)* consisting of two epimeric C_{15}-carboxylic acids. These acids were identified by gas-liquid chromatography [42].



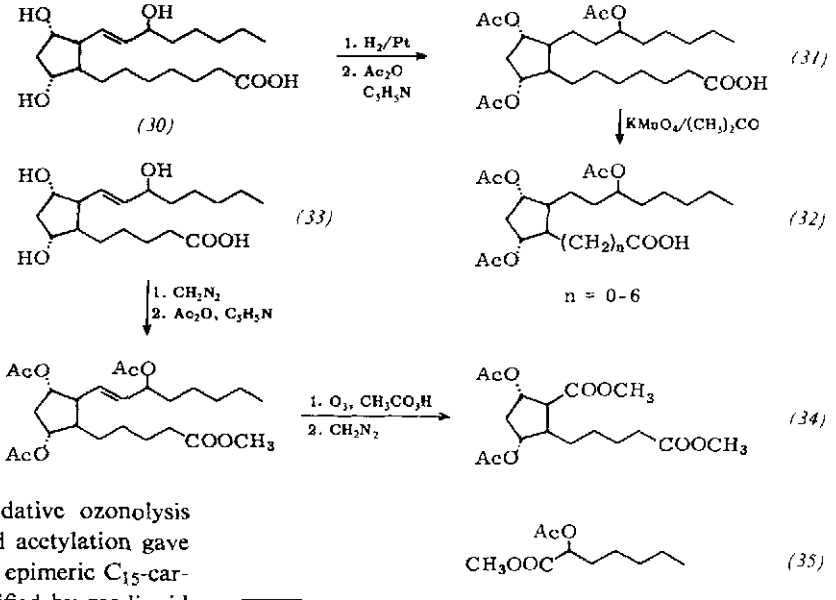
The least polar metabolite *(29)* was converted into 11α-hydroxy-9,15-dioxoprostanoic acid *(26)* by catalytic hydrogenation. Reduction by sodium borohydride followed by acetylation and oxidative ozonolysis gave the C_5-*(16)* and C_{15}-fragments *(28)*, demonstrating that the metabolite was 11α-hydroxy-9,15-dioxoprost-5-enoic acid. PGE_1 and PGE_2 are thus metabolized in the same way in lung tissue, *i.e.* by reduction of the Δ^{13}-double bond and oxidation of the secondary alcohol at C-15 to a ketone.

The metabolism of $PGF_{1\alpha}$ *(30)* was recently studied *in vivo* in the rat [43]. Labelled $PGF_{1\alpha}$ was prepared by borohydride reduction of [^{3}H]-PGE_1 *(24)*. The major part of the radioactivity excreted after administration of the labelled $PGF_{1\alpha}$ appeared in the urine (30% of the administered radioactivity) and about 8% appeared in feces. The structure of the major urinary metabolite *(33)*



was determined as follows: The infrared spectrum showed that the *trans* double bond was retained, and the mass spectrum indicated that the carboxyl side chain of the metabolite contained two methylene groups less than the administered $PGF_{1\alpha}$.

In order to prepare reference compounds for direct comparison, $PGF_{1\alpha}$ was hydrogenated and acetylated. The derivative *(31)* was then degraded from the caboxyl end



[43] *E. Granström, U. Inger,* and *B. Samuelsson,* J. biol. Chemistry *240*, 457 (1965).

by oxidation with permanganate in acetone. A series of seven acids *(32)*, n = 0–6, was obtained and analysed by gas-liquid chromatography. The relationship between the logarithms of the retention times of the methyl esters and the number of carbon atoms of the parent acids is shown in Figure 2. It was also confirmed by direct mass spectrometric analyses of the effluent from the gas chromatograph that the various components corresponded to the acids indicated. When the radioactive metabolite *(33)* was hydrogenated, acetylated, and subjected to gas chromatography, the main mass and radioactivity peaks had retention times corresponding to a parent acid with 18 carbon atoms.

The position of the double bond in the main metabolite *(33)* was determined by ozonolysis which yields the esters *(34)* and *(35)*.

The numbers on the curve are *m/e*-values for M– (3×60)
[M = mass of the molecular ion of the ester].

It is not the aim of this review to describe the large number of physiological studies which have been performed on the effects of prostaglandin on various smooth muscle organs. In recent studies, however, it has been possible to demonstrate effects of the prostaglandins on lipid metabolism and these experiments will be briefly discussed. The release of glycerol in rat adipose tissue, which is stimulated by catecholamine, was inhibited *in vitro* by PGE_1 [44]. The same effects were observed *in vivo* in dogs where PGE_1, PGE_2, and PGE_3 reduced the increased concentration of free fatty acids in blood plasma, induced by administration of norepinephrine [45]. Studies of the turnover rate of free fatty acids demonstrated that PGE_1 blocks the mobilization of lipids, which is induced by norepinephrine. The response of plasma glucose to epinephrine was only slightly diminished.

More recently, the effects of PGE_1 on the free fatty acids in plasma of man was investigated [46]. Intravenous infusion of PGE_1 caused an increase of the concentrations of free fatty acids and glycerol. However, when both norepinephrine and PGE_1 were infused together the increase of the concentrations of free fatty acids and glycerol due to norepinephrine was reduced by PGE_1.

The Use of Silylation in Organic Syntheses

BY PROF. DR. L. BIRKOFER AND DR. A. RITTER [**]

INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT KÖLN (GERMANY)

The term silylation is used to denote the introduction of a triorganosilyl moiety, especially the trimethylsilyl species, into organic compounds. – Silylated amino acids and sugars are particularly suitable for the syntheses of peptides and saccharides, respectively, since the silyl group can be cleaved off readily under mild conditions. Many diamines undergo ring closure, e.g. with phosgene, only after silylation. – O-Silylated lactim ethers (i.e. cyclic imino ethers) are converted into N-alkyl derivatives by alkyl halides. Compounds with a strongly polarized Si–C bond may be used for chain extension. Silyl esters of halogeno fatty acids yield lactones with silver cyanate. – Trimethylsilyl azide is thermally very stable and behaves like organic azides. It reacts with acetylenic compounds, trialkylphosphines, and triarylphosphines to yield silylated triazole derivatives, trialkylphosphine N-silylimines, and triarylphosphine N-silylimines, respectively, from which the silyl groups can be removed under mild conditions.

I. Introduction

1. Methods of Trimethylsilylation

The use of the trimethylsilyl moiety in organic syntheses is favored by the ready availability of trimethylchlorosilane *via* the Müller-Rochow synthesis [1] and by the relative compactness of the $Si(CH_3)_3$ group, which facilitates silicon elimination reactions. Although OH, NH, and SH groups can be silylated with trimethylchlorosilane even in the absence of an HCl acceptor, it is normally convenient to add a substance such as triethylamine or pyridine for this purpose, and thus to lower the reaction temperature, shorten the reaction time, and increase the yields. An auxiliary amine should be added during the silylation of primary or secondary amines which are difficult to obtain, in order to avoid loss of starting material by formation of its hydrochloride as the reaction proceeds.

Silylation with hexamethyldisilazane, which must usually be carried out by heating under reflux, yields no by-products other than NH_3. Hexamethyldisilazane is also the most suitable reagent [3] for direct trimethylsilylation of amino acids, for which trimethylchlorosilane cannot be used [2].

N-Trimethylsilylacetamide *(92)* is particularly useful, since it quantitatively trimethylsilylates hydroxy groups, sometimes even at room temperature [4]. Acetamide is formed as a by-product but can be removed easily by filtration.

Since nearly all organosilicon compounds containing O–Si, N–Si, or S–Si bonds are sensitive towards hydrolysis, moisture must be rigorously excluded.

Basically, only two methods of general applicability are known at present for *C*-silylation: reaction of a Grignard reagent or other organometallic compound with trimethylchlorosilane [5], or addition of silanes onto unsaturated systems [6].

2. Physical Properties of Organosilicon Compounds

The most striking feature of the organosilicon compounds under discussion is their excellent solubility in ordinary solvents which contain no active hydrogen. Substances which are insoluble in hydrocarbons owing to the presence of –OH, –NH–, $-CONH_2$ groups, *etc.* dissolve readily in these solvents on replacement of their protons by the trimethylsilyl group; reactions can then be carried out conveniently in a homogeneous organic phase.

Moreover, trialkylsilylation changes the volatility of organic compounds, many of which can then be distilled without decomposition [2,4,7,8]. However, crystallizability is sometimes considerably impaired.

II. Reactions Involving Substitution of Trialkylsilyl Groups

1. Cleavage of Si-N Bonds in Heterocyclic Compounds

N-Trialkylsilylated heterocyclic compounds are obtained by silylation of free N-heterocycles with trimethylchlorosilane, hexamethyldisilazane, or triethylaminosilane [9]. *N*-Trimethylsilylimidazole *(1)* (cf. Section VI.1) reacts almost quantitatively with acid halides, with elimination of trimethylchlorosilane *(3)* (see Table 1).

$$n\ R^1\text{-}Si(CH_3)_3 + R^2Cl_n \rightarrow R^1_n\text{-}R^2 + n\ (CH_3)_3SiCl$$

(1) *(3)*

R^1 =

N,N' Thionyldiimidazole *(10)* [11], was first prepared in analytical purity from *(1)* [10].

The Si-N bond in *N*-trimethylsilylimidazole *(1)* is so reactive that it even reacts with α-halogenocarboxylic esters *(11)* [9] which are inert towards free imidazole. Thus, trimethylsilyl α-(*N*-imidazolyl)acetate *(12)* is formed by the reaction of *(1)* with trimethylsilyl α-chloroacetate, and is quantitatively converted by water into α-(*N*-imidazolyl)acetic acid *(13)* [12], together with trimethylsilanol or its condensation product, hexamethyldisiloxane. Like *(1)*, *N*-trimethylsilyl-1,2,4-triazole *(14)* reacts with acid chlorides to give the acylated triazoles *(15)–(17)* [9].

2. The Course of *N*-Acylation

On acylation, *N*-trialkylsilyl-substituted heterocyclic compounds (see Table 2) show widely varying reactivities. It can therefore be concluded that the polarity of the Si–N bond differs from one compound to another and that the higher the polarity of the bond, the more reactive the compound. Comparative nuclear magnetic resonance measurements (see Table 3) on the methyl protons of the trimethylsilyl group [13, 14] show that the shielding effect of the silicon atom depends on the amine component, being particularly weak in *N*-trimethylsilyl-1,2,4-triazole *(14)* and *N*-trimethylsilylimidazole *(1)*.

The chemical shifts of the methyl protons may be regarded as a measure of the extent to which the silicon atom shares the lone pair of electrons on the nitrogen atom of the Si–N bond, increasing δ-values corresponding to reduced shielding.

Table 2. Reaction of heterocyclic compounds with hexamethyldisilazane to form *N*-trimethylsilyl compounds.

N-trimethylsilyl derivative of	Yield [%]	B.p. [°C/mm]
Imidazole *(1)*	85	91/12
Pyrazole	72	153/760
3,5-Dimethylpyrazole	59	73/12
1,2,4-Triazole *(14)*	81	74/12
Benzimidazole	89	112/0.3
Indazole	79	132/18
Pyrrolidine	72	142/760
Piperidine	42	161/760

Table 3. Chemical shifts δ of the methyl protons in the $(CH_3)Si$ group of trimethylsilylated heterocyclics and amines.
Internal standard: tetramethylsilane.

Parent compound	$\delta_{R-Si(CH_3)_3}$	$\delta_{R-C(CH_3)_3}$	Difference
Imidazole	−0.38	−1.46	1.08
Pyrrole	−0.23	−1.40	1.17
Pyrrolidine	0	−1.08	ca. 1.08
Diethylamine	0	−1.08	ca. 1.08
1,2,4-Triazole	0.40 *(14)*	1.47	1.07

The difference between the δ-values of *N*-trimethylsilyl compounds and those of the analogous t-butyl compounds is approximately constant. Since carbon is incapable of d_π p_π bonding, the different δ-values of the t-butyl compounds are simply due to the inductive effects of the amine or heterocyclic component. The chemical shifts of the methyl protons on the trimethylsilyl moiety are evidently reduced [16] by the back-donation [15] which can occur there. However, *N*-trimethylsilylpyrrole, whose δ-value of −0.23 is nearest to that of compounds *(1)* and *(14)*, is much more difficult to acylate than might be expected from the differences in the δ-values [17].

The differences in reactivity of the *N*-trimethylsilyl heterocyclics must therefore depend not so much on the ground state, but rather on the possible transition state formed during the course of acylation or alkylation. Compounds *(1)* and *(14)* may form an "onium" complex *(18)* which can eliminate the trimethylsilyl group by 1,3-induction.

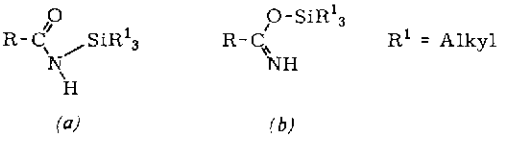
(18)  R = Acyl, Alkyl; X = Halogen

This mechanism is not possible with *N*-trimethylsilylpyrrole. Investigations are being carried out with a view to explaining this phenomenon.

3. The Structure of Trialkylsilylated Carboxamides

Trialkylsilylated carboxamides were first described by *Hurwitz* and *de Benneville* [18], who did not, however, discuss their structures.

In theory, silylation of a carboxamide can yield either compound *(a)* or compound *(b)*. However, since carboxamides are highly stabilized by resonance [19] and are susceptible to nucleophilic attack on both the nitrogen and oxygen atoms [20], it is possible that mono-trialkylsilylated carboxamides tend towards the *O*-silyl imino-ether structure *(b)*.



(a) *(b)*

O-Substitution would even be favored by the greater thermodynamic stability of the Si-O bond relative to the Si-N bond [21]. However, this is opposed by the fact that resonance stabilization is no longer possible in the *O*-silyl imino-ether, although the *N*-trialkylsilyl carboxamides benefit from this phenomenon. The irreversible isomerization of alkylated imino-ethers to *N*-alkyl carboxamides, which is known as the Chapman rearrangement [22], indicates the importance of resonance in the amide as a factor affecting its structure.

Infrared and NMR spectra [25] lead to the following conclusions regarding the substitution of silylated carboxamides:

1. The following open-chain mono-trialkylsilylated amides exist in the amide form *(a)* [23,24]: *N*-trimethylsilyl-acetamide *(92)* [26], -propionamide [26], -butyramide [26], -trichloroacetamide [26], -benzamide [26], -*N*-methylacetamide [25], -*N*-ethylacetamide [25], -acetanilide [26], -*N*-ethylpropionamide [25], and *N*-triethylsilylacetamide [25].

2. In the following alicyclic amides, the trimethylsilyl group becomes attached to the nitrogen atom: γ-butyrolactam [26], δ-valerolactam [26], and ε-caprolactam [25].

3. Only the *O*-silylated (lactim) form of the following six-membered cyclic lactams which can undergo heteroaromatization has been detected: 2-trimethylsiloxypyridine *(24)* [27], 2,4,6-tristriethylsiloxypyrimidine [28], 2,4-bistrimethylsiloxy-5,6-bistrimethylsilylaminopyrimidine [27], 2,3-bistrimethylsiloxyquinoxaline *(26)* [27], 2,4-bistrimethylsiloxyquinazoline [25], 3,6-bistrimethylsiloxypyridazine [25], and 1,4-bistrimethylsiloxyphthalazine [25]. For tristriethylsilylxanthine *(32)* [27], see Table 4.

4. Both *N*- and *O*-silylation occur simultaneously in 1-triethylsilyl-3-triethylsiloxy-4,4-diethylpyrazol-5-one *(19)* [29] and in the tetrakistrialkysilyluric acids *(20)*

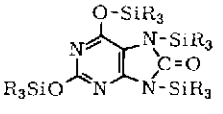
[7] and *(21)* [8] (cf. Sections VI.4 and VI.14, respectively). Despite numerous attempts [25,26], selective trimethylsilylation of carboxamides on either the nitrogen or the oxygen has not yet been achieved.



(20): R = C_2H_5
(21): R = CH_3

Silylation of acetamide and acrylamide with excess trimethylchlorosilane *(3)* yields the corresponding bistrimethylsilyl compounds *(22a)* or *(22b)* and *(23a)* or *(23b)*, respectively [30].

According to *Krüger, Rochow*, and *Wannagat* [31], *N,O*-bistrimethylsilylbenzamide can be obtained by a different route. An amide-type product *(a)* was ruled out by these authors, but should be given some consideration. Infrared spectra [25] and dipole moment data [13] support the imide form *(b)*, but the ^{1}H-NMR signals [25] do not indicate the presence of two non-equivalent trimethylsilyl groups, such as those in *(b)*. A splitting of about 5 cps below 0 °C in the methyl proton signal of the two trimethylsilyl groups might be due to a Chapman rearrangement [cf. [31]]. However, no corresponding effect is observed in the infrared spectrum of *(22a)* when recorded between −170 and +25 °C [32]. When heated in a sealed glass tube at 215 °C for 12 hours, bistrimethylsilylacetamide [*(22a)* or *(22b)*] is converted quantitatively into acetonitrile and hexamethyldisiloxane [25].

(23b): R = CH_2=CH

4. *N*-Alkylation of *O*-Silylated Carboxamides

Although the compounds mentioned in Section II.3 under 1. and 2. cannot be alkylated with methyl iodide, this alkylation does proceed with those listed under 3. and 4. Thus, *(24)* is alkylated to *(25)*, and *(26)* to *(27)*, (see Table 4). This method is preparatively valuable, since molecules with more than one amide group can be alkylated selectively, as shown by the examples *(20)* → *(28)*–*(31)* and *(32)* → *(33)*, *(34)*.

Acyl halogeno sugars react with *O*-silylated N-heterocyclic compounds (lactimethers) to form *N*-glycosides. *N*-Tetra-*O*-acetylglucosyl-α-pyridone *(35)*, which was prepared earlier in a different manner, is formed in 70% yield from *(24)* and acetobromoglucose [27,33].

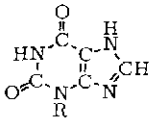
(24)

(35)

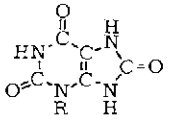
R = 1-(2,3,4,6-Tetra-*O*-acetyl)-glucosyl

Introduction of a glycosidic moiety into the 3-position of purine derivatives was first achieved using silyl compounds. Tristriethylsilylxanthine *(32)* and acetobromoglucose lead to 3-glucosylxanthine *(36)* [27], and tetrakistriethylsilyluric acid *(20)* and acetobromoglucose similarly to 3-glucosyluric acid *(37)* [27, 34].



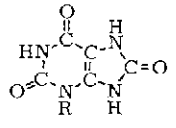
(36)

R = 1-Glucosyl



(37)

3-(1-Ribofuranosyl)uric acid *(38)*, which is present in ox blood [35, 36], was first synthesized starting from tetrakistriethylsilyluric acid *(20)* and 1-bromo-2,3,5-tri-*O*-benzoylribofuranose [34] (cf. Section VI.6).

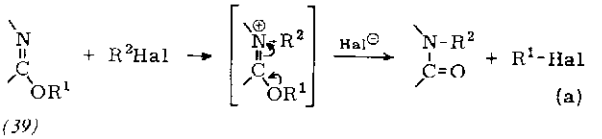


R = 1-Ribofuranosyl

(38)

5. The Course of *N*-Alkylation of *O*-Trialkylsilyl Lactims

The introduction of *N*-alkyl and *N* glycosyl groups *via* lactim ethers *(39)* was first described by *Hilbert* and *Johnson* [37] in 1930. Although no accurate studies appear to have been carried out, several authors believe that the course shown in Equation *(a)* is probable [38].



(39) (a)

There is no reason why this scheme should not also apply to *O*-silylated lactims.

This interpretation is unsatisfactory only for tetrakistriethylsilyluric acid *(20)* (Table 4), which can also be alkylated in the 7-position, although the five-membered ring of *(20)* has the lactam structure [25]. The alkylation in the 7-position observed with tristriethylsilylxanthine *(32)*, on the other hand, can be explained in a similar manner as the acylation of *N*-trimethylsilylimidazole *(1)*.

One disadvantage of the classical Hilbert-Johnson reaction [Equation (a)] is that the R^1-Hal present in the reaction medium increases in quantity as the reaction proceeds, and can react again. This competing reaction gives rise to a mixture of two products [37]. The side reaction is never observed when *O*-silyl lactims are used, since it would yield *N*-silylated compounds, and, in the case of six-membered heteroaromatic ring systems at least, these have never yet been detected.

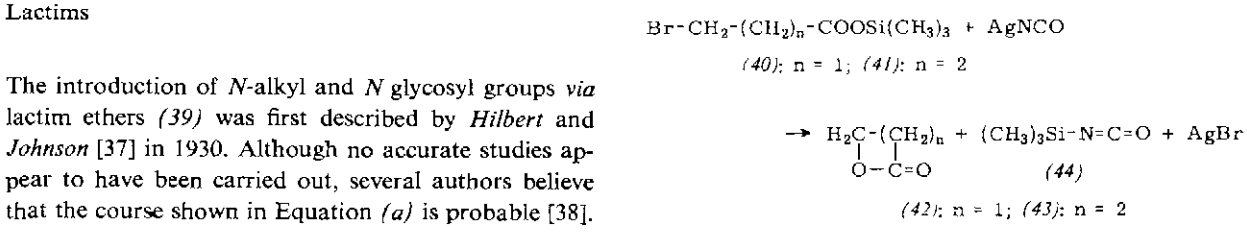
When carried out with *O*-silyl lactims, the Hilbert-Johnson reaction has two notable advantages over the classical procedure:

1. Ring systems which can undergo heteroaromatization can be converted in very good yields into *O*-silyl lactims by a one-step reaction, whereas *O*-alkyl or *O*-aryl lactims can generally be prepared only by multistage syntheses.

2. The yields are satisfactory (Table 4); this may be due to the uniform course of reaction and to the higher electrophilicity of the trialkylsilyl species compared to an alkyl group.

6. Cleavage of Si-O Bonds

When trimethylsilyl bromoalkanoates such as *(40)* or *(41)* are treated with silver cyanate, lactones and trimethylsilyl isocyanate *(44)* are obtained instead of the expected trimethylsilyl isocyanato fatty esters [39] (cf. Section VI, 7 and 8).



(40): n = 1; *(41)*: n = 2

(42): n = 1; *(43)*: n = 2

Lactones are also obtained with silver perchlorate [39]. Trimethylsilyl perchlorate $(CH_3)_3SiClO_4$ [40] should not be isolated by distillation from the reaction medium, since a serious explosion once occurred during this operation. Similarly, ω-halogenoalkoxytrialkylsilanes, Hal-$(CH_2)_n$-O-SiR_3, give cyclic ethers [39]. Thus, the reaction of 1-chloro-4-trimethylsiloxybutane *(45)* with silver cyanate yields tetrahydrofuran *(46)* and the isocyanate *(44)*.

Intramolecular transesterification of chloromethyldimethylsilyl acetate *(47)* in the presence of silver cyanate leads to acetoxymethyldimethylsilyl isocyanate *(48)* [39].

$$H_3C\text{-}COOSi(CH_3)_2\text{-}CH_2Cl + AgNCO \quad (47)$$
$$\rightarrow H_3CCOOCH_2\text{-}Si(CH_3)_2\text{-}NCO + AgCl \quad (48)$$

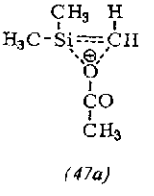
This rearrangement is the first Wagner-Meerwein reaction observed in the chemistry of organosilicon compounds [41].

7. The Course of Cyclization

The reaction of silver cyanate or silver perchlorate on the halogeno compounds *(40)*, *(41)*, *(45)*, and *(47)* probably results in the formation of the carbonium ions *(40a)*, *(41a)*, *(45a)*, and the bridged carbonium-siliconium ion *(47a)*, respectively; these then lead to the

$\overset{\oplus}{C}H_2\text{-}(CH_2)_n\text{-}COOSi(CH_3)_3$ *(40a)*: n = 1 *(41a)*: n = 2

$\overset{\oplus}{C}H_2\text{-}(CH_2)_3\text{-}O\text{-}Si(CH_3)_3$ *(45a)*



(47a)

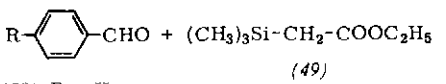
oxygenated cyclic compounds *(42)*, *(43)*, *(46)*, and the open-chain ester *(48)*, respectively.

8. Substitution at Si-C Bonds

The magnitude of the ionic component of the Si–C bond depends largely on the electronic effects of the neighboring groups. The value calculated for the Si–C bond in a normal C–C chain is 12% [42]. However, if electron-attracting substituents are present in the β-position with respect to the silicon, the susceptibility of the latter to nucleophilic attack will be considerably increased.

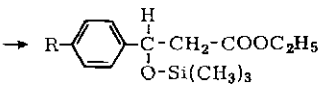
Gold, *Sommer*, and *Whitmore* [43] established that the Si–C bond in ethyl trimethylsilylacetate *(49)* can be cleaved even by absolute alcohol, ethoxytrimethylsilane and ethyl acetate being formed [44].

In the presence of basic catalysts such as solid NaOH and $K[Al(OCH_3)_4]$, *(49)* also reacts with aldehydes: the carbon chain is extended with formation of the ethyl β-trimethylsiloxycarboxylates [45]. With benzaldehyde *(50)*, anisaldehyde *(51)*, and *p*-nitrobenzaldehyde *(52)*, ethyl trimethylsilylacetate *(49)* gives the corresponding β-phenyl-β-trimethylsiloxypropionates *(53)*, *(54)*, and *(55)* (cf. Section VI.9).



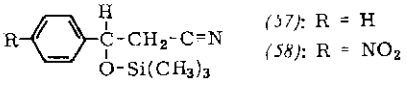
(49)

(50): R = H
(51): R = O-CH_3
(52): R = NO_2



(53): R = H
(54): R = O-CH_3
(55): R = NO_2

The yields decrease as follows: *(55)* ≫ *(53)* > *(54)*. Chain extension analogous to *(50)* → *(53)* also occurs when *(49)* is replaced by trimethylsilylacetonitrile $(CH_3)_3Si\text{–}CH_2\text{–}CN$ *(56)* [46, 45]. Compounds *(50)* and *(52)* form the β-phenyl-β-trimethylsiloxy propionitriles *(57)* and *(58)*, respectively.



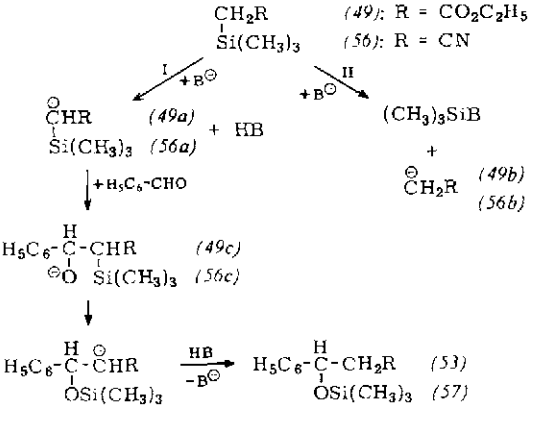
(57): R = H
(58): R = NO_2

p-Nitrobenzaldehyde *(52)* is again much more reactive than benzaldehyde *(50)*, as shown by the respective yields of 78 and 27% [45].

This method of chain lengthening is particularly useful when the required products are not obtained by the Reformatsky reaction, which often fails to give β-aryl-β-hydroxy esters, for example owing to dehydration during work-up of the reaction mixture, with consequent formation of α,β-unsaturated esters [47]. The free β-aryl-β-hydroxy esters or nitriles are obtained by alcoholysis of the trimethylsiloxy compounds *(53)*, *(54)*, *(55)*, *(57)*, and *(58)*. Although *(52)* does not undergo the Reformatsky reaction [48], it reacts almost quantitatively with ethyl trimethylsilyacetate *(49)* and trimethylsilylacetonitrile *(56)*.

9. The Mechanism of Substitution

The issue here is whether the catalytically active anion $B^{\ominus}$ splits off a proton from the α-methylene group in *(49)* and *(56)* to form a carbanion *(49a)* or *(56a)* [Reaction I], or whether the silyl group undergoes nucleophilic attack by $B^{\ominus}$, with cleavage of the Si–C bond and formation of a carbanion *(49b)* or *(56b)* [Reaction II].



(49): R = $CO_2C_2H_5$
(56): R = CN

[45] *L. Birkofer*, *A. Ritter*, and *H. Wieden*, Chem. Ber. *95*, 971 (1962).

[46] Prepared according to *M. Prober*, J. Amer. chem. Soc. *77*, 3224 (1955).

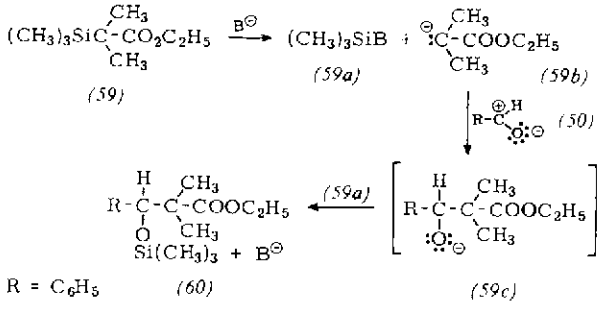
[47] *R. L. Shriner*: Organic Reactions. Wiley, New York 1947, Vol. I, 1, p. 11.

[48] *F. Bohlmann*, Chem. Ber. *90*, 1519 (1957).

Following Route I the carbanions *(49a)* or *(56a)* launch a nucleophilic attack on the aldehydic carbon atom to form a C-C bond. The resulting alkoxide anions *(49c)* or *(56c)* then give the corresponding β-siloxy compounds *(53)* or *(57)* by intramolecular "trans-silylation" and proton capture.

Since ethyl α-trimethylsilylisobutyrate *(59)*, which has no α-methylene group, also reacts with benzaldehyde *(50)* to form the β-trimethylsiloxy compound *(60)* [45], the reaction follows Route II in this case. The carbanion *(59b)* formed from *(59)* adds on as a nucleophile to the aldehyde carbonatom to form a C–C bond. Nucleophilic attack hy the resulting anion *(59c)* on *(59a)* gives *(60)*.

Route I [45] must be considered possible in the reaction with compounds *(49)* and *(56)* which contain α-methylene protons as well as the trimethylsilyl group.



R = C_6H_5 *(60)* *(59c)*

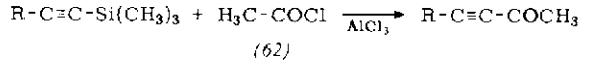
10. Substitution in Silylated Acetylenes

The Si–C bonds in ethyl trimethylsilylacetate *(49)*, trimethylsilylacetonitrile *(56)*, and ethyl trimethylsilylbutyrate *(59)* are easily broken, but –C≡C–Si– bonds are much less reactive [50], with only few exceptions [49].

The inertness of these bonds, even toward acyl chlorides, acid anhydrides, and α-chloroalkyl ethers, is readily overcome by using aluminum chloride as catalyst. Many new trimethylsilyl derivatives of acetylenic compounds containing ketonic or ether groups have been prepared in this way.

For example, bistrimethylsilylacetylene *(61)* reacts with acetyl chloride *(62)* or acetic anhydride to give 1-trimethylsilyl-1-butyn-3-one *(63)* in very good yield.

Similarly, the silyl group of unsymmetrically substituted trimethylsilylacetylenes, such as 1-phenyl-2-trimethylsilylacetylene *(64)*, can be replaced by an acyl group. Acetyl chloride reacts with *(64)* to give 1-phenyl-1-butyn-3-one *(65)* [51].

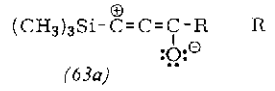


(62)

(61): R = $Si(CH_3)_3$ *(63)*: R = $Si(CH_3)_3$

(64): R = C_6H_5 *(65)*: R = C_6H_5

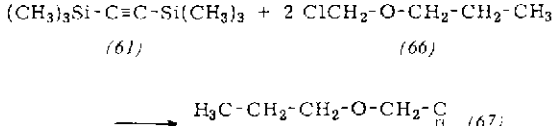
It is remarkable that only one trimethylsilyl group in *(61)* can be replaced by an acyl group. The resonance structure *(63a)* of the 1-trimethylsilylalkynones apparently inhibits complete desilylation and acylation.



(63a)

The acylium ion $R-\overset{\oplus}{C}=O$ resulting from the reaction of the acyl chloride or acid anhydride with the Lewis acid aluminum chloride can no longer attack here as an electrophile, as it does *(61)*; instead, the latter presumably reacts with the acylating agent to form the resonance structure *(61a)*.

In the reaction with α-chloroalkyl ethers, *e.g.* chloromethyl n-propyl ether *(66)*, disubstitution of bistrimethylsilylacetylene *(61)* is no more difficult than monosubstitution. Formation of 1,4-dipropoxy-2-butyne *(67)* [52] supports this argument.

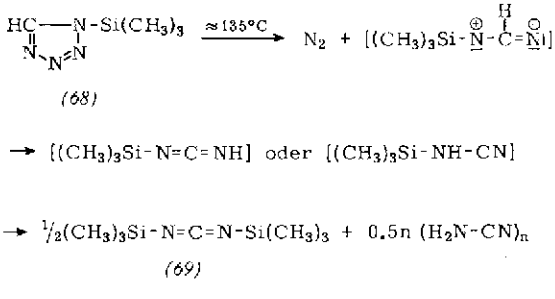


(61) *(66)* *(67)*

III. The Trimethylsilyl Group as an Electron Acceptor

1. Thermolysis of Silylated Tetrazoles

All the known *N*-trimethylsilyl derivatives of pyrrole, pyrazole, imidazole, and 1,2,4-triazole are thermally stable (see Section II.1), but silylated tetrazoles are decomposed by heat [53]. Thus at about 135 °C, 1-trimethylsilyltetrazole *(68)* loses one mole of nitrogen to form *N,N'*-bistrimethylsilylcarbodiimide *(69)* and polymeric cyanamide [54]. 2-Trimethylsilyl-5-phenyltetrazole *(70)* decomposes at about 190 °C to nitrogen and



(68)

3,5-diphenyl-1-bis(trimethylsilyl)amino-1,2,4-triazole *(72)*, hydrolysis of which yields 1-amino-3,5-diphenyl-1,2,4-triazole *(73)*. *C*-Phenyl-*N*-trimethylsilylnitrilimine *(71)*, the first known 1,3-dipolar organosilicon com-

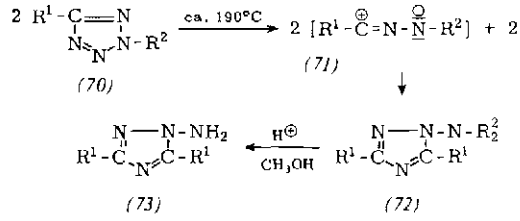
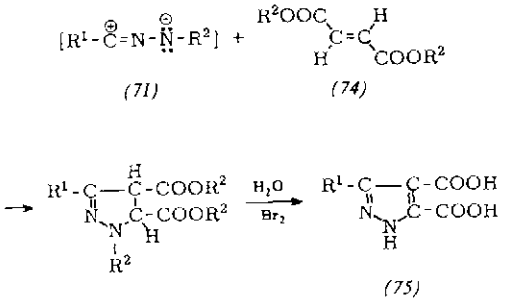
bound, can be trapped by 1,3-dipolar addition during the course of the complicated reaction [53].



(70) (71) (73) (72)

$R^1 = C_6H_5$; $R^2 = Si(CH_3)_3$

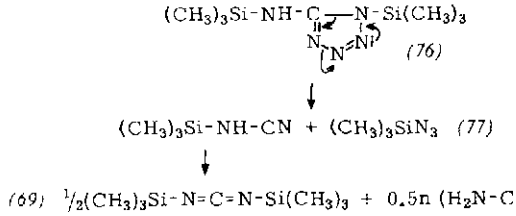
The formation of *(72)* during the thermolysis of *(70)* is prevented by the presence of compounds which react with 1,3-dipoles. Thermolysis of *(71)* in the presence of bistrimethylsilyl fumarate *(74)* followed by oxidation with bromine gives 3-phenylpyrazole-4,5-dicarboxylic acid *(75)*. This provides a general route for the preparation of pyrazole derivatives by reaction of 1,3-dipolarophiles with nitrilimines, *e.g. (71)* [55].



(71) (74) (75)

$R^1 = C_6H_5$; $R^2 = Si(CH_3)_3$

A third mode of decomposition of tetrazoles is illustrated by the thermolysis of 1-trimethylsilyl-5-(trimethylsilylamino)tetrazole *(76)* which yields trimethylsilyl azide *(77)*; compound *(77)* was first prepared by this method (cf. Section VI.10). In addition to *(77)* the carbodiimide *(69)*, which had previously been prepared by thermolysis of the tetrazole *(68)*, was also obtained. Other silyl azides have since been prepared [56, 57].



(76) (77) (69)

2. The Course of Thermolysis

The mechanism of the thermolysis of substituted tetrazoles has been elucidated by *Huisgen* [55]. The observation that silylated tetrazoles decompose at least as readily as correspondingly substituted phenyltetrazoles shows that by withdrawing electrons in the transition state the trimethylsilyl group favors the decomposition in the same way as does the phenyl group.

[55] Cf. *R. Huisgen, J. Sauer*, and *M. Seidel*, Chem. Ber. *94*, 2503 (1961); *R. Huisgen, M. Seidel, G. Wallbilich*, and *H. Knupfer*, Tetrahedron *17*, 3 (1962).

IV. The Trimethylsilyl Moiety as a Protective Group

1. Reactions of Trimethylsilyl Azide

This azide can be conveniently prepared from trimethylchlorosilane *(3)* and sodium azide [53] (cf. Section VI.10) and distilled (b.p. 95 °C) at normal pressure without decomposition.

a) *Addition of Trimethylsilyl Azide onto C≡C Bonds*

Since it is not dangerous, trimethylsilyl azide *(77)* can be used in reactions which must otherwise be carried out with highly explosive hydrazoic acid. The trimethylsilyl group can again be subsequently replaced by a proton under mild conditions.

The azide *(77)* adds onto phenylacetylene *(78)* in the same way as hydrazoic acid [58], and after desilylation, 4-phenyl-1,2,3-triazole *(80)* [51, 53] can be isolated in 64 % yield. Reaction of the dimethyl acetylenedicarboxylate *(79)* with *(77)*, followed by replacement of the trimethylsilyl group by a proton, gives dimethyl 1,2,3-triazole-4,5-dicarboxylate *(81)* [53, 59].

(77)

(78): $R^1 = H$; $R^2 = C_6H_5$ *(80)*: $R^1 = H$; $R^2 = C_6H_5$

(79): $R^1 = R^2 = COOCH_3$ *(81)*: $R^1 = R^2 = COOCH_3$

R = $(CH_3)_3Si$

1,2,3-Triazole derivatives containing both *N*- and *C*-trimethylsilyl substituents can be selectively desilylated: methanol cleaves N-Si bonds, while methanol/HCl [60] cleaves C-Si bonds as well, both with protonation [51].

b) *Reaction of Trimethylsilyl Azide with Triphenylphosphine*

Like phenyl azide [61], trimethylsilyl azide *(77)* also reacts with triphenylphosphine; here the product is triphenylphosphine trimethylsilylimine *(82)* [53, 62] (cf. Section VI. 11.).

(77) (82)

Removal of the trimethylsilyl group from *(82)* with isopropanol yields triphenylphosphine imine *(83)* and isopropoxytrimethylsilane *(84)* without subsequent attack on the labile P–NH group [62].

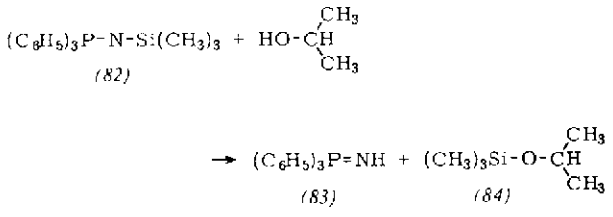
[58] *L. W. Hartzel* and *F. R. Benson*, J. Amer. chem. Soc. *76*, 667 (1954).

[59] Compound *(81)* is identical with the product obtained by another route by *S. Yamada, T. Mizoguchi*, and *A. Ayata*, J. pharmac. Soc. Japan (Yakugakuzasshi) *77*, 452 (1957); Chem. Abstr. *51*, 14697 (1957).

[60] *C. Eaborn*, J. chem. Soc. (London) *1956*, 4858.

[61] *H. Staudinger* and *J. Meyer*, Helv. chim. Acta *2*, 635 (1919).

[62] *L. Birkofer, A. Ritter*, and *S. M. Kim*, Chem. Ber. *96*, 3099 (1963).



(82) *(83)* *(84)*

Compound *(83)* can be prepared more simply and more safely in this way than from triphenylphosphine and chloramine [63]. The hitherto unknown trialkylphosphine imines can be obtained in a similar manner [64].

c) *Cause of the Thermal Stabilitiy of Trimethylsilyl Azide*

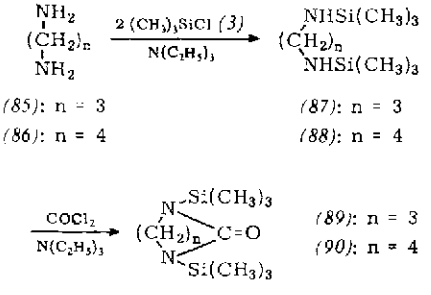
The thermal stability of trimethylsilyl azide *(77)* is unexpected when compared to organic azides, but may be due to its greater stabilization by resonance owing to $d_\pi - p_\pi$ bonding between the silicon and nitrogen atoms, which can occur provided the bond angle in the Si–NNN system is rather large.

Raman-spectroscopic measurements on trimethylsilyl isocyanate $(CH_3)_3Si-NCO$ *(44)* [66] and on trimethylsilyl azide *(77)* [65] indicate that the bond angle is over 120° in *(77)*, too. The trimethylsilyl azide molecule thus appears to be capable of resonance with participation of the silicon atom as well.

2. Carbamidation of Silylated Diamines; Cyclic Ureas and a New Uric Acid Synthesis

Cyclic ureas can be obtained from aliphatic ω,ω'-diamines such as trimethylenediamine *(85)* and tetramethylenediamine *(86)*, but only by way of the thioureas and subsequent replacement of sulfur by oxygen [67] and not by cyclization of the diamines with phosgene.

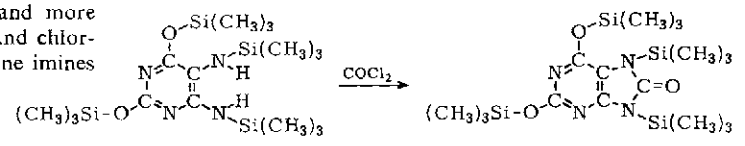
After conversion of *(85)* or *(86)* into the *N,N'*-bistrimethylsilyl compounds *(87)* and *(88)*, phosgene immediately brings about ring closure to *N,N'*-bistrimethylsilyltrimethyleneurea *(89)* or *N,N'*-bistrimethylsilyltetramethyleneurea *(90)*, which can be readily desilylated [8] (overall yields: 60 and 75%, respectively).



(85): n = 3 *(87)*: n = 3
(86): n = 4 *(88)*: n = 4

(89): n = 3
(90): n = 4

2,6-Bis-*O*-trimethylsilyl-4,5-bis(trimethylsilylamino)uracil *(91)*, which is obtained by silylation of 4,5 diaminouracil, reacts with phosgene in toluene by ring closure to form tetrakistrimethylsilyluric acid *(21)* [8] (cf. Sections VI.13 and VI.14). In this way, it has become possible for the first time to carry out syntheses with 4,5 diaminouracil in hydrocarbons as solvent. This is a typical example of a reaction in which the starting material becomes soluble in the organic phase only after silylation.

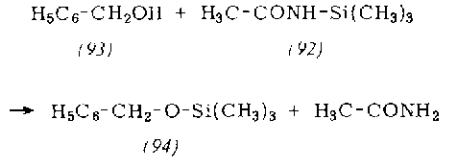


(91) *(21)*

The cylization of *(91)* to *(21)* can be effected even with CO_2 in 87% yield. Hydrolysis of *(21)* yields uric acid (cf. Section VI.15).

3. Preparation of Trimethylsilylalkoxy Compounds and Glucose Derivatives; Disaccharide Synthesis

The method regarded until now as the most suitable for the preparation of trimethylsilylalkoxy compounds was the alcoholysis of hexamethyldisilazane *(99)* [26,68]. However, hydroxy functions can be silylated quantitatively under milder conditions by mixing stoichiometric quantities of an alcohol and *N*-trimethylsilylacetamide *(92)*. Reaction of benzyl alcohol *(93)* and *(92)* yields benzoxytrimethylsilane *(94)* [4]. Isopropoxytrimethylsilane *(84)* [62] is equally easily obtainable.



(93) *(92)* *(94)*

Persilylated carbohydrates are best prepared by fusion of *(92)* with a carbohydrate for a short time. For example, glucose reacts in this way with *(92)* to give pentakis-*O*-trimethylsilylglucose [4] (cf. Section VI.16). The acetamide formed as by-product can be separated from the silylated sugar in a single operation by distillation or by addition of a solvent such as petroleum ether after the reaction, followed by filtration. The silylated carbohydrates are extremely soluble even in hydrocarbons. They can also be satisfactorily prepared from carbohydrates and *(92)* in solvents such as pyridine [4]. Until now, trialkylsilyl derivatives of carbohydrates were always prepared using trialkylchlorosilanes [69].

a) *Disaccharide Synthesis with 1,2,3,4-Tetrakis-O-trimethylsilylglucose*

Glucose can be selectively silylated with *N*-trimethylsilylacetamide in pyridine to give 1,2,3,4-tetrakis-*O*-trimethylsilylglucose *(95)* (cf. Section VI.17.). This reacts with α-

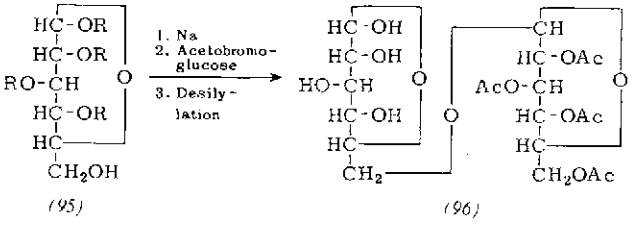
acetobromoglucose to form 1,2,3,4-tetrakis-*O*-trimethylsilyl-2′,3′,4′,6′-tetra-*O*-acetyl-β-gentiobiose, which yields tetra-*O*-acetyl-β-gentiobiose on desilylation *(96)* [70]. Acetylation of the latter leads to octaacetyl-β-gentiobiose [71].



(95) *(96)*

4. Peptide Syntheses Using Silylated Amino Acids and Peptides

Owing to the ease of removal of the silyl groups, trimethylsilyl esters of *N*-trimethylsilylamino acids [3,7] are more suitable for peptide syntheses than alkyl esters of amino acids.

a) *Trimethylsilyl Esters of N-Trimethylsilylamino Acids*

Trimethylsilyl esters of *N*-trimethylsilylamino acids are easy to prepare. An amino acid or its hydrochloride is heated in excess hexamethyldisilazane *(99)* together with a few drops of concentrated sulfuric acid [3,7,72] (cf. Section VI.18.).

Experiments with L-alanine, L-valine, and L-leucine show that no racemization occurs during silylation (see Table 5).

Table 5. Specific rotations of unsilylated and desilylated amino acids.

Amino acids	$[\alpha]_D^{20}$	
	Unsilylated	Desilylated
L-Alanine	+ 14.1 ± 1°	+ 13.5 ± 1°
L-Valine	+ 6.4 ± 1°	+ 6.0 ± 1°
L-Leucine	− 10.4 ± 1°	− 10.3 ± 1°

Triethylsilyl esters of *N*-triethylsilylamino acids are obtained in high yields by treatment of amino acids with triethylsilane and $PdCl_2$ catalyst in the presence of a little triethylaminosilane [73]. Silyl derivatives of amino acids have also been obtained [74] by reaction of the sodium salts of the amino acids with trimethylchlorosilane *(3)*. Free amino acids cannot be silylated with *(3)*, owing to their zwitterionic character [2].

b) *Trimethylsilyl Derivatives of Polyfunctional Amino Acids*

The trimethylsilyl residue has been used as a protective group for the SH and OH functions in peptide syntheses with cysteine *(97)* and serine *(98)*, since it can be removed simply by hydrolysis. The reactions of *(97)* and *(98)* with hexamethylsilazane *(99)* yield the trimethylsilyl esters of *N,S*-bistrimethylsilylcysteine *(100)* and *N,O*-bistrimethylsilylserine *(101)*, respectively [75].

(98): Y = O

(99)

(100): Y = S
(101): Y = O

c) *Peptide Syntheses with Trimethylsilyl Esters of N-Trimethylsilylamino Acids* [75]

Trimethylsilyl esters of *N*-trimethylsilylamino acids are preferable to alkyl esters of amino acids for peptide syntheses, *e.g.* by the phosphorus oxychloride [76] or imidazolide methods [77]. Unlike the alkyl esters of *N*-carbobenzoxy dipeptides, the resulting silyl esters of *N*-carbobenzoxy dipeptides need not be isolated and hydrolyzed in a separate operation, since they are hydrolyzed to the free carbobenzoxy dipeptides during the normal work-up.

Silylated amino acids can also be used in syntheses by the *p*-nitrophenyl ester [78] and ethyl chloroformate methods [79]. To prepare dipeptides by the *p*-nitrophenyl ester method in a one-step reaction [80], the *p*-nitrophenyl ester of the carbobenzoxy amino acid is fused with the desired amino acid and *N*-trimethylsilylacetamide *(92)*. After work-up, the yield of carbobenzoxy dipeptide is 80–95 %.

p-Nitrophenyl Ester Method:

$$CbzNHCH(R^1)COO\text{-}C_6H_4\text{-}NO_2 + H_2NCH(R^2)CO_2H + 2\ H_3C\text{-}CONHSi(CH_3)_3 \quad (92)$$

$$\rightarrow CbzNHCH(R^1)CONH\text{-}CH(R^2)CO_2H + HO\text{-}C_6H_4\text{-}NO_2 + 2\ H_3C\text{-}CONH_2 + (CH_3)_3SiOSi(CH_3)_3$$

Tripeptides in One Step-Reaction

Mixed anhydrides obtained from *N*-carbobenzoxyamino acids and ethyl chloroformate react with silyl esters of *N*-silylamino acids to form silyl esters of *N*-carbobenzoxy dipeptides. It is possible, without isolating the latter, to convert them once again into mixed anhydrides using ethyl chloroformate. Renewed addition of silylated amino acids to the mixed anhydrides of the preceding step yields the silyl esters of *N*-carbobenzoxy tripeptides, hydrolysis of which gives *N*-carbobenzoxy tripeptides [81].

Syntheses Using Silylated Di- and Tri-peptides

Like amino acids, di- and tri-peptides can also be silylated by hexamethyldisilazane *(99)*. However, the silyl esters of di- or tri-peptides cannot be distilled without undergoing side-reactions or decomposing. Nevertheless, they will react without previous isolation with *N*-carbobenzoxyamino acids or *N*-carbobenzoxy peptides by several methods to give higher peptides [81].

V. Removal of Carbobenzoxy Groups with Triethylsilane

The protective group can be removed from *N*-carbobenzoxyamino acids or peptides using triethylsilane with $PdCl_2$ as catalyst [73]. The resulting *N*-silylamino acid esters or *N*-silyl peptides are then converted into the free compounds by methanolysis. This method is particularly suitable for compounds containing sulfur: for example, *N*-carbobenzoxy-*S*-benzylcysteine gives *S*-benzylcysteine.

The trimethylsilyl ester of *N*-carbobenzoxyglycine, which contains no free carboxyl group, is also decarbobenzoxylated on reaction with triethylsilane; this shows that the cleavage is not brought about by the hydrogen initially liberated by silylation of carboxyl groups, but by the triethylsilane

$$R\text{-}\underset{\underset{HNCO_2CH_2C_6H_5}{|}}{CH}CO_2H \xrightarrow[PdCl_2]{(C_2H_5)_3SiH} H_2 + R\text{-}\underset{\underset{HNCO_2CH_2C_6H_5}{|}}{CH}CO_2Si(CH_3)_3$$

$$\xrightarrow{(C_2H_5)_3SiH} CO_2 + H_5C_6\text{-}CH_3 + R\text{-}\underset{\underset{HNSi(CH_3)_3}{|}}{CH}\text{-}CO_2Si(CH_3)_3$$

$$\xrightarrow{2\ CH_3OH} R\text{-}CH(NH_2)CO_2H + 2\ (C_2H_5)_3SiOCH_3$$

VI. Practical Procedures

1. *N- Trimethylsilylimidazole (1)* [9]

All reactions must be carried out in the absence of moisture. Imidazole (13.6 g) is heated under reflux in an oil bath for 2 h with 24.2 g of hexamethyldisilazane *(99)* plus 2 drops of concentrated sulfuric acid. On fractional distillation 23.8 g of *(1)* is obtained (b.p. 91 °C/12 mm; 85 % yield; $n_D^{20} = 1.4756$).

2. *N-Acetylimidazole (2)* [9]

N-Trimethylsilylimidazole *(1)* (0.1 mole) is dissolved in 25 ml of dry benzene, and 0.1 mole of acetyl chloride in 25 ml of dry benzene is added dropwise with stirring at 0 °C. After stirring for 15 min, the trimethylchlorosilane *(3)* formed and the benzene are removed *in vacuo*, leaving 10.5 g of *(2)*, 96 % yield; m.p. 105 °C.

3. *N,N'-Carbonyldiimidazole (6)* [9]

Phosgene (0.05 mole) is passed into a solution of 0.1 mole of *(1)* in 100 ml of dry benzene at 0 °C; 7.9 g of analytically pure *(6)*, m.p. 115 °C (98 % yield), is precipitated.

4. *Tetrakistriethylsilyluric Acid (20)* [7]

Uric acid (6.3 g) is boiled for 16 h with triethylsilylamine; excess triethylsilylamine and its condensation product, hexaethyldisilazane, are then removed by distillation at 12 mm. Afterwards 21 g of *(20)*, m.p. 43 °C (91 % yield), distils out of the residue at 200–205 °C/0.04 mm.

5. *1-Methyluric Acid (28)* [27]

Tetrakistriethylsilyluric acid *(20)* (5 g) is dissolved in 15 g of methyl iodide, 1.6 g of $AgClO_4$ is added, and the mixture is left standing for 10 min. Silver iodide precipitates out with liberation of heat, and is filtered off. Hydrolysis of the filtrate with aqueous ethanol gives 1.25 g of *(28)* (85 % yield) which decomposes at 400 °C. Small quantities of more highly methylated uric acids can be readily removed owing to their poor solubility in water.

6. *3-(1-Furanosyl)uric Acid (38)* [27,34]

Tetrakistriethyluric acid *(20)* (12 g) is dissolved in 50 ml of toluene and mixed with 4 g of $AgClO_4$. 1-Bromo-2,3,5-tribenzoylribofuranose (10 g) in 60 ml of toluene is added dropwise over 10 min with constant stirring. The AgBr precipitate is centrifuged out in a moisture-free atmosphere and the solution is poured into 500 ml of petroleum ether. The resulting precipitate is dissolved in a little toluene and hydrolyzed with methanol, to give 10 g (90 % yield) of 3-(tribenzoylribofuranosyl)uric acid. This is filtered off and redissolved in 200 ml of methanol. Ammonia is passed in until the solution is saturated, and the latter is left standing for 2 days at 20 °C. The solvent is then removed and the 3-ribofuranosyluric acid *(38)* is recrystallized from methanol. The yield is quantitative; the product decomposes at 220 °C.

7. *Trimethylsilyl β-Bromopropionate (40)* [39]

β-Bromopropionic acid (0.22 mole) in 100 ml of benzene is placed in a flask fitted with a reflux condenser and a dropping funnel, and 0.23 mole of trimethylchlorosilane *(3)* is added. A solution of 0.23 mole of triethylamine in 50 ml of benzene is added dropwise to this mixture. After heating on the water bath for 2–3 h with stirring, triethylamine hydrochloride is filtered off, the benzene is removed, and the ester *(40)* is distilled (b.p. 85.7 °C/13 mm; yield 66 %).

8. *β-Propiolactone (42)*

A suspension of 50 g of AgNCO in 30 ml of toluene is heated with stirring in an oil bath at 130–140 °C, and 68 g of *(40)* are added dropwise. After heating and stirring for a further hour,

[81] *L. Birkofer, A. Ritter*, and *P. Neuhausen*, Liebigs Ann. Chem. *659*, 190 (1962).

the AgBr formed is filtered off and the filtrate is distilled at normal pressure. Trimethylsilyl isocyanate *(44)* and toluene distil over, and fractionation of the residue gives 11 g (or 50 %) of *(42)*, b.p. 56 °C/14 mm. It is not advisable to replace the silver cyanate by silver perchlorate and to isolate the resulting trimethylsilyl perchlorate, owing to the danger of explosions (cf. Section II.6.).

9. *Ethyl β-Trimethylsiloxy-β-(p-nitrophenyl)-propionate (55)* [45]

A mixture containing 22.7 g of *p*-nitrobenzaldehyde, 30 g of ethyl trimethylsilylacetate *(48)* and 330 mg of $KAl(OCH_3)_4$ as catalyst is heated under reflux for 9 h at 160–180 °C in an oil-bath in the absence of moisture. The catalyst is filtered off, and the filtrate is fractionated using a spinning-band column. An 81 % yield (37.6 g) of *(55)*, b.p. 126 °C/0.1 mm, is obtained; recrystallization from ethanol/water furnishes yellow crystals melting at 44 °C.

10. *Trimethylsilyl Azide (77)* [53]

Sodium azide (9.8 g) and 16.3 g of trimethylchlorosilane *(3)* in 75 ml of tetrahydrofuran are refluxed with stirring for 48 h. The solution is filtered to remove NaCl and distilled at normal pressure in a spinning-band column to give an 87 % yield of *(77)*, b.p. 95 °C.

11. *Triphenylphosphine N-Trimethylsilylimine (82)* [53]

When 6.9 g of *(77)* is heated with 14.5 g of triphenylphosphine, vigorous evolution of nitrogen occurs at a bath temperature of 110 °C. As the temperature is raised gradually to 140 °C over a period of 4 h, 1320 ml of nitrogen is liberated. On distillation of the reaction mixture, *(82)* distils over at 170–171 °C/0.06 mm. The yield is 18.7 g (97 %). Compound *(82)* recrystallizes from acetonitrile to give colorless crystals, m.p. 76–77 °C.

12. *Triphenylphosphinimine (83)* [62]

Compound *(82)* (17.5 g) is mixed with two-thirds of a solution of 3 drops of concentrated sulfuric acid in 50 ml of absolute isopropanol in a 100-ml two-necked flask fitted with a dropping funnel and a column with a descending condenser. The solution is heated to boiling, and the remaining isopropanol solution is added dropwise at the same rate as the isopropoxytrimethysilane *(84)* (b.p. 75 °C) formed distils off. When *(84)* has distilled over completely (after about 1 h), excess isopropanol is removed *in vacuo*. Absolute petroleum ether (b.p. 40–70 °C) (40 ml) is added, and *(83)* precipitates out in crystalline form. Recrystallization from cyclohexane gives colorless plates, m.p. 127.5 °C; the yield is 14.8 g (85 %).

13. *2,6-Bis-O-trimethylsilyl-4,5-bis(trimethylsilylamino)uracil (91)* [8]

4,5-Diaminouracil (10 g) is refluxed for 2 h with 30 g hexamethyldisilazane *(99)* containing 2 drops of sulfuric acid. Fractional distillation gives a 90 % yield (29 g) of *(91)*, b.p. 105 °C/10^{-4} mm, which solidifies to give needles, m.p. 60 °C.

14. *Tetrakistrimethylsilyluric Acid (21)* [8]

Triethylamine (8.5 g) is added to 16.5 g of *(91)* in 100 ml of toluene, and the mixture is cooled to 0 °C. Phosgene (4 g) in 50 ml of toluene is added dropwise with stirring. After a few hours, the triethylammoniumchloride formed is filtered off, and the solution is fractionated. Distillation gives an 80 % yield (14.0 g) of *(21)*, b.p. 135–140 °C/0.02 mm. Recrystallization from acetonitrile gives needles, m.p. 114 °C.

15. *Uric Acid*

Trituration of *(21)* with ethanol gives a quantitative yield of uric acid.

16. *Pentakis-O-trimethylsilylglucose* [4]

D-Glucose (10 mmoles) is mixed with 70 mmoles of *N*-trimethylsilylacetamide *(92)*, and the mixture is heated for 15 min at 180 °C. Acetamide and excess *(92)* are removed by vacuum distillation. On fractionation, pentakis-*O*-trimethylsilylglucose distils over at 115 °C/0.08 mm in 98 % yield.

17. *1,2,3,4-Tetrakis-O-trimethylsilylglucose (95)* [4]

D-Glucose (50 mmoles) and 220 mmoles of *(92)* are dissolved in 100 ml of pyridine and boiled for 2.5 h. The pyridine and acetamide are distilled off, and the residue is fractionated to give a 73 % yield of *(95)*, b.p. 117 °C/0.01 mm.

18. *Trimethylsilyl Ester of N-Trimethylsilyl-L-leucine* [3, 7, 72]

L-Leucine (10 g) is heated in 45 g of refluxing hexamethyldisilazane *(99)* containing 2 drops of concentrated sulfuric acid (bath temperature 130–140 °C) until dissolved, and is then boiled for further 30 min. After cooling, 150 ml of benzene, 2.6 g of triethylamine, and 2.7 g of trimethylchlorosilane *(3)* are added and the mixture is allowed to stand at room temperature for 12 h. The precipitate is filtered off. On distillation of the filtrate at 12 mm, the excess *(99)* comes off first, followed by the ester. A 92 % yield (19.5 g) of the trimethylsilyl ester of *N*-trimethylsilyl-L-leucine, b.p. 104 °C/12 mm, is obtained.

19. *Peptide Syntheses*

a) *By the Phosphorus Oxychloride Method* [75]

A solution of 0.02 mole of *N*-carbobenzoxyglycine in 100 ml of tetrahydrofuran is cooled to −15 °C. A solution of 0.02 mole (1.84 ml) of pure phosphorus oxychloride in 10 ml of tetrahydrofuran is added dropwise with stirring. Next 0.02 mole (2.8 ml) of triethylamine is added; this is followed by dropwise addition of a solution of 0.02 mole of the trimethylsilyl ester of *N*-trimethylsilyl-DL-leucine and 0.02 mole of triethylamine in 20 ml of tetrahydrofuran, the rate of addition being adjusted so that the temperature does not exceed −10 °C. Stirring is continued for further 5–10 min. The reaction mixture is kept for 2 h at −10 °C, and the product is hydrolyzed by dropwise addition with stirring of 50 ml of water. On removal of the tetrahydrofuran at room temperature (12 mm) *N*-carbobenzoxyglycyl-DL-leucine precipitates out. After recrystallization from methanol/water, the product melts at 127 °C (yield = 85 %).

b) *By the Imidazolide Method* [81]

N-Carbobenzoxy-DL-valine (0.01 mole) and 1.75 g of *N,N'*-carbonyldiimidazole *(6)* are dissolved in 100 ml of tetrahydrofuran and heated at 50 °C for 1 h. After dropwise addition of 0.011 mole of the trimethylsilyl ester of *N*-trimethylsilylglycyl-β-alanine to the cooled solution, the mixture is refluxed for 3 h, and the tetrahydrofuran is then distilled off at 11 mm. The residue is decomposed with 40 ml of water, the hexamethyldisiloxane is removed, and the aqueous filtrate is

acidified to Congo red with 6 N HCl. The *N*-carbobenzoxy-DL-valylglycyl-β-alanine precipitates as crystals in 87 % yield. Recrystallization from water gives clusters of needles, m.p. 175 °C.

c) *By the Ethyl Chloroformate Method* [81]

N-Carbobenzoxy-Gly-Gly-Gly-β-Ala (0.01 mole) and 0.01 mole (1.4 ml) of triethylamine are dissolved in 100 ml of a 1:1 mixture of tetrahydrofuran and dimethyl sulfoxide. The solution is cooled to −5 °C, and 0.01 mole (0.96 ml) of ethyl chloroformate in 15 ml of tetrahydrofuran is added dropwise with stirring. Stirring is continued for further 30 min at this temperature, and 0.012 mole of the trimethylsilyl ester of *N*-trimethylsilyl-Gly-Gly-β-Ala in 30 ml of tetrahydrofuran is then added. The mixture is stirred for 90 min at −5 °C and then for 90 min at room temperature and finally boiled for a short time. The tetrahydrofuran is evaporated off at 12 mm on a water-bath at 40 °C, and then the dimethyl sulfoxide at 0.1 mm. The residue is hydrolyzed by addition of 40 ml of water containing 1 g of $NaHCO_3$. *N*-Carbobenzoxy-Gly-Gly-Gly-β-Ala-Gly-Gly-β-Ala is obtained in 92 % yield; after recrystallization from methanol/water (4:1 v/v), it melts at 276 °C (decomp.).

d) *By the p-Nitrophenyl Ester Method* [80]

The *p*-nitrophenyl ester of *N*-carbobenzoxy-L-proline (29.6 g), 10.1 g of L-proline, and 23 g of *N*-trimethylsilylacetamide *(92)* are fused together at 65 °C on a water-bath and heated with stirring for further 6 h. After cooling, 100 ml of saturated $KHCO_3$ solution are added, and the solution is extracted with three 40-ml portions of acetic acid/ether (1:2). After removal of the remaining organic solvent at 12 mm, the aqueous solution is filtered through active charcoal and acidified to pH 2 with 18 % HCl. Carbobenzoxyprolylproline precipitates as crystals, which recrystallize from methanol/water to give 25 g (90 % yield) of a product with m.p. 190 °C; $[\alpha]_D^{27} = -103° \pm 1$ (c = 1 in methanol).

Photocatalysed Cycloaddition of Dihalogenomaleimides and Dihalogenomaleic Anhydrides onto Olefins and Acetylenes [1]

By Dr. H.-D. Scharf and Prof. Dr. F. Korte

Shell Grundlagenforschung-Gesellschaft m.b.H.,
Schloß Birlinghoven, Siegkreis (Germany)

Dedicated to Professor Rudolf Tschesche on the occasion of his 60th birthday

The imides and anhydrides of dichloro- and dibromomaleic acids *(1)* can be added photochemically onto C—C double and triple bonds to form C_4 rings in good yields. The reactions proceed on irradiation of 2 moles of olefin or acetylene and 1 mole of *(1)* in dioxane with light of 302–313 mμ wavelength. Whereas the reactions with *(1)*, Z = Cl and X = O, only go to completion in the presence of benzophenone [**] as sensitizer, reactions with *(1)*, Z = Cl or Br and X = NH, are only slightly promoted by benzophenone.

The imide adducts can be obtained in crystalline form by evaporation of the solvent after irradiation. Purification by chromatography on SiO_2 was occasionally necessary. The anhydride adducts were isolated in the form of *cis*-cyclobutane-1,2-dicarboxylic acids, which are easier to handle and which can subsequently be reconverted into the anhydrides with thionyl chloride.

The method has been used to prepare the following compounds:

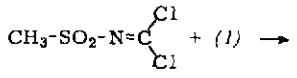
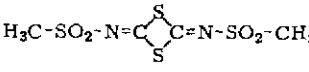
The reaction is exothermal and is conducted with suspensions of the anhydrous salts *(1)* in inert solvents (dichloromethane, benzene, or carbon tetrachloride) with cooling. The products *(2)* usually can be purified by distillation after removal of the potassium chloride by suction filtration and evaporation of the solvent.

Instead of phosgene, 2 moles of ethyl chloroformate [here ethyl pyrothiocarbonate is formed alongside *(2)*], phosphorus pentachloride, or less advantageously even thionyl or sulfuryl chloride can be used.

The *N*-sulfonyl isothiocyanates *(2)* are highly reactive acylating agents and react smoothly at room temperature with NH, alcoholic OH, or SH groups. Phenolic hydroxyl groups require longer reaction times or catalysis with tertiary amines.

Some *N*-sulfonyl isothiocyanates, *e.g. (2a)*, *(2j)*, and especially *(2i)*, tend to dimerize on standing. The structures *(3)* of the dimers were inferred from their formation from sulfonyl isocyanide dichlorides and *(1)*.





(3)

Compounds of type *(3)* dissociate completely into 2 moles of *(2)* on heating above their melting points.

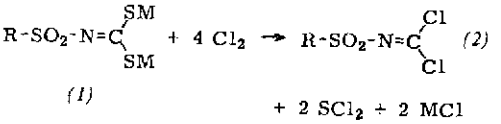
Sulfonyl Isocyanide Dichlorides and Sulfonyl Carbodiimides [1]

By Dr. B. Anders and Dr. E. Kühle

Wissenschaftliches Hauptlaboratorium
der Farbenfabriken Bayer AG., Leverkusen (Germany)

Sulfonyl isocyanide dichlorides *(2)* are obtained in good yields on chlorination of salts of *N*-(dithiomethylene)sulfonamides [sulfonylimides of dithiocarbonates] *(1)*, M = K.



(1) *(2)*

$$+ 2\,SCl_2 + 2\,MCl$$

(2), R =	M.p. [°C]	Yield [%] after recrystallization
CH_3	76–78	73
$Cl\text{-}C_6H_5$	75–77	52
$CH_3\text{-}C_6H_5$	80–85	89

The salt is suspended in a solvent resistant to chlorine, *e.g.* carbon tetrachloride, the equivalent amount of Cl_2 is passed in, keeping the temperature at about 25 °C by cooling with ice. The potassium chloride formed is filtered off. After evaporation of the solvent, the sulfonyl isocyanide dichlorides *(2)* are obtained as crystalline or oily residues which can be crystallized from hydrocarbons.

The infrared spectra of *(2)* contain the C=N band at 1650 cm^{-1} (alkyl or aryl isocyanide dichlorides: 1600–1610 cm^{-1}). The presence of the sulfonyl group in *(2)* makes these compounds much more reactive than alkyl or aryl isocyanide dichlorides [2].

N-Sulfonylcarbodiimides *(3)*, a group of compounds recently described [3], are obtained in very good yields (often 95 to 100 %) when sulfonyl isocyanide dichlorides *(2)* are heated to 100–140 °C with hydrochlorides of primary amines in inert solvents (*e.g.* toluene). The *N*-sulfonylcarbodiimides *(3)* are obtained in the form of crystals or oils. They are often

$$(2) + R'\text{-}NH_2\text{·}HCl \rightarrow R\text{-}SO_2\text{-}N{=}C{=}N\text{-}R' + 3\,HCl$$
(3)

quite stable, but some tend to polymerize. They add on water very rapidly, even without addition of acids, to form *N*-sulfonylureas. For example, after about 4 min in water/dioxane (7:3), *N*-cyclohexyl-*N'*-tosylcarbodiimide is converted to about 50 % into the corresponding urea derivative.

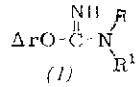
On the Addition of Amines to Cyanic Esters

By Dr. E. Grigat and Dr. R. Pütter

Wissenschaftliches Laboratorium der Zwischenproduktenabteilung der Farbenfabriken Bayer AG, Leverkusen (Germany)

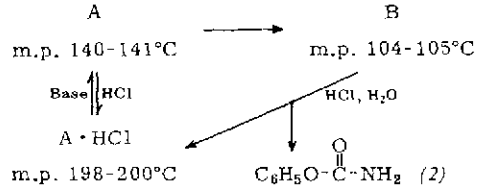
Martin et al. [1] recently reported on the formation of isoureas *(1)* from phenyl cyanate and amines. For the product *(1a)*, which we had described previously [2], they obtained a

melting point of 104–105 °C, which differs considerably from our value (140–141 °C) [3].



(1) *(1a)*, R = H, R^1 = C_6H_5, Ar = C_6H_5

We therefore carried out both syntheses and found that the product obtained by the procedure of *Martin* et al. (substance B) is composed of two moles of phenyl cyanate and one mole of aniline, whereas our method gave a mole ratio of 1:1 (substance A). Substance A can be converted into substance B with phenyl cyanate, and on treatment of B with aqueous HCl, the hydrochloride of A and phenyl carbamide *(2)* are obtained.



This proves that the compound with m.p. 140–141 °C is the iso-urea *(1a)*. The formation of the 2:1 adduct by the procedure of *Martin* et al. [1] confirms our observation [2] that free primary amines (in contrast to their salts) add on 2 moles of cyanic ester with the formation of iminobiscarbamidic esters.

Ammoniates of Uranium Trichloride and Tetrachloride

By Priv.-Doz. Dr. H. J. Berthold and Dr. H. Knecht

Institut für Anorganische Chemie und Kernchemie der Universität Mainz (Germany)

UCl_3 and UCl_4 react with gaseous ammonia at room temperature and with liquid ammonia at ≤ -34 °C to form ammoniates with the compositions $UCl_3 \cdot (6.8–6.9)NH_3$ and $UCl_4 \cdot (7.3–7.5)NH_3$ at 22–23 °C and 760–790 mm. If the reaction is conducted in liquid ammonia under pressure at room temperature and the excess ammonia is subsequently allowed to evaporate, UCl_3 gives the same ammoniate, but UCl_4 then binds 9–10 moles of NH_3.

In liquid ammonia, in addition to ammoniate formation, a small amount of ammonolysis also occurs, detectable from the reduction in chlorine content to 2.8 with UCl_3 and to 3.5 with UCl_4.

Isothermal decomposition of the ammoniates in a stream of nitrogen (70 ml/min) at ca. 20 °C leads to $UCl_3 \cdot 3NH_3$ and $UCl_4 \cdot 4NH_3$, which are both stable up to approximately 45 °C. Decomposition at higher temperatures leads without detectable intermediates to $UCl_3 \cdot NH_3$ and $UCl_4 \cdot NH_3$. These two ammoniates are stable up to about 300 °C. They decompose above 350 °C with partial ammonolysis.

With the exception of $UCl_4 \cdot NH_3$, all the ammoniates are crystalline and have characteristic X-ray diagrams. Ammoniates claimed to be stable above room temperature, namely $UCl_4 \cdot 12NH_3$, $UCl_4 \cdot 8NH_3$ [2], $UCl_4 \cdot 5NH_3$ [3], $UCl_4 \cdot 3NH_3$ [1,3], and $UCl_4 \cdot 2NH_3$ [4], could not be detected.

The higher ammoniates of uranium(III) and uranium(IV) chlorides absorb gaseous carbon dioxide with great rapidity; the CO_2 reacts with part of the bonded ammonia to form ammonium carbamate, which does not occur as a separate phase but is built into the lattices of the higher ammoniates without significant alterations of their spacious structures.

Comparison of these ammoniate-carbamates with the ammoniates obtained on pyrolysis reveals that only that portion of the ammonia reacts with CO_2 which is readily released at room temperature, and which is apparently only loosely bound inside the large hollows of the ammoniate lattices.

Consequently, by analogy to compounds containing water of crystallization, it seems as though a distinction must be made with ammoniates between "structural ammonia" and "coordinated ammonia". Since the coordinatively bonded ammonia ought not to react with carbon dioxide, the reaction of ammoniates with carbon dioxide should provide a means for differentiating between structural and coordinated ammonia.

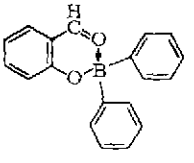
Benzoboradioxacyclohexadienes and Benzoazaboraoxacyclohexadienes

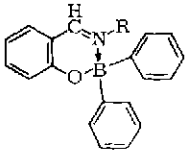
By Prof. Dr. F. Umland and Dipl.-Chem. C. Schleyerbach

Anorganisch-Chemisches Institut der Universität Münster
and
Institut für Anorganische Chemie der Technischen Hochschule Hannover (Germany)

The reaction of equimolar amounts of salicylaldehyde and diphenylborinic acid or its anhydride (tetraphenyldiboron oxide) leads to 3,3-diphenyl-3-bora-2,4-dioxabenzocyclohexa-1,5-diene *(1)*, which has the same basic skeleton as a complex prepared from acetophenone and boron trifluoride by *Kästner* [1].



(1)



(2)

When the reaction is conducted in the presence of amines or, preferably, when azomethine derivatives of salicylaldehyde are condensed with diphenylborinic acid, derivatives of the hitherto unknown ring system 3,3-diphenyl-2-aza-3-bora-4-oxabenzocyclohexa-1,5-diene *(2)* are formed.

	R	M.p. [°C]	UV [mμ] [a]	ε × 10⁻³	Color of solid
(1)	—	151	M 236	13.0	bright yellow
			M 325	2.7	
			S 370	1.0	
(2a)	H—	193	M 280	8.0	pale yellow
			M 375	2.5	
(2b)	HO—	157	M 259	10.0	white
			M 305	3.0	
(2c)	C_3H_7—	103	M 239	11.0	pale yellow

(2f)	C_6H_5—	154	M 269	10.0	ochre yellow
			M 337	8.0	
(2g)	o-HOC_6H_4—	159	M 355	9.5	lemon yellow
			M 418	9.5	

[a] In methanol; M = maximum, S = shoulder.

Equimolar amounts of the azomethines and tetraphenyldiboron oxide were dissolved separately in ethanol or ethanol/benzene (1:1 v/v), and the solutions were mixed and boiled briefly. The products crystallize out on cooling, generally in yields of about 70%, and can be recrystallized from ethanol/benzene (about 1:1). They melt without decomposition and are stable in air, in the solid state and in solution, even in neutral or weakly acidic aqueous solutions. They are decomposed by aqueous alkalies.

If the azomethines of salicylaldehyde obtained with aniline or *o*-aminophenol are treated with Flavognost® (β-aminoethyl diphenylborinate) instead of with tetraphenyldiboron oxide, then *(2e)* is formed instead of *(2f)* or *(2g)*.

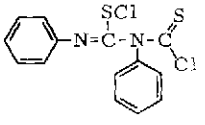
Synthesis of N-Phenyl-S-chloroisothiocarbamoyl Chlorides by Chlorination of Isothiocyanates [*]

By Dr. G. Ottmann and H. Hooks, Jr.

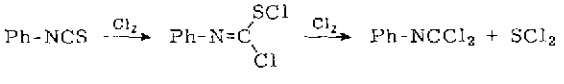
Olin Mathieson Chemical Corporation, Chemicals Division, New Haven, Conn. (U. S. A.)

During the preparation of phenyl isocyanide dichloride from the corresponding isothiocyanate and chlorine, *Helmers* [1] isolated an unstable adduct, to which *Dyson* and *Harrington*[2] assigned the structure *(1)*.



(1)

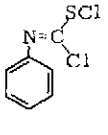
We have now found that the first step of the chlorination of phenyl isothiocyanates consists of the addition of one mole of chlorine onto one isothiocyanato group to form *N*-phenyl-*S*-chloroisothiocarbamoyl chlorides *(2)*, a hitherto unknown class of compounds. The compound *(1)* is merely a by-product formed in a side reaction.



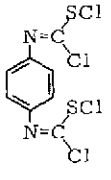
(2)

N-Phenyl-*S*-chloroisothiocarbamoyl chlorides *(2)* can be prepared in a pure state and in high yields by treating aromatic isothiocyanates in an indifferent solvent at 0–10 °C with one mole of chlorine per –NCS group. The solid representatives can be purified by recrystallization from pentane or hexane.

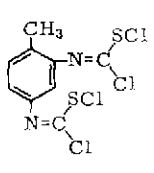
We have prepared the following derivatives: *N*-phenyl-*S*-chloroisothiocarbamoyl chloride *(3)* [yellow oil, $n_D^{24} = 1.6291$; 91.5% yield], *N,N'*-phenylene-1,4-bis-(*S*-chloroisothiocarbamoyl chloride) *(4)* [yellow crystals, m.p. 82–83 °C; 97.8%], and *N,N'*-toluylene-2,4-bis-(*S*-chloroisothiocarbamoyl chloride) *(5)* [yellow crystals, m.p. 75–75.5 °C; 65%].



(3)



(4)



(5)

Their structures are supported by combustion analysis, molecular weight determination, infrared and NMR spectroscopy, and by their chemical reactions which will be the subject of forthcoming publications. The *N*-phenyl-*S*-chloroisothio-

carbamoyl chlorides are sensitive to moisture and heat but remain unchanged for a long time when stored in a pure state below 0 °C in a completely dry nitrogen atmosphere.

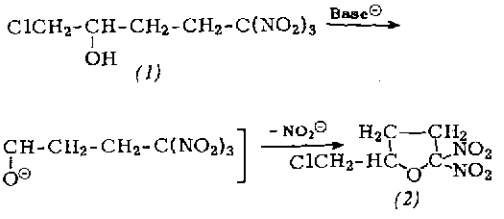
Synthesis of 5-Chloromethyl-2,2-dinitrotetrahydrofuran

By Dr. E. Steininger

Battelle Institut, Frankfurt/Main (Germany)

The reaction of 1-chloro-5,5,5-trinitropentan-2-ol *(1)* with triethylamine, sodium hydrogen carbonate, potassium hydroxide, or preferably sodium t-butoxide or sodium hydroxide in ether at 0 °C does not lead as expected to 1,2-epoxy-5,5,5-trinitropentane, but instead to 5-chloromethyl-2,2-dinitrotetrahydrofuran *(2)*. The yield is up to 86 %.



The starting material *(1)* is obtained in 90 % yield by reduction of 1-chloro-5,5,5-trinitropentan-2-one *(3)* with sodium borohydride in methanol, while *(3)* is produced in 85 % yield by addition of nitroform $CH(NO_2)_3$ onto chloromethyl vinyl ketone.

The structure of *(2)*, b.p. 104–105 °C/0.01 mm, $n_D^{20} = 1.4893$, was proved by elemental analysis and infrared and NMR spectroscopy (proton signals in ratios of 1:2:2:2 at 5.1, 3.9, 2.4, and 3.2 ppm).

This reaction appears to be the first example of the cyclization of a nitro compound by elimination of a nitrite ion.

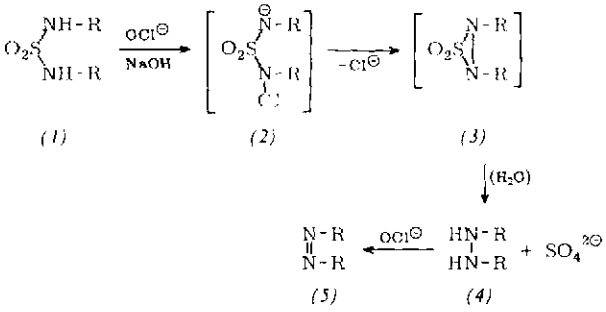
Preparation of Azo Compounds from N,N'-Dialkylsulfamides

By Dr. R. Ohme and Prof. Dr. Ernst Schmitz

Institut für Organische Chemie der Deutschen Akademie der Wissenschaften, Berlin-Adlershof (Germany)

We have found that *N,N'*-dialkylsulfamides *(1)* react in 1 N alkaline solution with sodium hypochlorite in a molar ratio of 1:2 at 20–60 °C to form aliphatic azo compounds *(5)*, *e.g.* azopropane *(5a)*, azo-n-butane *(5b)*, and azocyclohexane *(5c)* in yields of 100, 54, and 80 % respectively.

Cross experiments indicated that the reaction proceeds intramolecularly *via* the *N*-chloro anion *(2)* and the cyclic compound *(3)*: if a mixture of *N,N'*-dipropylsulfamide [1] and *N,N'*-di-n-butylsulfamide is subjected to the reaction, only azo-n-propane *(5a)* and azo-n-butane *(5b)* are obtained, none of the mixed azo compound $C_3H_7-N=N-C_4H_9$ being



formed. The isolation of di-n-propylhydrazine (m.p. of dihydrochloride 172 °C) in 50 % yield when insufficient hypochlorite was taken forms evidence for the intermediate occurrence of *N,N'*-dialkylhydrazines.

The azo compounds *(5a)* and *(5b)* were shown by gas chromatography to be identical with products obtained from *N,N'*-dialkylhydrazines by oxidation with hypochlorite; *(5c)*, m.p. 33 °C, was identified by comparing its infrared spectrum with that of a sample prepared according to [2]. The azo compounds *(5a)–(5c)* were rearranged by acids to alkylhydrazones [3], which were then hydrolysed to the parent carbonyl compounds and alkylhydrazines. Identification of the alkylhydrazines was accomplished by treatment with potassium cyanate [4] and precipitation of the 2-alkylsemicarbazides with *p*-nitrobenzaldehyde.

High-Temperature Ammonolysis of Uranium Trichloride and Tetrachloride

By Priv.-Doz. Dr. H. J. Berthold and Dr. H. Knecht

Institut für Anorganische Chemie und Kernchemie der Universität Mainz (Germany)

UCl_3 and UCl_4 undergo ammonolysis above 350 °C. Between 450 and 500 °C, UCl_3 gives rise to NH_4Cl and a mixture of amorphous amido-compounds [UNH_2Cl_2 plus $U(NH_2)_2Cl$]. At higher temperatures the latter are transformed *via* crystalline uranium imidochloride, U(NH)Cl, into uranium nitride with the composition $UN_{1.73-1.75}$. The uranium mononitride, UN, expected as a final product of the ammonolysis, is not formed. 1 g of UCl_3 is completely ammonolized after 15 min. at 800 °C.

UCl_4 reacts with ammonia at about 450 °C to form amorphous uranium(IV) amidotrichloride UNH_2Cl_3. At about 475 °C, this compound is reduced to crystalline UCl_3, which was detected analytically and by its X-ray diffraction pattern. The ammonolysis then continues as for UCl_3. Attention was first called to a reduction of UCl_4 to UCl_3 by NH_3 at higher temperatures by *Rammelsberg* [1].

U(NH)Cl obtained by various routes between 500 and 550 °C crystallizes in a PbFCl layer lattice (space group D_{4h}^7-P4/nmm) with two molecules in the tetragonal unit cell. The lattice constants are $a = 3.972 \pm 0.005$ Å and $c = 6.810 \pm 0.010$ Å. Intensity calculations gave the parameter $u = 0.168 \pm 0.002$ for uranium and the parameter $v = 0.63 \pm 0.01$ for chlorine. The distance between the $NH^{2\ominus}$ anions (2.809 Å) is remarkably short and suggests the occurrence of hydrogen bridges between the $NH^{2\ominus}$ ion layers. Other nearest neighbors are $U^{3\oplus}$–4 $NH^{2\ominus}$ = 2.292 Å, $U^{3\oplus}$–4 $Cl^{\ominus}$ = 3.127 Å, $U^{3\oplus}$–$Cl^{\ominus}$ = 3.146 Å. The chlorine-chlorine distance between neighboring layers is 3.32 Å.

Powder photographs of the chlorine-free nitrides $UN_{1.73\ 1.75}$ reveal only lines due to a face-centered cubic lattice such as occurs in UN_2 (CaF_2-type structure) [2]. The lattice constants correspond to those of nitrides of the same composition obtained by the reaction either of finely divided uranium (prepared from UH_3) with nitrogen at 350 °C or of UH_3 with ammonia at 250 °C. Measurements with a diffractometer gave a lattice constant of a = 5.287 ± 0.002 Å. The weak lines reported for nitrides of composition up to $UN_{1.75}$ [2], which require a body-centered cubic unit cell with doubled lattice constant (phase of $UN_{1.5} = U_2N_3$ crystallizing with the α-Mn_2O_3-type structure), were not observed.

Sensitivity of Pyrimidines and Purines towards Neutron Irradiation

By Prof. Dr. A. Wacker and P. Chandra

Institut für Therapeutische Biochemie
der Universität Frankfurt/Main (Germany)

Pyrimidines are much more sensitive towards X-rays than purines, among which adenine exhibits the highest resistance [1]. On the other hand, when aqueous solutions of pyrimidines and purines are irradiated with thermal neutrons, the bases are decomposed to an extent directly proportional to their nitrogen content – here the purines are more labile, and adenine is most extensively destroyed.

Base [a]	Reduction [%] of the UV extinction of the bases at λ_{max} following irradiation with neutron doses of				Nitrogen content of the bases [%]
	0.18×10^{14} n	0.54×10^{14} n	1.62×10^{14} n	2.7×10^{14} n

Azaguanine	22		53		55.0
Adenine		75		97	51.8

Polynucleotide [b]	Amino acid	Inhibition [%] of the incorporation of the amino acid into a polypeptide after irradiation of the polynucleotide with a neutron dose of			
		1.8×10^{13} n	3.6×10^{13} n	7.2×10^{13} n	16.2×10^{13} n
Poly(uridylic acid)	Phenylalanine	18	(10) [c]	38	(12) [c]
Poly(cytidylic acid)	Proline	17	53 (12)		(17)
Poly(adenylic acid)	Lysine	42	75 (27)		(36)

[a] Concentration of base = 50 µg/ml in water at pH 5.6 in a quartz tube; neutron flux = 3.0×10^{11} n/cm²/sec.

[b] Concentration of polynucleotide during irradiation = 1 mg/ml, during protein synthesis = 80 µg of poly-U per ml, 350 µg of poly-C per ml, and 120 µg of poly-A per ml. The incorporation of the amino acids was determined according to [2].

[c] The figures in parentheses indicate the decrease [%] in the ultraviolet optical density of the polynucleotides at λ_{max} in water at pH 5.6.

Whereas the destructive action of X-rays is probably due to the formation of oxygen-containing free radicals, that of the neutrons is proabably due to the nuclear reaction $^{14}N(n,p)^{14}C$.

If the pyrimidines and purines are part of a nucleic acid, they are more resistant to neutrons. However, polynucleotides irradiated with neutrons possess less activity in cell-free protein synthesis [2] than untreated specimens; poly-A is much more labile in this respect than poly-U or poly-C.

Synthesis of 2,5-Dibromo-1,2,4-triazole by Bromination of 1,2,4-Triazole [1]

By Doz. Dr. C.-F. Kröger and Dipl.-Chem. H. Frank

Institut für Organische Chemie
der Universität Greifswald (Germany)

With the exception of the hydroxymethylation with formalin [2], no electrophilic C-substitution of 1,2,4-triazole is known [3]. Moreover, direct halogenation of 1,2,4-triazoles was hitherto considered to be impossible [4].

We have found that, like 1,2,3-triazole [5], 1,2,4-triazole can be brominated even in aqueous solution at room temperature, only one equivalent of bromine being required to lead directly to the dibromo derivative. The yield obtained after treatment with two equivalents of bromine is 24–29 %. The strong acidifying effect of the bromine atoms manifests itself in a pK_a value of 5.23 for 3,5-dibromo-1,2,4-triazole, compared with the value of 10.26 for 1,2,4-triazole.

1,2,4-Triazole (1.4 g or 0.02 mole) is dissolved in 10 ml of water, and 3.2 g (0.02 mole) of bromine is slowly added. At first crystals are formed, but then an oil is deposited from which crystals separate out again after 5–6 h. The solid is filtered off, and the filtrate is treated with further 0.02 mole of bromine. After 2 days, further crops of crystals of the same product can be isolated. The total yield is 1.1 g or 24 %. If the reaction mixture is heated on a water bath right from the start for 24 h or longer, the yield increases to 29 %. 2,5-Dibromo-1,2,4-triazole crystallizes from chloroform as colorless needles, m.p. 211–212 °C.

(1,3,4,6-Tetra-O-acetyl-β-D-glucos-2-yl)-carbodiimides

By Dr. J. C. Jochims

Institut für Chemie, Max-Planck-Institut
für Medizinische Forschung, Heidelberg (Germany)

(1,3,4,6-Tetra-*O*-acetyl-β-D-glucos-2-yl)thioureas [1] can be desulfurized with yellow HgO to give (1,3,4,6-tetra-*O*-acetyl-β-D-glucos-2-yl)carbodiimides, which are very stable compounds that exhibit no mutarotation. Five grams of the thiourea were shaken with 2.5 molar equivalents of HgO [DAB 6 quality, from E. Merck, Darmstadt (Germany)] in 50 ml of chloroform plus 25 ml of carbon disulfide at room temperature until the suspension turned black (often only after 20–30 h). The solution was filtered and the solvent evaporated; the residual syrup was crystallized from ether/petroleum ether [*(1)* from benzene/petroleum ether, *(5)* from ethanol/petroleum ether]. The structures of the carbodiimides were inferred from their infrared spectra and for *(2)* from hydrogenation to the formamidine stage [2].

(1,3,4,6-Tetra-*O*-acetyl-β-D-glucos-2-yl)carbodiimides, R–N=C=N–R'

	R'	M.p. [°C]	$[\alpha]_D^{20}$ [a]	Yield [%]
(1)	1,3,4,6-Tetra-*O*-acetyl-β-D-glucos-2-yl [3]	from 72	25.4°	89
(2)	*p*-Tolyl	62–64	25.7	62
(3)	Cyclohexyl	78–79	17.4	93
(4)	Benzyl	72–73	19.9	88
(5)	9-Fluorenyl	171–172 (decomp.)	9.0	83
(6)	Diphenylmethyl	95–97	11.5	87

[a] c = 1 in dimethylformamide.

Bis-(1,3,4,6-tetra-*O*-acetyl-β-D-glucos-2-yl)carbodiimide *(1)* [3] crystallizes only after standing for several weeks in a refrigerator. It is recovered unchanged after boiling for 12 h in benzene with a molar equivalent of 1,3,4,6-tetra-*O*-acetyl-β-D-glucosamine; no trisubstituted guanidine derivative is formed.

During the formation of *(2)*, *N*-(1,3,4,6-tetra-*O*-acetyl-β-D-glucos-2-yl)-*N'*-(*p*-tolyl)urea is produced as a by-product.

Desulfuration of *N*-cyclohexyl-*N*-hydroxy-*N'*-(1,3,4,6-tetra-*O*-acetyl-β-D-glucos-2-yl)-thiourea [1] afforded a 90 % yield of the carbodiimide *(3)* and elemental sulfur. Carbodiimide *N*-oxide formed as an intermediate appears to oxidize unreacted starting material [4]. *N*-(1,3,4,6-*O*-Tetraacetyl-β-D-glucos-2-yl)-*N''*-phenylthiosemicarbazide cannot be desulfurated with HgO to an aminocarbodiimide.

Proton Activity of the 1,3-Dithiolium System

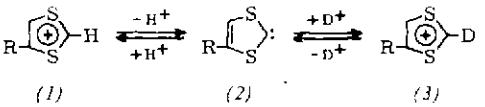
By Doz. Dr. H. Prinzbach, Dipl.-Chem. H. Berger, and Prof. Dr. A. Lüttringhaus

Chemisches Laboratorium
der Universität Freiburg/Breisgau (Germany)

Like their thiazolium [2], oxazolium [3], and imidazolium [4] analogues, 1,3-dithiolium cations *(1)* [1] have a considerable C–H acidity in the 2-position. On determining the half-lives of hydrogen-deuterium exchange by measuring the NMR spectra of *(1)* in 60 % v/v CF_3COOD/D_2O at 34 ± 2 °C we have obtained the following results:

	Concn. [mole/l]	$t_{1/2}$ [min]	$\tau_{H(2)}$ (TMS = 10)
(1a)	1.85	166 ± 15	−1.12
(1b)	0.91	36 ± 5	−1.19
(1c)	0.91	34 ± 5	−1.31

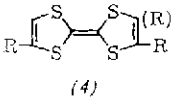
It can be noticed that the half-life decreases with the magnetic shielding of the 2-position. The rate of H/D exchange decreases with increasing activity of the CF_3COOD, parallel with the acid-base equilibrium below.



(1) *(2)* *(3)*

(a), R = CH_3 (ClO_4^-)
(b), R = C_6H_4–OCH_3(p) (HSO_4^-)
(c), R = C_6H_5 (HSO_4^-)

When the acids *(1a)*–*(1c)* are dissolved in acetonitrile and treated at 20 °C with an excess of *N*-ethyldiisopropylamine, the 1,4,5,8-tetrathiafulvalenes *(4a)*–*(4c)* [5] are immediately formed in 30–40 % yields as mixtures of the geometrical isomers.



(4)

(4a): yellow needles from ethanol, m.p. 96–100 °C; λ_{max} in tetrahydrofuran: 453 mμ (ε = 180), 298 (7500); NMR in CS_2: 4.28 τ [2 H, S]; 7.97 τ [6 H, S].

(4b): orange-yellow needles from benzene/ethanol, m.p. 254–256 °C; λ_{max} in tetrahydrofuran: 392 mμ (ε = 5100), 332 (12100); 270 (22700).

(4c): orange-yellow needles from benzene, m.p. 202–206 °C; λ_{max} in tetrahydrofuran: 403 mμ (ε = 2700); 329 (9000); 259 (12100); NMR in CS_2: 3.61 τ [2 H, S]; 2.71 τ [10 H, M]. The mass spectrum of the dimethyl derivative *(4a)* [Hitachi RMU-6A instrument, glass inlet system at 120 °C; 2000 V accelerating voltage, 80 eV electron voltage] contains the peak of the molecular ion (m/e = 232) and in comparable abundance the peak of the dithiacarbene *(2)* (m/e = 116) [6]. To our knowledge, this is the first time that such a carbene has been detected by mass spectrometry.

Nitryl Nitrato Complexes of Indium and Thorium

By Prof. Dr. M. Schmeisser and Dipl.-Chem. G. Köhler

Institut für Anorganische Chemie und Elektrochemie, Technische Hochschule Aachen (Germany)

The synthesis of anhydrous nitrates using chlorine nitrate and chlorides or bromides [1] has been applied to indium halides. On treatment of $InBr_3$ with excess $ClNO_3$ at 20 °C, a quantitative yield of nitryl tetranitratoindate(III) *(1)* was obtained as a white, readily hydrolysable solid:

$$2\,InBr_3 + 10\,ClNO_3 \rightarrow 2\,NO_2[In(NO_3)_4] + 3\,Br_2 + 5\,Cl_2 + O_2$$
(1)

The structure of the complex is supported by the fact that equimolar amounts of *(1)* and $CsNO_3$ react together in anhydrous nitric acid at 20 °C to give a quantitative yield of white crystals of cesium tetranitratoindate(III) *(2)*, which is also very sensitive towards hydrolysis.

$$NO_2[In(NO_3)_4] + CsNO_3 \rightarrow Cs[In(NO_3)_4] + N_2O_5$$
(1) *(2)*

The infrared spectrum of *(2)* does not contain a band for the nitryl cation, which occurs at 2360 cm^{-1} in the spectrum of *(1)* [2], nor the bands characteristic of $CsNO_3$.

Reaction of *(1)* with excess N_2O_4 at 20 °C proceeds quantitatively to white, easily hydrolysable nitrosyl tetranitratoindate(III) *(3)*:

$$NO_2[In(NO_3)_4] + N_2O_4 \rightarrow NO[In(NO_3)_4] + N_2O_5$$
(1) *(3)*

Instead of the band of the nitryl cation at 2360 cm^{-1}, the infrared spectrum of *(3)* contains a band due to the nitrosyl cation [3] at 2270 cm^{-1}.

At 135 °C in a high vacuum, compound *(1)* gives a clear, volatile, colorless melt, with partial decomposition to white, easily hydrolysable crystals of indium oxide nitrate *(4)*:

$$NO_2[In(NO_3)_4] \rightarrow InONO_3 + 2\,N_2O_4 + O_2$$
(1) *(4)*

Compound *(3)* decomposes at 90 °C to white, readily hydrolysable indium nitrate *(5)*:

$$NO[In(NO_3)_4] \rightarrow In(NO_3)_3 + N_2O_4$$
(3) *(5)*

The infrared spectra of compounds *(1)–(3)* and *(5)* contain bands characteristic of covalent nitrates with $-ONO_2$ groupings [4].

By analogy to the preparation of the new indium compounds, the following thorium compounds were obtained:

$$ThCl_4 + 8\,ClNO_3 \xrightarrow[-O_2]{-6\,Cl_2} (NO_2)_2[Th(NO_3)_6]$$
(6), white, readily hydrolysable

$$(NO_2)_2[Th(NO_3)_6] + 2\,CsNO_3 \xrightarrow{-2\,N_2O_5} Cs_2[Th(NO_3)_6]$$
(6) *(7)*, white, readily hydrolysable

$$(NO_2)_2[Th(NO_3)_6] + 2\,N_2O_4 \xrightarrow{2\,N_2O_5} (NO)_2[Th(NO_3)_6]$$
(6) *(8)*, white, readily hydrolysable

$$2\,(NO_2)_2[Th(NO_3)_6] \xrightarrow[-6\,N_2O_4,\,-3\,O_2]{190\,^\circ C,\ high\ vacuum} 2\,ThO(NO_3)_2$$
(6) *(9)*, white, readily hydrolysable

$$(NO_2)_2[Th(NO_3)_6] \xrightarrow[-2\,N_2O_4]{90\,^\circ C,\ high\ vacuum} Th(NO_3)_4$$
(8) *(10)*, white, readily hydrolysable

The infrared spectra of *(6)–(8)* and *(10)* also contain the bands characteristic of covalently bonded nitrate groups.

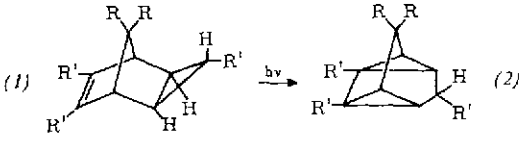
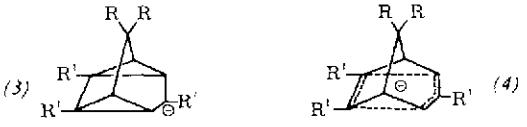
Photochemical Isomerization of the Tricyclo[3,2,1,$0^{2,4}$]octene System – a Homovinylcyclopropane System

By Doz. Dr. H. Prinzbach, Dipl.-Chem. W. Eberbach, and Dipl.-Chem. G. von Veh

Chemisches Laboratorium der Universität Freiburg/Breisgau (Germany)

The *exo*-tricyclo[3,2,1,$0^{2,4}$]octene derivatives *(1a)*, b.p. 136–140 °C/10^{-3} mm, *(1b)*, m.p. 235 °C, *(1c)*, m.p. 80.5 °C, and *(1d)*, m.p. 240–241 °C, can be isomerized photochemically (Hanau Q-81 lamp fitted with a Uviol filter) to the tetracyclo[3,3,0,$0^{2,8}$,$0^{4,6}$]octane compounds *(2a)–(2d)* [1]. Whereas the photoisomerization of the esters *(1a)* [λ_{max} = 230.2 mμ (ε = 6770)] and *(1c)* [λ_{max} = 240.8 mμ (ε = 5170)] [3] produces compounds *(2a)* and *(2c)* in yields of 40 % at the most together with at least three other products, the valence isomerization of the acids *(1b)* [λ_{max} = 254.3 mμ (ε = 6700)] and *(1d)* [λ_{max} = 261.5 mμ (ε = 5330)] [4] proceeds uniformly and in at least 90 % yield [5].





(a), R = H, R' = CO_2CH_3 *(b)*, R = H, R' = CO_2H
(c), R/R = C_2H_4, R' = CO_2CH_3 *(d)*, R/R = C_2H_4, R' = CO_2H

(2a): m.p. 59 °C; IR: no C=C valence vibration bands; UV in ethanol: only terminal absorption (ε_{220} = 440); NMR in CCl_4: 6.25 τ; 6.34 τ [CH_3O; $(CH_3O)_2$]; 7.27 τ [1 H, S]; 7.5–8.5 τ [6 H, M]; molecular weight: 280 (mass spectrum [6]).

(2b): m.p. 228 °C.

(2c): m.p. 92.5 °C; IR: no C=C valence vibration bands; UV in ethanol: only terminal absorption (ε_{220} = 570); NMR in CCl_4: 6.25 τ; 6.31 τ [CH_3O; $(CH_3O)_2$]; 7.05 τ [1 H, S]; 7.98 τ [4 H, AB spectrum; $\delta^A - \delta^B$ = 46.5 cps; J_{AB} = 9.0 cps]; 9.33 τ [4 H, S]; molecular weight: 306 (mass spectrum [6]).

(2d): m.p. 244–245 °C.

The tetracycles *(2a)* and *(2c)* are very stable towards heat; no isomerization or fragmentation is observed up to 250 °C. The mass spectra [6] (CEC Zl-103 C instrument; temperature

of the inlet system 125 °C; temperature of the ion source 250 °C) of the pairs of valence isomers *(1)/(2)* have approximately equal abundances of the various fragments [7]. The carbanion *(3a)* formed from *(2a)* with sodium methoxide reacts with methanol to yield at least four products in proportions of about 68:18:13:1; their structures are at present being investigated.

The carbanion *(3a)* can be formulated as a non-classical bishomocyclopentadienyl anion *(4a)* [8]. Compounds of type *(2)* are therefore representatives of a system which permits the study of such non-classical anions.

Detection of Atomic Sulfur and Phenylphosphinidene (C_6H_5P:) in Solution

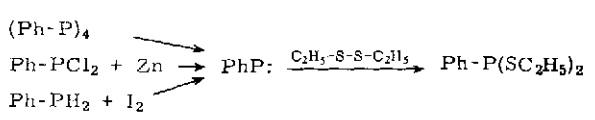
By Prof. Dr. Ulrich Schmidt and cand. chem. Ch. Osterroht

Chemisches Laboratorium
der Universität Freiburg/Breisgau (Germany)

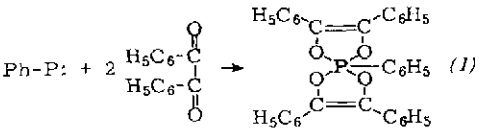
While searching for electronic states of elements of the second group of the periodic table corresponding to those of the carbenes and imenes (nitrenes, azenes), we have succeeded in detecting both atomic (electrophilic) sulfur and phenylphosphinidene (C_6H_5P:) in their solutions.

Atomic sulfur [1] is formed during the photochemical formation of isonitriles [2] from isothiocyanates with light of 254 mμ wavelength and was detected by its addition onto cyclohexene to form cyclohexene episulfide.

Phenylphosphinidene [3] is produced on heating tetraphenylcyclotetraphosphine $(C_6H_5-P)_4$ above 160 °C, or from phenyldichlorophosphine and zinc dust at 25 °C, or on oxidation of phenylphosphine with iodine in the presence of triethylamine. It was trapped by insertion into the $p_\pi-d_\pi$ double bond of disulfides, a reaction leading to phenylphosphonodithioites. This reaction is analogous to the formation of mercaptals on trapping of carbenes with disulfides [4].



Phenylphoshinidene made from phenyldichlorophosphine reacts with benzil to yield the 1,1′-spirobis(phosphadioxole) *(1)*.



Procedure: Nine grams of phenyldichlorophosphine are stirred for 2 h at 25 °C with 10 ml of tetrahydrofuran, 50 ml of diethyl disulfide, and 4 g of zinc dust. After extraction of the reaction mixture with water, distillation of the organic phase yields 7 g of diethyl phenylphosphonodithioite.

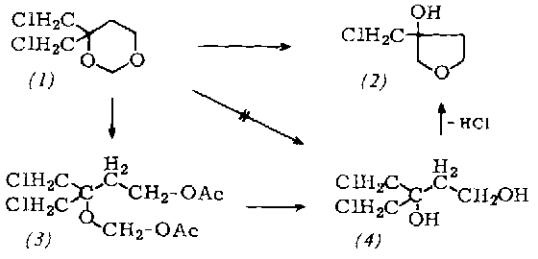
Synthesis and Polymerization of 1,5-Dioxaspiro[2,4]heptane

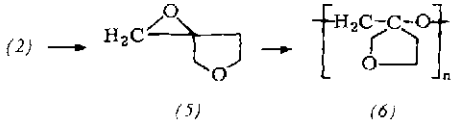
By Dr. E. Steininger

Battelle-Institut Frankfurt/Main (Germany)

On heating 4,4-bis(chlormethyl)-*m*-dioxane *(1)* [1] with 5 % by weight of conc. H_2SO_4 in ethanol in a sealed tube at 120 °C for 5 hours, 3-chlormethyl-3-hydroxytetrahydrofuran *(2)*, b.p. 109,5 °C, $n_D^{20} = 1{,}4868$, is formed in 73 % yield. Another synthesis of *(2)* is the transformation of *(1)* with acetic anhydride [molar ratio 1:7 in the presence of 10 % by weight referred to *(1)* of conc. H_2SO_4, 2 hours at 100 °C, addition of sodium acetate, filtration and distillation] into 3,3-bis(chloromethyl)-1,5-diacetoxy-2-oxapentane *(3)*, b.p. 135 to 137 °C/0.9 mm, yield 83 %. On alcoholysis (refluxing for 12 hours in excess ethanol with addition of small amounts of H_2SO_4) this gives in 76 % yield 4-chloro-3-chloromethylbutane-1,3-diol *(4)*, b.p. 90 °C/10^{-3} mm (molecular distillation), which on heating to 160 °C is quantitatively converted into *(2)*. It was not possible to obtain *(4)* directly from *(1)*.



Treatment of *(2)* with NaOH or sodium t-butoxide (molar ratio 1:1.1) in ether at 20–30 °C gives 1,5-dioxaspiro[2,4]-heptane *(5)*, b.p. 46 % C/14 mm, $n_D^{20} = 1{,}4423$, with a yield of over 80 %. With catalysts conventionally used in epoxide polymerization [*e.g.* $BF_3{\cdot}(C_2H_5)_2O$], *(5)* polymerizes in CH_2Cl_2 to give a polyglycol *(6)*, which is a viscous oil or a low-melting resin, depending on its molecular weight.



The compound *(5)* can also be copolymerized with ethylene oxide or propylene oxide.

Received: March 23rd, 1965 [Z 957/784 IE]
German version: Angew. Chem. 77, 455 (1965)

[1] The compound *(1)* is obtained from 3-chloro-2-chloromethylpropene and formaldehyde (molar ratio 1:3) in 80% H_2SO_4 by a Prins reaction [2] in 68% yield; b.p. 120 °C/12 mm, $n_D^{20} = 1{,}4927$. The byproduct 3-chloro-4-chloromethyl-4-hydroxytetrahydropyran, m.p. 104.5 °C, is formed with a yield of 11%.

Gold Complexes of Cycloalkenes and Cycloalkadienes

By Prof. Dr. R. Hüttel and Dipl.-Chem. H. Dietl

Institut für Organische Chemie
der Universität München (Germany)

Gold complexes of olefins were recently described for the first time [1]. We have found that cyclopentene, cyclohexene, *cis*-cyclooctene, and *trans*-cyclodecene react with aqueous solutions of $HAuCl_4$ or $NaAuCl_4$ or with finely pulverized $HAuCl_4 \cdot 4\,H_2O$ to form gold(I) complexes. These are colorless crystalline substances. When aqueous solutions of the inorganic gold compounds are used, they precipitate only slowly because their formation is preceded by the reduction of Au(III) to Au(I). They decompose at relatively low temperatures, *e.g.* the cyclopentene complex at 55–60 °C, and the cyclooctene complex at 81–85 °C. The olefin evaporates off to a considerable extent from the cyclopentene and cyclohexene complexes even during drying.

Cyclooctenegold(I) chloride is obtained in 74% yield with aqueous solutions of $HAuCl_4$ or in practically quantitative yield from the dry tetrahydrate. It crystallizes in rectangular prisms ($C_8H_{14}AuCl$, molecular weight = 308 by cryoscopy in bromoform). Its infrared spectrum resembles that of $(C_8H_{14}PdCl_2)_2$ [2] and exhibits a characteristic shift of the double-bond absorption of the cyclooctene moiety from 1655 to 1512 cm^{-1}.

Cyclodecenegold(I) chloride ($C_{10}H_{18}AuCl$) separates in 78% yield in the form of needles, m.p. 75–80 °C (decomp.), on shaking an aqueous solution of $HAuCl_4$ with excess olefin. Its molecular weight measured in a vapor pressure osmometer in chloroform is 386.

1,5-Cyclooctadiene reacts immediately with $HAuCl_4$ or $NaAuCl_4$ in water to give a 68% yield of yellow quadratic platelets or cubes of a substance $(C_8H_{12}AuCl)_n$, m.p. 85–90 °C (decomp.), which does not resemble the compound described by *Chalk* [1] in color, melting point, or composition. The compound is so insoluble that its molecular weight could not be determined. On reduction with methanolic sodium hydroxide solution [3], it reaffords 1,5-cyclooctadiene. Here, too, the infrared spectrum contains the double-bond absorption at 1515 cm^{-1}.

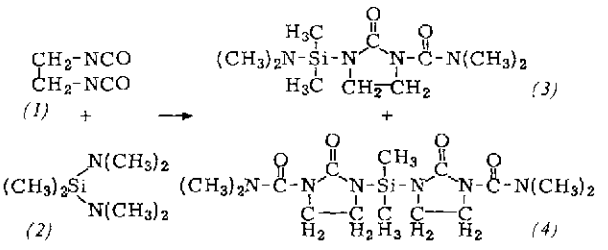
New N-Silylimidazolidinones

By Dr. O. J. Scherer and Prof. Dr. Max Schmidt

Institut für Anorganische Chemie der Universität Marburg (Germany)

Cyclic ureas can be directly silylated [1]. Other *N*-silylimidazolidinones are accessible by ring extension [2]. We have found a simple new route to this little-known class of compounds: ethylene diisocyanate *(1)* reacts with dimethylbis(dimethylamino)silane *(2)* to give 1-dimethylcarbamoyl-3-[dimethyl(dimethylamino)silyl]imidazolidinone *(3)* and dimethylbis(1-dimethylcarbamoyl-2-oxoimidazolidin-3-yl)silane *(4)*.



After slow, dropwise addition of a solution of *(1)* in ether to an etheral solution of the stoichiometric amount of *(2)* at −10 °C and removal of the solvent, *(3)* can be distilled in about 70% yield from *(4)* (yield about 20%); *(3)* has m.p. 67–69 °C, b.p. 108–109 °C/0,1 mm, *(4)* has m.p. 172 to 175 °C. Both compounds crystallize well and are sensitive to solvolysis. They were characterized by analysis and infrared and proton magnetic resonance spectra.

On reversing the order of adding the reagents, *i.e.* on adding *(2)* to *(1)*, only little *(3)* can be isolated, and apart from *(4)* polymers are formed, which have not yet been finally characterized. The relative yields of *(3)*, *(4)*, and polymer depend strongly on the conditions of reaction.

With anhydrous ethanol, *(3)* and *(4)* react quantitatively at room temperature with formation of 1-dimethylcarbamoylimidazolidin-2-one, m.p. 126–128 °C.

The reaction of bis(trimethylsilyl)methylamine with *(1)* is similar to that of *(2)* with *(1)*.

Reaction of Sodium Bistrimethylsilylamide with Carbon Monoxide and Metal Carbonyls [1]

By Prof. Dr. U. Wannagat and Dipl.-Chem. H. Seyffert

Institut für Anorganische Chemie
der Technischen Hochschule Graz (Austria)

Carbon monoxide reacts with sodium bistrimethylsilylamide *(1)* in petroleum ether or benzene at 80 °C and 100 atm to give sodium cyanide and bistrimethylsilyl ether in yields of over 80%. The same products are formed in 95% yield in the reaction of trimethylsilyl cyanide *(2)* and sodium trimethylsiloxide *(3)* in benzene at 80 °C. It is therefore possible that the reaction of *(1)* and CO proceeds *via (2)* and *(3)* as intermediates, *(2)* reacting as trimethylsilyl isocyanide.

$$CO + NaN[Si(CH_3)_3]_2 \rightarrow NaCN + O[Si(CH_3)_3]_2 \leftarrow (CH_3)_3SiCN + NaOSi(CH_3)_3$$
$$(1) \qquad\qquad (2) \qquad (3)$$

The reaction of carbon dioxide with *(1)* rapidly leads *via* several stages to bistrimethylsilylcarbodiimide $(CH_3)_3SiN{=}C{=}N{-}Si(CH_3)_3$, bistrimethylsilyl ether, and NaOCN [2]. Here, trimethylsilyl isocyanate occurs as an intermediate; this was shown by passing CO_2 over molten *(1)* at 200 °C and distilling off the trimethylsilyl isocyanate before it could react with *(1)* or *(3)*, which is also formed as an intermediate.

Both iron pentacarbonyl and nickel tetracarbonyl react vigorously with *(1)*, bistrimethylsilyl ether being produced

together with silicon-free carbonylcyano complexes of nickel and iron, which are decomposed by oxygen or moisture and whose structures have not yet been elucidated. The reaction is suspected to follow the overall equation:

$$M(CO) + NaN[Si(CH_3)_3]_2 \rightarrow [M(CN)]^{\oplus}Na^{\ominus} + O[Si(CH_3)_3]_2$$

M = $(OC)_4Fe$ or $(OC)_3Ni$

This was confirmed indirectly by trapping sodium trimethylsiloxide formed as an intermediate with trimethylchlorosilane (→ sodium chloride and bistrimethylsilyl ether) and by isolating tetracarbonyltrimethylsilylisonitriloiron *(4)*, which proved to be identical with the compound prepared by *Seyferth* [3].

$$(OC)_4Fe{=}C{=}N{-}Si(CH_3)_3 \qquad (4)$$

To our knowledge, the reactions of *(1)* with $Fe(CO)_5$ and $Ni(CO)_4$ are the first reactions of metal carbonyls in which substitution of the carbonyl oxygen occurs without cleavage of the metal-carbon bond. The isolation of *(4)* also implies that trimethylsilyl cyanide reacts in the form of trimethylsilyl isonitrile in the synthesis [3] of *(4)* from $Fe(CO)_5$ and $(CH_3)_3SiCN$ and that, although the latter compound is currently generally formulated as the nitrile, it is at least in equilibrium with the isonitrile form

$$(CH_3)_3Si{-}C{\equiv}N: \rightleftharpoons (CH_3)_3Si{-}\overset{\oplus}{N}{\equiv}\overset{\ominus}{C}:$$

Organocarboranes from Alkyldiboranes

By Dr. R. Köster and Dr. M. A. Grassberger

Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany)

In the preparation of alkali borohydrides MBH_4 from alkyldiboranes and alkali metals [1], organocarboranes are obtained as by-products.

Sodium (2.3 g; 0.1 g-atom) is simmered with tetraethyldiborane (28 g; 0.2 mole) with stirring (1–2 hours). The $NaBH_4$ is filtered off, washed several times with hexane, and the combined filtrate and washings are fractionally distilled. After removal of the solvent and triethylborane, about 1.5 g of a yellow fraction, b.p. 37–49 °C/10^{-3} mm, is obtained, which consists of about 15 % organocarboranes and of organoboranes which are sensitive to oxidation.

The composition of the carboranes here is similar to those obtained in the hydroboration of acetylene [2, 5] and in the pyrolysis of alkyldiboranes [3]. Mainly *C,C*-dimethyl-*B*-ethyl derivatives of the $C_2B_5H_7$ carboranes [2] with molecular weights of 254, 226 and 198 are present. The retention volumes in gas chromatography agree with those of the carboranes prepared by the hydroboration of acetylene. Compounds with molecular weights [4] of 230 and 202, which are alkyl derivates of $C_2B_5H_{11}$ [2], are also found. A carborane with three B atoms (molecular weight [4] 174) with a gas-chromatographic retention volume agreeing with that of 1,5-dimethyl-2,3,4-triethyl-1,5-dicarbaclovopentaborane(5) [5], appears as well.

In the formation of the carboranes from alkyldiboranes, the removal of hydrogen from the borohydrides is thought to be the initial step – in analogy to the dehalogenation of dialkylhaloboranes [6]:

$$2\ (C_2H_5)_2BH + Na \rightarrow (C_2H_5)_2B\cdot + Na[BH_2(C_2H_5)_2]$$

The formation of the B_3C group *via* radical intermediates [6] and all further steps in the synthesis should take place as in the dehalogenation. *C*-Dimethyl-*B*-pentaethyldicarbaclovoheptaborane(7) (with a molecular weight of 254) then results from tetraethyldiborane and sodium according to the equation:

$$44\ (C_2H_5)_2BH + 12\ Na \rightarrow 12\ NaBH_4 + 27\ B(C_2H_5)_3 + C_{14}H_{31}B_5$$

The reaction of alkyldiboranes with lithium is significantly slower than that with sodium. The same carboranes are obtained, but in lower yields. Carboranates could in no case be detected. Whereas the metal borohydrides – as described earlier [1] – are obtained in the pure state, evidently no "colloidal boron" [1] is formed.

Azido Complexes of Manganese(II) and Palladium(II) [1]

By Priv.-Doz. Dr. W. Beck, Dipl.-Chem. K. Feldl, and Dr. E. Schuierer

Anorganisch-Chemisches Laboratorium der Technischen Hochschule München (Germany)

So far only few homogeneous azido compounds of transition elements have been isolated [2]. The reaction of silver azide with $[(C_2H_5)_4N]_2[MnBr_4]$ in acetone has now led to colorless tetraethylammonium tetra-azidomanganate(II) $[(C_2H_5)_4N]_2[Mn(N_3)_4]$. This compound is readily soluble in water and acetone and is not detonated by mechanical shock. In agreement with its tetrahedral structure, the compound shows paramagnetism corresponding to five unpaired electrons, and an asymmetric azide valence vibration ν_3 from the $[Mn(N_3)_4]^{2\ominus}$ anion occurs at 2062 cm^{-1} in the infrared spectrum (solution in acetone).

Tetraphenylarsonium triazidopalladate(II) $[(C_6H_5)_4As][Pd(N_3)_3]$ can be precipitated from aqueous solutions of $Pd(NO_3)_2$ and NaN_3 (in a molar ratio of 1:4) with tetraphenylarsonium chloride; with the divalent cation $[Fe(phen)_3]^{2\oplus}$, the red, insoluble tetraazidopalladate(II) $[Fe(phen)_3][Pd(N_3)_4]$ can be precipitated. These compounds are diamagnetic and do not explode, although they deflagrate in a flame. On the other hand, the brown insoluble $Pd(N_3)_2$ that is formed as the initial product on adding sodium azide to aqueous solutions of palladium nitrate does detonate upon mere touch [3]. $[(C_6H_5)_4As][Pd(N_3)_3]$ crystallizes in brown needles and dissolves readily in acetone or chloroform to give orange-red solutions. The salt-like character of the compound is demonstrated by its conductivity in acetone (129 Ω^{-1} cm^2/mole). Two ν_3 azide bands

are observed in the infrared spectrum at 2069 and 2025 cm^{-1} (solution in acetone); accordingly, the $[Pd(N_3)_3]^{\ominus}$ anion cannot have a trigonal planar structure [*].

Triphenylphosphine reacts with aqueous solutions of $Pd(NO_3)_2$ and NaN_3, which were already suspected to contain the ions $[Pd(N_3)_3]^{\ominus}$ and $[Pd(N_3)_4]^{2\ominus}$ [4], by substitution of the azido ligands and formation of the yellow diamagnetic compound $[(C_6H_5)_3P]_2Pd(N_3)_2$. The occurrence of only one azide band at 2033 cm^{-1} (solution in chloroform) suggests that this non-ionic complex has a *trans*-planar structure.

Preparation and Properties of Tris(trifluoromethanesulfenyl)amine

By Dr. Dr. A. Haas, Dr. M. E. Peach, and cand. chem. P. Schott

Anorganisch-Chemisches Institut der Universität Göttingen (Germany)

By the reaction of stoichiometric quantities of CF_3SCl and ammonia in Carius tubes at −45 °C and 20 °C, CF_3SNH_2 and $(CF_3S)_2NH$, respectively, are obtained [1]. This method is not satisfactory for the preparation of large amounts.

We found that CF_3SNH_2 is formed in 80 % yield when CF_3SCl is bubbled into liquid ammonia at −80 °C. By the reaction of CF_3SSCF_3 with ammonia in a Carius tube at room temperature, NH_4SCN and NH_4F are formed as well as CF_3SNH_2:

$$CF_3SSCF_3 + 6\ NH_3 \rightarrow CF_3SNH_2 + NH_4SCN + 3\ NH_4F.$$

Stoichiometric quantities of CF_3SNH_2 and CF_3SCl, in the presence of trimethylamine as an HCl scavenger, react to form $(CF_3S)_2NH$.

Similarly it was possible to prepare tris(trifluoromethanesulfenyl)amine *(1)* for the first time from CF_3SCl and CF_3SNH_2 or $(CF_3S)_2NH$:

$$CF_3SNH_2 + 2CF_3SCl + 2(CH_3)_3N \rightarrow (CF_3S)_3N + 2(CH_3)_3N{\cdot}HCl \qquad (1)$$

The compound *(1)* is a yellow liquid, stable in air, soluble in benzene and nitrobenzene, and was identified by elementary analysis and molecular-weight determination. The vapor pressure obeys the equation

$$\log p = 7{,}55 - 1740/T$$

Extrapolation gives a b.p. of 99,6 °C/760 mm; this is in good agreement with the experimentally determined value of 99,0 °C/754 mm. The heat of evaporation was calculated to be 7960 cal/mole. The Trouton constant was found to be 21.36 $cal{\cdot}deg^{-1}{\cdot}mole^{-1}$.

The infrared spectrum in the NaCl and KBr regions showed the following strong absorptions: 1184 cm^{-1} (vs) [2], 1166 (vs), 1135 (sh), 1120 (vs), 844 (s), 757 (s), and 479 (m).

CONFERENCE REPORTS

Symposium on Reaction Mechanisms

The Winter Assembly of the Swiss Chemical Society took place in Berne (Switzerland) on February 20th, 1965. The following papers were among those presented:

The Mechanism of Catalysed Reactions of Formaldehyde with Amines and Amides

B. Glutz and *H. Zollinger*, Zurich (Switzerland)

The reaction of formaldehyde with semicarbazide and with urea in aqueous solution is general acid and base catalysed, as are most reactions of ketones and aldehydes with compounds containing amino groups. Whereas the reaction with semicarbazide is of 1st order relative to the formaldehyde concentration and independent of the semicarbazide concentration, the rate of reaction of urea is directly proportional to the concentration of both reactants. It appears that in the reaction with semicarbazide the rate-limiting step is the dehydration of methyleneglycol $CH_2(OH)_2$, whereas in the urea reaction it is the conversion of free formaldehyde. From the dependence of the rate of the urea reaction upon the concentration of numerous acids and bases (carboxylic acids and their anions, phosphoric acid and phosphates, HCO_3^- and CO_3^{2-}, tertiary amines and conjugate acids, H_3O^+, H_2O and OH^-) the Brönsted parameters were determined (acid catalysis: $\alpha = 0.28$, base catalysis: $\beta = 0.37$). The possibility of differentiating between a two-stage mechanism with an initial termolecular or quasi-termolecular multi-centered step and a three-stage mechanism consisting of purely bimolecular stages was discussed. The non-linear dependence of the reaction rate at pH > 11 is kinetically consistent with the two-stage mechanism and the preceding methyleneglycol ⇌ methyleneglycolate equilibrium. Moreover an acidity constant is obtained for methyleneglycol (pK_a 13.1) which corresponds to the expected value. Several bases exhibit markedly weaker $[N(CH_2CH_2OH)_3]$ or stronger $[HCO_3^-, H_2PO_4^-]$ catalytic activities than expected from the Brönsted relationship. Possible causes are solvation effects or bifunctional catalysis. The selection of catalysts is of importance in the preparation of macromolecular compounds (plastics) and in cross-linking reactions of textile fibers (cotton and other cellulosic fibers).

Mechanism and Stereochemistry of Fragmentation Reactions

C. A. Grob, Basel (Switzerland)

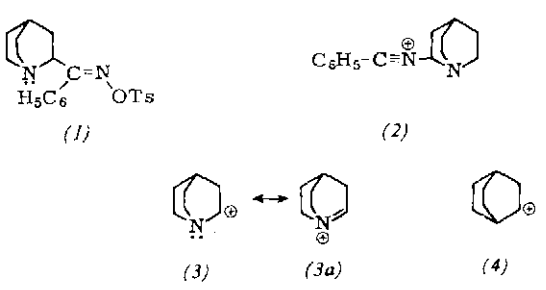
In a fragmentation reaction a molecule a–b–c–d–X breaks down into an electrofugal fragment $a–b^{\oplus}$, a nucleofugal fragment $X^{\ominus}$, and an unsaturated fragment c=d (the symbols a to d signify the atoms C, N, O, and in some cases S, in

variable sequence and with differing bond order). A large number of seemingly different reactions can thus be traced back to a single reaction type. Three basic mechanisms for fragmentations are possible: (a) the three fragments separate from one another simultaneously, (b) the nucleofugal fragment $X^{\ominus}$ separates first or (c) the electrofugal fragment $a\text{-}b^{\oplus}$ separates first from the molecule a–b–c–d–X. As yet only the first two mechanisms have been unequivocably established.

3-Aminoalkyl halides such as $(CH_3)_2N\text{-}CH_2\text{-}CH_2\text{-}C(CH_3)_2Cl$ undergo solvolysis reactions *via* carbonium ions $(CH_3)_2N\text{–}CH_2\text{–}CH_2\text{–}C(CH_3)_2^{\oplus}$, as can be seen from the substitution, elimination, ring-closure, and fragmentation products and from the fact that homomorphous alkyl halides [$(CH_3)_2CH$– in place of $(CH_3)_2N$–] exhibit practically the same reaction rate. In contrast, 3-aminoalkyl halides or 3-aminoaryl sulfonates $R_2N\text{–}C\gamma\text{–}C\beta\text{–}C\alpha\text{–}X$ (X = halogen or $ArSO_3$ respectively), in which the Cα–X bond and the axis of the free electron pair on the nitrogen are anti-coplanar to the Cβ–Cγ bond, react according to the first mechanism, *i.e.* with simultaneous separation of $R_2\overset{\oplus}{N}{=}C$ and $X^{\ominus}$. This mechanism is only observed with relatively rigid mono- and bicyclic 3-amino alcohols which meet the stereoelectronic requirement mentioned above. Examples are: 1-amino-4-bromoadamantane, 4-bromoquinuclidine, 3β-chlorotropane, 4α- and 5α-tosyloxydecahydroquinolines (tosyloxy groups equatorial). The solvolysis rate of these compounds in ethanol (80 % by vol.) is some 50 to 50000 times greater than that of the homomorphous compounds.

If, on account of configuration, the anti-coplanar orientation of the Cα–X bond or of the free electron pair relative to the Cβ–Cγ bond is prevented, fragmentation either does not occur or follows the non-accelerated two-step mechanism. This is the case for example with 3α-chlorotropane, decahydroquinolines with axial 4β- or 5β-tosyloxy groups, and with 7α- and 7β-tosyloxydecahydroquinolines.

Both the anti- and the syn-forms of α-aminoketoxime esters $R_2N\text{–}CH_2\text{–}C(R^1){=}N\text{–}X$ fragment completely by the synchronous mechanism to give carbimonium salts $R_2\overset{\oplus}{N}{=}CH_2X^{\ominus}$ and nitriles; the reaction is about 10^3 times as fast with the anti-form as with the syn-form. Moreover, the fragmentation proceeds 10^3 to 10^8 times as fast as the Beckmann rearrangement of corresponding ketoxime derivatives in which the amino group is replaced by a homomorphous alkyl group. If however the free electron pair is turned out of the stereoelectronically favored anti-coplanar orientation, as in (2-quinuclidyl)phenylketoxime tosylate *(1)*, a Beckmann rearrangement to the *N*-(2-quinuclidyl)phenylnitrilium ion *(2)* occurs, in place of the synchronous fragmentation. In aqueous media the ion *(2)* is 80 % converted into *N*-(2-quinuclidyl)benzamide, but it also gives the 2-quinuclidyl cation *(3)*, or secondary products, in 20 % yield by fragmentation. Since the homomorphous (2-bicyclo[2.2.2]octyl)-phenylketoxime tosylate [CH in place of N in *(1)*] reacts



(1) *(2)* *(3)* *(3a)* *(4)*

somewhat more slowly under these conditions to yield exclusively *N*-(2-bicyclo[2.2.2]octyl)benzamide, the 2-quinuclidyl cation must be slightly stabilized by mesomerism *(3)* ↔ *(3a)* which is impossible with the 2-bicyclo[2.2.2]octyl cation *(4)*. It follows, therefore, that the N–C(2) bond in the cation *(3)* ↔ *(3a)* assumes double-bond character and that Bredt's rule may not apply in the case of energy-rich intermediates.

Influence of the Nucleophile on Competing β-Elimination and S_N2 Substitution

R. F. Hudson and *G. Klopman*, Geneva (Switzerland)

The reaction between β-phenethyl bromide and sodium phenoxide in the presence of phenol in ethanolic solution gives approximately equal yields of ether *(1)* and olefin *(2)*.

$$ArO^{-} + Ar\text{-}CH_2\text{-}CH_2Br \rightarrow \begin{matrix} Ar\text{-}CH_2\text{-}CH_2\text{-}OAr\ (1) \\ + \\ Ar\text{-}CH{=}CH_2\ (2) + Br^{-} \end{matrix}$$

The elimination is shown to be general base catalysed (as required by a synchronous E_2 mechanism) [1]. When relatively high concentrations of phenol are used, the olefin produced by ethoxide ions present in the solution may be neglected, and the simultaneous S_N2 and E_2 reactions of the phenoxide ions may be followed. The yield of olefin is found to increase regularly with the pK_a of the *p*-substituted phenol used.

By measuring the total rate, constants (k) for the substitution and elimination reactions of several alkyl bromides were obtained and related to the pK_a of the corresponding phenol by the Brönsted equation ($\log k = \alpha pK_a + \text{const.}$) to give α for substitution (α_S) and for elimination (α_E) (cf. Table 1). We consider these coefficients to give a measure of the extent of bond formation in the transition state.

Table 1. α_S and α_E [*] for reactions of several alkyl bromides with *p*-substituted phenolate ions (*p*-R–C_6H_5OH, R–CH_3O, CH_3, H, Br, CH_3CO, and NO_2) in methanol.

	$(C_3H_7)_2CHBr$	$C_8H_{17}Br$	C_4H_9Br	$C_6H_5\text{–}CH_2CH_2Br$	$p\text{-}NO_2\text{–}C_6H_4\text{–}CH_2CH_2Br$
α_S	0.27	0.36	0.37	0.35	–
α_E	0.39	–	–	0.56	0.72

[*] Calculated from total rate constants for 0.1 M solutions.

Whereas α_S is not very sensitive to substitution at the β-carbon atom, α_E and hence the extent of bond formation at hydrogen in the β-elimination increases with conjugation in the incipient carbanion. This change in α_E is in the same direction as the primary isotope effect for the Hofmann elimination of the corresponding tetra-alkylammonium salts [2]. The present kinetic work and primary isotope effects thus lead to a consistent description of the transition states of β-elimination reactions.

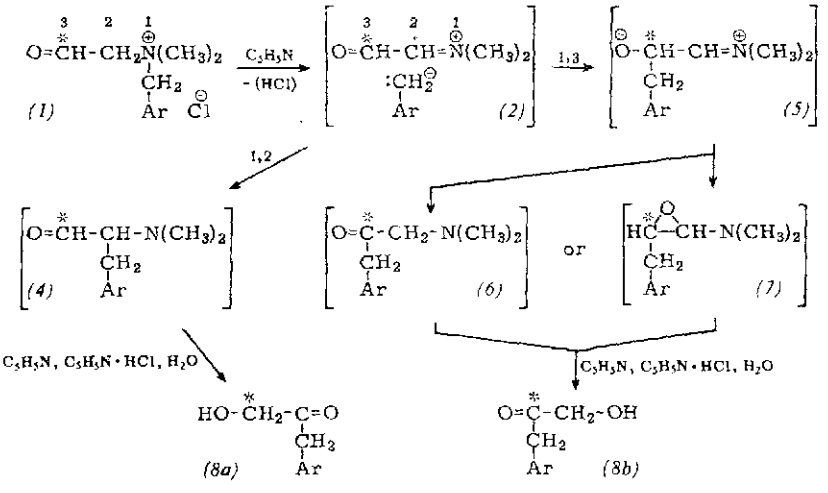
The Mechanism of Anionic Rearrangements. — A Stevens-1,3-Rearrangement

E. F. Jenny and *K. Schenker*, Basel (Switzerland)

Heating the ammonium salt *(1)*, labelled in the carbonyl group with ^{14}C, in moist pyridine affords the radioisomeric hydroxy ketones *(8a)* and *(8b)* in the ratio 57:43. The unusual course of this rearrangement is explained by the intermediate occurrence of the ion pair *(2)* [1]. The carbanion of *(2)* can add onto both electrophilic centers, C-2 and C-3, of the cation. In the first case the normal Stevens-1,2-rearrangement product, the amino aldehyde *(4)*, results; in the second case the amino ketone *(6)* or the oxide *(7)* is formed by a 1,3-shift *via* the zwitterion *(5)*. Compounds of type *(4)*, *(6)*, or *(7)* cannot be isolated, however, since they react further with pyridine and other amines [2]. Thus in the presence of aniline, *p*-nitrobenzyl anilinomethyl ketone[*(6)*,

[1] *R. F. Hudson* and *G. Klopman*, J. chem. Soc. (London) *1964*, 5.
[2] *H. Simon* and *G. Müllhofer*, Chem. Ber. *97*, 2202 (1964).

Ar = p-NO_2–C_6H_4 and –NH–C_6H_5 in place of –$N(CH_3)_2$] is obtained, which is relatively stable under the reaction conditions. In the absence of primary amines water can adopt their role: the hydroxy ketone *(8)* results in 40–50 % yield. In all these rearrangements the carbon skeleton remains intact. It can thus be concluded from the distribution of ^{14}C in compound *(8)* that the usual Stevens-1,2-rearrangement is accompanied by a hitherto unobserved Stevens-1,3-rearrangement. A subsequent isomerization of the end-



Ar = p-Nitrophenyl-

products *(8a)* and *(8b)* was experimentally excluded. An irreversible protonation of the carbanion in *(2)* yields p-nitrotoluene *(3)* as a by-product (12 %, estimated from the isotope dilution).

The ion-pair mechanism of the Stevens rearrangement clearly places it in the same class as other anionic 1,2-rearrangements. Like the Wittig rearrangement [3, 7], the Grovenstein-Zimmerman rearrangement [4, 5], and the thermal decomposition of alcoholates investigated by *Cram* [6], the Stevens rearrangement follows an S_Ei mechanism.

The nature of the intermediates satisfactorily explains the stereochemical course of these reactions. An S_Ni mechanism for anionic 1,2-migrations has until now only been found in the case of aryl shifts [4]. If a saturated carbon atom migrates, however, fragmentation and recombination (S_Ei) appear to be preferred.

Hydrogen- and Electron-Transfer in Reactions with Molecular Oxygen

Th. Kaden and *S. Fallab*, Basel (Switzerland)

Vanadium(III) and vanadium(IV) ions oxidize extremely slowly in acidic aqueous solution. A measurable autoxidation is observed only with the appearance of hydrolyzed species such as $V(OH)^{2+}$ in the case of vanadium(III). It must therefore be assumed that a hydrogen transfer to the oxidizing oxygen occurs, giving VO^{2+} or VO_2^+ respectively in one step.

$$V(OH)^{2+} + O_2 \rightarrow VO^{2+} + HO_2$$
$$VO(OH)^{+} + O_2 \rightarrow VO_2^{+} + HO_2$$

A detailed study of the autoxidation of a VO^{2+} chelate with α-picolinic acid in various pH regions gave the following results: in weakly acidic solutions there exists the chelate $VO(Pi)_2$ (Pi = α-picolinate), whose reactivity towards molecular oxygen is extremely low. An upper limit can be given for the apparent bimolecular rate constant: $k \leqslant 0.14$ mole^{-1} l min^{-1} (25 °C). Hydrogen transfer is impossible. It can be seen that an oxidation by electron transfer must also be slow, if it is assumed (the VO-bond axis being defined as the z-axis) that a d-electron of the central ion is located in d_{xy}. A direct electron transfer to the oxygen molecule coordinated in the *trans*-position to the VO-group is then difficult for reasons of symmetry.

Likewise the hydrolyzed ion $[VO(Pi)_2OH]^-$ can react only slowly with oxygen ($k \leqslant 1.4$ mole^{-1} l min^{-1}), for here all six coordination positions are occupied. On progressive hydrolysis in weakly alkaline solution, the rate of autoxidation increases in proportion to the concentration of hydroxyl ions. The structure and composition of the products are not yet conclusively proved. The dissociation of at least one ligand Pi^- creates free coordination positions, so that both H- and electron-transfer to a coordinately bound oxygen molecule are possible in principle.

$$VO(Pi)_2OH^- + OH^- \rightarrow VO(Pi)(OH)_2^- + Pi^- \qquad (a)$$

[6] *D. J. Cram* et al., J. Amer. chem. Soc. *81*, 5785 (1959) and previous publications.

[7] Alkyl ethers may rearrange by a free-radical mechanism: *P. T. Landsbury* and *J. D. Sidler*, Tetrahedron Letters *1965*, 691.

For the reaction of the hydrolyzed ion formed in (a) with O_2, an apparent rate constant k = 840 mole^{-1} l min^{-1} (25 °C) was found. To decide whether the oxidation with oxygen occurs by H- or e$^-$-transfer, the reaction kinetics in D_2O were investigated. Under conditions where the hydrolysis (a) remains incomplete, the isotope factor k_{H_2O}/k_{D_2O} is 4.1. Since however the oxidation rate is independent of the oxygen concentration under these conditions, it must be assumed that the rate-determining step occurs before the actual reaction with oxygen, and that the measured isotope effect is hence not kinetic but must be due to a hydrolysis reaction of type (a).

If, on the other hand, the hydrolysis (a) is complete, the rate of autoxidation is independent of pH but proportional to oxygen concentration. Under these conditions we determined the isotope factor k_{H_2O}/k_{D_2O} to be 0.92 (25 °C). The redox reaction between vanadium(IV) and molecular oxygen therefore very probably occurs by electron transfer.

Opening of the Four-Membered Chelate Ring of the Tetraamminecarbonatocobalt(III)Ion

H. Scheidegger and *G. Schwarzenbach*, Zurich (Switzerland)

According to *Werner*, tetramminecarbonatocobalt(III) complexes with the cation $N_4CoCO_3^+$ [1] (N signifies the N-atom of ammonia or amines such as ethylenediamine, "en") contain a four-membered chelate ring, as has recently been proved by X-ray analysis in the case of one of the solid salts [2]. On the basis of the expected (and now established) ring strain the view has often been expressed that the complex may be hydrated in solution and exist as $N_4Co(OH_2)OCO_2^+$. In particular the kinetics of isotope exchange with [^{14}C]-hydrogen carbonate seemed to confirm this [3].

It was now shown, however, that the ring is closed even in solution, for the complex *(1)* is aprotic between pH 3 and 11, while the aquocarbonato complex *(2a)* is transformed by OH^- into the hydroxo complex *(2)*, and by H^+ into the hydrogen carbonato complex *(2b)*. We employed a flow apparatus [4] in which the solutions of complex and acid can be mixed very rapidly and the pH-value measured within 10^{-2} sec at the most (a rapid decomposition occurs with CO_2 evolution). With NaOH *(1)* reacts slowly with ring opening; using the flow apparatus, the concentration of the complex *(2)* which is formed can be estimated acidimetrically. The rates and equilibrium constants given in the Table were obtained in this way. The *cis*-hydroxo complex *(2)* is slowly converted into the *trans*-isomer *(3)*. This conversion can be followed optically. The uncharged hydroxocarbonato complexes *(2)* and *(3)* can be separated from the other species by ion-exchange.

Geometry of the Transition State of the Claisen Rearrangement

H. Schmid, *A. Habich*, and *G. Frater*, Zurich (Switzerland)

Many experiments led to the postulate that the thermal Claisen and Cope rearrangements proceed *via* quasi-cyclic transition states. The geometry of these transition states may be similar to either a chair or a boat form. *Doering* and *Roth* have recently shown [1] that the stereochemistry of the Cope rearrangement of non-cyclic systems requires a chair-like transition state. Despite many investigations little is yet known about the stereochemistry of the Claisen rearrangement [1]. New experiments were therefore devised to obtain more information.

On heating in *N,N*-diethylaniline at 186 °C, both *cis*- and *trans*-4-methylphenyl crotyl ether yield 2-(α-methylallyl)-4-methylphenol exclusively. If, on the other hand, *cis*- and *trans*-3,5-dimethylphenyl crotyl ether are heated, the products are mixtures of 2-(α-methylallyl)-3,5-dimethylphenol and 4-crotyl-3,5-dimethylphenol [2], in the ratios 9.8:1 from the *cis*-ether and 3.1:1 from the *trans*-ether. The 4-crotyl-3,5-dimethylphenol formed from both ethers consists of over 95 % *trans*-isomer. The thermal rearrangement of *cis*- and *trans*-2,6-dimethylphenyl crotyl ethers affords mixtures of the stereoisomeric 4-crotyl-2,6-dimethylphenols, that from the *cis*-ether having a *trans*/*cis*-ratio of 2.2, that from the *trans*-ether a ratio of 9.6. 2,6-Dimethyl crotyl ether recovered from an experiment in which 90 % of the *cis*-ether had reacted contained only 7–8 % *trans*-ether. From these experiments it can be concluded that the rearrangements of allyl- and crotyl phenyl ethers to the *ortho*-phenols are essentially stereospecific and proceed *via* chair- or boat-like transition states. The subsequent *ortho* → *para* rearrangement is not necessarily stereospecific. Very probably all the compounds investigated have a chair-type transition state in the ether ⇌ *ortho*-phenol rearrangement, which also applies to the *ortho* → *para* rearrangement in the case of the *trans*-compounds.

Recent Developments in the Chemistry of Phosphorus

Marianne Baudler, Köln (Germany)

An apparatus for preparing higher phosphorus hydrides (phosphanes) has been developed in which, by controlled hydrolysis of calcium phosphide, 150 ml of crude liquid phosphanes can be obtained in a few days, from which solid white products seperate at −78 °C. After distilling off the P_2H_4, a pale yellow, viscous residue, decomposing at room temperature, remains which consists of a mixture of higher phosphanes: by gas chromatography five compounds, in

addition to P_2H_4, can be detected which belong to the homologous series of open-chain phosphanes P_nH_{n+2} and cyclic phosphanes P_nH_n.

For the analysis of mixtures of mono-, di-, and triphosphoric acids having phosphorus in different oxidation states, thin-layer chromatography on cellulose powder is preferable to paper chromatography. With a weakly acidic and an ammoniacal solvent a two-dimentional separation of the acids into three "branches" [*] according to the number of phosphorus atoms can be achieved. In the system containing ammonia the following relationships between R_f-values and structures of the acids are found:

1. The R_f-value decreases with increasing number of phosphorus atoms.

2. The R_f-value decreases with increasing oxidation state.

3. With acids of equal composition [*e.g.* acids of type P(II)–P(IV) and P(III)–O–P(III)] the R_f-value is higher for acids containing P–O–P bonds than for isomeric acids containing P–P bonds. The R_f-value also increases on passing from a P–P acid to a P–O–P acid containing an additional oxygen atom [*e.g.* P(II)–P(IV) → P(III)-O-P(V), or P(IV)-P(IV) → P(V)-O-P(V)].

The ultraviolet absorbtion of the aqueous solutions of these acids occurs at very short wavelengths. Only the long-wavelength ends of the bands are seen at about 450 mμ. The extinction coefficients of the acids with a P–P chain are always greater than those of the isomeric acids with a P–O–P skeleton. They increase markedly with the number of P–H bonds.

The Hydrolysis of Terpenyl Phosphates, Model Reactions of Terpene Biosynthesis

W. Rittersdorf, Göttingen (Germany)

In order to clarify the part played by geranyl phosphate in the biosynthesis of squalene [1] and to obtain a model for the biosynthesis of monoterpenes, the hydrolysis of geranyl phosphate and similar phosphates was studied.

The ortho- and pyro-phosphate monoesters of geraniol *(1)*, nerol *(2)*, linalool *(3)*, and α-terpineol *(4)* (prepared according to [2]) were hydrolysed with 1 N H_2SO_4 at room temperature. The terpenes formed were analysed by capillary gas chromatography on polyglycol columns (see Table 1). The mixtures formed from terpenyl phosphate and pyrophosphate were very similar, qualitatively and quantitatively. This indicates an S_N1 mechanism for the hydrolysis. Bicyclic terpenes were not detected.

Table 1. Composition of the mixtures formed by hydrolysis of the phosphate esters of some terpene alcohols.

Phosphate	Hydrocarbon [%]	*(3)* [%]	*(4)* [%]	*(2)* [%]	*(1)* [%]
Geranyl	2	75	—	—	20
Neryl	3	28	60	7	—
Linaloyl	2	65	15	6	10
Terpinyl	15	—	80	—	—

The results of the hydrolysis of geranyl *(5)* and neryl phosphate *(6)* show that the configuration of the intermediate geranyl and neryl cations is stable. Cyclization of *(6)* and of linaloyl phosphate *(7)* to yield *(4)* takes place by nucleophilic displacement of the phosphate group by the 2,3-double bonds. This was concluded from the following data:

a) Comparison of the rate of hydrolysis of *(6)* and of 2,3-dihydroneryl phosphate showed anchimeric acceleration of the reaction by the double bond by a factor of about 2.

b) (−)-(*R*)-Linaloyl phosphate *(8)* yielded (+)-(*R*)-terpineol *(9)* 40 % optically pure, in conformity with the stereochemistry of S_N2' reactions of allyl compounds [3].

The addition of water to the intermediate cyclic cation *(10)* seems not to be stereospecific, because preliminary experiments indicate that the hydrolysis of *trans*-nerolidyl phosphate *(11)* yields both diastereomers of bisabolol *(12)*. The diastereomers were separated gas-chromatographically after their conversion into the trimethylsilyl ethers.

Ageing of Precipitates by Ostwald Ripening

M. Kahlweit, Göttingen (Germany)

The theory of the ageing of precipitates by ripening is based on the Gibbs-Thomson equation, the initial size distribution of the precipitate and the kinetics of its growth in a nearly saturated solution. Growth kinetics, in the simplest case, is diffusion-controlled. Accordingly, it is necessary to know the surface tension σ and the diffusion coefficient D of the disperse phase, if theoretical and experimental results are to be compared.

For testing the theory, a system was chosen, in which diffusion-controlled growth may be assumed and σ and D are known, *viz.* an emulsion of amyl alcohol droplets in aqueous solution. Droplet growth in an emulsion of this type may be easily traced with an optical microscope, and quantitative agreement with theory was observed.

The second example to be studied was the ripening of crystalline TlI-precipitates in aqueous solution. It proceeds

much more slowly than would be expected according to theory. The reason is that the growth of crystalline precipitates at concentrations close to saturation is generally not diffusion-controlled.

A third example is the kinetics of phase separation in quenched supersaturated metal alloys, such as Ag-Pb. An interpretation of this separation as ripening of the clusters formed on quenching is suggested. The change in particle number and size may be traced by resistance measurements and with an electron microscope. Measurements have so far shown qualitative agreement with theory. Independent measurements of the diffusion coefficient in heterogeneous crystals are necessary, however, for reliable evaluation, especially with regard to a calculation of the interfacial tension between two solid phases.

Dehydration of Hydroxides

F. Freund, Göttingen (Germany)

A mechanism for the dehydration of $Mg(OH)_2$ and similar compounds has been suggested by *Taylor* [1], in which protons and cations are assumed to diffuse in opposite directions. Due to the high activation energy for the lattice diffusion of cations, this mechanism is, however, improbable or limited to special cases. More likely, the hydroxy groups must be assumed to be stationary, and water molecules to be formed at OH lattice positions by transfer of protons:

$$OH^- + OH^- \rightleftharpoons H_2O + O^{2-} \quad (a)$$

The water molecules then diffuse out of the lattice:

$$H_2O \longrightarrow + H_2O \text{ gas} \quad (b)$$

The diffusion process according to (b) is dependent on direction owing to the anisotropy of the lattice [2]. To form a water molecule, two OH groups must react with one another. The activation energy required for the proton transfer is less for adjacent, than for non-adjacent OH groups. At a given temperature, reaction (a) will therefore come to a standstill when all adjacent OH groups have reacted. Due to the statistical nature of the reaction, some OH groups will remain unreacted; thus the isothermal dehydration of such a hydroxide cannot be complete. Similarly, an oxide surface densely covered with OH groups cannot be freed of the last traces of water by merely evacuating at constant temperature, but only by simultaneously raising the temperature.

Statistical calculations of the number of OH groups remaining behind on a surface showed degrees of dehydration of around 90 %. Preliminary model calculations for three-dimensional lattices (hydroxides with layer structure) gave similar results.

The Influence of Alpha-Radiation on Metal Surfaces

D. Frenzel, Göttingen (Germany)

Single crystals were prepared by the Bridgman method from lead which had been purified by zone melting. All samples were handled *in vacuo* and irradiated at 22 °C and at pressures below 10^{-8} mm Hg with a 3 curie polonium-210 source. Platinum-shadowed carbon matrices were prepared from the surfaces for electron microphotography. The linear magnification was 40000.

The single-crystal surfaces, even before irradiation, proved to be relatively smooth. Apart from numerous small and irregularly occurring discontinuities [*], grooves separated by an average distance of about 500 Å were observed in the majority of samples. The samples were then irradiated with total doses of between 10^{14} and 10^{16} α-particles/cm², *i.e.* each surface atom, on the average, was hit by one α-particle. Surprisingly, the surfaces were levelled to a large extent, the degree of levelling being about 80 % for the largest dose. This corresponds to a rearrangement of about 5 lead atoms per incident α-particle.

It is reasonable to assume a diffusion mechanism for the movement of the atoms. Surface tension may be regarded as the driving force. It can be shown, with the aid of models permitting the calculation of these effects, that volume diffusion is negligible compared to surface diffusion, for a surface roughness with a periodicity of about 500 Å.

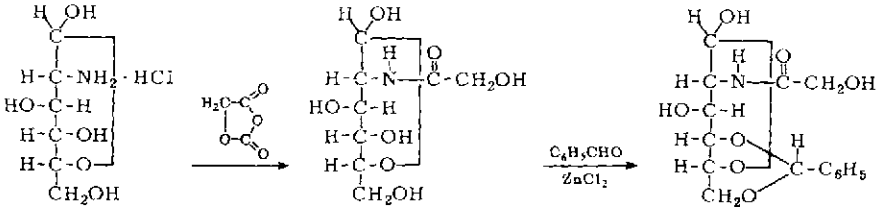
The Synthesis of N-Glycolylneuraminic Acid and the Biochemistry of Glycoproteins Containing Neuraminic Acid

H. Faillard, Köln (Germany)

N-Glycolyl-D-glucosamine *(1)* was obtained by the reaction of D-glucosamine hydrochloride with 1,3-dioxolane-2,4-dione, prepared from glycollic acid and phosgene in dioxane [1] (in collaboration with *M. Blohm*). In analogy to the method of *Okujama* and *Sinohara* [2] the *N*-glycolyl-D-glucosamine could be converted into the 4,6-benzylidene derivative *(2)* by reaction with benzaldehyde and zinc chloride.



(1) *(2)*

The 4,6-benzylidene-*N*-glycolylglucosamine *(2)* condenses with potassium di-t-butyl enoloxaloacetate to yield the corresponding t-butoxycarbonyl lactone [3]. Elimination of CO_2 and isobutylene from this compound and hydrogenolytic removal of the benzylidene residue afford the γ-lactone of *N*-glycolylneuraminic acid, which opens in alkaline media to give the free acid *(3)*. Both the 4,6-benzylidene-*N*-glycolyl-

[*] Size about 50 Å.

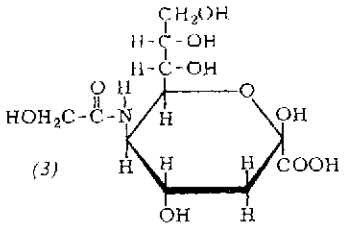
glucosamine ($[\alpha]_D^{20} = +32.3°$) and the *N*-glycolylneuraminic acid ($[\alpha]_D^{20} = -33.5°$) can be obtained in crystalline from.



(3)

The intrinsic factor, a glycoprotein of human gastric mucosa, contains *N*-acetylneuraminic acid, which protects the biologically active protein portion of this molecule from attack by trypsin in the digestive tract (research in collaboration with *W. Pribilla*). If *N*-acetylneuraminic acid is eliminated with neuraminidase, the intrinsic factor is attacked by trypsin and loses its power to promote the resorption of vitamin B_{12} in the intestine. Protection against trypsin is also obtained if *N*-acetylneuraminic acid in the intrinsic factor is replaced by the cation exchanger poly(acrylic acid vinyl pyrrolidone).

Nuclear Magnetic Relaxation Times and the Microdynamic Structure of Liquid Mixtures

H. G. Hertz, Münster (Germany)

There is relatively little knowledge, mostly from spectroscopic investigations, about the preferred spatial arrangement of molecules in liquid mixtures, *i.e.* about the "structure" of mixtures. The "microdynamic structure" of a liquid is characterized by dividing the liquid into microscopic regions and ascribing to each of these regions a molecular reorientation and residence time. Thus it is possible, for example, to correlate changes in the thermodynamic excess functions on variation of the composition of the mixture with changes in the microdynamic structure. The molecular reorientation and residence times may be obtained by measuring the nuclear magnetic relaxation times or the decay of the spin-echo amplitude (self-diffusion coefficient).

This method was applied to the study of the hydration of large, singly charged ions, *e.g.* Br^-, I^-, Rb^+ [1]. By combining results of measurements of relaxation times for protons with those for the large ions, it was shown that the range of the increased fluidity, as compared with pure water, extends right to the surface of the ion. In other words, the hydration sphere around the ions is not rigid. The activation energy for reorientation of the water molecules in the hydration sphere lies between 2 and 3 kcal/mole, *i.e.* below that for pure water. Measurements of relaxation times also show that the time for reorientation of the water molecules in the hydration sphere around non-polar groups (*e.g.* alkyl groups) is about twice as high as in pure water [2]. This effect has been described as "iceberg formation"[3] or "hydration of the second kind" [4]. The reorientation times of the dissolved particles and the activation energy for this process can be determined by isotopic substitution and extrapolation to infinite dilution. Smaller particles containing alkyl groups have a high mobility within their hydrate cages. These relationships were studied for the systems acetone/water and methanol/water over the entire composition range.

Control of Electrochemical Reactions by Means of Foreign Sorbates

Hellmuth Fischer, Karlsruhe (Germany)

The sorption of foreign substances and their orientation on a metallic surface largely depend on the surface charge of the metal, which may be varied by means of a potential. This constitutes the principal difference in the efficiency of such sorbates in electrochemical and in non-electrochemical heterogeneous reactions. The following examples were given for the effect, dependent on potential, of a sorbed foreign substance in electrode reactions:

1. During the dissolution of iron in acid, the anodic transfer of iron into the solution, which is accelerated by sorbed hydroxide ions, may be inhibited by more strongly surface-active sorbates, *e.g.* chloride, other anions or polar molecules such as phenylthiourea, as a function of the potential.

2. The drastic effect of a potential-controlled change from adsorption to desorption (or *vice versa*) is shown, *e.g.* in the evolution of H_2 or in the deposition of Ni on a nickel cathode (marked change in capacity, coverage of deposit, and overvoltage).

3. A galvanostatic formation of rhythmic-lamellar structures, coupled with periodic potential fluctuations, can be observed when copper is deposited in the presence of *o*-phenanthroline. The overvoltage alters with the abrupt changes in the sorptive coating, and in each period nucleation, specific crystal growth, and levelling of the deposit occur in turn.

4. In the case of electro-crystallization, the sorbates may be incorporated into the metal. Electron microscopy and spectrophotometry indicate occlusion densities of the same order, *e.g.* 10^{18}–10^{20} molecules/cm² for *o*-phenanthroline in Ni.

5. The inhibition by sorbed 5,6-benzoquinoline, which varies over a wide potential range (about 800 mV), was discussed using the redox system $V^{3+}/V^{2+}/Hg$ as an example. By comparing the current density *vs.* potential curves in 0.1 N HCl and in 0.1 N HCl + 0.9 N KCl, mechanical blocking of the surface may be distinguished from an electrokinetic effect (repulsion between V^{3+} and V^{2+}). Potential *vs.* capacity curves, taken in vanadium-free electrolytes under otherwise similar conditions, confirm the occurrence of inhibition and sorption of foreign substances within the same potential ranges.

Recent Investigations of Covalent Inorganic Fluorides

O. Glemser, Göttingen (Germany)

Difluorodiazine N_2F_2 is obtained by direct fluorination of NaN_3 in a continuous process at room temperature. On adding chlorine to the fluorine, highly explosive chlorofluorodiazine N_2FCl is produced. On passing NO with fluorine at 650 °C through a CaF_2 tube, nitrogen trifluoride is formed:

$$2\,NO + 2\,F_2 \rightarrow NO_2F + NF_3$$

NF_3 is often considered to be only slightly reactive. On being passed into molten sulfur at 200 °C it yields a little $N_3S_3F_3$, but at 400 °C good yields of thiazyl fluoride NSF and thiothionyl fluoride SSF_2 are obtained. In this way NSF and SSF_2 can be obtained easily on a preparative scale.

Nitrogen-sulfur-fluorine compounds can be divided into the acyclic compounds NSF, $S_3N_2F_2$, NSF_3, and the cyclic compounds $N_4S_4F_4$, $N_3S_3F_3$, S_4N_3F. Of the former, NSF_3 can be reacted with diethylamine to give the stable compound $NSF_2N(C_2H_5)_2$ which contains an N≡S triple bond as does NSF_3.

For the preparation of fluorides from chlorides by exchange, fused salts can be used as reaction media, *e.g.* a melt of NaF/KF/LiF or a solution of fluorides in molten $KCl/ZnCl_2$. In this way, large quantities of CSF_2 were prepared from $CSCl_2$ for the first time. Plastic polymers can be produced from CSF_2.

Fluorides of transition metals have been obtained in two ways: by fluorination of the metals with elemental fluorine under pressure, or by fluorination of metal powder in a fluidized bed. By the former method, yellow and very unstable chromium hexafluoride as well as unstable and hygroscopic osmium heptafluoride have been prepared for the first time. By fluorination in a fluidized bed CrF_6, ReF_7, MnF_4, PbF_4, and BiF_5 can be prepared simply and quickly. Depending on the reaction conditions, chromium powder reacts with hydrogen fluoride to yield either pure CrF_2 or pure CrF_3.

The Kinetics at Solid Phase Boundaries

H. Rickert, Karlsruhe (Germany)

Solid-state galvanic cells are often suited to kinetic studies on solids at elevated temperatures. We have studied the passage of silver through the phase boundary solid silver/solid silver sulfide [1]. This system is particularly favorable, because the conductivity of the silver in silver sulfide is already very high at 200 °C ($\sigma_{Ag^+} \approx 1\ \Omega^{-1}\ cm^{-1}$) and, as a result, stationary states and equilibria are rapidly established.

With silver iodide as auxiliary electrolyte, which shows virtually pure silver ion conduction, it is possible, despite the predominating electronic conduction of silver and silver sulfide at 200 to 300 °C, to measure the flow of silver – or the flow of silver ions or electrons alone – through the phase boundary solid silver/solid silver sulfide, as a function of the difference between the chemical potential of silver and the electrochemical potential of the silver ions and of the electrons.

Potentials were measured with given galvanostatic currents. Platinum electrodes exchange electrons; therefore, the electrochemical potential of the electrons in platinum, in the absence of current flow, is equal to that in the neighboring Ag_2S phase. Silver/silver iodide electrodes exchange Ag^+ ions; therefore, the electrochemical potential of the silver ions in silver, in the absence of current flow, is equal to that in the neighboring Ag_2S phase. Silver, freshly deposited as whisker, may transgress into silver sulfide, in which case the difference between the chemical potentials of silver in silver and silver sulfide is but a few percent of the difference found *e.g.* in the transition from cast silver. Some whiskers, surface-etched at right angles to the longitudinal axis, showed a helical structure [2], which points to screw dislocations in the axis of the whisker. The low polarization voltages for the transition of silver from whiskers into silver sulfide could be explained in this way.

Oxidation of Organic Compounds by Combustion in a Jet

G. Kainz, Vienna (Austria)

The direct oxidation of organic compounds in a tube is often not quantitative since the sample vapors are not always mixed with a sufficient quantity of oxygen. Quantitative oxidation is possible using the following arrangement: in a combustion tube there is an insert tube tapering to a jet which is surrounded by a platinum tube supported by spacers (analogous to a Bunsen burner). The sample is vaporized or decomposed in the insert tube, with exclusion of oxygen. The volume of the insert tube is such that it can contain the sample in the gaseous state. The volatile products are swept out by nitrogen through the heated jet, and burn with the formation of an intense flame (oxygen is fed into the outer tube). Non-volatile products remaining in the insert tube are subsequently burned with oxygen. Micro- and semimicro-quantities can be oxidized rapidly. The elements C, H, halogens including F, S, and P are then determined by the usual methods.

Combustion in a jet can also be used in the determination of traces of halogen and sulfur in the ppm region in volatile samples (natural gas, petrol). For these purposes an insert tube is used which has a ring of jets and is surrounded by a funnel-shaped tube. The sample vapors burn as in a Bunsen burner. The throughput is up to 2 ml of petrol per minute.

SELECTED ABSTRACTS

1,4a,8,8a-Triazaboradecalin *(1)* is a new bicyclic ring system containing boron, nitrogen, and carbon that has been described by *K. Niedenzu*, *P. Fritz*, and *J. W. Dawson*. It is formed in 75 % yield by transamination from trisdimethylaminoborane and bis-3-aminopropylamine in a 1:1 ratio in dilute solution in benzene; *(1)* melts at 38–41 °C.

$$B[N(CH_3)_2]_3 + [H_2N(CH_2)_3]_2NH \rightarrow \text{(1)} + 3\ HN(CH_3)_2$$

1,3,2-Diazaboracyclohexanes or -heptanes are formed analogously in inert solvents, *e.g.* benzene, from bisdimethylaminoboranes and aliphatic α,ω-diamines. / Inorg. Chem. *3*, 1077 (1964) / –La. [Rd 187/396 IE]

Quantitative analysis of sulfur hexafluoride and its derivatives was studied by *G. C. Demitras* and *A. G. MacDiarmid*. SF_6 is unusually resistant to chemical attack but does react with sodium in liquid ammonia even at −64 °C. A solution of sodium in 1,1-diphenylethylene/glycol dimethyl ether also reacts quantitatively with SF_6 within a few minutes at room temperature.

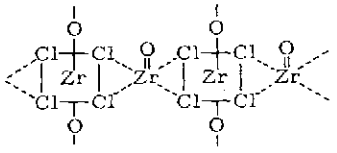
$$8\ Na + SF_6 \rightarrow Na_2S + 6\ NaF$$

The authors consider that the reaction proceeds as follows. The diphenylethylene first removes an electron from the sodium and the resultant "diphenylethyl radical ion" $[(C_6H_5)_2C-\dot{C}H_2]^{\ominus}$ passes the electron on to the SF_6 molecule. Here the electron is accomodated in to the relatively low-energy free 3d orbital of the sulfur to form a relatively unstable $SF_6^{\ominus}$ ion. This ion ejects a fluoride ion and the residual SF_5 radical reacts further with the "sodium solution". / Inorg. Chem. *3*, 1198 (1964) / –La. [Rd 188/397 IE]

The preparation of anhydrous zirconium(IV) oxide chloride has been achieved by *K. Dehnicke* and *K. U. Meyer* by the reaction of equivalent amounts of Cl_2O and $ZrCl_4$ in CCl_4 at −15 °C:

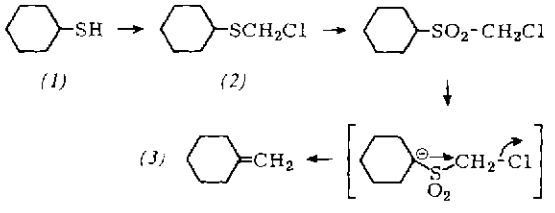
$$ZrCl_4 + Cl_2O \rightarrow ZrOCl_2 + 2\ Cl_2$$

Anhydrous $ZrOCl_2$ is a white, highly hygroscopic crystalline solid and is stable up to 250 °C. It forms adducts readily with $POCl_3$ and pyridine. With water, it forms hydrated ZrO_2 besides $ZrOCl_2 \cdot 8\,H_2O$. It decomposes slowly above 250 °C with release of $ZrCl_4$.



The structure proposed by the authors contains an arrangement of $ZrO^{2\oplus}$ ions and oxygen-bridged $ZrOCl_4^{2\ominus}$ ions. / Z. anorg. Chem. *331*, 121 (1964) / −La. [Rd 186/395 IE]

The conversion of thiols into homologous α-olefins is described by *L. A. Paquette*. Treatment of a thiol having at least one α-hydrogen atom, *e.g.* cyclohexane thiol *(1)* or 1-hexanethiol, with paraformaldehyde/HCl affords good yields of chloromethyl sulfides, *e.g.* chloromethyl cyclohexyl sulfide *(2)* (90% yield) or chloromethyl n-hexyl sulfide (71%). The sulfides can be oxidized with *m*-chloroperoxybenzoic acid in chloroform to the sulfones, which on refluxing with 25%



aqueous NaOH afford terminal olefins, *e.g.* methylenecyclohexane *(3)*, b.p. 88–92 °C (80% yield), or 1-heptene (77.6%). / J. Amer. Chem. Soc. *86*, 4383 (1964) / −Ma. [Rd 204/413 IE]

A derivative of „Dewar anthracene" has been made by *D. E. Applequist* and *R. Searle*. Anthracene and 9,10-dichloroanthracene were irradiated in benzene for 6 days under nitrogen to yield 9,10-dichlorodianthracene *(1a)*, m.p. 199 to 200 °C (decomp.), in 61% yield. The reaction of a suspension of *(1a)* in benzene/ether 69 °C at for 12 h with triphenylmethylsodium led to 9,10-dehydrodianthracene *(2)*, the desired derivative of "Dewar anthracene", in 26% yield.

(2)

(a): X = Cl
(b): X = Br

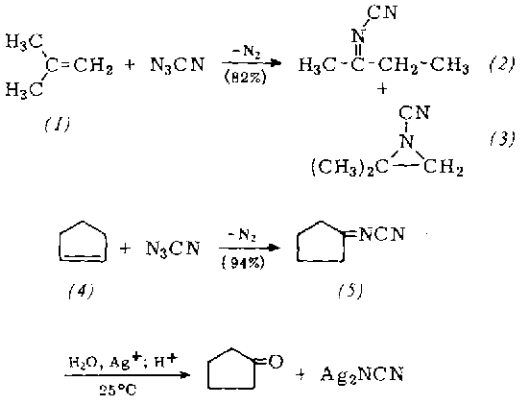
The ultraviolet spectrum of the product with λ_{max} = 269.3, 275.1, and 283.7 mμ and with ε = 4170, 4060, and 3020, respectively, is in accordance with structure *(2)*. The hydrocarbon *(2)*, m.p. 338–342 °C (decomp.), could be crystallized from xylene and sublimed at 180 °C/0.1 mm. Bromination of *(2)* afforded *(1b)*. Valence-bond isomerization of the electron system in the right-hand half of *(2)* to an anthracene-type distribution is prevented by the particular geometric configuration of the bridged structure. / J. Amer. chem. Soc. *86*, 1389 (1964) / −Eb. [Rd 193/402 IE]

Ethynylsulfur pentafluoride $F_5S{-}C{\equiv}CH$, b.p. 6 °C, was synthesized by *F. W. Hoover* and *D. D. Coffman* by thermal addition of sulfur chloride pentafluoride onto acetylene and subsequent bromination; *trans*-$F_5S{-}CH{=}CHCl$, $F_5S{-}CHBr{-}CHBrCl$, and *cis*- and *trans*-$F_5S{-}CBr{=}CHCl$ are formed. Besides $F_5S{-}C{\equiv}CH$, other derivatives can be prepared from these products: $F_5S{-}CHBr{-}CH_2Br$, $F_5S{-}CBr_2{-}CH_2Br$, $F_5S{-}CH_2{-}CH(OCH_3)_2$, $F_5S{-}CH_2{-}CH(OCOCH_3)_2$, and $F_5S{-}CBr{-}CH_2$. Diazomethane adds onto $F_5S{-}C{\equiv}CH$ in ether at 0 °C to form isomeric F_5S-substituted pyrazoles. Butadiene and dimethylbutadiene, for example, undergo Diels-Alder condensations with $F_5S{-}C{\equiv}CH$ to yield substituted 1,4-cyclohexadienes, which can be dehydrogenated to afford F_5S-substituted benzene derivatives. / J. org. Chemistry *29*, 3567 (1964) / −Jg. [Rd 241/449 IE]

The synthesis of cyanogen azide in almost quantitative yield has been achieved by *F. D. Marsh* and *M. E. Hermes* by the reaction of NaN_3 with cyanogen chloride in aprotic solvents, *e.g.* acetonitrile, at room temperature.

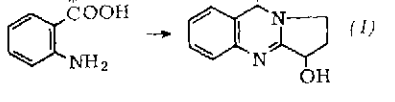
$$NaN_3 + ClCN \rightarrow N_3CN + NaCl$$

Cyanogen azide is a colorless oil which detonates on mechanical or thermal shock but is relatively safe to handle in solution. It behaves as an extremely reactive organic azide. It is reduced by H_2S to cyanamide in 80% yield; with triphenylphosphine it forms *N*-cyanotriphenylphosphinimine, m.p. 193–195 °C, in 88% yield. It reacts with olefins such as *(1)* or *(4)* at 0–35 °C to form *N*-alkylidenecyanamides such as *(2)* or *(5)* and/or *N*-cyanoaziridines *(3)*. The *N*-alkylidenecyanamides are rapidly hydrolysed to ketones with aqueous acids in the presence of $Ag^{\oplus}$ ions. This novel ketone synthesis is



generally applicable and proceeds without any rearrangement. / J. Amer. chem. Soc. *86*, 4506 (1964). [Rd 206/415 IE]

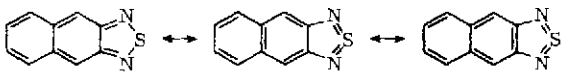
The incorporation of anthranilic acid into peganine (vasicine), a quinazoline alkaloid *(1)*, has been studied by *D. Gröger*, *S. Johne*, and *K. Mothes* by feeding [carboxy-^{14}C]-anthranilic acid to rooted leaves of *Adhatoda vasica* Nees. The labelled carbon atom recurred in the 4-position. The alkaloid can be degraded to (labelled) anthranilic acid by oxidation with permanganate, yielding 4-oxo-3,4-dihydroquinazolyl-3-acetic acid, esterification with diazomethane, and hydrolysis with 20% KOH. Pyrrolidinoquinazolines exhibit physiological



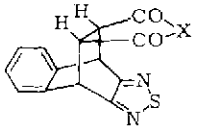
activity: *(1)* is a bronchioconstrictor, while its 4-oxo derivative is a bronchiodilator [1]. / Experientia *21*, 13 (1965) / −De. [Rd 229/437 IE]

[1] *D. R. Mehta*, *J. S. Naravane*, and *R. M. Desai*, J. org. Chemistry *28*, 445 (1963).

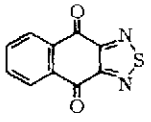
The synthesis of 1,2,5-naphtho[2,3-c]thiadiazole *(1)*, a very stable analogue of anthracene, has been reported by *M. P. Cava* and R. H. *Schlesinger*. Reaction of 2,3-diaminonaphthalene with thionylaniline in pyridine at 95 °C gave a 95% yield of the thiazole *(1)* as orange-red needles, m.p. 85–86 °C, which give Diels-Alder adducts *(2a)* and *(2b)* with *N*-phenylmaleimide and maleic anhydride. Oxidation of *(1)* with $Na_2Cr_2O_7$ in acetic acid produced the orange quinone *(3)*,



(1)



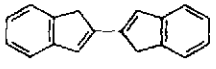
(2a): X = N-C_6H_5; *(2b)*: X = O



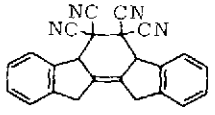
(3)

m.p. 246 °C (decomp.), in 46% yield. The heterocycle *(1)* exhibits aromatic properties. / Tetrahedron Letters *1964*, 3815 / –Ma. [Rd 197/406 IE]

The synthesis and properties of 2,2'-biindenyl *(1)* are described by *W. Lüttke* and *J. Grussdorf*. Although the dimerization of indene cannot be effected by debromination of 2-bromoindene with copper or silver powder or with alkali metals, the Grignard compound 2-indenylmagnesium bromide can be converted into *(1)*, m.p. 242–243 °C, by heating it in tetrahydrofuran with a solution of $CuCl_2$ in ether. Catalytic hydrogenation of *(1)* affords 2,2'-biindanyl, m.p. 165–166 °C. The conjugated diene system of *(1)* condenses with tetracyanoethylene



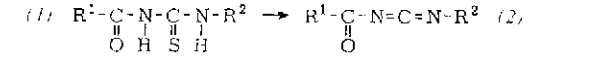
(1)



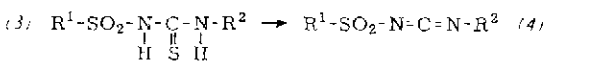
(2)

to give *(2)*, which decomposes above 180 °C. It is concluded from the ultraviolet spectrum of *(1)* that it probably occurs in the *s-trans*-form. / Chem. Ber. *98*, 140 (1965) / –Ma. [Rd 198/407 IE]

The synthesis of *N*-acyl- and *N*-sulfonylcarbodiimides has been described by *R. Neidlein* and *E. Heukelbach*. Phosgene plus triethylamine remove 1 mole of H_2S from acylthioureas *(1)* to form the *N*-acylcarbodiimides *(2)*, probably *via* *N*-acylformamidinium chlorides as intermediates. The derivatives of *(2)* with R^1 = H are highly reactive and polymerize within a few hours. Compounds obtained include *(2)*, R^1 = ethoxy, R^2 = cyclohexyl, b.p.80–82 °C/0.01 mm, in 37% yield, *(2)* R^1 = ethoxy, R^2 = isopropyl, b.p. 60–62 °C/0.01 mm, in 42% yield, and *(2)*, R^1 = ethoxy, R^2 = t-butyl, b.p. 63–65 °C/0.01 mm, in 45% yield. The products are colorless oils with a pungent odor. *N*-Sulfonylcarbodiimides *(4)* can be made from



(1) R^1-C(=O)-N(H)-C(=S)-N(H)-R^2 → R^1-N=C=N-R^2 *(2)*



(3) R^1-SO_2-N(H)-C(=S)-N(H)-R^2 → R^1-SO_2-N=C=N-R^2 *(4)*

sulfonylthioureas by elimination of H_2S with HgO in dry benzene, and are very stable. Derivatives of this type include *(4)*, R^1 = *p*-tolyl, R^2 = phenyl, b.p. 140–145 °C/0.05 mm, obtained in 12% yield, and *(4)*, R^1 = methyl, R^2 = phenyl, b.p. 115–120 °C, obtained in 18% yield. / Tetrahedron Letters *1965*, 149 / –Ma. [Rd 200/409 IE]

Transannular free-radical cycloadditions of *cis,cis*-**1,5-cyclooctadiene** *(1)* have been investigated for the first time by *R. Dowbenko* (reactions in the cyclooctane series which lead to bicyclic products by an ionic mechanism [1] or *via* a carbene intermediate [2] are already known). When *(1)* is refluxed in CCl_4 and a small amount of dibenzoyl peroxide is added, the 1:1 adduct *(2)*, b.p. 84–87 °C/0.1 mm, is formed in 63% yield. The same adduct is formed in 33.5% yield on irradiation of a solution of *(1)* in CCl_4 with ultraviolet light, or in 73% yield by an ionic reaction, when a mixture of *(1)*, CCl_4, isopropanol, and a little $FeCl_3$ is refluxed for 2 days.

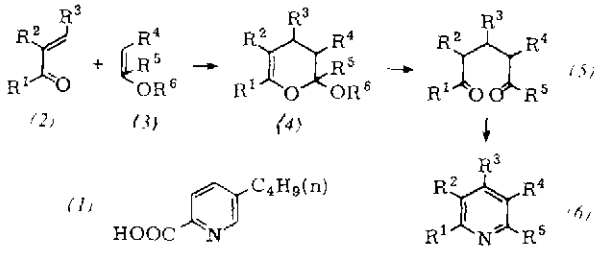
[3] Isolated as the phenylurea derivative.

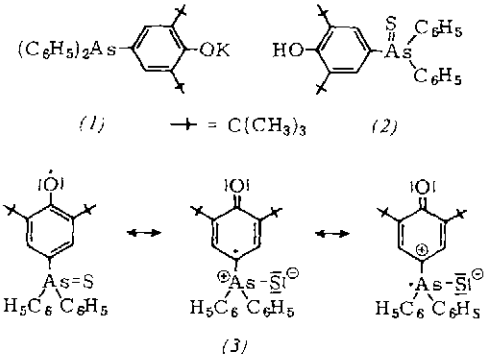
The synthesis of fusarinic acid *(1)* **and its isomers and homologues** has been achieved by *Yu. I. Chumakov* and *V. P. Sherstyuk*. The best means of preparing pyridines with two alkyl substituents is a diene condensation of α,β-unsubstituted aldehydes or ketones *(2)* with vinyl ethers *(3)*. The 2-alkoxy-3,4-dihydro-1,2-pyrans *(4)* formed in this way are hydrolysed to the 1,5-diketo compounds *(5)*, which condense with hydroxylamine to form substituted pyridines. For example, heating of equimolar amounts of 1-hexenyl ethyl ether and methyl vinyl ketone produces 2-ethoxy-3-n-butyl-6-methyl-3,4-dihydro-1,2-pyran, b.p. 106–107 °C/18 mm, in 47 % yield, which on hydrolysis with acetic acid and reaction with NH_2OH yields 37.5 % 2-methyl-5-n-butylpyridine, b.p. 220–221 °C. Oxidation of the latter compound with SeO_2 in pyridine affords 5-n-butylpyridine-2-carboxylic acid *(1)*, m.p. 100–101 °C. Isomeric and homologous pyridines and pyridinecarboxylic



(2) *(3)* *(4)* *(5)* *(1)* *(6)*

acids can be obtained analogously. / Tetrahedron Letters *1965*, 129 / –Ma. [Rd 201/410 IE]

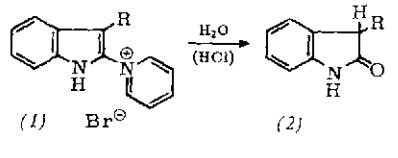
A mesomeric free arsenic radical has been synthesized by *E. Müller*, *H. Eggensperger*, *B. Teissier*, and *K. Scheffler*. The reaction of diphenylarsinylpotassium with 4-iodo-2,6-di-t-butylphenol produces *(1)*, which is then hydrolysed and treated with sulfur to yield the sulfide *(2)*. Dehydrogenation of *(2)* with PbO_2 or potassium hexacyanoferrate(III) in benzene produces the free radical *(3)* as a bright green solution, which rapidly turns light brown. The ESR spectrum of *(3)* contains four triplets, hence the unpaired electron is distributed over the *meta*-positions of the aroxyl



(1) *(2)* *(3)*

nucleus and the arsenic atom. Analogous free phosphorus radicals are already known. / Z. Naturforsch. *19b*, 1079 (1964) / –Ma. [Rd 202/411 IE]

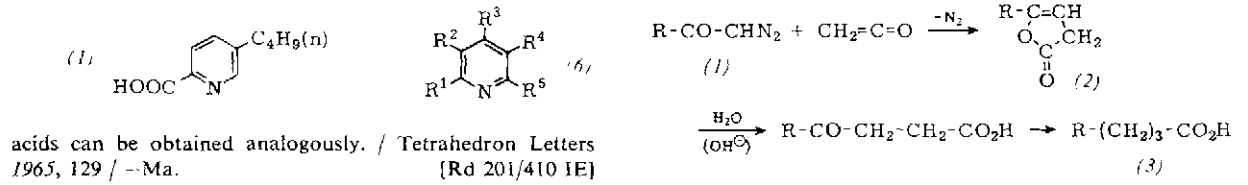
A new route from indoles to oxindoles has been discovered by *T. Kobayashi* and *N. Inokuchi*. The reaction of 3-substituted indoles with equimolar amounts of *N*-bromosuccinimide and pyridine in benzene at room temperature affords high yields of the yellow, crystalline pyridinium salts *(1)*. These salts are resinified by alkalies, but are readily hydrolysed by 3–6 N HCl to oxindoles *(2)*.



(1) *(2)*

Examples of the products obtained: R = CH_3, *(1a)*, 79.5 %, m.p. 231–233 °C, *(2a)*, 81.5 %, m.p. 123–124 °C; R = C_6H_5, *(1b)*, 100 %, m.p. 225 °C (decomp.), *(2b)*, 67 %, m.p. 181–184 °C; R = $-(CH_2)_2COOCH_3$, *(1c)*, 83 %, m.p. 225–226 °C, *(2c)*, 88 %, m.p. 168–170 °C; R = $-(CH_2)_2COOCH_3$, *(1d)*, 86 %, m.p. 169–170 °C (decomp.), *(2d)*, 89 %, m.p. 169–170 °C. Starting from methyl 3-indolylacetate (R = CH_2COOCH_3), hydrolysis of the oxindole ring and recyclization produces a 50 % yield of 2-oxo-1,2,3,4-tetrahydroquinoline-4-carboxylic acid, m.p. 214–215 °C. / Tetrahedron *20*, 2055 (1964) / –Bi. [Rd 176/385 IE]

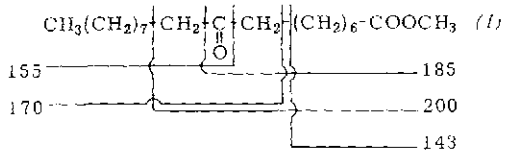
Extension of the chains of carboxylic acids by three carbon atoms can be achieved by a simple method developed by *W. Ried* and *H. Mengler*. Diazomethyl ketones *(1)* prepared from acid chlorides and diazomethane react with ketene in dry xylene on mild warming to yield β,γ-butenolides *(2)* by expulsion of nitrogen [1]; these enol lactones *(2)* are readily hydrolysed by 2 N NaOH to give γ-keto carboxylic acids. Wolff-Kischner reduction of each ketone produces the carboxylic acid *(3)* containing three carbons more than the original acid.



(1) *(2)* *(3)*

The whole sequence of reactions can also be applied to dicarboxylic acids. Acids extended in this way include: propionic acid → n-capronic acid (28 % yield); benzoic acid → γ-phenylbutyric acid (16 %); β-naphthoic acid → 4-(2-naphthyl)butyric acid (8.5 %); adipic acid → decane-1,10-dicarboxylic acid (22 %); suberic acid → dodecan-1,12-dicarboxylic acid (24.5 %). In exceptional cases the β,γ-butenolide can be converted into the corresponding carboxylic acid directly by catalytic hydrogenation, *e.g.* benzoic acid → γ-phenylbutyric acid (25.5). / Liebigs Ann. Chem. *678*, 113 (1964) / –Bi. [Rd 177/386 IE]

Location of a double bond in an olefinic chain by mass spectrometry was achieved by *G. W. Kenner* and *E. Stenhagen*. The olefin was converted into its epoxide with monoperoxyphthalic acid and isomerized with NaI to a mixture of two ketones: 5 mg of epoxide were heated in 2 ml of dimethylformamide plus 2 ml of methyl iodide with 40 mg of NaI. In the mass spectrometer, each ketone yielded the fragments from α-cleavage ($R-CH_2-C\equiv O^{\oplus}$ and $R'-CH_2-C\equiv O^{\oplus}$) and β-cleavage ($[R-CH_2-C(OH)=CH_2]^{\oplus}$ and $[R'-CH_2-C(OH)CH_2]^{\oplus}$), ocassionally together with a fragment of the type $RCH_2^{\oplus}$ also produced by β-cleavage. Treatment of methyl oleate with monoperoxyphthalic acid and NaI yielded methyl 9-oxooctadecanoate *(1)* and methyl 10-oxooctadecanoate *(2)*. The fragmentation of *(1)* can be represented schematically as follows:



(1)

Five analogous mass signals were obtained from *(2)*. Thus, a total of ten fragments were obtained from the mixture of *(1)* plus *(2)*, and these are therefore characteristic for methyl oleate. The same mass spectrum was obtained after analogous treatment of methyl elaidate. Here the mass numbers can be reconciled only with a double bond between C-9 and C-10. This technique has been applied to several long-chain esters with one double bond. / Acta chem. scand. *18*, 1551 (1964) / –Eb. [Rd 239/447 IE]

[1] Cf. *W. Ried* and *H. Mengler*, Angew. Chem. *73*, 218 (1961); Liebigs Ann. Chem. *651*, 54 (1962).

An alkoxide oxidation involving hydride transfer to dichlorocarbene and group migration during carbene reactions have been observed by *J. A. Landgrebe*. The strongly exothermal reaction of chloroform with sodium benzoxide in benzyl alcohol under argon and subsequent hydrolysis with aqueous NaOH produces 24.8–44.3% dibenzyl ether *(1)*, 15.4–44.3% benzyl orthoformate *(2)*, benzoic acid *(3)*, phenylacetic acid *(4)*, mandelic acid *(5)*, an unidentified acid, and methylene dichloride.

$$C_6H_5CH_2ONa + CHCl_3 \xrightarrow[2.\ H_3O^{\oplus}]{1.\ OH^{\ominus}} CH_2Cl_2 + (C_6H_5CH_2)_2O + (C_6H_5CH_2O)_3CH + C_6H_5COOH + C_6H_5CH_2COOH - C_6H_5CHOH{\cdot}COOH$$

(1) *(2)* *(3)* *(4)* *(5)*

Following the formation of dichlorocarbene, probably two reactions occur: abstraction of hydride from the alkoxide by the carbene dechlorination of the dichlorocarbene by alkoxide.

$$C_6H_5CH_2O^{\ominus} + :CCl_2 \rightarrow C_6H_5CHO + HCCl_2^{\ominus}$$

$$C_6H_5CH_2O^{\ominus} + :CCl_2 \rightarrow C_6H_5CH_2O\ddot{C}Cl + Cl^{\ominus}$$

(6)

Under the reaction conditions, the benzaldehyde undergoes a Tischenko reaction to give benzyl benzoate, which is recovered as benzoic acid. Sodium α-phenylethoxide reacts with $CHCl_3$ to form CH_2Cl_2, diphenyl ether, acetophenone, hydratropaic acid *(7)*, and atrolactic acid *(8)*. A chloroalkoxycarbene, *e.g. (6)*, is assumed to occur as an intermediate in these reactions. It is probably transformed *via* a short-lived isocarboxonium cation $ROC^{\oplus}$ into the carbonium ion $R^{\oplus}$, which then gives rise to the products isolated.

$C_6H_5CH(CH_3)-COOH$ *(7)* $\qquad$ $C_6H_5COH(CH_3)-COOH$ *(8)*

The formation of acids *(4)* and *(7)* can be explained by an O → C migration of a benzyl or α-phenylethyl group in the ion $ROC^{\oplus}$ or by rearrangement of the carbene $RO\ddot{C}Cl$ to the acyl chloride RCOCl. The formation of acids *(5)* and *(8)* can be explained by the action of a methylene dichloride anion, formed by hydride abstraction, on the carbonyl group of the

$$C_6H_5CHO - {}^{\ominus}CHCl_2 \rightarrow C_6H_5\underset{\underset{O^{\ominus}}{|}}{CH}CHCl_2 \quad (9)$$

benzaldehyde, giving rise to an anion of type *(9)*. / Tetrahedron Letters *1965*, 105 / – Ma. [Rd 199/408 IE]

BOOK REVIEWS

Mechanismen enzymatischer Reaktionen. 14. Kolloquium der Gesellschaft für physiologische Chemie vom 25.–27. April 1963 in Mosbach/Baden. [Mechanisms of Enzymatic Reactions. 14th Colloquium of the German Society for Physiological Chemistry, April 25–27th, 1963 in Mosbach/Baden (Germany)]. Springer-Verlag, Berlin-Göttingen-Heidelberg 1964. 1st Edit., IV + 366 pp., 104 illustrations, paperback DM 54.– (about $ 13.50).

The Gesellschaft für physiologische Chemie courageously ventured the subject "mechanisms of enzymatic reactions" as the main theme for its 14th "Mosbacher Kolloquium". The lectures have now appeared in print and make the results generally available. It is actually only the first group of five contributions which deals directly with this topic. In the other two groups, "Coenzymes" and "Hydrogen Transfer", with the exception of the lecture by *H. Sund* on "Die Struktur und Wirkungsweise NAD-abhängiger Dehydrogenasen" (the structure and mode of action of NAD-dependent dehydrogenases), problems are discussed which are only indirectly connected with enzymes. Not everything that was said at the conference and which has now been printed has the unblemished clarity of the contribution by *V. Prelog*, for example, "Über die Produkt- und Substratspezifizität der enzymatischen Reduktion von Carbonyl-Verbindungen" (on the product and substrate specificity of the enzymatic reduction of carbonyl compounds). Some reports read like verbatim copies of laboratory note-books: experimental data are given in abundance, but the relations among them or their consequences are not made directly apparent. This is admittedly due in part to the difficulties still encountered by any attempt to solve the problem of enzymatic catalysis, a situation which was perhaps best summarized by *Martius* in his remark: "Where the situation is so difficult and unsurveyable, there must be some doubt whether the center of the problem can be reached directly by purely chemical model experiments and considerations, as it were in a parachute jump".

Despite this scepticism, the volume gives a good – albeit incomplete – picture of the present status of this field of research.

H. Grünewald [NB 344/201 IE]

Advances in Heterocyclic Chemistry, Vol. 2. Edited by *A. R. Katritzky* in collaboration with *A. J. Boulton* and *J. M. Lagowsky*. Academic Press, New York - London 1963. 1st edit., XI + 458 pp., numerous tables, linen $ 14.00.

The essays in this second volume of the series can be classified into the following groups:

1. Equilibrium problems: Prototropic tautomerisms of five-membered rings containing one hetero-atom (25 pp.) or containing two or more hetero-atoms (55 pp.) [*A. R. Katritzky* and *J. M. Lagowski*].

2. Reactions of heterocyclic systems: Free-radical substitutions of heteroaromatic compounds (48 pp.) [*R. O. C. Norman* and *G. K. Radda*] and the reaction of diazomethane with heterocyclic compounds (42 pp.) [*R. Gompper*].

3. Reactions of specific heterocyclic systems: The action of metal catalysts on pyridine derivatives (25 pp.) [*G. M. Badger* and *W. H. F. Sasse*] and the acid-catalysed polymerization of pyrroles and indoles (24 pp.) [*G. F. Smith*].

4. New ring systems: Three-membered rings containing two hetero-atoms (48 pp.) [*E. Schmitz*].

5. Progress reports on specific systems: Advances in quinoxaline chemistry (41 pp.) [*G. W. H. Cheeseman*], 1,3-oxazine derivatives (33 pp.) [*Z. Eckstein* and *T. Urbanski*], the present state of selenazole chemistry (21 pp.) [*E. Bulka*], and recent developments in isoxazole chemistry (58 pp.) [*N. K. Kochetkov* and *S. D. Sokolov*].

The contributions all convey the impression of comprehensiveness and good knowledge of the subject matter on the part of the authors. The treatises of groups 1 and 2 are of particular importance since monograph series such as "Elderfield" and "Weissberger", by virtue of their fundamental aims, do not cover such topics. The efforts of *R. Gommper* demonstrate how difficult it is to attempt already an interpretation of the experimental results. The article on tautomerisms (in continuation of those in Vol. 1) lucidly reveals the supremacy of modern physical methods over classical methods and the precariousness of conclusions drawn from chemical findings. In the articles giving progress reports, the reader regrettably misses exact references to the research periods reviewed. Incidentally, it is probably unnecessary to

go too far back into the literature in most cases or to devote too detailed a treatment – as in the chapter on free-radical reactions – to analogies to processes with homocycles. However, references should be given to earlier review articles, *e.g.* 1,3-oxazines are dealt with in Vol. 6 of "Elderfield", even if only on 17 pages.

The organization of the book, the presentation of formulae and illustrations, and the numeration of compounds are clear and intelligible and help to find data rapidly. The volume is earnestly recommended to all working on the chemistry of heterocycles. *J. Goerdeler* [NB 301/160 IE]

Advances in Organometallic Chemistry. Vol. I. Edited by *F. G. A. Stone* and *R. West*. Academic Press, New York-London 1964. 1st Edit., XI + 334 pp., 10 Figs., 44 tables, linen £ 4.4.0 (about $ 11.75).

The exponential rise in the number of publications appearing in the field of organometallic chemistry makes it indispensible to have progress reports for both those with an active and those with only a casual interest in the subject. *F. G. A. Stone* and *R. West* are to be commended for having decided to initiate and edit a series on "Advances in Organometallic Chemistry"; the first volume has now appeared and further volumes will be issued annually.

The topics discussed in this first volume are highly variegated, in keeping with the nature of organometallic chemistry. The titles of the individual contributions are: "Diene Iron Carbonyl Complexes and Related Species" (43 pp., 134 references) [*R. Pettit* and *G. F. Emerson*]; "Reactions of Organotin Hydrides with Organic Compounds" (38 pp., 84 refs.) [*H. G. Kuivila*]; "Organic Substituted Cyclosilanes" (47 pp., 107 refs.) [*H. Gilman* and *G. L. Schwebke*]; "Fluorocarbon Derivatives of Metals" (73 pp., 156 refs.) [*P. M. Treichel* and *F. G. A. Stone*]; "Conjugate Addition of Grignard Reagents to Aromatic Systems" (16 pp., 59 refs.) [*R. C. Fuson*]; and "Infrared and Raman Spectral Studies of π-Complexes formed between Metals and C_nH_n Rings" (75pp., 156 refs.).

The reviews are fluently written and are almost generally critically descriptive. Frequently unpublished results from the authors' own work have been mentioned. The book is essentially free from printing and factual errors. Overlapping or repetitions in the text are rare, *e.g.* on pp. 27–28 and pp. 195–198, and are not disturbing. All in all, the editors have thus succeeded in creating a forum for the discussion of organometallic chemistry which will most certainly enjoy wide resonance. *G. N. Schrauzer* [NB 302/161 IE]

Analytische Anwendungen von Ionenaustauschern (Analytical Applications of Ion Exchangers). By *J. Inczédy*. Published by the Hungarian Academy of Sciences, Budapest 1964. 1st edit., 365 pp., 84 figs., 30 tables, linen DM 33.60 (about $ 8.50).

The title of this book indicates that discussion is restricted to the analytical applications of ion exchangers, but from its preface and table of contents the reader can see that the limits of the treatment are much more extensive. However, his expectations are then only partially fulfilled. The main emphasis in the book is placed upon the analysis of mixtures of inorganic ions (about 170 pp.), whereas "organic analysis" receives much less attention in about 40 pages. Thus, for example, the promising title "Separation of amino acids, peptides, and protein substances" heads merely a description of the separation of mixtures of amino acids; there is no reference to the many separations of peptides which have been carried out for some years, nor is there any mention of the analysis of protein mixtures. Correspondingly, there is also hardly any mention of ion exchangers constructed on a polysaccharide basis in other sections. On the other hand, there are chapters on the properties of synthetic resin-exchangers (16 pp.), the theory of ion exchange (27 pp.), and the use of ion-exchange columns in theory and practice (34 pp.) which go well into theoretical fundamentals but maintain due regard to practical aspects, *e.g.* procedures for testing synthetic resin exchangers (13 pp.). The text is frequently elaborated by lucid illustrations and well-packed tables; for example, one table is 21 pages long and summarizes information on the chromatographic separation of inorganic ions. The number of literature references is also correspondingly high (1200), and the layout of the book is excellent; for this reason and also because of its content of practical procedures which have frequently been checked by the author, the book can be earnestly recommended to analysts in inorganic laboratories. Apart from minor spelling errors – "y" causes the author particular difficulty – the German is quite good. *H. Determann* [NB 286/144 IE]

The Chemistry of Cationic Polymerization. Edited by *P. H. Plesch*. Pergamon Press, Oxford-London-New York-Paris 1963. 1st Edit., XV + 728 pp., numerous illustrs. and tables, linen £ 10.0.0 (about $ 27.75).

By adopting the reaction mechanism approach as a didactic principle, the editor of the present volume manages to correlate the cationically induced polymerizations of a number of rather different monomers. He is ably assisted in this extensive and difficult task by numerous colleagues from Anglo-American research teams, not only from universities and colleges, but also from the chemical industry. The specialized sections which are of recognizable individuality are aptly coordinated by introductory chapters on carbonium ions, on organic reactions related to cationic polymerization, and on comparisons between free-radical, cationic, and anionic polymerization mechanisms. These articles are extremely welcome, for they greatly facilitate comprehension of the frequently complex course of cationic polymerization reactions.

The specialized sections deal with all monomers which undergo cationic polymerization: aliphatic and aromatic mono-olefins (isobutylene and styrene in separate articles), conjugated and non-conjugated diolefins, vinyl ethers, cyclic ethers, aldehydes, ketones, and ketenes, vinyl thiocthers and cyclic thioethers, and cyclic imines. The book is well rounded off by concluding chapters on copolymerization, cationic reactions of polymers, cationic graft polymerization, cationic polymerizations induced by radiation, and experimental techniques.

The treatment given to the various topics is in correspondence with the title of the book, so that the chemistry and theoretical fundamentals of the subject are placed in the forefront. It is the editor's aim to produce a work that will be of interest primarily to pure scientists, and accordingly, the industrial importance, technology, and properties of the polymers are only touched upon. Also the literature reviewed (over 1500 references) is restricted to purely scientific publications. This volume will assuredly fill a gap in the literature on polymer chemistry, for it is full of topics for discussion.

H. Bestian [NB 307/166 IE]

Selected Values of Thermodynamic Properties of Metals and Alloys. By *R. Hultgren, R. L. Orr, P. D. Anderson*, and *K. K. Kelley*. John Wiley & Sons, New York-London 1963. 1st Edit., XI + 963 pp., numerous illustrs. and tables, linen £ 4.14.0 (about $ 13.00).

Knowledge of the thermodynamic properties of constructional materials is essential for numerous tasks encountered during the installation of nuclear reactors, and hence several books containing tables of data from this field have recently appeared, especially ones giving values of such properties at extreme temperatures. The tables in the present volume give the heat capacity C_p, the entropy, enthalpy, and free energy for 63 metallic elements both for low temperatures and for high temperatures up to the boiling points in the condensed phase (solid and liquid) and up to several thousand degrees Kelvin in the gaseous phase. In addition, very extensive data on the vapor pressures are frequently given. Introductory remarks about each element describe the experimental meth-

ods and give critical appraisals of the data. An especially valuable feature of the book is the inclusion of numerous equations for empirical representation of the thermodynamic functions of a given metal as a function of temperature.

The major portion of the book is devoted to binary alloys. Here the results for 168 systems are dealt with, and phase diagrams are included. The reader finds data on the integral and partial molar free energies, entropies, enthalpies, and activities or activity coefficients for individual temperatures; it is then easy to evaluate other thermodynamic quantities from these. Here the introductory comments frequently include data on the crystal structures of special alloy phases. In using this section, the experienced thermodynamist – who will normally skip the general introduction – must note that for liquid alloys, the standard states are generally the liquid elements and not the elements in the equilibrium state valid for the temperature in question; corresponding standards apply for solid alloys.

The literature index is long and rather complete; it covers publications up to about 1961. This and the critical evaluation of the data make the book an unusually helpful advisor for all scientists doing research in the field of thermodynamics at extreme temperatures. *K. Schäfer* [NB 304/163 IE]

Reagents and Reactions for Qualitative Inorganic Analysis. Fifth Report. Published by the International Union of Pure and Applied Chemistry, Analytical Chemistry Division, Commission on Analytical Reactions. Butterworths & Co. Publishers Ltd., London 1964. 1st edit., X + 88 pp., linen £1.12.6 (about $4.25).

This booklet contains a collection of qualitative reactions for the detection of 51 elements and radicals. These are mostly reliable color reactions, but sometimes also precipitation and crystal reactions. The performance of the tests requires only the most primitive facilities (they are mostly spot tests on filter paper and occasionally test-tube experiments). The limits of detection and interfering factors for each test are also given.

The value of the book lies principally in the fact that the reactions are described concisely, clearly, and uniformly, and that they have been checked in three different laboratories. However, some of the reactions included, *e.g.* a test for rhenium in which molybdenum interferes, or a test for vanadium which is also given by iron, will probably be of little use in practice. Nonetheless, since other reactions are also given in such cases, this is not a serious lapse, and the book can be thoroughly recommended.

R. Bock [NB 288/145 IE]

Progress in Inorganic Chemistry, Vol. 5. Edited by *F. A. Cotton.* Interscience Publishers, a Division of John Wiley & Sons, Inc., New York-London 1963. 1st edit., VIII + 564 pp., numerous illustrs. and tables, linen £ 5.5.0 (about $ 14.50).

Progress in inorganic chemistry – characterized both by development of new individual disciplines from solid state physics to organometallic chemistry, and by increasing numbers of research publications – has led to the innovation of the monograph series "Progress in Inorganic Chemistry" and "Advances in Inorganic Chemistry and Radiochemistry" alongside the classical abstract journals. In view of the current thirst for information, the general usefulness of both series is beyond question, but the present volume leaves some desires unfulfilled.

Its four articles deal with fields which lie very far apart: in his article "Dinitogen Trioxide", *I. R. Beattie* restricts his discussion mainly to the physical properties of this one compound; its interesting connections with other oxides of nitrogen is given only little consideration. *L. Mayer* has written a valuable review with 527 (!) references on the "Preparation of Primary, Secondary, and Tertiary Phosphines"; the readily surveyable systematic classification extends right up to the alphabetically arranged list of references.

In his treatise on the "Polarographic Behavior of Coordination Compounds", *A. A. Vlček* gives a well-planned introduction to the methods and scope of this section of electrochemistry. The book closes with a treatise by *A. D. Liehr*, "The Coupling of Vibrational and Electronic Motions in Degenerate and Nondegenerate Electronic States of Inorganic and Organic Molecules, Part III: Nondegenerate Electronic States"; Parts I and II are to be found in Volumes 3 and 4 of the series.

The last point mentioned induces the reviewer to direct a request at the editor: In consideration of the reasonable price of the volumes and above all of the excellent quality of most of the individual contributions, attempts should be made to avoid too great variances in the nature of the articles published together in one volume. Better coordination of the subject matter discussed can only be of benefit to the value of each individual volume.

H. Bock [NB 303/162 IE]

The Cyanine Dyes and Related Compounds. By *Frances M. Hamer.* Vol. 18 on The Chemistry of Heterocyclic Compounds, a Series of Monographs edited by *A. Weissberger.* Interscience Publishers, a Division of John Wiley & Sons, New York-London 1964. 1st edit., XXXVI + 790 pp., a few illustrs., numerous tables, linen £17.0.0 (about $47.00).

It is a long and laborious undertaking to describe over one hundred years of cyanine dyestuff chemistry, and hence the author of this volume deserves high recognition for working through the publications and patents on cyanine dyes since 1856 (the discovery of cyanine by G. Williams) until 1959 with such great care and for assorting the innumerable dyestuffs of this class as far as possible into an orderly system. The essential discoveries of the first 50 years of cyanine chemistry, during which the dyes were still produced mainly by empirical methods since their structures were unknown, have been lucidly reconstructed. The recapitulation of later developments has benefitted greatly from the fact that the author has herself participated in the research and applications of these dyes since the early nineteen-twenties. Thus she has succeeded in writing a book which is the only work of reference of this type available that the expert in this field can consult to find the numerous chemical syntheses and physical properties of even the most complicated dyestuffs.

Apart from describing the classical basic cyanines prepared from common and less usual heterocyclics, the book also includes other classes of polymethine dyes, *e.g.* hemicyanines, styryl dyestuffs, and the azacyanines, a class of dyes which has acquired new importance for coloring synthetics fibers. Long, detailed chapters are also devoted to dequaternized cyanines, the merocyanines, and hemioxonoles (neutrocyanines), and to acidic polymethines (oxonoles) and polynuclear cyanines. The book is also a treasure trove for dyestuff theorists, for example, thanks to its chapters on constitution and color and on spectral sensitization of silver halide emulsions. The fluently readable style of the text and the high quality of the print deserve a special mention. The only improvement to be desired in this volume is the inclusion of a patent index, and it is to be hoped that the author will be able to compile a sequel which is just as comprehensive and carefully edited to cover the developments in this subject since 1959. *O. Riester* [NB 295/153 IE]

Liquid Extraction. By *R. E. Treybal.* McGraw-Hill Series in Chemical Engineering, edited by *M. S. Peters.* McGraw-Hill Book Co. Inc., New York-San Francisco-Toronto-London 1963. 2nd Edit., 621 pp., numerous illustrs., linen, £ 6.8.0 (about $ 18.00).

The title of this book suffices to show the nomenclature difficulties encountered in the field of separations by distribution. The term "liquid extraction" here implies the technique normally called "liquid-liquid extraction" in America, "solvent extraction" in Britain, or "distribution between two

liquid phases" in Germany. Moreover, the content of the book is placed in the proper perspective only when it is considered that it is part of the "Series on Chemical Engineering", for it deals comprehensively and in detail with everything that seems to be of importance from the point of view of the U.S. chemical engineer, but contains little or nothing about the chemical fundamentals of distribution. For example, the chapters on "Prediction of Distribution" and "Choice of Solvent" do not discuss the question which solvents may be particularly suitable for separating a mixture of substances for chemical reasons, but contain graphic and mathematical aids for estimating the separatory effect to be expected for a given system of materials when the equilibrium data are only incompletely known.

The book is the accepted standard work on this topic in the U.S. American literature. The terminology coined therein – not always the best – has found acceptance in mineral oil technology even beyond the U.S.A., so that study of the book is the best introduction to literature on this theme. A few chapters (physico-chemical fundamentals, determination of the separatory effect – mostly *via* graphs or diagrams) are recommendable as an educational text on account of the clarity of the diction; others are hard to read, because for some chapters up to two pages are required solely for the key to the symbols used, because despite this other symbols occur the meaning of which is unclear, and because some definitions are insufficiently precise or even incorrect (*e.g.* the quantity A on p. 244). The book seems therefore rather inconvenient for the purpose of rapidly finding answers to isolated questions.

The new edition is some 50 % larger than the first edition of 1951; recent literature has been evaluated, and a short chapter on laboratory methods has been inserted. New examples from various fields – including inorganic chemistry – have been added, even though the book is presented from the viewpoint of the petroleum engineer (as shown, for example, by the frequently inapt use of the terms "raffinate" and "extract"). However, the problems discussed, including mass transfer and fundemental questions related to apparatus in particular, are presented in such great detail that anyone working on separations by distribution – even inorganic chemists – can read this book with profit.

Werner Fischer [NB 310/169 IE]

Progress in Reaction Kinetics, Vol. 2. Edited by *G. Porter*, in cooperation with *K. R. Jennings* and *B. Stevens*. Pergamon Press, Oxford-London-Edinburgh-New York-Paris-Frankfurt 1964. 1st Edit., VII + 391 pp., numerous illustrs. and tables, linen £ 4.4.0 (about $ 11.60).

Once again *G. Porter* has succeeded in securing prominent specialists to present excellent treatises on some important aspects of kinetics research.

G. C. Fettis and *J. H. Knox* give a review (36 pp., 64 references) on the rate constants of the reactions between halogen atoms on the one hand and molecules of hydrogen, hydrocarbons, and chlorocarbons on the other. The results are also discussed from the point of view of the methods involved. The fact that the reaction of hydrogen iodide is not a prototype of a bimolecular reaction deserves mention even in a book review.

R. J. Cvetanovic gives a comprehensive discourse (86 pp., 147 refs.) on energy transfer *via* excited mercury atoms. His formulation of the electron-deficient transition state involved (p. 127) is interesting.

H. M. Frey deals with the quantitative aspect of carbene chemistry (27 pp., 126 refs.). Insertion and addition reactions of carbene and substituted carbenes are described.

In the "Kinetics of *cis-trans*-isomerizations" of olefinic systems, *R. B. Cundall* deals with a field that has been studied with particular intensity within recent years (44 pp., 181 refs.). The same remark applies to the "Kinetics of Anionic Polymerization and Copolymerization" by *M. Swarc* and *J. Smid* (61 pp., 180 refs.). Both articles are characterized by their complete coverage of important publications on these subjects.

A review on the "Rate Constants of Protolytic Reactions in Aqueous Solution" by *M. Eigen, W. Kruse, G. Maars*, and *L. De Mayer* is necessarily a summary of *Eigen*'s publications. This is preceded by a discussion of the maximum reaction rate in solution. Regarding relaxation methods the reader is referred to specialized publications.

The chapter on "Reaction Rates of Some Haem Compounds" by *Q. H. Gibson* (12 pp., 67 refs.) gives an exemplary review of the status of kinetic investigations on biochemical systems. In conclusion, a non-review article by *R. M. Noyes* describes the formal kinetic treatment of secondary reactions in a general form. He defines and discusses the limits of validity of approximate solutions.

The final "Reaction Index" gives a list of more than 1000 reactions whose rate constants are discussed in the text. The book is an indispensible part of the libraries of chemical and physico-chemical laboratories. Its purchase for private use can be recommended even to individuals who are working in only one of the fields discussed. *H. Sinn* [NB 312/171 IE]

Volatile Silicon Compounds. By *E. A. V. Ebsworth*. Vol. 4 of the International Series of Monographs on Inorganic Chemistry, edited by *H. Taube* and *A. G. Maddock*. Pergamon Press, Oxford-London-New York-Paris 1963. 1st edit., vi + 179 pp., linen £2.2.0 (about $ 5.75).

The chemistry of the elements Si, Ga, and Sn has developed enormously during the last decade, and silicon compounds are in the forefront of this development. Here the author has disregarded silicates, silicones, silicon methylenes, and complicated carbon compounds containing silicon as a hetero atom in favor of simple compounds of silicon with other elements. This selection is particularly fortunate, since there is no comparable recent survey of this type, and since reliable statements about the nature of the bonding involved can best be made here. An introduction is followed by two chapters on the Si–H bond (simple compounds and their reactions). The third chapter deals with silicon halides. The fourth chapter deals with the Si–C and Si–Si group of compounds, the fifth chapter with those of Si and the elements N, P, and As, and the sixth chapter with the compounds of Si and elements of Group VI of the periodic table. Each chapter deals with the preparation of characteristic compounds and their physical and chemical properties, due regard being given to the results of spectroscopic investigations. The seventh chapter summarizes the data on compounds which do not fit well into the simple scheme selected. The literature has been covered up to 1961. A valuable feature of the book is the inclusion of much numerical data, *e.g.* energies of formation and bond lengths.

This book will prove a valuable companion to every chemist interested in this field. *G. Fritz* [NB 290/148 IE]

Zone Electrophoresis in Blocks and Columns. By *H. Bloemendal*. Elsevier Monographs. Elsevier Publishing Co., Amsterdam-London-New York 1963. 1st edit., viii + 219 pp., 75 figs., 13 tables, linen DM 22.50 (about $ 5.65).

Analytical and preparative zone electrophoresis is an inseparable part of protein chemistry nowadays. Separations of mixtures of similar proteins can be achieved on starch gels in an electrical field with an accuracy that is equalled by practically no other physical method. *Bloemendal* is therefore to be congratulated for this description of conventional apparatus for carrying out block, gel, and column electrophoresis (including continuous procedures), together with procedures for applying them in work with biological materials. The author has intentionally disregarded electrophoresis on paper or agar-agar and also electrophoresis without a solid support, since monographs on these topics have already been published, but he has included electrophoresis on columns with concen-

tration gradients, a technique which has recently been gaining more and more importance. The literature has been covered up to and including 1962, and numerous examples are given of separations of mixtures, with critical comparisons of the values of individual procedures. – A more readily surveyable arrangement of the examples according to the source of the materials or according to classes of compounds would have been of help to readers in finding suggestions for solving their own problems. A detailed discussion of methods for locating enzymes in the support after electrophoresis would also have been desirable, for this will undoubtedly become a large field of application in the future.

The whole of this small book is adapted to practical needs, and it is a helpful supplement to methodological manuals for biochemists, biologists, and physicians.

G. Pfleiderer [NB 292/150 IE]

Electrochemistry. Theoretical Principles and Practical Applications. By *G. Milazzo*. Translated from the Italian by *F. J. Mill*. Elsevier Publishing Co., Amsterdam-London-New York 1963. 1st edit., xv + 708 pp. numerous illustrs. and tables, linen DM 61.50 (about $15.50).

The present volume is an English version of a book which originally appeared in Italian in 1947. The new English edition is largely based on the German version which appeared in 1952 and which was thoroughly revised at that time.

A number of valuable additions have been included compared to the German edition, *e.g.* in the chapter on analytical applications and in the sections on electrochemistry in non-aqueous solutions and fused salts. However, by and large the text has been translated without much alteration. The apparent increase in the size of the book (708 pages in the English edition compared to 419 pages in the German edition) is mainly due to the smaller size of the pages in the English impression.

Therefore the book offers very little new material to the German reader. A radical revision including latest results has not been carried out. But the main disappointment here is that one of the major weaknesses of the earlier editions in the reviewer's opinion, namely the very unsystematic presentation of references to journal publications, has not been improved. In a book where many topics necessarily are summarized, it would be desirable that references to more detailed literature are included to a much larger extent.

A prominent feature of this book is its excellent survey of the technical applications of electrochemistry. The print and layout deserve special acknowledgement.

Color and Constitution of Azo Compounds

BY PRIV.-DOZ. DR. H. BOCK [1,2]

INSTITUT FÜR ANORGANISCHE CHEMIE DER UNIVERSITÄT MÜNCHEN (GERMANY)

BASED ON INVESTIGATIONS CARRIED OUT IN COLLABORATION WITH DR. G. RUDOLPH, DR. E. BALTIN, AND DIPL.-CHEM. J. KRONER

Attempts to explain the surprising violet color of the new azobisphosphonic acid derivatives $Y_2OP{-}N{=}N{-}POY_2$ have led to the preparation and spectroscopic characterization of more than 60 azo compounds. The long-wavelength $n \rightarrow \pi^*$ transitions on which the color depends exhibit regularities which justify the assumption of substituent-specific absorption increments. The complex relation between color and constitution of azo compounds can be qualitatively explained with the aid of orbital models. Infrared and ultraviolet spectral data show that conjugation is inhibited by tetra-coordinated phosphorus(V). The π-system of these compounds therefore comprises only four atoms, P–N–N–P. The unexpected violet color of the phosphorus azo compounds can be ascribed to a π^*/d orbital interaction. The substituent effects described have general significance, and $n \rightarrow \pi^*$ transitions of other chromophores are similarly affected.

A. Inorganic Azo Compounds

The first azo compound was prepared in 1834 by *Mitscherlich* [3], who obtained azobenzene by adding an alcoholic solution of nitrobenzene to one of potassium ethoxide. In 1858 *Griess* [4] discovered the diazonium salts, and this discovery initiated the rapid development of azo dyes, in which the N=N double bond is stabilized by aromatic nuclei. Less interest was subsequently

[3] *E. Mitscherlich*, Annal. Pharm. (Liebigs Ann. Chem.) *12*, 311 (1834).

[4] *P. Griess*, Liebigs Ann. Chem. *106*, 123 (1858).

aroused by the less stable azoalkanes R–N=N–R, the azodicarboxylic acid derivatives YOC–N=N–COY, and the tetrazenes R_2N–N=N–NR_2. Finally, four azo compounds *(1)*, *(2)*, *(3)*, and *(4)* with inorganic substituents have been independently reported.

HO–N=N–OH KO_3S–N=N–SO_3K

(1) *(2)*

F–N=N–F H–N=N–H

(3) *(4)*

The colorless, explosive hyponitrous acid *(1)* is formed by the oxidation of hydroxylamine or by the reduction of nitrous acid [5]; its structure has been proved spectroscopically [6, 7]. The yellow dipotassium azobissulfonate *(2)*, unstable above 0 °C, is obtained by oxidation of hydrazine-1,2-bissulfonate [8] or amidosulfonic acid [9]. The colorless, stable difluorodiazine *(3)* is formed during thermal decomposition of fluoroazide [10, 11], electrolysis of ammonium fluoride [12, 13], or syntheses of N_2F_4 [14]. The yellow diimide *(4)*, which is stable at low temperatures only, has been detected after electrical discharges in atmospheres of hydrazine or hydrazoic acid [15].

The thermal stability of the azo compounds YX–N=N–XY is governed by the strength of the bond between the ligand XY and the azo nitrogen, since the bond energy of the molecular nitrogen formed on decomposition is 126 kcal/mole greater than that of the N=N double bond. The decomposition temperature is raised by conjugation involving an extensive π-electron system, or by a -I effect of electronegative substituents. For example, azobenzene boils at 297 °C without decomposition, and difluorodiazine survives the drastic conditions of N_2F_4 syntheses. Considerations of the similarity of the bond energies of P–N and C–N bonds [16], and a stabilizing π/d-conjugation between the N=N group and adjacent phosphorus atoms [17], led us to the synthesis of another class of inorganic azo compounds, namely the azobisphosphonic acid derivatives *(5)* [18, 19, 20].

B. Preparation of Compounds

1. Azobisphosphonic Acid Derivatives

The hydrazine derivatives *(7)* required as starting materials were unknown, with the exception of the tetraphenyl ester (Y = OC_6H_5) [21]. It was first necessary to find a simple method of obtaining anhydrous hydrazine [22], in order to be able to carry out the hydrazinolysis of the readily hydrolysed phosphoric acid chlorides. The hydrazinolysis proceeds *via* intermediates *(6)* which can be isolated, and ultimately leads to the 1,2-bisphosphinylhydrazines *(7)*.

$$Y_2OPCl \xrightarrow[-HCl]{+N_2H_4} Y_2OP\text{-}NH\text{-}NH_2 \quad (6)$$

$$\xrightarrow[-HCl]{+Y_2OPCl} Y_2OP\text{-}NH\text{-}NH\text{-}POY_2 \quad (7)$$

Y = OC_6H_5, R

Finally, there was no known method for the oxidation of the readily solvolysed compounds *(7)*. *N*-Bromosuccinimide was found to be suitable for the selective oxidation of hydrazines in inert solvents [23], the formally (+1)-valent bromine being reduced to the element or, in the presence of pyridine, to hydrogen bromide.

The *N*-bromosuccinimide method permitted the preparation of the azobisphosphonic acid derivatives *(5)* with Y = OC_6H_5, C_6H_5, and $N(CH_3)_2$, the thio compound *(8)*, and the unsymmetrically substituted diphenylphosphinylbenzoyldiazene *(9)* [*]. The potassium azobisphosphonates *(14)* and *(13)* were obtained by hydro-

$(C_6H_5)_2SP$–N=N–$PS(C_6H_5)_2$ $(C_6H_5)_2OP$–N=N–CO–C_6H_5

(8) *(9)*

lysis of tetraphenyl hydrazine-1,2-bisphosphonate *(10)* *via* compounds *(11)* and *(12)* [18].

[16] *P. A. Fowell* and *C. T. Mortimer* [J. chem. Soc. (London) *1959*, 2913] obtained a value of 66.8 kcal/mole for the energy of the P–N single bond in $P(NR_2)_3$, compared with the value of 72.8 kcal/mole for the mean C–N bond energy.

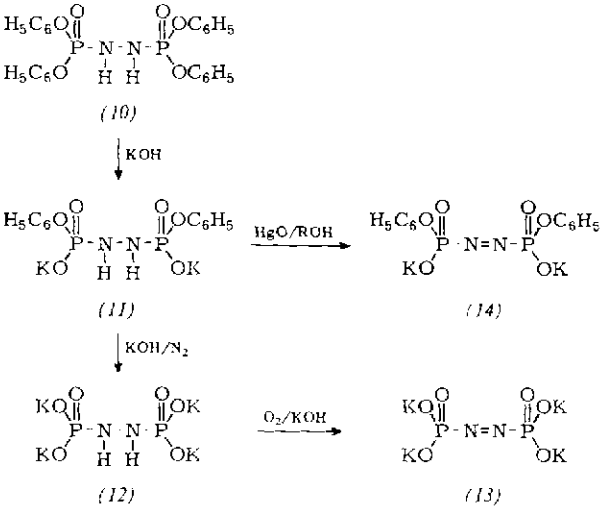
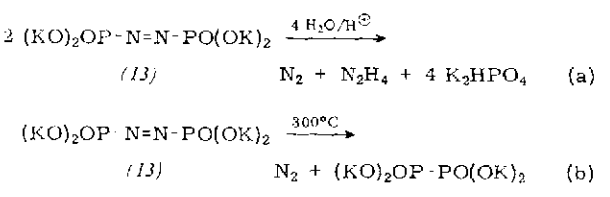
[23] *H. Bock*, *E. Baltin*, and *G. Rudolph*, Chem. Ber., in the press.

[*] In accordance with *McBride* and *Bens* [J. Amer. chem. Soc. *81*, 5546 (1959)], it is suggested that the azo compounds be named "diazenes" [18], in agreement with the systematic nomenclature for nitrogen hydrides; this suggestion will be followed in the present paper where there is no simple trivial name.



The azobisphosphonic acid derivatives differ in their stabilities according to the substituents present, and show their "azo character" by intermolecular hydrolytic (a) and intramolecular thermal (b) decompositions [18, 20].



Tetrapotassium azobisphosphonate *(13)* loses nitrogen quantitatively only above 300 °C, whereas dipotassium azobissulfonate *(2)* does so already at 0 °C [8].

However, the preparative and spectroscopic investigations described in the present paper started from a much more fascinating phenomenon, namely the violet color of the azobisphosphonic acid derivatives.

2. Substances for Spectroscopic Comparison

The unexpectedly high wavelength of absorption of the small π-electron system of the azobisphosphonic acid derivatives is described in the LCAO–MO scheme by a considerable bathochromic shift of the weak $n \rightarrow \pi^*$ band in the visible region of the spectrum (cf. Section C.1). Whereas investigations into the cause of the violet color were baulked by the largely unknown effects of inorganic substituents with unoccupied d-orbitals, literature searches showed that the $n \rightarrow \pi^*$ band of the azo compounds YX–N=N–XY undergoes an increasing bathochromic shift with decreasing electronegativity of the substituents XY (Table 1). In order to find regularities, it was first necessary to obtain spectroscopic data for comparison.

Owing to the work involved in the synthesis of new azo compounds and because of their unknown thermal stability, attention was focussed on known classes of compounds. The empirical rule that, in azo compounds having a phenyl substituent on only one of the nitrogens,

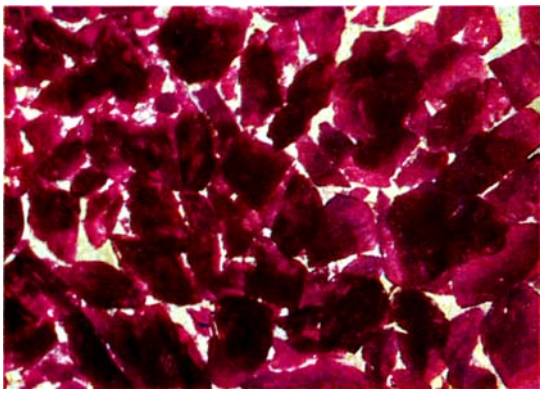


Fig. 1. Crystals of tetraphenyl azobisphosphonate in transmitted light (magnification ca. 4×).

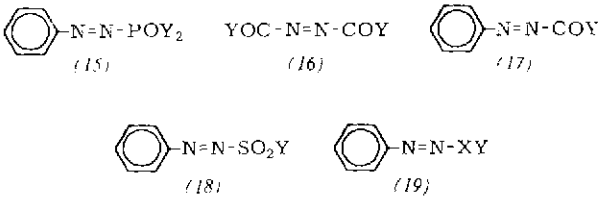
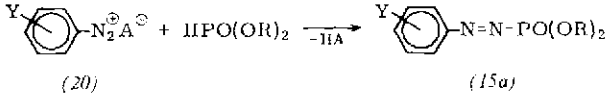
the substituent-nitrogen bond is stabilized by becoming part of the conjugated system, was found useful in this work. We prepared more than 60 known and unknown derivatives of phenylazophosphonic acid *(15)*, azodicarboxylic acid *(16)*, phenylazocarboxylic acid *(17)*, and phenylazosulfonic acid *(18)*, as well as other phenylazo compounds *(19)* [24–26].



The *N*-bromosuccinimide method developed for the oxidation of the 1,2-bisphosphinylhydrazines usually led to good yields of pure azo compounds.

a) Phenylazophosphonic Acid Derivatives

Phenylazophosphonic acid derivatives *(15)*, which were first prepared in 1958 by *Suckfüll* and *Haubrich* [27] from *p*-substituted phenyldiazonium salts *(20)* and dimethyl phosphonate, have a reasonable thermal stability.



The principle underlying this reaction, *i.e. Fischer*'s [28] synthesis of diazosulfonates, was adapted to non-aqueous solvents by using phenyldiazonium tetrafluoroborate [25]. Higher yields of phenylazophosphonic acid derivatives *(15b)* were always obtained, however, by synthesis *via* the hydrazines *(21)*, although some Lewis bases of the type $HPOY_2$ were not easily accessible.

[24] Cf. the summaries of unpublished work: *H. Bock*, *E. Baltin*, and *G. Rudolph*, Angew. Chem. *75*, 789 (1963); Angew. Chem. internat. Edit. *2*, 484 (1963); *H. Bock*, *E. Baltin*, *J. Kroner*, and *G. Rudolph*, Angew. Chem. *76*, 575 (1964), Angew. Chem. internat. Edit. *3*, 645 (1964); *H. Bock*, Lecture, Schloss Elmau, (April 22nd, 1964).

[27] *F. Suckfüll* and *H. Haubrich*, Angew. Chem. *70*, 238 (1958).

[28] *E. Fischer*, Liebigs Ann. Chem. *190*, 67 (1878).

$$H_5C_6\text{-}NH\text{-}NH_2 + ClPOY_2 \xrightarrow[-HCl]{} H_5C_6\text{-}NH\text{-}NH\text{-}POY_2 \quad (21)$$

$$\xrightarrow[-H_2]{} H_5C_6\text{-}N{=}N\text{-}POY_2 \quad (15b)$$

The 1-phenyl-2-phosphinylhydrazines *(21)* and phenylazophosphonic acid derivatives *(15b)*, with the exception of the dimethyl ester, were previously unknown, as were the thio and tosylimido compounds *(22)* and *(23)*.

$H_5C_6\text{–}N{=}N\text{–}PS(C_6H_5)_2$ *(22)* $\quad H_5C_6\text{–}N{=}N\text{–}P(C_6H_5)_2{=}N\text{–}Ts$ *(23)*

In the course of investigations on the relationship between *Hammett*'s σ-values and the $n \rightarrow \pi^*$ frequencies, other substituted dimethyl phenylazophosphonates *(15a)* were prepared with *p*-Y = NO_2, NNC_6H_5, CN, COOR, Cl, R, OR, NR_2, and *m*-Y = NO_2, CN, CF_3, COOR, Cl, OR, R [29].

b) Azodicarboxylic Acid Derivatives

The symmetrically substituted azodicarboxylic acid derivatives *(16)* desired for the spectroscopic investigations were all known, with the exception of the phenyl ester (Y = OC_6H_5) and the dimethylamide [Y = $N(CH_3)_2$] [30–33]. They were synthesized in the usual manner, *via* the hydrazines *(24)* and *(25)*.

$$YOCCl \xrightarrow[-HCl]{+N_2H_4} YOC\text{-}NH\text{-}NH_2 \quad (24) \xrightarrow[-HCl]{+YOCCl}$$

$$YOC\text{-}NH\text{-}NH\text{-}COY \quad (25) \xrightarrow[-H_2]{} YOC\text{-}N{=}N\text{-}COY \quad (16)$$

The following oxidizing agents were used: *N*-bromosuccinimide for dibenzoyldiazene (Y = C_6H_5), di-*p*-chlorobenzoyldiazene (Y = C_6H_4Cl), and diphenyl azodicarboxylate (Y = OC_6H_5) [26]; bromine for diacetyldiazene (Y = R) [30]; potassium dichromate for azodicarboxamide (Y = NH_2) [31]; and nitric acid for the dialkyl azodicarboxylates (Y = OR) [32]. Reaction of the esters with dialkylamines led to high yields of the azodicarboxylic dialkylamides (Y = NR_2) [26, 33].

The substitution of the carboxylic hydrazides *(24)* with other carbonyl chlorides, followed by oxidation of the hydrazine *(25)* with *N*-bromosuccinimide, led to unsymmetrically substituted azodicarboxylic acid derivatives ($Y^1 \neq Y^2$) [26].

$H_5C_6\text{–}CO\text{–}N{=}N\text{–}CO\text{–}C_6H_4Cl$ *(26)* $\quad H_5C_6\text{–}CO\text{–}N{=}N\text{–}CO\text{–}OR$ *(27)*

$RO\text{–}CO\text{–}N{=}N\text{–}CO\text{–}N(C_2H_5)_2$ *(28)*

Compound *(26)* is important for the calculation of the dipole moments of azo compounds [34], *(27)* for the proof of substituent-specific increments in the $n \rightarrow \pi^*$ absorption (Section C.3), and the phenyl-free derivative *(28)* for the assignment of the N=N vibration frequency in the infrared spectrum [26].

c) Phenylazocarboxylic Acid Derivatives

The first phenylazocarboxylic acid derivatives *(17)* (Y = C_6H_5, NH_2) were described by *E. Fischer* [28] in 1878; subsequently, the ethyl ester (Y = OC_2H_5) and the potassium salt (Y = OK) were found [35, 36]. A number of substituted phenylazocarboxamides (Y = NH_2) have recently been characterized by their electronic spectra [37]. This class of compounds also has not yet been systematically studied.

N-Bromosuccinimide was found to be an excellent oxidizing agent for the phenylhydrazine derivatives *(29)* also [25].

$$H_5C_6\text{-}NH\text{-}NH_2 + ClCOY \xrightarrow[-HCl]{} H_5C_6\text{-}NH\text{-}NH\text{-}COY \quad (29)$$

$$\xrightarrow[-H_2]{} H_5C_6\text{-}N{=}N\text{-}COY \quad (17)$$

(Y = C_6H_5, C_6H_4Cl, R, NR_2, OC_6H_5, OR)

The dimethylamide *(30)* (R = CH_3), however, is preferably prepared by aminolysis, and the potassium salt *(32)* (Y=OK) by hydrolysis of methyl phenylazocarboxylate [25].

$$H_5C_6\text{-}N{=}N\text{-}CO\text{-}NR_2 \quad (30) \xrightarrow{+H_2} H_5C_6\text{-}NH\text{-}NH\text{-}CO\text{-}NR_2 \quad (31)$$

$$+HNR_2 \uparrow \; -ROH$$

$$H_5C_6\text{-}N{=}N\text{-}CO\text{-}OR$$

$$-ROH \downarrow \; +KOH$$

$$H_5C_6\text{-}N{=}N\text{-}CO\text{-}OK \quad (32) \xrightarrow{+H_2} H_5C_6\text{-}NH\text{-}NH\text{-}CO\text{-}OK \quad (33)$$

Reduction of these compounds gives excellent yields of the hydrazines *(31)* and *(33)* [25].

d) Phenylazosulfonic Acid Derivatives

As expected, the thermal stability of the phenylazosulfonic acid derivatives *(18)* is considerably greater than that of similarly substituted azobissulfonic acid derivatives *(34)*.

$H_5C_6\text{–}N{=}N\text{–}SO_2Y$ *(18)* $\quad YO_2S\text{–}N{=}N\text{–}SO_2Y$ *(34)*

Thus dipotassium azohissulfonate *(2)*, or *(34)* with Y = OK, rapidly and quantitatively loses N_2 above 0 °C [25], whereas potassium phenylazosulfonate, *(18)* with Y = OK, loses nitrogen only above 215 °C. Phenylazophenyl sulfone, *(18)* with Y = C_6H_5, melts at 76 °C without decomposition [38], whilst 1,2-ditosylhydrazine lost nitrogen even at −50 °C during oxidation experiments [19].

We prepared known phenylazosulfonic acid derivatives *(18)* *via* diazosulfonates [28] or by oxidation of the hydrazines with *N*-bromosuccinimide (Y = C_6H_5, R) [38, 39]. The preparation of new phenylazosulfonic acid derivatives failed in most cases because suitable starting compounds were not obtainable; for example, phenylhydrazine reacts with dimethylaminosulfonyl chloride or methoxysulfonyl chloride

YO_2SCl (Y = NR_2, OCH_3) in an inert solvent with liberation of sulfur dioxide. Methyl phenylazosulfonate *(36)* was finally obtained in almost 100 % yield as an unstable red oil *via* silver phenylazosulfonate *(35)* [25].

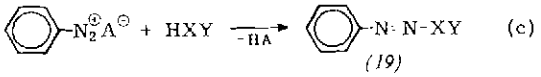
$$H_5C_6\text{-}N{=}N\text{-}SO_2\text{-}OK \xrightarrow[-KNO_3]{+AgNO_3} H_5C_6\text{-}N{=}N\text{-}SO_2\text{-}OAg \quad (35)$$

$$\xrightarrow[-AgI]{+CH_3I} H_5C_6\text{-}N{=}N\text{-}SO_2\text{-}OCH_3 \quad (36)$$

e) Other Phenylazo Compounds

The position of the $n \rightarrow \pi^*$ absorption maximum for azo compounds YX–N=N–XY is much more strongly influenced by the substituent X (adjacent to the azo group) than by Y (cf. Section C.1). Therefore phenylazo compounds *(19)* containing various substituents X (= B, C, N, O, Si, P, S, As, Se) were of great interest for spectrascopic investigations.

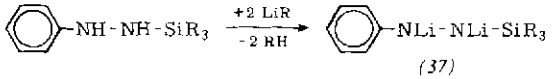
A number of phenylazo compounds *(19)*, XY = NR_2, S-C_6H_5, were obtained by diazo coupling [40,41]:



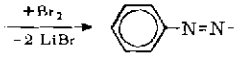
(c)

(19)

The interesting blue 1-phenyl-2-trialkylsilyldiazenes *(38)* are formed on oxidation of the dilithium hydrazide *(37)* with bromine [42]. The *p*-nitrophenylazo derivative *(39)* was obtained by methylation of silver *p*-nitrophenyldiazotate [43].

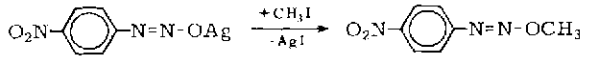


(37)



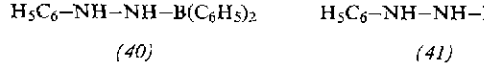
(38)

The unsubstituted 1-methoxy-2-phenyldiazene *(19)*, with XY = OCH_3, is explosive [44].



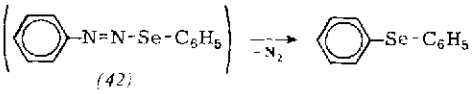
(39)

The phenylazo compounds mentioned above appear to exhaust the preparative possibilities: thus all attempts so far to oxidize new phenylhydrazine derivatives, such as *(40)* and *(41)*, containing boron or trivalent phosphorus led to brownish-black decomposition products [25,45].



(40) *(41)*

Similarly, 1-phenyl-2-selenophenyldiazene *(42)* could not be obtained by diazo coupling with sodium selenophenoxide, even at −5 °C; the reaction product was found to be diphenyl selenide [25].



(42)

C. Spectroscopic Investigations

1. Absorption of Light by the Azo System

The weak absorption of azo compounds YX–N=N–XY in the visible is described in the LCAO–MO scheme by the excitation of a non-bonding (n) electron of the azo nitrogen into the lowest antibonding (π^*) orbital of the molecule (Fig. 1) [46–50]. Contrary to the assumption of *Burawoy* [51], who distinguished between $\pi \rightarrow \pi^*$ transitions or K bands (K = conjugation) and $n \rightarrow \pi^*$ transitions or R bands (R = radical), the latter are in most cases singlet-singlet excitations with retention of the electron spin [52].

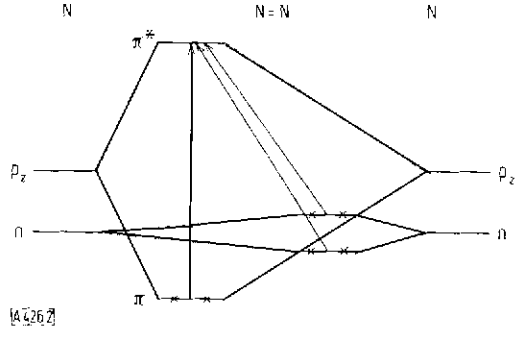


Fig. 2. Energy-level diagram for the azo group [49].

The low $n \rightarrow \pi^*$ intensity (molar extinction coefficients ε_m up to 10^3 l/mole/cm and oscillator strengths f up to 10^{-2}) follows from general selection rules: in planar *trans*-azo compounds with C_{2h} symmetry [46], the $n_s \rightarrow \pi^*$ ($^1B_g \leftarrow {}^1A_g$) transition is forbidden and the $\pi \rightarrow \pi^*$ ($^1B_u \leftarrow A_g$) transition is allowed. The assignment of the allowed $n_a \rightarrow \pi^*$ ($^1A_u \leftarrow {}^1A_g$) transition is uncertain [53]; the interaction of the *trans*-n orbitals probably remains small [49].

According to *Kasha* [52], $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions can be differentiated with the aid of solvatochromic effects, which were first discovered by *Scheibe* [54] and

later investigated by *Burawoy* [51]: as the polarity of the solvent is increased, n → π* bands in general undergo hypsochromic shifts (negative solvatochromism), and π → π* bands bathochromic shifts (positive solvatochromism). These phenomena may be due to hydrogen bonding and dipole-dipole interactions [46–50]. Measurements of solvatochromism of the azo compounds prepared are reported in Section C.2.g.

The configuration of the excited state in azo compounds is unknown, since the N=N group masks any vibrational fine structure, even in the vapor state [46]. The electronic spectra of N=N systems (except azobenzene and its derivatives) have so far attracted little interest, although *Hantzsch* and *Lifschitz* [55] discovered as early as 1911 that the spectra of azo compounds are greatly influenced by the subsituents present. In 1941, *Kortüm* verified the n → π* assignment of the long-wavelength azo band by protonating the azo nitrogens [56]. *Birnbaum*, *Linford*, and *Style* measured substituent effects in *p*-substituted *cis*- and *trans*-azobenzenes [57]. The LCAO–MO approximation has been applied not only to azobenzene [58,59], but also to diisopropyldiazene [53]. *Robin* and *Simpson* [53] also discussed possible assignments of the three absorption bands present in the spectrum. *Gerson* and *Heilbronner* investigated the electronic spectra of phenylazoazulenes, but the weak long-wavelength bands of these compounds are due to the azulene skeleton [60]. The direction of the n → π* transition moment in azobenzene was determined by *Hochstrasser* and *Lower* [61], who attribute the residual intensity of the symmetry-forbidden n → π* transition to antisymmetric molecular vibrations of the class a_u.

Comparison of the weak absorption maxima in the visible region of azo compounds YX–N=N–XY shows a decrease in the n → π* frequency with decreasing electronegativity of X. Note the appreciable variation in excitation energies ($\Delta E \approx 65$ kcal/mole) over the range of substituents listed in Table 1. Variations in the long-wavelength absorption as a result of changes in Y, on the other hand, lie within the limits shown.

Table 1. Color, long-wavelength absorption maxima, and absorption intensities for azo compounds YX–N=N–XY.

XY	F [10–14]	OY [6]	NY_2 [26,56]	CY_3 [53,56,62]
Color	colorless	colorless	colorless	yellowish

[a] Assignment uncertain.

2. Electronic Spectra of the Azo Compounds

a) Azobisphosphonic Acid Derivatives

The electronic spectra of the azobisphosphonic acid derivatives (Fig. 3 and Table 2) each contain one isolated band. The weak n → π* transitions, which determine the color, are of interest owing to their unusually low frequency. Changes in substituents Y cause displacements only within the narrow range of 17600 to 18800 cm^{-1}, and have little effect on the intensities (oscillator strengths $f = 1.8\times10^{-4}$ to 3.5×10^{-4}). The n → π* maximum of an unsymmetrically substituted azo compound in this series always lies between the maxima of the two symmetrically substituted compounds [for example, compare *(5d)* with *(5c)* and *(5e)*, or *(5g)* with *(5a)* and dibenzoyldiazene *(16a)* (Table 4)]. The n → π* bands of all phosphorus azo compounds are steeper on the long-wave length side; with the aid of the *Franck-Condon* principle it is possible to explain this asymmetry by conjugational effects (Section C.3).

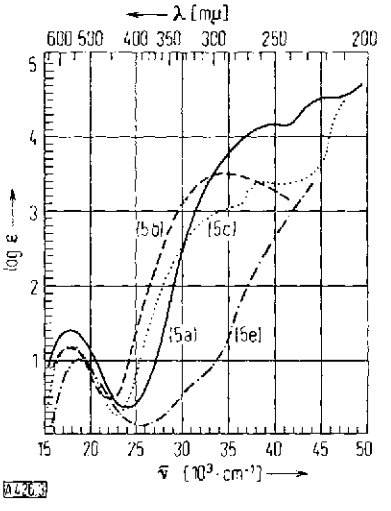

Fig. 3. Electronic spectra of some azobisphosphonic acid derivatives $Y_2OP–N=N–POY_2$ (cf. Table 2).

The absorption of the azobisphosphonic acid derivatives increases in the ultraviolet region, with no distinct maximum; care is therefore required in making assignments. The phenyl esters *(5c)* and *(5d)* clearly show ^1L_b bands due to the

[63] The electronic spectra referred to here and in the remainder of this paper were measured in dioxane, except where otherwise noted. The positions of the absorption maxima ν_m are expressed in cm^{-1} and molar extinctions ε_m in liter/mole/cm. The oscillator strengths were obtained from the band-widths $\Delta\nu_{1/2}$ at half the maximum intensity with the approximation $f = 4.315\times10^{-9}\cdot\varepsilon_m\cdot\Delta\nu_{1/2}$ [49]. For π → π* bands in which the short-wavelength side was partly masked by adjacent bands, $\Delta\nu_{1/2}$ was taken from the long-wavelength side assuming symmetrical bands. For partly masked n → π* branches, ν_m and ε_m were calculated using the equation of a symmetrical or unsymmetrical Gauss curve [65] selected to fit the unmasked part of the band. The agreement between experimental and calculated values confirms that the n → π* bands are unsymmetrical for phosphorus azo-compounds, and symmetrical for all other classes of azo compounds investigated (Section C.3).

[64] The maximum errors in the spectral data recorded are estimated to be, in general, ±100 cm^{-1} in the positions of the bands, and ±10% in the molar extinctions (cf. [67]). The azo compounds studied exhibit little solvatochromism (Section C.2.a). With few exceptions, their spectra were all recorded in dioxane. All the solutions obeyed the Beer-Lambert law.

benzene nucleus, confirmed by both the fine structure and the fact that the extinction of *(5c)* is twice that of *(5d)*. However, a molar extinction five times as great and the lack of fine structure in the tetraphenyl compound *(5a)* raises doubts regarding a similar ^1L_b assignment in this case. The first indication of the position of the $\pi \rightarrow \pi^*$ band of the P–N=N–P chromophore is provided by the maximum of the

tetrakis(dimethylamino) derivative *(5b)*, which contains no phenyl groups. Of the many attempts to locate the $\pi \rightarrow \pi^*$ bands of other azobisphosphonic acid derivatives by analysis of the ascending part of the long-wave length curve, the method employing the subtraction of the hydrazine absorption led unexpectedly to smooth difference curves.

The symmetrical Gauss curves which may be used to approximate the difference curves have maxima at roughly the same frequencies irrespective of the substituent Y [$\nu_m^{(1)}$ ca. 31000 cm^{-1}; $\nu_m^{(2)}$ ca. 35000 cm^{-1}], but different heights. Further information regarding the $\pi \rightarrow \pi^*$ absorption of the phosphorus azo compounds will be provided by qualitative model considerations (Section D.3.a).

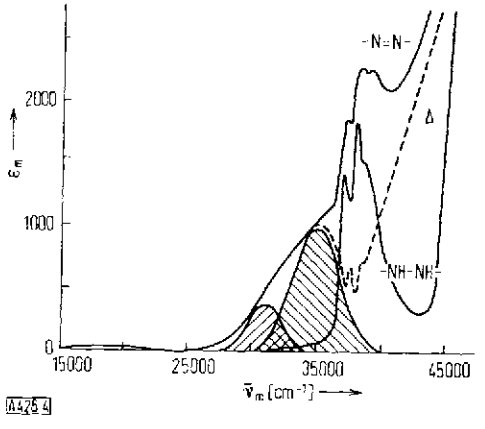

Fig. 4. Absorption difference (broken line) of tetraphenyl azobisphosphonate and tetraphenyl hydrazino-1,2-bisphosphonate.

b) Phenylazophosphonic Acid Derivatives

Three bands can be distinguished in the electronic spectra of the phenylazophosphonic acid derivatives (Fig. 5 and Table 3).

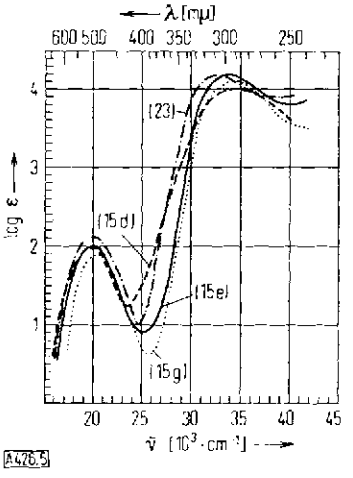

Fig. 5. Electronic spectra of representative phenylazophosphonic acid derivatives $H_5C_6-N=N-PZY_2$ (cf. Table 3).

The weak absorption in the visible region is identified as an $n \rightarrow \pi^*$ transition by a slight but distinct negative solvatochromism (cf. Section C.2.a). The maxima lying between 32000 and 35000 cm^{-1} (f ca. 0.3) are assigned to $\pi \rightarrow \pi^*$ transitions. Another band characteristic of the particular substance occurs above 40000 cm^{-1}; this band will not be discussed here, since the solvent (dioxane) absorbs in this region.

Attention should again be drawn to the steeper descent on the long-wavelength side of the $n \rightarrow \pi^*$ bands; this asymmetry cannot be attributed to interference by adjacent bands on the short-wavelength side, in view of the low extinctions at 25000 cm^{-1}.

c) Azodicarboxylic Acid Derivatives

The electronic spectra of some azodicarboxylic acid derivatives are presented in Fig. 6 and Table 4. The $n \rightarrow \pi^*$ transitions fit in well with the regularities observed in the azo-bisphosphonic acid derivatives (Section C.2.a). Thus the maxima and the extinctions of the unsymmetrical compounds *(16g)* or *(16h)* again lie between those of the symmetrically substituted compounds *(16a)* and *(16f)*, or *(16f)* and *(16c)*.

[a] Unstable.
[b] Spectrum of the ethanolic hydrolysis solution at about 75 % conversion.

The n → π* oscillator strengths of the azodicarboxylic acid derivatives are about three times those of the phosphorus analogues, and the bands are symmetrical. The wavelength of the n → π* transition of dibenzoyldiazene *(16a)* is surprisingly high (21300 cm^{-1}), but the π → π* transition indicates an energetically favorable π-electron system involving the benzene nuclei. The same is true of ethyl benzoylazocarboxylate *(16g)*, the π→π* molar extinction of which is eight times that of diphenyl azodicarboxylate *(16e)* in the same region.

Azodicarboxylic acid derivatives in general exhibit peculiar ultraviolet spectra: the spectra in dioxane show only inflections, whereas those in methanol show maxima shifted to the blue. Investigations are in progress to determine whether this behavior is due to photo-induced *cis-trans* isomerization [66].

[a] In ethanol.

a π → π* band between 34000 and 38000 cm^{-1}, and a further band above 42000 cm^{-1}, which was not measured owing to the incipient dioxane absorption. The oscillator strengths are roughly the same as those of the phenylazophosphonic acid derivatives (Section C.2.b). The two groups of phenylazo compounds differ, however, in the shape of the n → π* band, which in the case of the phenylazocarboxylic acid derivatives is symmetrical. The symmetry of the long-wavelength bands, which are only discernible as shoulders, can be ascertained by comparison with calculated symmetrical and unsymmetrical Gauss curves [63].

d) Phenylazocarboxylic Acid Derivatives

The electronic spectra of the phenylazocarboxylic acid derivatives (Fig. 7 and Table 5) also contain three absorption maxima: an n → π* band falling within the narrow range of 22500 to 24000 cm^{-1} (depending on the substituent Y),

e) Phenylazosulfonic Acid Derivatives

As in the case of the phenylazocarboxylic acids, three maxima can be distinguished in the electronic spectra of the phenylazosulfonic acid derivatives (Fig. 8 and Table 6). The n → π*

[65] *C. Sandorfy*: Die Elektronenspektren in der Theoretischen Chemie, Verlag Chemie, Weinheim 1961, p. 32.

[66] *E. Koerner von Gustorf* and *B. Kim*, Lecture, Freiburg 1964; Angew. Chem. 76, 592 (1964).

bands are symmetrical. The spectrum of the oily, readily decomposed methyl ester *(18c)* is unreliable, since this compound could not be purified.

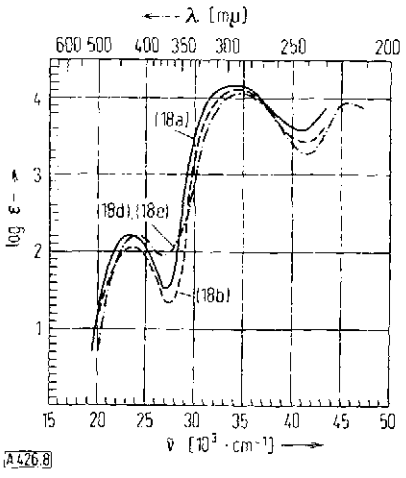

Fig. 8. Electronic spectra of representative phenylazosulfonic acid derivatives $H_5C_6-N=N-SO_2Y$ (cf. Table 6).

Table 6. Absorption maxima and intensities for phenylazosulfonic acid derivatives $H_5C_6-N=N-SO_2Y$ [63, 64].

	XY	$n \rightarrow \pi^*$			$\pi \rightarrow \pi^*$		
		ν_m [cm^{-1}]	ε_m	f	ν_m [cm^{-1}]	ε_m	f
(18a)	$SO_2(C_6H_5)$	23400	159	0.0035	33900	14000	0.36

(18c)	$SO_2(OCH_3)$ [a]	(24100)	(117)	—	—	—	—
(18d)	$SO_2(OK)$ [b]	24200	154	0.0028	34750	11200	0.26
(18e)	$SO_2(OAg)$ [b]	24250	169	0.0030	34750	10200	0.26

[a] Unstable above 0 °C. [b] In water.

The close agreement between the spectra of the stable potassium phenylazosulfonate *(18d)* and silver phenylazosulfonate indicates that the reproducibility of the measurements is satisfactory, assuming that the influence of the cation is the same in both cases [64].

f) Other Phenylazo Compounds

In the electronic spectra of phenylthiophenyldiazene *(19a)*, 1-phenyl-3,3-dimethyltriazene *(19b)*, and methoxy-*p*-nitrophenyldiazene *(39)* (Fig. 9 and Table 7), the $n \rightarrow \pi^*$ bands, which have been displaced towards shorter wavelengths, are

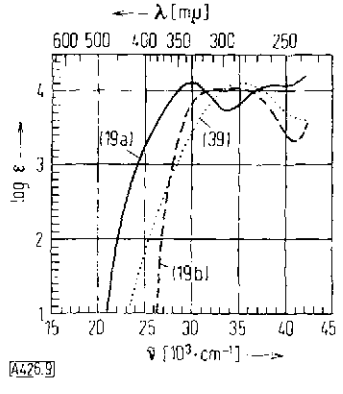

Fig. 9. Electronic spectra of 1-phenyl-2-thiophenyldiazene, 1-phenyl-3,3-dimethyltriazene, and methoxy-*p*-nitrophenyldiazene (cf. Table 7).

presumably masked by the intense $\pi \rightarrow \pi^*$ absorptions; thus the yellow color of these compounds is due to the $\pi \rightarrow \pi^*$ bands, which extend into the visible region of the spectrum.

Table 7. Absorption maxima and intensities for phenylazo compounds $H_5C_6-N=N-XY$ and $O_2N-C_6H_4-N=N-OR$ [63, 64].

	XY	$\pi \rightarrow \pi^*$		
		ν_m [cm^{-1}]	ε_m	f
(19a)	$S(C_6H_5)$	29950	12300	0.31
(19b)	$N(CH_3)_2$	(34300)	(10200)	—
(39)	$O(CH_3)$	25500	13200	0.37

The weak long-wavelength band is absent from the spectra of the colorless tetraalkyltetrazenes, too; the $n \rightarrow \pi^*$ maximum must therefore lie above 32000 cm^{-1} in the case of *trans*-dialkylamino groups (C_{2h}) (cf. Table 1).

g) Solvatochromic Effects

The effects of solvatochromism on the $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ bands of the azo compounds YX–N=N–XY are only slight [25]; appreciable shifts are observed only when the Z values of the solvents differ greatly [67, 68] and with unsymmetrical azo compounds. Thus the $n \rightarrow \pi^*$ band of phenylazophosphonic tetramethyldiamide exhibits the expected hypsochromic shift (cf. Section C.1); the $n \rightarrow \pi^*$ excitation energy in water is 2.1 kcal/mole higher than in cyclohexane. At the same time the $\pi \rightarrow \pi^*$ transition undergoes a 2000 cm^{-1} bathochromic shift corresponding to a 5.7 kcal/mole decrease in the $\pi \rightarrow \pi^*$ excitation energy. The constancy of the molar extinctions [69], which is required for conjugational effects, is satisfied within experimental error, except in the case of the $n \rightarrow \pi^*$ value in water (Table 8).

It may be concluded (with some caution) from the small solvatochromic effects that the differences in polarity between the ground states and the excited states of azo compounds YX–N=N–XY are also small (cf. Section D.2.a).

3. Discussion of the Electronic Spectra of the Azo Compounds

The starting point of our investigations was the unexpected violet color of the azobisphosphonic acid derivatives. The spectroscopic data obtained were used to construct a Platt diagram (Fig. 10), from which it should be possible to discern relationships between color and constitution

[67] *K. Dimroth, C. Reichardt, T. Siepmann,* and *F. Bohlmann,* Liebigs Ann. Chem. *661*, 1 (1963). Cf. also the extensive studies on solvatochromism in substituted azobenzenes [*K. Dimroth,* S.-B. Ges. Beförd. ges. Naturwiss. Marburg *76*, 3 (1963); Chem. Zbl. *1954*, 9481]. The latter exhibit considerably solvatochromism of the $\pi \rightarrow \pi^*$ bands, in contrast to azobenzene itself [25, 57, 59].

of azo compounds. In the azo systems YX-N=N-XY examined, the substituents XY affect the positions, intensities, and shapes of the bands as follows:

The $n \rightarrow \pi^*$ maxima exhibit a bathochromic shift as the electronegativity (EN) of the substituent X adjacent to the azo group is reduced [$EN_C(2.5) \approx EN_S(2.5) > EN_P(2.1)$]. At the same time, the excitation energies of the $n \rightarrow \pi^*$ bands in the region of from 25000 to 17600 cm^{-1} (Fig. 10) decrease by 21 kcal/mole; the total difference $\Delta E_{n \rightarrow \pi^*}$ over the entire range of substituents XY is about 65 kcal/mole (Table 1). The more distant substituents Y, on the other hand, cause only minor bathochromic shifts ($\Delta E_{n \rightarrow \pi^*} \approx 3$ to 10 kcal/mole) in the order $C_6H_5 \approx R \approx NR_2 > OR > O^{\ominus}$ [70]. To a first approximation, therefore, each substituent group XY contributes a definite increment to the $n \rightarrow \pi^*$ absorption; consequently, the $n \rightarrow \pi^*$ maxima of unsymmetrically substituted azo compounds A–N=N–B lie between those of A–N=N–A and B–N=N–B (Table 9).

The $n \rightarrow \pi^*$ intensities follow the same rule (Table 9). The *trans*-azobenzenes have the highest oscillator strengths ($\bar{f} = 135 \times 10^{-4}$ [57]), followed by phenylazo compounds ($\bar{f} = 20 \times 10^{-4}$) and finally azodicarboxylic acid and azobisphosphonic acid derivatives ($\bar{f} = 5 \times 10^{-4}$). Of the substituents Y, the highest extinctions are often exhibited by C_6H_5, and the lowest frequently by $O^{\ominus}$.

The $n \rightarrow \pi^*$ bands of azocarboxylic acid and azosulfonic acid derivatives are symmetrical, whilst those of phosphorus azo compounds are unsymmetrical. According to the Franck-Condon principle [71,72], if the interatomic distances in the ground state and in the first excited state

[a] Decomposition at –20 °C.

[70] On consideration of negative solvatochromism (Section C.2.g) for the anions studied in water (Y = $O^{\ominus}$), the order would be $O^{\ominus} > OR$.

[71] The discussion of the shapes of the bands was suggested by Dr. *F. Dörr*, Technische Hochschule, München.

[72] Cf. *H. A. Staab*: Einführung in die Theoretische Organische Chemie. Verlag Chemie, Weinheim 1960; ref. [49], p. 134.

are not too different, transitions close to the O,O-transition should be energetically favored and therefore lead to a steeper descent on the long-wavelength side of the band (Fig. 11). Thus the spectra indicate that excitation into the π^* state of the P–N=N–P system does not cause appreciable lengthening of the N–N bond. The required compensation by conjugation in the ground state of phosphorus azo compounds could involve empty phosphorus d-orbitals of suitable symmetry (see Section D.3.b).

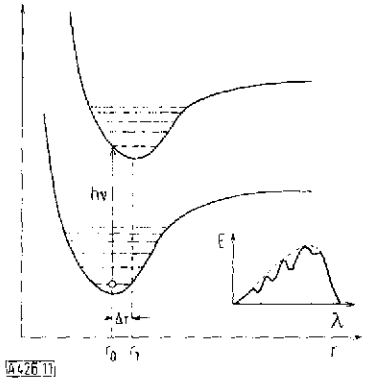

Fig. 11. Application of the Franck-Condon principle to the discussion of the shape of the $n \rightarrow \pi^*$ band.

In the $\pi \rightarrow \pi^*$ transitions of azo compounds, the excitation energies increase and the oscillator strengths decrease from azobenzene ($\nu_m = 31000\ cm^{-1}$, $f = 0.6$), through phenylazo compounds ($\nu_m = 33000$ to $35000\ cm^{-1}$, $\bar{f} = 0.3$) to azobisphosphonic acid and azodicarboxylic acid derivatives ($\nu_m > 35000\ cm^{-1}$, $\bar{f} = 0.05$). The narrow absorption region of phenylazo compounds with such different substituents XY as OR, NR_2, COY, SO_2Y, and POY_2 points to the determining influence of the phenylazo chromophore.

Further investigations, made to compare the above substituent effects on the $n \rightarrow \pi^*$ transitions with those on P=O and C=O stretching frequencies [19,25,26] or on ^{14}N- and ^{31}P-NMR signals [73] will be reported later.

D. Model Considerations

An important result arising from the discussion of the azo absorption in the visible and ultraviolet regions of the spectrum is that the positions and intensities of the $n \rightarrow \pi^*$ bands can be described by substituent-specific increments. However, the complex mechanism of the effect of the substituent XY on the excitation of the N=N group still remains to be elucidated. We shall therefore consider the following possible substituent effects in qualitative LCAO–MO models: inductive displacement of the n level in relation to the π^* orbital, modification of the π system with the n level constant, and interaction of the molecular orbitals of the azo group with empty d-orbitals of suitable symmetry.

[73] The ^{14}N and ^{31}P nuclear resonance spectra were kindly recorded by Dr. *G. Englert*, Freiburg.

1. Inductive Substituent Effects on the n Level

The n level (Fig. 2) of the lone electron pairs on the azo nitrogen atoms, which are orthogonal to the π system, is not taken into account numerically by the simple LCAO–MO theory, and is therefore usually regarded as constant [53,57–59], obviously an unsatisfactory approximation. Till now, n levels and inductive effects acting on them are considered only in small molecules [46] and are allowed for by empirical parameters. Thus *Nagakura* [74], *Jansen* [75], and *Sandström* [76] took as the n level of the lone electron pair the Coulomb integrals of the hetero-atoms in question, made self-consistent by ω-iterations (cf. Section D.2). We shall now attempt to estimate the result of the inductive substituent effect on the energy of the n level.

The energy of the lone electron pair on the uncharged nitrogen atom is taken to be

$$E_n^\circ = A_n\,(Z_{eff,n}^\circ)^2 \qquad (d)$$

where A_n is a constant and Z_{eff} the effective nuclear charge corresponding to the principal quantum number n [77]. On introduction of the inductive substituent effect, the energy of the lone electron pair is changed as a result of the partial charge now carried by the nitrogen. Let the new energy be

$$E_n' = A_n\,(Z_{eff,n}')^2 = A_n\,(Z_{eff,n}^\circ + \sigma\Delta Q)^2 \qquad (e)$$

The value of the screening constant σ for electronic interactions within the same shells is 0.35 [77]. ΔQ expresses the change in the electron density on the nitrogen atom as a result of induction. The quantities involved in Equation (e) can be estimated as follows: the constant A_n is given by the effective nuclear charge $Z_{eff,n}^\circ$ of the uncharged nitrogen atom [78] acting on an electron, and the ionization energy of the nitrogen [79]. According to *Pauling*, ΔQ can be obtained from the relationship between the ionic character of a bond and the difference in the electronegativities of the two bonded atoms [80]. On substitution in Equation (e), it is found that the energy E_n° of the n level in the azo group can vary by about ± 25 kcal as a result of the inductive effect of the substituent XY.

[74] *S. Nagakura*, Bull. chem. Soc. Japan *25*, 164 (1952).

[75] *M. J. Janssen*, Recueil Trav. chim. Pays-Bas *79*, 1066 (1960).

[76] *J. Sandström*, Acta chem. Scand. *16*, 1616 (1962); *17*, 678, 731, 937, 1380 (1963).

[77] *J. C. Slater*, Physic. Rev. *36*, 57 (1930).

[78] According to *Slater* [77], $Z_{eff,n}^\circ = (Z - \sigma)/n = 1.95$ electronic charges for nitrogen, where the nuclear charge $Z = 7$, and the principal quantum number $n_L = 2$. The screening constant σ is made up of the components 2×0.85 for the K-shell and 4×0.35 for the L-shell.

[79] The ionization energy E_N^I of nitrogen is 14.54 ev (cf. *R. W. Kiser*: Tables of Ionization Potentials. United States Atomic Energy Commission, TID-6142). Putting $E_n^\circ = E_N^I$, Equation (d) gives $A_n = 3.83$ ev.

[80] The ionic character IC of a bond can be estimated from the difference ΔEN in the electronegativities of the bonded atoms, using the equation $IC = 1 - \exp[-0.25\,(\Delta EN)^2]$ (*L. Pauling*: The Nature of the Chemical Bond. 3rd Edit., Cornell University Press, Ithaca 1960). Thus the difference in the electronegativities of nitrogen and possible substituents on the azo group ($EN_F = 4.0$; $EN_N = 3.0$; $EN_P = 2.1$) is about ± 1, causing a change in the electron density on the nitrogen of $\Delta Q \approx IC = \pm 0.22$. The equation of *N. B. Hannay* and *C. P. Smith* [J. Amer. chem. Soc. *68*, 171 (1946)] gives I. C. = 0.195

With these assumptions, the inductive effects on the n level of azo compounds range from 27000 cm^{-1} ($\Delta EN_{N-P} = +0.9$) to 45000 cm^{-1} ($\Delta EN_{N-F} = -1.0$), based on a tetrazene standard with the $n \rightarrow \pi^*$ maximum $\nu_m \equiv 36000$ cm^{-1} and the value $\Delta EN_{N-N} \equiv 0$. From the spectroscopic evidence (cf. Table 1), such a result appears to be reasonable.

2. $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ Transitions in the LCAO-MO Scheme

a) Substituent Effects on the π and π^* Levels

The overlapping of coplanar p_z atomic orbitals of azo nitrogen atoms and substituents XY gives rise to a conjugated system which is described in the LCAO–MO scheme by bonding (π) and antibonding (π^*) molecular orbitals, the former containing two electrons each, the latter being empty (Fig. 2). Differences in the electronegativities of the azo group and the substituent XY cause a displacement of the levels of these molecular orbitals similar to the displacement of the n level (Section D.1). Both π and π^* levels in the quasi-alternant systems present are lowered by -I effects [81] and raised by +I effects. Thus, the energy difference $\Delta E_{\pi\rightarrow\pi^*} = \Delta E_{\pi^*} - \Delta E_{\pi}$ should be kept small by small changes in the electron densities on the azo nitrogens during the $\pi \rightarrow \pi^*$ transition (cf. Section C.2.g), and in contrast to the $n \rightarrow \pi^*$ transition, the $\pi \rightarrow \pi^*$ band should be displaced only slightly (Fig. 12a).

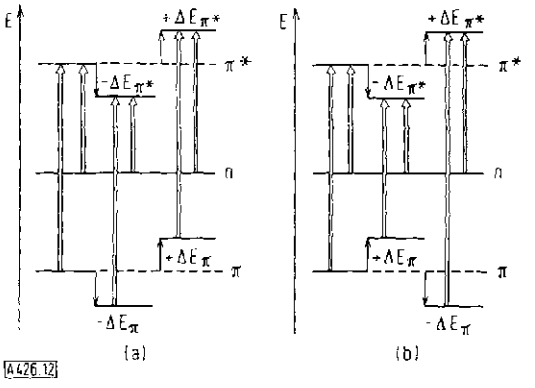

Fig. 12. Inductive (a) and conjugative (b) substituent effects on π and π^* levels of azo compounds.

Conjugative substituent effects, on the other hand, can alter the $\pi \rightarrow \pi^*$ energy difference considerably, since π and π^* levels are affected in an opposing manner in quasi-alternant systems (Fig. 12b). Thus increasing the number of centers of the π-system or decreasing the interaction between the atomic orbitals results in a bathochromic shift of the $\pi \rightarrow \pi^*$ bands.

Owing to the orthogonality of the n level with respect to the π-electron system, conjugative substituent effects act only as second-order perturbations on the former, by changing the effective nuclear charge of the azo nitrogen atoms (Section D.1).

[81] In accordance with *H. A. Staab* (ref. [72], p. 559), the -I effect is defined as the withdrawal of electrons by more strongly electronegative substituents.

b) Calculation of the Electronic Transitions of Organic Azo Compounds

The effects of substituents on π and π^* levels, which have been qualitatively discussed in Section D.2.a, can be verified with satisfactory results in the single-electron scheme of the simple *Hückel* theory [82, 83]. This is best illustrated in the case of the organic azo compounds, where the N=N group is not flanked by hetero-atoms which are difficult to deal with. Since the results were expected to be at best semi-quantitative, we have not carried out parameter variations using spectroscopic data, but simply used verified literature values [83–85]. In spite of this limitation, the calculation yields values for the $\pi \rightarrow \pi^*$ excitation energies in satisfactory agreement with the experimental values (Table 10).

Table 10. Comparison of calculated and spectroscopically determined values of the $\pi \rightarrow \pi^*$ excitation energies in organic azo compounds [86].

[83] *A. Streitwieser* Jr.: Molecular Orbital Theory. Wiley, New York 1961. This also includes a detailed list of the common hetero-atom parameters.

[84] The set of parameters used for the azodicarboxylate anion was adjusted by *A. Zweig* and *A. K. Hoffmann* [J. Amer. chem. Soc. *85*, 2736 (1963)] with the aid of polarography and electron spin resonance data.

[85] The calculations were carried out according to $\alpha_x = \alpha_0 + h_x\beta_0$ and $\beta_{xx} = k_{xx}\beta_0$ with the following hetero-atom parameters (in β units): $h_N = 0.5$ and $k_{N=N} = k_{C=N} = k_{C=C} = 1$ [58, 60, 83, 84] $h_O = 1.2$ and $k_{C=O} = 1.6$ [83, 84], and $h_O = 2.0$ and $k_{C-O} = 0.8$ [83, 84]. Each carboxyl group supplies four electrons to occupy the levels.

[86] The calculation was carried out on an IBM 7090 computer at the Rechenzentrum München-Garching; the complete HMO program was set up by Dipl.-Phys. *P. Straub* and Dr. *E. Weltin*, Zürich. For the spectroscopic data, see Section C.2.d and the literature cited there.

substituents are insufficiently accounted for in simple HMO calculations. The $\pi \rightarrow \pi^*$ transition moments Q and the oscillator strengths f were not determined, since the calculated values for these quantities disagree with the experimental values even in the case of azobenzene, which is well conjugated and contains only two hetero-atoms ($f_{exp} = 0.56$; $f_{calc.} = 1.70$ [58]). On the other hand, satisfactory values of the Coulomb integrals α_N (as an approximate measure of the n level of the azo nitrogen atoms) were obtained by the ω-technique [74–76, 83] [Equation (f), $\omega = 1.4$], after a single iteration step (Table 11).

$$\alpha_N = \alpha_0 + (1 - q_N)\omega\beta_0 \qquad (f)$$

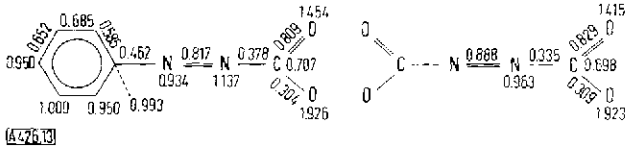
[c] The second q_N value applies to the substituent B; the α_N values are arithmetic means.

The $n \rightarrow \pi^*$ wave numbers, again taking the azobenzene $\pi \rightarrow \pi^*$ transition as standard, place most of the organic azo compounds in the correct order, *i.e.* dibenzoyldiazene > benzoylphenyldiazene > azobenzene > phenylazoalkanes > alkylazocarboxylates > dialkyldiazenes. The close agreement of the value for azobenzene is probably fortuitous. On the other hand, the low $n \rightarrow \pi^*$ excitation energies of all the compounds containing $-CO_2-$ groups require further iteration steps or a parameter variation, using values which follow from the MO molecular diagrams of phenylazocarboxylates and azodicarboxylates (Fig. 13).



A 426.13

Fig. 13. MO diagrams for phenylazocarboxylates and azodicarboxylates showing charge densities and bond orders.

At a hetero-atom/carbon ratio of 3:1, the greatest error is due to ester carbon atom, which is far from self-consistency. The azo nitrogen should also be assigned a higher value of the Coulomb integral α, owing to the high negative charge on the $-CO_2-$ group. Moreover, the C–N bond order appears to be too low. A new set of parameters [90] found by perturbation methods gives, *e.g.* for azodicarboxylates, the correct $n \rightarrow \pi^*$ excitation energy $\nu_m = 24900$ cm^{-1} together with an almost unchanged $\pi \rightarrow \pi^*$ value ($\nu_m = 50100$ cm^{-1}).

3. Participation of d-Orbitals in the $n \rightarrow \pi^*$ Transition in Phosphorus Azo Compounds

a) Arguments for the Hindrance of Conjugation by Tetracoordinated Phosphorus (V)

The violet color of the phorphorus azo compounds cannot be explained by the above orbital models. Before discussing the possibility of a π^*/d orbital interaction (Section D.3.b), we shall show that the π-electron system of the azobisphosphonic acid derivatives comprises only the four atoms P–N–N–P. New arguments will be presented in support of the still controversial [91–96] hindrance of conjugation by tetracoordinated phosphorus (V) [97–99], which passes on electronic effects as second-order perturbations [99].

The frequencies of the P=O valence vibrations of all phosphorus azo compounds obey the empirical electronegativity relationship proposed by *Bell, Heisler, Tannenbaum*, and *Goldenson* [100], indicating that substituent effects on phosphorus atoms are predominantly inductive [18, 19, 25]. Correspondingly no similar relationship could be established for the C=O valence vibrations in conjugated azocarboxylic acid derivatives [25, 26].

[90] First- and second-order perturbation calculations from eigenvectors and polarizabilities [83] gave the following adjusted parameters [85]: $\alpha_C = \alpha_C + 0.3\beta$; $\alpha_N = \alpha_C + 0.75\beta$; $\beta_{C-N} = 0.8\beta$.

The $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ bands of the phenylazodiphenylphosphinic acid derivatives $H_5C_6-N=N-PZ(C_6H_5)_2$, where Z = NR, O, S, (Table 3) confirm that within the accuracy of the measurements [64], no modification of the conjugated system occurs through the tetracoordinated phosphorus(V).

Phosphorus-nitrogen chains synthesized by us [18,25, 101] confirm by their color the inhibition of conjugation by tetracoordinated phosphorus [*].

$$=\overset{|}{\underset{|}{P}}-N=N-\overset{|}{\underset{|}{P}}= \quad \text{violet} \qquad -N=\overset{|}{\underset{|}{P}}-N=N- \quad \text{deep red}$$

$$-\overset{|}{\underset{|}{P}}=N-N=N- \quad \text{golden yellow}$$

$$-\overset{|}{\underset{|}{P}}=N-\overset{|}{\underset{|}{P}}=N- \quad \text{colorless}$$

In particular, phosphinimido chains [93,94] are always colorless, no matter how many chain units are present, and the longest-wavelength absorption of the phenyl-substituted compounds is the ^1L_b band of the benzene nucleus [102]. Comparison of these compounds with the corresponding diphenylpolyenes [103], which absorb in the visible region when the number of C=C units is greater than 3, shows that linear combination of p_z and

$$(H_5C_6)_3P=N-\overset{|}{\underset{|}{P}}=N-\overset{|}{\underset{|}{P}}=N-\overset{|}{\underset{|}{P}}=N-PO(C_6H_5)_2 \quad (43)$$

$$\nu_m > 36700\ cm^{-1} \quad (^1L_b)$$

$$(H_5C_6)_2C=\underset{|}{\underset{|}{C}}-\underset{|}{\underset{|}{C}}=\underset{|}{\underset{|}{C}}-\underset{|}{\underset{|}{C}}=\underset{|}{\underset{|}{C}}-\underset{|}{\underset{|}{C}}=C(C_6H_5)_2 \quad (44)$$

$$\nu_m = 25100\ cm^{-1}$$

d-orbitals does not give a π-electron system similar to that given by p_z-p_z orbitals.

Consequently, the only picture which remains plausible for the azobisphosphonic acid derivatives *(5)* is that proposed by *Dewar*, *Lucken*, and *Whitehead* [97]. This model involves overlap of two unoccupied orthogonal d-orbitals of suitable symmetry (*e.g.* d_{xz} and d_{yz}) with the p_z-orbitals of the azo nitrogen and the P=O oxygen, which are localized at two corners of the sp^3-phosphorus tetrahedron, with slight increase of the bond angle. Each of the resulting π-electron systems, which are practically perpendicular to each other, ends on the phosphorus atom, and their conjugative interaction is negligible.

b) Discussion of a π^*/d Orbital Interaction

In the above model, electronegative substituents place a positive partial charge on the phosphorus, thus contracting the empty d-orbitals by which the azophosphorus system is defined. The possible combinations of a d-orbital of phosphorus with the π, n, or π^* orbitals of the N=N group (Fig. 24) can be discussed only qualitatively, owing to the lack of data. π/d and n/d interactions are in contradiction with the spectroscopic findings, and can therefore be immediately ruled out: the π/d model would require a hypsochromic shift of the resulting $n \rightarrow \pi d^*$ transition with increasing interaction, whilst the n/d model requires an allowed $nd \rightarrow nd^*$ transition of high intensity owing to the fact that the ground state (nd) and the first excited state (nd*) have the same symmetry. The π^*/d model [104], in which the combination of the π^* level and the d-orbital are favored by energy considerations, is the only one which reproduces a bathochromic shift of the forbidden $n \rightarrow \pi\ d_1^*$ band with increasing interaction (Fig. 14).

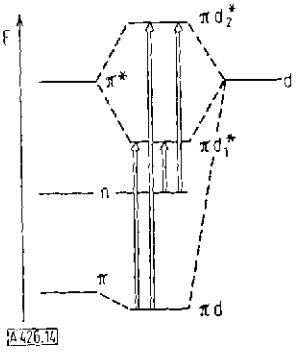

Fig. 14. Energy level diagram for π^*/d interactions.

The spectroscopic arguments in favor of the postulated π^*/d interaction in the azobisphosphonic acid derivatives are as follows:

Comparison with azodicarboxylic acid derivatives (Section C.2.e) shows that the azobisphosphonic acid derivatives have twice as many bands in the $\pi \rightarrow \pi^*$ region, as required (Fig. 3), those at the longest wavelengths having a low intensity ($n \rightarrow \pi d_x^*$ transitions?). Although the exact position of the $\pi d \rightarrow \pi d_2^*$ transition for phosphorus azo compounds is unknown ($\nu_m \geqslant 46000\ cm^{-1}$), the farther-reaching requirement of the model, namely that the energy difference between the πd_1^* and πd_2^* levels should be constant for transitions from the same ground state, appears to be satisfied: the difference in the wave numbers of the two (x = 1,2) $n \rightarrow \pi d_x^*$ bands is about 15000 cm^{-1}, whilst that in the case of the two $\pi d \rightarrow \pi d_x^*$ bands seems to be at least 13000 cm^{-1} (Section C.2.a).

E. Summary: Color and Constitution of Azo Compounds

The complex relationship between color and constitution in azo compounds can be qualitatively explained by orbital models. If the other variables are arbitrarily kept constant, the effects of substituents on the $n \rightarrow \pi^*$ transition, on which the color depends, are as follows:

1. Substituents XY can cause a considerable change in the position of the n level by an inductive effect, the change depending on the electronegativity of the substituent in relation to the azo nitrogen. An increase in the effective nuclear charge of the azo nitrogen lowers the n

level, and causes a hypsochromic shift of the $n \rightarrow \pi^*$ transition, and *vice versa*.

2. The π^* level is affected by inductive and conjugative effects of the substituent XY. In the quasi-alternant systems in question, the π^* level is lowered (raised), with a consequent bathochromic (hypsochromic) shift of the $n \rightarrow \pi^*$ transition, by $-I$ ($+I$) effects, and by expansion (contraction) of the π-electron system or decrease (increase) in the interaction of the orbitals, respectively.

3. Inductive and conjugative effects of the substituent XY on the occupied π level also affect the n level in accordance with (1), by changing the effective nuclear charge of the azo nitrogen.

4. Additional interaction with unoccupied d-orbitals of suitable symmetry should lead to a splitting of the π^* level, and hence once more to a bathochromic displacement of the resulting $n \rightarrow \pi d^*$ transition.

The model outlined in the present paper, which has been simplified by considering the various substituent effects separately and by disregarding the intensity ratios, is only crude, although probably correct in principle. Further spectroscopic studies and further calculations should lead to a gradual refinement of our knowledge of the fascinating relationships between color and constitution in azo compounds.

F. Outlook: $n \rightarrow \pi^*$ Transitions as Molecular Probes

The substituent effects which were first described in detail for azo compounds have general significance: $n \rightarrow \pi^*$ bands occur in all π-electron systems which contain hetero-atoms with lone electron pairs, and in which the weak long-wavelength absorptions are not totally masked by an intense $\pi \rightarrow \pi^*$ band. In addition to numerous hetero-aromatic compounds, such systems are also found in the important unsaturated groups C=O, C=S, and N=O. In all these cases, literature values and our own results confirm that the $n \rightarrow \pi^*$ excitation depends on the substituents in the same manner as in the azo compounds. Thus the $n \rightarrow \pi^*$ transition always undergoes a bathochromic shift (F < O < N < C) with decreasing electronegativity of the substituents XY; participation in conjugation (*e.g.* XY = C_6H_5) and, above all, interaction with a d-orbital (*e.g.* XY = SiR_3) act in the same direction (Table 12).

Table 12. Substituent effects on the $n \rightarrow \pi^*$ transition (ν_m in cm^{-1}) in azo, carbonyl, thiocarbonyl, and nitroso compounds.

XY	F	OR	NR_2	CR_3	C_6H_5	SiR_3/C_6H_5
YX=N-N=XY	(45000)	(40000)	(36000)	28000	22600	17000 [42]
$(YX)_2C=O$	–	49000	45000	36400	30100	24200 [105]
$(YX)_2C=S$	–	33000 [106]	30300 [106]	19800 [106]	16500 [106]	–
YX=N-O	32180 [107]	28100	27700	15050	13250	–

Substituent-specific absorption increments (Section C.3) are also found, for example, in thiocarbonyl compounds; the $n \rightarrow \pi^*$ absorptions of unsymmetrically substituted compounds ABC=S always lie between those of the symmetrically substituted compounds $A_2C=S$ and $B_2C=S$ (see Table 13).

Table 13. $n \rightarrow \pi^*$ maxima and molar extinctions of some symmetrically and unsymmetrically substituted thiocarbonyl compounds $(YX)_2C=S$ [106,108].

A	B	$A_2C=S$		ABC=S		$B_2C=S$	
		ν_m [cm^{-1}]	ε_m	ν_m [cm^{-1}]	ε_m	ν_m [cm^{-1}]	ε_m
C_6H_5	R	16000	185	17600	48	20000	3.5
R	SR	20000	3.5	21700	18	23300	35
R	OR	20000	3.5	26500	19	33000	– [a]
R	NH_2	20000	3.5	27300	36	34500	100
SR	OR	23300	35	28000	52	33000	– [a]
$NH(OCH_3)$	OR	26200	42	30000	95	33000	– [a]

[a] Shoulder in the absorption curve.

Table 14 confirms that the magnitudes of the substituent increments in various π-electron systems are comparable. The differences in $n \rightarrow \pi^*$ excitation energies of compounds with alkoxy and phenyl substituents agree within $\pm 10\%$.

Table 14. Energy differences for the $n \rightarrow \pi^*$ transitions of various π-electron systems with the substituents YX=OR and C_6H_5.

π-System	YX=N-N=XY	$(YX)_2C=O$	$(YX)_2C=S$	YX=N-O
ν_m (OR)	(40000) [a]	49000	33000 [106]	28100
ν_m (C_6H_5)	22600	30100	16500 [106]	13200
$\Delta\nu_m$ [cm^{-1}]	17400	18900	16500	14900
ΔE [kcal]	49	54	47	43

[a] Assignment uncertain.

Current spectroscopic investigations present the possibility of using the $n \rightarrow \pi^*$ transitions as "molecular probes" to obtain information regarding the mechanism of the contraction of empty d-orbitals with increasing nuclear charge, and of obtaining in this way a general theory of substituent effects on π-electron systems.

My colleagues and I are very grateful to Prof. E. Wiberg for his generous support and assistance. Thanks are also due to Dr. G. Rudolph (now at Nattick, Mass.), Dr. E. Baltin (Höchst), and Dipl. Chem. J. Kroner (Munich) for the skill and patience exercized in obtaining the experimental data. The program for the IBM 7090 was written with kind permission of Prof. E. Heilbronner by Dipl.-Phys. P. Straub and Dr. E. Weltin (Zurich). I am grateful to Prof. E. Heilbronner (Zurich), Dr. G. Hohlneicher (Munich), Prof. H. Labhart (Zurich), Dr. H.-W. Preuss (Munich), Dr. R. Sizmann (Munich), and Dr. E. Weltin (Zurich) for discussions or for perusal of the manuscript.

New Methods in Preparative Organic Chemistry IV

Isonitrile Syntheses

BY PRIV.-DOZ. DR. I. UGI, DR. U. FETZER, DR. U. EHOLZER, DR. H. KNUPFER, AND DR. K. OFFERMANN

WISSENSCHAFTLICHES HAUPTLABORATORIUM DER FARBENFABRIKEN BAYER AG., LEVERKUSEN (GERMANY)

In spite of the large number of reactions which involve the formation of isonitriles, the only preparative routes to these compounds, until recently, were the classical isonitrile syntheses discovered about one hundred years ago by Gautier and Hofmann. These methods are not generally applicable, and give satisfactory yields only in exceptional cases. Isonitriles have recently become readily available by the elimination of water from N-substituted formamides, using acyl halides of Group IV–VI elements in the presence of bases as dehydrating agents. A dehydrating system with a particularly wide range of application consists of phosgene with tertiary amines. This system generally provides the easiest and most productive route to isonitriles, particularly where large quantities (> 1 mole) are to be prepared.

1. Introduction

Almost one hundred years have passed since the discovery of isonitriles by *Gautier* [1–1d] and *Hofmann* [2–2b].

Although fundamental problems in organic chemistry, such as the problem of isomerism [1–4] and the question of whether carbon can exist in the divalent state [5–9], have at times stimulated investigations of the isonitriles, little experimental effort has been devoted to the chemistry of these compounds, in spite of their wide reactivity.

The principal reason for the relatively small volume of publications on the subject [3] is that convenient and generally applicable methods for the preparation of isonitriles have only become available in the last few years (cf. Section 4).

The development of the chemistry of isonitriles has probably suffered only little delay through the characteristic odor of volatile isonitriles, which has been described by *Hofmann* and *Gautier* as "highly specific, almost overpowering", "horrible", and "extremely distressing". It is true that many potential workers in this field have been turned away by the odor, but this is heavily outweighed by the fact that isonitriles can be detected even in traces, and that most of the routes leading to the formation of isonitriles were discovered through the odor of these compounds.

In the early days of isonitrile chemistry, the isonitriles were formulated as compounds of divalent carbon [1–1d, 5–5d]

$$R-N{=}C^{II}$$

As the picture of the chemical bond became more refined, this was replaced by a semipolar formula and by two resonance structures [6].

$$R-N{\equiv}C \qquad \left\{R-\underline{N}=\underline{C} \longleftrightarrow R-\overset{\oplus}{N}{=}\overset{\ominus}{C}\right\}$$

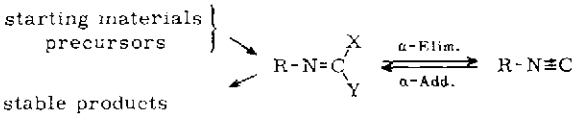
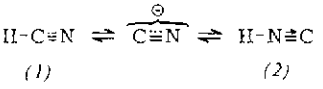
Nevertheless, even modern quantum chemistry does not oppose the continued use of the classical concept of the formal divalence of the isonitrile carbon. This picture is quite convenient, since it comprises the entire chemistry of the isonitriles, which is ultimately reducible to α-eliminations and α-additions [3].



Apart from the alkylation of the cyanide ion or of hydrogen cyanide *(1)*, the tautomer *(2)* of which [10] already contains formally divalent carbon, reactions in which



isonitriles are formed always involve the loss of two monovalent groups or one divalent group from a compound containing formally tetravalent carbon, either by α-elimination or by redox reactions.

2. The Alkylation of Cyanides

Hydrogen cyanide is tautomeric with the parent compound of the isonitriles, *i.e.* hydrogen isocyanide [10]. It reacts with diazomethane to form a mixture of acetonitrile and methyl isonitrile [11].

$$CH_2N_2 + HCN \rightarrow CH_3{-}CN + CH_3{-}NC$$

Hydrogen cyanide adds onto ethylene, under the action of a silent electrical discharge, to yield ethyl isonitrile [12].

$$C_2H_4 + HCN \xrightarrow{\Delta E_{el}} C_2H_5{-}NC$$

The principal products of nucleophilic attack of the free ambident cyanide ion [13] on alkylating agents, such as alkyl halides, alkali monoalkyl sulfates, and dialkyl sulfates, are nitriles. Isonitriles are formed only in small quantities (≪ 25%) [4, 5b, 14–15]:

$$R{-}X + CN^{\ominus} \rightarrow R{-}CN + R{-}NC$$

The alkylation of complexed or internally complexed cyanides, on the other hand, occurs preferentially on the nitrogen.

Isonitriles were first prepared by *Gautier* [1–1d], by the reaction of silver cyanide with alkyl iodides; isonitrile complexes are formed [15–18], from which the isonitriles are liberated by potassium cyanide. This method gives yields of up to 55%, based on the silver cyanide [17].

$$R{-}I + [AgCN] \rightarrow [R{-}NC{\cdot}AgI] \xrightarrow{KCN} R{-}NC$$

Considerable quantities of alkyl isonitriles are also formed on decomposing the products of the reaction of alkyl iodides and copper(I) cyanide [4, 16a], whereas very little isonitrile (about 3%) is obtained when zinc, cadmium, and nickel cyanides are treated in a similar manner [4].

Alkyl isonitriles can be eliminated by heat [20] or by the action of alkali metal hydroxides [19] or cyanides [4, 16a, 21] on the alkylation products of alkali metal or silver hexacyanoferrates(II) [19] or hexacyanocobaltates(III).

When ethanolic solutions of hydrogen hexacyanoferrate(II) containing hydrogen cyanide are heated to 120 °C, they yield up to 40% of ethyl isonitrile [22]. The partial "esterification" of the hydrogen hexacyanoferrate(II) is followed by the replacement of isonitrile ligands by hydrogen cyanide. Similar behavior is observed with hydrogen hexacyanocobaltate(III) [22–24].

$$H_4[Fe(CN)_6] \xrightarrow{n\,C_2H_5OH} H_{4-n}[(C_2H_5{-}NC)_nFe(CN)_{6-n}] \xrightarrow{n\,HCN} n\,C_2H_5{-}NC$$

3. The Reaction of Primary Amines with Dichlorocarbene

The carbylamine reaction, *i.e.* the reaction of primary amines with chloroform [25] and strong bases, such as ethanolic potassium hydroxide solution [2–2b, 27–29], solid alkali metal hydroxide [6, 30–34], or potassium

t-butoxide [34–36], has been recommended [84] for the qualitative detection of primary amines, and was considered for a long time to be the most useful method for the preparation of isonitriles [36–36f].

In 1897, *Nef* [5c, 37] interpreted the Hoffmann carbylamine reaction as the addition of dichlorocarbene [38] to primary amines [39–41], followed by β-elimination of one molecule of hydrogen chloride and α-elimination of another.

$$R{-}NH_2 \xrightarrow{CCl_2} R{-}\overset{\oplus}{N}H_2{-}\overset{\ominus}{C}Cl_2 \longrightarrow R{-}NH{-}CHCl_2$$
$$\xrightarrow{\beta\text{-Elim.}} R{-}N{=}CHCl \xrightarrow{\alpha\text{-Elim.}} R{-}NC$$

A similar mechanism is followed in the formation of isonitriles (15–43% yield) by the thermal decomposition of sodium trichloroacetate in the presence of arylamines, such as aniline, *p*-toluidine, or *p*-anisidine [42],

$$3\,Ar{-}NH_2 + CCl_3{-}CO_2Na \rightarrow Ar{-}NC + 2\,Ar{-}NH_2{\cdot}HCl + NaCl + CO_2$$

and possibly also in the reaction of primary amines (n-butylamine, aniline) and carbon tetrachloride with copper [43].

4. α-Eliminations from Formic Acid Derivatives of Primary Amines

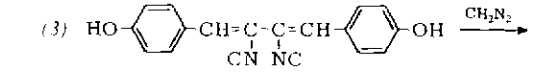
4.1 The Elimination of Water from N-Monosubstituted Formamides

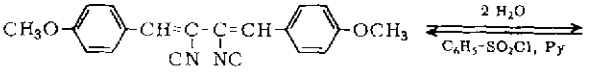
Considering their hydrolysis products, *Gautier* [1b–1d] suggested that isonitriles might be regarded as formic acid derivatives of primary amines, and that it should therefore be possible to prepare them by elimination of water from *N*-monosubstituted formamides. However, *Gautier*'s attempts [1d] to achieve such dehydrations did not have the desired result.

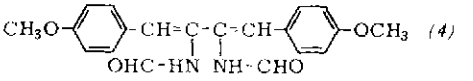
$$R{-}NH_2 + HCOOH \underset{+H_2O}{\overset{-H_2O}{\rightleftharpoons}} R{-}NH{-}CHO \underset{+H_2O}{\overset{-H_2O}{\rightleftharpoons}} R{-}NC$$

Wegler [44] re-examined this idea in 1938. On treating *N*-monosubstituted formamides with thionyl chloride, he found traces of isonitriles among the products. The low yields were probably due to the sensitivity of the isonitriles to acids.

The reaction of a formamide with a dehydrating halide in the presence of a base was first carried out by *Hagedorn* and *Tönjes* during an attempt to elucidate the constitution of xanthocillin *(3)* [45–47]. The starting material was "*O,O'*-dimethylxanthocillin dihydrate" *(4)* and the dehydrating agent used was benzenesulfonyl chloride in pyridine.



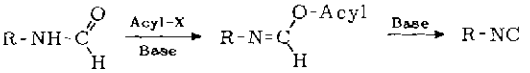




The antibiotic xanthocillin *(3)*, which was discovered [47] by *Rothe* in 1948 in cultures of *Penicillium notatum* Westling and *Penicillium chrysogenum*, is the only known naturally occurring isonitrile. It presumably arises by oxidative dimerization of tyrosine, the isonitrile group being formed from a formylamino group under the dehydrating action of an energy-rich phosphate [*] (see Section 4.14).

It has also been shown that many acylating agents (phosgene (Section 4.11), cyanuric chloride (Section 4.12), benzenesulfonyl chloride and toluenesulfonyl chloride (Section 4.13), phosphorus tribromide [48], phosphorus trichloride [48], phosphorus oxychloride (Section 4.14), phosphorus pentachloride [48], phosphorus pentoxide [48], and thionyl chloride [48]) eliminate water from *N*-monosubstituted formamides in the presence of bases [trialkylamines and dialkylarylamines (Section 4.11), pyridine (Sections 4.13 and 4.14), quinoline (Sections 4.11 and 4.13), potassium carbonate (Section 4.12), and potassium t-butoxide (Section 4.14)]. Particularly suitable combinations for the preparation of isonitriles are phosgene/triethylamine (Section 4.11), benzenesulfonyl chloride or toluenesulfonyl chloride/pyridine or quinoline (Section 4.13), and phosphorus oxychloride/pyridine or potassium t-butoxide (Section 4.14).

The reaction of *N*-monosubstituted formamides with acylating agents and bases proceeds in two steps: the base-catalyzed *O*-acylation is followed by the nucleophilic α-elimination of a proton and an acid anion.



[35] *T. Shingaki* and *M. Takebayashi*, Bull. chem. Soc. (Japan) *63*, 617 (1963).

[36] The yields of the carbylamine reaction are: up to 20% with ethanolic potassium hydroxide solution as the base, up to 45% with solid alkali, and up to 55% with potassium t-butoxide. Higher yields claimed in the literature ([32, 35, 36a] *inter alia*), probably relate to mixtures of isonitriles and primary amines.

The elimination of hydrogen sulfide from *N*-monosubstituted thioformamides with cyanogen bromide or picryl chloride in the presence of bases [50] proceeds in a similar manner.

4.11 The Phosgene Method

4.111. General

The elimination of water from *N*-monosubstituted formamides using phosgene in the presence of tertiary amines (trimethylamine, triethylamine, tri-n-butylamine, *N,N*-dimethylcyclohexylamine, *N,N*-diethylaniline, pyridine, quinoline) [51] has been found to be convenient, economical [52], and very versatile with regard to the constitution of the starting materials. Most of the isonitriles recorded in the present paper were obtained by the phosgene method (cf. Table 1).

$$R{-}NH{-}CHO + COCl_2 + 2R_3^1N \rightarrow R{-}NC + CO_2 + 2R_3^1N{\cdot}HCl$$

In a recently developed, preferred variant of the phosgene method, a fast current of phosgene is, without external cooling, led into a vigorously stirred solution or suspension [53] of an *N*-alkylformamide or *N*-arylformamide in triethylamine/methylene chloride, until the refluxing caused by the heat of the reaction [51a] ceases (cf. Section 4.112). The isonitrile is isolated by introducing ammonia into the reaction mixture, filtering to remove the precipitated ammonium chloride, and concentrating the filtrate *in vacuo* [51b, 54]. The residual crude isonitrile is purified by distillation, recrystallization, reprecipitation, or chromatography. A particularly suitable method for the purification of crystalline isonitriles which are thermally unstable is by treating them (in a homogenizer [55]) with solvents which dissolve the impurities from the suspended isonitrile, followed by suction filtration.

For the preparation of low-boiling (b.p. $<100\,^{\circ}C/760$ mm Hg) isonitriles or of isonitriles which are unstable or sensitive towards ammonia, cf. the examples given in Section 4.112.

A variant of the phosgene method is the "one-step synthesis" of ester isonitriles. Hydroxyalkylformamides or hydroxyarylformamides react with phosgene (for conditions, see Section 4.112e) to form isocyanodialkyl carbonates or isocyanodiaryl carbonates.

$$2CHO{-}NH{-}A{-}OH + 3COCl_2 + 6R_3N \rightarrow CN{-}A{-}O{-}CO{-}O{-}A{-}NC + 2CO_2 + 6R_3N{\cdot}HCl$$

If hydroxyalkylformamides or hydroxyarylformamides are reacted with acylating halides (acyl chlorides, chlorophosphates) before treatment with phosgene, the reaction finally yields the isonitriles of the corresponding esters (see Section 4.112k).

$$Acyl{-}C + HO{-}A{-}NH{\cdot}CHO + COCl_2 \rightarrow Acyl{-}O{-}A{-}NC + CO_2 + 3R_3N{\cdot}HCl$$

As can be seen from Table 1, it is possible with the aid of the phosgene method to synthesize mono- and polyisonitriles [51–51b, 53, 56] of almost any constitution, provided that structural elements which destabilize the isonitrile [58] or which react with phosgene under the reaction conditions used [59] are avoided.

4.112. Procedures [67]

(a) *Ethyl Isonitrile*

730 g (10.0 moles) of *N*-ethylformamide, 5.0 l of tri-n-butylamine, and 3.0 l of 1,2,4-trichlorobenzene are placed in a 10 l three-necked flask, fitted with a stirrer, a wide gas inlet tube

[49] *I. Ugi* and *R. Meyr*, Angew. Chem. *70*, 702 (1958).

[50] German Published Patent Application 1158499 (Mar.2nd, 1962/Dec. 5th, 1963), Farbenfabriken Bayer AG., inventors: *W. Betz* and *I. Ugi*.

[51] *I. Ugi, W. Betz, U. Fetzer*, and *K. Offermann*, Chem. Ber. *94*, 2814 (1961); German Published Patent Application 1177146 (Aug. 3nd, 1960/Sept. 3rd, 1964), inventors: *I. Ugi* and *W. Betz*.

[51a] German Patent Application, Farbenfabriken Bayer AG., inventors: *H. Knupfer, I. Ugi, U. Fetzer*, and *U. Eholzer*.

[51b] German Patent Application, Farbenfabriken Bayer AG., inventor: *I. Ugi*.

[52] Even for large preparations (10–100 moles), the maximum time required, including working up, is only 8–15 hours; yields are up to 97%; auxiliary materials are cheap.

[53] German Published Patent Application 1158500 (Apr. 6th, (1962/Dec. 5th, 1963), Farbenfabriken BayerAG., inventor: *I. Ugi*.

[54] The triethylamine/methylene chloride distilled off can be used again for similar preparations without prior purification.

[55] For example, "Ultra-Turrax" from Messrs. Janke & Kunkel KG., Staufen i. Br. (Germany).

[56] Even the *N*-isocyanodialkylamines, which cannot bee obtained by the Hofmann method (see Section 3) [33], have been prepared by the phosgene method [57].

[57] *H. Bredereck et. al.*, Angew. Chem. *74*, 388 (1962); *76*, 580 (1964); Angew. Chem. internat. Edit. *1*, 334 (1962); *3*, 647 (1964).

[58] For example, 2,4-dinitrophenyl isonitrile and 1,4-dichloro-2,5-diisocyanobenzene cannot be obtained.

[59] *p*-Amino-, *p*-carboxy-, and p-aminosulfonylphenyl isonitriles, which can be prepared by the carbylamine reaction [9, 36d], cannot be obtained by the phosgene method. Isonitriles are very reactive towards phosgene [5–5b, 61] in the absence of bases [60].

[65c] *R. Neidlein*, Arch. Pharm. *297*, 589 (1964).

[66] According to a personal communication from *H. Herlinger*, $[\alpha]_D^{20} = -49.5\,^{\circ}$ for *(S)*-α-phenylethyl isonitrile (from *(S)*-(−)-α-phenylethylamine), cf. [36b].

[67] (a) The tertiary amines used must be free from water and from amines which can undergo acylation. The hydrogen chloride content of the phosgene should be low. *N*-Alkylformamides are generally readily available from primary aliphatic amines and the calculated quantity of commercial grade 70 to 95 per cent formic acid, by refluxing in chlorobenzene, toluene, or xylene and removing the water formed with the aid of a water separator. *N*-Arylformamides are obtained by heating primary arylamines for 2–15 hours at 70 to 105 °C with 2–10 times their weight of 85 to 100 per cent formic acid. The formamides used as starting materials must contain neither formic acid nor dimethylformamide. Sparingly soluble formamides are suspended and thoroughly stirred in a homogenizer before the reaction. Suitable drying agents for isonitrile solutions include anhydrous potassium carbonate or magnesium sulfate. Bath temperatures higher than 50 °C should be avoided for the concentration of isonitrile solutions.

(b) With a few exceptions, isonitriles exhibit no appreciable toxicity for mammals (cf. [1a]). As has been found in the toxicological laboratories at Farbenfabriken Bayer AG., Elberfeld, oral and subcutaneous doses of 500–5000 mg/kg can be tolerated by mice.

Data regarding the fungicidal, acaricidal, and insecticidal properties of isonitriles are reported in Belg. Pat. 641379 (June 12th, 1964; German priority: Dec. 17th, 1962), Farbenfabriken Bayer AG., inventors: *I. Ugi, U. Fetzer, F. Grewe, W. Behrenz, P. E. Frohberger, B. Homeyer, H. Scheinpflug,* and *G. Unterstenhöfer*; Spanish Pats. 294587 and 294588 (Febr. 7th, 1964; German priority: Dec. 17th, 1962) and Belg. Pats. 641309 and 641311 (June 12th, 1964; German priority: Dec. 17th, 1962), Farbenfabriken Bayer AG., inventors: *U. Fetzer, I. Ugi, G. Unterstenhöfer, W. Behrenz, P. E. Frohberger,* and *H. Scheinpflug*; cf. also [68, 74].

[68] U.S. Pat. 3012932 (Dec. 12th, 1961), Standard Oil of Indiana, inventor: *F. Bussert.*

dipping deeply into the liquid, and a wide gas outlet. The flask is cooled and stirred, and 1.00 kg (10.1 moles) of phosgene is led in at 20–30 °C over a period of 3–4 h, followed 1 hour later by 100 g of ammonia. The reaction product is distilled *in vacuo* (about 150 mm Hg) at 30–50 °C and collected in traps cooled by dry ice. The crude product (430 g) is distilled through a helix-packed column with reflux control; b.p. 32–35 °C/120 mm Hg, yield: 358 g (65 %).

(b) *Ethyl Isocyanoacetate*

105 g (1.06 mole) of phosgene dissolved in 900 ml of methylene chloride is added dropwise to a refluxing solution of 131 g (1.00 mole) of the ethyl ester of formylglycine in 320 ml of triethylamine and 500 ml of methylene chloride. The reaction mixture is concentrated *in vacuo* and 200 ml of benzene is added. The mixture is then filtered, concentrated once more, and distilled *in vacuo*; b.p. 76–78 °C/4 mm Hg, yield: 87 g (77 %).

(c, d) *t-Butyl Isonitrile*

(c) 1.00 kg (10.1 moles) of phosgene is led into a stirred solution of 1.01 kg (10.0 moles) of *N*-t-butylformamide in 1.30 kg of trimethylamine and 7.0 l of *o*-dichlorobenzene. The heat of the reaction is dissipated with the aid of a reflux condenser carrying cooling brine (−20 °C). Water is added, the layers are separated, and the non-aqueous layer is dried over anhydrous potassium carbonate or magnesium sulfate and fractionated; b.p. 90–92 °C/750 mm Hg, yield: 681 g (82 %).

(d) 1.00 kg (10.1 moles) of phosgene is added to 1.01 kg (10.0 moles) of t-butylformamide in 5.4 l of tri-n-butylamine and 2.5 l of 1,2,4-trichlorobenzene at 10–20 °C (cf. Section 4.112a). After the introduction of 50 g of ammonia, the reaction product is distilled at 120–150 mm Hg (bath temperature 80–85 °C) and purified by fractionation, yield: 648 g (78 %).

(d_1) If the product of a preparation according to 4.112d is isolated by steam distillation, the yield is 413 g (50 %).

(d_2) If the tri-n-butylamine of 4.112 d is replaced by 3.50 kg of *N*,*N*-diethylaniline, the yield of t-butylisonitrile is 582 g (70 %)

(d_3) If the tri-n-butylamine of 4.112d is replaced by 3.00 kg of quinoline, the yield is 222 g (24 %).

(e) *Di-(2-isocyanoethyl) Carbonate*

300 g (3.03 moles) of phosgene is led into a boiling solution of 178 g (2.00 moles) of 2-formylaminoethanol (prepared from 2-aminoethanol and methyl formate) in 1.00 l of triethylamine and 1.50 l of methylene chloride. The solution is then cooled to 20 °C, 110 g of ammonia is introduced, and the mixture is filtered and concentrated. The residue solidifies on standing; m.p. 58–60 °C, yield: 145 g (86 %).

To prepare diisocyanodiaryl carbonates by a similar method, it is recommended that the reaction mixture is worked up in analogy to the procedure given in Section 4.112 n.

(f) *Cyclohexyl Isonitrile*

1.27 kg (10.0 moles) of *N*-cyclohexylformamide, 3.20 l of triethylamine, and 4.50 l of methylene chloride are placed in the reaction vessel. The solution is stirred, and phosgene is led in sufficiently rapidly (300–400 g/h) to cause vigorous refluxing. When the solution ceases to boil (after about 1.04 kg of phosgene has been introduced), the introduction of phosgene is immediately stopped and the solution is cooled to about 20 °C. About 400 g of ammonia is led into the solution over a period of 1–2 hours, and the mixture is filtered and then concentrated *in vacuo*. The residue is distilled; b.p. 67–72 °C/14 mm Hg, yield: 955 g (88 %).

(g) *t-Butyl Isocyanoacetate*

100 g (1.01 mole) of phosgene is led into a boiling, stirred solution of 159 g (1.00 mole) of the t-butyl ester of formylglycine [51] in 400 ml of triethylamine and 400 ml of methylene chloride over a period of one hour. The solution is cooled in ice, saturated with ammonia (55 g in 50 min), and filtered. The residue is washed with methylene chloride, the solution is concentrated *in vacuo*, and the crude product is purified by distillation *in vacuo*; b.p. 52–58 °C/0.3 mm Hg, yield: 106 g (75 %).

(h) *p-Nitrobenzyl Isonitrile*

36 g (0.364 mole) of phosgene dissolved in 300 ml of methylene chloride is added to a boiling solution of 60.0 g (0.333 moles) of *N*-formyl-*p*-nitrobenzylamine in 110 ml of triethylamine and 400 ml of methylene chloride. The solvent is distilled off *in vacuo*, and the residue is taken up in 100 ml of benzene. The resulting solution is concentrated, filtered, and washed with cyclohexane; m.p. 103–104 °C, yield: 45.3 g (84 %).

(i) *p-Methylsulfonylphenyl Isonitrile*

796 g (4.00 moles) of *p*-methylsulfonylformanilide, 1.30 l of triethylamine, and 3.0 of methylene chloride are placed in the reaction vessel. 415 g (4.20 moles) of phosgene are led in without external cooling. The solution is saturated with ammonia at about 20 °C, filtered, and concentrated. The residue is mixed with ether/isopropanol (1:3), stirred in a homogenizer, and filtered; m.p. 88–89 °C, yield: 613 g (85 %).

(j) *α-Phenylethyl Isonitrile*

99 g (1.00 mole) of phosgene is led into an ice-cooled, stirred solution of 147 g (1.00 mole) of *N*-formyl-α-phenylethylamine in 350 ml of triethylamine and 1.0 l of methylene chloride. Water is added, the layers are separated, and the non-aqueous layer is dried and distilled *in vacuo*; b.p. 41–45 °C/0.001 mm Hg, yield: 112 g (87 %).

(k) *2-Methyl-2-isocyanopropyl Methacrylate*

314 g (3.00 moles) of methacryloyl chloride is added to a boiling solution of 351 g (3.00 moles) of 2-methyl-2-formylaminopropanol and a spot of phenothiazine in 1.50 l of triethylamine and 2.50 l of methylene chloride. 300 g of phosgene is then passed into the solution. Ice water is added; the non-aqueous layer is separated, washed with sodium bicarbonate solution, dried, and concentrated *in vacuo*. The crude product (498 g) can be purified in portions by distillation *in vacuo*; b.p. 65–70 °C/0.008 mm Hg, yield: 187 g (37 %).

(l) *N,N-Di-(3-isocyanopropyl)-methylamine*

1.02 kg (1.03 mole) of phosgene is led into a stirred, boiling solution of 1.015 kg (5.00 moles) of *N,N*-di-(3-formylaminopropyl)methylamine in 3.20 l of triethylamine and 5.00 l of methylene chloride. The solution is saturated with ammonia at 20 °C, filtered, and concentrated. The residue (730 g) is purified by molecular distillation; b.p. 131–134 °C/0.25 mm Hg, yield: 445 g (54 %).

(m) *2,7-Diisocyanonaphthalene*

107 g (0.50 mole) of 2,7-diformylaminonaphthalene is suspended in 320 ml of triethylamine and 1.20 l of methylene chloride, and thoroughly mixed in a homogenizer. 100 g (1.01 mole) of phosgene is led into the boiling suspension, followed by 35 g of ammonia. The suspension is filtered and the filtrate concentrated. The residue is stirred in isopropanol, filtered, and washed with ether; m.p. 142–144 °C, yield: 82 g (93 %).

(n) *4-Isocyanoazobenzene*

225 g (1.0 mole) of 4-formylaminoazobenzene, 320 ml of triethylamine, and 2.50 l of methylene chloride are placed in the reaction vessel. The mixture is cooled in ice and stirred, and 100 g (1.01 mole) of phosgene is led in. After one hour, water is added, the layers is separated, and the non-aqueous layer is dried and distilled *in vacuo*. The residue is washed with light petroleum; m.p. 102–104 °C, yield: 151 g (73 %).

(o) *4,4'-Diisocyanodiphenylmethane*

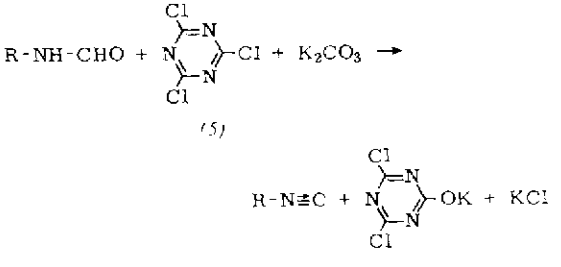
254 g (1.00 mole) of 4,4'-diformylaminodiphenylmethane is suspended in 650 ml of triethylamine and 1.0 l of methylene chloride, and thoroughly mixed in a homogenizer. The suspension is stirred and 200 g (2.02 moles) of phosgene is led in, whereupon the reaction mixture refluxes owing to the heat of the reaction. The mixture is saturated with ammonia at 20 °C, and the precipitated ammonium chloride is filtered off and washed with methylene chloride. The filtrate is concentrated *in vacuo* and the residue (219 g) is mixed with 150 ml of ether and 8 ml of isopropanol, stirred at 0 °C in a homogenizer, and separated by suction filtration; m.p. 131–133 °C, yield: 181 g (83 %).

(p) *N,N-Di-(3-isocyanopropyl)-n-dodecylamine*

200 g (2.02 moles) of phosgene is led into a stirred, boiling solution of 355 g (1.00 mole) of *N,N*-di-(3-formylaminopropyl)-n-dodecylamine, 650 ml of triethylamine, and 1.50 l of methylene chloride. The solution is saturated with ammonia at 20 °C, filtered, and concentrated. Steam is passed through the residue for a short time (about 5 min) to remove volatile impurities (mainly 3-chloropropyl isonitrile). Dark resins are removed by making use of their insolubility in ether. Concentration of the dried ether solution yields 218 g (71 %) of a light brown oil which cannot be distilled without decomposition.

4.12 Cyanuric Chloride as the Dehydrating Agent

The reaction of *N*-monosubstituted formamides with cyanuric chloride *(5)* and potassium carbonate in acetone has only been used for the preparation of a few simple isonitriles (n-butyl isonitrile, cyclohexyl isonitrile,



(5)

benzyl isonitrile) [69]. It may be a particularly mild method in special cases.

4.13. The Sulfochloride Method

Benzenesulfonyl chloride and toluenesulfonyl chloride in pyridine [45a, 70] are relatively mild dehydrating

[69] *R. Wittmann*, Angew. Chem. *73*, 219 (1961).

[70] *W. R. Hertler* and *E. J. Corey*, J. org. Chemistry *23*, 1221 (1958).

agents, and are particularly suitable for the preparation of small quantities of isonitriles.

$$R\text{-}NHCHO + Ar\text{-}SO_2Cl + 2\,Py \rightarrow R\text{-}NC + Py\cdot ArSO_3H + Py\cdot HCl$$

Quinoline is a useful base and solvent for the preparation of low-boiling, aliphatic isonitriles, since its high boiling point facilitates the isolation of the reaction product [71] by distillation.

Some examples of preparations by the sulfochloride method are described in references [45a, 70–72].

4.14 The Phosphorus Oxychloride Method

The synthesis of isonitriles from *N*-monosubstituted formamides using phosphorus oxychloride as the dehydrating agent requires more work and material than when phosgene is used. This may be important in the preparation of large quantities of isonitriles. Moreover, the phosgene method generally gives higher yields. Nevertheless, in laboratories where safety provisions are inadequate for safe handling of the extremely poisonous, volatile phosgene, the choice must fall on phosphorus oxychloride, or even on a sulfochloride, as the dehydrating agent.

Aliphatic or araliphatic isonitriles can be prepared from the corresponding formamide simply by a combination of phosphorus oxychloride and pyridine [48, 49, 73, 73a].

$$2\,R\text{-}NHCHO + POCl_3 + 4\,Py \rightarrow 2\,R\text{-}NC + Py\cdot HPO_3 + 3\,Py\cdot HCl$$

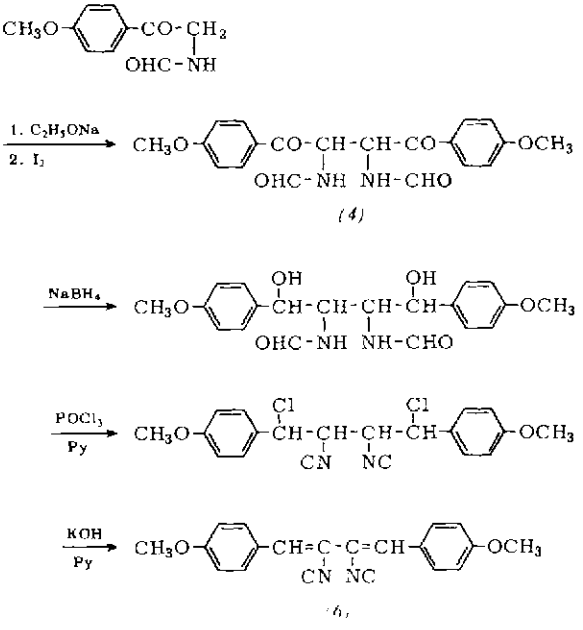
This method gives 58–95% yields of aliphatic isonitriles but only 7–54% of aromatic isonitriles [48, 74].

The elimination of water from *N*-arylformamides by phosphorus oxychloride proceeds satisfactorily, however, if potassium t-butoxide is used as the base. The reason for this is probably that the anion formed from *N*-arylformamides by the t-butoxide [75] is more readily *O*-acylated by phosphorus oxychloride than the starting material itself.

$$2\,[R\text{-}N\text{:}\,CH\,\,O]^{\ominus}K^{\oplus} + POCl_3 + 2(CH_3)_3COK \rightarrow 2\,RNC + KPO_3 + 3\,KCl + 2(CH_3)_3COH$$

It is possible in this way to prepare mono- and diisonitriles in 56–88% yield [48, 76].

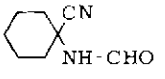
The phosphorus oxychloride method can also be used for the dehydration of *N*-formylhydrazones to form isocyanamide derivatives [77], and for the preparation of aliphatic β-oxo-, β-hydroxy-, and β-chloro-isonitriles. α,β-Unsaturated isonitriles are accessible by dehydrochlorination of β-chloro-isonitriles [77, 78]. The last steps in the recent synthesis [77, 79] of *O,O'*-dimethylxanthocillin *(6)* (cf. Section 4.1) correspond to this type of reaction.



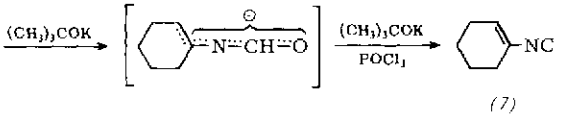
(4)

(6)

The synthesis of 2-cyclohexenyl isonitrile *(7)* (57% yield [80]) from *N*-(1-cyanocyclohexyl)formamide *(8)* represents another variant of the phosphorus oxychloride method.



(8)



(7)

4.2. The Thermolysis of N,N'-Diaryl-N-hydroxyformamides

In the course of his investigations on cycloadditions, *Ingold* observed that nitrosobenzene and *p*-chloronitrosobenzene form stable adducts with *N*-methylenaniline or its *p*-bromo, *p*-chloro, or *p*-methyl derivatives [81].

These adducts were found to be *N,N'*-diaryl-*N*-hydroxyformamidines *(9)*, instead of the expected 1,4-diaryl-

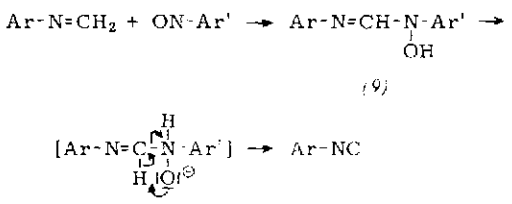
1,2,4-oxadiazetidines [82]. They decompose on heating to form isonitriles, presumably by α-elimination *via* a cyclic mechanism.



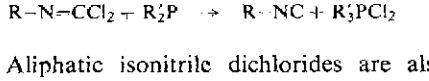
(9)

5. Redox Reactions

The reduction of readily available derivatives of iminocarbonic acid could provide a valuable addition to the above methods for the preparation of isonitriles, if it could be made to proceed under mild conditions and in high yield. Usually, however, drastic reaction conditions are required, and the yields are only moderate.

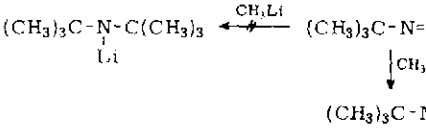
Isocyanates are reduced by heating with triethyl phosphite (17–57% yield [83]), whereas isothiocyanates can be reduced with triethylphosphine [84], triphenyltin hydride [84b], copper [84a], or by photolysis [85].

Tertiary phosphines dehalogenate isonitrile dichlorides [86].



Aliphatic isonitrile dichlorides are also reduced by iodide. The intermediate isonitrile diiodide is unstable and dissociates spontaneously into isonitrile and iodine [87].

Isonitrile halides can also be converted to isonitriles by organometallic compounds. Attempts to obtain di-t-butylamine by the reaction of t-butyl isocyanide di-



(10)

(11)

chloride with methyl-lithium [88] led to the formation of t-butyl isocyanide *(11)*, probably by halogen-metal exchange and subsequent α-elimination. Tetrabromo-*N,N'*-dimethylenehydrazine *(12)* cannot be reduced by metals to diisocyanogen [89].

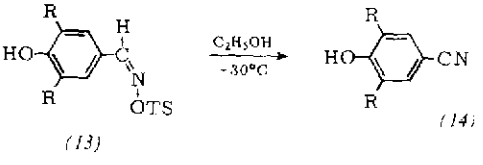
(12)

During the oxidation of 1-cyclohexyl [34] and 1-phenyl [90] thiosemicarbazides with sodium chlorite or hypochlorite or with mercuric oxide, small amounts of isonitriles are formed.

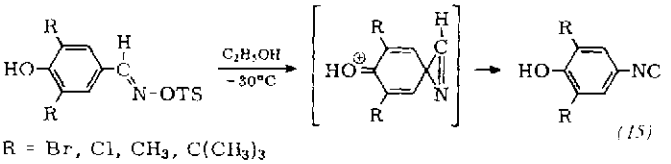
Brackman and *Smit* [90a] believe that the oxidation of n-butylamine/methanol with oxygen, which is catalysed by copper(II) chloride, leads to n-butyl isonitrile. A reaction of this type would necessarily proceed *via* *N*-methylene-n-butylamine, and would be a counterpart to the reduction of iminocarbonic acid derivatives.

6. Abnormal Beckmann Rearrangements

According to *Müller* and *Narr* [91], the *O*-tosyl oximes of 3,5-disubstituted 4-hydroxybenzaldehydes *(13)* and of *p*-dimethylaminobenzaldehyde, which are obtained from the sodium salts of the oximes and *p*-toluenesulfonyl chloride, give mixtures of the corresponding nitriles *(14)* and isonitriles *(15)* in 40 to 92% yield on elimination of *p*-toluenesulfonic acid. The formation of the nitriles corresponds to nucleophilic β-elimination of a proton and a tosylate anion [92], whereas the isonitrile is formed from the *syn*-isomer by an abnormal Beckmann rearrangement [93–95].



(13) *(14)*



(15)

R = Br, Cl, CH_3, $C(CH_3)_3$

A similar interpretation can be given for the reaction of the *syn*-oximes of benzaldehyde, *p*-methylbenzaldehyde,

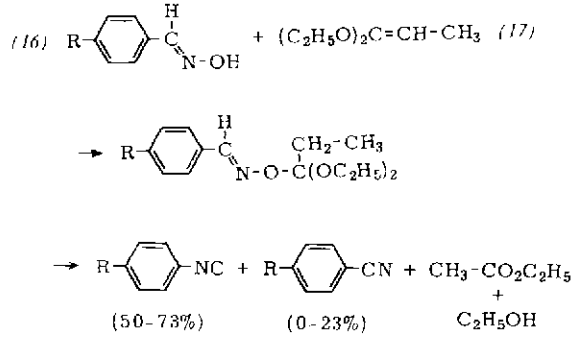
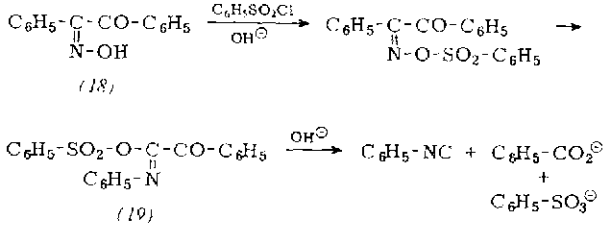
and *p*-nitrobenzaldehyde *(16)* with methylketene diethylacetal *(17)* [96], which is catalysed by boron trifluoride/mercuric oxide.

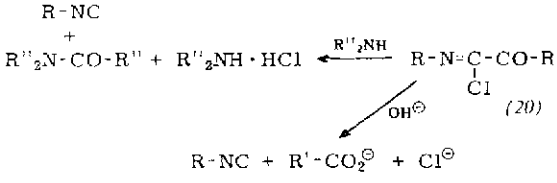
Similar treatment of the *anti*-oximes yields only the nitriles (60–80%) [92].



On attempting to carry out a Beckmann rearrangement of γ-benzil monoxime *(18)* by the action of benzenesulfonyl chloride and alkali, *Werner* and *Piquet* [93] obtained products containing benzoic acid, phenyl isonitrile, and a sulfur compound which was decomposed by alkali to yield benzoic acid and phenyl isonitrile. The reaction was interpreted as a Beckmann rearrangement of the γ-benzil monoxime *O*-benzenesulfonate to phenylglyoxyl anilide *O*-benzenesulfonate *(19)*, followed by



alkaline cleavage of the latter [93,94]. This interpretation is supported by the α-fragmentation of α-ketocarboxylic imide chlorides *(20)* by alkali [5–5b,61,97] and by amines [61,97].



It is not yet known whether the α-fragmentation occurs during or after the abnormal Beckmann rearragement of *p*-benzoin oxime [98].

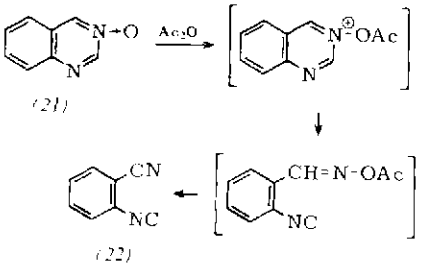
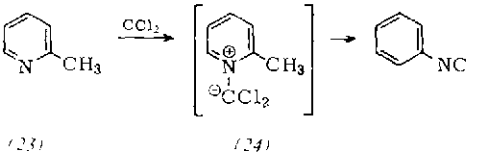
7. Ring-Cleavage Reactions of Heterocyclic Compounds

The cleavage of heteroaromatic rings to form isonitriles may be regarded as a further indication of the strong tendency of the isonitriles to be formed (*i.e.* isonitriles are thermodynamically favorable and a large number of reactions with suitable activation energies are available). Quinazoline 3-oxide *(21)* is converted by acetic anhydride into 2-isocyanobenzonitrile *(22)* [99].



According to *Ploquin*, 2-methylpyridine *(23)* reacts with dichlorocarbene, *via* the ylide *(24)*, to form phenyl isonitrile by ring cleavage followed by ring closure in a new arrangement [41].



Indole reacts with nitrosobenzene to form phenyl isonitrile [100]. The reaction is assumed to proceed *via* intermediates *(25)* and *(26)* [101], corresponding to those postulated by *Grundmann* to explain the tetramerization of phenyl isonitrile to indigo dianil *(27)* [103].

No investigations have as yet been carried out, to our knowledge, to find whether indigo dianil can also be prepared "directly" from indole and nitrosobenzene.

The anomalous Hofmann degradation of β-arylglycidamides *(28)* is an example of the formation of isonitriles by ring cleavage of nonaromatic heterocyclic systems.

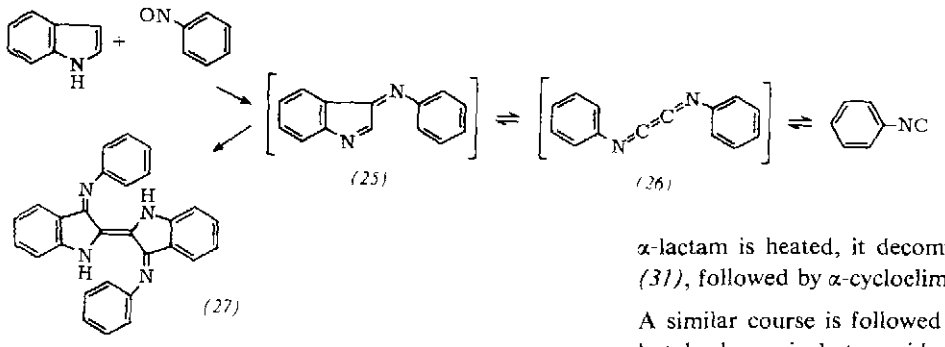
[100] *W. Madelung* and *M. Tencer*, Ber. dtsch. chem. Ges. *48*, 953 (1915).

[101] "Dimeric phenyl isocyanide", which may exist in small quantities in equilibrium with phenyl isocyanide, can probably also be regarded as an intermediate in the synthesis of 2-hydroxy-1-naphthylglyoxal [102].

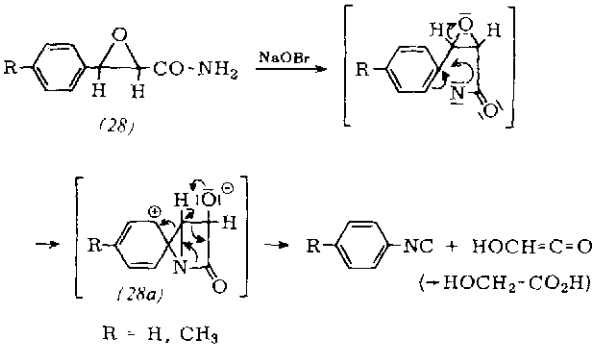
[102] *M. Passerini*, Gazz. chim. ital. *54*, 185, 633 (1924); *55*, 555 (1925); *M. Passerini* and *A. Neri*, ibid. *64*, 934 (1934).

[103] *C. Grundmann*, Chem. Ber. *91*, 1380 (1958).



(25) (26) (27)

As an alternative to the mechanism proposed by *Abraham* and *Hajela* [104] an intermediate *(28a)* may be assumed [105] (a differentiation between these mechanisms could be made by labelling with ^{14}C).

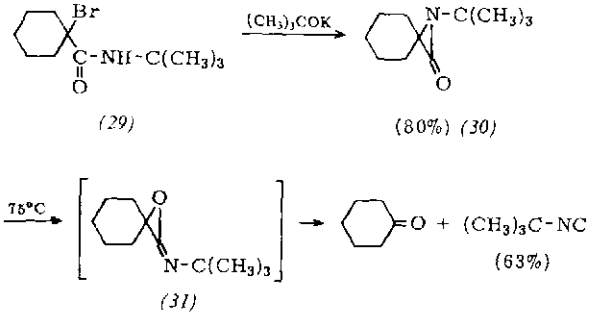


(28) (28a)

R = H, CH_3

8. Ring-Closure Reactions of α-Halogenoacylamines Followed by α-Cycloelimination

According to *Sheehan* and *Lengyel* [106], *N*-t-butyl-1-bromocyclohexanecarboxamide *(29)* can be cyclized to the α-lactam *(30)* by potassium t-butoxide. When the



(29) (80%) (30) (31)

[105] Cf. *M. S. Newman* and *C. Courduvelis*, J. Amer. chem. Soc. *86*, 2942 (1964).

[106] *J. C. Sheehan* and *I. Lengyel*, J. Amer. chem. Soc. *86*, 746 (1964).

α-lactam is heated, it decomposes by isomerization to *(31)*, followed by α-cycloelimination.

A similar course is followed in the conversion of *N*-t-butyl-α-bromoisobutyramide to 1-t-butyl-2,2-dimethylaziridin-3-one (54%) and the thermal dissociation of the latter into acetone (12%), t-butyl isonitrile (12%), and *N*-t-butylmethacrylamide (65%) [106a].

Reactions proceeding by related mechanisms are the formation of small quantities of cyclohexyl isonitrile from *N*-cyclohexyldichloroacetamide and potassium t-butoxide [107] and the formation of 4-chlorophenyl isonitrile from the sodium salt of *N*-(4-chlorophenyl)dichloromethylsulfonamide [108]. It is not yet known whether, in the latter reaction, the intermediate α-sultam *(33)* decomposes by α-cycloelimination followed by α-dehydrochlorination, or whether the opening of a three-membered carbene ring *(34)* [109] is followed by cleavage of the cumulative double-bond system.

Equilibrium and Transport Properties of Concentrated Electrolyte Solutions

BY PROF. DR. R. HAASE

INSTITUT FÜR PHYSIKALISCHE CHEMIE DER TECHNISCHEN HOCHSCHULE AACHEN

A historical survey is followed by a discussion of a number of problems associated with concentrated solutions of electrolytes containing two ion constituents: general thermodynamic properties, dissociation equilibria, phase separation, analytical representation of the thermodynamic functions over the entire range of concentrations, and general relationships in electrical conductivity, diffusion, and sedimentation. A number of relationships valid at all concentrations is formulated, and known relationships pertaining to dilute solutions are derived from these as special cases. The discussion of concentrated solutions is illustrated by numerical examples, most of which are based on recent results.

I. Introduction

The beginnings of physical chemistry are closely linked with the experimental and theoretical study of the equilibrium and transport properties of electrolyte solutions, a field which also covers investigation of galvanic cells. Consider, for example the contributions made during the second half of the last century by *Arrhenius*, *Gibbs*, *Helmholtz*, *Hittorf*, *Kohlrausch*, *Nernst*, *Ostwald*, *Planck*, and *van't Hoff*.

The properties in question were described in these early investigations on the basis of the theory of ideal dilute solutions. In this simple approximation, the electrolyte solutions are assumed to be so dilute that the interactions between the ions are negligible. Consequently, the only thermodynamic difference between such electrolyte solutions and ideal dilute non-electrolyte solutions is the increase in the number of solute particles as a result of dissociation in the former case. The dissociation equilibrium is described by the classical law of mass action. An effect of the approximation is that the dependence of the equivalent conductivity on the concentration appears to be due only to changes in the degree of dissociation of the electrolyte, whilst the mobilities of the ions are independent of concentration. This statement, together with the classical law of mass action, leads to *Ostwald*'s dilution law, which was confirmed for dilute aqueous solutions of weak electrolytes, *e.g.* dilute acetic acid, to within the experimental accuracy possible at that time (*Ostwald* 1888). The diffusion coefficient of the electrolyte in an ideal dilute solution also can easily be related to the ionic mobilities (*Nernst* 1888).

It soon became clear, however, that even at very high dilutions, solutions of strong electrolytes (*e.g.* hydrochloric or sulfuric acid or salts in water) exhibit such wide deviations from the laws known at that time that the equations for ideal dilute solutions could no longer be regarded as being applicable. These deviations were even observed for concentrations at which non-electrolyte solutions still show approximately ideal behaviour. Thus these "anomalies of strong electrolytes" are undoubtedly connected with the relatively high concentrations, and consequent interactions, of the ions. Quantitative description of these interactions was soon attempted. It was not until 1923, however, that a useful molecular statistical theory was evolved by *Debye* and *Hückel*. This theory was later extended and re-stated by *Onsager* (1926–1927) for application to electrical conductivity. Some consequences of these laws had already been discovered empirically, by *Kohlrausch* (1869–1880) in the case of conductivity, and by *Bjerrum* (1916), *Brönsted* (1922), *Lewis* (1921–1923), and others in the case of the thermodynamic functions.

It is now known that the equations proposed by *Debye*, *Hückel*, and *Onsager* are themselves limiting laws: they correspond to the first approximation beyond the laws of ideal dilute solutions. The molecular concepts on which they are based are as follows:

The electrolyte solution consists of a system of charged particles embedded in a non-conducting medium with the same density, dielectric constant, and viscosity as the solvent. The ion concentration is so small that elimination of the charges would yield an ideal dilute solution. The ions move in a disordered manner (Brownian movement). When transport processes take place, an ordered motion is superposed on the thermal movement; in particular, during conduction of electricity, cations and anions migrate in opposite directions, giving rise to relaxation and electrophoretic effects, the complete mathematical treatment of which is extremely complicated.

The present molecular theories of the equilibrium and transport properties of electrolyte solutions still reduce to the limiting laws of *Debye*, *Hückel*, and *Onsager* at sufficiently low concentrations. The range of validity has been extended to include higher electrolyte concentrations by taking into account such factors as incomplete dissociation and ion association or solvation. However, general applicability of the equations to electrolyte solutions of any concentration is ruled out right from the start by the fundamental simplification of the theory, according to which ions and aggregates of ions are regarded as discrete entities and the solvent as a structureless continuum.

If it is desired to cover the entire range of concentrations from pure solvent to pure liquid electrolyte, as is possible experimentally *e.g.* with the systems water/acetic

acid, water/hydrochloric acid, or water/sulfuric acid, we cannot base our considerations on the theoretical or semi-empirical equations which have been used in the past. Instead, we must build up an entirely new picture in which (at least for the equilibrium properties) the non-electrolyte and the electrolyte are no longer regarded as the "solvent" and the "solute", respectively, but as equivalent components. In this new scheme, which is essentially empirical at the moment, and which will be developed below for thermodynamic functions, the *Debye-Hückel* limiting law retains its validity. This law, together with *Onsager*'s limiting law, is one of the few results of the molecular theory of electrolyte solutions which has been accepted as reliable by all research workers.

Our discussion of the equilibrium and transport properties of concentrated electrolyte solutions is confined to solutions of a single electrolyte containing two ion constituents, *e.g.* $CaCl_2$, H_2SO_4, or H_3PO_4, in an inert solvent, *e.g.* H_2O.

For the sake of simplicity we exclude electrolytes with three or more ion constituents (*e.g.* $KHSO_4$), mixed electrolyte solutions, and fused salts. Moreover, we cannot concern ourselves with details of liquid-vapor and liquid-solid equilibria or osmotic phenomena, since although these are important for experimental determinations of thermodynamic functions, they are not limited to electrolytes. It will also be necessary, in our consideration of transport processes, to omit discussion of viscosity and non-isothermal processes (thermal conduction, thermal diffusion, etc.), as well as of galvanic cells.

II. Equilibrium Properties

1. General

Consider a binary liquid mixture, in which component 1 is a non-electrolyte ("solvent"), and component 2 an electrolyte containing two ion constituents. At high electrolyte concentrations we therefore have at least four types of particles present: non-electrolyte molecules, undissociated electrolyte molecules, and at least one kind of cation and one kind of anion.

We assume for the moment that the liquid is free from electric potential or concentration gradients, *etc.*, since we are at present concerned only with equilibrium properties.

As independent variables with which to describe the macroscopic state of the liquid mixture, we choose the absolute temperature T, the pressure P, and a single concentration variable, which we take to be either the stoichiometric mole fraction x of the electrolyte or the molality m (moles electrolyte per kg solvent). The quantities x and m are related as shown in Equation (1), where M_1 is the kilogram-molecular weight of the non-electrolyte.

$$m = \frac{x}{M_1 \cdot (1-x)} \quad \text{or} \quad x = \frac{M_1 \cdot m}{1 + M_1 \cdot m} \tag{1}$$

The pure solvent is described according to Eq. (1) by $x = 0$ or $m = 0$, and the pure liquid electrolyte by $x = 1$ or $m \to \infty$. The pure liquid electrolyte corresponds to a real state only in systems such as H_2O/HCl or H_2O/H_2SO_4; for systems with a saturation limit, e.g. $H_2O/NaCl$, it represents a hypothetical state (*e.g.* "fused sodium chloride at 25 °C and 1 atm"). Nevertheless, the two components are treated in principle as equivalent.

It is possible to calculate all equilibrium properties of the electrolyte solution, with the exception of the dissociation constant, provided that we know the chemical potentials μ_1 and μ_2 of the two components or the molar Gibbs free energy, $\overline{G} = (1-x)\mu_1 + x\mu_2$, of the liquid mixture as a function of T, P, and x. We need not know the absolute values of μ_1, μ_2, and $\overline{G}$, but simply the differences between these quantities and their values for the pure liquid components. Let μ_{0i} be the chemical potential of the pure liquid component i at the given values of T and P, and R the gas constant. We then make use of the dimensionless quantities defined by equations (2) and (3), which we consider as functions of T, P, and x.

$$\psi_1 \equiv \frac{\mu_1 - \mu_{01}}{RT} \; ; \; \psi_2 \equiv \frac{\mu_2 - \mu_{02}}{RT} \tag{2}$$

$$\Gamma \equiv (1-x)\cdot\psi_1 + x\cdot\psi_2 = \frac{(1-x)(\mu_1 - \mu_{01}) + x\cdot(\mu_2 - \mu_{02})}{RT}$$

$$= \frac{\overline{G} - (1-x)\cdot\mu_{01} - x\cdot\mu_{02}}{RT} \tag{3}$$

The function ψ_1 is related to the "activity" a_1 of component 1 (which we do not require in this discussion) by the equation $\psi_1 = \ln a_1$.

Equations (4) and (5) follow from the Gibbs-Duhem equation.

$$(1-x)\left(\frac{\delta\psi_1}{\delta x}\right)_{T,P} + x\left(\frac{\delta\psi_2}{\delta x}\right)_{T,P} = 0 \tag{4}$$

$$\psi_1 = \Gamma - x\left(\frac{\delta\Gamma}{\delta x}\right)_{T,P}; \psi_2 = \Gamma + (1-x)\left(\frac{\delta\Gamma}{\delta x}\right)_{T,P} \tag{5}$$

The other properties of the quantities ψ_1 and ψ_2 or Γ, *e.g.* those relating to the conditions for stability and coexistence, are also similar to those of the chemical potentials μ_1 and μ_2 or the molar free energy $\overline{G}$.

Two other quantities are generally used in the literature instead of ψ_1, ψ_2, and Γ: these are the osmotic coefficient φ of the solvent and the conventional activity coefficient γ of the electrolyte, which are considered as functions of T, P, and m.

Let ν_+ and ν_- respectively be the number of cations and anions which result from complete dissociation of one molecule of electrolyte (*e.g.* H_2SO_4: $\nu_+ = 2$, $\nu_- = 1$; H_3PO_4: $\nu_+ = 3$, $\nu_- = 1$). Moreover, let $\mu_2^{\ominus}$ be a standard value of the chemical potential of the electrolyte, depending, like μ_{01} and μ_{02}, only on T and P.

The functions φ and γ can then be defined as follows.

$$\varphi \equiv \frac{\psi_1}{\nu \cdot M_1 \cdot m} \tag{6}$$

$$\nu \cdot \ln(\nu_+ \cdot m \cdot \gamma) \equiv \psi_2 + C_2 \tag{7}$$

with

$$\nu = \nu_+ + \nu_- \; ; \; \nu_\pm^\nu \equiv \nu_+^{\nu_+} \cdot \nu_-^{\nu_-} \tag{8}$$

and

$$C_2 \equiv \frac{\mu_{02} - \mu_2^{\ominus}}{RT} \tag{9}$$

In the case of electrolytes such as HCl or Na_2SO_4, which give only two types of ions on dissociation, irrespective of the concentration, it is possible to use the degree of dissociation α of the electrolyte and the mean ionic activity coefficient $\gamma_\pm$ [on the molality (m) scale] in accordance with Equation (10). The quantity which can be measured directly is γ, not $\gamma_\pm$.

$$\gamma = \alpha \cdot \gamma_\pm \quad (10)$$

Whereas φ, C_2, and α are dimensionless, γ and $\gamma_\pm$ as defined in equations (7) and (10) have the same dimensions as 1/m and M_1, namely kg/mole. In this connection, we use the following abbreviations:

$$m\dagger \equiv 1 \text{ mole/kg}; \gamma\dagger \equiv M\dagger \equiv 1 \text{ kg/mole}.$$

An ideal dilute electrolyte solution is characterized by the condition $\gamma_\pm = \gamma\dagger$. Furthermore, if the electrolyte in such a solution is completely dissociated, then $\varphi = 1$; $\alpha = 1$; $\gamma_\pm = \gamma = \gamma\dagger$.

Using Equations (1), (4), (6), and (7), and integrating between $m = 0 (\varphi = 1; \gamma = \gamma\dagger)$ and $m = m (\varphi = \varphi; \gamma = \gamma)$ at constant temperature and pressure, we obtain Equations (11) and (12), which are important for the evaluation of experimental data.

$$\varphi = 1 + \frac{1}{m} \cdot \int_0^m m \cdot d \ln \frac{\gamma}{\gamma\dagger} \quad (11)$$

$$\ln \frac{\gamma}{\gamma\dagger} = \varphi - 1 + \int_0^m \frac{\varphi - 1}{m} \cdot dm \quad (12)$$

If both components are volatile, the quantities ψ_1 and ψ_2 can be found from the partial vapor pressures, and these are used together with Equations (6) and (12) to find the functions φ and γ. If only the solvent is volatile, then vapor pressure measurements (generally by the indirect isopiestic method) lead to ψ_1, and hence to φ and γ, but not to ψ_2. If only the electrolyte is volatile, then only ψ_2 can be obtained from the vapor pressure. One can also find φ, and hence ψ_1 and γ, from freezing point determinations. E.m.f. measurements lead to the quantity γ, from which φ can be determined by Equation (11), and hence ψ_1 by Equation (6). The constant C_2 for volatile electrolytes can be obtained from γ and ψ_2 with the aid of Equation (7).

2. Dissociation Equilibria

A dissolved electrolyte such as HCl or Na_2SO_4 yields only two types of ions, irrespective of the concentration, *e.g.*

$$Na_2SO_4 \rightleftarrows 2\,Na^+ + SO_4^{2-}. \quad (13)$$

Electrolytes such as H_2SO_4 or H_3PO_4, on the other hand, dissociate in two or three stages. We shall disregard these more complicated cases in the present discussion.

A single-step dissociation of the type (13) can be described by the general equilibrium condition (14) [1].

$$\frac{\nu_+^\nu \cdot m^{\nu-1} \cdot \gamma^\nu}{(1-\alpha) \cdot \gamma_u} = K_m \quad (14)$$

[1] *R. Haase*, Z. physik. Chem. N.F. *39*, 360 (1963).

In the above equation, γ_u is the activity coefficient of the undissociated electrolyte and K_m the dissociation constant of the electrolyte (both quantities on the m scale). K_m is dimensionless and depends only on T and P.

For our example (13), we have: $\nu = 3$; $\nu_\pm = 4^{1/3}$. However, the dissociation equilibria discussed below are of the simplest type (15).

$$HNO_3 \rightleftarrows H^+ + NO_3^-. \quad (15)$$

Here $\nu = 2$; $\nu_\pm = 1$, so that Equation (14) reduces to

$$\frac{m \cdot \gamma^2}{(1-\alpha)\gamma_u} = K_m \quad (16)$$

Since

$$\lim_{m \to 0} \gamma_u = \gamma\dagger \quad (17)$$

it follows from Equation (16) [2, 3] that

$$\lim_{m \to 0} \left[\ln \frac{m \cdot \gamma^2}{(1-\alpha)\gamma\dagger} \right] = \ln K_m \quad (18)$$

Using Equation (18), therefore, we can find the dissociation constant K_m at given pressure for any temperature, provided that $\gamma(m)$ and $\alpha(m)$ are known. The standard values of the affinity $A^\ominus$, the heat of dissociation $h_{TP}^\ominus$, and the entropy of dissociation $s_{TP}^\ominus$ (on the m scale) can be obtained from K_m by means of Equations (19), (20), and (21).

$$A^\ominus = RT \ln K_m \quad (19)$$

$$h_{TP}^\ominus = RT^2 \left(\frac{\partial \ln K_m}{\partial T} \right)_P = -R \left(\frac{\partial \ln K_m}{\partial (1/T)} \right)_P \quad (20)$$

$$Ts_{TP}^\ominus = h_{TP}^\ominus + A^\ominus \quad (21)$$

We also have

$$T \left(\frac{\partial s_{TP}^\ominus}{\partial T} \right)_P = \left(\frac{\partial h_{TP}^\ominus}{\partial T} \right)_P \quad (22)$$

Whereas some method can always be found for the measurement of the activity coefficient γ, the experimental determination of the degree of dissociation α presents a problem. The usual methods, particularly for strong electrolytes, depend on assumptions, *e.g.* that of a certain concentration dependence of the electrical conductivity. It was a great advance, therefore, when several authors, and *Redlich* in particular, pointed out the possibility of determining the concentrations of ions by the relatively direct spectroscopic methods. Thus values of the function $\alpha(m)$, obtained from Raman [3] and nuclear resonance spectra [4], are now available for aqueous nitric and perchloric acids at several temperatures. We base our calculations on the results reported by *Hood* and *Reilly* [4], since these appear to be the most precise so far.

We have determined the activity coefficients from partial vapor pressure and isopiestic measurements, for the

[4] *G. C. Hood, O. Redlich*, and *C. A. Reilly*, J. chem. Physics *22*, 2067 (1954); *G. C. Hood* and *C. A. Reilly*, ibid. *32*, 127 (1960).

systems H_2O/HNO_3 and $H_2O/HClO_4$, as far as possible in the concentration and temperature range for which the degrees of dissociation are known. These activity coefficients were used to calculate K_m, $A^{\ominus}$, $h^{\ominus}_{TP}$, and $s^{\ominus}_{TP}$ [2] with the aid of equations (18) to (21) at atmospheric pressure. The results are listed in Table 1. HNO_3 and $HClO_4$ are strong acids of comparable strengths. The quantity $h^{\ominus}_{TP}$ and hence also [by Eq. (22)] $s^{\ominus}_{TP}$, is found to be practically constant over the temperature range studied.

Table 1. Dissociation constant K_m and standard values of the affinity $A^{\ominus}$, heat of dissociation $h^{\ominus}_{TP}$, and entropy of dissociation $s^{\ominus}_{TP}$, for aqueous nitric and perchloric acids [2].

Temp. [°C]	K_m		$A^{\ominus}$ [kcal/mole]		$h^{\ominus}_{TP}$ [kcal/mole]		$s^{\ominus}_{TP}$ [cal·deg^{-1} mole^{-1}]	
	HNO_3	$HClO_4$	HNO_3	$HClO_4$	HNO_3	$HClO_4$	HNO_3	$HClO_4$
10		41.1		+2.09		−1.99		0.36
25	33.5	34.5	+2.08	+2.10	−3.51	−1.99	−4.81	0.36
40		29.3		+2.10		−1.99		0.36
50	20.3		+1.94		−3.51		−4.81	
75	14.5		+1.85		−3,51		−4.81	

We then used the values of $\alpha(m)$, $\gamma(m)$, and K_m for both acids, together with Equations (10) and (16), to determine the mean ionic activity coefficient $\gamma_{\pm}(m)$ and the activity coefficient $\gamma_u(m)$ of the undissociated acid [2]. By way of example, Fig. 1 shows the three functions $\gamma(m)$, $\gamma_{\pm}(m)$, and $\gamma_u(m)$ for aqueous perchloric acid at 25 °C.

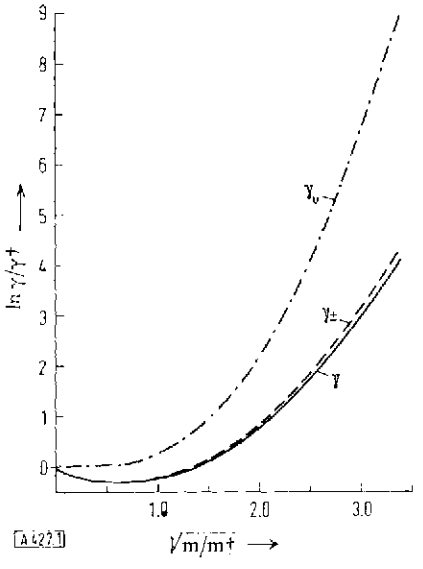

Fig. 1. The system $H_2O/HClO_4$ at 25 °C: Logarithms of the conventional activity coefficient γ, the mean ionic activity coefficient $\gamma_{\pm}$, and the activity coefficient γ_u of the undissociated electrolyte, *vs.* the square root of the molality m, according to [2].
($\gamma\dagger \equiv 1$ kg/mole, $m\dagger \equiv 1$ mole/kg).

Remarkably high values are found for γ_u in concentrated acids, in contrast to the values of about 1 kg/mole found for dilute acids. For example, 16 molal aqueous perchloric acid at 25 °C has $\gamma_u \approx 5 \times 10^5$ kg/mole. On the other hand, the highest conventional activity coefficient previously known, *i.e.* that of 35 molal hydrobromic acid at 25 °C, is $\gamma \approx 4800$ kg/mole, obtained from vapor pressure measurements [5].

[5] *R. Haase, H. Naas,* and *H. Thumm,* Z. physik. Chem. N.F. *37*, 210 (1963).

3. Phase Separation

In a two-component liquid mixture, phase separation results in two coexistent binary liquid mixtures with different compositions in equilibrium with each other. This phenomenon is relatively rare in electrolyte solutions, and is usually not mentioned even in modern monographs on electrolytes.

As early as 1888, *Bakhuis Roozeboom* [6] observed phase separation at high acid concentrations in the systems H_2O/HCl and H_2O/HBr. The former system has been quantitatively investigated [7] over the entire miscibility gap, together with the solid-liquid equilibria which occur at low temperatures. We have verified these early results with the aid of vapor pressure measurements [5], supplemented them by quantitative investigations on the H_2O/HBr system, and showed that phase separation also occurs in the system H_2O/HI.

All three of these systems exhibit miscibility gaps without accessible critical temperatures for phase separation. Thus the upper limit of the range in which the two liquids coexist is formed by the critical point for evaporation (which almost coincides with the critical point of the pure hydrogen halide), and the lower limit is fixed by equilibrium with a solid hydrate. All the phase separation curves are extremely unsymmetrical, one phase always containing almost pure acid.

The miscibility gaps found for the three systems are given in Table 2. The results relate to the pressures at which the three phases coexist (*i.e.* the vapor pressure over the two liquid phases), but the values at atmospheric pressure should be practically the same. We can therefore construct two isobaric phase separation diagrams from the data given in Table 2 (x″ and x‴ as functions of T at constant P).

Table 2. Phase separation in aqueous hydrogen halides. Stoichiometric mole fractions x″ and x‴ of the acid in the water-rich and acid-rich phases respectively, as functions of temperature.

System	Temp. [°C]	x″		x‴	
		from [7]	from [5]	from [7]	from [5]
H_2O/HCl	5	0.485	0.478	0.9990	
	10	0.480	0.473	0.9985	
	15	0.475	0.468	0.9982	
	20	0.470	0.464	0.9980	
	25	0.465	0.459	0.9977	
	30	0.460	0.454	0.9975	
	35	0.455	0.450	0.9972	
H_2O/HBr	15		0.423		0.999
	20		0.418		0.999
	25		0.411		0.998
	30		0.403		0.996
	35		0.400		0.994
H_2O/HI	25		0.346		0.995

The occurrence of a miscibility gap in any binary system can be seen from the form of the function $\Gamma(x)$ for given values of T and P. If the entire curve of $\Gamma(x)$ is convex towards the x-axis, miscibility is complete. If phase separation occurs, the curve contains two points of inflection and a bend which allows the construction of a double tangent (*cf.* Fig. 4 below). The range of concentrations over which Γ is concave towards the x-axis corresponds to labile (absolutely unstable) states.

[6] *H. W. Bakhuis Roozeboom,* Z. physik. Chem. *2*, 449 (1888).
[7] *F. F. Rupert,* J. Amer. chem. Soc. *31*, 851 (1909).

The limits of stability are given by the points of inflection. The region between the points of inflection and the points of contact of the double tangent correspond to metastable states. All other concentrations correspond to stable one-phase systems. The points of contact of the double tangent show the compositions (x'' and x''' in Table 2) of the two coexistent liquid phases. If these points of contact are found from the Γ-x curves for various temperatures at a given pressure and transferred to a T-x diagram, the isobaric phase separation diagram results.

We shall give some examples of the shapes of Γ-x curves which have been obtained from experimental results for aqueous electrolyte solutions at 25 °C and 1 atm.

4. Analytical Representation of the Equilibrium Properties

To obtain an analytical representation of the equilibrium properties of an electrolyte solution at any concentration, it is best to start with the function Γ (T, P, x). All other thermodynamic quantities can then be obtained by differentiation.

We express function Γ in the form of Equation (23) [1, 8], which is valid for solutions of an electrolyte with two ion constituents over the entire range of concentrations from $x = 0$ to $x = 1$.

$$\Gamma = (1-x)\cdot\ln(1-x) + \nu\cdot x\cdot\ln x + (C+\nu-1)\cdot x - \frac{2}{3}B_0\cdot x^{3/2} \quad (23)$$
$$+ \frac{1}{2}B_1\cdot x^2 + \frac{2}{5}B_2\cdot x^{5/2} + \frac{1}{3}B_3\cdot x^3 + \frac{2}{7}B_4\cdot x^{7/2} + \frac{1}{4}B_5\cdot x^4 + \ldots.$$

In equation (23), C, B_0, B_1, B_2, ... are dimensionless parameters depending only on T and P and related by Equation (24).

$$\frac{1}{2}B_1 + \frac{2}{5}B_2 + \frac{1}{3}B_3 + \frac{2}{7}B_4 + \frac{1}{4}B_5 + \ldots = \nu - 1 + C + \frac{2}{3}B_0 \quad (24)$$

Differentiation of (23) with respect to T or P gives the corresponding expressions for the dependence of the entropy of mixing and heat of mixing, or of the volume effects, on concentration.

The first three terms on the right-hand side of Equation (23) correspond to the equations for ideal solutions of fully dissociated electrolytes. The constant C appearing in the third term is given by the general expression (25), where C_2 has the same meaning as in Equations (7) and (9). For volatile electrolytes, C_2 can be derived directly from the experimental results (cf. Section II, 1), so that we can immediately find C.

$$C = C_2 - \nu\cdot\ln\nu_+ + \nu\cdot\ln\frac{M_1}{M_l} \quad (25)$$

The fourth term of Equation (23), which contains B_0, corresponds to the Debye-Hückel limiting law. Thus B_0 is related to the Debye-Hückel coefficient a by

$$B_0 = -\frac{a}{\sqrt{M_1}}\cdot z_+\cdot z_-\cdot\nu\cdot\sqrt{\frac{I}{2}(z_+^2\cdot\nu_- + z_-^2\cdot\nu_-)} \quad (26)$$

In this equation, z_+ and z_- are the electrochemical valences of the cations and the anions respectively, formed from the electrolytes in the last stage of dissociation (*e.g.* $CaCl_2$: $z_+ = 2$; $z_- = -1$; H_2SO_4: $z_+ = 1$; $z_- = -2$). Consequently B_0 is always known at the outset.

If component 1 is water, then at 25 °C and 1 atm:

$$M_1 = 18.016 \times 10^{-3}\ \text{kg/mole};\quad a = 1.176\ \text{kg}^{1/2}/\text{mole}^{1/2} \quad (27)$$

Equation (27), together with Equations (25) and (26), gives for aqueous electrolyte solutions at 25 °C and 1 atm the Equations (28) and (29). Numerical values of C and B_0 are given in Table 3.

$$C = C_2 - \nu\cdot\ln\nu_- + \nu\cdot\ln(18.016\cdot10^{-3}) \quad (28)$$

$$B_0 = -\frac{17.53\, z_+\cdot z_-\cdot\nu}{2}\sqrt{\frac{I}{2}(z_+^2\nu_+ + z_-^2\cdot\nu_-)}. \quad (29)$$

The terms in Equation (23) which contain B_1, B_2, ... *etc.* are empirical terms corresponding to a continuation of the expansion of Γ (x) in fractional powers of x. If the electrolyte is not volatile, there are n independent parameters (B_1, B_2, ... B_n), and the quantity C is determined from Eq. (24). For volatile electrolytes (*e.g.* HCl, HBr, HI, HNO_3), C can be determined from vapor pressure data, so that Equation (24) gives a relationship between B_1, B_2, ... B_n. We then have (n-1) independent parameters. If $\nu = 1$, $B_0 = 0$, $B_2 = 0$, $B_4 = 0$, ... etc., Equation (23) reduces to the ordinary power series for binary solutions of non-electrolytes.

Using Equations (1), (5), (6), and (7), it is possible to derive expressions for ψ_1, ψ_2, φ, and γ from Equation (23) [1, 8]. We shall confine ourselves here to giving the equation (30) for the activity coefficient γ, which is derived from (1), (5), (7), (23), and (25).

$$\nu\cdot\ln\frac{\gamma}{\gamma\dagger} = \nu\cdot\ln(1-x) - B_0\cdot x^{1/2} + (B_1 - \nu + 1)\cdot x$$
$$+ \left(\frac{1}{3}B_0 + B_2\right)\cdot x^{3/2} + \left(B_3 - \frac{1}{2}B_1\right)\cdot x^2 + \left(B_4 - \frac{3}{5}B_2\right)\cdot x^{5/2}$$
$$+ \left(B_5 - \frac{2}{3}B_3\right)\cdot x^3 - \frac{5}{7}B_4\cdot x^{7/2} - \frac{3}{4}B_5\cdot x^4 - \ldots. \quad (30)$$

As can be seen from Equation (30), which does not involve C, the slope of the curve of $\ln(\gamma/\gamma\dagger)$ against $x^{1/2}$ at $x = 0$ is $-B_0/\nu$. This corresponds to the Debye-Hückel limiting law.

Table 3 shows the values of the adjustable parameters B_1, B_2, ... *etc.* for aqueous solutions of 17 electrolytes at 25 °C and 1 atm, as obtained by us [2, 8] from experimental data. These are practically the only electrolyte solutions for which reliable data covering a wide range of concentrations exist. The constants ν, C, and B_0 are also included in Table 3. The C values for the hydrogen halides and nitric acid were determined from experimental values of C_2, using Equation (28), that for perchloric acid (in brackets) was subsequently determined from B_0, B_1, B_2, etc., with the aid of Equation (24). It can be seen that three, four, or five independent parameters are required.

Measurements extending to pure liquid electrolyte ($x = 1$) are possible in only a few cases (*e.g.* sulfuric acid). The continuation of the investigations up to $x = 1$ usually is prevented by fundamental or practical difficulties, *e.g.* a miscibility gap in the case of the hydrogen halides, a

[8] *R. Haase, H. Naas,* and *K.-H. Dücker,* Z. physik. Chem. N.F. *39*, 383 (1963).

saturation limit in the case of bases and salts, or decomposition of the electrolyte in the cases of nitric and perchloric acids.

Fig. 2 shows a plot of $\ln(\gamma/\gamma\dagger)$ as a function of $m^{1/2}$ for hydrochloric acid. The calculated values agree closely with the experimental results. The measurements on which the experimental curve of Fig. 2 is based [5] extend as far as the miscibility limit (cf. Table 2).

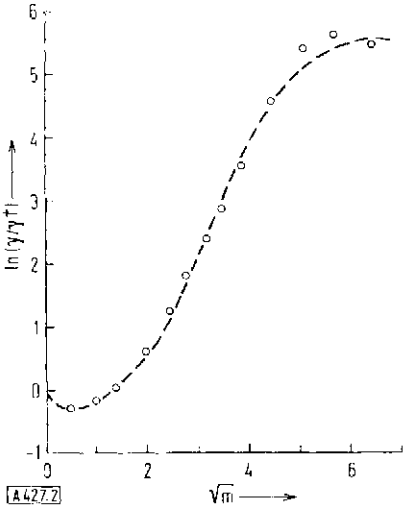

Fig. 2. The system H_2O/HCl at 25 °C: Logarithm of the conventional activity coefficient γ *vs.* the square root of the molality m according to [8]. Experimental: (ooo); calculated from Equations (1) and (30), using the constants in Equation (27) and Table 3: (— —). ($\gamma\dagger \equiv$ 1 kg/mole, $m\dagger \equiv$ 1 mole/kg).

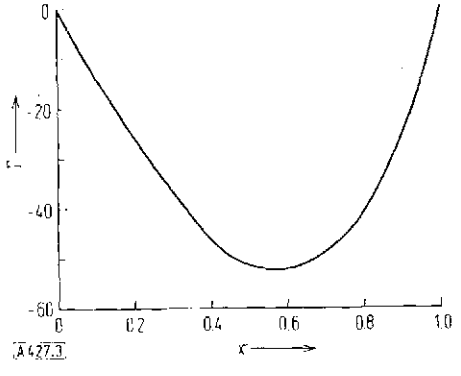

Fig. 3. The system H_2O/$HClO_4$ at 25 °C: Γ (x) as a function of the stoichiometric mole fraction x of the electrolyte, as calculated by Equation (23) using the constants in Table 3.

With the constants listed in Table 3, a miscibility gap for the hydrogen halides and complete miscibility for the other systems can be predicted. In the example of Fig. 3 (perchloric acid), the course of the Γ–x curve is characteristic of complete miscibility. Fig. 4, on the other hand, shows a typical example (hydrochloric acid) of the Γ–x curve in a system which exhibits phase separation. The

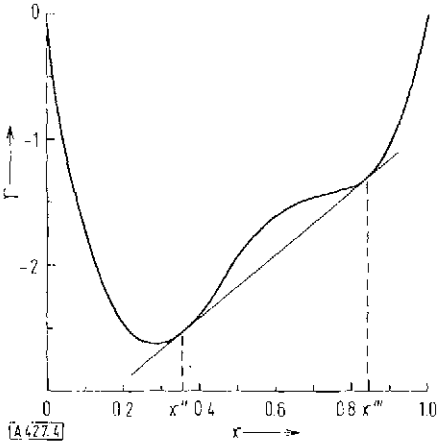

Fig. 4. The system H_2O/HCl at 25°C: Γ (x) as a function of the stoichiometric mole fraction x of the electrolyte, according to [8], calculated by Equation (23) using the constants in Table 3 (x'', x''': values of x for the two coexistent liquid phases).

compositions of the two coexisting liquid phases ($x'' = 0.35$ and $x''' = 0.84$) as obtained from the points of contact of the double tangent are reasonably close to the values obtained by direct measurement (Table 2: $x'' = 0.46$ and $x''' = 0.998$). Similar results were found for hydrobromic and hydriodic acids [8].

III. Electrical Conductivity

1. General

In an electrolyte solution which is situated in an external electric field, but which is otherwise homogeneous, *i.e.* exhibits no gradients other than the potential gradient, conduction of electricity occurs, associated with migration of the ions. If we discregard extremely high field strengths, Ohm's law expressed in the form (31) applies to each volume element.

$$\vec{I} = \varkappa \vec{\mathfrak{E}} = -\varkappa \operatorname{grad} \varphi \quad (31)$$

In Equation (31), the vectors $\vec{I}$ and $\vec{\mathfrak{E}}$ are the electric current density and field strength, respectively, φ is the electric potential, and $\varkappa$ is the specific conductivity.

The result of the mutual opposition of the electrostatic force on the ions and the resistance of the medium (resistance due to friction and electrostatic interaction whith other ions) is that, after a brief acceleration, an ion moves at a constant average velocity with respect to the solvent. If the magnitude of this velocity of migration is divided by the magnitude of the electric field, we obtain a positive quantity u_i, the mobility of ions of type i. Within the range of validity of Ohm's law, u_i is inde-

pendent of the field strength, but is a function of the intensive variables of the system (temperature, pressure, concentration). It is convenient to replace u_i by the ionic conductivity λ_i of the ions of type i, as defined in Equation (32); F is the Faraday constant.

$$\lambda_i \equiv F \cdot u_i \tag{32}$$

It can be shown [9] that, provided that Ohm's law is valid, the relationship (33) must always be satisfied. In this equation, $|z_i|$ is the magnitude of the electrochemical valence and c_i the molarity of ions of type i. The summation must be carried out over all types of ions present.

$$\varkappa = F \cdot \sum_i z_i c_i \cdot u_i = \sum_i z_i c_i \cdot \lambda_i \tag{33}$$

When more than two types of ions are present, the discussion of equation (33) becomes complicated. In the next section, therefore, we shall confine ourselves to solutions of electrolytes containing two types of ions (*e.g.* HCl or Na_2SO_4). We shall also assume, for the sake of simplicity, that the solvent (*e.g.* H_2O) does not form ions. After the discussion of transport numbers, we shall also examine whether the ionic mobilities and conductivities can be derived from experimental data in this case.

2. Equivalent Conductivities

We shall now deal with electrolyte solutions containing two types of ions, using either the molarity c or the equivalent concentration c* of the electrolyte as the macroscopic concentration variable. We then have [cf. Equation (1)]:

$$c = \frac{\rho \cdot m}{1 + M_2 \cdot m} \; ; \; c^* = z_+ \nu_+ c = z_- \nu_- c \tag{34}$$

In this equation ρ is the density of the solution and M_2 is the formula weight of the electrolyte.

We also have

$$c_+ = \nu_+ \cdot \alpha \cdot c; \; c_- = \nu_- \cdot \alpha \cdot c \tag{35}$$

which, together with Equation (34), gives

$$z_+ c_+ = z_- \cdot c_- = \alpha \cdot c^* \tag{36}$$

Equation (37) defines the equivalent conductivity Λ

$$\Lambda \equiv \varkappa / c^* \tag{37}$$

which can be measured. This relationship, together with Equations (33) and (36), leads to a fundamental equation

$$\Lambda = F \cdot \alpha \cdot (u_+ + u_-) = \alpha \cdot (\lambda_+ + \lambda_-) \tag{38}$$

for the electrical conductivity in electrolyte solutions containing two types of ions.

For infinite dilution, Equation (38) becomes

$$\lim_{c \to 0} \Lambda = \Lambda^0 = F \cdot (u_+^0 + u_-^0) = \lambda_+^0 + \lambda_-^0 \tag{39}$$

in which the superscript ^{0} signifies the limiting value of the quantity in question when $c \to 0$. According to the law of independent migration of ions, first formulated by *Kohlrausch* in 1893 and repeatedly verified since that time, u_i^0 (or λ_i^0) is characteristic of ions of the type i in a given solvent at a given temperature and pressure, independent of the oppositely charged ion. Thus Λ^0 is a sum of contributions due to the individual ions.

For very dilute solutions of weak electrolytes, we can put $\lambda_i = \lambda_i^0$ in Equation (38). We then obtain from (38) and (39) that $\Lambda/\Lambda^0 = \alpha$. This relationship leads to Ostwald's dilution law when it is combined with the classical law of mass action for dissociation equilibria of type (15), *i.e.* with Equations (10) and (16) and $\gamma_\pm \quad \gamma_u = \gamma\dagger$.

For very dilute solutions of strong electrolytes, on the other hand, $\alpha = 1$, and λ_+, λ_-, and Λ contain terms proportional to $c^{1/2}$ which can be calculated from the valences of the ions and properties of the solvent, using Onsager's limiting law. An extension of the theoretical treatment of electrical conduction in dilute solutions of strong electrolytes beyond the square root law has recently been developed by *Onsager* and *Fuoss* [10], again on the basis of the relaxation and the electrophoretic effects.

Concentrated electrolyte solutions show a complicated dependence of α, λ_+, λ_-, and Λ on concentration which is at present not amenable to theoretical treatment. We have determined Λ over a wide range of concentrations for the systems H_2O/HNO_3 and $H_2O/HClO_4$, for which α-values are available from spectroscopic data [11].

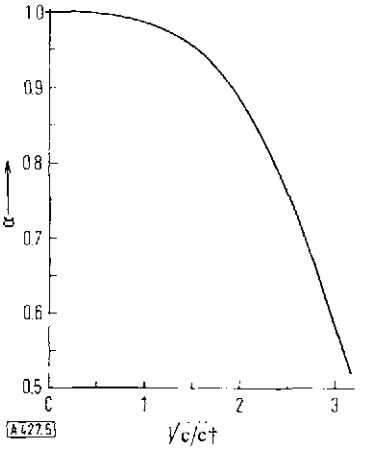

Fig. 5. The system H_2O/HNO_3 at 25 °C: Degree of dissociation α of the electrolyte as a function of the square root of the molarity c according to [4]. ($c\dagger \equiv 1$ mole/l).

Fig. 5 shows the degree of dissociation α of the electrolyte, Fig. 6 the measured values of Λ, together with the values of $(\lambda_+ + \lambda_-)$ calculated with Equation (38), as functions of $c_{1/2}$ for aqueous nitric acid (at 25 °C and 1 atm). Aqueous perchloric acid presents a similar picture [11]. The effect of incomplete dissociation at high concentrations can be clearly recognized.

In order to obtain an analytical representation for the entire concentration range from $x = 0$ to $x = 1$ (for which experimental values are available for aqueous nitric acid

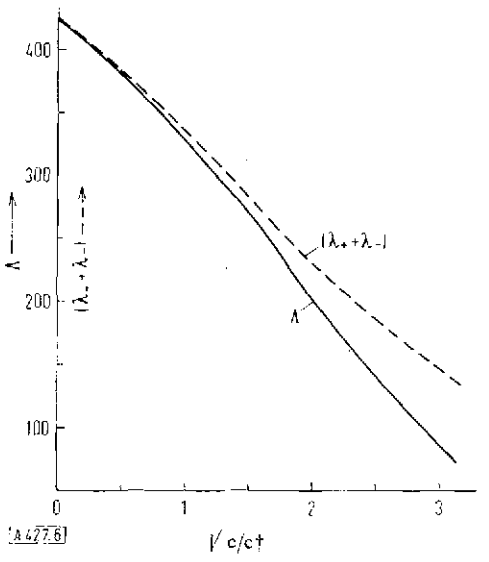

Fig. 6. The system H_2O/HNO_3 at 25 °C: Equivalent conductivity Λ and sum $(\lambda_+ + \lambda_-)$ of the ionic conductances, according to [11] (units ohm^{-1} cm^2 eq^{-1}; $c^\dagger$ = 1 mole/l).

and sulfuric acid [11], it would be necessary to find empirical expressions for $\Lambda(x)$ or $\lambda_+(x)$ and $\lambda_-(x)$ which would reduce, at high dilution, to the equations of *Onsager* and *Fuoss* [10] (cf. the method used in the case of equilibrium properties, Section II.4). No attempt has so far been made in this direction, partly owing to the complicated form of the *Onsager-Fuoss* equations, and partly because of the difficulties encountered in the experimental determination of the fundamental quantities λ_+ and λ_- in concentrated solutions (cf. Section III.4).

3. Transport Numbers

Contrary to widely held beliefs, neither the Hittorf transport number nor the true transport number of an ion can be measured at all electrolyte concentrations [9]. The quantity measured is the transport number of an ion constituent, which corresponds to the Hittorf transport number only at sufficiently high dilutions [9]. This fact can be demonstrated for each of the methods used for the determination of transport numbers, *i.e.* Hittorf's method [12], the moving boundary method [13], and e.m.f. measurements in concentration cells [9, 12] and in gravity or centrifugal cells [9].

For the sake of simplicity, let us again consider solutions of a single electrolyte containing two types of ions. The transport numbers of the cation and anion constituents respectively are ϑ_+ and $\vartheta_- = (1-\vartheta_+)$. ϑ_+ and ϑ_- are equal to the number of equivalents of the cation and anion constituents, respectively, passing through a reference plane which is stationary with respect to the solvent, during the passage of 1 faraday of electricity through the solution. The term "ion constituent" refers to the parts (atoms or radicals) of the electrolyte molecule which can form ions, irrespective of the extent to which these components are actually present as ions.

Thus in an aqueous solution of sodium sulfate, the atom Na and the radical SO_4 are the cation and anion constituents respectively: Na occurs in the species Na^+ and Na_2SO_4, and sulfate occurs as SO_4^{2-} and Na_2SO_4.

If dissociation of an electrolyte is incomplete, it is necessary to take into account transport of the undissociated electrolyte molecules, relative to the solvent, in the electric field. This relative migration of the undissociated electrolyte may be either direct (association of the neutral electrolyte molecules with ions) or indirect (solvation of ions and consequent movement of the solvent relative to the electrolyte molecules). Corresponding to the mobility u_i and the ionic conductance λ_i, therefore, we also introduce the mobility u_u of the undissociated electrolyte and the quantity $\lambda_u = F.u_u$.

$$\vartheta_+ = \frac{u_+}{u_+ + u_-} \pm \frac{1-\alpha}{\alpha} \cdot \frac{u_u}{u_+ + u_-} = \frac{1}{\lambda_+ + \lambda_-}\left(\lambda_+ \pm \frac{1-\alpha}{\alpha}\cdot\lambda_u\right) \quad (40)$$

$$\vartheta_- = 1-\vartheta_+ = \frac{u_-}{u_+ + u_-} \mp \frac{1-\alpha}{\alpha}\frac{u_u}{u_+ + u_-}$$

$$= \frac{1}{\lambda_+ + \lambda_-}\left(\lambda_- \mp \frac{1-\alpha}{\alpha}\cdot\lambda_u\right) \quad (41)$$

The general expressions (40) and (41) can be derived for the dimensionless quantities ϑ_+ and ϑ_- [13].

The upper (lower) sign applies when the undissociated electrolyte molecules migrate in the same direction as the cations (anions). It can be seen that, when dissociation is complete ($\alpha = 1$) or if transport of the undissociated electrolyte is negligible ($u_u = 0$; $\lambda_u = 0$), ϑ_+ and ϑ_- reduce to the Hittorf transport numbers t_+ and $t_- = (1-t_+)$ of the cations and the anions, respectively. At infinite dilution ($c \to 0$; $\alpha \to 1$), we have

$$\vartheta_+^0 = t_+^0 = \frac{u_+^0}{u_+^0 + u_-^0} = \frac{\lambda_+^0}{\lambda_+^0 + \lambda_-^0} \quad (42)$$

$$\vartheta_-^0 = t_-^0 = \frac{u_-^0}{u_+^0 + u_-^0} = \frac{\lambda_-^0}{\lambda_+^0 + \lambda_-^0} \quad (43)$$

in which ϑ_i^0 and t_i^0 are the limiting values of the transport numbers at infinite dilution.

We have determined transport numbers for concentrated aqueous solutions of HNO_3, $HClO_4$, and $AgNO_3$ at 25 °C, using the moving boundary method [14]. Fig. 7

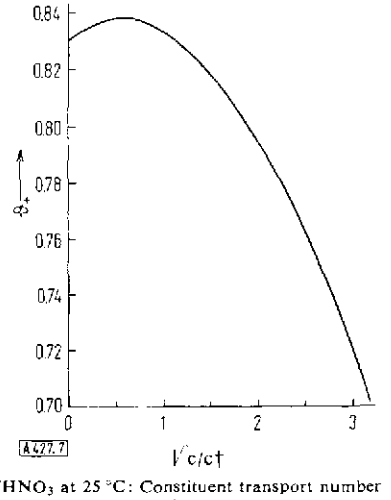

Fig. 7. The system H_2O/HNO_3 at 25 °C: Constituent transport number ϑ_+ of the cation vs. $c^{1/2}$, according to [11]. ($c^\dagger \equiv 1$ mole/l).

shows the curve of ϑ_+ against $c^{1/2}$ for aqueous nitric acid. A significant feature is the maximum, which is also found with aqueous perchloric acid.

4. Ionic Conductivities

We have seen that, in solutions of a single electrolyte containing two ionic species, it is possible to measure the following quantities: the equivalent conductivity Λ, the stoichiometric transport numbers ϑ_i, and in some cases the degree of dissociation α. Experimental data can also be used to find the limiting values Λ^0 and t_i^0.

It is therefore possible to determine the limiting values λ_+^0 and λ_-^0 of the ionic conductivities, using Equation (44), which is derived from Equations (39), (42), and (43).

$$\lambda_+^0 = t_+^0 \cdot \Lambda^0; \quad \lambda_-^0 = t_-^0 \cdot \Lambda^0 \tag{44}$$

These quantities, which were mentioned earlier, are tabulated in modern monographs and reference books for many ions at various temperatures.

The equations

$$\lambda_+^* \equiv \vartheta_+ \cdot \Lambda; \quad \lambda_-^* \equiv \vartheta_- \cdot \Lambda \tag{45}$$

$$\lambda_+' \equiv \frac{\vartheta_+ \cdot \Lambda}{\alpha}; \quad \lambda_-' \equiv \frac{\vartheta_- \cdot \Lambda}{\alpha} \tag{46}$$

can be used for all concentrations with the experimental values of ϑ_+ and Λ or of ϑ_i, Λ, and α.

From (38), (40), (41), (45), and (46), we find [11]:

$$\lambda_+^* = \alpha \cdot \lambda_+ + (1-\alpha) \cdot \lambda_u \tag{47}$$

$$\lambda_-^* = \alpha \cdot \lambda_- + (1-\alpha) \cdot \lambda_u \tag{48}$$

$$\lambda_+' = \lambda_+ + \frac{1-\alpha}{\alpha} \cdot \lambda_u \tag{49}$$

$$\lambda_-' = \lambda_- \mp \frac{1-\alpha}{\alpha} \cdot \lambda_u \tag{50}$$

from which we obtain the identities:

$$\lambda_-^* + \lambda_+^* = \Lambda \tag{51}$$

$$\lambda_+' + \lambda_-' = \lambda_+ + \lambda_- \tag{52}$$

In accordance with Equation (51), λ_+^* and λ_-^* may be referred to as the equivalent conductivities of the cation and anion constituents of the electrolyte respectively. According to Equations (49) and (50), λ_+' and λ_-' may be identified with the ionic conductivities λ_+ and λ_- only if dissociation is complete ($\alpha = 1$), or if the migration of undissociated electrolyte in the electric field is negligible ($\lambda_u = 0$). Consequently, at high concentrations λ_+ and λ_- cannot be separately determined. Provided that experimental data for α are available, however, it is possible to find the sum $(\lambda_+ + \lambda_-)$, using Equation (38) or (52) (cf. Fig. 6).

Fig. 8 shows values of λ_+^*, λ_+', λ_-^*, and λ_-' for aqueous nitric acid at 25 °C, over a wide range of concentrations. These values were determined from the data of Figs. 5, 6, and 7, using Equations (45) and (46). A similar picture is found with aqueous perchloric acid [11]. A striking feature is the strong dependence of λ_+^* and λ_+' (for H^+) on concentration, compared with that of λ_-^* and λ_-' (NO_3^- and ClO_4^-). This feature is related to the proton jump mechanism of the migration of H^+ ions, which becomes increasingly noticeable with increasing dilution.

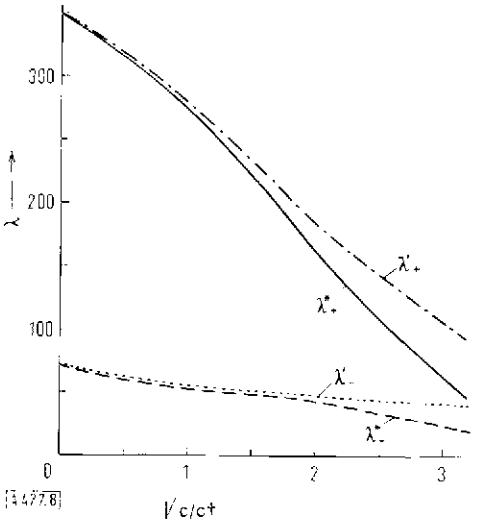

Fig. 8. The H_2O/HNO_3 system at 25 °C: The quantities λ_+^*, λ_+', λ_-^*, and λ_-' as functions of the square root of the molarity c [mole/l], according to [11] (units $ohm^{-1}\,cm^2\,eq^{-1}$; $c^\dagger = 1$ mole/l).

Sufficient data for the determination of λ_i^* over a wide range of concentrations are available for only a few other electrolyte systems (*e.g.* aqueous hydrochloric acid [11], silver nitrate [14,15], and silver perchlorate [15]).

IV. Diffusion

Diffusion is the transport of matter in a mixture, caused by concentration gradients. Let us again consider a solution of a single electrolyte containing two ion constituents. As a result of the conditions of electroneutrality and local dissociation equilibrium (which normally are satisfied by every volume element, even in a medium in which transport processes are taking place), all electrolyte particle types move at the same average velocity. Apart from the (average) velocity of the solvent molecules (vector $\vec{v}_1$), therefore, there is only one other independent velocity, *i.e.* the common (average) velocity $\vec{v}_2$ of the ions and undissociated electrolyte molecules (*e.g.* the species H^+, HSO_4^-, SO_4^{2-}, and H_2SO_4 in aqueous sulfuric acid). We also have only one independent concentration variable, for which (as in the case of electrical conductivity) we shall choose for the moment the molarity c of the electrolyte.

The transport of matter is characterized by a vector $(\vec{v}_2 - \vec{v}_1)$ or $c(\vec{v}_2 - \vec{v}_1)$. The latter quantity is the diffusion current density of the electrolyte in the "solvent-fixed" frame of reference, ("Hittorf's reference system") and is denoted by $\vec{J}_2$. Thus

$$\vec{J}_2 \equiv c \cdot (\vec{v}_2 - \vec{v}_1). \tag{53}$$

[15] *A. N. Campbell* and *K. P. Singh*, Canad. J. Chem. *37*, 1959 (1959).

In this reference system, the velocity of the solvent $\vec{v}_1$ is taken as the reference velocity. There are also other reference systems, such as that in which the reference velocity is the mean volume velocity $\vec{w}$ (Fick's reference system). The corresponding vector for the diffusion current density is

$$_w\vec{J}_2 \equiv c\cdot(\vec{v}_2 - \vec{w}). \tag{54}$$

Hittorf's system is related to Fick's system by equation (55) [9], where $\bar{V}$ is the molar volume of the mixture, V_1 and V_2 are the partial molar volumes of the solvent and the electrolyte respectively, and x is the stoichiometric mole fraction of the electrolyte.

$$_w\vec{J}_2 = (1 - c\cdot V_2)\cdot {}_1\vec{J}_2 = \frac{(1-x)\cdot V_1}{V}\cdot {}_1\vec{J}_2 \tag{55}$$

The above discussion is true not only for diffusion but also for other transport processes which occur in the absence of an electric current, *e.g.* sedimentation (cf. Section V) and thermal diffusion. For the present, however, we shall confine our discussion to pure diffusion, *i.e.* we shall ignore external force fields, as well as pressure and temperature gradients. In Section V we shall consider pressure gradients in addition to concentration gradients.

For pure diffusion in a solution of an electrolyte containing two ion constituents, each volume element obeys Fick's law in the form

$$_w\vec{J}_2 = -D\cdot \operatorname{grad} c \tag{56}$$

in which D is the diffusion coefficient. Equation (56) is analogous to Ohm's law (31), and is always valid unless the concentration gradients are extremely high. As the electric conductivity $\varkappa$ in Equation (31), so the diffusion coefficient D in Equation (56) is a measurable positive quantity (in stable mixtures not at their critical points), which depends on the intensive (local) variables of state (temperature, pressure, concentration).

It is often desirable to convert from Fick's reference system to Hittorf's system, and from the molarity c to the molality m. From Equation (34), it is possible to derive

$$\operatorname{grad} c = \frac{c\cdot(1-c\cdot V_2)}{m}\cdot \operatorname{grad} m \tag{57}$$

Combination of Equations (55), (56), and (57) gives Equation (58), which is Fick's law expressed in Hittorf's system.

$$_1\vec{J}_2 = -D\cdot\frac{c}{m}\cdot \operatorname{grad} m \tag{58}$$

We shall now restrict the discussion to completely dissociated electrolytes containing two ionic species. Thus we exclude compounds such as H_2SO_4 or H_3PO_4, and set $\alpha = 1$. The solution then contains only three types of particles: non-electrolyte molecules, cations, and anions. The condition $\alpha = 1$ stipulates dilute solutions of strong electrolytes. Application of the thermodynamics of irreversible processes to such systems leads to the general equation (59) for the diffusion coefficient D [9, 16, 17].

$$D = b\cdot q^2\cdot\frac{\nu\cdot RT}{c}\left[1 + m\left(\frac{\partial \ln \gamma}{\partial m}\right)_{T,P}\right] \tag{59}$$

$$q \equiv \frac{z_+ - z_-}{\nu} = \frac{z_+}{\nu_-} = \frac{-z_-}{\nu_+} \tag{60}$$

$$b \equiv \frac{a_{11}\cdot a_{22} - a_{12}^2}{z_+^2\cdot a_{11} + 2 z_+\cdot z_-\cdot a_{12} + z^2\cdot a_{22}} \tag{61}$$

In the above equations, a_{11}, a_{22}, and a_{12} are phenomenological coefficients related to the ionic conductivities λ_+ and λ_- by Equations (62) and (63).

$$\lambda_+ = \frac{F^2}{\nu_+\cdot c}\, z_+\cdot a_{11} + z_-\cdot a_{12} \tag{62}$$

$$\lambda_- = \frac{F^2}{\nu_-\cdot c}\, z_+ a_{12} + z_-\cdot a_{22} \tag{63}$$

As previously mentioned, in diffusion the ions move at the same average speed and in the same direction, namely opposite to the direction of the chemical potential gradient. Consequently, in contrast to the conduction of electricity, only the electrophoretic effect is active, the relaxation effect being absent. The coefficients a_{11}, a_{22}, and a_{12} in (61) must therefore lead to elimination of the relaxation effect which is still accounted for in Equations (62) and (63). Thus if we have a kinetic molecular theory of electrolytic conduction with explicit expressions for λ_+ and λ_-, the condition of non-occurrence of the relaxation effect in Equation (61), together with Equations (62) and (63), provide the three equations required for the calculation of a_{11}, a_{22}, and a_{12} from molecular-physical data. Consequently, any kinetic treatment of electrical conduction in dilute solutions of strong electrolytes, combined with Equation (59), leads to an explicit expression for D. *Onsager* and *Fuoss* [18] first reported such an expression. At higher concentrations, the molecular-kinetic theory of diffusion, like that of electrical conduction, meets with difficulties which cannot at present be overcome.

For very dilute, but not necessarily ideal dilute solutions (in the thermodynamic sense), the kinetic theory shows [18] that it is possible to disregard the electrophoretic effect, and use the approximation:

$$a_{12} = 0;\ \lambda_+ = \lambda_+^0;\ \lambda_- = \lambda_-^0 \tag{64}$$

From Equation (64), together with (59)–(63), we obtain Equation (65) [18, 19],

$$D = \frac{RT}{F^2}\cdot\left(\frac{1}{z_+} - \frac{1}{z_-}\right)\cdot\frac{\lambda_+^0\cdot\lambda_-^0}{\lambda_+^0 + \lambda_-^0}\left[1 + m\left(\frac{\partial \ln \gamma}{\partial m}\right)_{T,P}\right] \tag{65}$$

which relates the diffusion coefficient in very dilute solutions of strong electrolytes to the limiting values λ_+^0 and λ_-^0 of the ionic conductances and to thermodynamic properties of the electrolyte solution.

At infinite dilution ($m \to 0$), combination of (66) with (65) gives the limiting law (67):

$$\lim_{m\to 0} D = D^0;\ \lim_{m\to 0}\left[m\cdot\left(\frac{\partial \ln \gamma}{\partial m}\right)_{T,P}\right] = 0 \tag{66}$$

$$D^0 = \frac{RT}{F^2} \cdot \left(\frac{1}{z_+} - \frac{1}{z_-} \right) \frac{\lambda_+^0 \cdot \lambda_-^0}{\lambda_+^0 + \lambda_-^0} \qquad (67)$$

proposed by *Noyes* in 1908. For 1:1 electrolytes ($z_+ = -z_- = 1$) Equation (67) reduces to

$$D^0 = \frac{2\,RT}{F^2} \cdot \frac{\lambda_+^0 \cdot \lambda_-^0}{\lambda_+^0 + \lambda_-^0} \qquad (68)$$

given by *Nernst* in 1888.

V. Sedimentation

Sedimentation is the transport of matter in a mixture caused by gravitational or centrifugal fields. If we confine the discussion to solutions of a single electrolyte containing two ion constituents, then the general considerations regarding concentration variables, velocities, and diffusion current densities as discussed in Section IV are still valid.

Consider first an electrolyte solution subject to no fields other than the external force field (gravitational or centrifugal acceleration $\vec{g}$), and no gradients other than the pressure gradient (grad P). We may assume local mechanical equilibrium, so that if ρ is the density of the solution, then

$$\rho \cdot \vec{g} = \text{grad } P \qquad (69)$$

Moreover, if we disregard extremely high force fields, each volume element satisfies the equation

$$\vec{v}_2 - \vec{w} = s \cdot \vec{g} \qquad (70)$$

or, combining this with Equations (54) and (69):

$${}_w\vec{J}_2 = c \cdot s \cdot \vec{g} = s \cdot \frac{c}{\rho} \cdot \text{grad } P, \qquad (71)$$

or with Equations (1), (34), and (55):

$${}_1\vec{J}_2 = s \cdot \frac{M_1 \cdot m}{\bar{V}_1} \cdot \vec{g} = s \cdot \frac{M_1 \cdot m}{\bar{V}_1 \cdot \rho} \cdot \text{grad } P. \qquad (72)$$

Equations (71) and (72) correspond respectively to (56) and (58). The measurable quantity s is the sedimentation coefficient. It may be either positive or negative, and (like the diffusion coefficient D) depends on the intensive variables of the volume element.

Sedimentation in a mixture initially uniform in concentration gives rise to a concentration gradient, which in turn leads to diffusion. In general, therefore, we must consider the simultaneous occurrence of a pressure gradient and a concentration gradient, and hence a superposition of the two transport processes (diffusion and sedimentation). Experience has shown that this superposition is linear. Starting with Equations (58) and (72), we can therefore write

$${}_1\vec{J}_2 = -D \cdot \frac{c}{m} \cdot \text{grad } m + s \cdot \frac{M_1 \cdot m}{\bar{V}_1} \cdot \vec{g} \qquad (73)$$

Equation (73) describes the simultaneous occurrence of diffusion and sedimentation in the solvent-fixed reference system.

After sufficient time, the opposing effects of sedimentation ("separation") and diffusion ("mixing") lead to the establishment of a steady state characterized by ${}_1\vec{J}_2 = 0$, which under the conditions assumed (uniform temperature) corresponds to an equilibrium state. According to classical thermodynamics [9], this sedimentation equilibrium is described by

$$(M_2 - \bar{V}_2) \cdot \rho \cdot \vec{g} = \left(\frac{\partial \mu_2}{\partial m} \right)_{T,P} \cdot \text{grad } m \qquad (74)$$

On the other hand, by applying the condition ${}_1\vec{J}_2 = 0$ to Equation (73), we obtain

$$s \cdot \frac{M_1 \cdot m}{\bar{V}_1} \cdot \vec{g} = D \cdot \frac{c}{m} \cdot \text{grad } m \qquad (75)$$

The equilibium conditions (74) and (75) immediately lead to

$$\frac{D}{s} = \frac{M_1 \cdot m^2 \cdot (\partial \mu_2 / \partial m)_{T,P}}{c \cdot \bar{V}_1 \cdot (\bar{M}_2 - \bar{V}_2 \rho)} \qquad (76)$$

Equations (1), (2), (7), and (9) give the following relationships:

$$\frac{M_1 \cdot m^2}{c} = m \cdot (1 + M_1 \cdot m) \cdot \bar{V} \qquad (77)$$

$$\left(\frac{\partial \mu_2}{\partial m} \right)_{T,P} = \frac{\nu \cdot RT}{m} \left[1 + m \cdot \left(\frac{\partial \ln \frac{\gamma}{\gamma_\pm}}{\partial m} \right)_{T,P} \right] \qquad (78)$$

and from these, together with Equation (76), we obtain

$$\frac{D}{s} = \frac{(1 + M_1 \cdot m) \cdot \bar{V}}{\bar{V}_1 \cdot (M_2 - \bar{V}_2 \cdot \rho)} \cdot \nu \cdot RT \left[1 + m \left(\frac{\partial \ln \frac{\gamma}{\gamma_\pm}}{\partial m} \right)_{T,P} \right] \qquad (79)$$

Equation (79) is valid at all concentrations, and relates the transport coefficients D and s. The quantities on the right-hand side can be found from equilibrium data alone, *i.e.* from experimental values of $\rho(m)$ and $\gamma(m)$. Equivalent expressions were derived earlier by various methods [9, 20]. Our derivation [21] has the advantage of generality and simlicity. The above form of Equation (79) is particularly suitable for electrolyte solutions. For other purposes, however, particularly for high molecular weight non-eletrolytes, other forms of this relationship, which can also be derived from Equation (76), are more suitable [9, 20].

Creeth [22] has recently confirmed experimentally an equation corresponding to (79) (but using the "c" scale and not involving $\bar{V}$ and V_1) for aqueous solutions of Tl_2SO_4 at 25 °C at electrolyte concentrations of 8 to 50 g/l. The functions $V_2(m)$ and $\rho(m)$ were determined by density measurements, $\gamma(m)$ by e.m.f. measurements,

[20] For a review containing historical data, see *R. Haase* in *J. W. Williams*: Ultracentrifugal Analysis in Theory and Experiment. Academic Press, New York-London 1963, p. 13.

[22] *J. M. Creeth*, J. physic. Chem. *66*, 1228 (1962); *J. M. Creeth* and *B. E. Peter*, J. physic. Chem. *64*, 1502 (1960).

D(m) from diffusion experiments, and s(m) from experiments with the ultracentrifuge. The order of magnitude of the diffusion coefficient D is 10^{-5} cm²/sec in this system, and that of s is 10^{-13} sec.

Equation (65) applies to very dilute solutions of strong electrolytes containing two ionic species. In this case we can also apply the approximations

$$M_1 \cdot m \ll 1 ; V \approx V_1 \tag{80}$$

Thus from Equations (65) and (79) we obtain

$$s = \frac{M_2^* \cdot (1-\tilde{V}_2 \cdot \rho)}{F^2} \cdot \frac{\lambda_+^0 \cdot \lambda^0}{\lambda_+^0 + \lambda_-^0} \tag{81}$$

in which M_2^* is the equivalent weight of the electrolyte, defined by

$$M_2^* \equiv \frac{M_2}{z_+ \nu_+} = \frac{M_2}{z_- \nu_-} \tag{82}$$

and in which we have made use of (60) and

$$V_2 = M_2 \cdot \tilde{V}_2 \tag{83}$$

($\tilde{V}_2$ is the partial specific volume of the electrolyte).

In the limit $m \to 0$, we find from Equations (81) and (79), together with Equations (66), (80), and (83):

$$\lim_{m \to 0} s = \frac{M_2^* \cdot (1-\tilde{V}_2^0 \cdot \rho_{01})}{F^2} \cdot \frac{\lambda_+^0 \cdot \lambda_-^0}{\lambda_+^0 + \lambda_-^0} \tag{84}$$

$$\lim_{m \to 0} \frac{D}{s} = \frac{\nu \cdot RT}{M_2 \cdot (1-\tilde{V}_2^0 \cdot \rho_{01})} \tag{85}$$

In Equations (84) and (85), $\tilde{V}_2^0$ is the limiting value of the partial specific volume of the electrolyte at infinite dilution, and ρ_{01} is the density of the pure solvent. The limiting law (85) is known as Svedberg's equation (*Svedberg* 1925), particularly under the condition $\nu = 1$, (non-electrolyte solutions). This relationship can be used to determine the quantity M_2/ν. Equation (85) can also be derived from Equations (67) and (84) using (60) and (82).

Since the molecular theory of sedimentation is fundamentally simpler than that of diffusion, Equation (79) is useful in calculating D from s. On the other hand, D is the more easily measured quantity, so that (79) will also be used for the reverse calculation.

Chemistry and Stereochemistry of Fluorophosphoranes [*]

BY DR. R. SCHMUTZLER

UNIVERSITY CHEMICAL LABORATORY, CAMBRIDGE, ENGLAND [**]

Fluorophosphoranes are a recently discovered new type of phosphorus compound derived from phosphorus pentafluoride by substitution of fluorine atoms with various groups. Synthesis, chemistry, and stereochemistry of this class of compounds containing phosphorus in the comparatively rare coordination number 5 will be discussed.

A. Introduction

Until recently, relatively few examples of pentacoordination were known; some halides of group V elements were recognized as typical representatives of pentacoordinated species. For phosphorus in particular, pentacoordinated halides with trigonal-bipyramidal configuration (in the gas phase) have long been known, *e.g.* PBr_5, PCl_5 (covalent form), PF_5, and the covalent forms of the halofluorides PX_nF_{5-n} (X = Cl, Br; n = 2,3,4). The chemistry of P(V)-halofluorides, which are distinguished in several instances by the interconversion of covalent and ionic forms, has recently been reviewed [1–3].

In the present article, a review is presented on chemical and stereochemical aspects of a further class of phosphorus-halogen compounds containing pentacoordinate phosphorus. The compounds of this type are derived from phosphorus pentafluoride by substitution of fluorine atoms with various groups. The following types of these "fluorophosphoranes" will be considered:

1. Fluorophosphoranes containing hydrocarbon groups as substituents, R_nPF_{5-n} (n = 1,2,3).
2. Aryltrifluorophosphorus hydrides, $ArPF_3H$. Compounds of this type are not true fluorophosphoranes within the scope of this article. Because of the stereochemical relationship to other fluorophosp horanes, however, aryltrifluorophosphorus hydrides will also be considered here.
3. Arylchlorotrifluorophosphoranes, $ArPF_3Cl$.
4. Alkyl(aryl)-dialkylaminotrifluorophosphoranes, $R(Ar)PF_3NR'_2$.
5. Dialkylaminofluorophosphoranes, $(R_2N)_nPF_{5-n}$ (n = 1,2).
6. Perhaloalkyldihalodifluorophosphoranes, $R_{Hal}PF_2X_2$ (Hal = F,Cl; X = Cl, Br).

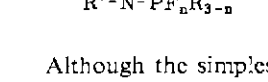
7. Fluoro-1,3,2,4-diazadiphosphetidines *(1)* (n = 2,3; R,R' = hydrocarbon groups).



(1)

Although the simplest fluorophosphorane, the "parent compound" PF_5, is known since 1876, since well before the discovery of elemental fluorine, a fluorophosphorane within the scope of the above definition was first referred to in the patent literature in 1955 [4,5]. Fluorophosphoranes were not isolated and characterized in detail until 1958–59 when *A. B. Burg* and his co-workers [6] and *W. C. Smith* [7] reported some perfluoroalkyl derivatives [6] and phenyl- and isooctenyl-tetrafluorophosphorane [7]. Numerous publications on synthesis and chemistry of fluorophosphoranes have appeared since then.

B. Synthesis of Fluorophosphoranes

I. Compounds of Composition R_nPF_{5-n}

1. The first preparative method to be reported involves fluorination of the readily accessible complexes of PCl_3 or alkyldichlorophosphines with alkyl halides and $AlCl_3$ using HF [4,5,8], AsF_3, SbF_3 [8,9], or KF [8].

$$[R_nPCl_{4-n}][AlCl_4] \rightarrow R_nPF_{5-n}\ (n = 1,2) \qquad (a)$$

2. Dichlorophosphines react with SbF_5 or a mixture of stoichiometric amounts of $SbCl_5$ and SbF_3 with formation of tetrafluorophosphoranes according to (b) and (c):

$$3\,RPCl_2 + 3\,SbF_5 \rightarrow 3\,RPF_4 + SbF_3 + 2\,SbCl_3 \qquad (b)$$

$$3\,RPCl_2 + 3\,SbCl_5 + 4\,SbF_3 \rightarrow 3\,RPF_4 - 7\,SbCl_3 \qquad (c)$$

3. Especially straightforward is the reaction (d) of chlorophosphines with group V trifluorides, in particular AsF_3 and SbF_3. In a simultaneous halogen exchange and oxidation-reduction reaction, elemental As or Sb and the corresponding trichloride, $AsCl_3$ or $SbCl_3$, are formed besides fluorophosphoranes. This method was discovered during attempts at the synthesis of fluorophosphines, R_nPF_{3-n} [8,10–12].

$$3\,R_nPCl_{3-n} + (5-n)\,MF_3 \rightarrow 3\,R_nPF_{5-n} + 2\,M + (3-n)\,MCl_3$$

$$M = As, Sb;\ n = 1,2 \qquad (d)$$

The course of reaction (d) is independent of whether the chlorophosphine is added to the fluorinating agent, or *vice versa*. AsF_3 is particularly suitable for the preparation of higher-boiling fluorophosphoranes (the highest boiling by-product is $AsCl_3$, b.p. 131 °C), whereas for low-boiling compounds (b.p. <200 °C) SbF_3 is preferred (b.p. of $SbCl_3$ 225 °C).

No oxidation-reduction reaction takes place when electronegative substituents are attached to the trivalent phosphorus. Perfluoroalkylhalogenophosphines [6,13–17] or CCl_3PCl_2 [18], for instance, react with SbF_3 with exclusive formation of fluorophosphines. The influence of the substituents is expecially illustrative on comparing CH_3PCl_2 with $ClCH_2PCl_2$: whereas the former reacts with SbF_3 under mild conditions to give the tetrafluorophosphorane [11], the latter is converted in high yield to the difluorophosphine, which is spontaneously flammable in air [10,19]. Only when the strong oxidizing agent SbF_5 is used can $ClCH_2PCl_2$ be converted into $ClCH_2PF_4$ [10,11].

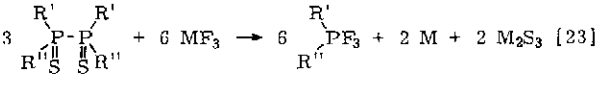
The formation of fluorophosphoranes by the reaction of chlorophosphines with SbF_3 (or AsF_3) presumably proceeds *via* the fluorophosphines. Reaction (e), for example, was shown to occur almost quantitatively [20]. $C_6H_5PF_3H$ also reduces SbF_3 to elemental Sb [32].

$$3\,C_6H_5PF_2 + 2\,SbF_3 \rightarrow 3\,C_6H_5PF_4 + 2\,Sb \qquad (e)$$

Dialkylaminodichlorophosphines, R_2NPCl_2 [21], and chlorophosphites, $(RO)_nPCl_{3-n}$ (n=1,2), [22] undergo only halogen exchange with SbF_3, and no oxidation-reduction reactions were noted. Dihaloarsines are converted to difluoroarsines by SbF_3 [11].

The above methods are very useful wherever the required halophosphines are readily accessible. Such is usually not the case for monochlorophosphines, R_2PCl. Dialkyltrifluorophosphoranes are readily available, however, by an alternate route based on a different starting material.

4. Tetraalkyldiphosphine disulfides *(2)*, which are readily obtained from Grignard reagents and $PSCl_3$, react smoothly with the group V trifluorides AsF_3 and especially SbF_3.



(2) M = As, Sb

Tertiary phosphine sulfides react similarly with SbF_3 with formation of difluorophosphoranes and Sb_2S_3:

$$3\,R^1R^2R^3P{=}S + 2\,SbF_3 \rightarrow 3\,R^1R^2R^3PF_2 + Sb_2S_3 \qquad (f)$$

Not all types of P=S bonds react with SbF_3 in an analogous manner. Thus, no reaction is observed between thiophosphates, $(RO)_3P=S$ [23], or tris(dialkylamino)phosphine sulfides, $(R_2N)_3P=S$ [24], and SbF_3, the hitherto unknown compounds $(RO)_3PF_2$ and $(R_2N)_3PF_2$, respectively, being expected. The phosphonothioic dihalide $ClCH_2PSCl_2$ reacts readily with SbF_3 to give $ClCH_2PSF_2$ in high yield; no $ClCH_2PF_4$ is formed [25]. On the other hand, only a 25 % yield is obtained in the fluorination of $C_6H_5PSCl_2$ with SbF_3, possibly owing to formation of $C_6H_5PF_4$ [26].

5. Some perhaloalkyl derivatives as well as some aromatic fluorophosphoranes were obtained by fluorination of the products resulting from addition of chlorine to dichlorophosphines [6, 8, 12, 27–29]:

$$R_nPCl_{3-n} \xrightarrow{Cl_2} R_nPCl_{5-n} \xrightarrow{SbF_3} R_nPF_{5-n} \quad (n = 1,2) \qquad (g)$$

6. An interesting method of synthesis employs sulfur tetrafluoride as a fluorinating agent. The various possible reactions are illustrated by Equations (h)–(m).

$$RPO(OH)_2 + 3\,SF_4 \rightarrow RPF_4 + 2HF + 3\,SOF_2 \quad [30,31] \quad (h)$$

$$R_2PO(OH) + 2\,SF_4 \rightarrow R_2PF_3 + HF + 2\,SOF_2 \quad [31] \quad (i)$$

$$RPOF_2 + SF_4 \rightarrow RPF_4 + SOF_2 \quad [30,31] \quad (k)$$

$$2\,R_3P + SF_4 \rightarrow 2\,R_3PF_2 + S \quad [27,31] \quad (l)$$

$$R_3PO + SF_4 \rightarrow R_3PF_2 + SOF_2 \quad [23,31] \quad (m)$$

The reaction of phosphonic acids with SF_4 can also be directed to give predominantly phosphonic difluorides, $RPOF_2$. All reactions are conducted under autogenous pressure with excess SF_4 at temperatures ranging between 50 and 150 °C. Reactants containing aliphatic substituents require lower reaction temperatures than aromatic compounds [23].

In an extension of this reaction to aromatic arsonic acids and arsines, arylarsenic(V) fluorides, Ar_nAsF_{5-n}, were obtained [31].

II. Aryltrifluorophosphorus Hydrides

The known representatives of this class of compounds were obtained by the reaction of the corresponding dichlorophosphines with KHF_2 [32]:

$$ArPCl_2 + 2\ KHF_2 \rightarrow ArPF_3H + 2\ KCl + HF \qquad (n)$$

Table 4. Aryltrifluorophosphorus hydrides $ArPF_3H$ [32].

Compound	Method of preparation	B.p. [°C/mm Hg]
$C_6H_5PF_3H$	II	57–58/20
$p\text{-}CH_3C_6H_4PF_3H$	II	90–91/40
$p\text{-}ClC_6H_4PF_3H$	II	90–91/35

III. Arylchlorotrifluorophosphoranes

The few compounds of this type known so far were obtained by chlorination of the respective hydrides.

$$ArPF_3H + Cl_2 \rightarrow ArPF_3Cl + HCl \qquad (o)$$

Instead of pure $ArPF_3Cl$, mixtures of the composition $ArPF_{4-n}Cl_n$ ($n \geq 1$) are usually formed [32, 33].

IV. Dialkylaminofluorophosphoranes

1. Secondary amines react with PF_5 in toluene to give 1:1 adducts which decompose at 100 °C with the formation of R_2NPF_4 [Eq. (p)]. $(CH_3)_2NPF_4$ (but not the ethyl or propyl compound, presumably owing to steric hindrance) forms another adduct with $(CH_3)_2NH$, which is pyrolysed to $[(CH_3)_2N]_2PF_3$ [34, 35] [Eq. (q)]. Under the conditions employed thus far, no further reaction of $(R_2N)_2PF_3$ with secondary amine was observed [34].

$$R_2NH + PF_5 \xrightarrow{\text{toluene}} R_2HN{\rightarrow}PF_5 \xrightarrow{100\,^\circ C} R_2NPF_4 \qquad (p)$$

$$(CH_3)_2NH + (CH_3)_2NPF_4 \rightarrow (CH_3)_2HN{\rightarrow}PF_4N(CH_3)_2 \xrightarrow{100\,^\circ C} [(CH_3)_2N]_2PF_3 \qquad (q)$$

2. PF_5 reacts with *N,N*-dialkylaminotrimethylsilanes [36, 37, 40]:

$$R_2NSi(CH_3)_3 + PF_5 \rightarrow R_2NPF_4 + (CH_3)_3SiF \qquad (r)$$

$$R_2NPF_4 + R_2NSi(CH_3)_3 \rightarrow (R_2N)_2PF_3 + (CH_3)_3SiF \qquad (s)$$

Whereas the reactions with PF_5 (r) proceed with evolution of heat, heating to about 150 °C is necessary with the presumably weaker Lewis acid R_2NPF_4 (s). In the reaction of PF_5 with $(CH_3)_3SiN(CH_3)_2$, formation of a 1:1 adduct was found to occur, which decomposes irreversibly even at –78 °C according to Equation (r) [36].

Table 5. Dialkylaminofluorophosphoranes $(R_2N)_nPF_{5-n}$ (n = 1, 2).

VII. Fluoro-1,3,2,4-diazadiphosphetidines

1. This novel type of compound was obtained in the following reactions (x) which proceed highly specifically with respect to ring size [36,42].

$$2\ PF_5 + 2\ [(CH_3)_3Si]_2NCH_3 \rightarrow \begin{matrix} F_3P\text{-}N\text{-}CH_3 \\ | \quad | \\ H_3C\text{-}N\text{-}PF_3 \end{matrix} + 4\ (CH_3)_3SiF \qquad (x)$$

$$2\ R(Ar)PF_4 + [(CH_3)_3Si]_2NCH_3 \rightarrow \begin{matrix} (Ar)RF_2P\text{-}N\text{-}CH_3 \\ | \quad | \\ H_3C\text{-}N\text{-}PF_2R(Ar) \end{matrix} + 4\ (CH_3)_3SiF$$

2. Small yields of $[F_3PNCH_3]_2$ were also obtained by fluorination of the corresponding chloride with KSO_2F in nitrobenzene [43].

3. A further method of preparation of $[F_3PNCH_3]_2$ involves reaction of PF_5 with CH_3NH_2 in the presence of trimethylamine [43] according to (y).

$$6\ PF_5 + 2\ CH_3NH_2 + 4\ (CH_3)_3N \rightarrow \begin{matrix} F_3P\text{-}N\text{-}CH_3 \\ | \quad | \\ H_3C\text{-}N\text{-}PF_3 \end{matrix} + 4\ (CH_3)_3NH^+PF_6^- \qquad (y)$$

4. The 1:1 adduct between aniline and PF_5 reacts at 10–25 °C in benzene with the 1:1 adduct of $(C_2H_5)_3N$ with PF_5, the *N*-phenyl compound $[C_6H_5NPF_3]_2$ being formed [44] [Eq. (z)].

$$2\ C_6H_5NH_2 \cdot PF_5 + 4\ (C_2H_5)_3N \cdot PF_5 \rightarrow \begin{matrix} F_3P\text{-}N\text{-}C_6H_5 \\ | \quad | \\ H_5C_6\text{-}N\text{-}PF_3 \end{matrix} + 4\ (C_2H_5)_3NH^{\oplus}PF_6^{\ominus} \qquad (z)$$

VIII. Miscellaneous Ways of Formation of Fluorophosphoranes

An unusual mode of formation of CH_3PF_4 was observed during the disproportionation of CH_3PF_2, which proceeds slowly at room temperature in accordance with

[42] *R. Schmutzler*, Chem. Comm. (London) *1965*, 19.

[43] *P. Haasemann*, Doctorate Dissertation, Technische Hochschule Stuttgart (Germany), 1963; *J. Goubeau*, personal communication.

[44] *J. J. Harris* and *B. Rudner*, Paper presented at the 145th Meeting, American Chemical Society, Philadelphia 1964; *J. J. Harris*, personal communication.

[45] *L. M. Yagupol'skii* and *Zh. M. Ivanova*, Zhur. Obshch. Khim. *30*, 4026 (1960).

(a'). The rate of conversion may be increased by heating. The related $ClCH_2PF_2$ apparently undergoes a similar transformation [29].

$$10\,CH_3PF_2 \rightarrow 5\,CH_3PF_4 + (CH_3P)_5 \qquad [16] \qquad (a')$$

Bis(trifluoromethyl)trifluorophosphorane is formed on contact of SF_4 with $(CF_3)_2PI$ at room temperature [28]. Also unusual is the formation of $(C_6H_5)_3PF_2$ in the reaction of bis(perfluoroisopropyl)disulfide *(3)* with $(C_6H_5)_3P$ [46]:

$$(CF_3)_2CF\text{-}S\text{-}S\text{-}CF(CF_3)_2 + (C_6H_5)_3P \rightarrow 2\,(CF_3)_2C{=}S + (C_6H_5)_3PF_2$$

$(n\text{-}C_4H_9)_3PF_2$ is obtained in good yield upon reaction of hexafluorothioacetone with tributylphosphine [46].

C. Physical and Chemical Properties of Fluorophosphoranes

1. General

All fluorophosphoranes are sufficiently stable to be handled in glass apparatus, but glass frequently is attacked slowly if moisture is not rigorously excluded. Fluorophosphoranes are stable indefinitely in containers made of inert materials such as stainless steel or Teflon®. Upon standing of tetra- and trifluorophosphoranes in glass containers, they are converted to phosphonyl or phosphinyl fluorides, respectively, which on prolonged contact with glass or with excess water may be converted to the corresponding acids [7, 10, 11, 23]:

$$R_nPF_{5-n} \xrightarrow[-HF]{H_2O} R_nPOF_{3-n} \xrightarrow[-HF]{H_2O} R_nPO(OH)_{3-n} \qquad (b')$$

The hydrolytic stability of fluorophosphoranes with hydrocarbon substituents may be classified qualitatively as follows:

$$R_3PF_2 > R_2ArPF_2 \approx Ar_2PF_3 > RArPF_3 > R_2PF_3 > R(Ar)PF_4\ (> PF_5)$$

A difluorophosphorane such as $(n\text{-}C_4H_9)_3PF_2$, for example, is unchanged in glass over at least one year, whereas during the synthesis of dialkyltrifluorophosphoranes from tetraalkyldiphosphine disulfides and SbF_3, formation of phosphinic fluorides, $R_2P(=O)F$, even with careful exclusion of moisture, cannot be suppressed completely. In contrast to other difluorophosphoranes, the compound $(CH_3)_2PF_2CH_2CH_2PF_2(CH_3)_2$ is hydrolysed with extreme ease to give $(CH_3)_2P(=O)CH_2CH_2P(=O)(CH_3)_2$.

Little is known about the hydrolytic behavior of fluorophosphoranes containing substituents other than hydrocarbon groups. Aryltrifluorophosphorus hydrides, for instance, react with excess water in accordance with (c').

$$ArPF_3H + 2\,H_2O \rightarrow 3\,HF + ArPO_2H_2 \qquad [32] \qquad (c')$$

The hydrolysis of aryldialkylaminotrifluorophosphoranes with excess water has been shown to proceed as in (d') [33]. Conceivably this hydrolysis involves an

$$ArPF_3NR_2 + 2\,H_2O \rightarrow 2\,HF + R_2NH_2^{\oplus}\,ArPO_2F^{\ominus} \xrightarrow{\text{aniline}} \text{anilinium salt} \qquad (d')$$

$ArPOFNR_2$ intermediate. Formation of the anionic species $ArPO_2F^{\ominus}$ was also observed when (aryl)tetrafluorophosphoranes were brought in contact with aniline or *p*-toluidine in the presence of atmospheric moisture [12] [Eq. (e')].

$$ArPF_4 + 2\,H_2O + 4\,Ar'NH_2 \rightarrow 3\,Ar'NH_3F + Ar'NH_3^{\oplus} + ArPO_2F^{\ominus}$$

$$(Ar = C_6H_5, p\text{-}ClC_6H_4;\ Ar' = C_6H_5, p\text{-}CH_3C_6H_4) \qquad (e')$$

Phosphonyl difluorides, $ArPOF_2$, also enter this type of reaction. This fact suggests their intermediate role [12].

Fluorophosphoranes containing the 1,3,2,4-diazadiphosphetidine ring system are remarkably stable towards hydrolysis. For instance, $[C_6H_5PF_2NCH_3]_2$ could be recovered to an extent of 83% after having been boiled with water for 3 hours [42].

The majority of the known fluorophosphoranes is thermally stable. There were no indications for any disproportionation on heating $C_6H_5PF_4$ to 350 °C for 8 h in a sealed vessel [31]. Thus, with regard to thermal stability, fluorophosphoranes are significantly different from the only formally analogous chlorophosphoranes, R_nPCl_{5-n}. The latter usually are thermally unstable and salt-like, thus being comparable to the "parent compound" PCl_5 ($[PCl_4][PCl_6]$). Chlorophosphoranes usually cannot be volatilized without decomposition [48].

It was noted, however, that the thermal stability of certain fluorophosphoranes is limited, too. The perfluoroalkyl compound $(CF_3)_3PF_2$, for instance, may undergo a reversible transformation to $(CF_3)_2PF_3$ with elision of difluorocarbene, CF_2. $(CF_3)_2PF_3$ undergoes further transformations until the stage of the stable PF_5 is reached [27, 28] [Eqs. (f')].

$$\begin{aligned} (CF_3)_3PF_2 &\rightleftharpoons (CF_3)_2PF_3 + CF_2 \\ (CF_3)_2PF_3 &\rightleftharpoons CF_3PF_4 + CF_2 \\ CF_3PF_4 &\rightleftharpoons PF_5 + CF_2 \end{aligned} \qquad (f')$$

At 25 °C, $(CF_3)_2PF_3$ disproportionates to the extent of 10% per day with formation of $(CF_3)_3PF_2$ and CF_3PF_4. The latter undergoes a similar but slower disproportionation to give $(CF_3)_3PF_2$, $(CF_3)_2PF_3$, and PF_5. The reaction of excess PF_5 with $(CF_3)_3PF_2$ (100 °C/4 h) is a good method of synthesis of CF_3PF_4 [27, 28].

In the absence of other reagents, CF_2 originating from CF_3-substituted fluorophosphoranes is converted irreversibly to the dimer, $CF_2{=}CF_2$, trimer (hexafluorocyclopropane), and to higher polymers. By means of suitable reagents, CF_2 formed in the decomposition of $(CF_3)_3PF_2$, usually at 100 °C, may be intercepted. Reactions with I_2, HCl, and O_2, leading to CF_2I_2, HCF_2Cl, and COF_2, respectively, have been reported, for example. A reaction with hydrogen was not observed, whereas UF_6 and MoF_6 were reduced. Reaction with Cl_2 proceeds in a more complicated manner, all three possible chlorofluoromethanes being formed. No reaction with CF_2 was observed when $(CF_3)_3PF_2$ was pyrolysed at

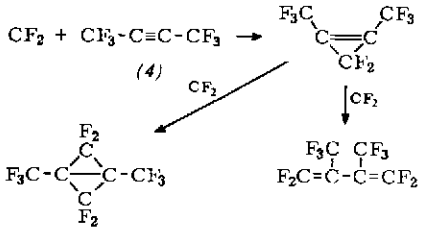
[46] *W. J. Middleton*, personal communication.

[47] *R. Schmutzler*, unpublished work.

[48] *W. Kuchen, H. Buchwald, K. Strolenberg*, and *J. Metten*, Liebigs Ann. Chem. *652*, 28 (1962).

120 °C in the presence of BF_3, NO, NF_3, N_2O, PF_3, CS_2, SO_2, or CF_3I [27, 28].

It is of special interest that a bicyclobutane derivative is formed when the pyrolysis of $(CF_3)_3PF_2$ is conducted in the presence of hexafluorobut-2-yne *(4)*. The main line of reaction may be represented as follows [49]:



II. Chemistry of Fluorophosphoranes

The chemistry of the tetrafluorophosphoranes, RPF_4, is characterized and determined by their electron acceptor (Lewis acid) properties which are similar to those of the parent compound, PF_5 [50].

The acceptor strength of tetrafluoropbosphoranes is lower than that of PF_5, although $C_6H_5PF_4$, for instance, reacts with some typical Lewis bases, such as dimethylformamide or pyridine, with formation of 1:1 adducts. Alkyltetrafluorophosphoranes also react with organic donor molecules, but no complexes stable enough to be isolated at room temperature are obtained [51]. ^{19}F-NMR spectroscopy gives no evidence that R_2PF_3 and R_3PF_2, which are presumably very weak electron acceptors, interact with donors at all. There is an increase in hydrolytic stability of the fluorophosphoranes with decreasing Lewis acidity (cf. C.I).

According to ^{19}F-NMR studies, tetrafluorophosphoranes undergo an interesting transformation in solutions in dimethyl sulfoxide. At first, formation of a solvated fluorophosphonium cation *(5)*, besides $RPF_5^{\ominus}$, was thought to have occurred:

$$2RPF_4 \cdot OS(CH_3)_2 \rightleftharpoons \{RPF_3[OS(CH_3)_2]_2\}^{\oplus} + RPF_5^{\ominus} \qquad (5)$$

It was subsequently found, however, that the presumed cation decomposes with formation of $H^{\oplus}$ and $RPOF_2$. The identity of $[RPF_5]^{\ominus}$ (R = C_6H_5) as an octahedral species with four fluorine atoms (F_e) in equatorial and one (F_a) in axial position was established from the following NMR parameters: $J_{P-Fe} \approx 830$ c.p.s., $J_{P-Fa} \approx 680$ c.p.s., $J_{FaFe} = 41$ c.p.s., $\delta_{FaFe} = 3.7$ p.p.m. The ^{19}F-NMR spectrum consists of a doublet of doublets (F_e) and a doublet of quintets (F_a). Similarly, the species $[CH_3PF_5]^{\ominus}$ (besides CH_3POF_2) was detected in the system $CH_3PF_4/(CH_3)_2SO$. The following NMR parameters were found for $[CH_3PF_5)]^{\ominus}$:

$J_{P-Fe} = 830$ c.p.s., $J_{P-Fa} = 691$ c.p.s., $J_{FaFe} = 39$ c.p.s., $J_{H\ Fe} = 8$ c.p.s., $\delta_{FaFe} = 10.3$ p.p.m. [51].

It may be noted that use has been made of the Lewis acids $C_6H_5PF_4$ and $i\text{-}C_8H_{15}PF_4$ in the polymerization of tetrahydrofuran [7, 30].

Stable salts containing alkyl(aryl)pentafluorophosphate anions were obtained according to (g') [38].

$$2\ R(Ar)PF_4 + 2\ R_2'NH \xrightarrow[0-10\,^{\circ}C]{\text{ether}} R(Ar)PF_3NR_2' + [R_2'NH_2][R(Ar)PF_5]. \qquad (g')$$

Formation of an organopentafluorophosphate was also observed when $C_6H_5PF_3N(CH_3)_2$ was allowed to stand at room temperature over prolonged periods [52]:

$$2\ C_6H_5PF_3N(CH_3)_2 \rightarrow C_6H_5PF[N(CH_3)_2]_2^{\oplus}\ [C_6H_5PF_5]^{\ominus}. \qquad (h')$$

The course of this interesting reaction is independent of the method of preparation of $C_6H_5PF_3N(CH_3)_2$. It is noteworthy that the closely related $C_6H_5PF_3N(C_2H_5)_2$, even after prolonged storage, does not show any indication of such a transformation.

The identity of the ion $[C_6H_5PF_5]^{\ominus}$ is confirmed especially by ^{31}P- and ^{19}F-NMR spectroscopy [52]. The ^{31}P spectra of the transformation product in acetonitrile show a doublet at low field (85 % H_3PO_4 reference) due to the cation. At high field there is another doublet ($J_{P-Fa} = 697$ c.p.s.), each of whose components are split into a quintet as a result of spin-spin coupling between ^{31}P and the four equatorial fluorine atoms of the octahedral $[C_6H_5PF_5]^{\ominus}$ ($J_{P-Fe} = 816$ c.p.s.). Particularly revealing is the high positive value of the ^{31}P chemical shift (+136.0 p.p.m.), which is only slightly lower than that for the highly symmetrical $PF_6^{\ominus}$ (+143.7 p.p.m.) [52]. The ^{19}F-NMR spectrum is also in agreement with the C_{4v} symmetry suggested for $[C_6H_5PF_5]^{\ominus}$ ($J_{P-Fe} = 818$ c.p.s.; $J_{P-Fa} = 690$ c.p.s.; $J_{FaFe} = 41$ c.p.s.). Identical data were obtained for a series of further dialkylammonium-RPF_5 salts [38]. The facile formation of the $[RPF_5]^{\ominus}$ ion is noteworthy in view of the paucity of hexacoordinate phosphorus species, aside from the well known ions $PF_6^{\ominus}$ (and $PCl_6^{\ominus}$).

$C_6H_5PF_4$, like PF_5, forms a 1:1 adduct with NOF, which is not very stable thermally, in contrast to $NO^{\oplus}PF_6^{\ominus}$. Various reactions, *e.g.* (i')–(l'), suggest the structure $NO^{\oplus}[C_6H_5PF_5]^{\ominus}$ for the adduct.

$$NO^{\oplus}[C_6H_5PF_5]^{\ominus} + BF_3 \rightarrow NOBF_4 + C_6H_5PF_4 \qquad (i')$$

$$NO^{\oplus}[C_6H_5PF_5]^{\ominus} + CH_3OH \rightarrow ClH_3ONO, C_6H_5P(:O)F_2 \qquad (k')$$

$$NO^{\oplus}[C_6H_5PF_5]^{\ominus} + 2,4\text{-}(CH_3)_2C_6H_3NH_2 \rightarrow 2,4\text{-}(CH_3)_2C_6H_3F\ \textit{etc.} \qquad (l')$$

Of particular interest is the reaction with secondary amines which proceeds smoothly in accordance with (m').

$$NOF \cdot C_6H_5PF_4 + 2\ R_2NH \rightarrow R_2N \cdot NO + [R_2NH_2]^{\oplus}\ [C_6H_5PF_5]^{\ominus} \qquad (m')$$

Again, formation of stable dialkylammonium phenylpentafluorophosphates is observed [38].

Hydrolysis of $NOF \cdot C_6H_5PF_4$ gives phenylphosphonic acid as the only product, and an attack of the NO group on the aromatic ring may be excluded from consideration.

In contrast to NOF, NO_2F reacts with $C_6H_5PF_4$ even at −30 °C exclusively with nitration of the aromatic ring. The substitution takes place presumably in the *p*-position, since hydrolysis of the nitration product leads to the stable *p*-nitrophenylphosphonic acid [38].

[49] *W. Mahler*, J. Amer. chem. Soc. *84*, 4600 (1962).

[50] *E. L. Muetterties, T. A. Bither, M. W. Farlow*, and *D. D. Coffman*, J. inorg. nucl. Chem. *16*, 52 (1960).

[51] *E. L. Muetterties* and *W. Mahler*, Inorg. Chem. *4*, 119 (1965).

[52] *R. Schmutzler*, J. Amer. chem. Soc. *86*, 4500 (1964).

Among further reactions related to the Lewis acid character of fluorophosphoranes, the smooth cleavage of oxygen bridges is especially worth noting. Such reactions occur particularly readily with tetrafluorophosphoranes, whereas $(C_6H_5)_2PF_3$, the only trifluorophosphorane to enter this type of reaction, reacts much less readily. The following examples are typical[11,53]:

$$RPF_4 + (R'CO)_2O \rightarrow RPF_2O + 2\ R'COF$$

$$C_6H_5PF_4 + \text{(cyclic anhydride)} \xrightarrow{10h;\ 100°C} C_6H_5PF_2O + \text{polymers} \quad (89\%)$$

$$C_6H_5PF_4 + \text{(cyclic anhydride)} \rightarrow F\text{-}CO\text{-}CH_2\text{-}CH_2\text{-}CO\text{-}F + C_6H_5PF_2O$$

$$RPF_4 + R'_3Si\text{-}O\text{-}SiR'_3 \rightarrow RPF_2O + 2\ R'_3SiF$$

$$(C_6H_5)_2PF_3 + R'_3Si\text{-}O\text{-}SiR'_3 \rightarrow (C_6H_5)_2PFO + 2\ R'_3SiF$$

$$RPF_4 + R'_3Si\text{-}OR'' \rightarrow RPF_2O + R'_3SiF + R''F$$

$$(C_6H_5)_2PF_3 + R_3Si\text{-}OR' \rightarrow (C_6H_5)_2PFO + R_3SiF + R'F$$

The decrease in reactivity in going from RPF_4 to $(C_6H_5)_2PF_3$ is evident in all these reactions. Whereas the former type of compound usually reacts fast and exothermally, similar reactions of $(C_6H_5)_2PF_3$ require prolonged heating. In the case of carboxylic anhydrides, open-chain compounds react much more readily than maleic or succinic anhydride.

The reaction of RPF_4 or $(C_6H_5)_2PF_3$ [(o') and (p')] with trialkylsilyl ethers was originally devised for the preparation of the alkyl(aryl)alkoxytrifluorophosphoranes RPF_3OR', which were expected to be of interest with regard to their stereochemistry.

$$RPF_4 + R'_3SiOR'' \rightarrow RPF_3OR'' + R'_3SiF \qquad (o')$$

$$(C_6H_5)_2PF_3 + R_3SiOR' \rightarrow (C_6H_5)_2PF_2OR' + R_3SiF \qquad (p')$$

The observed instability of such compounds reflects the marked tendency of phosphorus to avoid the coordination number 5 by stabilization with formation of tetracoordinated species, such as RPF_2O and $(C_6H_5)_2PFO$. Formation of the polar phosphoryl group presumably enhances this tendency.

All reactions between fluorophosphoranes and Si–O compounds proceed in high yields in accordance with the above equations. In a similar manner, fluorophosphoranes react with Si–N compounds. This reaction provides a rather general approach toward the synthesis of various types of phosphorus-fluorine-nitrogen compounds [36,40,42] (cf. Sections B IV, V, VII). PF_5 and RPF_4 react with dialkylaminotrimethylsilanes in accordance with (q') and (r').

$$PF_5 + (CH_3)_3SiNR_2 \rightarrow R_2NPF_4 + (CH_3)_3SiF \qquad (q')$$

$$RPF_4 + (CH_3)_3SiNR'_2 \rightarrow RPF_3NR'_2 + (CH_3)_3SiF, \textit{etc.} \qquad (r')$$

[53] *R. Schmutzler*, J. chem. Soc. (London) *1964*, 4551.

The reaction of the above phosphorus fluorides with *N*-substituted hexamethyldisilazanes leads to formation of 1,3,2,4-diazafluorodiphosphetidines. It may also be noted that $C_6H_5PF_4$ and $(C_6H_5)_2PF_3$ react with hexamethyldisilazane with formation of polymeric phenyliminophosphonic and -phosphinic fluorides, respectively. Phosphonitrilic type compounds result on removal of HF from the latter, *e.g.* by means of CsF [54].

$$C_6H_5PF_4 + [(CH_3)_3Si]_2NH \xrightarrow[-2(CH_3)_3SiF]{} [C_6H_5PF_2(NH)]_n \rightarrow \xrightarrow[(CsF)]{-HF} [(C_6H_5)(F)P{=}N]_n \qquad (s')$$

$$(C_6H_5)_2PF_3 + [(CH_3)_3Si]_2NH \xrightarrow[-2(CH_3)_3SiF]{} [(C_6H_5)_2PF(NH)]_n \rightarrow \xrightarrow[(CsF)]{-HF} [(C_6H_5)_2P{=}N]_3 \qquad (t')$$

The reactions between fluorophosphoranes and Si–N compounds presumably proceed with an electrophilic attack of phosphorus on the silazane nitrogen. Subsequent nucleophilic attack of fluorine on the silicon leads to simultaneous cleavage of the Si–N bond.

$$\begin{array}{ccccc} R'_3SiNR''_2 & & R'_3Si\text{-}NR''_2 & & R'_3SiF \\ + & \rightarrow & FPF_{4-n} & \rightarrow & + \\ R_nPF_{5-n} & & R_n\ (6) & & R_nPF_{4-n}NR''_2 \end{array}$$

R = Alkyl, Aryl; R', R'' = Alkyl; n = 0,1

The presumed intermediate $RNPF_{3-n}$ (n = 0, 1) in the case of the *N*-substituted hexaalkyldisilazanes is obtained exclusively as the dimer [42].

The course of the reaction is markedly determined by the Lewis acidity of the phosphorus fluoride. A limit in reactivity is reached with $(C_6H_5)_2PF_3$, and $(CH_3)_2PF_3$ does not react with Si–N compounds even under forcing conditions. There is also no reaction between phosphorus trifluoride and heptamethyldisilazane [42], whereas a reaction between the closely related *N*-ethylhexamethyldisilazane and PCl_3 has been observed [55].

Based on the experience with SF_4 [56a,b], and $C_6H_5SF_3$ [57a,b] as unusual fluorinating agents, consideration has been given to employing fluorophosphoranes for this purpose. As the majority of the known fluorophosphoranes are liquids at room temperature, they are easier to handle than the gaseous SF_4. Although a reaction between carbonyl compound and fluorophosphorane was observed in almost every instance, the expected fluorination did not take place, and polymers were the predominant products. The only clear example of a carbonyl fluorination was observed in the system $(C_6H_5)_2PF_3/C_6H_5CHO$ [11] [Eq. (u')].

$$(C_6H_5)_2PF_3 + C_6H_5CHO \rightarrow (C_6H_5)_2PFO + C_6H_5CHF_2 \qquad (u')$$

The reaction of tetrachlorophosphoranes, obtained by the chlorination of dichlorophosphines, with SO_2 is one of the most important methods for the preparation of phosphonic dichlorides. As to the reaction of SO_2 with tetrafluorophos-

[57] (a) *W. A. Sheppard*, J. Amer. chem. Soc. *82*, 4751 (1960); (b) *W. A. Sheppard*, ibid., *84*, 3058 (1962).

phoranes, two somewhat conflicting observations have been reported: CH_3PF_4 has been found to react with SO_2 at 100 °C to give $CH_3P(=O)F_2$ [4, 5], whereas $C_6H_5PF_4$, under identical conditions, does not react with SO_2 [12].

Upon reaction of $C_6H_5PF_4$ with diazomethane, followed by hydrolysis, fluoromethylphenylphosphinic acid *(7)* is formed [45].

$$C_6H_5PF_4 \xrightarrow[2.\ H_2O]{1.\ CH_2N_2;\ -30\,^\circ C} \begin{matrix} C_6H_5 \\ CH_2F \end{matrix}\!\!>\!P(=O)\text{-}OH \quad (7)$$

Fluorides of phosphono- or phosphinothioic acids are formed on passing alkyl-tetra- and -trifluorophosphoranes over elemental sulfur, K_2S, ZnS, Al_2S_3, As_2S_3, PbS, SnS_2, Sb_2S_5, P_2S_3, or CS_2 [8].

Aryltrifluorophosphorus hydrides react with sulfur in 90% yield in accordance with (v') [32].

$$ArPF_3H + S \rightarrow ArPSF_2 + HF \qquad (v')$$

Finally, the reactions (w') and (x') of $C_6H_5PF_4$ with a carboxylic acid or its lithium salt may be mentoined.

$$C_2H_5COOH + C_6H_5PF_4 \rightarrow C_2H_5COF + C_6H_5POF_2 + HF \quad (w')$$

$$C_2H_5COOLi + C_6H_5PF_4 \rightarrow C_2H_5COF + C_6H_5POF_2 + LiF \quad [26]. \qquad (x')$$

III. Electron-Donor Properties of Fluorophosphoranes

Fluorophosphoranes form a number of crystalline, colorless 1:1 adducts with electron-acceptor molecules such as BF_3 or SbF_5, *e.g.* $(CH_3)_2PF_3 \cdot SbF_5$, $C_2H_5PF_4 \cdot SbF_5$, $(CH_3)_2PF_3 \cdot BF_3$ (dissociation pressure 1 mm at 25 °C). In general, dialkyltrifluorophosphoranes form more stable complexes with acceptor molecules than tetrafluorophosphoranes.

The formation of complexes of fluorophosphoranes with PF_5 as an acceptor molecule was established tensimetrically. The dissociation pressure of $CH_3PF_4 \cdot PF_5$, for instance, is given by the equation log p(mm) = 9.89 − 1882/T [51].

The donor properties of fluorophosphoranes may be due either to ionization,

$$R_nPF_{5-n} \rightleftharpoons [R_nPF_{4-n}]^{\oplus}F^{\ominus} \qquad (n = 1,2)$$

or to the presence of lone electron pairs on the ligands. No such properties have been observed for unsubstituted PF_5.

The complexes of fluorophosphoranes with acceptor molecules possibly contain fluorophosphonium cations, $RPF_3^{\oplus}$ or $R_2PF_2^{\oplus}$, besides the corresponding acceptor anions, such as $BF_4^{\ominus}$ or $SbF_6^{\ominus}$ [51].

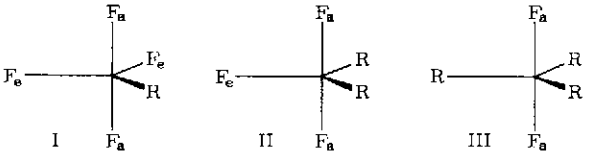
D. Stereochemistry of Fluorophosphoranes

I. General

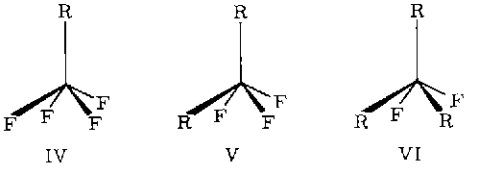
Whereas in the related molecules PCl_5 and $SbCl_5$ two different bond lengths, corresponding to equatorial and axial positions, have been observed, only one P–F bond distance has been found for PF_5 [*]. Likewise, in the ^{19}F-NMR spectrum of PF_5 only a single line is observed, split into a doublet by coupling between ^{19}F and ^{31}P [58]. The ^{19}F-NMR spectrum of PF_5 is independent of the temperature over a wide range [59], and there are no indications for intermolecular fluorine exchange.

These findings cannot be rationalized readily by either the trigonal-bipyramidal or square-pyramidal model generally accepted for pentacoordinate molecules. It is interesting to note that the ^{19}F- and ^{31}P-NMR spectra of the monosubstituted derivatives of PF_5 also indicate equivalence of the fluorine atoms over a wide temperature range [60–62].

The bonding in pentacoordinate molecules is characterized by the presence of five sp^3d hybrid orbitals. In case of combination with the d_{z^2} orbital, a trigonal-bipyramidal configuration results. The hybrid orbitals are directed towards the corners of a square pyramid if the $d_{x^2-y^2}$ orbital is used. Assuming that significant steric interactions occur between groups at an angle of 90° only, and that the ligand repulsion increases in the order F–F < F–R < R–R, the models I–III may be considered as the most likely configurations of trigonal-bipyramidal fluorophosphoranes.



Similar considerations for square-pyramidal arrangements lead to models IV to VI [60]:



II. Experimental Observations

1. Compounds of the Type R_3PF_2

In all compounds of this type NMR-spectroscopic equivalence of fluorine atoms and R groups is observed. Equivalence of fluorine atoms due to an intermolecular

[*] Note added in proof (April 25th, 1965): Previous electron diffraction studies on PF_5 indicated a single value for all P–F bond lengths [*H. Braune* and *P. Pinnow*, Z. physik. Chem. *B 35*, 239 (1937); *L. O. Brockway* and *J. Y. Beach*, J. Amer. chem. Soc. *60*, 1836 (1938)]. In a recent investigation, however, two different P–F bond lengths were observed: P–F (equatorial) = 1.499 ± 0.004 Å; P–F (axial) = 1.549 ± 0.005 Å (*O. L. Hersh*, Dissertation, University of Michigan 1963.

[58] *H. S. Gutowsky, D. W. McCall*, and *C. P. Slichter*, J. chem. Physics *21*, 279 (1953).

exchange process is ruled out since F–H coupling is observed. Intramolecular exchange is also unlikely because of the size of the substituents, and especially because of the internal consistency of the ^{19}F chemical shifts in the various types of compounds, as will be discussed below.

The remarkable variation in the P–F coupling constants of R_3PF_2 seems to be due mainly to differences in electronegativity of the substituents, which are also reflected in the P–F stretching frequencies in the infrared spectra [60], *e.g.* in

R_3PF_2 (R = alkyl)	ν_{P-F} – ca. 620 cm^{-1}
R_2ArPF_2 (R = alkyl, Ar = aryl)	ν_{P-F} 640 cm^{-1}
$(CF_3)_3PF_2$	ν_{P-F} = 855 cm^{-1}.

Similar shifts in the P–F stretching frequencies as a result of the presence of different substituents are also noted in the infrared spectra of R_2PF_3 and RPF_4 [60].

2. Compounds of the Type R_2PF_3

The ^{19}F-NMR spectra of these compounds indicate the presence of two kinds of fluorine atoms, the remaining two substituents occupying equivalent positions [38–40, 60,61].

For instance, the spectrum of the simplest compound, $(CH_3)_2PF_3$, comprises two (P–F coupling) triplets of intensity one at high field (equatorial fluorine atom), and a multiplet of intensity two at low field (axial fluorine atom). The multiplet comprises two (J_{P-Fe}) doublets (J_{FaFe}), whose components are further split due to coupling between the axial fluorine atoms and the H atoms of the alkyl groups. Thus in the case of $(CH_3)_2PF_3$, a septet fine structure is observed.

These data are in accord with model II. A square-pyramidal arrangement cannot be ruled out, however, but is rendered unlikely on the basis of the internal consistency of the ^{19}F chemical shifts to be discussed below.

The spectra of the other trifluorophosphoranes differ from that of $(CH_3)_2PF_3$ only in the details of the low-field multiplets. A quartet fine structure is observed for $(CH_3)(C_6H_5)PF_3$, for instance, and in $(C_6H_5)_2PF_3$ the low field resonance signals are doublets. Further, there is much stronger coupling between the hydrogens of (equatorial) alkyl groups and axial fluorine atoms than with those in equatorial positions, *e.g.* in $(CH_3)(C_6H_5)PF_3$: J_{Fa-CH_3} = 12.9 c.p.s., J_{Fe-CH_3} = 1.9 c.p.s. A comparison of the ^{19}F-NMR spectra of various R_2PF_3 compounds shows that, as a rule, axial P–F coupling constants are about 100–200 c.p.s. smaller than equatorial ones. This finding, as well as the observed infrared P–F frequencies, suggest that axial P–F bonds are longer than equatorial bonds. Likewise, the axial bond lengths in R_3PF_2 seem to be larger than in R_2PF_3. The predictions of *Pauling*'s valence-bond theory are in contrast to this finding, axial bonds in the trigonal bipyramid having been suggested to be stronger than equatorial ones. The experimental data available for some other trigonal-bipyramidal molecules, such as PCl_5, also suggest equatorial bonds to be stronger than axial bonds. The situation has been represented correctly in a recent M.O. calculation, using Slater orbitals [64]; c.f. also [65].

[65] *R. J. Gillespie*, J. chem. Soc. (London) *1963*, 4672.

Of special interest among trifluorophosphoranes is the stereochemistry of the cyclic compound *(8)*. The ^{19}F spectrum at room temperature is a simple doublet (P–F coupling), suggesting equivalence of fluorine atoms.

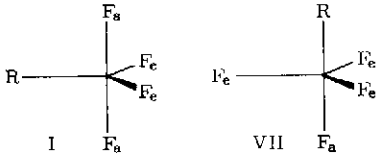
(8) *(9)*

Both lines are split into a quintet as a result of coupling between fluorine and the four α-protons. When a solution of $(CH_2)_4PF_3$ in toluene is cooled, a broadening of the resonance signals is first observed, and below −70 °C the typical R_2PF_3 spectrum appears. Apparently the strain in the PC_4 ring system lowers the energy of activation for the fluorine-exchange process. In accord with this assumption, a similar exchange process is not observed in the presumably less strained ring system *(9)*, even at temperatures up to 100 °C [60].

P–F and C–F fluorine atoms in the perfluoroalkyltrifluorophosphoranes $(CF_3)_2PF_3$ [60] and $(C_2F_5)_2PF_3$ [61] are found to be equivalent at room temperature. Possibly all three fluorine atoms in these compounds occupy identical positions. NMR-spectroscopic equivalence is also observed in the spectra of Cl_2PF_3 and Br_2PF_3 at room temperature. The equivalence in these cases, however, is due to a temperature-dependent exchange process [60]. C_{2v} symmetry has been proved for Cl_2PF_3 (and also for H_2PF_3 [68]) by infrared and Raman spectroscopy [68,69]. Two fluorine atoms occupy axial positions, one is equatorial.

3. Compounds of the Type RPF_4

The ^{19}F-NMR spectra of all compounds investigated thus far show the fluorine atoms to be equivalent at room temperature [29,34,60,61]. This suggests a square-pyramidal structure with four fluorine atoms occupying equatorial positions. The equivalence of fluorine atoms in the RPF_4 spectra is not compatible with either one of the two trigonal-bipyramidal models I and VII except on



the assumption of intramolecular positional exchange taking place. This kind of an intramolecular pseudorotation process, in which the position of one of the five ligands is retained, was proposed originally for the parent compound PF_5 [66]. In the case of the tetrafluorophosphoranes, the exchange process is independent of temperature over a wide range. It is of

[66] *R. S. Berry*, J. chem. Physics *32*, 933 (1960).

[67] *K. Moedritzer, L. Maier*, and *L. C. D. Groenweghe*, J. chem. Engng. Data *7*, 307 (1962).

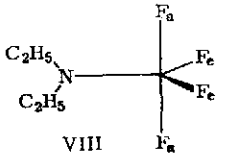
special interest, therefore, that for the recently synthesized tetrafluorophosphorane $(C_2H_5)_2NPF_4$ [40], nonequivalence of fluorine atoms has been found in the ^{19}F-NMR spectrum at low temperature [61]. Two doublets have been observed, each component showing triplet fine structure. This finding is in accord with the trigonal-bipyramidal model VIII in which a fast intramolecular exchange process takes place. The energy of activation for the fluorine exchange has been estimated as 12.8 ±2 kcal/mole [61].



VIII

Chemical shifts for equatorial fluorine atoms in trifluorophosphoranes are found between −10 to +16 p.p.m., and extreme values are noted only for a few perfluoroalkyl derivatives. Strongly negative values are observed for δ_F of axial fluorine atoms, usually between −35 and −75 p.p.m., and only the perfluoroalkyl derivatives and some dialkylaminofluorophosphoranes show more positive values. ^{19}F chemical shifts in R_2PF_3 mostly fall in the region −39 to −73 p.p.m., *i.e.* in the same region as for axial fluorine atoms in R_2PF_3.

4. ^{19}F Chemical Shifts of Fluorophosphoranes

Important conclusions as to the stereochemistry of fluorophosphoranes may be drawn from the ^{19}F chemical shifts δ_F [29,38–40,60,61,63]. With the exception of CF_3PF_4, CCl_3PF_4, and $(C_2H_5)_2NPF_4$ (ca. −10 p.p.m.), all values for δ_F of tetrafluorophosphoranes fall in the narrow range −23 to −31 p.p.m. (relative to CF_3COOH).

Especially revealing is a comparison of δ_F for axial fluorine atoms in R_2PF_3 and R'_3PF_2, where R = R'. There usually is very good agreement, the greatest deviation (12 p.p.m.) being found in the butyl series [60].

The differences in δ_F for equatorial and axial fluorine atoms in R_2PF_3 and R_3PF_2 usually are substantial. Therefore, it seemed justified to use these data to calculate approximate values for δ_F of the corresponding tetrafluorophosphoranes in which fast positional exchange of fluorine atoms takes place. Assuming equatorial substitution, excellent agreement was found for alkyl and aryl derivatives [60].

5. ^{31}P-NMR Spectra of Fluorophosphoranes

Most of the ^{31}P-NMR data for various types of pentacoordinate P–F compounds are summarized in [62]. Difluorophosphoranes show a 1–2–1 triplet in the ^{31}P-NMR spectrum. The spectra of the trifluorophosphoranes consist of a doublet (J_{P-F_e}), each component being split into a triplet (J_{P-F_a} – cf. formula *(2)*). A quintet is observed for RPF_4, in accord with the equivalence of the four fluorine atoms due to fast positional exchange which is also noted in the ^{19}F spectra (cf. above). For the same reason, the ^{31}P-NMR spectrum of the ring compound, $(CH_2)_4PF_3$, shows a quartet at room temperature.

Almost without exception, the ^{31}P chemical shifts of fluorophosphoranes are positive, as high as +71.6 p.p.m., characteristic of phosphorus in coordination number 5. The very low value of δ_P for $(CH_2)_4PF_3$ is due to phosphorus being part of a strained ring system. The perfluoroalkyl compounds, $(R_F)_nPF_{5-n}$, are distinguished by particularly high positive values of δ_P. P–F coupling constants for pentacoordinate P–F compounds are usually below 1000 c.p.s.

6. Conclusions

In summarizing the ^{19}F- and ^{31}P-NMR data, the conclusion may be drawn that alkyl and aryl groups in R_3PF_2 and R_2PF_3 normally occupy equatorial positions of a trigonal bipyramid. In RPF_4, R is located either in the axial position of a square pyramid, or, more likely, in the equatorial position of a trigonal bipyramid in which fast positional exchange takes place. Similar exchange processes are known for other pentacoordinate molecules, *e.g.* $Fe(CO)_5$, AsF_5, SOF_4, *etc.* [60].

7. Stereochemistry of Fluoro-1,3,2,4-diazadiphosphetidines

The NMR data on this class of compounds available to date do not permit definite conclusions with regard to their stereochemistry. Especially complicated a situ-

[a] Relative to 85 % H_3PO_4 as external standard.

[b] J_{P-CF_3} = 172 c.p.s.

[c] J_{P-CF_3} = 174 c.p.s.

[d] J_{P-CF_3} = 167 c.p.s.

[e] $J_{P-CF(\alpha)}$ = 129 c.p.s.

ation is encountered in the case of the "parent" compound $[F_3PNCH_3]_2$, whose ^{19}F-NMR spectrum exhibits a mirror image (doublet) of four groups of resonances. The two strongest signals are separated by 880 c.p.s. [63].

The P–F coupling constant in compounds of the type $[RPF_2NCH_3]_2$ is also around 880–900 c.p.s., a 1–1 doublet being observed in the ^{19}F-, and a 1–2–1 triplet in the ^{31}P resonance. For the compound $[F_3PNC_6H_5]_2$, the ^{19}F-NMR spectrum has been reported to indicate two different fluorine atom environments in a 2:1 ratio. Accordingly, one of the P–N bonds has been suggested to be axial and the other equatorial; thus the P–N–P bond angle would be 90° [44].

Aside from molecular-weight data, an important argument in favour of a P–N–P–N ring structure may be drawn from the ^1H-NMR spectra of the compounds $[R_nPF_{3-n}NCH_3]_2$. In every instance, a 1–2–1 triplet is observed which is due to coupling between NCH_3 protons and the two adjacent ^{31}P nuclei. There is no evidence for interaction between ^1H and ^{19}F in the compounds investigated thus far.

According to the infrared spectra, delocalization of nonbonding electrons on the NCH_3 groups into the four-membered ring does not occur to a significant extent. C–H stretching frequencies characteristic of $\rangle\ddot{N}-CH_3$ groups, where the lone pair of electrons is retained, are known to disappear when the lone pair becomes involved in bonding. Distinct absorptions due to $\rangle\ddot{N}-CH_3$ are observed in all the compounds investigated. It may be noted that a zero dipole moment has been found for $[F_3PNCH_3]_2$ [42].

Automation of X-Ray Structural Analysis [1]

Part I. Automation of the Measuring Process [2]

BY PROF. DR. W. HOPPE

ABTEILUNG FÜR RÖNTGENSTRUKTURFORSCHUNG AM MAX-PLANCK-INSTITUT FÜR EIWEISS- UND LEDERFORSCHUNG, MÜNCHEN, AND ABTEILUNG FÜR STRUKTURFORSCHUNG AM PHYSIKALISCH-CHEMISCHEN INSTITUT DER TECHNISCHEN HOCHSCHULE MÜNCHEN (GERMANY)

The present paper is the first of two reports describing the principles which can be applied to the construction of automatic counter-tube diffractometers for the X-ray analysis of crystals. These instruments can reduce the time required for the analysis of an organic crystal (measurement of a few thousand intensities) from several months (by the photographic method) to a few days.

Introduction

X-Ray structural analysis of a crystal of a medium-sized organic molecule (20 to 40 atoms, excluding hydrogen) involves the measurement of several thousand intensities. Since each of these intensities must be measured several times to minimize uncertainty, it is by no means unusual to carry out about 10 000 measurements in a single analysis. It is therefore not surprising that automatic instruments have now been developed to collect these data. This development has its counterparts in other fields of physics and physical chemistry. However, the automatic recording of infrared spectra or of electron and nuclear resonance signals supplies only the "raw material" from which the scientist then has to

[1] Extension of a lecture given during the Symposium on Modern Methods in the Analysis of Organic Compounds at the invitation of the Analytical Chemistry Division of the Gesellschaft Deutscher Chemiker and the Sectie voor Analytische Chemie van de Koninklijke Nederlandse Chemische Vereniging, Eindhoven (Holland), in May, 1964.

[2] X-Ray structural analysis has long been known as a method of determining the structure or (knowing only the overall formula) the constitution of organic molecules, and has been the subject of articles in this journal [cf. *W. Hoppe*, Angew. Chem. 69, 639 (1957); *G. Habermehl*, ibid. 75, 78 (1963); *M. F. Perutz*, ibid. 75, 589 (1963); *J. C. Kendrew*, ibid. 75, 595 (1963)]. Advances have recently been made both in experimental methods and in evaluation with the aid of large electronic computers, as a result of which it may become possible to solve at least some of the structural problems "automatically".

extract the physical or chemical information required. In X-ray structural analysis, on the other hand, an attempt is being made for the first time to entrust the calculation of the structure of the unit cell to machines, too. Since the beginning of crystal structure analysis, many thousands of structures have been elucidated by an extraordinary display of mental brilliance and intuition, so that it might justifiably be asked whether it is in fact possible to introduce automation into investigations of this type. This point will be examined in greater detail in the second paper of the present series. The first part will deal with the simpler question of how to design automatic devices for the measurement of data required for the evaluation of a structure.

Survey of Automatic Devices

Various classifications are possible (Table 1).

Table 1. Automatic single-crystal diffractometers.

Number of adjustable angular coordinates	Input control	Checking of results
One-circle instruments (powder diffractometer)	Built-in analog computer	Inspection of data by the experimenter
Two-circle instruments (Weissenberg type) (Linear diffractometer)	Punched paper tape or similar program control	Partial automatic checking in the computer (reference reflections and equivalent reflections)
Three- and four-circle instruments (Eulerian-cradle diffractometer)	Digital computer connected to instrument	Self-checking diffractometer

According to *Bragg*, the diffraction of X-rays can be formally regarded as selective reflection at crystal lattice planes running through the crystal in a strictly regular pattern and oriented in various ways with respect to the axes. From the intensities of the selective reflections at the glancing angles of incidence, it is possible to determine a quantity known to the crystallographer as the structure amplitude (the absolute value of the structure factor). The more strongly the primary beam is "reflected" at the lattice plane, the greater is the structure amplitude. In order to measure this quantity, therefore, it is necessary to direct a finely focussed beam of X-rays (the primary beam) onto the lattice plane at the glancing angle of incidence, and measure the intensity of the reflected beam. This measurement may be carried out either directly by counting the X-ray quanta, or indirectly by means of a photograph. The latter method was normally used in non-automated structural analysis. In the automatic measuring devices, however, direct electrical measurement with scintillation counters or proportional counters is used for the sake of accuracy and speed.

A crystallographic diffractometer must obviously contain angle adjusters to bring the lattice plane of the crystal into the correct orientation with respect to the primary beam for selective reflection, and to align the radiation detector so that it can measure the intensity of the reflected beam. In an automatic diffractometer, this angle adjustment must be automatic, and the same holds for the measuring process.

In principle, therefore, an automatic measuring instrument consists of (1) the diffractometer proper, *i.e.* the instrument in which the primary beam, the lattice plane, and the counter tube are brought into the correct geometrical position with respect to one another, (2) the electronic measuring equipment, *i.e.* a system of supply units, an amplifier, a discriminator, an electric clock, and a counter which permits the determination of the number of X-ray quanta in the scattered beam at preset times, and (3) the electronic control equipment, responsible for the correct setting of the angles in the diffractometer and for the correct running of the measurement program.

A universal feature is that the measured data are given out on an information carrier such as punched cards or paper tape. This arrangement is essential in view of the quantity of information to be processed. It would be a waste of time if these data were simply printed out, since the punched-code output can be fed directly into a computer. A greater variety is found in the input control electronics. The need for a control which must be adjusted to suit the crystal under investigation can be avoided by allowing the crystal and the counter tube to assume all possible angle settings and carrying out a measurement in each position. The results will then necessarily include the reflections from lattice planes. This principle of searching for reflections makes the measurements very time-consuming, since a large number of unwanted settings and measurements go with those yielding useful results. Therefore, this principle has only been utilized in a variant for single crystals. On the other hand, controls which pick out the reflections selectively are quite common.

In these systems the angles for all reflections are calculated from the lattice constants by a computer which works together with the automatic measuring instrument. The angle adjustment of the instrument is set to each of these angles in turn, and the measurements are carried out. The calculations may be done by an electrical or mechanical analog computer, or by a digital computer connected to the automat. Finally, it is also possible to calculate the angles for the individual reflections in advance, using a digital computer, and to feed the information to the automatic device on paper tape or on punched cards, which are then referred to in the course of the measurements. This is the most usual method. It is very accurate, since the digital computer can calculate the angles as accurately as is desired. It is however also very economical since the automatic device does not require its own computer. Built-in analog computers are

also used, but apart from the higher outlay, these frequently lead to limitations in the measurements as a result of constructional factors. The most elegant method, although admittedly the most expensive one, is to connect a digital computer to the automatic measuring instrument.

When an automatic measuring instrument has completed its work, it supplies its results in the form of *e.g.* an extremely long paper tape. It may now be asked how it can be verified that the values are not subject to errors in measurement. The simplest method is to check the results against those obtained by occasional manual measurements, although this is a very laborious process. Some indication of the stability of the apparatus can also be gained by making repeated measurements of selected reflections; if these always give the same value, it may at least be concluded that the intensity of the primary beam has not changed, and that the crystal has not moved out of adjustment. Another criterion is provided by the measurement of symmetrically equivalent reflections. The method which is most in keeping with the idea of automation, however, is to provide an automatic check for errors. This brings us to the self-checking devices. An instrument of this type is programmed to record both actual and check measurements. The check data are then evaluated by a computer, so that the investigator can ascertain whether the results on his output tape are correct.

From the point of view of their function, the automatic devices can be logically classified according to the number of angular coordinates (circles) which are automatically adjusted. As will be shown later, adjustment of at least three circles is essential if the reflections are to be measured for a three-dimensional analysis. A fourth circle is frequently also provided, the essential purpose of which is to permit (in combination with the other angular adjustments) rotation about the normals to the lattice planes. It is not absolutely necessary, however, that all angle adjustments should be automatic. If the geometry of the instrument and the arrangement of the measurements are such that one or two angles remain constant for a group of measurements, these angles can be adjusted manually.

Single-Circle Devices

The best known single-circle device is the powder diffractometer, which has been used in many forms over a long period (Fig. 1). The coordinate adjusted automatically is the glancing angle of incidence ϑ. The counter tube is coupled to the crystal through a 2:1 gear, so that the beam reflected from the powder always enters the counter tube. A necessary condition for reflection is that the lattice planes lie in the plane of the powder layer, but since all lattice planes are present in all orientations in a powder, this condition is satisfied for every lattice plane.

The corresponding single-crystal instrument is the Bragg spectrometer. The orientation of the lattice plane is indicated in Fig. 1 by the line N. In contrast to the powder diffractometer, this instrument can record only the various-order reflections of the correctly oriented lattice plane, and if it is desired to measure a number of different lattice planes, the crystal must be rotated by hand through an angle φ. Since only a few reflections, namely the individual orders of each lattice plane, can be measured after each adjustment, an apparatus of this type is practically useless as an automatic device and is only mentioned here as a limiting case for the sake of completeness.

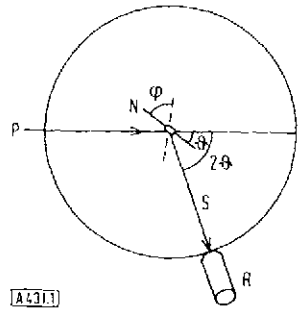

Fig. 1. Powder diffractometer. The glancing angle of incidence ϑ between the lattice plane N and the primary beam P, and the scattering angle ϑ of the scattered beam S, are adjusted together (mechanically coupled in a gear ratio of 1:2). For a single crystal (Bragg spectrometer) only the individual orders of a single lattice plane can be measured. To measure another lattice plane (*e.g.* that indicated by the broken line) it is necessary to turn the crystal through an angle φ. — R = Counter tube.

Two-Circle Devices

The situation becomes different when the adjustment of the angle φ is also carried out automatically. We then have the simplest form of a two-circle device, in which the coordinates are ϑ (and hence 2ϑ) and φ. A device of this type permits the measurement of the reflections of only one zone, *i.e.* the zone which lies parallel to the axis of rotation of the diffractometer. It is not difficult, however, to equip such an instrument for three-dimensional measurement (Fig. 2). As is known from the principle of

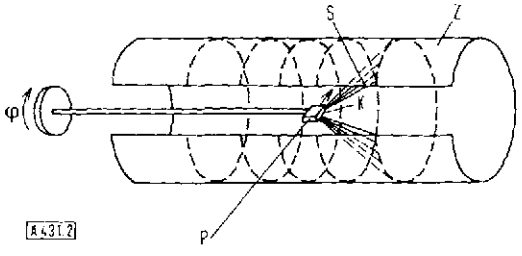

Fig. 2. Principle of the rotating-crystal camera. If a crystal K is oriented along a zone axis, the scattered beams S form cones. The intersections of these with the encircling cylindrical film Z are shown as broken lines in the diagram. — P = Primary beam.

the rotating-crystal camera, if a crystal is rotated about a zone axis, the scattered beams form concentric cones, which contain the reflections with the indices (hk0), (hk1), (hk2), *etc.* The reflections of the zone with the index (hk0) lie on a cone with an apical angle of 180°, *i.e.* on a circular disk. We have already considered the measurement of these reflections in the course of the discussion of the generalized Bragg spectrometer with the aid of Figure 1. It is easy to see that the reflections of the higher layer lines can be measured if the counter tube is directed along the directrices of the cone. Thus the measurement with a two-coordinate automatic device of

this type is carried out in several steps. The axis of the counter tube is first oriented in the equator and all (hk0) reflections are measured automatically. The counter tube is then inclined into the next cone, and all the (hk1) reflections are measured automatically, and so on, until all obtainable reflection cones have been accounted for.

It is recommended, however, that not only the axis of the counter tube, but also the primary beam should be inclined with respect to the axis of rotation of the diffractometer (Fig. 3). Both are inclined through the same angle, and the

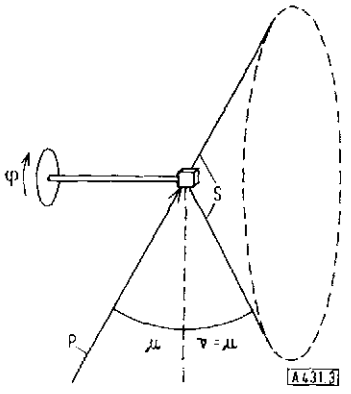

Fig. 3. Equi-inclination adjustment. The angle of incidence μ and the angle of the scatter cone ν are equal.

corresponding layer-line adjustment is consequently also named the equi-inclination adjustment. This procedure has been in use for some time in making photographic diagrams with the Weissenberg goniometer. It has the advantage that it permits the measurement of more layer lines than if the primary beam were kept perpendicular to the angle of rotation. Moreover, all reflections with an equator-like geometry are measured, and all reflections which can possibly be measured with radiation of the wavelength used can be collected on a single layer plane (elimination of the "blind spot".)

Two-circle devices of this type are relatively simple mechanically. Only two high-precision coaxial bearings are required for the adjustment of the angles φ and χ [χ corresponds to the φ of (hk0)]. The electronics of the apparatus are also relatively simple, since automatic adjustment is necessary for only two angular coordinates. It is, however, unfortunate that the diffractometer must be reset by hand after a relatively short period of operation, so that operation during the night, for example, is difficult. It must be remembered that even an automatic diffractometer requires several days for the three-dimensional measurement of a complicated single crystal. The situation is not quite the same as in the case of computers, which can reduce the time required for calculation from a matter of years to a few seconds. The main difference is that the measuring time in the case of the diffractometer is governed by the intensity of the source of X-rays and the size of the crystal, and so cannot be made as short as we wish [3]. It can be reckoned that an automatic measuring instrument is about three times as fast as a well-trained operator. Taking into account the 24-hour day for the device as opposed to the 8-hour day for the human operator, we find that the time required for measurements is shortened by a factor of about 10.

The device described above does not however permit complete three-dimensional measurement of the crystal with a single adjustment, since very high layer lines cannot be measured owing to spatial factors. Finally, a diffractometer based on the rotating-crystal principle requires accurate orientation of the crystal with respect to one of its axes. It must therefore be carefully adjusted before the measurement is carried out. We shall subsequently see that the crystal can be measured in any orientation with the aid of three- and four-circle devices. It is then possible to leave the adjustment, and even the determination of the unit cell and the space group, to the automatic device.

The angles φ and χ in the two-circle diffractometer can be set automatically in various ways. The simplest method is to scan the entire φ,χ field and record all reflections encountered. This is the principle of one of the earliest two-circle devices, *i.e. Bond*'s "hunting goniometer" [4]. ϑ and φ are coupled in such a way that a rotation of the crystal through $\varphi = 360°$ is associated with a rotation of the counter tube through $\chi = 2°$. The diffractometer scans rapidly until the flash of a reflection is recorded. The control electronics then ensure a slow, careful measurement of the reflection. As we have already pointed out, however, this simple principle is very time-consuming, since the diffractometer must pass through all possible settings of φ and χ in succession. Consequently, wide use is now made in two-circle devices of the system used in three-circle instruments, namely the direct automatic setting of the angle according to instructions from a paper tape or punched card, *i.e.* indirect program control as used in digital computers.

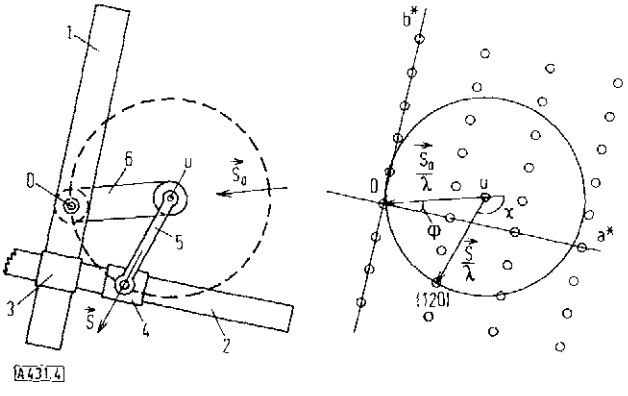

Fig. 4. Principle of the linear diffractometer. The right-hand half of the figure shows the geometrical relationships, and the left-hand half their mechanical counterparts. The reflection condition for the (120) reflection is satisfied in the position shown.
φ - Angle of rotation of the crystal.
χ - Complementary angle of the scattered beam.
The numbers are explained in the text.

An interesting method of setting is used in a variant of the two-circle device, the linear diffractometer [5,6] (Fig. 4). This method is based on a graphical construction of the scatter directions in a layer line of a crystal, which was first proposed some time ago by *P. P. Ewald* (Ewald's sphere). The principle of this construction is shown on the right of Figure 4. The diffraction reflec-

[3] Further reduction of the measuring time is possible only if the geometry of the diffractometer is such that several reflections can be measured simultaneously. Owing to the danger of "umweganregung", such a procedure is not really permissible. However such "multichannel diffractometers" are being discussed for crystals with very large numbers of reflections (large proteins, virus crystals).

[4] *W. L. Bond*, Acta crystallogr. *8*, 741 (1955).

[5] *U. W. Arndt* and *D. C. Phillips*, Acta crystallogr. *14*, 807 (1961).

[6] *J. Ladell, N. Spielberg*, and *K. Lowitzsch*, Acta crystallogr. *13*, 205 (1960).

otins corresponding to the individual lattice planes can be arranged in a manner which cannot be discussed in detail in the present paper, to form what is known as a reciprocal lattice [7]. The lattice constants of the reciprocal lattice bear a very simple relationship to the parameters of the crystal in question. The reflections of a layer line lie on a plane of the reciprocal lattice. A reciprocal lattice plane can be easily drawn if we know the unit cell of the crystal and the axis of rotation [8]. The small circles in Fig. 4 represent the reciprocal lattice points of such a plane. The arrow marked $\vec{s}_o/\lambda$ indicates the direction of the primary beam. To carry out *Ewald*'s construction, we draw a circle with a radius $1/\lambda$. We imagine the representation of the reciprocal lattice plane to be pivoted at the other end of the primary beam vector $\vec{s}_o/\lambda$, *i.e.* at a point on the circumference of the circle. Scattering is then always encountered whenever one of the reciprocal lattice points touches the circumference of the circle during the rotation of the reciprocal lattice plane about 0. The required angle of rotation φ of the lattice plane is the angle through which the crystal must be rotated to bring it into the reflecting position. The direction of the scattered beam is given hy the line joining the center of the circle to the reciprocal lattice point lying on the circumference. The corresponding vector is marked $\vec{s}/\lambda$ in Fig. 4.

This geometrical construction can be mechanized in a very obvious manner. The two principal coordinates of the reciprocal lattice plane are represented by two rails. Rail 1 can pivot about the fixed point 0, while rail 2 is mounted on rail 1 by means of a slide 3, so that it can be moved. A slide 4 on this second rail carries a lever 5 of length $1/\lambda$, which is connected *via* a ball-bearing to the axis of rotation of the crystal. The rotation of the crystal axis is synchronized with that of the first rail. The rotation is transmitted through a system 6 of gears, steel band transmissions, *etc.* The slide 3 is now moved together with the second rail until it coincides with a reciprocal lattice line. If the slide 4 is slowly moved from left to right along the rail 2, this parallelogram-lever combination turns the crystal so as to present the successive reflections of the lattice planes arranged on this lattice line. Thus a comparison of the left-hand and right-hand halves of the photograph shows that this movement satisfies *Ewald*'s condition for these lattice planes in turn. Since the lever 5 always points in the direction of the scattered beam, it is only necessary to fix a counter tube to the lever to ensure that the recording meter is also held in the correct orientation for the measurement. The movement of the slide 3 with rail 2 (setting to the lattice line) and the movement of slide 4 with the lever 5 (scanning of the lattice points) can both be carried out by servomotors. The scan of a reciprocal lattice line in the reciprocal lattice of a protein crystal is shown in Figure 5. It can be seen that, since the distances between the reciprocal lattice points on the lattice line are equal, the individual reflections are also equally spaced.

[7] Cf. *e.g. P. P. Ewald*, Z. Kristallogr., Mineralog. Petrogr., Abt. A *90*, 493 (1935).

[8] The dimensions of the reciprocal lattice constant and the reciprocal wavelength $1/\lambda$ are those of reciprocal length. We must therefore define a conversion constant (*e.g.* 1 $Å^{-1}$ = 20 cm) for the diagram.

The arrangement described above is basically a mechanical analog computer for calculating the positions of reflections from the unit cells of the crystal. Linear diffractometers have been built with the aim of considerably simplifying the control electronics. This end is also achieved if the instrument records the lattice lines as it scans, as in a powder diffractometer, although automation of the shift from one lattice line to another requires a certain outlay.

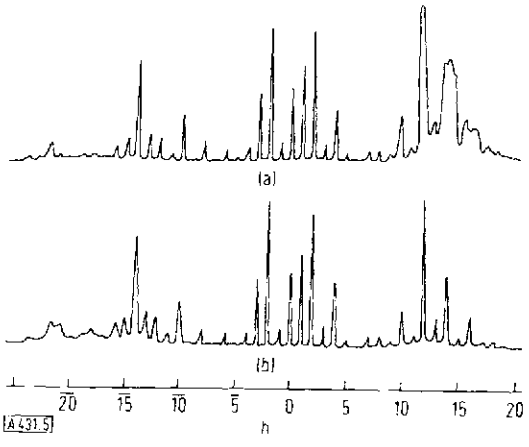

Fig. 5. Scanning a reciprocal lattice line (myoglobin) in the Arndt linear diffractometer (cf. [5]).

Even in these cases, however, further development has led to the digital punching of reflection and background intensities with scanning over narrow angular fields. The simplification in the electronics simply consists in the fact that the setting of the angles in accordance with instructions from a punched paper tape is replaced by the setting of lattice constants by the operator. This is offset to some extent by the complication introduced by the mechanical analog computer, and by the fact that the instrument is restricted to the rigid program of measurement in successive lattice lines. Furthermore, in some instruments (cf. [5]) the range of reflections which can be recorded is considerably reduced owing to the analog computer.

Three- and Four-Circle Devices

In principle, any two-circle device can be converted into a three-circle one by introducing automatic control of the inclination of the primary beam and counter tube with respect to the axis of rotation of the diffractometer. This principle is used in a French instrument [9]. Generally, however, use is made of a geometry derived from the powder diffractometer and first applied by *Furnas* and *Harker* in a hand-operated diffractometer [10]. In the powder diffractometer (cf. Fig. 1), lattice planes are measured which are oriented parallel to the plane of the powder layer. If it is desired to measure a crystal using a geometry similar to that of the powder diffractometer, all that is required is to rotate each of the lattice planes of the crystal into this plane in turn. It follows from geometrical considerations that this can be done by turning the crystal in such a manner as to change two angular coordinates. The principle of the instrument is shown in Figure 6. The two lower circles characterize the ϑ- and 2ϑ-circles of the powder diffractometer. The crystal rotates in a sort of gimbals consisting of the vertical χ circle and

[9] *J. Clastre*, Acta crystallogr. *13*, 986 (1960).

[10] *T. C. Furnas* and *D. Harker*, Rev. sci. Instr. *26*, 446 (1955).

the φ circle, which is perpendicular to the latter. This device is known in crystallography as a Eulerian cradle. The three-circle device requires three servomotors, two of which control φ and χ, and so bring the lattice plane of the crystal into the axis of rotation of the powder diffractometer, while the third motor operates the ϑ–2ϑ shaft of the powder diffractometer (symmetric setting).

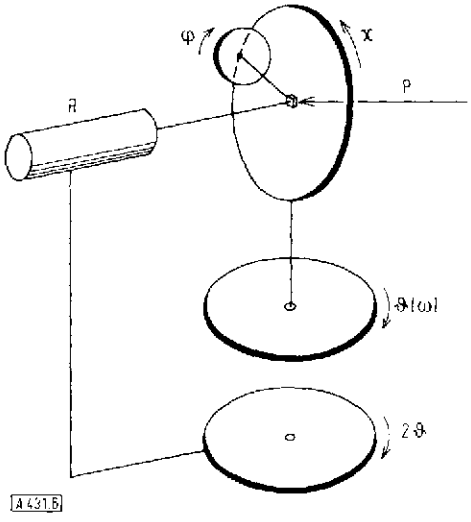

Fig. 6. Principle of the Eulerian cradle diffractometer. A "gimbals" arrangement with the angle circles φ and χ brings the crystal into various spatial orientations. The crystal can also be rotated with respect to the primary beam P in the equatorial plane of the instrument, using the ϑ (ω) circle (equatorial circle). The coaxial ϑ circle, which carries the counter tube R, is also situated in the equatorial plane. In measurements in the symmetrical setting (three-circle operation), the normals to the lattice planes are turned into the equatorial plane and into the plane of the χ circle by means of the φ and χ circles. The lattice plane thus has the same orientation as the reflecting lattice planes in a powder diffractometer. As in the powder diffractometer, therefore, the ϑ and 2ϑ circles can be coupled in a gear ratio of 1:2 (cf. Fig. 1). In the unsymmetrical setting (four-circle operation), the lattice plane is turned into the equatorial plane, but not into the χ plane. The angle (ω) of the ϑ circle is therefore different from that of the scatter angle ϑ.

For less fundamental reasons, it has become usual to design the ϑ and 2ϑ circles so that they can be operated independently, or even to provide a fourth circle (the ω circle), concentric with the coupled ϑ–2ϑ circles (four-circle instrument).

In instruments with Eulerian cradles, in which the mechanics can be simplified if the χ circle is in the form of a closed, eccentrically mounted ring [11, 12], the uncoupling of ω and ϑ is essential to avoid serious restriction, owing to shadowing, of the number of reflections which can be measured. Where the χ circle is in the form of an open segment, the independent adjustment would be superfluous, since shadowing cannot occur in the coupled position. However, it may be an advantage in many problems [Reminger effect ("Umweganregung"), absorption], since the four-circle adjustment corresponds to an additional rotation about the normal to the lattice plane. The setting of three- and four-circle devices is done by program control. With the aid of suitable programs, it is possible to carry out any measurement of crystal reflections or of the background scatter. The automatic instruments can be directly coupled with digital computers, and this coupling appears logical in view of the extreme flexibility of the Eulerian-cradle diffractometer.

As already pointed out, it is possible, for example, to place an unoriented crystal in the diffractometer. All the crystal reflections occurring in a small region of the reciprocal space are recorded. The computer which is attached to the instrument determines the unit cell and the orientation of the crystal from the angular coordinates of the recorded reflections. It also works out a program which allows determination of the reflections of the principal axes up to high angles of diffraction. This measurement provides the basis for the accurate calculation of lattice constants. With the aid of these data, the computer sets up a program permitting the measurement of reflections which could exhibit extinctions. The presence or absence of such reflections provides the computer with the information required for the determination of the possible space groups. The computer finally produces a punched paper tape which contains the angle settings of all reflections for the unoriented crystal. The computer can now be uncoupled from the instrument. In the normal "off-line operation", the automatic device determines the intensities of all X-ray reflections of the crystal in accordance with the instructions on the paper tape. However, the scheme which has just been described has never yet been put into practice, although there is no reason why it should not work. Owing to the high cost of a special computer, however, it will still be preferable in future to use crystals of known geometry and in known orientations, for which the measuring programs can be worked out in advance on an external computer.

The mechanical construction of three- and four-circle devices is more difficult than that of the two-circle instruments, since up to four automatically adjustable circles are required, all of which must intersect accurately at one point. High standards of precision and stability of the mechanics are required in automatic instruments, which must operate continuously, day and night. All play in the motor parts must be avoided by special construction of the bearings and by spring-loading of the worm drives. It is advisable to install the diffractometer in a thermostatically controlled room to eliminate the effect of temperature on the lattice constants, as well as the influence of temperature gradients on the mechanism. Two- to four-circle devices have been developed in various laboratories (cf. *e.g.* [13]), and instruments of this type have recently been even offered on the market.

The construction of automatic three- and four-circle devices was started a few years ago in our Institute. Our first instrument [14, 15] incorporates a complete, centrally arranged χ circle and is controlled by a tube-relay circuit. The number of servomotors is reduced to two by a mechanical artifice: the φ ajustment is carried out *via* a drive of the (2:1 coupled) ϑ–2ϑ circles. To make this adjustment, the φ circle is connected to the ϑ circle by a magnetic coupling which can be switched on by the program. The angles are adjusted by one of the most suitable methods for this purpose, *i.e.* the "impulse counting method". A perforated disk coupled to the drive motor transmits light impulses every hundredth of a degree, and these impulses are counted in an electric counter. Thus, for example, an angle of 14.56° corresponds to 1456 impulses. When this number is reached, the counter emits a "stop" impulse, which switches off the drive motor.

[15] *W. Hoppe* and *E. Berkl*, Z. angew. Physik *14*, 434 (1962).

On the basis of the experience gained with this instrument, a new, greatly improved mechanical diffractometer was designed (cf. Fig. 7). The electronics were subsequently developed further and transferred to transistorized printed circuits. Finally, an automatic checking

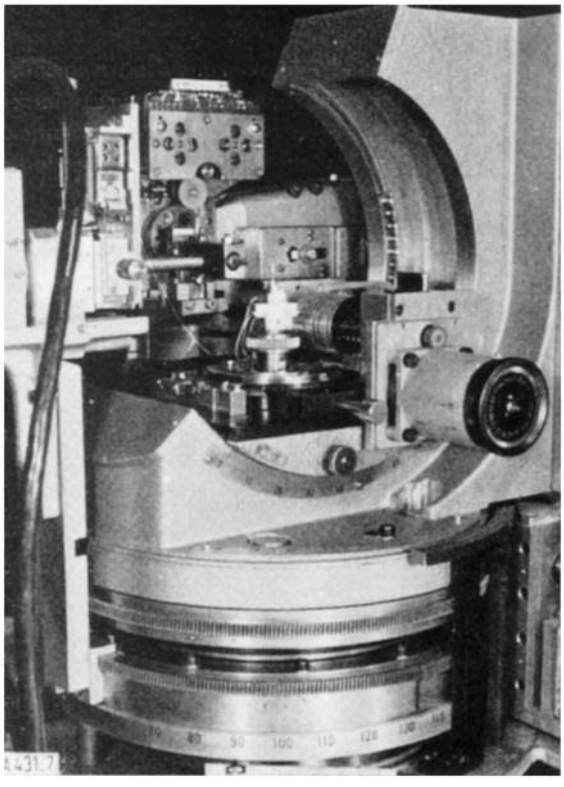

Fig. 7. The new Munich single-crystal diffractometer.

device was incorporated, which kept a constant check on the recorded data for errors in adjustment or in the lattice constants (cf. also Table 1). The device is described in detail below to show the points which require particular attention in the design and use of such instruments.

We have already referred to the importance of mechanical stability and precision. Accuracy can be maintained only if there is no possibility of plastic or elastic deformations. Figure 8 shows how this point was taken into account in the design of the ϑ and 2ϑ bearings. The diffractometer is supported on a cylinder 1 with an accurately ground surface, on which is mounted a large-diameter roller-thrust bearing 2 (needle roller bearing). The ϑ circle takes the form of a flat disk 3 which runs on this bearing, centered by a radial bush bearing. The play in the thrust bearing is very slight, since the rollers and bearing surfaces can be accurately ground. On the other hand, the weight of the ϑ disk superstructure (Eulerian cradle and accessories) is transferred directly to the cylindrical support 1 by the wide-based thrust bearing, and an additional flexible roller-relief bearing (not shown in the illustration) ensures that the forces are distributed symmetrically with respect to the ϑ axis. The 2ϑ bearing (which is subject to less stringent requirements, since it carries no other circle which must be centered) is a collar bearing 4. The vertical χ circle (cf. Fig. 6) was no longer designed as a complete circle, again for the sake of stability and accuracy. An open circle 5 can be made very rigid without cutting out reflections. This also allows symmetrical measurement (cf. Fig. 6) of all reflections, which not only presents the advantage of uniform organization of the preliminary calculations, but also leads to a reduction in the absorption for reflections of needle-shaped crystals set parallel to the φ axis. The ϑ circle and the 2ϑ circle are magnetically coupled in a gear ratio of 1:2. Separate automatic adjustment of the ϑ disk (angle ω) is possible if the two circles are uncoupled (four-circle operation, cf. Fig. 6); the uncoupling can be controlled by the program. The φ disk 7, which is also adjusted by means of a worm gear, is fixed to the slide 6 of the χ circle. The goniometer head 8 and the crystal 9 are mounted on the φ disk. Three drive motors are provided [φ, χ, ϑ–2ϑ (ω)]. To obtain short adjustment times without endangering the worm drives of the individual circles, the motors are run simultaneously. The angles are electrically checked and small errors are automatically corrected, if necessary (accuracy of angle setting is 0.01°, and hence 0.02° in the case of 2ϑ).

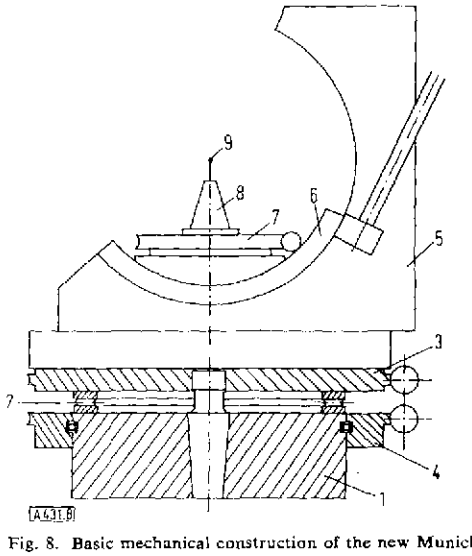

Fig. 8. Basic mechanical construction of the new Munich single-crystal diffractometer.
The numbers are explained in the text.

An important factor in the use of a "measuring robot" is the logic of the measuring program. We differentiate here between "internal measuring programs", which are built into the instrument, and "external measuring programs" fed in on paper tapes. After characteristic data have been supplied to the instrument by paper tapes, the internal program carries out the automatic measurement of a reflection. Internal programs can be avoided by breaking down each measurement into its elementary steps, and making each step an instruction in the external program. This procedure seems at first sight to be very flexible. However, it can lead to disadvantages if used to excess: the new program becomes long and involved, owing to the constant repetition of operations. Moreover, internal programs can often make decisions which are difficult to introduce with an external program, since they are undetermined before the measurement is carried out. A typical example is the measuring time for a reflection. The intensities of the X-ray reflections vary over a wide range. It is therefore desirable to match the measuring time (which governs the error of the measurement)

to the expected intensity. A suitable measuring time can be incorporated into an external program only if the intensities are already known. Since, however, the number of reflections is very large, even a very rough estimation (*e.g.* from photographs) would be extremely laborious and time-consuming. An internal program, on the other hand, can be so designed that an approximate intensity measurement is first carried out; the internal program then fixes the measuring time in accordance with the desired statistical accuracy, and taking into account a maximum measuring time which can be adjusted externally. Our instruments were the first to use internal programs for fixing the measuring times.

An internal program will always include a fixed sequence of "measuring steps". *It is therefore essential to measure not* only the reflections, but also the adjacent background (cf. Fig. 9), which results from non-monochromatic radiation

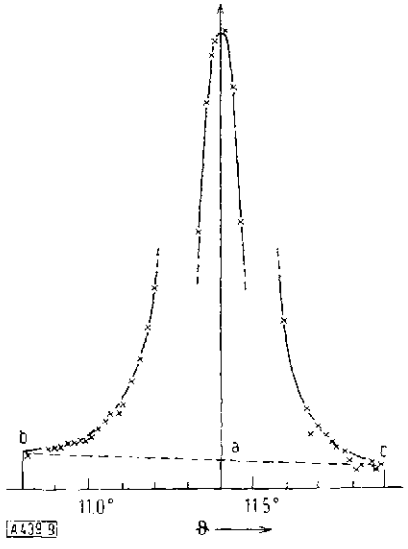

Fig. 9. Differential reflection curve of basic beryllium acetate, (004) plane, $\vartheta = 11.4°$.

ϑ–2ϑ coupled; step width 0.02°; a = maximum of the reflection curve. The ordinates correspond to numbers of impulses, measured over a constant time Δt, integrated over the angle increment of 0.02°. These ordinates are punched out in digital code.

"Five-point measurement":

1. Integral over the reflection curve from a to b.
2. Background measurement at the point on the reflection curve.
3. Integral of the reflection curve from b to c.
4. Background measurement at the point c.
5. Integral of the reflection curve from c to a.

The ratio of measurements 1 and 5 gives a measure of the centering of the reflection curve.

and from incoherent radiation (Compton scattering, thermal scattering). Since the background is not the same on both sides of a reflection, at least two background measurements are required. The radiation can be made more monochromatic by discrimination of the impulses according to magnitude and by filters and Ross filters. Strictly monochromatic radiation can be obtained by the use of crystal monochromators in conjunction with a discriminator (to cut out the $\lambda/2$ reflection). Unfortunately, however, flat monochromators form an image of the most non-homogeneous focus of the tubes in the cross-section of the beam; they therefore produce a non-uniform primary-ray plateau at the position of the crystal. This may give rise to systematic errors in the intensity measurements. The scanning method using a filtered primary beam or with a curved monochromator crystal makes no demands on uniformity of the focus. A primary beam with a slight angular divergence is masked off. During the measurement, the crystal is slowly rotated through its reflection field. The internal or external program must therefore also control the angle through which the crystal is to turn during the measurement (cf. Fig. 6).

This brief excursion into a few physical problems of the measurement shows that the internal organization of an automatic measuring device must be given careful consideration if it is to take into account the wide range of possible measuring procedures. In our device, an external program which could be broken down into elementary steps was used in conjugation with a number of internal programs which could be combined with one another. This arrangement permits the use of all the procedures described. It would take too long to describe the structure of the program system in detail; we shall simply explain the automatic check on errors in measurement, in view of its general interest.

A measurement is free from error when:

(1) the crystal is suitable for measurement and the measuring procedure is used correctly;

(2) the intensity of the primary beam is constant and the electronic equipment is stable;

(3a) the reflection is situated in the center of the counter-tube aperture;

(3b) in the case of the scanning method, the maximum of the reflection curve falls in the correct position between the two background measurements.

The experimenter himself must ensure that point (1) is satisfied (by carefully taking photographs before the measurement in the diffractometer, by the choice of apertures to suit the size of the crystal, *etc.*). Point (2) requires a stable source of X-rays and stable electronic equipment; long-term fluctuations, which are troublesome and particularly difficult to eliminate, can be checked by regularly repeated measurements of reference reflections, and prevented from interfering by interpolation. Point (3a) is checked in our diffractometer by measuring each reflection three times; in the second measurement the right-hand half of the counter-tube aperture is masked, and in the third measurement the lower half is masked, by screens which are controlled by the program. If the reflection is centered in the aperture of the counter tube, the difference between the first and second readings must be equal to the second reading, and the difference between the first and third readings equal to the third reading ("automatic cross-wires"). The computer which carries out the evaluation can assess the extent of decentering from the deviations. Since this check triples the measuring time, it is controlled by the external program in such a way that it is carried out on only a certain proportion of the reflections.

Point (3b) can be checked from the shape of the reflection curve. In the differential measuring program of our instrument, the ordinates of the reflection curves at arbitrary angular increments are recorded in digital code. The resulting reflection profile is fed in punched paper tapes to the computer, which can then calculate the position of the maximum. This check can be carried out on shorter punched paper tapes using our "five-point method". In addition to three values for the intensity of the reflection and the background on the left and right of the reflection, the reflection intensities to the left and right of

the glancing angle of incidence are also measured (cf. Fig. 9) and punched out. The computer can determine any displacement of the reflection curve from the ratio of these two values. This method involves no additional measuring time, since the three measurements of the reflections for the evaluation can be added together; the sum determines the statistical error for the overall measurement.

Concluding Remarks

It was mentioned in the Introduction that the experimental automation which is now being introduced into the analysis of crystal structures has its parallel in the automation of other physicochemical measurements (infrared analysis, gas chromatography, analysis of amino acids). The detailed discussion has however shown a number of differences. One of these is the digital coding of the problem, and another is the relatively complex logical structure of the program. We are therefore inclined to look for parallels in the complicated control and regulation problems of an automated factory, rather than in the known measuring procedures of physics and chemistry. This relationship becomes even more pronounced when we consider the automatic X-ray diffractometers controlled by computers; we may regard this as being possibly the first "process-calculation procedure" in measuring technology. This development has been necessitated by the large volume of information to be measured, and by the dependence of the results on several coordinates.

A Code for the Classification of the Ultraviolet Spectra of Organic Compounds

BY PROF. DR. M. PESTEMER, PRIV.-DOZ. G. BERGMANN, PROF. DR. H.-H. PERKAMPUS, AND DR. B. SCHRADER

FARBENFABRIKEN BAYER AG., LEVERKUSEN; INSTITUT FÜR CHEMISCHE TECHNOLOGIE, TECHNISCHE HOCHSCHULE CLAUSTHAL; INSTITUT FÜR ORGANISCHE CHEMIE, ABTEILUNG FÜR MOLEKÜLSPEKTROSKOPIE, TECHNISCHE HOCHSCHULE BRAUNSCHWEIG, AND INSTITUT FÜR SPEKTROCHEMIE UND ANGEWANDTE SPEKTROSKOPIE, DORTMUND (GERMANY)

The ultraviolet spectra of all organic compounds can be classified according to the chemical constitution with the aid of a simple code based on a ten-digit decimal system, each digit indicating the "spectroscopic weight" of the encoded information. The code discussed here will shortly be used in the Atlas of Ultraviolet Spectra which appears in the Documentation of Molecular Spectroscopy Series.

Owing to the large and ever increasing number of published ultraviolet absorption spectra, there is a need for their systematic classification. The chemist's interest in this respect is focussed on the connection between chemical constitution and ultraviolet absorption spectrum.

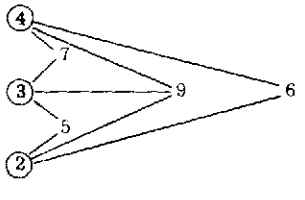
Classification according to the molecular formula would be futile, because the ultraviolet spectra are mainly determined by the system of double bonds (π-electrons) and non-bonding electrons (n-electrons) present in the molecule. This may be illustrated by the fact that all compounds of a homologous series can exhibit identical spectra. It is therefore better to devise a key, using as the principle of classification the structural elements containing π- and n-electrons and taking into account their positions with respect to each other. Rapid classification and retrieval of the spectra, as well as maintenance of the system in the event of any future expansion of the material are desirable.

It is hoped that these requirements have been met by the following "one-dimensional" system, which can be used both for the classification of spectra and for setting up a peephole or edge-punched card index [1].

Explanation of the Code

Each compound is described by a ten-digit code number characterizing – from left to right – 10 groups of chromophoric and structural features (criteria) arranged in decreasing order of "spectroscopic weight".

Each of these 10 sets of criteria comprises three subcriteria, which – again in decreasing order of spectroscopic weight – define more closely each criterion by code numbers 4, 3, and 2, as shown in Table 1. If, in the case



[1] The authors of the Varian NMR Spectra Catalog (*N. S. Bhacca, L. F. Johnson*, and *J. N. Shoolery*: NMR Spectra Catalog, Varian Assoc., Palo Alto, California, 1962) have apparently been governed by similar considerations. They devised an index for functional groups, in which the vicinity of a proton is characterized by a code word consisting of numbers and upper-case and lower-case letters.

of more complicated compounds, these subcriteria occur in combinations, then each combination is characterized by the sum of the code numbers.

Thus the code number 6 denotes the presence of subcriteria 4 and 2, and the code number 9 the simultaneous occurrence of subcriteria 2, 3, and 4. The multiplicity of identical criteria is indicated by a separate code number, and it is therefore possible to characterize both the subcriteria and their combinations by a single number, so that only one position in the total code number is needed for one set of subcriteria. The absence of a criterion is denoted by "0". Numbers 8 and 1 are not used here. It is only in position (3) that "8" is employed for free radicals; this number must not however be combined with the code numbers of other subcriteria in the same group.

The ten code digits are arranged, according to the spectroscopic properties encoded by them, in groups of two or three, in such a way that each of the two principal groups contains five decimal positions, for example

33.270/20.222

The subcriteria of the first decimal position (1) subdivide the unsaturated compounds containing ultraviolet-active chromophores into heterocyclic and homocyclic systems as well as unsaturated chains, and emphasize the aromatic compounds among the homocyclic systems (see Table 1).

Table 1. The coding of the spectroscopically active structural elements of organic compounds.

Decimal position	Code-number	Criterion	Examples
(1)		*Unsaturated rings and multiple CC-bonds*		4	unsaturated heterocycles	
	3	aromatics	
	2	homocycles or chains with C–C bonds	
(2)		*Fused unsaturated heterocyclic and aromatic systems, and conjugated unsaturated homocyclic systems*		4	angularly or peri-fused systems with three or more rings	
	3	three or more rings fused linearly	
	2	two rings	
(3)		*Conjugation and cumulation*		8	free radicals	
	4	cumulation	
	3	cross conjugation or peri-fusion	
	2	conjugation in molecular ions with charge-resonance	
(4)		*Conjugation of*	
	4	aromatic rings (homo- or heterocycles)	
	3	triple bonds (including those with hetero-atoms)	
	2	double bonds (in non-aromatic rings and in chains), and three-membered rings (including heterocycles)	
(5)		*Conjugation with*	
	4	doubly bonded hetero-atoms in a conjugated system	–N=N–, –C=N–
	3	doubly bonded hetero-atoms in the terminal position of a conjugated system	–C=O, –C=NR, >C=S
	2	singly bonded hetero-atoms in the terminal position of a conjugated system	–C=C–X, where X = NR_2, OR, Halogen
(6)		*Saturated heterocycles containing* (only the hetero-atoms in the ring are considered)	
	4	N (and other trivalent atoms)	
	3	S, Se, Te	
	2	O	
(7)		*Number of the hetero-atoms in the ring*	
	4	two or more different hetero-atoms in one ring	
	3	two or more identical hetero-atoms in one ring	
	2	one hetero-atom common to two rings	
(8)		*Ring size* (counting each formal ring including the perimeter in the case of fused ring systems [2])	
	4	three, four, seven, or more atoms in one ring	
	3	five atoms in one ring	
	2	six atoms in one ring	
(9)		*Substituents*	
	4	multiply bonded and containing multiple bonds	>C=O, >C=N–, –N=N–, $>SO_2$
	3	singly bonded and containing multiple bonds	$-NO_2$, –N=O, –C≡N
	2	containing single bonds only	$-NH_2$, -OH, -Halogen, -OR, >Si<, -B<
(10)		*Multiple occurrence of one of the above criteria*	
	4	four times or more	
	3	three times	
	2	twice	

The second decimal position (2) characterizes the type of ring fusion in the unsaturated systems entered under (1). The appearance of "0" in the second position would mean that the characteristics of set (1) are not present as a fused system, so that a subdivision into mononuclear and polynuclear ring systems is thereby achieved. The first two code digits therefore characterize the skeleton of the chromophoric system.

The subsequent three positions, (3), (4), and (5), determine the conjugation within the skeleton. The absence of conjugation is indicated by three zeros. Thus the combination 20000/ would mean the presence of unconjugated double bonds; 30000/ would denote an isolated benzene ring, which can be further characterized by the code numbers in positions (5), (9), and (10). The sequence 40000/ denotes pyridine or other mononuclear heterocycles.

Heterocyclic systems are further defined by code numbers in positions (6) and (7). Position (6) is the "latest position" for heterocycles, *i.e.* here the saturated heterocycles appear. The combination 00000/40220 would denote singly substituted piperidines, *e.g.* chloropiperidine. The corresponding five-membered heterocycle, for example a chloropyrrolidine, is designated by the combination 00000/40320.

[2] Examples for determining the code number for position (8):

Compound	Criteria	Code number
	6- plus 14-membered rings	2 + 4 = 6
	6- plus 10-membered rings	2 + 4 = 6
	6- plus 5- plus 9-membered rings	2 + 3 + 4 = 9
	6- plus 5- plus 10-membered rings	2 + 3 + 4 + = 9
	6- plus 5-membered rings	2 + 3 = 5

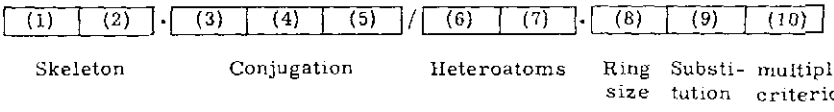
[3] Examples illustrating the use of this code, and a summary of the systematic classification of chromophoric systems, are obtainable from Prof. *H.-H. Perkampus*, 33 Braunschweig (Germany), Institut für Organische Chemie, Abteilung für Molekülspektroskopie, Technische Hochschule, Schleinitzstrasse.

The last three digits describe the ring size (8), the substitution (9), and the multiple occurrence of some particularly typical characteristic (10).

A zero in the first position indicates that all criteria of groups (1) -(3) are absent, since the criteria in groups (2) and (3) require the presence of a criterion of group (1). Saturated compounds containing no heteroatoms are denoted only by the last triad, and it can be immediately seen whether a chain or a ring is present. For example, numbers in positions (8) and (9) characterize dichlorohexane by 00000/00022 and dichlorocyclohexane by

00000/00222.

The code can be summarized in the following manner [3]:



The code can be extended by using additional decimal positions.

For example, the total number (up to 97) of carbon atoms present in a compound can be indicated by combining positions (11) and (12). Code number "98" in these positions would then designate monomeric compounds having 98 and more carbon atoms, whereas oligo(poly)-mers, oligo(poly)adducts, and oligo(poly)condensates containing 98 and more carbon atoms would be described by "99".

Complexes containing organic components are coded according to the latter, even if there is strong interaction within the complex. The sum of the organic components is coded as if the latter were bonded by CH_2-bridges without conjugation.

An additional decimal position (13) may be used to describe the nature of the inorganic components of such complexes. Here the code number 4 would be used to denote groups containing elements with atomic numbers up to 18 ($AlCl_3$, BF_3), 3 coding groups with elements above 18 (UO_2), and 2 indicating single atoms (Fe^{II}, N^{III}). Complexes with inorganic components always follow their organic components.

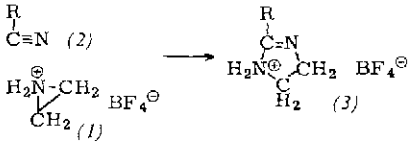
Synthesis of Imidazolines and Imidazolidines by the Reaction of Aziridinium Tetrafluoroborate with Nitriles and Benzylideneaniline

By Prof. Dr. E. Pfeil and Dipl.-Chem. U. Harder

Chemisches Institut der Universität Marburg/Lahn (Germany)

Aziridinium tetrafluoroborate *(1)*, which can be prepared from aziridine and fluoroboric acid in ether [1] adds onto nitriles *(2)* to form 2-imidazolinium fluoroborates *(3)*.



(3), R	M.p. [°C]	Yield [%]
CH_3	107	53
C_6H_5	102–103	49
$C_6H_5CH_2$	68	43

The salt *(1)* is heated with two to three times its molar amount of *(2)* for 24–48 h at 100 °C. After removal of excess *(2)* by vacuum distillation, sodium methoxide is added to liberate the imidazoline from the salt *(3)*. The free base is then purified by distillation.

Benzylideneaniline *(4)* reacts with *(1)* in diglyme [2] [molar ratio of *(4)*:*(1)* = 1:1] at 130 °C to yield 1,2-diphenylimidazolidinium fluoroborate *(5)*. The free base obtained from *(5)* in a crude yield of 62 % by treating it with potassium hydroxide is a very labile substance which is decomposed by all acids, even carbonic acid. 1,2-Diphenylimidazolidine is extremely difficult to crystallize. A finely crystalline yellow-white product obtained by recrystallization from decalin sinters at 110–120 °C.

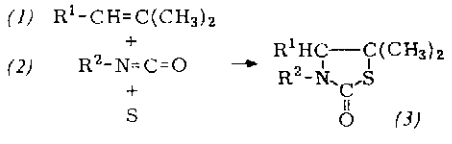
Synthesis of 1,3-Thiazolidin-2-ones from Aminoalkenes, Isocyanates, and Sulfur [1]

By Dr. habil. K. Ley and Dr. R. Nast

Wissenschaftliches Hauptlaboratorium der Farbenfabriken Bayer AG., Leverkusen (Germany)

Dedicated to Professor Eugen Müller on the occasion of his 60th birthday

α-Aminoalkenes *(1)*, sulfur, and isocyanates *(2)* condense together in an exothermal reaction to give 1,3-thiazolidin-2-ones *(3)*. The best yields (up to 90 %) of *(3)* are obtained if



the sulfur is first condensed with the amino-olefin *(1)* in a solvent containing carhonyl groups, preferably dimethylformamide, and the adduct is then treated with the isocyanate *(2)*.

3,5,5-Trimethyl-4-piperidino-1,3-thiazolidin-2-one:

N-Isobutenylpiperidine (69.5 g) is stirred for 3 h with 16 g of sulfur in 40 ml of dimethylformamide. Methyl isocyanate (38.5 g) is then added dropwise, the temperature rising gradually to 60 °C. The mixture is stirred for 30 min and then cooled to 10 °C, whereupon it solidifies. The crystals are sucked off and dried. The yield is 110 g of the title compound, m.p. 114–116 °C after recrystallization from ethanol.

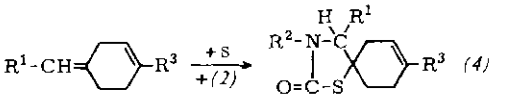
5,5-Dimethyl-3-phenyl-4-pyrrolidino-1,3-thiazolidin-2-one:

A mixture of 60 g of phenyl isocyanate, 16 g of sulfur, and 100 ml of dimethylformamide is stirred, and 62.5 g of *N*-Isobutenylpyrrolidine is added dropwise. The temperature is maintained at 35 °C by cooling. The solution becomes clear as the reaction proceeds. After further stirring (15 min) and cooling to 20 °C, the reaction mixture solidifies. When the product is sucked off and dried, 100 g of the title compound is obtained. After recrystallization from ethanol the m.p. is 117–118 °C.

5,5-Dimethyl-3-(p-toluenesulfonyl)-4-pyrrolidino-1,3-thiazolidin-2-one:

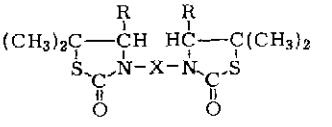
Eight grams of sulfur and 31 g of α-pyrrolidinoisobutene are stirred for 1 h at 65 °C in 60 ml of pyridine. The mixture is cooled to room temperature, and 49 g of *p*-toluenesulfonyl isocyanate is added dropwise. The temperature rises rapidly and is kept at 40 °C by cooling. The mixture is stirred for 30 min, and the solvent is then distilled off *in vacuo*. The crystalline residue is washed with methanol and sucked dry, leaving 61 g of analytically pure title compound, m.p. 144 °C (decomp.).

Condensation of derivatives of aminomethylenecyclohexane (or aminomethylenecyclohexene) with sulfur and *(2)* yields the spiro compounds *(4)*.

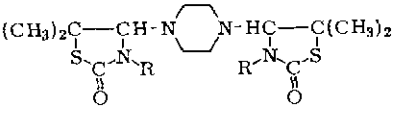


(4), R^1 = *N*-Morpholino, R^2 = C_6H_5, R^3 = CH_3, m.p. 200–203 °C
R^1 = *N*-Morpholino, R^2 = C_6H_5, R^3 = H, m.p. 168–170 °C

If the reaction is carried out with di-isocyanates or diaminodienes, the corresponding bicyclic compounds *(5)* and *(6)* are formed.



(5), R = *N*-Piperidinyl, X = $(CH_2)_6$, m.p. 164 °C (decomp.)
R = *N*-Piperidinyl, X = C_6H_4, m.p. 247 °C (decomp.)



(6), R = C_6H_5, m.p. 268 °C (decomp.)

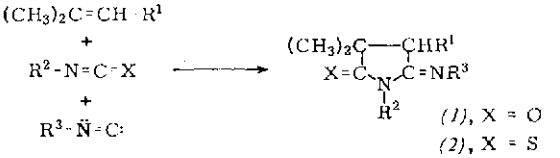
Synthesis of Iminopyrrolidones and Iminothiopyrrolidones from Aminoalkenes and Isonitriles plus Isocyanates or Isothiocyanates [1]

By Dr. habil. K. Ley, Dr. U. Eholzer, and Dr. R. Nast

Wissenschaftliches Hauptlaboratorium der Farbenfabriken Bayer AG., Leverkusen (Germany)

Dedicated to Professor Eugen Müller on the occasion of his 60th birthday

α-Aminoalkenes react with isonitriles and either isocyanates or isothiocyanates in polar solvents to give high yields of *N*-substituted 2-imino-5-pyrrolidones *(1)* and 2-imino-5-thiopyrrolidones *(2)*, respectively.



(1), X = O
(2), X = S

2-Cyclohexylimino-4,4-dimethyl-1-phenyl-3-piperidino-5-pyrrolidone:

Phenyl isocyanate (11.9 g) is added dropwise to a stirred solution of 13.8 g of *N*-isobutenylpiperidine and 10.8 g of cyclohexyl isonitrile in 25 ml of dimethylformamide. The temperature rises to 33 °C. The mixture is then heated to 50 °C for 30 min. On cooling, 33 g of the title compound crystallizes out; after recrystallization from acetonitrile it melts at 95–97 °C.

2-(t-Butylimino)-1-(p-chlorophenyl)-4,4-dimethyl-3-pyrrolidino-5-pyrrolidone:

When 12.5 g of *N*-isobutenylpyrrolidine, 8.3 g of t-butyl isonitrile, and 15.4 g of *p*-chlorophenyl isocyanate are dissolved in 40 ml of dimethylformamide, the temperature rises to 62 °C. On cooling, 30 g of the title compound crystallizes out; after recrystallization from acetonitrile, the m.p. is 84–85 °C.

2-Cyclohexylimino-4,4-dimethyl-3-pyrrolidino-1-(p-toluenesulfonyl)-5-pyrrolidone:

p-Toluenesulfonyl isocyanate (19.7 g) is added dropwise to a solution of 12.5 g of *N*-isobutenylpyrrolidine and 10.8 g of cyclohexyl isonitrile in 60 ml of acetonitrile, the temperature rising to 65 °C. On cooling, 40 g of title compound is deposited; after recrystallization from acetonitrile, the m.p. is 110–113 °C.

4,4-Dimethyl-2-(2-methyl-3-nitrophenylimino)-1-phenyl-3-pyrrolidino-5-pyrrolidone:

Phenyl isocyanate (23.8 g) is added dropwise to 25.0 g of *N*-isobutenylpyrrolidine and 32.4 g of 6-methyl-3-nitrophenyl isonitrile in 100 ml of acetonitrile, the solution being cooled to keep the temperature below 60 °C. On cooling, 65 g of the title compound precipitates as orange-yellow crystals, which after recrystallization from acetonitrile melt at 164–165 °C.

1-Cyclohexyl-2-cyclohexylimino-4,4-dimethyl-3-pyrrolidino-5-thiopyrrolidone:

Twenty-five grams of *N*-isobutenylpyrrolidine, 28.2 g of cyclohexyl isothiocyanate, and 20.6 g of cyclohexyl isonitrile are heated together in 100 ml of dimethylformamide for 3 h at 120 °C. On cooling, 68 g of colorless crystals separate out, m.p. 76–77 °C from ethanol.

2-Cyclohexylimino-4,4-dimethyl-1-(p-nitrophenyl)-3-piperidino-5-thiopyrrolidone:

A solution of 36 g of *p*-nitrophenyl isothiocyanate, 20.6 g of cyclohexyl isonitrile, and 28.0 g of *N*-isobutenylpiperidine in 100 ml of acetonitrile is refluxed for 1 h. On cooling, 77 g of bright yellow crystals are deposited, m.p. 119–120 °C from ethanol.

2-Cyclohexylimino-3-pyrrolidino-1,4,4-trimethyl-5-thiopyrrolidine:

A solution of 25 g of *N*-isobutenylpyrrolidine, 14.6 g of methyl isothiocyanate, and 20.6 g of cyclohexyl isonitrile in 50 ml of acetonitrile is refluxed for 6 h. On cooling, 42 g of title compound is deposited, m.p. 97–98 °C from ethanol.

4,4-Dimethyl-2-(3,3'-dimethyl-4-azophenylimino)-1-(p-nitrophenyl)-3-piperidino-5-thiopyrrolidone:

A solution of 47 g of 3,3'-dimethyl-4-isocyanoazobenzene, 36 g of *p*-nitrophenyl isothiocyanate, and 28 g of *N*-isobutenylpiperidine in 300 ml of acetonitrile is refluxed for 3 h. On cooling, 85 g of orange-yellow crystals are obtained, m.p. 141–142 °C from ethanol.

If diaminodienes, di-isocyanates, or di-isothiocyanates are used as starting materials, the corresponding bicyclic heterocycles are obtained. The reaction has great scope.

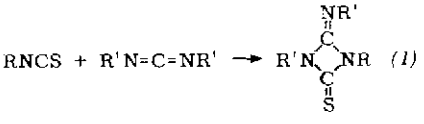
[1] Multicomponent Reactions, Part 2. Part 1: *K. Ley* and *R. Nast*, Angew. Chem. 77, 544 (1965); Angew. Chem. internat. Edit. 4, 519 (1965).

Synthesis of 2-Imino-4-thioxo-1,3-diazetidine Derivatives by Cycloaddition of Isothiocyanates onto Carbodiimides

By Dr. H. Ulrich and Dr. A. A. R. Sayigh

The Upjohn Company, Carwin Research Laboratories, North Haven, Connecticut (U.S.A.)

The addition of isothiocyanates onto carbodiimides has not yet been observed. We found that 2-imino-4-thioxo-1,3-diazetidines *(1)* are formed in quantitative yields when isothiocyanates activated by an electron withdrawing substituent (such as p-nitrophenyl or alkyl- and arylsulfonyl) and carbodiimides are mixed at room temperature in a molar ratio of 1:1 with or without solvent. The reaction can be followed by infrared spectroscopy by the disappearance of the absorptions in the cumulative double bond region (4.7–4.9 μ) and by the appearance of a new C=N absorption at 6.05 μ in the case of *(1a)* and *(1b)*, at 6.19 μ in the case of *(1c)*, and at 6.25 μ in the case of *(1d)*.



RNCS + R'N=C=NR' → (*1*)

(a), R = *p*-Nitrophenyl,	R' = Isopropyl,	m.p. 51–52 °C
(b), R = *p*-Nitrophenyl,	R' = Cyclohexyl,	m.p. 73–75 °C
(c), R = Methylsulfonyl,	R' = Phenyl,	m.p. 173–174 °C
(d), R = *p*-Tolylsulfonyl,	R' = Tolyl,	m.p. 128–129 °C

The structure of the compounds *(1)* was determined by elemental analysis, molecular weight determination and cleavage into the starting components on heating in an inert solvent (*o*-dichlorobenzene, 180 °C). In no instance was cleavage with formation of the unsymmetrically substituted carbodiimide observed. With compounds *(1c)* and *(1d)*, especially, such a reaction would have been detected easily since sulfonyl isothiocyanates absorb at 5.25 μ, while other isothiocyanates absorb at 4.9 μ.

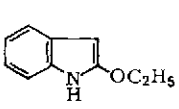
Formation of Indirubin and 2-Ethoxy-3-(indol-2-yl)indole from 2-Ethoxyindole

By Prof. Dr. H. Plieninger, Dr. U. Lerch, and Dipl.-Chem. D. Wild

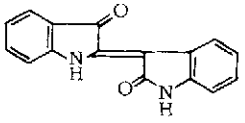
Organisch-Chemisches Institut der Universität Heidelberg (Germany)

2-Ethoxyindole *(1)* [1] in solution or in the solid state turns red-violet on admission of oxygen. After a crystalline sample of *(1)* has stood for several weeks in air, unchanged starting material can be extracted with ether or ethanol, and the undissolved residue of pigment can be recrystallized from acetic acid/ethanol. The melting point, infrared spectrum,

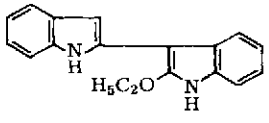
and behavior on thin-layer chromatograms of the colored product are those of indirubin *(2)*



(1)



(2)



(3)

A similar "dimerization" is observed on treating 2-ethoxyindole in dioxane at 20 °C with boron trifluoride etherate. A BF_3 complex is deposited from which colorless 2-ethoxy-3-(indol-2-yl)indole *(3)* is formed on adding aqueous ammonia. The structure of *(3)* was proved by its elemental analysis, infrared spectrum (two NH absorptions at 3440 and 3380 cm^{-1}), and NMR spectrum [signals at 1.16 τ (NH), 2.1–2.9 τ (multiplet; aromatic protons and 1 NH), 3.16 τ (singlet; β-proton), 5.86 τ (quartet), and 8.62 τ (triplet) in area ratios of 1:9:1:2:3]. Compound *(3)* gives a deep blue color in the Ehrlich reaction and is oxidized in air. Indirubin *(2)* could be isolated from the oxidation products.

The introductory step in both reactions is possibly an electrophilic attack [by oxygen in the autoxidation to *(2)* and by BF_3 during the formation of *(3)*] at C-3 of the ethoxyindole skeleton.

Synthesis of Tetrakis(trifluorophosphine)-platinum(0) and Tetrakis(trifluorophosphine)-palladium(0) [1]

By Priv.-Doz. Dr. Th. Kruck and Dipl.-Chem. K. Baur

Anorganisch-Chemisches Laboratorium der
Technischen Hochschule München (Germany)

The reductive fluorophosphination of simple transition metal salts has proved to be a generally applicable method of preparing metal trifluorophosphines, which are largely analogous to the metal carbonyls [1, 2].

On treating anhydrous platinum(II) chloride and palladium(II) chloride with trifluorophosphine in the presence of copper powder as halogen acceptor at 100 °C and initial PF_3 pressures of 300 atm (with $PdCl_2$) or 100 atm (for $PtCl_2$), the tetrakis-(trifluorophosphine) derivatives of the two platinum metals are formed. The yields are 70–80 % and 80 %, respectively.

These volatile, hydrophobic compounds deserve attention, since volatile, four-coordinate complexes, including carbonyls, of these metals in the zerovalent state had previously not been known. In appearance and other properties the new compounds resemble nickel trifluorophosphine and nickel carbonyl.

$Pt(PF_3)_4$ is a colorless, mobile liquid with m.p. −15 °C, b.p. 86 °C/730 mm, which decomposes above 90 °C with deposition of the metal. In a nitrogen atmosphere the liquid can be distilled at normal pressure with only little decomposition. The pale yellow distillate must however be recondensed in vacuum at 20 °C to render it colorless and analytically pure. In the infrared spectrum [3] of the diamagnetic compound, only two P–F valence vibration bands are observed, as with $Ni(PF_3)_4$, namely at 906 (vs) and 867 cm^{-1} (vs) (gas-phase measurement), which indicate a tetrahedral structure (T_d). $Pd(PF_3)_4$ is thermally less stable than $Pt(PF_3)_4$. It is also a colorless, mobile liquid and melts at −41 °C. Decomposition occurs above −20 °C with deposition of a palladium mirror. Rapid decomposition with PF_3 literally boiling off occurs at room temperature. The infrared spectrum of the compound was therefore measured at −25 °C between KCl plates [4]; the two P–F valence vibration frequencies expected for a tetrahedral structure were found at 910 (vs, b) and 860 (s) cm^{-1}.

[2] *Th. Kruck*, *W. Lang*, and *A. Engelmann*, Angew. Chem. *77*, 132 (1965); Angew. Chem. internat. Edit. *4*, 148 (1965), and literature cited there.

[3] The infrared spectra were obtained using a Perkin-Elmer Model 21 spectrophotometer with NaCl optics. s = strong, vs = very strong, b = broad.

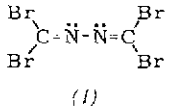
[4] Gas-phase measurements at room temperature reveal only the ν_{P-F} vibration bands at 892 and 853 cm^{-1} of the liberated PF_3, together with an intense broad band at 865 cm^{-1}, which is ascribed to an as yet unidentified decomposition product.

Synthesis of Bis(diaziridin-1-ylmethylene)-hydrazine

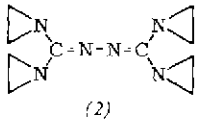
By Doz. Dr. R. Neidlein and W. Haussmann

Institut für Pharmazeutische Chemie und Lebensmittelchemie
der Universität Marburg (Germany)

Starting from isocyanogen tetrabromide *(1)* [1, 2], which can be regarded as a derivative of the (as yet unknown) isocyanogen, we have synthesized various tetra-amino derivatives of isocyanogen.



(1)



(2)

Bis(diaziridin-1-ylmethylene)hydrazine *(2)* is prepared by dissolving 3.71 g (0.01 mole) of isocyanogen tetrabromide *(1)* in 20 ml of anhydrous tetrahydrofuran, adding 1.6 g (0,04 mole) of finely powdered sodium hydroxide, cooling in ice, and adding 3.44 g (0.08 mole) of ethylenimine dropwise with vigorous stirring. Stirring is continued for 2 h at room temperature. After filtering off the KBr and distilling the tetrahydrofuran from the filtrate, a colorless oil remains, which crystallizes on standing in a refrigerator for several days; yield 1.5 g (68 %), m.p. 134–135 °C.

Bis(dipiperidinomethylene)hydrazine is prepared analogously; yield 2.9 g (76 %), m.p. 148.5 °C.

The compound *(2)* is very sensitive to acids, of which even traces cause an explosion-like polymerization.

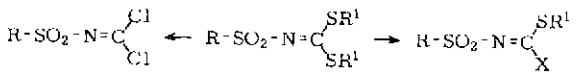
Synthesis of N-(Alkylthiohalogenomethylene) Sulfonamides

By Doz. Dr. R. Neidlein and W. Haussmann

Institut für Pharmazeutische Chemie
und Lebensmittelchemie der Universität Marburg (Germany)

N-Dichloromethylene sulfonamides *(1)* [1, 2] are obtained by the action of elemental chlorine on *S,S*-dialkyl-*N*-sulfonyldithiocarbonimides *(2)* [3,4] in boiling carbon tetrachloride.

Reaction of *(2)* under analogous conditions with an equimolar amount of bromine, on the other hand, leads to



(1) *(2)* *(3)*

N-(alkylthiobromomethylene) sulfonamides *(3)*, X = Br. Moreover, when *(2)* is cleaved under the same conditions with an equimolar amount of sulfuryl chloride, the product is an alkylthiochloromethylene sulfonamide *(3)*, X = Cl.

(3)

X	R	R^1	M.p. [°C]	Yield [%]
Br	C_6H_5	CH_3	68–69	39
Cl	CH_3	CH_3	52–53	74
Cl	C_6H_5	CH_3	65–66	93
Cl	p-CH_3-C_6H_4	CH_3	89–90	89

The structures of the new compounds have been confirmed by their infrared spectra. The alkylthiobromomethylene sulfonamides have absorption bands at 6.5 and 11.2 μ that are characteristic for the *C*-bromoimide grouping, and the alkylthiochloromethylene sulfonamides have bands between 6.4 and 6.6 μ and between 10.6 and 10.9 μ due to the chloroimido grouping. Satisfactory elemental analyses have been obtained for all of the halogeno compounds *(3)*.

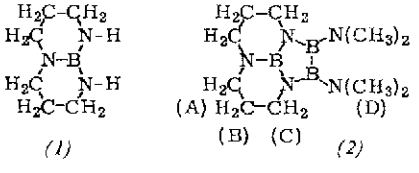
Synthesis of a 2,5-Diaza-1,3,4-triborolidine

By Doz. Dr. H. Nöth and Dipl.-Chem. G. Abeler

Institut für Anorganische Chemie der Universität München (Germany)

N-Metalation of triazaboradecalin *(1)* [1] with methyllithium in ether and subsequent reaction with symmetrical bis(dimethylamino)diboron dichloride gives 1,2-bis(dimethylamino)perhydro-2a,5a,8a-triaza-1,2,8b-triboracenaphthylene *(2)*, b.p. 105 °C/high vacuum, in about 30 % yield. This compound is a derivative of the new B–N ring system 2,5-diaza-1,3,4-triborolidine *(3)*.



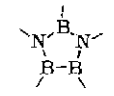
(1)

(A) (B) (C) (D)

(2)

The structure of *(2)* was confirmed by analysis, molecular-weight determination, and by infrared and NMR spectroscopy. The ^{1}H-NMR spectrum of the substance in benzene exhibits a triplet at 3.85 p.p.m. (C), a triplet with a singlet superposed at 4.35 p.p.m. (A+D), and a quintuplet at 5.57 p.p.m. (B), the areas being in the ratio of 1:4:1. The ^{11}B-signal of the B–B group occurs at −35 p.p.m., that of the B atom of the BN_3 group at −28.4 p.p.m. [2].

The compound is being examined with regard to the question of whether the system *(3)* is more stable than 2,3,5-triaza-1,4-



(3)

(4)

diborolidine *(4)* [3]. Calculations using the LCAO-MO method indicate a higher stability for the heterocycle *(3)* [4], are however not free from contradictions [5].

Isomer Formation in the Monochlorination of n-Heptane with Phosphorus Pentachloride and with Phosphorus Trichloride/Chlorine

By Dr. B. Fell

Institut für Technische Chemie der Technischen Hochschule Aachen (Germany)

n-Heptane was chlorinated with chlorine or phosphorus pentachloride (98 °C; 2 moles of n-heptane, 0.2 mole of chlorinating agent, 0.1 mole of dibenzoyl peroxide) or with PCl_3/Cl_2 (2 moles of n-heptane, 0.2 mole of PCl_3, 0.1 mole of dibenzoyl peroxide). The isomer composition of the monochloro-n-heptane fraction was determined gas chromatographically:

	x-Chloro-n-heptane [% by weight]			
	1–	2–	3–	4–
Cl_2	15.1	34.6	33.8	16.5
PCl_5	2.5	36.4	41.5	19.5
PCl_3/Cl_2	traces	24.0	52.0	24.0

The results show that the hydrogen atoms of the methyl groups react significantly more slowly with PCl_5 than with gaseous Cl_2. It is particularly surprising that the first methylene group reacts more slowly with PCl_5 than those further along the molecule, whereas no such differences occur with gaseous Cl_2 [1]. The effect found with PCl_5 is even more marked in the chlorination with Cl_2 in the presence of excess PCl_3.

The cause of the different isomer distribution is probably the fact that different chlorine radicals act on the n-heptane. The chlorination employing PCl_5 or PCl_3/Cl_2 does not occur *via* atomic chlorine (as in the reaction using chlorine alone), but rather *via* complex, polarized Cl-containing radicals:

$$Cl\cdot + PCl_3 \rightleftharpoons [Cl_3P^{\delta+}:\rightarrow Cl\cdot^{\delta-}]$$

The analogy with chlorination of an n-alkane in benzene with free chlorine, where the probability of substitution on the first secondary carbon atom is also lower [2], supports this hypothesis. A benzene-chlorine complex is formed [3]:

$$C_6H_6 \rightarrow Cl\cdot^{\delta-}$$

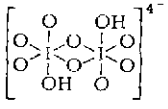
The Crystal Structure of Dipotassium Periodate Hydrate

By Prof. Dr. H. Siebert and Dr. H. Wedemeyer [1]

Anorganisch-Chemisches Institut
der Bergakademie Clausthal, Technische Hochschule,
Clausthal-Zellerfeld (Germany)

Dipotassium periodate crystallized from aqueous solution was previously assigned the formula $K_4I_2O_9 \cdot 9\,H_2O$ because of its behaviour on dehydration [2]. Its infrared spectrum shows the presence of IOH groups, however, so that the structure $K_2HIO_5 \cdot 4\,H_2O$ containing five-coordinate iodine appears more likely [3]. An X-ray analysis was therefore carried out to settle this question.

The substance crystallizes in the triclinic system with the space group $C_i^1 - P\bar{1}$. The unit cell has the dimensions a = 7.16 Å, b = 10.55 Å, c = 7.08 Å, $\alpha = 98.0°$, $\beta = 116.1°$, $\gamma = 90.1°$, and contains two formula units of $K_2HIO_5 \cdot 4\,H_2O$. *Patterson* and *Fourier* projections in the directions [100], [010], and [001] showed the anion to be dimeric, *i.e.* $H_2I_2O_{10}^{4-}$. Each iodine atom is surrounded almost octahedrally by six oxygen atoms; the octahedra have one edge in common, thus forming an I_2O_2 ring.



Ten of the twelve I–O bonds – including those in the ring – are 2.0 Å long, the remaining two 2.2 Å. The last-named may be the I–OH bonds. The reliability indices of the structure analysis were about 0.2.

This structure does not appear to be unique; the infrared spectra of previously prepared alkali periodates $M_2^IHIO_5$ [3] indicate that these, too, contain the dimeric anion $H_2I_2O_{10}^{4-}$. The same holds for several salts $M^{II}HIO_5$, *e.g.* with M = $[Mg(H_2O)_6]^{2+}$, Ca^{2+}, Sr^{2+}, $[Co(NH_3)_5NO_2]^{2+}$, $[Co(NH_3)_5N_3]^{2+}$, and $[Co(NH_3)_5NCS]^{2+}$. The compounds previously formulated as the double salts $Na_3IO_5 \cdot Na_2HIO_5 \cdot 14H_2O$ and $Li_3IO_5 \cdot Li_2HIO_5 \cdot 11H_2O$ [3] probably contain the ion $HI_2O_{10}^{5-}$; the infrared spectra of the compounds designated $[Co(NH_3)_6]HI_2O_9 \cdot 3H_2O$ and $[Co(en)_3]HI_2O_9 \cdot 4H_2O$ [4] indicate the presence of the anion $H_3I_2O_{10}^{3-}$.

A structure similar to that of the $H_2I_2O_{10}^{4-}$ ion and containing a four-membered As_2O_2 ring was found for the anion of the dimeric tetrafluoroarsenates $M_2^IAs_2O_2F_8$ [5].

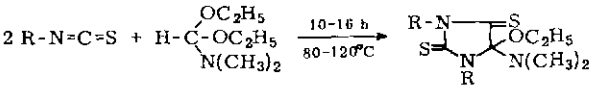
Reactions of Amide Acetals with Isothiocyanates

By Prof. Dr. H. Bredereck, Dr. G. Simchen, and
cand. chem. S. Rebsdat

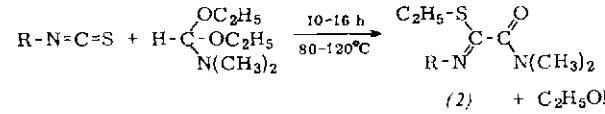
Institut für Organische Chemie der Technischen Hochschule
Stuttgart (Germany)

Recently we reported on reactions of amide acetals with isocyanates which result in *O,N*-acetals of parabanic acid [1].

We have now found that isothiocyanates, which are less electrophilic than isocyanates, also react with dimethylformamide acetals between 80 and 120 °C, directly or in toluene solution. After 10–16 h, probably after primary acylation at the formyl C-atom, 1,3-disubstituted 2,4-dithioxoparabanic *O,N*-acetals *(1)*, which have not previously been described, and/or α-alkyl-(or aryl)-imino-α-(ethylthio)dimethylacetamides *(2)*, are formed, depending on the size of the residue R (see Table below).



(1) + C_2H_5OH



(2) + C_2H_5OH

The ethanol formed together with *(1)* or *(2)* adds only slowly onto the isothiocyanate to give thiourethane.

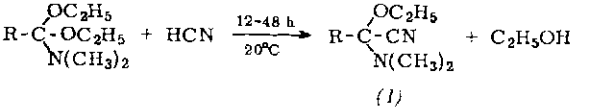
Syntheses of O,N- and N,N-Acetals of α-Ketonitriles

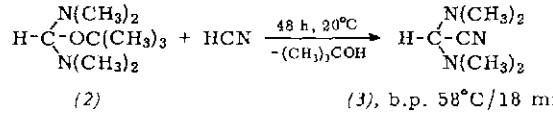
By Prof. Dr. H. Bredereck, Dr. G. Simchen, and
Dipl.-Chem. P. Horn

Institut für Organische Chemie der Technischen Hochschule
Stuttgart (Germany)

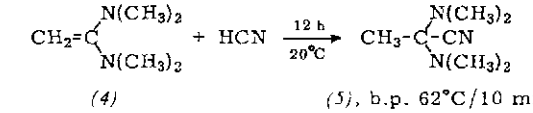
In the course of investigations on the reactions of carboxamide acetals with CH-acidic compounds [1,2], we treated amide acetals with the equivalent amount of hydrocyanic acid at room temperature and obtained *O,N*-acetals *(1)* of α-ketonitriles in good yields.



(1)



(2) *(3)*, b.p. 58°C/18 mm, $n_D^{20} = 1.4282$ yield 92%



(4) *(5)*, b.p. 62°C/10 mm, $n_D^{20} = 1.4359$ yield 51%

R	B.p [°C/mm]	n_D^{20}	Yield [%]
H	64–66/16	1.4143	87
CH_3	57/10	1.4200	73
n-C_3H_7	78–80/10	1.4305	67

N,N-Acetals *(3)* and *(5)* of α-ketonitriles were obtained in the same way from bis(dimethylamino)-t-butoxymethane *(2)* [3] or 1,1-bis(dimethylamino) ethylene *(4)* [4].

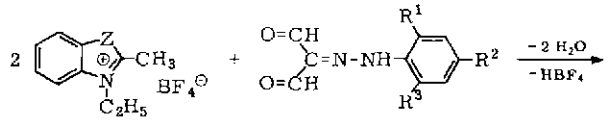
Synthesis of γ-Phenylazopentamethinecyanine Dyes [1]

By Dr. C. Reichardt

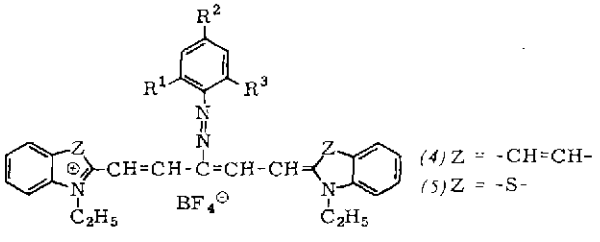
Chemisches Institut der Universität Marburg (Germany)

Condensation of phenylazomalondialdehydes with heterocyclic quaternary salts results in compounds ("azocyanines" [2]) which occupy a position between the cyanine and azo dyes. On heating a solution of 10 mmoles of 1-ethyl-2-methylquinolinium fluoroborate *(1)* with 5 mmoles of phenylazomalondialdehyde *(3)* [3] (or a derivative of *(3)*) [4] in 25 ml pyridine/0.5 ml piperidine for 2 h at 100 °C, γ-phenylazopentamethinecyanines *(4)* are formed, usually in good yields. Using *(2)* instead of *(1)* and without addition of piperidine the dyes *(5)* are obtained.



(1) Z = -CH=CH-
(2) Z = -S-

(3)



(4) Z = -CH=CH-
(5) Z = -S-

	R^1	R^2	R^3	M.p. [°C]	Yield [%]	CH_3OH λ_{max} [mμ]	log ε
(4a)	H	H	H	240–241	71	688	5.10
(4b)	Cl	Cl	Cl	255–256	74	656	5.15
(4c)	H	NO_2	H	307–308	88	660	5.08
(4d)	NO_2	NO_2	H	259–260	35	622	4.94
(5a)	H	H	H	257–259	19	645	4.88
(5b)	Cl	Cl	Cl	244–245	76	615	5.15
(5c)	H	NO_2	H	255–256	18	617	5.00

The structures of the compounds *(4)* and *(5)* are supported by the similarity of their ultraviolet spectra with those of the unsubstituted pentamethinecyanines. The introduction of the phenylazo group (a substituent with −I and −M effects) results a hypsochromic shift of the long-wavelength bands, which in the unsubstituted cyanines are at 708 and 650 mμ. This shift is analogous to that occurring on replacement of the middle methine group of a symmetrical polymethine chain with a nitrogen atom (aza-perturbation). Increase in the electron-attracting effect of the phenylazo group by introduction of Cl or NO_2 groups magnifies the hypsochromic shift (see Table).

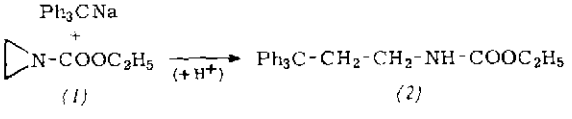
β-Aminoethylation of CH-Acidic Compounds with N-Acylaziridines

By Dr. H. Stamm

Institut für Pharmazeutische Chemie und Lebensmittelchemie der Universität Marburg (Germany)

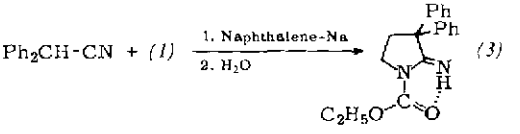
N-Acylated aziridines react with bases with ring opening [1]. We found that tritylsodium, prepared from triphenylmethane and naphthalenesodium, reacts in tetrahydrofuran at room temperature with 1-ethoxycarbonylaziridine *(1)* to give *N*-ethoxycarbonyl-3,3,3-triphenylpropylamine *(2)* in 30 % yield.



(1) *(2)*

Depending on the concentration, the product crystallizes from cyclohexane in one of two modifications, m.p. 126 to 128 °C and 133–134 °C, which have different infrared spectra in KBr, but identical spectra in CCl_4 ($\nu_{C=O}$ in CCl_4: 1727 cm^{-1}).

An analogous reaction was carried out with diphenylacetonitrile. 1-Ethoxycarbonyl-2-imino-3,3-diphenylpyrrolidine *(3)* [yield 24 %, m.p. 148–150 °C, ν_{N-H} in KBr: 3320 cm^{-1}, in



(3)

CCl_4: 3335 cm^{-1}, $\nu_{C=N}$ and $\nu_{C=O}$ ca. 1650 and 1608 cm^{-1}, respectively] can be saponified with alkali to give 2-imino-3,3-diphenylpyrrolidine [m.p. 213–213.5 °C, $\nu_{C=N}$ = 1663 cm^{-1} (KBr)] which is also formed in 3.5 % yield as a by-product in the synthesis of *(3)*.

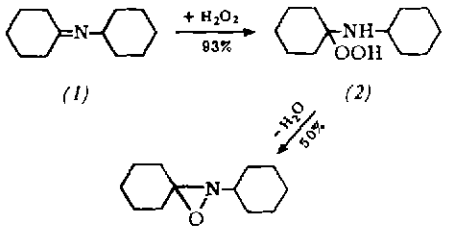
Addition of Hydrogen Peroxide onto Schiff Bases

By Dr. E. Höft and Prof. Dr. A. Rieche

Institut für Organische Chemie der Deutschen Akademie der Wissenschaften zu Berlin, Berlin-Adlershof (Germany)

Schiff bases react with peroxyacids to give oxaziridines [1]. However, when solutions of *N*-cyclohexylidenecyclohexylamine and hydrogen peroxide in anhydrous ether are mixed,

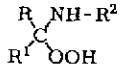
a good yield of a hydroperoxide is obtained whose elemental analysis and content of active oxygen indicate the structure *(2)*.



(1) *(2)* *(3)*

The infrared spectrum of *(2)* in KBr does not contain the band at 1660 cm^{-1} due to the C=N group which is observed in the spectrum of *(1)*; a new band at 3275 cm^{-1} can be ascribed to an N–H valence vibration. In solution at room temperature the hydroperoxide *(2)* is partially dissociated into starting components, but on heating for a short time at 80 °C in an inert solvent, *e.g.* benzene, it loses a molecule of water to yield pentamethylene-*N*-cyclohexyloxaziridine *(3)*.

The addition of hydrogen peroxide can also be effected with other Schiff bases; the products are invariably α-hydroperoxyamines *(4)*.



(4)

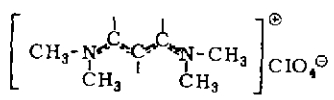
Photochemical trans-cis Rearrangement of Simple Polymethine Dyes. Determination of the Quantum Yield and Establishment of the Configuration Using the Oscillator Strength

By Prof. Dr. G. Scheibe, Dr. J. Heiss, and Dipl.-Chem. K. Feldmann

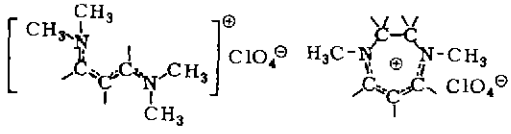
Gruppe „Strukturchemie" and Physikalisch-Chemisches Institut der Technischen Hochschule München (Germany)

Dyes containing polymethine chains can occur in different configurations, which are reversibly interconverted on irradiation with light of wavelength corresponding to the chief absorption band [1, 2]. The probable configuration of simple polymethine dyes is all-*trans*, and that of the photochemically produced dye is assumed to be mono-*cis* [3]. One may assume that in the excited singlet state, two parts of the molecule tend to be oriented at 90° to each other, so that the probabilities of obtaining the all-*trans* or a mono-*cis* form on return to the ground state are almost the same. According to this assumption, the quantum yield (based on one of the two forms) should be 0.5 or less. The value obtained [4] was 0.5 ± 0.1, independent of temperature within the limits of error between 130 and 220 °K. This means that a photorearrangement *via* metastable intermediates of both forms is very unlikely.

The configuration of the mono-*cis* form *(2)* produced photochemically from *(1)* was confirmed by synthesis of a di-*cis* form *(3)* and by calculation of the oscillator strengths f of the main absorption bands (see Table).



(1)



(2) *(3)*

	(1)	*(2)*	*(3)*
$\tilde{\nu}_{00}$ [cm^{-1}]	31800	29400	28400
f	0.63	0.47	0.27

The oscillator strengths calculated by the method of *H. Kuhn* [5] were found to be in good agreement with experimental values provided that a factor of two in *Kuhn*'s derivation is ignored. Comparison with previous results shows further that the oscillator strength is almost independent of whether the chromophore is partly built into an aromatic ring or not [6].

The synthesis of *(3)* is carried out as follows [7]: Equimolar amounts of 3-(*N*-methylanilino)prop-2-en-1-ylmethylphenylammonium perchlorate and *N,N'*-dimethylethylenediamine in methanol are added dropwise to a large volume of boiling methanol over a period of several hours, to give a final concentration of about 0.003 mole/l. The solution is concentrated (about 25 : 1), and *(3)* is precipitated with ether. After several recrystallizations from ethanol, the colorless crystals have m.p. 99.5 °C (yield 75 %).

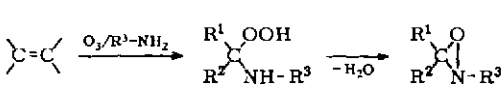
Preparation of Oxaziridines from Olefins

By Dr. Manfred Schulz, Dipl.-Chem. D. Becker, and Prof. Dr. A. Rieche

Institut für Organische Chemie der Deutschen Akademie der Wissenschaften zu Berlin, Berlin-Adlershof (Germany)

We have found that when olefins are ozonized in the presence of primary amines at −20 °C in carbon tetrachloride (molar ratio of olefin : amine = 1 : 1), oxaziridines *(2)* are formed *via* α-hydroperoxyamines *(1)*, which had already been postulated by other investigators [1] to occur during "amozonolysis". We managed to detect the α-hydroperoxyamines *(1)* [3] alongside *(2)* by thin-layer chromatography [2].



(1) *(2)*

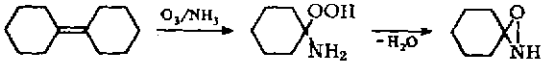
The oxaziridines *(2)* can be removed from the highly viscous products of ozonization by distillation *in vacuo*.

Ozonization of a mixture of 1-hexene and cyclohexylamine leads to crystalline *N*-cyclohexyl-*N*-(1-hydroperoxypent-1-yl)-amine *(1a)*, R^1 = n-C_4H_9, R^2 = H, R^3 = C_6H_{11}, m.p. 80 °C, in 20 % yield based on 1-hexene. When heated for 1 h in toluene at 80 °C, *(1)* was converted into n-butyl-*N*-cyclohexyloxaziridine *(2a)*.

Olefin	Amine	Oxaziridine *(2)*	Yield [%]	B.p. [°C/mm]	Purity [%]
1-Hexene	Cyclohexyl-amine	*(a)*, R^1 = n-C_4H_9; R^2 = H; R^3 = C_6H_{11}	33	70–72/0.01	97
1-Hexene	n-Butylamine	*(b)*, R^1 = n-C_4H_9; R^2 = H; R^3 = n-C_4H_9	23	58–61/0.01	93
1-Hexene	Isopropyl-amine	*(c)*, R^1 = n-C_4H_9; R^2 = H; R^3 = iso-C_3H_7	28	55–57/0.01	95
Tetramethyl-ethylene	Cyclohexyl-amine	*(d)*, R^1 = R^2 = CH_3; R^3 = C_6H_{11}	36	47–50/0.02	93 [4]
Tetramethyl-ethylene	Isopropyl-amine	*(e)*, R^1 = R^2 = CH_3; R^3 = iso-C_3H_7	25	32–34/0.1	94 [4]
Biscyclo-hexylidene	Cyclohexyl-amine	*(f)*, R^1–R^2 = $(CH_2)_5$; R^3 = C_6H_{11}	30	78–79/0.1	91 [4]

The ozonization reaction also leads to *N*-substituted amides in addition to *(2)*. After separation of *(2a)* and *(2b)* from the appropriate reaction products by vacuum distillation, *N*-cyclohexyl-n-valeramide, m.p. 208 °C, and *N*-n-butyl-n-valeramide, m.p. 181 °C, crystallize out of the residue in respective yields of 33 and 23 % based on 1-hexene.

Ozonolysis of biscyclohexylidene *(3)* in carbon tetrachloride at −35 °C in the presence of an equimolar amount of ammonia yields the isoxime of cyclohexanone *(5)*, which can be recovered in 18 % yield [based on *(3)*] in the form of its crystalline benzoyl derivative [5].



(3) *(4)* *(5)*

An unstable intermediate *(4)* can be detected by thin-layer chromatography.

Owing to the danger of explosions, not more than 0.5 g of olefin should be used, and all necessary precautions taken.

Photochemical Rearrangement of a Trimethinecyanine Dye from the all-trans Form to a mono-cis and a di-cis Form

By Dr. J. Heiss and Dipl.-Chem. K. Feldmann

Gruppe „Strukturchemie" and Physikalisch-Chemisches Institut der Technischen Hochschule München (Germany)

The cyanine dye *(1a)* [1] surprisingly shows the same absorption as the dye *(1b)* (in which there is no phenyl substituent in the meso position) except for the almost additively superposed benzene spectrum in *(1a)* around 10000 cm^{-1} [see Fig. 1: *(1b)* and *(1a₁)*]. This finding leads to the conclusion that the phenyl ring is perpendicular to the plane of the dye molecule and that therefore resonance cannot occur between the π-electron system of the ring and that of the cyanine system. When the dye *(1a)* is irradiated with light of wavelength corresponding to the principal absorption band this band disappears, accompanied as in previous investigations [2] by the appearance of a new band which is, however, displaced to unusually high wavelengths [cf. Fig. 1: *(1a₂)*]. This phenomenon can be explained with the assumption that a mono-*cis* form is obtained at first, as occurs with unsubstituted open-chain cyanines, and that the phenyl ring then turns into the plane of the dye because of the more favorable steric relationships. Resonance is then possible, which results in a red-shift of the absorption band by $\Delta\tilde{\nu}$ = 4700 cm^{-1}, compared with $\Delta\tilde{\nu}$ = 2500 cm^{-1} [3] for mono-*cis* forms of trimethinecyanines. When light corresponding to the new absorption band is now used, a further band displaced to high wavelengths appears [cf. Fig. 1: *(1a₃)*], which can be ascribed to the di-*cis* form, as could be confirmed by synthesis of a sterically fixed di-*cis* form [4]. Isosbestic points were found for both transformations which are completely reversible. The extinction of the original dye *(1a₁)* at the wavelength of maximum absorption is reduced by a factor of almost 100 during the rearrangement. These observations are readily made because the absorption maximum of *(1a)* almost coincides with the absorption minimum of the new dye [at 32000 cm^{-1} for *(1a₁)*, all-*trans*, ε = 54000, for *(1a₂)*, mono-*cis*, ε = 680]. Dyes of this kind could become

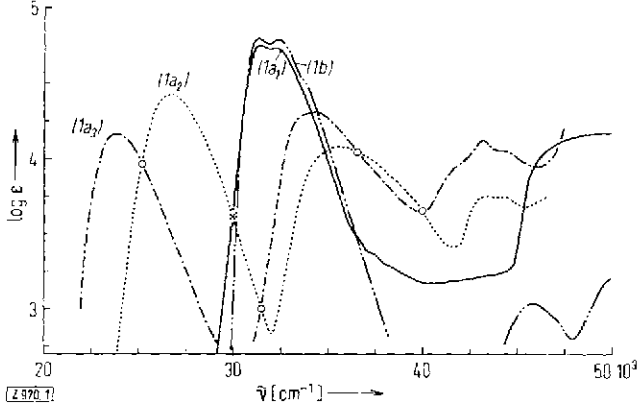

Fig. 1. Absorption spectra of the trimethinecyanine dyes *(1a)* [*(1a₁)*: all-*trans* form; *(1a₂)*: mono-*cis* form; *(1a₃)*: di-*cis* form] and *(1b)* [all-*trans* form].

× Isosbestic point for *(1a₁)* ⇌ *(1a₂)*.

○ Isosbestic points for *(1a₂)* ⇌ *(1a₃)*.

significant as passive Q-switches in the production of giant laser pulses [5].

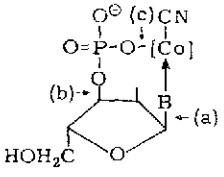
Course of the Microbial Conversion of Cobalamine Analogues into Vitamin B_{12} [1]

By Dr. P. Renz

Lehrstuhl für Biochemie und Biotechnologie
der Technischen Hochschule Stuttgart (Germany)

Dedicated to Prof. K. Bernhauer on the occasion of his 65th birthday

Cobamides containing various benzimidazole or purine bases, *e.g. (2)* or *(3)*, are converted into vitamin B_{12} *(1)* by *Propionibacterium shermanii* in the presence of 5,6-dimethylbenzimidazole [2].



(1), B = 5,6-Dimethylbenzimidazole
(2), B = Adenine
(3), B = Benzimidazole
[Co] = Cobinamide moiety

The bond (c) must remain intact during this process, for when [^{32}P]-adenylcobamide *(2)* [3] is transformed into *(1)* by *P. shermanii* [2], 93.5 % of the radioactivity recurs in *(1)*.

In order to differentiate between the two remaining possible positions of cleavage, *viz.* bonds (a) and (b), we synthesized [^{14}C]-benzimidazolylcobamide *(3)* from cobinamide, benzimidazole, and [u-^{14}C]-D-glucose using *P. shermanii*. It was shown by degradation with cerium hydroxide [5] that all the radioactivity [4264 counts/min/mg] was present in the ribosyl residue.

The vitamin B_{12} *(1)* formed from the ^{14}C-labelled *(3)* was not radioactive [2]. It must therefore be the bond (b) that is split during this transformation. The complete nucleoside is apparently replaced by preformed α-ribazole.

This conclusion is supported by the observation that α-ribazole can be detected in cultures [6] of *P. shermanii* and α-ribazole-5-phosphate in extracts [7] from the same microorganism.

α-Aminoalkylation of White Phosphorus [1]

By Dr. Ludwig Maier

Monsanto Research SA., Zürich (Switzerland)

In continuation of studies on the direct synthesis of organophosphorus compounds from elemental phosphorus [2] we have found that the reaction of white phosphorus with *N*-hydroxymethyldialkylamines provides a simple method of preparing tertiary phosphine oxides. Phosphonic and phosphinic acids and sometimes even the tertiary phosphine are formed as by-products.

$$2\ P_4 + 19\ R_2NCH_2OH \rightarrow R_2NCH_2PO(OH)_2 + 3\ (R_2NCH_2)_2PO(OH) + (R_2NCH_2)_3P + 3\ (R_2NCH_2)_3P{=}O + 7\ H_2O$$

The yields of tertiary phosphine oxide depend upon the ratios of the reagents and upon the solvent used. The highest yield is obtained with a molar ratio phosphorus: *N*-hydroxymethyldialkylamine of 2:5 and with 50 % aqueous alcohol as solvent at 80 °C for 1-8 h; the phosphine oxide is isolated by extraction with benzene or ether and recrystallization from hexane or petroleum ether.

A New Synthesis of γ-Pyrones

By Dipl.-Chem. H. Schiefer and Prof. Dr. G. Henseke

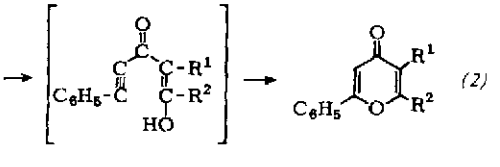
Institut für Organische Chemie
der Bergakademie Freiberg (Germany)

When phenylethynyl ketones *(1)* are acylated with carboxylic esters in the presence of strongly basic condensing reagents, *e.g.* sodium or sodium ethoxide, sodio derivatives of β-diketones are obtained which on protonation mostly cyclize immediately to γ-pyrone derivatives *(2a–g)*.

$$C_6H_5\text{-}C{\equiv}C\text{-}CO\text{-}CH_2\text{-}R^1 + R^2\text{-}COOC_2H_5$$

(1a), R^1 = H
(1b), R^1 = CH_3

$$\rightarrow C_6H_5\text{-}C{\equiv}C\text{-}CO\text{-}\underset{R^1}{CH}\text{-}CO\text{-}R^2$$



(2)

A mixture of 1 mole of ketone and 2 moles of ester is added dropwise within 1–4 h to a stirred solution in alcohol or ether of 2 moles of condensing agent. The whole is then left standing for 1–2 days at 0 °C. Alkaline alcoholic solutions are then acidified with alcoholic sulfuric acid, filtered, and concentrated *in vacuo*. If alcohol-free sodium ethoxide or metallic sodium in ether is used as condensing agent, the reaction mixture is subsequently treated with water, and the pyrone is isolated by acidification, extraction with ether, and vacuum sublimation of the residue left after evaporation of the ether from the extract. Compound *(2c)* is isolated as its picrate, made by boiling the β-dicarbonyl compound with picric acid in ethanol.

	R^1	R^2	Solvent	Condensing agent	Reaction temp. [°C]	Yield [%]	M.p. [°C]	Ref.
(2a)	H	$COOC_2H_5$	Alcohol	$NaOC_2H_5$	−15	75	118–119	[1]
(2b)	H	COOH	Ether	$NaOC_2H_5$	−15	80	238 (decomp.)	[1]
(2c)	H	H	Ether	$NaOC_2H_5$	0	40	103–104	[1]
(2d)	H	CH_3	Ether	$NaOC_2H_5$	0	25	86–87	[1, 2]
(2e)	H	$CHCl_2$	Ether	Na	−15	50	141–142	
(2f)	CH_3	H	Ether	$NaOC_2H_5$	−15	45	132–133	[3]
(2g)	CH_3	$COOC_2H_5$	Alcohol	$NaOC_2H_5$	0	40	127–128	
(2h)	CH_3	COOH	[a]				280 (decomp.)	
(2i)	H	CH_2Cl	[b]			90	124–125	
(2j)	H	CHO	[c]				121–122	

[a] Obtained from *(2g)* by hydrolysis with conc. HCl.

[b] Obtained from *(2e)* by refluxing in acetic acid for 1 h with $SnCl_2$.

[c] Obtained from *(2i)* via the pyridinium salt, m.p. 223–224 °C (decomp.), and the nitrone, m.p. 207 °C (decomp.).

The chlorine atoms in *(2e)* are very firmly attached and can be removed only under drastic conditions with simultaneous ring-opening. Catalytic hydrogenation of *(2e)* over palladium-charcoal in ethanol affords a 90 % yield of *(2d)*.

CONFERENCE REPORTS

Colloquium on Macromolecular Chemistry

A Colloquium on Macromolecular Chemistry, organized by the Institut für Makromolekulare Chemie der Universität Freiburg/Breisgau, was held in Freiburg/Breisgau (Germany) on March 11–13th, 1965.

Chemical Synthesis and Biosynthesis of Coding Nucleic Acids

F. Cramer, Göttingen (Germany)

Condensation of thymidylic and adenylic acids with picryl chloride, *N,N*-dimethylformamide dichloride, $(CH_3)_2NCHCl_2$, or dicyclohexylcarbodiimide leads to oligothymidylic acids and oligoadenylic acids containing up to 20 units per chain. Dinucleotides and trinucleotides of the deoxy series can be condensed analogously to give oligodoublets and oligo-triplets. The method was used to make (pCpT)n and $(pGpApT)_n$. Some of the oligonucleotides prepared can be used for coding, *i.e.* in enzymatic tests they function as templates for the synthesis of "copied" deoxyribonucleic acids or messenger ribonucleic acids.

When protective groups are used, oligoribonucleotides also can be synthesized; the largest molecule of this type made so far is a trinucleoside diphosphate, *viz.* UpUpC. The enzyme polynucleotide phosphorylase was used to make mixed polynucleotides, for example poly-UG (79:1) This ribonucleic acid is cleaved by T_1 ribonuclease adjacent to the guanylic acid residues exclusively, yielding UpUp....UpG, a polynucleotide with the terminal triplet UUG. When this polynucleotide is used for ribosome adaptation, it codes the amino acid leucine, which proves that UUG is the code triplet for leucine.

On the Chemistry of the Recombination of Insulin Chains to Give Biologically Active Insulin

H. Zahn, B. Gutte [*], and *O. Brinkhoff*, Aachen (Germany)

Crystallized bovine insulin was reduced in urea solution with mercaptoethanol at pH 5. The mixture of SH-chains was oxidized with air at pH 9 and 4–8 °C and dialysed. Gel filtration on Bio-Gel P-150 in ammonium hydrogen carbonate buffer of pH 8.15 gave in 50 % yield a fraction with a molecular weight of about 140000. In this fraction, the proportion of B-chains was 70 % (determined by amino acid analysis, amperometric disulfide analysis, and lysine analysis with the FDNB method [1]). In the position of native insulin, the recombination product was found in only 5 % yield. In the last peak, the content of A-chains is higher. The main reason for the low yield on recombination of reduced A- and B-chains appears to be the formation of polydisulfides from B- and A-chains.

Du, Jiang, and *Tsou* [2] achieved yields of 50 % on the renaturation of insulin. Presumably polymerization is prevented here by the high pH of 10.6, since according to *Fredericq* [3] insulin does not aggregate at this pH.

Using another route up to 44 ± 14 % yields of insulin were obtained, as determined on the basis of the oxydation of

[*] *B. Gutte*, Diploma Thesis, Technische Hochschule Aachen 1964.

[1] FDNB = fluorodinitrobenzene.

[2] *Y.-C. Du, R.-Q. Jiang*, and *C.-L. Tsou*, Scientia Sinica (Peking) *14*, 229 (1965).

[3] *E. Fredericq*, Nature (London) *171*, 570 (1953).

glucose in rat adipose tissue: The reduced A-chain alone was oxidized with air at pH 8.8 for the time necessary in order to give an optimum yield of biologically active insulin on subsequent combination with the reduced B-chain. In one experiment, the regenerated activity was optimum after 60 min of preoxydation, in another after 100 minutes.

On gel-filtration on Sephadex G-25, these products of renaturation give a definite peak in the position expected for native insulin. They can also be extracted with acid/sec-butanol according to the method of *Du* et al. [4]. The yield of insulin crystals was about 20–25 % of the total activity.

Oligomerization of Peptides by Enzymatic Catalysis

H. Determann, Frankfurt/Main (Germany)

In the reverse reaction of peptide proteolysis, only condensation products of relatively low molecular weight are obtained when well-defined oligopeptides are used in the "plastein reaction"

oligopeptide $\xrightarrow{\text{pepsin}}$ polypeptide.

Thirty such peptide "monomers" – mostly pentapeptides – with acidic, basic, or neutral character, of very good to good solubilities, and with various amino acids in the chain and at the ends, gave rise to mixtures of homologous oligomers, provided they could be condensed at all. Earlier, however, the formation of protein-like macromolecules from protein hydrolysates of complex composition had been reported. Hydrolysates of this type were now separated according to molecular weight on Sephadex G-25; subsequent treatment of the low molecular-weight fractions with pepsin also produced only low molecular-weight plasteins. It is probable that the products of high molecular weight described in the older literature – where they are already contested – are to be explained by inclusion of larger aggregates in the peptide mixture used, or by association. – The specificity of pepsin for hydrolysis and condensations is the same with regard to the carboxyl groups involved. Attempts were made to explain the premature standstill that occurs in the condensation reaction on the basis of thermodynamic considerations and an assumption of the mechanism of pepsin catalysis.

Specific Polysaccharides of Enterobacteria

O. Westphal, O. Lüderitz, Barbara Jann, and *K. Jann*, Freiburg/Breisgau (Germany)

Comparative analyses of the cell-wall lipopolysaccharides of the S-forms of over one-hundred strains of *Salmonella* and as many *Escherichia coli* strains indicated that these bacteria can synthesize a large number of monosaccharides, including hitherto unknown deoxyhexoses and aminohexoses, and build them into their highly branched polysaccharides. All these polysaccharides are constructed according to the same principle: there is a main chain of poly(heptose phosphate) to which long side-chains are attached, which in turn may be branched. They are the carriers of the immunological species specificity (serotypes). The structures of the side chains were determined by chemical, immunochemical, and biochemical procedures; valuable information was derived from studies of mutants (R-forms) with enzyme blocks (of synthetases and transferases) in the polysaccharide biosynthesis. Serological and chemical analysis of the R-forms revealed that all the polysaccharides from *Salmonella* S-forms (wild strains) have a common basic skeleton (basal polysaccharide) in which short oligosaccharide chains containing glucose, galactose, and glucosamine are linked to poly(heptose phosphate). In S-forms, the recurrent units of the long O-specific side chains are attached to the terminal glucosamine residue of the basal polysaccharide.

Chemical and genetic classification of *Salmonella* and other enterobacterial genera will be possible on the basis of the structure of the recurrent oligosaccharide units and their structural variation. On treatment with phages, various structures can be transformed into others (lysogenic conversion). In this way, the serological classification (Kauffmann-White scheme) is supplemented by a biochemical-genetic system of classification.

Many strains of *E. coli* form not only cell-wall (lipo)polysaccharide (O-antigen) but also a capsule antigen (K-antigen), which forms a layer on the cell wall over the O-antigen. Many, but not all K-antigens have been found to be long-chain polysaccharides containing uronic acids. The structural principle of some K-antigens and the structures of their determinant group(s) were determined. – In addition to O- and K-antigens, mucoid coli bacteria produce another mucoid substance (M-antigen; called colanic acid by *W. F. Goebel*), which is also an acidic polysaccharide. With the aid of the phenol/water procedure, all the polysaccharides can be extracted from the bacteria and can then be separated with Cetavlon® [5] into purified K- and M-antigens (acidic polysaccharides) and O-antigen (lipopolysaccharide). Highly diverse sugar monomers can be involved in the construction of the K-, M-, and O-specific polysaccharides from one and the same bacterium.

An Enzymatic Method for Kinetic Investigations of Endohydrolases: Assay of the Activity of α-Amylase

R. Werner and *G. Keilich*, Freiburg/Breisgau (Germany)

The kinetics of the degradation of polysaccharides by endohydrolases – which split the macromolecule within the chain – normally can be studied accurately only if the alterations in molecular weight are followed. Determination of the number-average molecular weight is possible with the aid of an exohydrolase, which splits off single monomers from the chain ends, because the rate of reaction of the exohydrolase depends on the number of end groups available. Since the action of the endohydrolase gives rise to new end groups, the rate of the exohydrolase reaction increases; its acceleration is therefore a measure for the activity of the endohydrolase.

This new method for assaying endohydrolases was illustrated with α-amylase. The exohydrolase used was a polysaccharide phosphorylase. Its rate of reaction can be measured by determining spectrophotometrically the glucose-1-phosphate formed using phosphoglucomutase and glucose-6-phosphate dehydrogenase. The activity of the α-amylase is expressed directly in international units, namely μmoles of glucosidic bonds hydrolysed per minute. The method can in principle be applied to any endohydrolase, provided specific exohydrolases are known for its substrate.

The Molecular Weights of Native Dextrans

K. Ebert, München (Germany)

On the basis of determinations carried out in the ultracentrifuge or by light scattering, extremely high values, *viz.* about 5×10^8, had been obtained for the molecular weights of native dextrans. According to molecular kinetic estimations, based on the molecular activity of the synthesizing enzymes, such large molecules should be formed only after prolonged reaction times.

A method was developed for measuring the number-average molecular weights (M_n) of native dextrans: the terminal saccharose grouping is split off with an enzyme and the resulting aldehydic end group is reduced with tritium-labelled lithium

[4] *Y.-C. Du, Y.-S. Zhang, Z.-X. Lu*, and *C.-L. Tsou*, Scientia Sinica (Peking) *10*, 84 (1961).

[5] Cetyltrimethylammonium bromide.

borohydride; the specific radioactivity can then be correlated to M_n. In this way, M_n values of around 2×10^5 were obtained for dextrans formed at low substrate concentrations. These values are in agreement with the results of fractionation in a Baker-Williams column. The higher values previously found are ascribed to aggregates.

Kinetic Studies on the Biosynthesis of Cellulose

M. Marx-Figini, Mainz (Germany)

The amounts of cellulose and its degree of polymerization in hairs from cottonseed at different stages of ripening were determined and correlated with the age of the seeds.

The results showed that the biosynthesis of cellulose proceeds in two phases. In the first phase, the synthesis is slow, and only little cellulose is formed. The majority is produced during the second stage, which starts spontaneously; here the synthesis proceeds much faster. The assignment of the first and second phase to the formation of the primary and secondary cell wall, respectively, was confirmed by the values found for the degrees of polymerization (D. P.) and by the swelling properties of the seed hairs, the longitudinal growth, and the amount of non-cellulosic materials formed at the various stages of maturity.

The DP increases by almost one order of magnitude on passing from the first to the second reaction phase and then remains constant throughout the entire synthesis of the secondary cell wall. It is independent of the conversion and the rate of reaction and is practically completely uniform. It must therefore be concluded that during the biosynthesis of cellulose in higher plants, templates ensure the maintenance of a constant DP.

Model Concepts of Cellulose Synthesis and of the Formation of Plant Cell Walls

G. V. Schulz, Mainz (Germany)

The studies of *M. Marx-Figini* (see report above) make it appear probable that the biosynthesis of cellulose is controlled by templates. Attempts were made to develop concepts as to the nature of the synthesizing system on the basis of the properties of cellulose and of morphological observations. It follows from the molecular weight that the template must be about 5×14000 Å $= 7\,\mu$ long.

Electron micrographs of cell walls (*Frey-Wyssling*, *Mühlethaler*, *Preston*) reveal that the secondary cell wall consists of fibrils of uncertain lengths and with diameters between 50 and 150 Å. These are arranged parallel in layers which cross at definite angles. This structure excludes the possibility that cellulose molecules synthesized on the template are released directly into the cell plasma. If this were so, the long glucosidic chains would fold up into single molecule crystals (*Bittiger* and *Husemann*), which could afterwards hardly combine to form fibrils and become properly oriented in the highly organized tissue of the secondary cell wall. Moreover, a simple calculation, and degradation experiments carried out with cellulose (*Rånby*), have made it appear likely that the crystallographic micelle described by *Hengstenberg* and *Mark* [ca. $50 \times 100 \times (\leqslant 600)$ Å^3] is in reality a folded single molecule and that the fibrils are linear sequences of folded molecules.

By consideration of the electron-microscopical observations of *Mühlethaler* and *Ledbetter*, a mechanism is proposed for cellulose synthesis which incorporates three partial processes: (1) synthesis, (2) fibril formation (spinning process), and (3) deposition of fibrils in criss-cross layers (weaving process). The template occurs (stretched or spirally coiled) in a pipe- or tube-like structure. The interlinking of the glucose units begins at one end in such a way that a continuously folding chain molecule is formed which on completion reaches the other end of the tube in the form of a "folded package". There the loops of the folds become inserted into those of the end of the fibril already present there, and are bonded by hydrogen bridges. The layers of parallel fibrils result because a system of synthesis tubes slides along the cell wall, carried along by the flow of the cell plasma.

Fractionation of High Molecular-Weight Materials on Silica Gels Having a Defined Cavity Structure

H. W. Kohlschütter, Darmstadt (Germany)

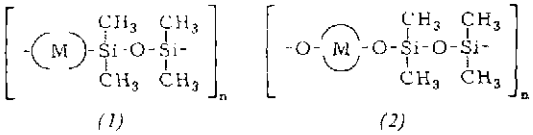
In connection with systematic investigations of the structural material, the cavity systems, the surface, and the natural grain formation of silica gel, high molecular-weight polystyrenes dissolved in chloroform were fractionated and polystyrene/paraffin mixtures were separated on silica gel columns. The separations are occasioned by partition of the dissolved materials between the mobile phase of the solvent flowing around the silica gel grains and the quasi-stationary phase of the solvent entrained within the large pores in the grains. The partition of the dissolved materials and the separatory efficiency of the column can be related by a simple equation. The chromatograms were evaluated with the aid of molecular-weight determinations. The component with the highest molecular weight correponds to the smallest, that with the lowest molecular-weight to the greatest retention volume. The efficiency of the columns increased when silica gel preparations with larger specific pore volumes were used.

The same silica gel preparations were used to separate inorganic salts and colloids in aqueous solutions. Analogous relationships were found between the particle weights and the retention volumes, and between the specific pore volume of the silica gel and the separatory efficiency of the columns.

Polychelated Siloxanes

A. Hofer [†], *H. Kuckertz*, and *M. Sander*, Frankfurt/Main (Germany)

Polymethylsiloxanes of types *(1)* and *(2)* containing metal chelate groups were synthesized in various ways. Type *(1)* compounds contained mainly M = Be or Al with β-diketones (acetylacetone) as chelating agents. The siloxanes containing



(1) *(2)*

beryllium attain a viscosity number of 0.4 dl/g, are solid at room temperature, and have a broad plasticity range between 60 and 200 °C. They decompose above 170 °C, the main pyrolysis gas being methane.

Type *(2)* compounds could be obtained only with titanium chelates (8-hydroxyquinoline). These polymers are generally brittle up to 100 °C. Above 200 °C, rearrangements of Si–O–Ti bonds to Si–O–Si and Ti–O–Ti bonds occur.

The Preparation and Polyaddition Reactions of Ferrocene Derivatives with Two Dimethylsilyl Groups

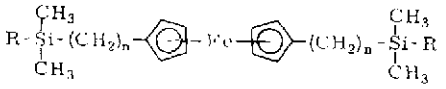
G. Greber and *M. L. Hallensleben*, Freiburg/Breisgau (Germany)

Reduction of 1,1′-bisdimethylethoxysilylferrocene and 1,1′-bis(dimethyl-n-butoxysilylmethyl)ferrocene with $LiAlH_4$ leads to good yields of 1,1′-bisdimethylsilylferrocene *(1a)* and 1,1′-bis(dimethylsilylmethyl)ferrocene *(1b)*, respectively.

In the presence of H_2PtCl_6 as catalyst, these add onto acetylene to form 1,1′-bis(dimethylvinylsilyl)ferrocene *(2a)* and 1,1′-bis(dimethylvinylsilylmethyl)ferrocene *(2b)*, respectively.

[†] Since deceased.

Polyaddition of *(1a)* and *(2a)* or of *(1b)* and *(2b)* as well as of *(1a)* or *(1b)* and other organosilicon compounds containing two alkenylsilyl end groups or of *(2a)* or *(2b)* and other organosilicon compounds containing two terminal H—Si groups



(1a), n = 0, R = H

(1b), n = 1, R = H

(2a), n = 0, R = $-CH=CH_2$

(2b), n = 1, R = $-CH=CH_2$

affords thermostable polymers containing ferrocene residues as links in the main chain. Depending on the ratio of the reagents used, the end groups in the final product may be either two hydrosilyl or two alkenylsilyl moieties.

On heating for 6 h at 300 °C, polyadducts made from *(1a)* and *(2a)* decrease in weight by only 0.1 %, whereas those from *(1b)* and *(2b)* by about 5 %.

Polymeric Reaction Products Made from Formaldehyde and Nitriles Containing Activated Methylene Groups

W. Funke, Stuttgart (Germany)

When phenylacetonitrile is condensed with formaldehyde in methanol in the presence of sodium methoxide as catalyst, liquid or crystalline polymeric products of relatively low molecular weights are obtained, depending on the molar proportions of the reactants and on the reaction conditions. Insoluble polymers are obtained similarly from phenylenediacetonitrile.

Experiments with low molecular-weight model substances based on phenylacetonitrile revealed that under the conditions used, the condensation reaction leads first to α-cyanostyrene and that it depends largely on the ratios of coreactants and on the temperature whether this product undergoes a Michael addition with unchanged phenylacetonitrile to form 2,4-diphenylglutarodinitrile or whether an anionic polymerization occurs in which low molecular-weight poly-α-cyanostyrene is formed as a result of premature chain termination. The polymers obtained contain methoxy and some hydroxymethyl end groups. In addition, some terminal nitrile groups are converted into imino ether groupings.

Oligomers Obtained in Cationic and Anionic Polymerization of ε-Caprolactam

M. Rothe, Mainz (Germany)

The mechanism of the cationic and anionic polymerization of ε-caprolactam and the structures of the resultant polymers were studied using oligomers of uniform molecular size [6]. Reaction of ε-caprolactam for short times with equimolar amounts of initiator (in cationic polymerization: HCl, sulfonic acids, ortho-, pyro-, or polyphosphoric acid, or BF_3-H_2O; in anionic polymerization: Na lactamate plus *N*-acyl-ε-caprolactam) yielded mixtures of oligomers which were separated by chromatography and electrophoresis; the products were studied by spectroscopy and identified by comparison with authentic synthetic samples of caprolactam oligomers.

On cationic polymerization, oligo-(ε-aminocaproyl)caprolactams up to the hexamer were detected and isolated on a micropreparative scale. Their structures were confirmed either by their synthesis from *N*-protected oligoaminocaproyl chlorides and caprolactam with subsequent removal of the protecting group (carbobenzoxy or azido residues) or by their reaction with hydroxylamine, which cleaves off the terminal lactam rings to give the corresponding oligoaminocaproylhydroxamic acids. The chain initiation and chain growth reactions were studied using the model reaction between caprolactam and *N*-methylacetamide hydrochloride, which gives rise to acetylcaprolactam and oligo(aminocaproyl)-*N*-methylacetamides.

In anionic polymerizations, the first three members of the series of *N*-acetyloligo(aminocaproyl)caprolactams were detected. In order to test for branching, bis-(ε-aminocaproyl)-ε-aminocaproic acid was synthesized.

Cationic and anionic lactam polymerization lead *via* different mechanisms to polymers with the same lactam end-groups.

[6] In collaboration with *H. Boenisch, D. Essig, K. Gehrke, G. Reinisch*, and *I. Rothe*.

Radical Polymerization of Itaconic Acid

D. Braun and *I. A. Aziz El Sayed*, Darmstadt (Germany)

During free-radical polymerization of itaconic acid

(1)

the carboxyl group content in the polymerizing system decreases in proportion to the amount of polymer formed. At the same time, carbon dioxide is liberated to an extent independent of the nature of the initiator and of the solvent. The polymers have only about one-half of the carboxyl group content to be expected for poly(itaconic acid). — In free-radical copolymerizations of itaconic acid, carbon dioxide is also evolved.

The carbon dioxide liberated originates from the primary carboxyl group in the monomer *(1)*; no carbon dioxide is released during the polymerization of the corresponding monoester of itaconic acid.

Analytical and spectroscopic investigations of the polymers yield some information concerning their structures. Subsequent reactions of the carboxyl radicals split off give rise to hydroxyl and formyl radicals during the polymerization, and some of these are incorporated into the polymer and can later be determined therein.

The mechanism of the free-radical polymerization of itaconic acid is not yet completely explained, but model reactions permit conclusions to be drawn as to the nature of the course of reaction.

Metal Chelate Complexes as Polymerization Initiators

N. Naarmann, Ludwigshafen/Rhein (Germany)

Metal chelates (acetylacetonates) can be used to initiate vinyl polymerizations.

The efficiency of the complexes as initiators depends on the central atom and on the complexing ligand, as illustrated by the polymerization of styrene. Manganese(III) and cobalt(III) chelates of aliphatic β-dicarbonyl compounds are the most effective.

The metal chelate initiators can be activated by high-energy radiation or by combination with cocatalysts such as organic halogen compounds (*e.g.* n-amyl chloride) or polyunsaturated hydrocarbons (*e.g.* cyclooctadiene).

Several findings indicate a free-radical mechanism. The central metal atom influences the steric structure of the polymer chains. Thus the content of *cis*-1,4-residues in polybutadiene is particularly large when the chelated metals have ionic radii of 0.6—0.7 Å. A minimum content of *cis*-1,4-linkages occurs when the ionic radius lies around 1.0 Å.

Emulsion polymerization of butadiene with metal chelate complexes as initiators gives polymers with significantly higher contents of *cis*-1,4-configurations and correspondingly low glass transition temperatures.

Graft Polymerization of Vinyl Compounds onto Ethylene/Vinyl Acetate Copolymers

H. Bartl and *D. Hardt*, Leverkusen (Germany)

Because of their active hydrogen atoms, ethylene/vinyl acetate copolymers form good bases for graft polymers. They were used as substrates for graft polymers with vinyl acetate, acrylic and methacrylic esters, acrylonitrile, styrene, vinylidene chloride, and vinyl chloride. The greatest amount of grafting is achieved by using the technique of suspension polymerization; here the ethylene/vinyl acetate copolymer is dissolved in monomer, the solution is dispersed in water containing a protective colloid, and allowed to polymerize.

The tendency towards graft polymerization is proportional to the activity of the monomer radicals (under comparable conditions): vinyl chloride captures the greatest amounts of substrate, and the acrylic esters and acrylonitrile respectively less; styrene has only a very low capacity for grafting on ethylene/vinyl acetate copolymers.

The physical properties of the graft copolymers depend largely on whether the final products are mutually compatible. Styrene graft polymers have a low compatibility, while vinyl chloride graft polymers are compatible at all compositions and even in admixture with pure poly(vinyl chloride). Graft copolymers with high vinyl chloride contents have properties akin to hard poly(vinyl chlorides) of high impact strength, while those with high substrate contents are similar to soft poly(vinyl chlorides).

Polymerization of Formaldehyde by Adsorbed Water

G. Schröder, Darmstadt (Germany)

If anhydrous gaseous formaldehyde is passed into a suspension of an inorganic salt in a hydrocarbon, high molecular-weight polyoxymethylene dihydrates are obtained under certain conditions. Experimental findings lead to the conclusion that the polymerization proceeds by an anionic mechanism. The reaction is started at the crystal surface by the water adsorbed there. Although the polymer deposited is compact, the inorganic salt can be readily extracted with water.

This process has the following technical advantages over the polymerization of formaldehyde in the presence of tertiary amines:

1. Because of the compactness of the polymer formed, reactors of a given capacity can be used more economically.

2. Any traces of catalyst remaining in the polymer do not accelerate degradation of the polymer during subsequent processing.

3. The demands placed on the purity of the monomer and solvents in order to attain technically utilizable molecular weights are less stringent.

Transfer Reactions during the Cationic Polymerization of Trioxane

V. Jaacks, Mainz (Germany)

During the cationic polymerization of trioxane in the presence of low molecular-weight esters, anhydrides, acetals, or readily hydrolysable ethers, transfer reactions occur leading to thermostable polyoxymethylenes containing ester or ether end-groups. Analogous transfer reactions can also occur at the C–O–C groups of high molecular-weight polyesters, polyethers, or polyacetals. The products are then thermostable block or graft polymers, depending on whether the transferring group is in the main chain of the polymer, as for example in poly-1,3-dioxolane or poly(ethylene terephthalate), or in a side group as in poly(vinyl acetate). The influence exerted on the transfer reaction by water was discussed.

It is surprising that polyoxymethylenes stable to heat and alkalies are obtained in yields up to 65 % of the total products during homopolymerization of highly purified trioxane as well; this is ascribed to intramolecular transfer reactions.

Copolymerization of Formaldehyde with Cyclic Formals

H.-D. Hermann, Frankfurt/Main-Höchst (Germany)

Formaldehyde was copolymerized with cyclic formals in the presence of cationic catalysts. Pure monomeric formaldehyde was passed into an inert hydrocarbon in which the catalyst was dissolved, the comonomer being added simultaneously. Series of experiments were conducted by varying the polymerization temperature between −20 and +80 °C, the catalyst concentration between 0.01 and 0.2 % by weight (based on the monomers), and the comonomer concentration between 2 and 20 % by weight. The comonomers used were 1,3-dioxolane, 1,3-dioxane, 1,3-dioxacycloheptane, 1,3,6-trioxacyclooctane, and 1,3-dioxa-5-cycloheptene. The catalysts were $TiCl_4$, $BF_3{\cdot}(C_4H_9)_2O$, $SbCl_5$, and $SnCl_4$.

The copolymerization did not follow the equation of *Mayo* and *Lewis*. It is striking that the incorporation of comonomer is favored by increase in temperature and catalyst concentration. The nature of the catalyst is also an important factor influencing the composition of the copolymer. Antimony pentachloride and tin tetrachloride proved to be particularly effective catalysts.

Chemically uniform copolymers of high molecular weight, stable towards alkali, were obtained only over a restricted range of polymerization conditions, *e.g.* from formaldehyde plus 10 % by weight of 1,3-dioxacycloheptane with about 0.05 % by weight (based on monomers) of $SnCl_4$ at 60–80 °C.

The anomalous behavior of the copolymerization reaction is explained by transacetalizations between polymer molecules. This transacetalization [7] is promoted by increases in temperature and catalyst concentration, and its occurrence is proved by the fact that a uniform copolymer was obtained on polymerization of formaldehyde in the presence of a prepolymer containing formal groups.

Synthesis and Autoxidation of Poly(vinylthiol)

W. H. Daly, *K. Burg*, and *C. G. Overberger*, Brooklyn New York (U.S.A.) and Mainz (Germany)

S-Vinyl-*O*-t-butyl thiocarbonate was produced by simultaneous esterification and dehydrohalogenation of *S*-(β-chloroethyl) chlorothioformate with potassium t-butoxide. On polymerization with free-radical initiators, it yielded poly-(*S*-vinyl-*O*-t-butyl thiocarbonate), which was transformed into poly(vinylthiol) by removal of the t-butoxycarbonyl groups either by treatment with anhydrous hydrogen bromide or by thermolysis of the thiocarbonate substituents. The course of the latter reaction is analogous to that of the decomposition of methyl xanthate according to *Tschugaeff*.

The autoxidation of poly(vinylthiol) to the disulfide was studied in dimethyl sulfoxide using ferric sulfate as catalyst. The rates of oxidation of low molecular-weight dithiols were measured under standardized conditions and compared with that of the polymer; the following sequence of reactivities was observed: poly(vinylthiol) > 2,4-pentanedithiol > 2,5-hexanedithiol > 2,6-heptanedithiol. The reaction was of the

[7] *Cf. K. Weissermel, E. Fischer, K. Gutweiler*, and *H. D. Hermann*, Kunststoffe *54*, 410 (1964).

first order with respect to the Fe(III) ion and zero order with respect to the thiol content of the dithiols within the concentration range examined. A redox reaction between an Fe(III)- and an Fe(II)-thiol complex is postulated as a step of the autoxidation. The oxidation of the poly(vinylthiol) was not independent of the thiol concentration. Shielding of mercapto groups within the polymer coil and their reduced mobility may be possible explanations.

Investigations on the Molecular-Weight Jump Reaction of 1,4-cis-Polybutadiene

W. Ring and *H.-J. Cantow*, Marl (Germany)

The stereospecific polymerization of butadiene according to *Ziegler* to give *cis*-polybutadienes with a catalyst system containing an organocobalt and an organoaluminum compound occurs in homogeneous solution. Limits are set to the technical polymerization by the increase in viscosity resulting from the progress of the reaction and the increase in molecular weight of the polymer. However, an increase in molecular weight can be achieved after conclusion of the polymerization by adding reagents such as alkyl or acyl halides [8].

The mechanism of this molecular-weight jump reaction and its influence on the structure of the molecules was studied. It was shown that a cationic reaction mechanism is involved by using [^{14}C]-t-butyl chloride as reagent for boosting the molecular weight, by determining the molecular-weight distribution using a Baker-Williams column, and by viscometry and light-scattering photometry.

The average molecular weight, the distribution of molecular weights, and the molecular configuration can be controlled by selecting suitable reaction conditions.

Oxidation of Transition Elements by Organic Halides; Detection of Radicals by Polymerization Kinetics

G. Henrici-Olivé and *S. Olivé*, Zürich (Switzerland)

Colloidal suspensions of transition elements in tetrahydrofuran undergo electron transfer reactions with organic halides such as carbon tetrachloride or benzyl chloride. The metal is oxidized, *e.g.* $Co^0 \rightarrow Co^{2\oplus}$, and the carbon-halogen bond is split, giving rise to a free radical capable of initiating the polymerization of vinyl compounds.

Polymerization of methyl methacrylate was started in this way with the following metals: V^0, Cr^0, Fe^0, Co^0, Ni^0, and Pt^0. The free-radical mechanism of the polymerization was proved by the observed validity of the usual rate equations for free-radical kinetics and by copolymerization of methacrylate and styrene.

The rate of formation of the free radicals can be estimated from the overall rate of polymerization by following the reaction dilatometrically, and is different from one metal to another. For example, under comparable conditions at 90 °C, it is at least 300 times slower for vanadium than for cobalt.

Consequently, the polymerizations can be carried out with V^0 at this temperature to high conversions with a practically constant free-radical concentration, whereas the concentration of free radicals from Co^0 falls off with a half-life of 4–5 min.

Some New Aspects for the Quantitative Interpretation of Flow Birefringence

H. Janeschitz-Kriegl and *U. Daum*, Delft (Holland)

The flow properties of solutions of macromolecular substances are generally characterized by two phenomena: a) the dependence of the viscosity on the velocity gradient, and b) the occurrence of elastic stresses.

Investigation of flow birefringence proves to be a powerful tool for appraisal of the elastic properties. With this technique, the average coil expansion occurring during flow can be determined for dilute solutions at least [9]. This parameter can be considered as a (reduced) contribution of the individual molecules to the (elastic) tensile stress in the direction of flow. The experimental results obtained with solutions of anionically prepared polystyrenes show that the theory developed by *Zimm* [10] for the dynamic behavior of macromolecules applies up to an expansion which corresponds to an average increase in the end-to-end distance of about 10 % (relative to the value at rest). Surprisingly, even for these small expansions, tensile stresses can be expected in dilute solutions of a magnitude corresponding to viscometrically determined shearing stresses.

The situation becomes more complicated with polydisperse substances. The coil expansion corresponding to the tensile stress becomes an effective parameter which can be referred to the average expansion of the molecules with the aid of a polydispersity factor (*Peterlin*). The polydispersity factor increases sharply as the molecular-weight distribution becomes wider. When the distribution of molecular weights is broad, it also depends critically on the form of the distribution function. For example, the applicability of a Schulz distribution could be excluded for Marlex 5065 – a linear polyethylene – on the basis of the flow birefringence of its solution in *trans*-decalin at 135 °C.

Crystalline Compounds of Poly(ethylene oxides) and Polyesters with Urea and Thiourea

A. Kohler, *G. Hild*, and *R. Mayer*, Strasbourg (France)

Crystalline adducts of urea with poly(ethylene oxide), its derivatives containing end groups, or its block copolymers, are formed in a heterogeneous reaction on saturation of crystalline urea with a solution of the polymer in benzene. On the average, these adducts contain 28 % poly(ethylene oxide).

These compounds have a hexagonal crystal lattice which however does not resemble that of the channel-like inclusion compounds of urea.

Thiourea behaves similarly, but the content of poly(ethylene oxide) in its adducts is much higher.

Adducts of urea with polyesters are obtained in both heterogeneous and homogeneous media. They have a maximum polymer content of 33 % and belong to the hexagonal crystal system which characterizes the classical inclusion compounds of paraffins in urea.

We can now interpret the fractionation of polyesters on urea observed by *W. Kern* as being due to selective addition of the urea to the polymer fractions with the highest molecular weights. Poly(ethylene oxides) can also be fractionated by formation of their urea adducts.

Chlorinated Poly(vinyl chloride)

W. Trautvetter, Troisdorf (Germany)

The technical chlorination of poly(vinyl chloride) is carried out mainly by two methods: 1. in solution, and 2. in gels made by swelling PVC in a non-solvent. The products have the same chlorine contents but different properties (shape retention, solubility, stability, *etc.*).

The causes for the differences in properties were investigated, assuming that chlorinated products with approximately equal amounts of $-(CH_2-CHCl)-$, $-(CHCl-CHCl)-$, and $-(CH_2-CCl_2)-$ units are formed by both processes. Cross-linking during the chlorination of the gels or great non-

[8] *E. F. Engel*, Marl (Germany), 3rd International Synthetic Rubber Symposium, London, October 13-15th, 1964.

[9] *A. Peterlin*, J. chem. Physics *39*, 224 (1963).

[10] *B. H. Zimm*, J. chem. Physics *24*, 269 (1956).

uniformity in the degree of chlorination as possible explanations may be excluded. It is probable that products are formed during the chlorination in gels with great differences in the lengths of the sequences of the three basic structural units.

Elucidation of the Microstructure of Polymers by Nuclear Magnetic Resonance Spectroscopy

U. Johnsen, Darmstadt (Germany)

The proton resonance spectra of vinyl polymers with a simple α-substituent are much easier to analyse when the coupling between the α- and β-protons is cancelled by double resonance. This method was used to elucidate the microstructures of some poly(vinyl chlorides).

The spectra reveal that on chlorination of PVC, the methylene groups are substituted with three to four times higher probability than the chloromethylene groups. In addition to non-chlorinated monomer units, the chains contain only the structural units $-(CHCl-CHCl)-$ and $-(CCl_2-CH_2)-$. The frequency of recurrence of these structural units, the average lengths of uniform blocks made up of these units, and the chlorine contents of the products studied were determined.

[VB 910/228 IE]
German version: Angew. Chem. 77, 509 (1965)

On the Chemistry of Amphoteric Oxides

R. Hoppe, Münster (Germany)

Amphoteric metal oxides can react with "acidic" non-metal oxides [*e.g.* $Tl_2O_3 + 3\ SO_3 \rightarrow Tl_2(SO_4)_3$] as well as with "basic" metal oxides [*e.g.* $Tl_2O_3 + Na_2O \rightarrow 2\ NaTlO_2$]. Little has been reported on ternary oxides of the alkali metals which, like $NaTlO_2$, belong to the second group of compounds.

Many new oxides have been prepared which, according to their crystal structure, represent transitions between the extreme types "mixed oxide" and "oxo complex". Of these, the following are noteworthy:

The previously unknown oxogallates $KGaO_2$, $RbGaO_2$, and $CsGaO_2$ were prepared at 400–450 °C in 20–24 hours under dry nitrogen, *e.g.*

$$2\ CsO_{1.25} + Ga_2O_3 \rightarrow 2\ CsGaO_2$$

They are colorless powders and extremely sensitive to moisture. The crystal structure of $KGaO_2$ was determined on single-crystals using Fourier methods. $KGaO_2$ crystallizes pseudocubic, orthorhombic with $a = 5.51_5$ Å, $b = 11.07_6$ Å, and $c = 15.81_8$ Å, with $Z = 16$ formula units per unit cell [$d_{x\text{-}ray} = 3.87$ and $d_{pyk} = 3.78$ g·cm^{-3}] in the space group D_{2h}^{15}-Pbca. All particles occupy the equivalent position 8 (c) with the following provisional parameters:

	x	y	z	−B
Ga_1	0.260	0.008	0.189	0.59
Ga_2	0.279	0.264	0.065	0.68
K_1	0.749	0.014	0.062	1.71
K_2	0.796	0.264	0.186	1.12
O_1	0.578	0.298	0.014	2.46
O_2	0.170	0.404	0.100	0.46
O_3	0.286	0.173	0.155	1.75
O_4	0.905	0.479	0.224	2.77

Of 976 possible reflections (0kl) to (4kl), 663 have been observed; Mo–K_α radiation; I_o determined photometrically from "integrated" Weissenberg photographs, $R = 0.15_3$ and $R' = 0.25$.

$KGaO_2$ is the first compound of the $KFeO_2$ structure-family with a proven structure. According to powder photographs this family includes the cubic or pseudocubic compounds $KFeO_2$ ($a = 7.95_8$ Å) [1], $RbFeO_2$ ($a = 8.10$ Å) [2], $CsFeO_2$ ($a = 8.32$ Å) [2], $KAlO_2$ ($a = 7.79$ Å) [3], $RbAlO_2$ ($a = 7.73$ Å) [4], $CsAlO_2$ ($a = 8.10$ Å) [4], $RbGaO_2$ (rhombic, $a = 5.64$ Å, $b = 11.37$ Å, $c = 16.19$ Å, isotypic with $KGaO_2$) [4], $CsGaO_2$ (rhombic, $a = 5.83$ Å, $b = 11.68$ Å, $c = 16.50$ Å, perhaps isotypic with $KGaO_2$, possibly also cubic with $a = 16.50$ Å) [4], and, according to single-crystal investigations, the cubic $CsScO_2$ ($a = 17.45$ Å) [4]. As already supposed from powder photographs these compounds have a "filled framework structure" of the β-cristobalite type. Distances for $KGaO_2$: Ga–O = 1.68–1.95 Å (4×); K–O = 2.53–3.52 Å (8×).

$NaGaO_2$ [5] occurs as two modifications; the low-temperature form (α) is of the β-$NaFeO_2$ type according to single-crystal investigations, and is a variant of the wurtzite-type. The rhombic unit cell with $a = 5.30_1$ Å, $b = 5.51_9$ Å, $c = 7.20_1$ Å, space group C_{2v}^9–$P2_1nb$, contains four formula units; all particles occupy the equivalent positions 4 (a), with the parameters:

	x	y	z	−B
Na	0.240	0.410	0.126	2.70
Ga	0.746	0.061	0.123	1.05
O_1	(0.81)	0.395	0.173	1.70
O_2	0.418	0.060	0.102	1.60

38 of 49 possible reflections (0kl) with $R = 0.12$ and $R' = 0.14$, and 26 of 28 possible reflections (h0l) with $R = 10.7$ and $R' = 10.7$ were observed, Cu–K_α radiation, "integrated" Weissenberg photographs, I_o determined photometrically. Distances: Ga–O = 1.75–1.98 Å (4×); Na–O = 2.16–2.43 Å (4×). Refinement is in progress [$x(O_1)$ still uncertain].

β-$NaGaO_2$, prepared by heating α-$NaGaO_2$, crystallizes analogous to $KGaO_2$ according to powder photographs.

Recent Investigations on Oxidases and Peroxidases

C. Baron, Dijon (France)

Preparative, enzymological, and physiological investigations of two liver enzymes were discussed. These enzymes play a role in the metabolism of healthy and cancerous cells which has but little been studied. They are catalase, an otherwise well-investigated enzyme, and amine oxidase, of the properties of which relatively little is known.

As catalase has a healing effect on skin injuries, experiments with artificially (by calcium triphosphate) produced granulomas were performed. Catalase caused intensive fibroblast proliferation and the formation of collagen fibres.

The enzyme preparations were crystalline catalase and less pure amine oxidase preparations. This second enzyme is firmly attached to mitochondria and thus difficult to enrich. Detergents, especially a 0.2 % solution of sodium lauryl sulfate at pH 7 and 20 °C, proved most effective in loosening this attachment. In this way, it was possible to bring into solution about 30 % of the enzyme, without loss of activity, in the first step, and a further 20 % in the second step. The preparations were free from diamine oxidase activity.

[4] Author's own investigations.

[5] Recently prepared by *B. N. Ivanov-Emin* and *J. I. Rabovik*, Zhur. obshch. Khim. *17*, 1061 (1947).

Metabolic products of cancer cells have an inhibiting action on catalase. That healthy cells also contain catalase inhibitors was shown by inhibition experiments, chiefly with cell extracts from chicken embryos, which are characterized by accelerated cell growth similar to cancer tissue. Thermostable, dialysable catalase-inhibitors were found in decreasing concentrations in liver, heart, and brain. In the cells of these organs, the inhibitors are distributed in decreasing amounts in mitochondria, cell nuclei, and cell membranes.

Nothing is known about the chemical character of these inhibitors. Catalase-inhibitors of known constitution fall into three groups: diphenols, metabolic products of tryptophane or 5-hydroxytryptophane, and quaternary ammonium compounds. Tryptamine and serotonin, which are substrates of amine oxidase, belong to the second group.

Besides the hydrazides, iodine derivatives of noradrenaline and tyramine are inhibitors for amine oxidase. It must be assumed that amine oxidase-inhibiting substances also occur in cell extracts.

German version: Angew. Chem. 77, 549 (1965)

Preparation and Rearrangement of Distyrylmethanol Derivatives and a New Route to Reductones

G. Hesse, Erlangen (Germany)

The alcohols *(1a)–(1d)* were prepared from dibenzylideneacetones with $NaBH_4$ [1]. The reduction proceeds the more slowly, the richer the allyl system is in electrons. $NaBH_4$ does not attack compounds where $X = Y = N(CH_3)_2$, while on reduction with $LiAlH_4$ the hydroxy group is eliminated and 1,5-bis-(*p*-dimethylaminophenyl)-1,3-pentadiene is formed. Acids or activated aluminum oxide cause an *allylic* rearrangement of the alcohols *(1)* to the alcohols *(2)*. The reaction is of first order with regard to the alcohol concentration. The rate constants are proportional to the H^+ ion concentration. The methyl ethers of *(2)* are formed in methanol. The rearrangement proceeds $^1/_{10}$ as fast in dioxane or methanol containing 20 % water as in the anhydrous solvents. Its rate increases again at higher water content. Compound *(1c)* rearranges more slowly, *(1b)* and *(1d)* rearrange more rapidly than *(1a)*. This corresponds to the basicity of the hydroxy group in these compounds. The reaction probably takes the following course:

$$X\text{-}C_6H_4\text{-}CH{=}CH\text{-}CHOH\text{-}CH{=}CH\text{-}C_6H_4\text{-}Y \rightarrow X\text{-}C_6H_4\text{-}CHOH\text{-}(CH{=}CH)_2\text{-}C_6H_4\text{-}Y$$

(1) *(a)*: X = Y = H; *(c)*: X = Y = Cl — *(2)* *(b)*: X = Y = OCH_3; *(d)*: X = H, Y = OCH_3

$$R\text{-}OH + H^{\oplus} \xrightarrow{\text{slow}} R\text{-}\overset{\oplus}{O}H_2 \xrightarrow{-H_2O}$$

(1)

$$R^{\oplus} \leftrightarrow R'^{\oplus} \xrightarrow{H_2O} R'\text{-}OH + H^{\oplus}$$

(2)

$$R'^{\oplus} \xrightarrow{CH_3OH} R'\text{-}OCH_3 + H^{\oplus}$$

The (colored) carbonium ions can be rendered visible during the rearrangement by a special procedure: If the rearrangement is carried out in absolute benzene in the presence of acidic anhydrous silica gel, the reactants of the final step – water and $R'^{\oplus}$ – are adsorbed at separate points for a short time before they react with each other. Distyrylmethanol and its derivatives absorb oxygen after a long induction period, which can be abolished by the addition of dibenzoyl peroxide. The stability of the preparations increases in the order *(1b)* < *(1d)* < *(1a)* < *(1c)*.

[1] Experiments in cooperation with *P. Thieme*.

Compound *(1c)* yields triose reductone on ozonolysis, followed by catalytic hydrogenation. The formation of reductic acids from α,α-dibenzylidenecyclopentanol and -hexanol was shown in preliminary experiments [2].

An Oscillating Fermentation System from Yeast

B. Hess, Heidelberg (Germany)

Fermentation by *Saccharomyces carlsbergensis* (inositol-lack mutant) begins to oscillate when oxidative phosphorylation is prevented. By means of gentle high-pressure extraction or ultrasound treatment, the oscillating system can be obtained as a homogeneous cell-free extract of high concentration. Warming or addition of glucose 6-phosphate causes the system to oscillate with a period of about 0.1 min^{-1}, a damping factor of 1.1–1.4 and a Q-value of 4–6 at 25 °C. Analysis of the enzyme distribution pattern indicates that all known components of fermentation are present, but the activity of phosphofructokinase is relatively low. The metabolite pattern of the cold extract (+2 °C) shows the proportions and levels of an almost frozen fermentation with a relatively high magnesium concentration and a pyridine nucleotide concentration of 48 % which takes part in the oscillations. The rest of the metabolite pattern corresponds to the concentrations which are necessary for a feedback control of phosphofructokinase and of the glyceraldehyde-3-phosphate dehydrogenase/phosphoglycerate kinase system. Addition of substrates and metabolic intermediates can influence the partly sinusoidal wave forms, in part with a shift in phase. Additions of pure fermentation enzymes lead to shifts of the stationary equilibria of the components involved in the oscillation. Additions of phosphoglycerate kinase, phosphoglycerate mutase, and enolase sufficient to cause a doubling of the endogenous enzyme concentration lead to a raise in the frequency of the oscillations and to their stabilization. The activity of these enzymes decreases in the order given. They cause the average redox state of the pyridine nucleotides to be shifted toward the oxidized side. Conversely, the addition of highly purified phosphofructokinase brings about an increase in frequency and a shift of the average redox state of the pyridine nucleotide system to the reduced side. These findings demonstrate the cooperative activity of the glycolytic enzymes during oscillation. It may be assumed that oscillation is a phenomenon which can be induced in many varieties of cells and which is of importance for periodic biological processes.

New Aspects of the Koch Carboxylic Acid Synthesis

K. E. Möller, Mülheim/Ruhr (Germany)

The addition of CO and CH_3OH to cyclic mono-olefins in the presence of $H[BF_3\text{-}OCH_3]$ as catalyst [3] does not lead, in the case of cyclo-octene, cyclononene, and cyclodecene, to the expected methyl esters of secondary cycloalkanecarboxylic acids. Instead, the methyl esters of tertiary

[2] Experiments in cooperation with *E. Bayer*.

[3] *K. E. Möller*, Angew. Chem. 75, 1122 (1963); Angew. Chem. internat. Edit. 3, 148 (1964).

1-alkylcycloalkane carboxylic acids are formed by ring contraction. The secondary cycloalkyl cation first formed in the proton-catalysed reaction therefore isomerizes to the tertiary alkylcycloalkyl cation before it reacts with CO. Since the stability of a tertiary carbonium ion is greater than that of a secondary carbonium ion the Koch carboxylic acid synthesis starting from 1-methylcycloalkenes should yield tertiary 1-methylcycloalkanecarboxylic acids with preservation of the ring system. All the 1-methylcycloalkenes from 1-methylcyclobutene to 1-methylcyclododecene were reacted at 15 °C and a CO-pressure of 150 atmospheres in the presence of $H[BF_3{\cdot}OCH_3]$. In every case the methyl ester of the expected 1-methylcycloalkanecarboxylic acid was formed. A yield of only 10 % of methyl 1-methylcyclononanecarboxylate in the isomer mixture shows that under the conditions used the nine-membered ring possesses the lowest stability; the eight- and the seven-membered rings follow, with yields of 50 % and 60 % respectively. All the other methylcycloalkenes react to give exclusively, or at least over 90 %, methyl 1-methylcycloalkanecarboxylate.

[GDCh-Ortsverband Marl/Kr. Recklinghausen (Germany),

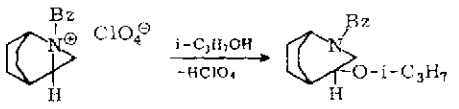
Experiments with Bridged Cyclic Systems Containing Nitrogen

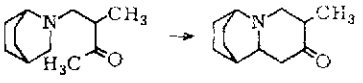
W. Schneider, Karlsruhe (Germany)

On dehydrogenation with mercuric acetate, tertiary isoquinuclidines are dealkylated or converted into imonium salts, depending on the nature of the substituent on the nitrogen [1]. The action of diazomethane on the *N*-benzylimonium salt yields the tricyclic aziridinium salt *(1)*, which reacts with isopropanol to afford *(2)*:



(1) *(2)*

With formaldehyde and CH-acidic compounds, isoquinuclidine yields Mannich bases, *e.g. (3)*; on dehydrogenation with mercuric acetate, *(3)* is cyclized to *(4)*.



(3) *(4)*

The *N*-acetyl derivative of nortropinone can be converted *via* the dicyanomethylene compound (70 % yield) by successive hydrolysis, hydrogenation, and esterification into ethyl nortropanyl 3-acetate, which possesses α-configuration and is not suitable for cyclization to quinuclidine derivatives. *N*-Acetylpseudopelletierine affords the dicyanomethylene compound in only 14 % yield, which suggests a diminished reactivity at C-3 as a result of steric hindrance.

1,2,6-Trimethyl-4-piperidone is converted, like nortropinone, *via* analogous intermediates into ethyl 1,2,6-trimethylpiperidin-4-yl malonate or acetate. 1,2,6-Trimethylpiperidin-4-ylethyl chloride, obtainable from the corresponding alcohol, can be cyclized to the 1,2,6-trimethylquinuclidinium salt.

The OH···N bridges in pyridine/methanol mixtures formed the subject of valence bond calculations and ^{14}N nuclear magnetic resonance studies by *H. Saito, K. Nukada, H. Kato, T. Yonezawa*, and *K. Fukui*. If the OH···N bridges are regarded to be formed by delocalization of the proton, then three structures, *viz.* I: X–H Y (covalent); II: $X^{\ominus}H^{\oplus}$ Y (ionic); and III: $X^{\ominus}$ $H{-}Y^{\oplus}$ (charge transfer), must be considered; the coefficients of the complete wave function then give the percentage weights w of the structures I, II, and III shown in the table.

X–H···Y	X···Y [Å]	X–H [Å]	Bridge bond energy [kcal/mole]	w_I [%]	w_{II} [%]	w_{III} [%]
O–H···N	2.80	1.05	12.0	76.7	14.1	9.2
O–H···O [1]	2.80	0.986	6.8	85.2	12.0	2.8

The shift of the ^{14}N–NMR signal in pyridine/methanol at the mole fraction $x = 0.5$ is 9 ± 3 ppm compared to the signal of pure pyridine. The shift of the proton signal for the methanol hydroxy group is greatest at $x = 0.5$; this indicates that a 1:1 complex with a bridge stronger than the OH···O bridge is present. For the actual structure, the effective shift is calculated to be $\delta = w_I\delta_I + w_{II}\delta_{II} + w_{III}\delta_{III}$. Since $\delta_I = 0$ and $\delta_{II} \approx 0.2$ ppm, then $\delta \approx w_{III}\delta_{III}$. If it is assumed that the $^{\ominus}N$–H distance, the paramagnetic shielding, and the excitation energy in the (pyridine·H)$^{\oplus}$ ion and in structure III are almost identical, then δ_{III} can be taken as 123 ± 11 ppm, *i.e.* as the shift of the (pyridine·H)$^{\oplus}$ signal relative to that of free pyridine. It follows that $w_{III} = 7 \pm 3$ %, a value in satisfactory agreement with that given in the table. Previously, a structure III had been assumed, but no evidence for it was available. / Tetrahedron Letters *1965*, 111 / - Jg. [Rd 242/452 IE]

Charge-transfer complexes between rhodane and aromatic hydrocarbons have been observed and characterized by spectroscopy by *W. Scholz, A. Trutia*, and *V. Vantu*. The absorption spectra were independent of the concentration

λ_{max}, ε_{max}, and the equilibrium constants K_{CT} for the 1:1 charge-transfer complexes between $(SCN)_2$ and aromatic hydrocarbons in n-heptane at 20 °C.

Donor	λ_{max}	ε_{max}	K_{CT}
Benzene	279	5720	0.98
Toluene	286	3490	2.35
o-Xylene	290	4200	2.55
m-Xylene	290	3890	2.94
p-Xylene	293	2750	3.35
Mesitylene	303	3285	5.01
m-Dioctylbenzene	–	–	≈18

and could be evaluated using the simple Benesi-Hildebrand equation [Equation (a)] for 1:1 equilibria. The rhodane absorption (in n-heptane: $\lambda_{max} = 294$ mμ, $\varepsilon_{max} = 203$; $\lambda_{max} = 240$–230 mμ, $\varepsilon_{max} = 689$–1052) overlaps the strong charge-transfer band with all donors.

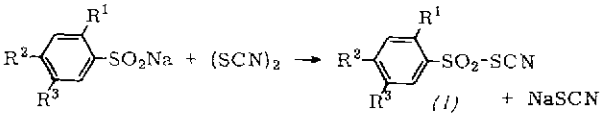
$$1/(\varepsilon_a - \varepsilon_A) = 1/(\varepsilon_C - \varepsilon_A) + [(1/K_{CT})(\varepsilon_C - \varepsilon_A)]/d \qquad (a)$$

ε_A and ε_C = molar extinction coefficients for the acceptor and complex, respectively; $\varepsilon_a = m/a$; m = optical density of the solution; a and d = amounts of acceptor and donor taken.

Photochemical reactions or polymerization of the $(SCN)_2$ did not occur; however, the solutions of the mesitylene complex decompose after a few minutes. The values for K_{CT} are very similar to those of the analogous bromine and iodine complexes. / Tetrahedron Letters *1965*, 57 / –Jg. [Rd 240/451 IE]

[1] Values for comparison taken from *C. A. Coulson* and *U. Danielsson*, Ark. Fysik *8*, 239, 245 (1954).

Arylsulfonyl thiocyanates have been obtained by *J. Goerdeler* and *P. Rosenthal* by adding sodium or silver salts of a sulfinic acid at 0 °C to a solution of dithiocyanate ($C_2N_2S_2$) in CCl_4. The products decompose on heating. Nucleophilic reagents attack mainly their S–S bond. Diazomethane becomes inserted between the two sulfur atoms to give for example *(3)*. The sulfonyl thiocyanates *(1)* add onto olefinic bonds to give β-thiocyanato sulfones *(2)*; this reaction is accelerated by radical formers. Products prepared include *(1)*, $R^1 = R^2 = R^3 = H$, m.p. 28–29 °C, in 49% yield, *(1)*, $R^1 = R^3 = H$, $R^2 = CH_3$, m.p. 35–36 °C, in 84% yield, *(1)*, $R^1 = CH_3O$, $R^2 = R^3 = H$, m.p. 47–48 °C, in 71% yield, and *(1)*, $R^1 = Cl$,



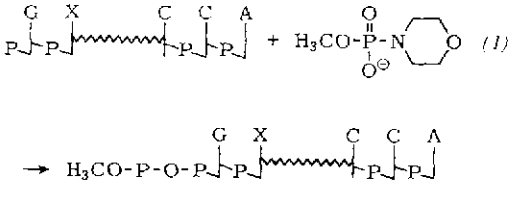
(1) + NaSCN

H_5C_6-CH(SCN)-CH_2-SO_2-C_6H_4-Cl(p) *(2)*

(p)Cl-C_6H_4-SO_2-CH_2-SCN *(3)*

$R^2 = R^3 = H$, m.p. 76–77 °C, in 75% yield. / Tetrahedron Letters *1964*, 3665 / –Ma. [Rd 203/412 IE]

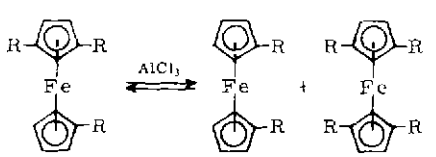
The labelling of terminal groups in polynucleotides can be achieved by two new methods discovered by *H. G. Khorana* et al. Both ribopolynucleotides and deoxyribopolynucleotides can be phosphorylated at the terminal phosphoric monoester group using methyl phosphoromorpholidate *(1)*. The cetyltrimethylammonium salt of the polynucleotide is made at pH 7.5 with cetyltrimethylammonium bromide and dissolved in dimethylsulfoxide, where it reacts slowly with *(1)* at room temperature (100 h), 70–85% of the end groups being phosphorylated. Amino-acid transfer RNA (sRNA) labelled in this way retains its full capacity as an amino-acid acceptor. The second method entails specific acetylation of terminal hydroxy groups with acetic anhydride in aqueous solution at



(1)

pH 7 and room temperature, but is restricted to deoxyribopolynucleotides. Here 60–90% labelling occurs, and the resultant esters are stable below pH 8. / J. biol. Chemistry *239*, 3875, 3885 (1964) / –Hö. [Rd 213/422 IE]

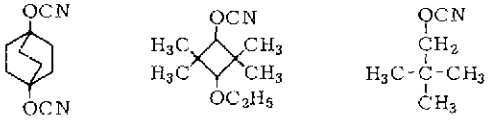
Ring migration and transalkylation in alkylated ferrocenes has been observed by *D. E. Bublitz*. Alkylferrocenes undergo disproportionation in boiling methylene dichloride under nitrogen in the presence of $AlCl_3$ or $GaCl_3$ to give ferrocene and 1,1′-dialkylferrocenes. For example, equilibrium mixtures containing 1,1′,3-triethylferrocene *(1)*, 1,1′-diethylferrocene *(2)*, and 1,1′,3,3′-tetraethylferrocene *(3)* were obtained in this



(1) R = C_2H_5 *(2)* *(3)*

way. 1,1′-Diethylferrocene becomes equilibrated with ethylferrocene (3.88%) and 1,1′,2-triethylferrocene (2.70%). Partial dealkylation also occurs, although only to a small extent. / Canad. J. Chem. *42*, 2381 (1964) / –Ma. [Rd 205/414 IE]

The synthesis of aliphatic cyanates ROCN has been carried out by *J. C. Kauer* and *W. W. Henderson*. Stable products are obtained only if the alkyl group R is bulky enough to prevent trimerization of the cyanates and if the carbonium ion $R^{\oplus}$ has enough energy to suppress solvolysis. Thus, for example, the action of either NaH or butyl-lithium plus ClCN on 1,4-dihydroxybicyclo[2,2,2]octane, 3-ethoxy-2,2,4,4-tetramethyl-1-cyclobutanol, and neopentyl alcohol gives rise to the cyanates *(1)*, m.p. 155–156 °C (41% yield), *(2)*, b.p. 63 °C/0.1 mm (30%), and *(3)*, b.p. 123 °C/185 mm (4.4%), respectively.

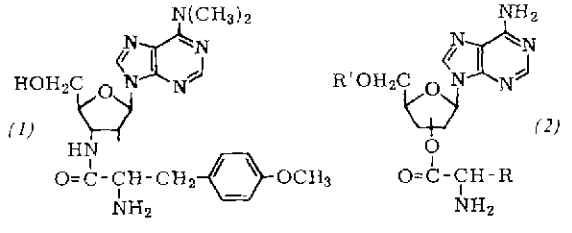


(1) *(2)* *(3)*

The dicyanate *(1)* rearranges on treatment with BF_3 etherate to the diisocyanate, m.p. 111.5–112 °C. / J. Amer. chem. Soc. *86*, 4732 (1964) / –Ma. [Rd 207/416 IE]

The synthesis of organophosphorus compounds by alkylation of elemental phosphorus is described by *H. P. Angstadt*. Phosphorus reacts with alkylcarbonium ions to give alkylphosphorus compounds. When 1.5 mole of t-butyl chloride is added dropwise to a solution of 1.0 mole of white phosphorus in CS_2 containing 1.5 mole of $AlCl_3$ at –10 °C under an atmosphere of HCl and the resultant mixture is poured into ice-cold 4 N HNO_3 (or 30% H_2O_2), di-t-butylphosphinyl chloride $(C_4H_9)_2POCl$, m.p. 80.1–80.9 °C, is obtained in 30% yield, together with some di-t-butylphosphine oxide. Other alkyl halides and Lewis acids alkylate phosphorus analogously. t-Amyl chloride gives rise to di-t-amylphosphinyl chloride, di-t-butylphosphinyl chloride, and t-amyl-t-butylphosphinyl chloride, together with the corresponding secondary phosphine oxides, since disproportionation occurs under the influence of the $AlCl_3$. Isopropyl, n-butyl, cyclohexyl, and n-octyl chlorides also react smoothly. / J. Amer. chem. Soc. *86*, 5040 (1964) / –Ma. [Rd 210/419 IE]

Inhibition of protein synthesis by puromycin has been observed by *D. Nathans*. The reason for this inhibition probably is the similarity between puromycin *(1)* and the adenosine end of aminoacyl-5RNA *(2)*, which enables puromycin to become incorporated into the growing amino-acid chain instead of *(2)*. This reaction is catalysed by an amino-acid transfer enzyme. The oligopeptide chain cannot continue to grow after incorporation of the puromycin and is released from the ribosome.

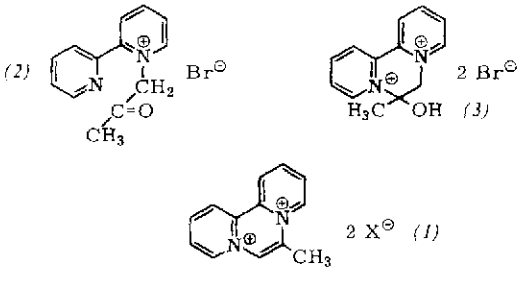


(1) *(2)*

Hence only oligopeptides are produced in protein-synthesizing systems in the presence of puromycin; these cannot be precipitated with trichloroacetic acid. It was shown that radioactively labelled puromycin is incorporated into these oligopeptides. Uniform results were obtained with the following systems: polyuridylic-acid controlled polyphenylalanine synthesis in *E. coli* extracts, synthesis of the protein fraction of RNA coliphages MS2 in *E. coli* extracts, and hemoglobulin synthesis in rabbit reticulocytes. / Federat. Proc. *23*, 984 (1964) / –Hö. [Rd 214/423 IE]

A regulator gene determines a protein. *A. Garen* and *N. Otsuji* proved this for the repression of the alkaline phosphatase from *E. coli* by isolating, purifying, and identifying the protein determined by the regulator gene R2a. Three functions are essential for repression of the alkaline phophatase; these are directed by the regulator genes R1, R2a, and R2b. Mutants which are constitutive for alkaline phosphatase have one protein less than the wild strain. This protein, which is determined by the regulator gene R2a, was purified by ammonium sulfate fractionation and high-voltage electrophoresis; its purity was checked by sedimentation analysis and by its immunochemical properties. Its connection with gene R2a was proved by the fact that mutations of R2a alter the electrophoretic mobility of the protein. The formation of the protein is induced and repressed by the same factors as the formation of alkaline phosphatase. It is therefore thought that the R2a protein is not the repressor itself, but either a precursor of the repressor or a substance which participates in the synthesis of the repressor. The alkaline phosphatase constitutes about 6% of the total cell protein, and the R2a protein 0.25%. / J. molecular. Biol. *8*, 841 (1964) / –Hö. [Rd 216/425 IE]

The 9-methyl-8a,10a-diazoniaphenanthrene cation *(1)*, an aromatic ring system containing two quaternary nitrogen atoms in a single ring, has been made by *I. C. Calder* and *W. H. F. Sasse*. 1-Acetonyl-2-(α-pyridyl)pyridinium bromide *(2)*, m.p. 163–164 °C, was prepared from 2,2'-bipyridyl and bromoacetone in 73% yield and reacted with 48% HBr at room temperature to give 9-hydroxy-9-methyl-9,10-dihydro-8a,10a-diazoniaphenanthrene dibromide *(3)*, m.p. 220–225 °C (decomp.). The latter could be converted with refluxing $SOCl_2$ into a mixture of the dibromide and dichloride of *(1)*; its



(2) *(3)* *(1)*

picrate melts at 243–245 °C (decomp.). Aqueous solutions of *(1)* are stable in diffuse daylight but are decomposed by ultraviolet light. / Tetrahedron Letters *1964*, 3871 / –Ma. [Rd 208/417 IE]

The crystal structure of methyl-lithium has been worked out from its Debye-Scherrer diagram by *E. Weiss* and *E. A. C. Lucken*. Its body-centered cubic unit cell has a = 7.24 ± 0.01 Å and contains 8 CH_3Li. Groups of four lithium atoms form regular tetrahedra with an Li–Li distance of 2.56 Å. There is a methyl group situated above the center of every tetrahedral surface. Within this tetrameric structural unit $(CH_3Li)_4$, the carbon atoms form a system of polycentered bonds with the three neighboring lithium atoms and the other three carbon atoms. The molecular-orbital term series for the tetrameric methyl-lithium was set up on the assumption that the lithium atoms make their s and p orbitals available. There is one non-degenerate lowest state and a slightly higher threefold degenerate state in which the eight valence electrons can be distributed. Interaction of each tetrameric molecule with its neighbors causes an association of discrete terms to bands with simultaneous lowering of the total energy content. It is this effect which causes the three-dimensional interlinking of methyl-lithium by bonds which are stronger than normal van der Waals forces, and this determines essentially the properties of methyl-lithium (*e.g.* its low volatility and solubility). / J. organometallic Chem *2*, 197 (1964) / –Eb. [Rd 192/401 IE]

Anorganische Chemie [Inorganic Chemistry]. By *K. A. Hofmann*. Edited by *U. Hofmann* and *W. Rüdorff*. Verlag Friedrich Vieweg & Sohn, Braunschweig 1963. 17th completely revised and extended edit., XII + 862 pp., 122 figs., 10 colored spectra, linen DM 28.– (about $ 7.–).

Even the exterior of this new edition of "Hofmann-Rüdorff" differs from its predecessors; the format of the book is larger, and the typographic appearance has been improved. The individual chapters are now organized more clearly; simultaneously, numerous significant transpositions and revisions have taken place in many sections, with great benefit to the book as a whole. Numerous illustrations have been modernized or replaced, without significant increases in the length of the book. The well proved division into metals and nonmetals has been retained, and a good supplementary chapter deals with organometallic compounds, water-like solvents, the solid state, catalysis, molecular structure, atomic nuclei, and extraterrestial chemistry.

After an introduction comes the discussion of the elements oxygen and hydrogen and of the properties of water, including osmosis, the ionic theory, the law of mass action and its applications, followed by sections on the rare gases and the periodic system, and explanations of ionization, oxidation, and reduction. Next nitrogen and its compounds and the Group VI elements and their compounds are discussed. Sections on atomic structure and the chemical bond follow. The reviewer suggests that in future editions, atomic structure and the fundamentals of the chemical bond should be described immediately after the laws of stoichiometry, for then numerous phenomena such as oxidation and reduction and concepts involved in the ionic theory can be explained and derived in the logical manner.

The treatment of the chemical bond, particularly in complexes, where recourse is made to valence bond methods and the ligand field theory, is particularly good. The descriptions of the elements and their compounds are mostly brought up to date. A few minor errors may be referred to here: nitrous acid is known in the gaseous – *i.e.* the free – state; the so-called stannic acids are not oxide hydrates; the dark red polyvanadate that occurs transiently on acidification of vanadate solutions is not an octavanadate, but probably a dodecavanadate; the existence of trichromate and tetrachromate ions is very questionable; in the formula CrO_5, the ligand occupying the fourth coordination site (ether, pyridine, *etc.*) is missing; $Mn^{3\oplus}$ ions and not $MnO_4^{\ominus}$ are formed during the oxidation of manganese(II) sulfate with peroxodisulfate in the presence of $Ag^{\oplus}$ ions.

All in all, this is a praiseworthy textbook which will certainly gain many new friends in addition to its old acquaintances.

O. Glemser [NB 354/212 IE]

Chemisches Praktikum für Mediziner und Studierende sonstiger an Chemie interessierter Wissenschaften (Practical Chemistry for Medical Students and Students of Other Sciences Affiliated to Chemistry). By *R. Schwarz* and *P. W. Schenk*. Verlag Johann Ambrosius Barth, Leipzig 1964. 13th Edit., 152 pp., 3 figs., stiff covers, DM 4.20 (about $1.10).

The group of students for whom this book is intended consists mainly of medicine and biology students. Consequently the principles of chemical education conveyed – experiments in the chemistry of the individual elements, wet separation of cations, anion analysis – are tailored to fit the needs of this group. However, there is a lack of experiments acquainting the student with biochemically important methods of analysis (*e. g.* adsorption and extraction, including chromatography, pH measurements and titrations using the glass electrode, colorimetric and photographic experiments, ion-exchange techniques, *etc.*). Instead of a chapter on the standardization of sodium hydroxide solutions for titrations with oxalic acid, a short note on commercially available ampoules containing standardized solutions would have sufficed .– The theoretical discussions are sometimes good (*e. g.* bases) but often too short (*e. g.* the chemical bond). It might be more advantageous to omit this chapter on the chemical bond and refer the student to good textbooks – for it is not intended to spare the student the study of these – and instead to give a more profound treatment to topics (*e. g.* the law of mass action, the ionic theory, buffers, and pH) that are of prime importance for medical and biology students. The formula for nitric acid with two double bonds should be modernized.

Ulrich Schmidt [NB 320/178 IE]

Diuretics. Chemistry and Pharmacology. By *G. de Stevens*. Vol. I of the Series: Medicinal Chemistry. Edited by *G. de Stevens*. Academic Press, New York-London 1963. 1st Edit. XIII + 186 pp., numerous illustrs., linen $7.00.

George de Stevens, who is well known on account of his fundamental work on diuretics, presents with his monograph on the pharmacology and chemistry of diuretics the first volume of a new series on medicinal chemistry.

The book is divided into nine chapters. Following general physiological and pharmacological considerations, xanthenes and pyrimidines, triazines, organomercury compounds, sulfonamides, thiazides and hydrothiazides, aldosterones, and compounds which do not belong to any of these classes are dealt with in seven separate chapters. The final chapter is devoted to therapeutic applications of diuretics for treatment of hypertonic disturbances.

The first chapter contains two sections, one on the functions of the kidneys, and the other on the pharmacological use of diuretics. The latter section (2 pp.) is unfortunately far too short and does not do justice to the vast importance of this field. – The xanthenes and pyrimidines receive attention on about 15 pp., the triazines on 6, and the organomercury compounds on 10. In view of the diminished practical importance of these groups, this treatment is absolutely adequate. – Sulfonamides, thiazides, and hydrothiazides are dealt with thoroughly on about 70 pp., and the aldosterone derivatives on about 25, with coverage of all aspects. The concluding chapter on the therapeutic applications of diuretics for reducing high blood-pressure is well written and gives valuable information and incentives for further work on this extremely important field of indications.

In contrast to the series "Fortschritte der Arzneimittelforschung" founded in 1959 and the series "Progress in Medicinal Chemistry" started in 1961, *de Stevens* appearently wants to treat a single field of chemico-medical research in each individual volume. The volumes planned for the future will sometimes deal with research topics that have so far not been reviewed comprehensively, and hence the series is to be welcomed. However, monographs on analgetics and psychopharmaceuticals are stated to be in preparation, and it is therefore questionable whether this duplicity and overlapping of topics with analogous articles which have, in some cases, been published only recently is worthwhile and advantageous. However, if we are to restrict our criticism to the present first volume, then the author/editor is to be commended for his comprehensive and fine presentation of this difficult material, and the publishers for the purposeful outlay and orderly appearance of the book.

E. Jucker [NB 329/187 IE]

Infrared Spectroscopy of High Polymers. By *R. Zbinden*. Academic Press, New York-London 1964. 1st. Edit., XII + 264 pp., numerous figures and tables, linen, $9.50.

This book is a valuable aid to chemists and physicists who wish to apply infrared spectroscopy for studying the structures of polymers. The first of its five chapters gives a general survey

of the fundamentals of the subject matter dealt with in the subsequent sections. Thereafter, selection rules, the calculation of structural vibrations, and the infrared dichroism of high polymers are discussed in detail. Here some knowledge of the fundamentals is assumed, and only references to standard textbooks on this subject are given. The list of references at the end of each chapter and in the appendix is remarkably comprehensive, but only goes up to the beginning of 1961.

The section on the analytical applications of infrared spectroscopy to high polymers is unfortunately restricted to 12 pages and deals with relatively trivial examples; it is therefore not up to the standards of the other chapters. Extension of this part would be desirable. The parts of spectra used as illustrations are occasionally unsatisfactory because of poor measurement technique and reproduction.

Special praise must be given to the complete and comprehensive manner in which the calculation of the normal vibrations of linear high polymers is derived from theory and illustrated with examples. To those intending to do work in this field the book can be recommended. *H. Günzler* [NB 336/194 IE]

Recent Progress in Microcalorimetry. By *E. Calvet* and *H. Prat*, edited and translated from the French by *H. A. Skinner*. Pergamon Press, Oxford-London-New York-Paris 1963. Ist Edit., XII + 178 pp, numerous illustrs., linen £3.0.0 (about $8.25).

This book is a revised transcription and partly mere translation into English of the volumes "Microcalorimétrie; Applications physico-chimiques et biologiques", Masson Ed., Paris 1956, and "Récents Progrès en Microcalorimétrie", Dunod Ed., Paris 1958. It is divided into three parts: 1.apparatus and microcalorimetric methods,2.physico-chemical applications, and 3. biological applications.

Part 1 gives a terse description of the principle and construction of differential calorimeters of the Tian-Calvet type. The theory of the gain and loss of heat in calorimeters, the methods for determining the constants which occur in the equations for thermal equilibrium, and the evaluation of the thermovoltages registered are lucidly described. In explaining the construction of the calorimeter and its accessories, particular attention is paid to details which make the calorimeter a precision instrument. – In the second part of the book, a host of examples of applications are given: measurements of specific heats, thermal conductivities, heats of mixing, heats of reaction, *etc.* with samples weighing only a few milligrams. The high sensitivity and precision of the calorimeter are particularly striking in studies of absorption kinetics. – The third part of the book deals with applications in zoology and botany; here the thermogenesis of insects and of germinating seeds are worthy of mention.

The book is a kind of progress report from the Institute of Microcalorimetry and Thermogenesis in Marseilles (France) which propagates the use of the microcalorimetric methods, but it will be of service to anyone interested in the construction and use or improvement of calorimeters of any type.

H. Schreiber [NB 319/177 IE]

Computation of Molecular Formulas for Mass Spectrometry. By *J. Lederberg*. Holden-Day Series in Physical Techniques in Chemistry. Edited by *C. Djerassi*. Holden-Day, Inc., San Francisco-London-Amsterdam 1964. 1st Edit., VII + 69 pp., paperback, $ 4.25.

High resolution mass spectrometry can he used to determine the masses of ions with molecular weights of up to about 1000 with an accuracy of a few thousandths of a mass unit. This permits to cut down to relatively few the many molecular formulae which can be assigned to an ion whose molecular weight is not known with such precision. However, for this purpose, all the molecular formulae differing in a thousandths of a mass unit, which are possible for a whole mass number, must be tabulated. As the molecular weight increases, the number of the molecular formulae also increases, and thus the size of the tables becomes larger and larger. *Lederberg* has found an amazingly simple method of limiting the tables to 48 pages by taking recourse to a few mathematical operations, which can be mastered in a few minutes. Consequently, his book becomes an indispensible tool in all laboratories in which organic compounds are investigated with high-resolution mass spectrometers. This verdict of the reviewer is not at all modified by the fact that the example used for demonstration on p. 8 is rather unfortunate: a structural formula is derived for the compound $C_7H_{15}NO_3$ which contains two pentavalent carbon atoms, and in which one carbon atom is missing.

G. Spiteller [NB 346/203 IE]

Gas Analysis by Gas Chromatography. By *P. G. Jeffery* and *F. J. Kipping*. International Series of Monographs on Analytical Chemistry, Volume 17. Edited by *R. Belcher* and *L. Gordon*. Pergamon Press, Oxford-London-Edinburgh-New York-Paris-Frankfurt 1964. 1st Edit., XI + 216 pp., 68 figures, 11 tables, linen £3.10.0 (about $10.00).

Because it is so difficult to survey the literature on gas chromatography, every monograph covering some specialized section of this field is to be welcomed. However, a monograph on gas analysis using gas chromatography should fit the specific needs of gas analysis alone and keep any discussion of the well known fundamentals of gas chromotagraphy as short as possible. This is not the case in all parts of this book. On the other hand, a comparison of the value of gas chromatography with that of other physical and chemical methods of gas analysis would have been useful.

The book is doubtlessly useful for the gas analyst because of the large number of practical examples; nevertheless it can be recommended only with some reservations:

The treatment given to methodical questions is often neither thorough nor critical (*e. g.* calibration procedures, sample injection). The discussion of instrumentation does not do enough justice to commercially available apparatus and overlooks special set-ups such as multicolumn chromatographs, apparatus for reaction gas chromatography, *etc.* There are no numerical data given for the response factors of the most important gases in detectors such as heat conductivity cells and flame ionization detectors, and comparative data for the properties of the various detectors such as sensitivity, linear dynamic range, dead volume, *etc.* are lacking as well. Too much space is allocated to argon detectors.

G. Schomburg [NB 337/195 IE]

Nucleophilic Substitution at a Saturated Carbon Atom. By *C. A. Bunton*. Volume 1 of the Series: Reaction Mechanisms in Organic Chemistry. Edited by *E. D. Hughes*. Elsevier Publishing Co., Amsterdam-London-New York 1963. 1st Edit., X + 172 pp., 4 figs. 9 tables, linen DM 22.50 (about $ 5.75).

It is a commonplace statement to remark that the flood of chemical publications – even on a limited topic – has nowadays become almost unsurveyable for the individual. The consequent necessity of procuring information through review articles has led to the ever increasing appearance of specialized series within recent years, so that the publication of a new series of monographs can be justified only by excellent presentation of the subject matter.

The series on mechanisms in organic chemistry initiated in 1963 has made a promising start with this first volume, which deals with substitutions at saturated carbon atoms. The book is divided into six chapters; three of these deal with the fundamental phenomena, structural effects, and the stereochemistry of substitutions, while the other three (about one-third of the book) deal with solvent, salt, and catalytic effects. Here the reader finds all the significant results, and despite the straightforwardness and lucidity of the discussion, at least attention is called to controversial interpretations. The book is therefore not only suitable as an introduction to

this subject, but also welcome as a work of reference on account of its ample references to the literature (mainly up to 1962), which might however have been better collected into a single list.

G. Köbrich [NB 311/170 IE]

Progress in Physical Organic Chemistry. Vol. 1, Edited by *S. G. Cohen, A. Streitwieser, Jr.*, and *R. W. Taft*. Interscience Publishers, a Division of John Wiley & Sons, New York-London 1963. 1st Edit., X + 411 pp., numerous tables, linen $ 15.00.

The stream of publications, in which organic chemical reactions are dealt with from the viewpoint or with the quantitative methods of physical chemistry, has become so fast flowing that physical-organic chemistry must now be veriewed periodically by volumes in the "Progress" series. The first volume in such a series has appeared under the editorship of three leading capacities in this field. It presents critical, detailed reviews of current problems and is intended to stimulate further work and discussions. As stated in the foreword, the editors have encouraged their authors to give comprehensive reports, with enough numerical data, and without disdaining speculative outlooks for the future.

The present volume begins with a relatively short review (30 pp.) by *A. Streitwieser* of the ionization potentials of organic radicals, hydrocarbons, and compounds with heteroatoms. *S. N. Ross* then reports on nucleophilic aromatic substitution (44 pp.), and *N. N. Lichtin* deals with ionization and dissociation equilibria in liquid sulfur dioxide (34 pp.). Two long articles by *E. A. Halevi* and *E. M. Arnett*, respectively, give abundant data on secondary isotope effects (182 pp.) and on the quantitative comparison of weak organic bases (114 pp., including about 80 pp. with basicity values). All the articles are supplemented with numerous references and are written clearly and intelligibly. Because the theory of the topics is dealt with first, and then sometimes the experimental methods are described, the experimental results being given at the end, the essays will supply information and incentives not only to the theoretician, but also to the organic chemist engaged in synthetic work. The next volumes of this series can be looked forward to.

W. Lüttke [NB 328/186 IE]

Comprehensive Analytical Chemistry, Vol. II A: Electrical Methods. Edited by *C. L. Wilson* and *D. W. Wilson* in cooperation with *C. R. N. Strouts*. Elsevier Publishing Co., Amsterdam-London-New York 1964. 1st Edit., XVI + 268 pp., numerous illustrs. and tables, linen, price for separate volume DM 33.50 (about $ 8.50).

The series "Comprehensive Analytical Chemistry" by *C. L. Wilson* and *D. W. Wilson* is continued by the appearance of this first part of Volume II. This part contains the sections "Electrogravimethy" by *A. J. Lindsey*, "Potentiometric Titration" and "Conductometric Titrations", both by *D. G. Davis*, and a chapter on "Impedimetric Titration" (high frequency titration) by *T. S. Burkhalter*. The outward appearance of the book is excellent.

All chapters are built up according to the same pattern: a short introduction describing the fundamentals and principles followed by a discourse on methods with data on commercially available apparatus and their mode of functioning. Each section is closed by indications of the applications, together with a number of analytical procedures and with occasionally very comprehensive lists of references. The treatment of polarography, amperometry, and coulometry and related electrical analytical methods is reserved for Volume II B.

Despite the lucid and terse style of the readable text, the editors' original aim of presenting the book as a practical manual is, in the reviewer's opinion, only partially fulfilled, and this for two reasons: first, whenever points come up which cannot be described in detail in the space available, references to explicatory literature should be given to support the argument; second, a good survey of the analytical methods available for solving definite problems should be given, together with information on the apparatus to be used. Both of these requirements are insufficiently fulfilled when it is considered that in a manuscript completed in 1963, the latest reference is from 1959 – and this only in the section on potentiometry – and no notice is taken of recent handbooks, monographs, and journal publications, and that in the chapter on impedimetry – the latest technique discussed and one that is still developing – the literature has only been checked up until 1957. Furthermore, the significant contributions that all European countries have made to the development of the instrumentative side of the fields discussed by the production of reliable analytical apparatus are hardly mentioned.

K. Cruse [NB 309/168 IE]

Synthetic Methods of Organic Chemistry. By *W. Theilheimer*. Vol. 18, Annual for 1964, with a key to the index in German. Verlag S. Karger AG., Basel-New York 1964. 1st Edit., XVI + 565 pp., linen DM 170.– (about $ 43.00).

The form and quality of the 1964 volume of "Theilheimer" are completely in keeping with the high standards of the well known earlier volumes. A selection of 998 characteristic reactions has been made from publications in the field of preparative organic chemistry which appeared in the years 1961–1963. The examples include both stereospecific reactions and transformations of numerous hetero-organic compounds. Pared out of the cumbersome context of the original publications, the vast array of reactions given here appear in a readily surveyable form which provoke the reader to attempt analogous syntheses. Readers who encounter difficulties with the classification scheme used, which is not very simple to grasp but which is used with unerring uniformity throughout, will find welcome assistance in the excellent key-word index (102 pp.), which covers Vols. 16–18. However, it remains a moot point whether an additional punched card catalogue would not augment the value of this series.

The Hetarynes

BY PROF. DR. TH. KAUFFMANN [*]

INSTITUT FÜR ORGANISCHE CHEMIE DER TECHNISCHEN HOCHSCHULE DARMSTADT (GERMANY)

Dedicated to Professor Fritz Micheel on the occasion of his 65th birthday

Investigations carried out during the last six years have shown that, as in the case of benzene, an extra bond can be introduced into heteroaromatic rings. Since this possibility does not appear to be confined to exceptional cases, the heterocyclic arynes (hetarynes) promise a much wider variety than the carbocyclic arynes. Hetarynes occur mainly as intermediates in nucleophilic substitutions on halogenated heterocyclic compounds. Since the replacement of a CH group in dehydrobenzene by a nitrogen atom and the condensation of benzene rings have stabilizing effects, the stability of hetarynes is expected to increase with the number of N atoms and with the number of condensed aromatic rings.

I. Introduction

The discovery of dehydrobenzene [1], which is associated with the names *G. Wittig*, *J. D. Roberts*, and *R. Huisgen*, raised the question of whether heteroaromatic compounds could also, like benzene, be converted into *o*-dehydro compounds.

Chance observations suggested that this conversion is in fact possible. Thus *Stoermer* and *Kahlert* [2] observed the formation of 2-ethoxycoumarone when sodium ethoxide was treated with 3-bromocoumarone; they explained this as resulting from the intermediate formation of 2,3-dehydrocoumarone *(1)*. Similarly the reactions of 3-bromothionaphthene with potassium hydroxide and with piperidine yield 2-hydroxythionaphthene (15 %) [3] and 2-piperidinothionaphthene (20 %) [4] respectively. Furthermore, 4-aminopyridine (10 %) and 4-phenacylpyridine (13 %) are obtained by the reaction of 3-bromopyridine with sodamide in liquid NH_3 containing acetophenone; this was explained by the intermediate formation of 3,4-dehydropyridine *(2)* [5].

(1)   *(2)*

[*] New address: Organisch-Chemisches Institut der Universität Münster (Germany).

[1] Most recent review on dehydrobenzene and related compounds: *H. Heany*, Chem. Reviews *62*, 81 (1962).

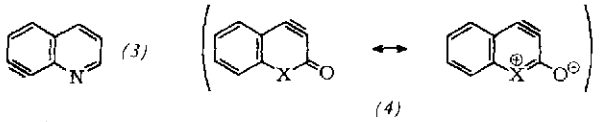
[5] *R. Levine* and *W. W. Leake*, Science (Washington) *121*, 780 (1955).

In spite of these observations, it was only at the end of the 1950's that any systematic studies on heterocyclic *o*-dehydroaromatic compounds were undertaken. Within a short time it was shown, for pyridine [6–14], quinoline [9, 15], thiophene [16, 17], and coumarone [17, 18], that an extra bond can be introduced into six- and five-membered heteroaromatic rings [19].

II. Nomenclature

The term "hetarynes" has been proposed [9, 21] for *o*-dehydroaromatic compounds (arynes [20]) with heteroatoms in the ring. This permits the formation of simple compound names such as hetaryne *N*-oxides or hetarynium ions, and appears to be gaining wide acceptance.

In order to define the applicability of the term "hetarynes", it is necessary first to settle two questions, namely whether the term is to include *o*-dehydroaromatic compounds in which, as in the case of 7,8-dehydroquinoline *(3)*, the extra bond is situated in a carbocyclic ring, and what criterion of aromaticity is to be used. It seems reasonable to answer the first of these questions in the affirmative, since heteroatoms in neighboring rings affect the reactions of the extra bond (cf. the addition of piperidine to 7,8-dehydroquinoline; Section III,7); this answer is also consistent with the fact that the individual compounds are best named on the basis of the parent heterocyclic system, as in "7,8-dehydroquinoline". With regard to the second question, we suggest that, as in the textbook by *Katritzky* and *Lagowski* [23], the criterion of aromaticity adopted should be that proposed by *Hückel*, *i.e.* the possibility of cyclic mesomerism involving six π-electrons. According to this criterion, compounds such as 3,4-dehydrocoumarin *(4)* (X = O) [24] and 1-methyl-2-phenyl-4,5-dehydropyridazine-3,6-dione *(70)* should also be regarded as hetarynes.



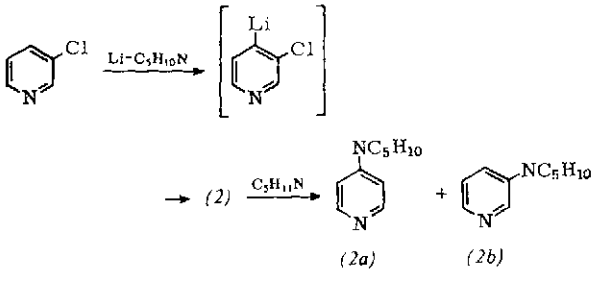
(3) *(4)*

III. Hetaryne Intermediates in Nucleophilic Substitutions

1. The EA, AE_n, and AE_a Mechanisms

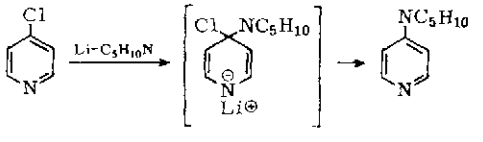
The hetarynes are particularly important as intermediates in nucleophilic substitutions on heterocyclic aryl halides. There are three possible mechanisms for these reactions:

(a) The elimination-addition (EA) mechanism [24, 25], *e.g.* [11]:



(2) *(2a)* *(2b)*

(b) The normal addition-elimination (AE_n) mechanism [24, 25], *e.g.* [11]:



(5) [27]

(c) The abnormal addition-elimination (AE_a) mechanism [24, 28]:

[27] Adducts such as *(5)*, in which the anionic group becomes attached to the C-atom that carried the halogen, are referred to in the present paper as "normal", whereas adducts in which this is not the case are referred to as "abnormal". The corresponding addition reactions are designated in a similar manner.

[28] *F. G. Bordwell*, *B. B. Lampert*, and *W. H. McKellin*, J. Amer. chem. Soc. *71*, 1702 (1949).

[29] The structure of the adduct *(6a)* melting at 139–140 °C has not been established.

In the EA mechanism, which is of particular interest here, the halogeno compound is first deprotonated or else gains a metal atom from the base, this first attack taking place in the *o*-position with respect to the halogen. This is followed by the elimination of halide or metal halide. The resulting aryne generally adds on bases in both of the possible orientations, so that the usual product is a mixture of an "unrearranged" and a "rearranged" substitution product. The AE_n and AE_a mechanisms, on the other hand, lead to uniform products ("unrearranged" and "rearranged", respectively).

The only halogenated quasi-aromatic heterocyclic compound for which the AE_a mechanism has been observed is 2-bromothionaphthene *S*-dioxide *(6)* [28]; thus this mechanism appears to be very rare. Where a "rearranged" substitution product ("cine-substitution" [30]) is obtained, therefore, the EA mechanism is likely, but by no means certain since competition between an AE_n and an AE_a mechanism would also be possible. If, however, the ratio of the isomers in the product is independent of the nature of the halogen in the starting compound, it is reasonable to conclude that the reaction follows the EA mechanism [26], since this is the only mechanism in which the isomer ratio depends entirely on reactions of halogen-free compounds (addition of base to the aryne). In the case of competition between an AE_n and an AE_a mechanism, on the other hand, this ratio is determined by reactions of the halogenated compound (attachment of base to the aryl halide or elimination of halide from the adducts). The ratio also depends on reactions of the halogenated compound in the case of competition between an EA and an AE_n or AE_a mechanism.

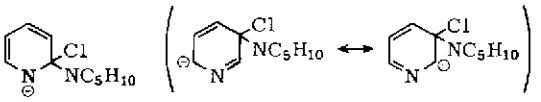
Another method often used to show that a reaction proceeds by an EA mechanism is to intercept the aryne intermediate by means of a weak base that does not react with the aryl halide (cf. Section III.6) or by means of a diene (cf. Section IV).

2. Hetarynes with the Grouping —C≡C—C=N— in the Ring

a) 3,4-Dehydropyridines and 3,4-Dehydroquinoline

α) Lithium Amides as Bases

In the "normal" addition [27] of an anion to 2- and 4-halogenopyridines or 2- and 4-halogenoquinolines, the negative charge can be taken over by the N-atom of the heteroaromatic compound, as shown in *(7)* and *(5)*; this should favor an AE_n mechanism. In agreement with this, the reactions of 2-chloro-6-methylpyridine, 4-chloropyridine, 2-chloroquinoline, and 4-chloroquinoline with lithium piperidide/piperidine in boiling ether yield exclusively or almost exclusively the 2- or 4-piperidino compound, as shown in Table 1 [11,15,31, 32]. The only exception is, rather surprisingly, 2-chloropyridine [11] (cf. Section VIII).



(7) *(8)*

The conditions favoring the AE_n mechanism are less satisfactorily fulfilled in the case of the 3-halogeno derivatives of pyridine and quinoline. In these cases the "normal" anion adducts [27], *e.g. (8)*, should be less stable, since the negative charge cannot be taken over by the pyridine or quinoline N atom as in *(5)* or *(7)*. In this case, therefore, the EA mechanism is most likely. In fact, the reactions of 3-halogenopyridines [6,7,11] or 3-halogenoquinolines [9,15] with lithium piperidide/piperidine in boiling ether lead to mixtures of the 3- and 4-piperidino compounds. The isomer ratios are independent of the nature of the halogen (Cl, Br, and Cl, Br, I, respectively) within the limits of accuracy of the measurements (cf. Table 1). Therefore, these reactions can be assumed to proceed largely or entirely by the EA mechanism, *i.e. via* 3,4-dehydropyridine *(2)* or 3,4-dehydroquinoline *(9)*.

It should be pointed out that these hetarynes have also been detected, although in a different reaction (cf. Section IV), by interception with furan.

Table 1. Yield of aromatic piperidino compounds and percentages of the two isomers on reaction of halogenopyridines [7, 11] and halogenoquinolines [15] with lithium piperidide/piperidine in boiling ether.

Starting compound	Aromatic piperidino compound			
	Total yield [%]	Distribution of x-isomers [%]		
		x = 2	x = 3	x = 4
Halogenopyridines				
2-F	97	100	—	—
2-Cl	< 1 (resin)	traces	—	—
2-Cl; 6-CH_3 [31]	75 [11]	100	—	—
3-F	84 [7]; 92 [11]	—	100 [7]; 96 [11]	0 [7]; 4 [11]
3-Cl	66 [7]; 87 [11]	—	52 [7]; 48 [11]	48 [7]; 52 [11]
3-Br	78 [7]; 88 [11]	—	48 [7]; 48 [11]	52 [7]; 52 [11]
4-Cl	88 [7]; 95 [11]	—	0 [7]; 0,4 [11]	100 [7]; 99,6 [11]
Halogenoquinolines				
2-Cl [32]	93	100	—	—
3-F	75	—	100	0
3-Cl	45	—	48	52
3-Br	61	—	50	50
3-I	58	—	49	51
4-Cl [31]	85	—	1	99

Since the aromatic piperidino compounds are stable under the reaction conditions [33], the percentages of the isomers as given in Table 1 correspond to the frequencies of the addition of piperidine to *(2)* and *(9)* in the two possible orientations. A comparison of these ratios [which are given in formulae *(2')* and *(9)*] with corresponding values for the addition of piperidine to

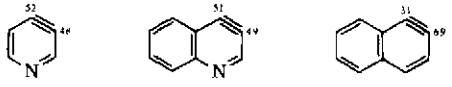
[30] *J. F. Bunnett*, Quart. Rev. (chem. Soc., London) *12*, 1(1958); *J. F. Bunnett* and *R. E. Zahler*, Chem. Reviews *49*, 294 (1951).

[31] *Th. Kauffmann* and *R. Weber*, unpublished work, 1964.

[32] *R. Wirthwein*, Doctorate Dissertation, Technische Hochschule Darmstadt.

[33] *R. Nürnberg*, Diploma Thesis, Technische Hochschule Darmstadt, 1965.

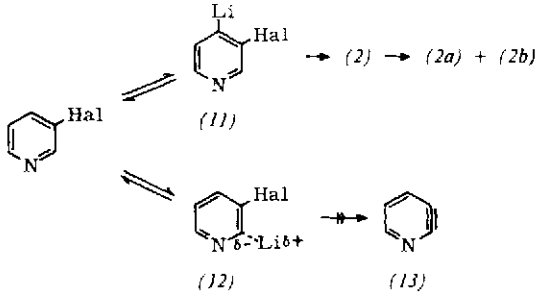
1,2-dehydronaphthalene *(10)* under the same conditions [26] shows that the fusion of a benzene ring to 3,4-dehydropyridine has hardly any effect on the orientation of the addend, whereas the replacement of a CH group in 1,2-dehydronaphthalene by a nitrogen atom profoundly influences the orientation (cf. Section VII).



(2') *(9)* *(10)*

As can be seen from Table 1, the 3-fluoro compounds represent a special case. In these compounds, substitution proceeds largely or entirely "without rearrangement", *i.e.* probably by the AE_n mechanism. This agrees with the finding [34] that the AE_n mechanism is more strongly favored by aromatic fluoro compounds than by other aromatic halogeno compounds. It is only when 3-fluoropyridine is treated with lithium piperidide in the absence of piperidine that the resulting piperidinopyridine contains 30% of the 4-isomer in addition to the 3-isomer [7].

In the reactions of the 3-halogenopyridines and 3-halogenoquinolines, no trace of the aromatic 2-piperidino compounds has been obtained. Thus the intermediate formation of 2,3-dehydropyridine *(13)* or 2,3-dehydroquinoline is unlikely, since the piperidino group should become attached to these mainly in position 2 [35]. Since we cannot assume that there is absolutely no attachment of the metal to C-2 of the 3-halogeno compound [11], and since 2,3-dehydropyridine and 2,3-dehydroquinoline should be more stable than the 3,4-isomers (cf. Section VI), this finding can only be explained as follows: The partial negative charge on C-2 of the hypothetical 3-halogeno-2-lithiopyridine, which is a result of the polarization of the C-Li bond, is strongly attracted by the adjacent nitrogen atom; consequently the halogen atom does not receive a sufficiently large negative charge to permit its elimination as a halide ion [11]. The isomeric 4-lithio compounds *(11)* which are in equilibrium with the 2-lithio compounds, on the other hand, lose LiHal.



[34] AE_n substitution also occurs in the reaction of fluoronaphthalenes with lithium piperidide/piperidine [*R. Huisgen, J. Sauer, W. Mack*, and *I. Ziegler*, Chem. Ber. *92*, 441 (1959)] or of *p*-fluorotoluene with sodium hydrazide/hydrazine [*Th. Kauffmann* and *H. Henkler*, Chem. Ber. *96*, 3159 (1963)], whereas the corresponding chloro and bromo compounds under the same conditions react by the EA mechanism.

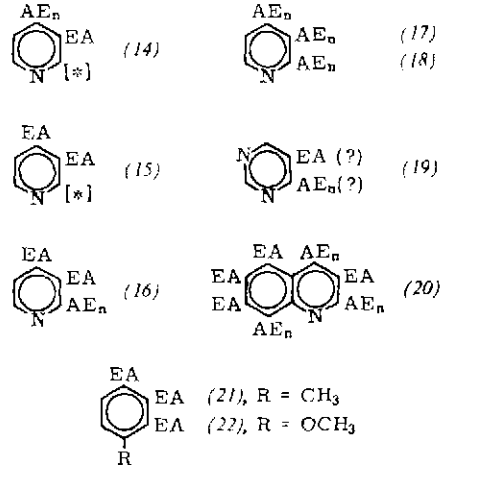
[35] Nothing is known about the rate constants for the addition of bases onto 2,3-dehydropyridine and 2,3-dehydroquinoline in the two possible orientations.
However, since the addition of anionic groups onto 4,5-dehydropyrimidine [36,37] and onto 2-methyl-4,5-dehydropyrimidine [38] takes place predominantly at the end of the extra bond α to the ring nitrogen, this is also to be expected for 2,3-dehydropyridine and 2,3-dehydroquinoline.

The nucleophilic substitution of aryl halides can be represented by "mechanism maps", as shown in Table 2. The mechanism maps *(14)*, *(17)*, and *(20)*, are essentially based on results given in Table 1 and in Section III.7. As is shown in *(15)*, the reaction of 4-chloropyridine with lithium diethylamide, unlike the reaction with lithium piperidide, proceeds largely or wholly by the EA mechanism, possibly owing to the bulky nature of the diethylamide ion. The ratio of 3- and 4-diethylaminopyridine in the product is approximately 1:1, irrespective of whether the starting material is 3- or 4-chloropyridine. In the case of 2-chloropyridine, surprisingly, resinification also takes place with lithium diethylamide (cf. Section VIII).

In contrast to their behavior towards lithium piperidide/piperidine, the chloropyridines react with piperidine alone at 140 °C by an AE_n mechanism to give "unrearranged" substitution products, as is shown by *(18)*. It can be seen from *(19)*, however, that "cine-substitution" can also occur, probably by the EA mechanism (cf. Section III.3.b), on heating with piperidine.

Table 2. "Mechanism maps" for the nucleophilic substitution of heterocyclic and carbocyclic aryl halides. (The reaction mechanisms observed for the various substitution positions are indicated in these positions).

Mechanism map	Substituent	Base	Temp. [°C]	Ref.
(14)	Cl	$LiC_5H_{10}N/C_5H_{11}N$	35	[6,7,11]
(15)	Cl	$LiN(C_2H_5)_2/HN(C_2H_5)_2$	35	[31,33]
(16)	Cl	KNH_2/NH_3	−33	[12,22]
(17)	F	$LiC_5H_{10}N/C_5H_{11}N$	35	[11,31]
(18)	Cl	$C_5H_{11}N$	140	[11,39,40]
(19)	Br	$C_5H_{11}N$	106	[36,37]
(20)	Cl	$LiC_5H_{10}N/C_5H_{11}N$	35	[15,32,41]
(21)	Br	$Li_5H_{10}N/C_5H_{11}N$	35	[26]
(22)	Cl, Br	KNH_2/NH_3	−33	[26]



[*] The reaction of 2-chloropyridine leads to resinification.

[37] *K. Udluft*, Doctorate Dissertation, Technische Hochschule Darmstadt.

[38] *Th. J. Schwan* u. *H. Tieckelmann*, J. org. Chemistry *29*, 941 (1964).

[39] *R. Graf*, J. prakt. Chem. [2] *138*, 239 (1933).

[40] *J. P. Wibaut* and *G. Tilmann*, Recueil Trav. chim. Pays-Bas *52*, 987 (1933).

[41] *Th. Kauffmann, J. Hansen*, and *R. Wirthwein*, Liebigs Ann. Chem. *680*, 31 (1964).

Thus the nucleophilic substitution of heterocyclic aryl halides is much more complicated than that of the halides of typical benzene derivatives such as toluene or anisole, which on reaction with lithium piperidide or KNH_2 undergo substitution exclusively by the EA mechanism [26], as is shown in *(21)* and *(22)*.

β) Potassium Amide as Base

While the work described above was being carried out, *den Hertog* and his co-workers [12, 14, 22, 42, 43] studied the action of KNH_2 in liquid NH_3 (−33 °C) on halogenopyridines. Pyridines containing halogen (Cl, Br, I [44]) in position 3 give 60 to 70 % yields of a mixture of 3- and 4-aminopyridine. The ratio of the isomers is constant (1:2) and independent of the halogen, indicating that the reaction proceeds entirely *via* 3,4-dehydropyridine. No 2-aminopyridine is formed [12, 22]. For reasons that are not yet known, pyridines containing halogen (Cl, Br, I) in position 4 give the same reaction mixture [12, 22] (in contrast to the reactions with lithium piperidide, cf. Section 2.a.α), *i.e.* they probably react quantitatively *via* 3,4-dehydropyridine, whereas the reaction with 2-chloropyridine leads to 2-aminopyridine, and does not result in resinification. The AE_n mechanism is more likely for this last reaction than the equally feasible EA mechanism *via* 2,3-dehydropyridine [35], since no trace of 3-aminopyridine is found, and since the yield of 2-aminopyridine is the same as in the reaction with 2-fluoropyridine, which almost certainly proceeds by the AE_n mechanism [34].

The influence of the ethoxy group on the orientation of the amino group in the addition of NH_3/KNH_2 [45] to ethoxy-3,4-dehydropyridines can be found from extensive experimental data (Table 3) regarding the action of KNH_2/liquid ammonia on ethoxybromopyridines [12, 42]. As can be seen from Table 4, the ethoxy group in the β-position to the extra bond in *(23)* has practically no effect. The ethoxy groups in the α-position to the extra bond in *(24)* and *(25)*, on the other hand, profoundly influence the orientation. Like the methoxy group of 2,3-dehydroanisole *(26)* [46], they force the amino group into the position farther away from the substituent.

Table 3. The reaction of substituted bromopyridines with liquid NH_3 at −33 °C.

Starting pyridine	Pyridine obtained	Isomer distribution [%]	Total yield [%]
3-Bromo-2-ethoxy-	3-Amino-2-ethoxy-	3	90
	4-Amino-2-ethoxy-	97	
3-Bromo-5-ethoxy-	3-Amino-5-ethoxy-	100	90

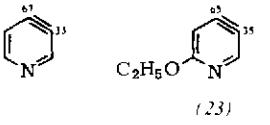
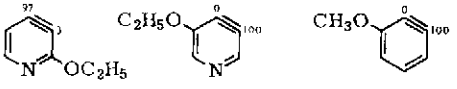
	3-Amino-4-methyl-	by-product	

Table 4. Distribution of products [47] obtained by the addition of NH_3/KNH_2 [45] to 3,4-dehydropyridines [12, 22, 42] and 2,3-dehydroanisole [46].



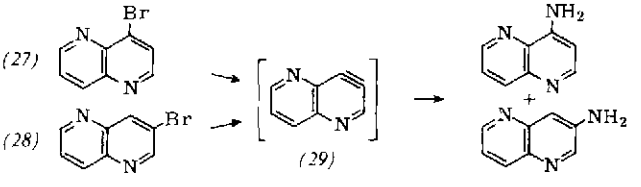
(23)



(24) *(25)* *(26)*

b) 3,4-Dehydro-1,5-naphthyridine

The action of KNH_2 in liquid NH_3 at −33 °C on the bromo-1,5-naphthyridines *(27)* and *(28)* again leads to mixtures of the 3-amino and 4-amino compounds, so that both reactions probably proceed *via* the common hetaryne intermediate *(29)*. Depending on whether the starting material is the 3-bromo or the 4-bromo compound, the ratio of the 3- and 4-amino derivatives in the product is 85:15 or 78:22. One or both of these substitutions, therefore, probably involve competing EA and AE_n mechanisms [48]. Since, as we have seen above, 3- and 4-bromopyridines react quantitatively by the EA mechanism under the same conditions [12, 22], the heterocyclic ring fused to the brominated ring in *(27)* and *(28)* evidently favors the AE_n mechanism.



(27) *(28)* *(29)*

The same phenomenon (which we shall meet again in Section III.7) is found in the case of 3-bromo-2-ethoxy-1,5-naphthyridine. In contrast to 3-bromo-2-ethoxypyridine (EA mechanism, cf. Table 3), this compound reacts with KNH_2/NH_3 (−33 °C) to give only the 3-amino compound [48], *i.e.* the reaction seems to proceed entirely by the AE_n mechanism.

[42] *H. J. den Hertog, M. J. Pieterse,* and *D. J. Buurman,* Recueil Trav. chim. Pays-Bas *82*, 1173 (1963).

[43] *R. J. Martens* and *H. J. den Hertog,* Recueil Trav. chim. Pays-Bas *83*, 621 (1964).

[44] According to *R. J. Martens, H. J. den Hertog,* and *M. van Ammers,* Tetrahedron Letters *1964*, 3207, the corresponding reaction with 3-fluoropyridine leads to several fluorinated dipyridyls; when excess KNH_2 is present, a little 3-aminopyridine is also formed.

[45] It is not yet known whether, in the reactions of heterocyclic aryl halides with KNH_2/NH_3, the compound that adds onto the intermediate hetaryne is mainly the potassium compound or the free base. Since the NH_3 is present in large excess, and since it is known that lithium piperidide and piperidine add equally rapidly to the aryne 9,10-dehydrophenanthrene [26], it is likely that the addition of NH_3 predominates.

[46] *J. D. Roberts, C. W. Vaughan, L. A. Carlsmith,* and *D. A. Semenow,* J. Amer. chem. Soc. *78*, 611 (1956).

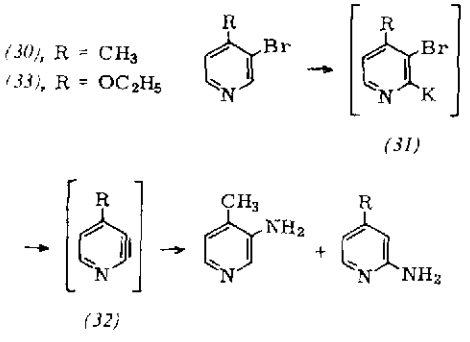
[47] It is assumed that the addition products are stable under the experimental conditions.

[48] *W. Czuba,* Recueil Trav. chim. Pays-Bas *82*, 997 (1963).

3. Hetarynes with the Grouping —C≡C—X– (X = N, O, S) in the Ring

a) 2,3-Dehydropyridines and 3,4-Dehydroisoquinoline

The fact that the action of alkali metal amides on 3-halogenopyridines yields only 3,4-dehydropyridine *(2)* with no 2,3-dehydropyridine *(13)* was ascribed (cf. Section III.2.a) to the much more rapid elimination of metal halide from 3-halogenopyridines with a metal atom on C-4 than from those with a metal atom on C-2. In agreement with this explanation, 3-bromo-4-methylpyridine *(30)*, in which the metal cannot become attached to C-4, reacts only slowly with KNH_2/NH_3 (–33 °C) [22], and gives only a small yield (5 %) of a mixture of the 2- and 3-amino compounds, in which the former predominates [22]. Thus the 2,3-dehydro compound *(32)*, R=CH_3, is probably formed when reaction *via* the 3,4-dehydro compound is blocked; since the bromine carries only a small negative charge (cf. Section III. 2a), however, the reaction is very slow.



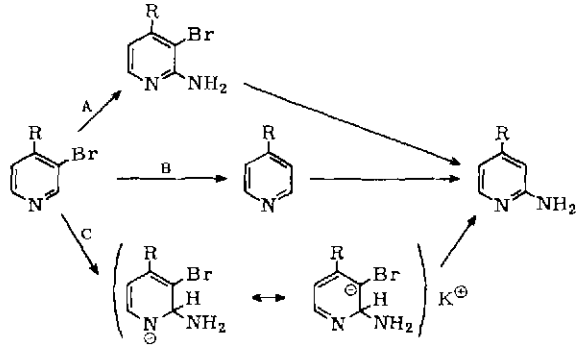
(30), R = CH_3
(33), R = OC_2H_5

(31)

(32)

A group on C-4 that tends to impose a negative charge on the halogen should facilitate the removal of halide from compounds such as *(31)*. This explains the fact that *(33)* reacts rapidly with KNH_2/NH_3 (–33 °C) to form 2-amino-4-ethoxypyridine (55–60 %). The 3-isomer is apparently not formed [12,42].

Apart from the route involving the hetaryne intermediates *(32)* routes A, B, and C in Scheme 1 are also feasible for these cine-substitutions. Of these, A and B are particularly important possibilities in the case of the ethoxy compound *(33)*, since *o*-bromoanisole is reductively dehalogenated by metal amides [49], and since up to 5 % of 4-ethoxypyridine has been isolated from the reaction mixture. Both of these routes, however, have been ruled out by experiment [14]. Until route C (AE_a mechanism) can also be ruled out, the occurrence of *(32)* as an intermediate cannot be regarded as certain.

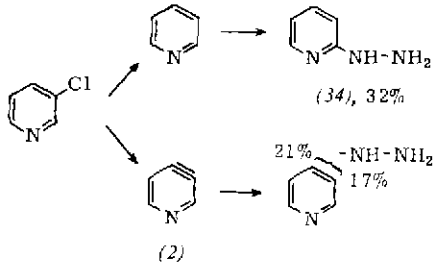


Scheme 1. Possible routes for the cine-substitution of pyridines not involving hetaryne intermediates.

[49] *R. A. Benkeser* and *C. E. De Boer*, J. org. Chemistry *21*, 281 (1956).

It should be pointed out that 2,3-dehydropyridine has been intercepted by furan in another type of reaction, which is discussed in Section IV.

The need for caution in the interpretation of cine-substitutions on the pyridine system when the point of attachment of the new substituent is α to the nitrogen atom can be seen from the fact that the reaction of 3-chloropyridine with sodium hydrazide in ether at 20 °C to form 2-hydrazinopyridine *(34)* [50] involves pyridine as an intermediate [51]. An AE substitution with formation of 3- and 4-hydrazinopyridine competes with this reaction.



(34), 32%

21% 17%

(2)

The amination of pyridine with $NaNH_2$ (Chichibabin reaction) was assumed by *L. S. Levitt* and *B. W. Levitt* [52] to proceed *via* 2-pyridylsodium and 2,3-dehydropyridine. This mechanism cannot, however, be generally applicable, since 3-substituted pyridines, which cannot form 2,3-dehydro intermediates, are also aminated on C–2. Other impressive arguments against this mechanism have also been advanced [53 to 56]. It is clear, however, that the possibility of the formation of hetaryne intermediates makes it necessary sometimes to reconsider currently accepted views on mechanism.

In 4-bromoisoquinoline *(35)*, as in *(30)* and *(33)*, the *p*-position with respect to the heteroatom is occupied. Consequently, the reaction of *(35)* with lithium piperidide/piperidine was expected to result in cine-substitution with formation of 3-piperidinoisoquinoline *(36a)*. However, neither *(36a)* nor the 4-isomer *(36b)* is formed at 35–80 °C. Instead, most of the compound *(35)* is recovered unchanged after hydrolysis of the reaction mixture [57]; this could be due to introduction of the metal in the "wrong" position to form *(37a)* (cf. Section III.7.b), or alternatively the "correct" product *(37b)* may be very stable [58]. Compound *(36a)* and the 4-isomer (ratio 1:9) are, however, formed when 4-bromoisoquinoline is heated to 180 °C with anhydrous piperidine. Under these conditions, therefore, 3,4-de-

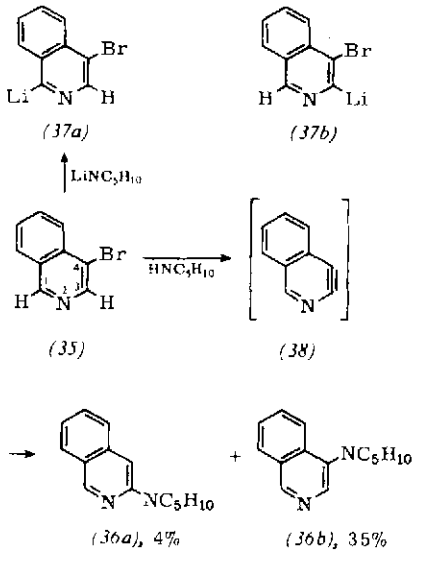
[56] *Y. Ban* and *T. Wakamatsu*, Chem. and Ind. *1964*, 710.

[57] *J. Hansen*, Doctorate Dissertation, Technische Hochschule Darmstadt.

[58] The attachment of the metal to C-1 is not unlikely, since calculations by *H. C. Longuet-Higgins* and *C. A. Coulson*, Trans. Faraday Soc. *43*, 87 (1947), have shown that the π-electron density in unsubstituted isoquinoline is lowest on C-1 (0.767). The value for C-3 is much higher (0.942).

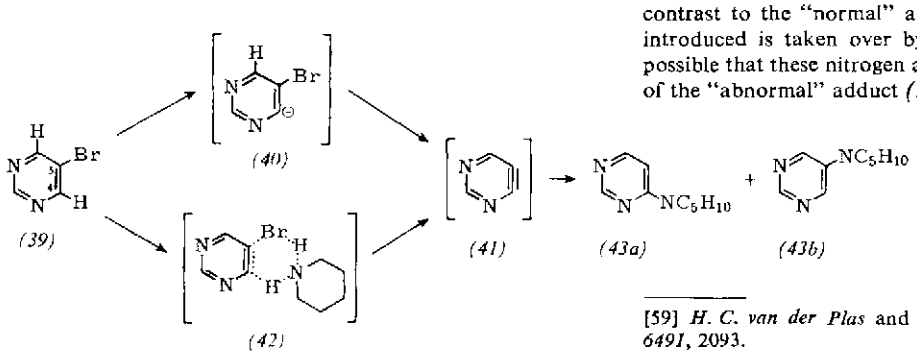
hydroisoquinoline *(38)* may be assumed to be formed as an intermediate. The proton affinity of piperidine is apparently sufficient to permit the removal of the hydrogen atom in position 3 of 4-bromoisoquinoline, from which electrons are withdrawn by the neighboring



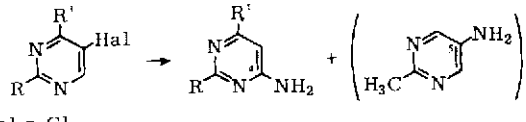
nitrogen and Br atoms. The high proportion of the "unrearranged" substitution product suggests competition between EA and AE_n mechanisms.

b) 4,5-Dehydropyrimidines

In 5-bromopyrimidine *(39)*, which contains two electronegative ring members, the hydrogen *ortho* to the bromine should carry an even stronger positive charge than that in *(35)*. It is not surprising, therefore, that *(39)* reacts with piperidine at 106 °C to give 4-piperidinopyrimidine *(43a)* in 29 % yield [36,37]. Possibly the 5-isomer *(43b)* is also formed in small amounts. The reaction of *(39)* with lithium piperidide/piperidine in benzene at 80 °C also gives rise to *(43a)* in 7 % yield. In a similar experiment in ether at 35 °C, the starting material *(39)* was recovered unchanged on hydrolysis of the reaction mixture, indicating that the hypothetical 5-bromo-4-lithio-pyrimidine has a relatively high stability. If the reaction of 5-bromopyrimidine with piperidine proceeds *via* the anionic intermediate *(40)* and 4,5-dehydropyrimidine *(41)* (a synchronous elimination of HBr, *e.g.* involving the transition state *(42)* would also be feasible), the reaction should be inhibited by a proton donor stronger than piperidine, owing to protonation of *(40)*. At 106 or 160 °C, in fact, the reaction is completely suppressed by the addition of aniline or ethanol. This is reminiscent of the inhibition [26] of the EA mechanism in the reaction of lithium piperidide and 1-fluoronaphthalene by the addition of free piperidine.

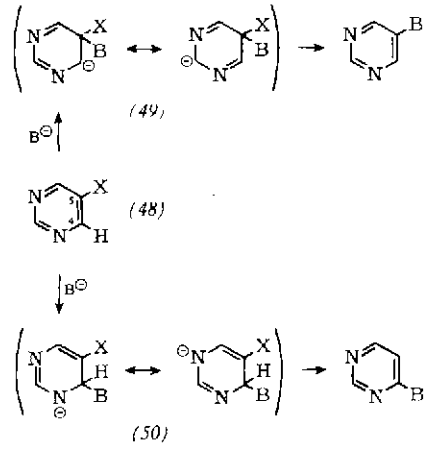


The occurrence of a substituted 4,5-dehydropyrimidine was first indicated by the formation of small quantities of the isomers *(46)* and *(47)* during the reaction of 5-chloro-2-methylpyrimidine *(44)* with KNH_2/NH_3 (−33 °C) [38]. *Van der Plas* and *Geurtsen* [59] obtained much better yields of cine-substitution product (Table 5) under the same conditions from 5-bromopyrimidines *(45)* containing (-I)-substituents (OCH_3 and OH) α to the halogen (cf. Section III.3a); no "unrearranged" substitution products were detected in these cases.



(44): Hal = Cl
R = CH_3; R' = H (5%)
R = H; R' = C_6H_5 (15%)
(45): Hal = Br
R = H; R' = OCH_3 (70%)
R = H; R' = OH (75%)

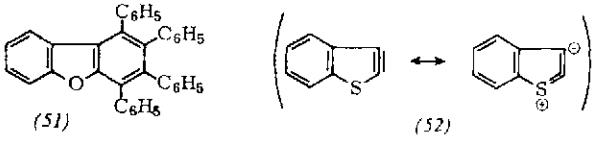
Although there is much to suggest that the cine-substitutions observed with 5-halogenopyrimidines are due to the EA mechanism, it should not be overlooked that there is as yet no proof of this (*e.g.* evidence that the ratio of the isomers is independent of the halogen), and that these compounds also present favorable conditions for the AE_a mechanism (cf. Section III.1): since the attachment of an anion ($B^{\ominus}$) to C—4 of compound *(48)* would lead to a product *(50)* in which, in contrast to the "normal" adduct *(49)*, the negative charge introduced is taken over by two nitrogen atoms, it seems possible that these nitrogen atoms would force the formation of the "abnormal" adduct *(50)*.



[59] *H. C. van der Plas* and *G. Geurtsen*, Tetrahedron Letters *6491*, 2093.

c) 2,3-Dehydrocoumarone and 2,3-Dehydrothionaphthene

Stoermer and *Kahlert*'s theory [2] that the conversion of 3-bromocoumarone to 2- and 3-ethoxycoumarone at 200 °C involves 2,3-dehydrocoumarone *(1)* as an intermediate was convincingly corroborated by *Wittig* and *Boos* [18], who found that in the presence of tetraphenylcyclopentadienone (tetracyclone), the adduct *(51)* of the latter with 2,3-dehydrocoumarone (20 %) as well as the ethoxycoumarones are formed.

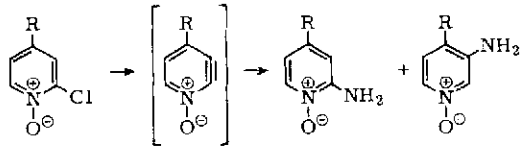


(51) *(52)*

Cine-substitutions were observed during the reaction of 3-bromothionaphthene with KOH (24 h at 200–220 °C in ethanol) [3] or with piperidine (46 h at 250–260 °C) [4]. In these reactions, which have not yet been reinvestigated, only 2-hydroxy- (15 %) and 2-piperidinothionaphthene (20 %) were isolated, but not the 3-isomers. If 2,3-dehydrothionaphthene *(52)* (which has been detected elsewhere, cf. Section IV) is involved as an intermediate, the preferred position for the entry of anionic groups into this molecule is probably on C-2.

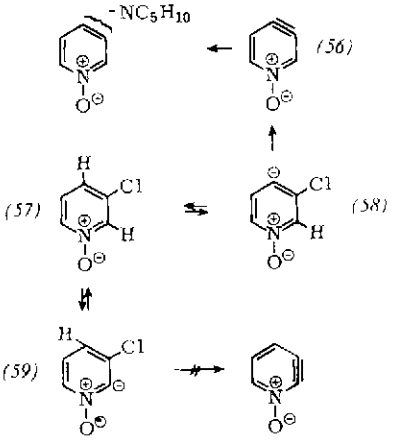
4. Hetaryne N-Oxides

Martens and *den Hertog* [43] have reported findings that point to the occurrence of 2,3-dehydropyridine-*N*-oxides *(54)* as intermediates. Thus in contrast to 3-chloropyridine *N*-oxide, from which only the 3-amino compound was obtained, the 2-chloropyridine *N*-oxides *(53)* reacted with KNH_2/NH_3 at −33 °C to form a mixture of the 2-amino (15 % and < 1 %) and 3-amino (1 % and 13–14 %) compounds *(55a)* and *(55b)*. These results have been confirmed by Japanese workers [60].

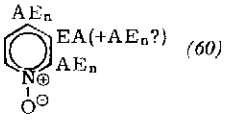


(53): R = H, OC_2H_5 *(54)* *(55a)* *(55b)*

Our own investigations [61], in which piperidine was used as the base, gave different results. Both 3-chloropyridine *N*-oxide *(57)* and 3-bromoquinoline *N*-oxide reacted at about 100 °C to give a mixture of the 3-piperidino (82 % and 20 %) and 4-piperidino (4 % and 22 %) compounds; no 2-isomer was formed in either case. This is in complete agreement with the results obtained in the reactions of 3-halogenopyridines and 3-halogenoquinolines with lithium piperidide, which have been shown to proceed by the EA mechanism. Consequently the reactions of these *N*-oxides probably also proceed by an EA mechanism involving 3,4-dehydropyridine *N*-oxide *(56)* and 3,4-dehydroquinoline *N*-oxide as intermediates, particularly since, owing to the electron-attracting properties of the NO group, it is to be expected that *(57)* and 3-bromoquinoline *N*-oxide can be deprotonated by piperidine. In addition to *(58)*, the deprotonation product *(59)* is probably also formed; owing to the withdrawal of electrons from C-2 by the nitrogen atom, however, *(59)* would lose halide only very slowly or not at all (cf. Section III.2.a).



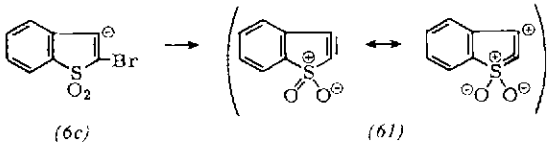
The *N*-oxides of 2-chloropyridine, 4-chloropyridine, and 4-chloroquinoline, when heated at about 100 °C with piperidine, give only the "unrearranged" substitution product in almost quantitative yield, so that these reactions may be assumed to proceed by the AE_n mechanism. The current views regarding the mechanisms followed by the reactions of chloropyridine *N*-oxides with piperidine are summarized in the mechanism map *(60)*.



(60)

5. Hetaryne S-Oxides

The reaction of 2-bromothionaphthene *S*-dioxide *(6)* (cf. Section III.1) with piperidine in ethanol follows the AE_a mechanism, yielding the 3-piperidino compound *(6b)* (90 %) *via* the "abnormal" adduct *(6a)* [28]. The reaction in benzene is five times as fast, and although the end product is the same (71 % yield), it can be shown [28] that the adduct *(6a)* does not occur as an intermediate. If the faster reaction is assumed to proceed *via* the carbanion *(6c)* and 2,3-dehydrothionaphthene *S*-



(6c) *(61)*

[60] *T. Kato*, *T. Niitsuma*, and *N. Kusaka*, J. pharmac. Soc. Japan (Yakugakuzasshi) *84*, 432 (1964).

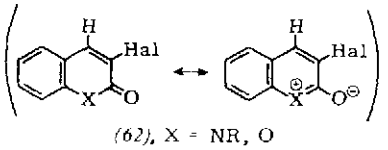
dioxide *(61)* [24], it is easy to see that this reaction would be suppressed by ethanol (cf. Section III.3.b). It has not been established whether small quantities of the 2-piperidinocompound are formed during the reaction in benzene.

The detection [62] of another hetaryne *S*-oxide, namely 4,5-dehydro-2,3;6,7-dibenzothiepin *S*-dioxide *(96)*, as an intermediate in a substitution will be described in Section IV.

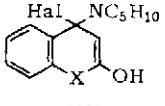
6. Hetarynes with the Grouping —C≡C—CO—X— (X = N, O) in the Ring

a) 3,4-Dehydrocarbostyrils and 3,4-Dehydrocoumarin

The hydrogen atom adjacent to the halogen in halides of the type *(62)*, as in the halogenated *N*-oxides, probably carries a relatively strong positive charge. It was therefore likely that piperidine would again be able to react by the EA mechanism. The halides listed in Table 5 do, in fact, react with anhydrous piperidine to give a mixture of two piperidino compounds [24, 36].



(62), X = NR, O



(63)

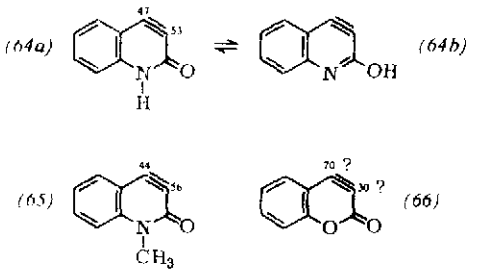
In the case of the 3-halogenocarbostyrils and 3-halogeno-1-methylcarbostyrils, the ratio of the 3- and 4-piperidino compounds is practically the same for the chloro as for the bromo compound. A pure EA mechanism involving 3,4-dehydrocarbostyril *(64)* [63] or 1-methyl-3,4-dehydrocarbostyril *(65)* as the intermediate is therefore likely [24].

Table 5. Reactions of halogenocarbostyrils and halogenocoumarins with piperidine [64].

Halogeno compound	Temp. [°C]	Piperidino compound [a] Total yield [%]	Isomer distribution [%] 3-isomer	4-isomer
3-Chlorocarbostyril	180	96 (0)	54	46
3-Bromocarbostyril	180	90 (65)	52 (62)	48 (38)
3-Chloro-1-methylcarbostyril	180	90 (0)	55	45
3-Bromo-1-methylcarbostyril	180	98 (0)	57	43
3-Chlorocoumarin	80	52 (27)	39 (60)	61 (40)
3-Bromocoumarin	80	79 (44)	30 (72)	70 (28)

[a] Values not in brackets: reaction with excess piperidine in dry benzene or with piperidine alone. Values in brackets: reaction in ethanol under otherwise identical conditions (lower yields owing to incomplete reaction of the halogen).

Table 5 also shows the good agreement between the ratios of the isomeric piperidino compounds obtained from 3-halogenocarbostyrils and 3-halogeno-1-methylcarbostyrils; the oxo form *(64a)* is therefore more likely as an intermediate than the tautomeric hydroxy form *(64b)*.



(64a) *(64b)* *(65)* *(66)*

The ratio of the isomers obtained from the reactions of 3-halogenocoumarins was found to depend on the halogen (cf. Table 5). This could be due to competition between EA and AE_n, EA and AE_a, or AE_n and AE_a mechanisms. It has been shown [31, 36], however, that 3-bromocoumarin gives 4-methoxycoumarin or 4-anilinocoumarin, as well as the piperidino compound when treated with piperidine in the presence of methanol or aniline. Since 3-bromocoumarin is stable towards methanol or aniline under the experimental conditions, this indicates the occurrence of 3,4-dehydrocoumarin *(66)* as an intermediate, so that the change in the ratio of the isomers must be due to competition between EA and AE_n, or EA and AE_a.

The reactions of halogenocarbostyrils and halogenocoumarins with piperidine are inhibited by ethanol. Where the inhibition is not complete, the isomer ratio is displaced in favor of the "unrearranged" product (cf. Table 5); as a result of blockage of the EA mechanism (cf. Section III.3.b), therefore, substitution by the AE_n mechanism becomes dominant.

The 4-isomers of the halides listed in Table 5 give only the 4-piperidino compounds on reaction with piperidine [24]. The adducts *(63)* postulated as intermediates appear to be readily formed.

b) 1-Methyl-2-phenyl-4,5-dehydropyridazine-3,6-dione and 4,5-Dehydrouracil

Druey [65] treated *(67)* (Hal = Cl) with sodium methoxide and obtained only the 5-methoxy compound *(68)*. This and similar [65] cine-substitutions with secondary amines have not yet been explained. Detailed investigations [24, 66, 67] showed that the reactions of the 4-halogeno compounds *(67)* of Table 6 with piperidine always give both the 4-piperidino and 5-piperidino compounds. Since the ratio of the isomers is independent

[63] *A. Baeyer* and *F. Bloem,* Ber. dtsch. chem. Ges. *15*, 2151 (1882) formulated 3,4-dehydrocarbostyril and tried to prepare it more than 80 years ago.

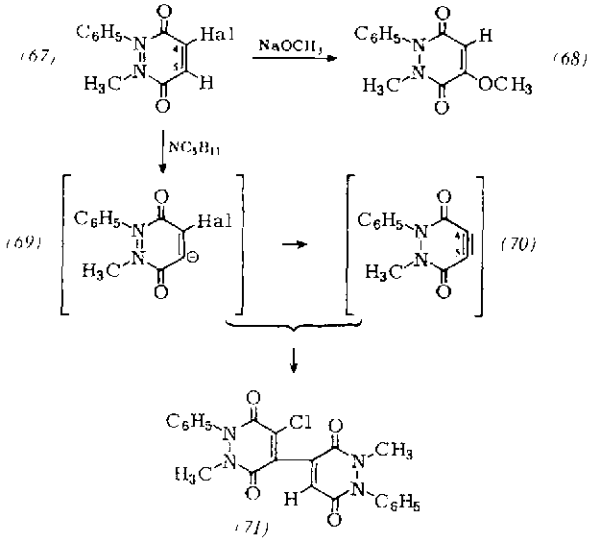
[64] 3-Bromo-1,1-dimethyl-2-oxo-1,2-dihydronaphthalene [*N.H. Cromwell* and *R. D. Compbell*, J. org. Chemistry *22*, 520 (1957)] and 8-bromoperinaphthen-7-one [*N. H. Cromwell, D. B. Capps,* and *S. E. Palmer*, J. Amer. chem. Soc. *73*, 1226 (1951)] react similarly with morpholine to give 4-morpholino-1,1-dimethyl-2-oxo-1,2-dihydronaphthalene and 8- and 9-morpholinoperinaphthen-7-one. The mechanism of this reaction has not been established.

[65] *J. Druey*, Angew. Chem. *70*, 12 (1958); *J. Druey, K. Meier,* and *A. Staehelin*, US.-Pat. 3004972 (Oct. 1961); Chem. Abstr. *56*, 12909 (1962).

[66] *Th. Kauffmann* and *A. Risberg*, Tetrahedron Letters *1963*, 1459.

[67] *A. Risberg*, Doctorate Dissertation, Technische Hochschule Darmstadt.

of the halogen, the reaction probably involves the halogen-free intermediate 1-methyl-2-phenyl-4,5-dehydropyridazine-3,6-dione *(70)*. This view is supported by the inhibition of the reaction and the pronounced change in the isomer ratio (see Table 6) caused by

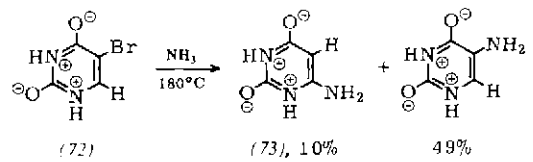


ethanol (cf. Section III.3.b), and by the formation of the 5-methoxy compound *(68)* (yield = 63 %) when piperidine and methanol are reacted simultaneously with *(67)*, Hal = Cl, (which is inert towards methanol alone). The ratio of the isomeric piperidino derivatives obtained from the 5-chloro compound in Table 6 indicates that the AE_n mechanism is involved in this case as well as the EA mechanism.

Table 6. Reaction (22 hours at about 20 °C) of halogenopyridazinediones with excess piperidine in benzene or in ethanol (values for ethanol in brackets).

Halogeno-1-methyl-2-phenylpyridazine-3,6-dione	Piperidino compound		
	Total yield [%]	Isomer distribution [%]	
		4-isomer	5-isomer
4-Chloro-	86 (78)	17 (77.5)	83 (22.5)
4-Bromo-	96 (81)	15.5 (53)	84.5 (47)
5-Chloro-	90	7	93

Attempts have been made [67] to intercept the hypothetical hetaryne *(70)* with furan or phenyl azide during the reaction of *(67)* (Hal = Cl) with strong bases (piperidine, potassium t-butoxide, azaquinuclidine). However, no adducts have so far been isolated. Apart from substitution products, these attempts yielded only ring cleavage products and a "dimer" with the overall formula $C_{22}H_{17}ClN_4O_4$. This "dimer" is presumably formed by the addition of the anion *(69)* to *(70)*, and probably has the structure *(71)*. The electron attraction of two oxygen and two nitrogen atoms probably makes *(70)* so strongly electrophilic that it adds on strong bases such as *(69)* much more rapidly than the weakly basic phenyl azide or the non-basic furan. Owing to the failure of the attempted interceptions, however, the assumption of a mechanism involving *(70)* must be viewed with caution.



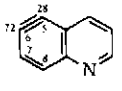
(72) *(73)*, 10% 49%

The recently observed [68], but not yet closely studied formation of 4-aminouracil *(73)* when 5-bromouracil *(72)* is heated at 180 °C in liquid ammonia, may result from the intermediate formation of 4,5-dehydrouracil. Ethanol again retards the reaction and directs it in such a way that only the "unrearranged" isomer is formed [68].

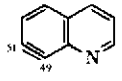
7. Hetarynes Containing a Dehydrobenzene Ring

a) 5,6- and 7,8-Dehydroquinolines

The reactions of 5-, 6-, and 7-halogenoquinolines (Hal = Cl, Br) with lithium piperidide/piperidine in boiling ether apparently proceed entirely (the isomer ratio is independent of the halogen) *via* 5,6-dehydroquinoline *(74)*, or in the case of the 7-halogenoquinolines, *via* 7,8-dehydroquinoline *(3')*, the products being mixtures of 5- and 6-, or 7- and 8-piperidinoquinolines [41]. 8-Halogenoquinolines (Hal = Cl, Br, I), on the other hand, react under the same conditions by the AE_n mechanism, giving only 8-piperidinoquinoline [41]. These results are indicated in the mechanism map *(20)* (Table 2) together with other results described earlier (Section III.2.a).

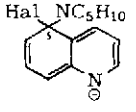


(74)

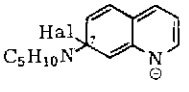


(3')

The exceptional behavior of the halogen in position 8 is surprising and has not as yet been satisfactorily explained. The AE_n mechanism is more likely with the 5- and 7-halogenoquinolines, since the negative charge in the hypothetical piperidine adducts of these halides can be taken over by the quinoline nitrogen as shown in *(75)* and *(76)*; this is impossible in the corresponding adducts of the 6- and 8-halogenoquinolines.



(75)



(76)

6- and 7-halogenoquinolines yield 5,6- and 7,8-dehydroquinolines, respectively, but no 6,7-dehydroquinoline [41]. This corresponds to *Huisgen*'s observation [26] that the elimination of hydrogen halide from 2-halogenonaphthalenes under the same conditions leads only to 1,2-dehydronaphthalene, but not to the 2,3-isomer [69].

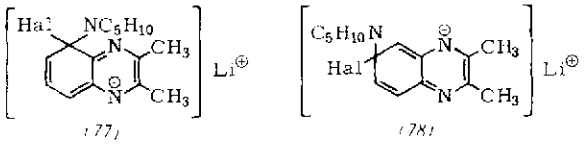
[68] *K. Forberger*, Diploma Thesis, Technische Hochschule Darmstadt.

[69] A change of the α-/β-piperidinonaphthalene ratio in favor of the β-isomer when the reaction temperature is raised from 35 °C (ether) to 106 °C (boiling piperidine) has been explained [*J. Sauer*, *R. Huisgen*, and *A. Hauser*, Chem. Ber., *91*, 1468 (1958)] by partial elimination to form 2,3-dehydronaphthalene at the higher temperature. This appears questionable, as the β-isomer (6-isomer) is also favored at the higher temperature in the corresponding reactions with 6-chloroquinoline (ratio of 5- and 6-isomers = 20:80 [32] instead of 28:72 [41]); the fact that no 7-piperidinoquinoline is formed practically rules out the occurrence of 6,7-dehydroquinoline as an intermediate, and points to competition between the EA and AE_n mechanisms.

The partial rate constants [47] [cf. *(74)* and *(10)*] as determined from the yields of aromatic piperidino compounds are almost the same in the addition of piperidine to 5,6-dehydroquinoline [41] as in the addition of piperidine to 1,2-dehydronaphthalene [26] in boiling ether; thus the nitrogen atom has practically no effect on the yields. In 7,8-dehydroquinoline *(3')* [41], on the other hand, the closer proximity of the nitrogen atom to the extra bond favors the introduction of the piperidino group into the α-position.

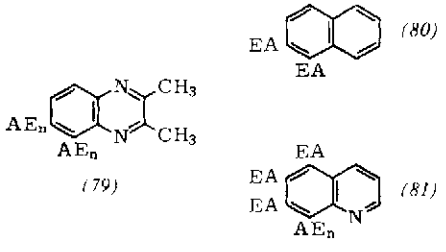
h) Attempts to Detect 5,6-Dehydroquinoxalines

5- and 6-chloro-2,3-dimethylquinoxalines react slowly with lithium piperidide/piperidine in boiling toluene, yielding only 5- and 6-piperidino-2,3-dimethylquinoxalines, respectively. It is very probable, therefore, that these reactions do not involve 2,3-dimethyl-5,6-dehydroquinoxaline as an intermediate, but that they proceed by the AE_n mechanism with the adducts *(77)* and *(78)*, respectively, as intermediates [32].



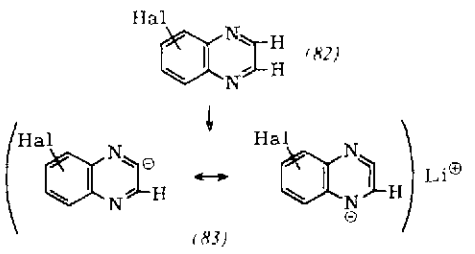
(77) *(78)*

A comparison of this result, as expressed in the mechanism map *(79)*, with the mechanism maps *(80)* and *(81)* for the analogous reactions of the halogenonaphthalenes [26] and quinolines having a halogen substituent on the carbocyclic ring [41] shows that the AE_n mechanism is favored by increasing substitution of nitrogen atoms for CH groups in the unhalogenated ring (cf. Section III.2.b).



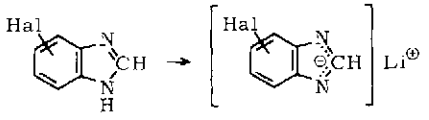
(79) *(80)* *(81)*

In contrast to the behavior of the chloro-2,3-dimethylquinoxalines, 5- and 6-chloroquinoxalines *(82)* are largely recovered unchanged after treatment with lithium piperidide/piperidine in boiling toluene; only traces of the piperidino compounds are formed, and these have been found to be the "unrearranged" products [32]. It may be assumed that the electron attraction of two nitrogen atoms leads to the replacement of a hydrogen atom of the heterocyclic ring by lithium, and that the negative charge of the resulting mesomeric anion [*e.g.* *(83)*] prevents the first step of the substitution, *i.e.* the introduction of metal in the *o*-position with respect to the halogen or the addition of lithium piperidide.



(82) *(83)*

A similar inhibition of substitution by the introduction of metal in the "wrong" place could also explain the resistance of the halogen in halides of the type *(84)* [51] and in 4-bromoisoquinoline (cf. Section III.3.a) and 5-bromouracil [68] towards lithium piperidide.

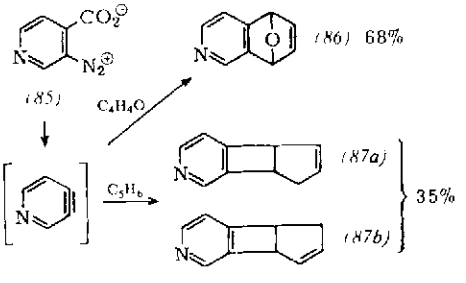


(84)

IV. Cycloadditions with Hetarynes

Although the results described in Section III.2 provide evidence for the occurrence of 3,4-dehydropyridine *(2)*, it could be objected that *(2)* might be capable of existing only in loose association with a metal cation or a halide ion. That this is not the case is shown by the production of 3,4-dehydropyridine during the thermal decomposition of pyridine-3-diazonium-4-carboxylate *(85)* [10].

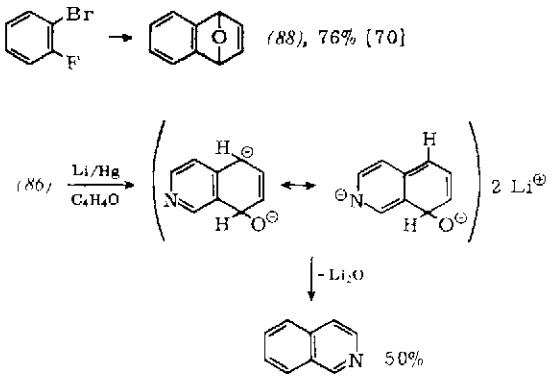
Like dehydrobenzene [70], the 3,4-dehydropyridine obtained in this way combines with furan in a Diels-Alder reaction [10]; unlike dehydrobenzene [71], however, it reacts with cyclopentadiene to form a cyclobutene derivative having the structure *(87a)* or *(87b)* [36, 37]. The lower reactivity of 3,4-dehydropyridine as compared with dehydrobenzene is shown by the fact that the former, unlike dehydrobenzene [72, 73], does not undergo appreciable addition to anthracene or bicyclo-[2,2,1]hepta-2,5-diene [36, 74], as well as by selectivity studies (cf. Section VI).



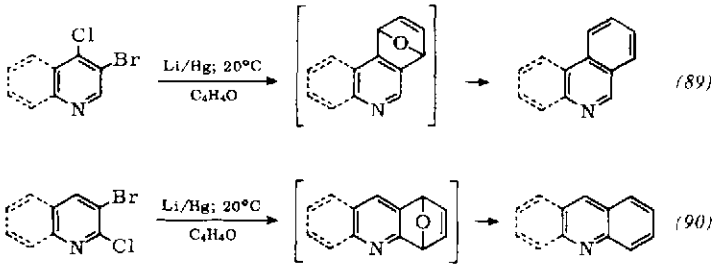
(85) *(86)* 68% *(87a)* *(87b)* 35%

[70] *G. Wittig* and *L. Pohmer*, Chem. Ber. *89*, 1334 (1956).
[71] *G. Wittig* and *E. Knauss*, Chem. Ber. *91*, 895 (1958).
[72] *G. Wittig*, Org. Syntheses *39*, 75 (1959).
[73] *H. E. Simmons*, J. Amer. chem. Soc. *83*, 1657 (1961).
[74] The products, which are formed only in small quantities, have not yet been subjected to gas-chromatographic analysis.

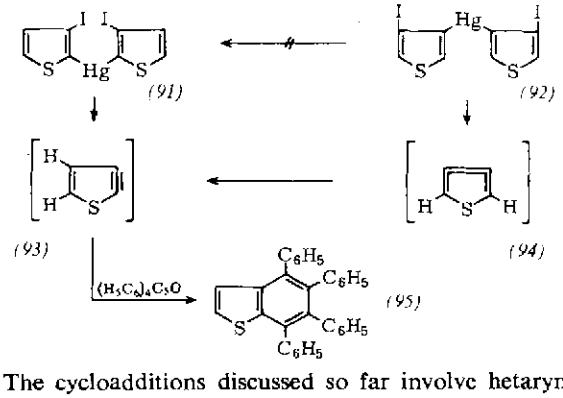
In contrast to the 1,4-dihydronaphthalene-1,4-epoxide *(88)*, which can be prepared from *o*-bromofluorobenzene, the analogous 5,8-dihydroisoquinoline-5,8-epoxide *(86)* rapidly loses oxygen to form isoquinoline on shaking with lithium amalgam in furan [10].



This explains why the reactions of heteroaromatic *o*-dihalogeno compounds with lithium amalgam in furan lead to the oxygen-free heteroaromatic compounds *(89)* (14 % of isoquinoline [10] and 9 % of phenanthridine [15]) and *(90)* (2 % of quinoline [13,43] and 4 % of acridine [37,75]), and not to the hetaryne-furan adducts

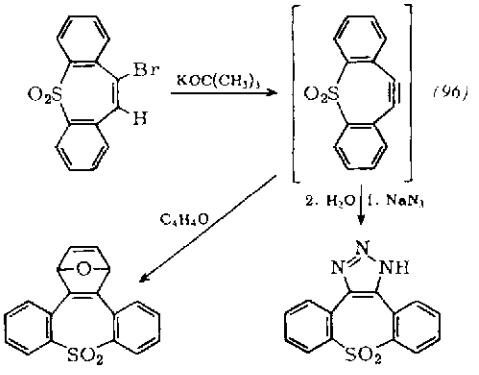


corresponding to *(86)*. The preparations of quinoline and acridine from 3-bromo-2-chloropyridine and 3-bromo-2-chloroquinoline, respectively, are important in spite of the low yields obtained, since they point to the intermediate formation of 2,3-dehydropyridine *(13)* and 2,3-dehydroquinoline; these compounds, unlike the 3,4-analogues, have not so far been detected by any other means (cf. Section III.3.a).



The cycloadditions discussed so far involve hetarynes with a six-membered ring. *Wittig* and *Wahl* [16] were the first to intercept a five-membered ring hetaryne by cycloaddition: on fusion with tetraphenylcyclopentadienone, the mercury compound *(91)* obtained from 3-iodo-2-lithio-thiophene gives a 12 % yield of 4,5,6,7-tetraphenylthionaphthene *(95)*, indicating the intermediate formation of 2,3-dehydrothiophene *(93)*. Compound *(95)* is also formed when *(92)* is fused with tetraphenylcyclopentadienone. Since *(92)* does not isomerize to *(91)* under the conditions of this reaction, it is assumed that the 2,3-dehydrothiophene is formed by rearrangement of the initially formed 3,4-isomer *(94)* [17,18].

1-Methyl-2,3-dehydroindole[18], 2,3-dehydrocoumarone *(1)* [17], and 2,3-dehydrothionaphthene *(52)* [76] have also been produced and intercepted in a similar manner (adduct yields of 13 %, 70 %, and 54 %, respectively). The detection of 2,3-dehydrocoumarone as an intermediate in the reaction of 3-bromocoumarone with sodium ethoxide by interception with tetraphenylcyclopentadienone was mentioned in Section III.3.c. *Tochtermann* [62] first demonstrated the intermediate formation of a seven-membered cyclic hetaryne, namely 4,5-dehydro-2,3;6,7-dibenzothiepin *S*-dioxide *(96)*, as shown in Scheme 2.



Scheme 2. Detection of a hetaryne containing a seven-membered ring [62].

It should be noted, finally, that the isolation of a diene adduct does not in itself constitute satisfactory proof of the existence of an *o*-dehydroaromatic compound. If this is the only evidence available, it must be shown by experiment that no other reaction route is possible (cf. [77]); alternatively, further evidence must be found, as in the cases of 3,4-dehydropyridine and 3,4-dehydroquinoline (cf. Section III.2.a).

V. Hetarynium Ions

When heated without solvent, the compound *(98)* decomposes into 2-hydroxypyridine (93 %), N_2, and sulfur. If the thermal decomposition is carried out in chloroform containing HN_3, or in methanol, the products include tetrazolopyridine (9 %) or 2-methoxypyridine (36 %) [78]. It is therefore assumed that the decom-

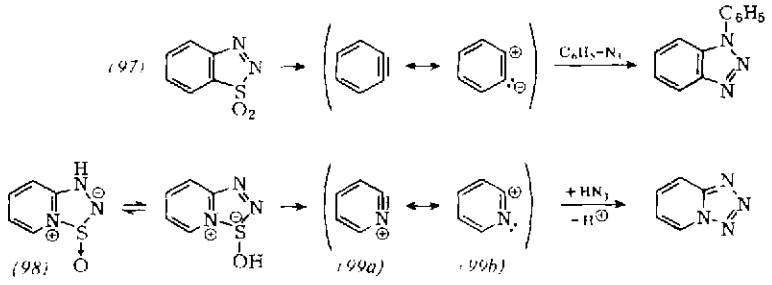
[75] *Th. Kauffmann* and *K. Udluft*, Angew. Chem. *75*, 89 (1963); Angew. Chem. internat. Edit. *2*, 45 (1963).

[76] *G. Wittig* et al., personal communication.

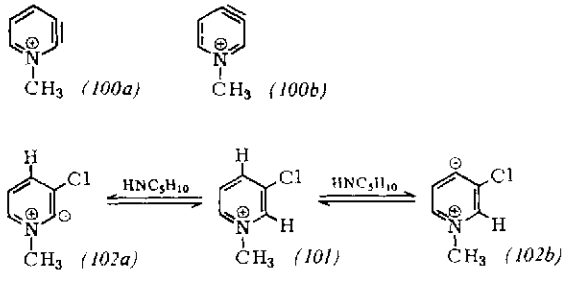
[77] *W. Tochtermann*, *K. Oppenländer*, and *U. Walter*, Chem. Ber. *79*, 1318 (1964).

[78] *Th. Kauffmann* and *H. Marhun*, Chem. Ber. *96*, 2519 (1963).

position of *(98)* leads to the mesomeric hetarynium-carbenium ion *(99a)* ↔ *(99b)* (cf. the thermal decomposition of *(97)* to dehydrobenzene [79]), and that this ion reacts with the hydroxide ion which is also formed, the ultimate product being 2-hydroxypyridine. Under suitable conditions, however, the ion *(99a)* ↔ *(99b)* also reacts with HN_3 (1,3-dipolar cycloaddition) or methanol and loses a proton to form tetrazolopyridine or 2-methoxypyridine. Since our present knowledge [80] indicates that the phenyl cation is less stable than dehydrobenzene, the hetarynium form *(99a)* is presumably more important than the carbenium form *(99b)*.



Besides the hypothetical hetarynium ion *(99)*, other hetarynium ions of the type *(100)* can theoretically be derived from pyridine. So far, no experimental evidence has been found for the occurrence of such an ion. In attempts [67] to react monochloro-1-methylpyridinium halides with anhydrous piperidine at room temperature, the 2- and 4-chloro compounds gave only the corresponding 2- and 4-piperidino compounds, respectively. 3-Chloro-1-methylpyridinium chloride, however was largely recovered unchanged. Neither the 2- nor the 4-piperidino compound was obtained in this case; this was also true of a reaction at 100 °C, which resulted in vigorous resinification. Since it may be assumed that piperidine is capable of removing the highly positive hydrogen atoms on C–2 and C–4 of the cation *(101)*, the EA substitution is evidently prevented by the reluctance of the zwitterions *(102a)* and *(102b)* to lose Cl.



VI. Selectivity and Structure

The higher the energy of an intermediate, the smaller is the activation energy required for further reaction, and the lower is its selectivity when two or more reaction partners are available at the same time.

Huisgen [81] has determined the selectivity of the carbocyclic arynes dehydrobenzene, 1,2-dehydronaphthalene, and 9,10-dehydrophenanthrene in the competitive addition of phenyl-lithium and lithium piperidide. His values show that the fusion of benzene rings to dehydrobenzene leads to an increase in selectivity, *i. e.* has a stabilizing effect. Since the distance between the carbon atoms between which the extra bond is to be formed decreases in the order benzene > naphthalene > phenanthrene (1.39, 1.365, and 1.35 Å respectively), *Huisgen* [81] believes that the increasing selectivity (and hence the increasing stability) is due to an increasing overlap of the extra orbitals.

If this were the only stabilizing effect, 3,4-dehydropyridine should be less selective than dehydrobenzene, since the (C-3)–(C-4) bond of pyridine is slightly longer (1.400 Å [82]) than the C–C bond in benzene (1.39 Å). However, experiments [33, 83] in which piperidine and diethylamine were used as the competing bases (since phenyl-lithium readily adds onto the CN double bond in pyridines [84]) indicated that the opposite is true. Figure 1 shows the results of gas-chromatographic measurements for the competitive addition of piperidine and diethylamine to the arynes dehydrobenzene, 1,2-dehydronaphthalene, and 3,4-dehydropyridine obtained by the action of lithium diethylamide and lithium piperidide [85] on chlorobenzene, 1-chloro-

[82] *B. Back*, *L. Hansen*, and *J. Rastrup-Andersen*, J. chem. Physics *22*, 2013 (1954); the bond length was determined from microwave measurements.

[83] *M. Daum*, Doctorate Dissertation, Technische Hochschule Darmstadt.

[84] According to *F.-P. Boettcher* (Doctorate Dissertation, Technische Hochschule Darmstadt, 1961), the successive action of phenyl-lithium and acetic anhydride on 3-chloropyridine leads to 1-acetyl-3(or 5)-chloro-2-phenyl-1,2-dihydropyridine; cf. also *K. Ziegler* and *H. Zeiser*, Ber. dtsch. chem. Ges. *63*, 1848 (1930).

[85] The ratio (lithium diethylamide + lithium piperidide): (diethylamine + piperidine) was 1:9. Since the rates of addition of lithium piperidide and piperidine to 9,10-dehydrophenanthrene are roughly equal [26], probably mainly the free bases added onto the arynes in the selectivity determinations.

naphthalene, and 3-chloropyridine. The slopes of the lines joining the experimental points show a 1.0-, 1.1-, and 1.5-fold preference for piperidine.

Thus 3,4-dehydropyridine is more selective than dehydrobenzene and 1,2-dehydronaphthalene [85a].

Since this cannot be plausibly explained by a better overlap of the extra orbitals, it must be assumed that the aromatic π-electron cloud has a considerable influence on the extra bond in arynes; this is supported by the fact that dehydrobenzene is more stable than cyclohexyne [18] and by quantum-mechanical calculations [86]. Since the selectivity is increased by the fusion of a benzene ring to dehydrobenzene or by the substitution of a nitrogen atom for a CH group, it can be expected that 3,4-dehydroquinoline [15] and 4,5-dehydropyrimidine [36] will be more selective in the addition of bases than 3,4-dehydropyridine. 2,3-Dehydropyridine [13] should also be more selective, since the extra orbitals (probably sp^2) in this case can overlap with the orbital (sp^2) of the free electrons on the nitrogen atom (the expected [11] decrease in energy is supported by quantum-mechanical calculations [87]).

Overlapping of this nature could provide the driving force for a rearrangement of 3,4- to 2,3-dehydrothiophene [17] (cf. Section IV).

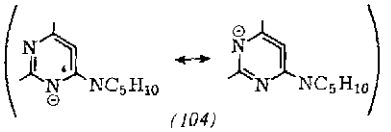
Since hetarynes (apart from those with the extra bond in a carbocyclic ring) contain a nucleophilic center (the heteroatom) and a highly unsaturated electrophilic bond in the same ring, the possibility of stabilization by a transannular reaction to form valence-isomeric forms [*e.g.* formation of *(103)* from *(70)*] must also be considered [24].

(70) *(103)*

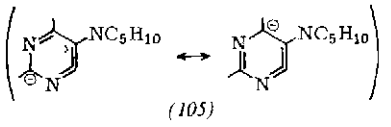
VII. Oriented Addition of Bases to Hetarynes

In the addition of a base to a hetaryne, it is generally possible to predict which of the two isomers formed will predominate, if the energy contents of the anion-hetaryne adducts corresponding to the isomers are estimated from the mesomeric distribution of the negative charge (assuming that similar energy relationships apply in the transition states of the additions) [88].

This can be illustrated by the addition of piperidine to 4,5-dehydropyrimidine. The hypothetical "C-4 adduct" *(104)* of the piperidide ion and 4,5-dehydropyrimidine should have a lower energy than the "C-5 adduct" *(105)*, since according to the resonance structures, the negative charge introduced into the aromatic system can be accommodated by nitrogen atoms only in *(104)*. In agreement with this, the anionic piperidide group appears (cf. Section III.3.b) to add predominantly onto C-4 of 4,5-dehydropyrimidine.



(104)

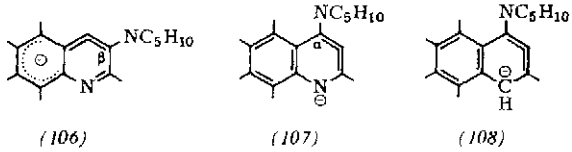


(105)

For similar reasons, the addition of bases to 3,4-dehydropyridine should result in attachment of the anionic group mainly to C-4. In fact, in the addition of NH_3/KNH_2 at −33 °C [12, 22] and in the addition of piperidine at 0 °C [51], the amino and piperidino groups show a pronounced preference for C-4 (ratios of the 3- and 4-isomers = 33:67 and 42:58).

In the addition of piperidine onto 3,4-dehydropyridine, the preference for C–4 is less at 35 °C (ratio of 3- and 4-isomers= 48:52) than at 0 °C. This agrees with the expectation that the selectivity of addition to an asymmetric aryne will decrease as the energy content (which increases with temperature) increases. It is not impossible, however, that the change in the isomer ratio is due to a slight participation of the AE_n mechanism in the reactions giving the ratio 48:52 [11] (cf. Section III.2.a).

It is not possible to decide directly which of the two mesomeric piperidide/3,4-dehydroquinoline adducts represented by *(106)* and *(107)* has the lower energy. The energy relationships in the "α-adduct" *(107)*, however, appear to be more favorable than in the corresponding adduct *(108)* of 1,2-dehydronaphthalene. It was to be expected, therefore, that attachment of the piperidide group in the α-position with respect to the undehydrogenated ring would occur to a greater extent in 3,4-dehydroquinoline than in 1,2-dehydronaphthalene. The ratio of the α- and β-adducts in the former case is, in fact, 49:51 [15], as opposed to 31:69 [26] in the case of 1,2-dehydronaphthalene [89].



(106) *(107)* *(108)*

[85a] Note added in proof: When dehydrobenzene or 3,4-dehydropyridine are treated with lithium piperidide and lithium diethylamide in boiling ether, the diethylamide (!) is added on 1.7- or 2.2-times as fast, respectively, as the piperidide [33]. Thus, 3,4-dehydropyridine here again exhibits a higher selectivity.

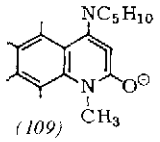
[86] *C. A. Coulson*, Special Publ., Chem. Soc. (London) *12*, 85 (1958).

[87] *H. L. Jones* and *D. L. Beveridge*, Tetrahedron Letters *1964*, 1577.

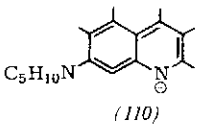
[88] Note that the orientation phenomena in the addition of bases onto substituted dehydrobenzenes has been explained on the basis of the inductive effects of the substituents [26, 46].

[89] It is of interest in connection with the addition of bases onto arynes containing corresponding groups that open-chain alkynes of the type $C_6H_5-C(\alpha)\equiv C(\beta)$-Alk [addition of $NaNH-NH_2$: *S. Sobel*, Doctorate Dissertation, Technische Hochschule Darmstadt; addition of phenylisopropylpotassium (Alk = CH_3): *K. Ziegler* and *H. Dislich*, Chem. Ber. *90*, 1111 (1957)] and $O=C(R)-C(\alpha)\equiv C(\beta)-R$ [*e.g.* addition of piperidine (R=C_6H_5): *E. R. Watson*, J. chem. Soc. (London) *85*, 1319 (1904)] add anionic groups predominantly or exclusively on C-β. Similar behavior is expected with open-chain alkynes $R-N=C(R)-C(\alpha)\equiv C(\beta)-R$.

Whereas the negative charge in *(107)* can be taken over by the nitrogen atom, it can be accommodated by the carbonyl oxygen in "α-adducts" such as *(109)* of hetarynes of the type *(4)*. In agreement with this, the frequency of attachment of the piperidide group to the α-position is greater in the addition of piperidine onto hetarynes of the type *(4)* [cf. *(64a)* to *(66)*] than onto 1,2-dehydronaphthalene. However, this could also be partly due to steric hindrance of the "β-addition" by the carbonyl oxygen.



(109)



(110)

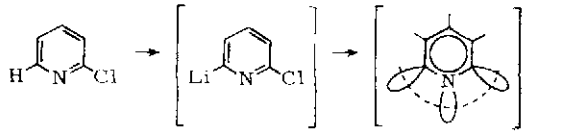
It is not yet clear why the preference for "α-addition" is greater in the addition of piperidide to 7,8-dehydroquinoline *(3)* than to 1,2-dehydronaphthalene [cf. *(3')* and *(10)*], since addition in accordance with formula *(110)* should be more likely in the β-position.

VIII. The 2,6-Dehydropyridine Problem

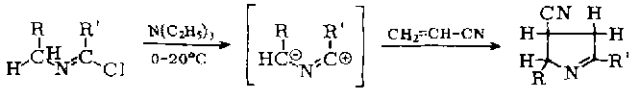
Since all attempts to detect carbocyclic *m*- and *p*-dehydroaromatic compounds have so far been unsuccessful, it must be assumed [26] that *o*-dehydroaromatic compounds can exist only because of the energy-lowering overlap of the orbitals of the extra electrons. Owing to the possibility of overlap between the orbitals of the extra electrons and those of the lone electrons on the nitrogen in hypothetical *m*-dehydroaromatic compounds of the type *(112)*, it appears that such compounds may be capable of existing [87].

Of interest in this connection is the surprising discovery mentioned in Section III.2.a. that the action of lithium piperidide on 2-chloropyridine *(111)* in boiling ether leads to resinification, whereas less than 1 % of the expected 2-piperidinopyridine and none of the 3-piperidino compound are formed [11]. The other 2-halogenopyridines, with the exception of the fluoro compound (Table 1), also yield resins and lithium halide on reaction with lithium piperidide. The same result is obtained if lithium diethylamide or lithium dicyclohexylamide is used instead of lithium piperidide [31].

Since resinification occurs only when the 2-halogenopyridine has a hydrogen on C-6 (and hence does not take place with 2-chloro-6-methylpyridine or 2-chloroquinoline), and since the analogous reaction *(113)* → *(114)* of open-chain compounds proceeds remarkably easily [90], the reactions leading to resin formation may involve 2,6-dehydropyridine *(112)* [formed by the elimination of lithium halide from *(111a)*] as a short-lived intermediate.



(111) *(111a)* *(112)*



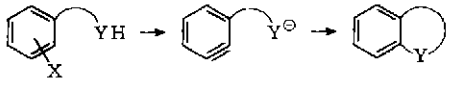
(113), R = C_6H_4-NO_2
R' = C_6H_5

(114)

IX. Outlook

The main method used in future efforts to produce various kinds of hetarynes will still be the reaction of bases with halogenated heteroaromatic compounds, owing to the ease of obtaining the starting materials. A primary aim in future work should be to find rules which allow reliable predictions regarding the mechanisms and products of nucleophilic substitutions in heterocyclic aryl halides.

Since new methods are continuously being found for the production of dehydrobenzene in non-basic media [70, 79, 91–94], it will probably also become possible to produce an ever-widening range of hetarynes in non-basic media, *i.e.* under conditions which will permit the interception of these compounds in good, and possibly even preparative yields with a diene or a 1,3-dipolar compound. The incentive is great, in view of the possible variety in the heterocyclic series. For the same reason, it is possible that the method shown in Scheme 3 for building up ring systems [26, 95] will be modified for the synthesis of heterocyclic aryl halides, in which field it should find many applications.



Scheme 4. Synthesis of ring systems *via* arynes [26, 94].

The "chemistry of transient species", *i.e.* the rapidly expanding chemistry of unstable molecules such as carbenes, nitrenes, arynes, or "hot" 1,3-dipolar compounds, will probably be greatly enriched by future investigations on heterocyclic arynes.

The investigations carried out by my colleagues Dr. F.-P. Boettcher, M. Daum, K. Forberger, J. Hansen, H. Marhan, R. Nürnberg, A. Risberg, J. Schulz, K. Udluft, R. Weber, and R. Wirthwein, were generously supported by the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Vereinigung von Freunden der Technischen Hochschule zu Darmstadt, to whom we are sincerely grateful. The author also wishes to thank Prof. C. Schöpf for discussions, Prof. H. J. den Hertog, Prof. R. Huisgen, Dr. W. Tochtermann, and Prof. G. Wittig for making available unpublished results.

Anaplerotic Sequences in Microbial Metabolism [1]

BY PROF. DR. H. L. KORNBERG

DEPARTMENT OF BIOCHEMISTRY, UNIVERSITY OF LEICESTER (ENGLAND)

In addition to catabolic and anabolic pathways, which enable nutrients to enter and to be withdrawn from the central routes of metabolism, enzymic sequences operate to ensure that intermediates, removed from these central routes in the course of biosynthesis, are replenished. These obligatory pathways of replenishment are generically designated "anaplerotic sequences". The nature of these sequences, operative in micro-organisms growing on C_3- and C_2-compounds, is discussed in outline, and the mode of regulation of one of them (the glyoxylate cycle) is examined in detail.

Metabolic routes are sequences of chemical steps, catalysed by enzymes, which enable living organisms to obtain from their food both the ingredients required for the synthesis of cell constituents and the energy necessary to effect such and other endergonic processes. The routes whereby this is achieved are generally divided into three distinct types. Catabolic routes serve primarily to promote the entry of individual nutrients into the central, energy-yielding pathways of metabolism (the glycolytic sequence and tricarboxylic acid cycle); anabolic routes utilize the intermediates of these pathways as precursors of the organism's own macromolecules. The central pathways thus play a dual role, and the intermediates which lie upon them are indispensable to the provision both of energy and of the carbon skeletons of the multitudinous components of the cell: by virtue of this dual function, these pathways have been termed amphibolic [2].

However, these three types of metabolic routes are not sufficient to account for the growth of micro-organisms, provided with a single compound as sole carbon source, when the catabolism of that compound cannot directly yield an intermediate of the tricarboxylic acid cycle: some route ancillary to that cycle must operate to ensure that the intermediates of the cycle, which are drained away during growth, are replenished. It is the main purpose of this article to discuss the nature of these obligatory routes of replenishment, which may be generically described as anaplerotic sequences [3].

1. Anaplerotic CO_2-Fixation

The catabolism of hexoses, glycerol, or other precursors of pyruvate yields C_3-compounds which, in aerobic organisms, are totally combusted *via* the tricarboxylic acid cycle. Pyruvate initially loses one of its carbon atoms to form acetyl-coenzyme A, which enters the cycle after condensation with oxaloacetate. Each turn of the cycle then results in the loss of a further two carbon atoms as carbon dioxide and regeneration of the oxaloacetate necessary to accept a further C_2-unit. In the growing cell, however, the operation of anabolic routes for the synthesis of, for example, porphyrins, and amino acids of the glutamate and aspartate "families", removes the intermediates required for this necessary regeneration of oxaloacetate: unless an anaplerotic reaction also occurs, which enables this loss of tricarboxylic acid cycle intermediates to be made good, both energy provision and biosynthesis must cease.

In the example cited, this anaplerotic function is borne by carboxylation reactions (Fig. 1). In *Pseudomonas* [4], oxaloacetate may be formed by the direct carboxylation of pyruvate (Reaction a) but this reaction does not appear to occur in the Enterobacteriaceae [5]. Instead, three other enzymes theoretically capable of effecting the net formation of C_4-acids from the carboxylation of

$$CH_3{-}CO{-}CO_2H + ATP + CO_2 \rightarrow HO_2C{-}CH_2{-}CO{-}CO_2H + ADP + H_3PO_4 \qquad (a)$$

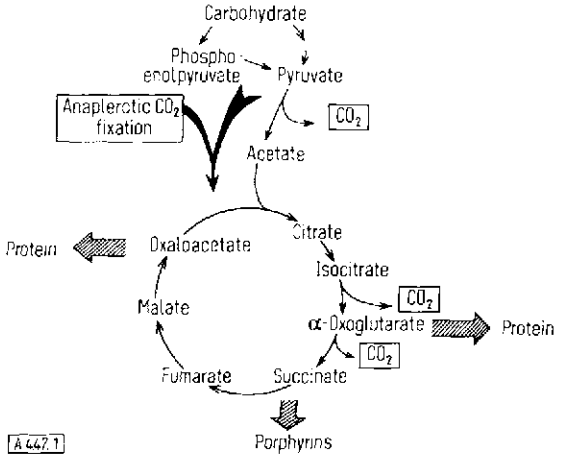

Fig. 1. Anaplerotic fixation of carbon dioxide. The net formation of C_4-compounds through the carboxylation of C_3-acids (indicated by black arrow) is necessary for replenishment of tricarboxylic acid cycle intermediates, removed in the course of growth.

C_3-compounds have been found to be present: these are (Reaction b) phosphoenolpyruvate carboxylase [6],

$$CH_2{=}C(CO_2H){-}OPO_3H_2 + CO_2 + H_2O \rightarrow HO_2C{-}CO{\cdot}CH_2{-}CO_2H + H_3PO_4 \quad (b)$$

(Reaction c) "malic enzyme" [7],

$$CH_3{-}CO{-}CO_2H + NADPH_2 + CO_2 \rightleftarrows HO_2C{-}CHOH{-}CH_2{-}CO_2H + NADP \quad (c)$$

and (Reaction d) the ATP-linked oxaloacetate decarboxylase [8]

$$CH_2{=}C(CO_2H){-}OPO_3H_2 + ADP + CO_2 + H_2O \rightleftarrows HO_2C{-}CO{-}CH_2{-}CO_2H + ATP \quad (d)$$

It was possible to distinguish the enzyme bearing the anaplerotic function by studies [5] with a mutant of *Escherichia coli* which, though unable to grow on glucose plus ammonia, grew readily if this medium was supplemented with any intermediate of the tricarboxylic acid cycle able to penetrate the cell. Washed suspensions of this mutant oxidized pyruvate only to the level of acetate, which accumulated; however, pyruvate was totally combusted if catalytic amounts of L-malate were also provided.

Ultrasonic extracts of the mutant contained as much of enzymes for reactions (c) and (d) as did similar extracts of the parent, wild-type organism, but differed from them in being devoid of the ability to catalyse reaction (b). This showed that the enzyme necessary for the net formation of C_4-compounds was a (virtually irreversible) phosphoenolpyruvate carboxylase, and suggested that anaplerotic enzymes are distinguishable from others which, while effecting similar reactions, serve a different function in the cell.

2. Anaplerotic Sequences in Acetate Metabolism

Although mutants of *E. coli* devoid of phosphoenolpyruvate carboxylase are unable to grow on pyruvate or precursors thereof, such mutants grow readily on acetate as sole carbon source [9]. This shows that some other anaplerotic sequence operates under these conditions to effect the net formation of tricarboxylic acid cycle intermediates as these are removed in the course of growth. This sequence has been shown [10] to consist of two enzymes, the concerted action of which serves to bypass the decarboxylative steps of the tricarboxylic acid cycle and to lead to a net increase in the organic carbon content of the cell (Fig. 2).

The first of these enzymes, isocitrate lyase (Reaction e), catalyses the aldol cleavage of *threo*-D_s-isocitrate [11] to

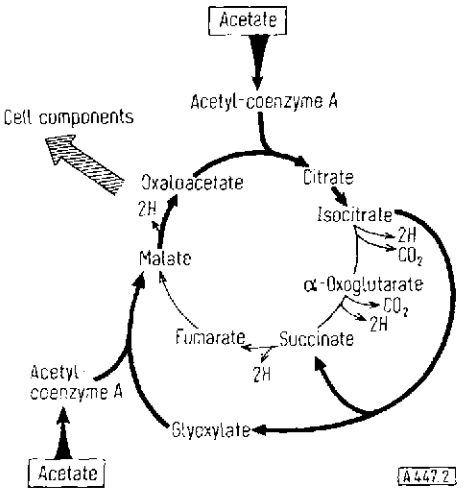

Fig. 2. The tricarboxylic acid cycle and the glyoxylate cycle. The anaplerotic nature of the latter is indicated by heavy arrows.

succinate and glyoxylate [12–14], the second, malate synthase (Reaction f) catalyses the condensation of the glyoxylate thus formed with acetyl-coenzyme A to yield malate [15]. Together with the steps of the tricarboxylic acid cycle (which, of course, provides the energy for growth on acetate) leading from malate to isocitrate, this anaplerotic route serves to maintain the supply of tricarboxylic acid cycle intermediates as they are removed for biosyntheses. The overall effect of this sequence (Reaction g), which has been termed the glyoxylate cycle [16,17], is formally identical with the often-postulated "Thunberg condensation" [18] though the mechanism is quite different.

\end{aligned}$$

3. Anaplerotic Sequences in Glyoxylate Metabolism

When glyoxylate, or precursors of glyoxylate, serve as carbon source for growth, the tricarboxylic acid cycle still serves to supply biosynthetic intermediates but does not act as the terminal respiratory pathway. Instead, glyoxylate is totally combusted *via* a dicarboxylic acid cycle (Fig. 3), which comprises some but not all of the component reactions of the tricarboxylic acid cycle.

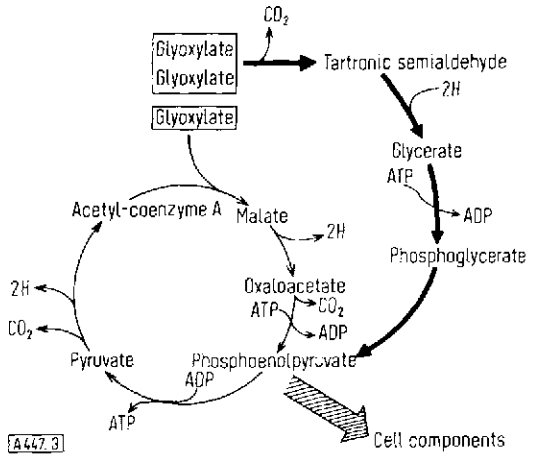

Fig. 3. The dicarboxylic acid cycle for the oxidation of glyoxylate (light arrows) and the glycerate pathway (heavy arrows) which maintains the necessary levels of dicarboxylic acid cycle intermediates.

In this cycle, malate synthetase (Reaction f) plays a respiratory role. The initial condensation of glyoxylate with acetyl-coenzyme A, catalysed by this enzyme, yields malate, which is further oxidized *via* oxaloacetate and pyruvate to regenerate the acetyl-coenzyme A acceptor molecule [19]. The removal of precursors for cellular syntheses from this cycle (and all the intermediates of the cycle can act as such) would cause oxidation to cease: an anaplerotic sequence must therefore operate to effect the net formation of such intermediates from glyoxylate. This sequence has been shown [20] to consist of three enzymes: glyoxylate carboligase [21], which catalyses the formation of tartronic semialdehyde from the condensation of 2 moles of glyoxylate, with elimination of 1 mole of carbon dioxide (Reaction h); tartronic semialdehyde reductase [22] which effects the reduction to glycerate of the tartronic semialdehyde thus formed (Reaction i); and glycerate kinase [23], which enables the glycerate to be transformed into phosphoglycerate (Reaction k), an intermediate of an amphibolic pathway. The overall reaction (l) is that of the glycerate pathway [24] (Fig. 3).

$$2\ \text{glyoxylate} \rightarrow \text{tartronic semialdehyde} + CO_2 \quad \text{(h)}$$

$$\text{tartronic semialdehyde} + 2H \rightarrow \text{glycerate} \quad \text{(i)}$$

$$\text{glycerate} + ATP \rightarrow \text{phosphoglycerate} + ADP \quad \text{(k)}$$

$$2\ \text{glyoxylate} + ATP + 2H \rightarrow \text{phosphoglycerate} + ADP + CO_2 \quad \text{(l)}$$

The phosphoglycerate thus produced is metabolized to acetyl-coenzyme A and, by condensation with a further molecule of the growth substrate, *i.e.* of glyoxylate, enables the dicarboxylic acid cycle to be replenished.

4. Quantitative Aspects of Anaplerosis

The observation that cell-free extracts of micro-organisms catalyse a variety of different chemical reactions is, in itself, not sufficient to show that any particular sequence of such reactions plays an important role in the economy of the cell as an anaplerotic pathway. Such evidence can, however, be readily obtained with auxotrophic mutants. It has already been mentioned that mutants of *E. coli* devoid of phosphoenolpyruvate carboxylase (Reaction b) are unable to grow on glucose, glycerol, or C_3-acids, though they readily grow on these compounds when their media are supplemented with any intermediate of the tricarboxylic acid cycle to which the cells are permeable; such mutants also grow on acetate or glycolate as sole carbon sources, since the anaplerotic sequences necessary under these conditions (Figs. 2 and 3) do not involve the carboxylation of phosphoenolpyruvate. Similarly, mutants of *E. coli* devoid of isocitrate lyase (Reaction e) do not grow on acetate but grow readily on glucose, intermediates of the tricarboxylic acid cycle or glycolate; revertants of such mutants, which regained the ability to grow on acetate, were found concomitantly to have regained isocitrate lyase activity [25]. It is further of interest that *E. coli* has been found [26] to contain two malate synthases with different properties: this may reflect the catabolic role of this enzyme in the dicarboxylic acid cycle and its anaplerotic function in the glyoxylate cycle and glycerate pathway.

A second type of evidence for the intracellular operation as metabolic pathways of the enzymic sequences here described comes from measurement of the amounts of pacemaker enzymes [27] present in extracts of *E. coli* grown on appropriate carbon sources (Table 1): the activities of these enzymes are more than adequate to account for the replenishment of tricarboxylic acid cycle intermediates during growth. It may thus be concluded that the various anaplerotic sequences are both necessary and sufficient for growth.

Table 1. Levels of some anaplerotic enzymes in extracts of *E. coli W* at 30 °C (adapted from [24]).

Growth substrate	Average specific activity [μmoles/mg protein/hour] of			
	Isocitrate lyase (Reacn. e)	Malate synthetase (Reacn. f)	Glyoxylate carboligase (Reacn. h)	Tartronic semialdehyde reductase (Reacn. i)
Lactate	0.5	0.4	1	4
Acetate	15	9	1	4
Glycolate	3	35	28	75

5. Regulation of Anaplerotic Sequences

It is further apparent from the data presented in Table 1 that the pacemaker enzymes of anaplerotic sequences are under metabolic control: the appropriate enzyme is found to be abundant in extracts of cells only when the activity of that enzyme is necessary for growth on the relevant carbon source. This phenomenon, whereby micro-organisms apparently select [24] the correct

metabolic route from the range of routes which they are genetically capable of using, is illustrated by the changes in the ratio of malate synthase to citrate synthase as lactate-grown *E. coli* continue to grow on lactate, or adapt to growth on acetate or glycolate (Fig. 4).

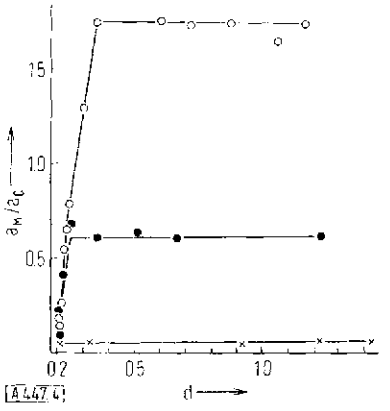

Fig. 4. Variation with growth of the ratio of malate synthase to citrate synthase in lactate-grown *E. coli W* continuing to grow on lactate (×) or adapting to growth on acetate (●) or on glycolate (○).

Ordinate: Activity of malate synthetase/activity of citrate synthetase. Abscissa: Cell density [mg dry weight/ml].

In all of these circumstances, the correct ratio of enzymic activity appears to be achieved before any major increase in the number of cells has occurred: these ratios are then maintained throughout subsequent growth [28]. This suggests that the differential rate of synthesis of pacemaker enzymes of anaplerotic sequences is regulated by variations in the intracellular levels of specific metabolites.

6. "Coarse Control" of the Glyoxylate Cycle

Although the "selection" of a particular metabolic route is a general phenomenon (and is by no means confined to anaplerotic sequences [29]), the mechanisms whereby anaplerotic sequences are regulated have been studied in detail for only one such sequence: the glyoxylate cycle. This study [30] has concentrated largely on analysis of the factors which regulate the formation of isocitrate lyase in *E. coli W*, *E. coli M 22–64* (a mutant of *E. coli W*, devoid of citrate synthase [31]), *E. coli M 191–6* (a mutant of *E. coli W*, devoid of pyruvate oxidase [32]), *E. coli Bm* [33] (a mutant of *E. coli B*, devoid of phosphoenolpyruvate carboxylase [9]), and *Achromobacter d–15* [34].

a) Influence of Growth Substrates on Isocitrate Lyase Levels

The specific activity of isocitrate lyase found in extracts of acetate-grown *E. coli*, strain *W*, was 15.3 μmoles of glyoxylate formed/mg of protein/hour, which was considerably higher than after growth on other carbon sources (Fig. 5).

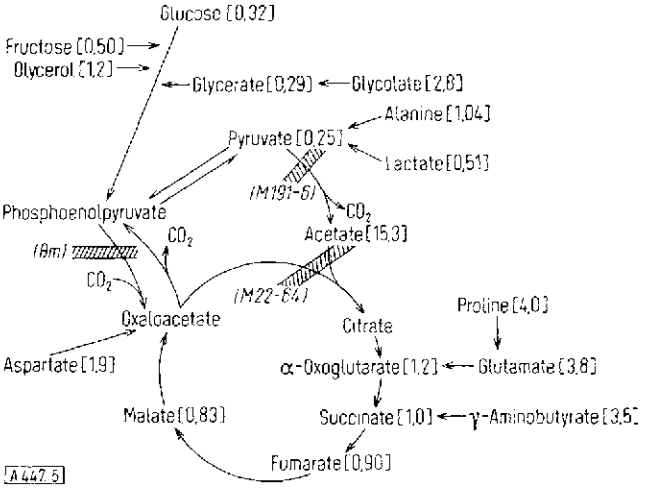

Fig. 5. Influence of growth substrates on isocitrate lyase levels in extracts of *E. coli W*. The observed specific activity of the enzyme is given in square brackets after the name of the growth substrate. The hatched bars indicate the site of the lesions in the mutants used.

However, even the magnitude of these lower specific activities was influenced by the nature of the growth substrate, as the values observed ranged from 0.25, for pyruvate-grown cells, to 4.0, for proline-grown cells. An indication of the probable nature of the phenomena underlying these variations is derived from two correlations:

a) The enzyme levels achieved on any carbon source appear to be related to the place which that carbon source occupies on the "metabolic map" (Fig. 5). Thus, growth on pyruvate and on direct precursors of pyruvate is accompanied by the lowest specific activities of isocitrate lyase, and the interposition of an additional enzymic step before the growth substrate can enter the metabolic pathways leading to C_3-compounds is accompanied by an increased production of the enzyme.

b) The enzyme levels achieved during growth on any carbon source (other than acetate) appear to be inversely related to the growth rate on that carbon source (Fig. 6).

The highest specific activities of isocitrate lyase were found during growth on substrates such as proline, glutamate, γ-aminobutyrate, and glycolate, which require the occurrence of one or more reactions before they can enter the Embden-Meyerhof pathway or the tricarboxylic acid cycle: growth on these substances was slower than on the intermediates of the main metabolic routes to which they are transformed.

These observations support the view that the rate of formation of isocitrate lyase is governed by the intracellular levels of metabolites which act as repressors. Among the factors determining these levels would be the rate of entry of the growth substrate into the main metabolic routes, which would thus influence the rate of growth of the organism.

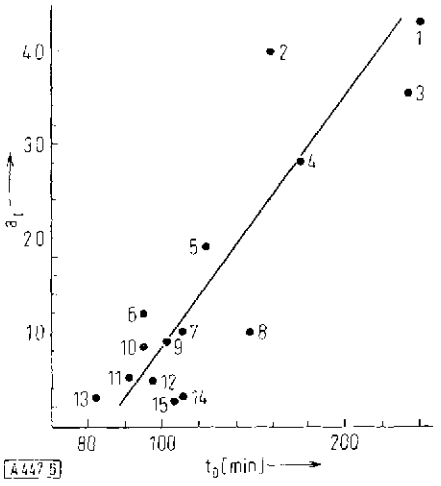

Fig. 6. Relation between mean doubling time and specific activity of isocitrate lyase in *E. coli W*, grown on the following substances as sole carbon sources: 1: Proline, 2: glutamate, 3: γ-aminobutyrate, 4: glycolate, 5: aspartate, 6: glycerol, 7: succinate, 8: alanine, 9: fumarate, 10: malate, 11: lactate, 12: fructose, 13: glucose, 14: glycerate, 15: pyruvate.
Ordinate: Specific activity of isocitrate lyase.
Abscissa: Mean doubling time.

b) The Role of Acetate in Isocitrate Lyase Induction

The high rate of enzyme synthesis during growth on acetate appears to be an exception to these two correlations (a) and (b) and might imply that acetate, or acetyl-coenzyme A, acts as a direct inducer of isocitrate lyase synthesis. There are several lines of evidence against this [35].

Identical specific activities of isocitrate lyase were obtained when *E. coli* were grown on media containing the carbon sources listed in Fig. 6 (with the exception of proline, glutamate, and γ-aminobutyrate) at 20 mM concentration, and in similar media which, in addition, contained 20 mM acetate. This showed that, in the presence of these substances, acetate did not induce isocitrate lyase formation. Only when proline, glutamate, or γ-aminobutyrate were the growth substrates did the inclusion of acetate in the growth medium stimulate the rate of isocitrate lyase synthesis: this "inducer-like" effect of acetate [36] which resulted in isocitrate lyase levels 2–3 times higher than those observed with organisms grown in the absence of acetate, was obtained also when ammonium chloride was omitted from the growth medium and the amino acids thus served as the sole nitrogen as well as the main carbon sources.

However, whereas growth of the wild-type organism *(E. coli*, strain *W)* on proline plus acetate, glutamate plus acetate, or γ-aminobutyrate plus acetate, resulted in higher rates of isocitrate lyase formation than observed during growth on these amino acids alone, the rates of enzyme formation in the mutant *M 22–64* (which lacked the ability to form citrate from oxaloacetate and acetyl-coenzyme A, see Fig. 5) were unaffected by the presence of acetate (Fig. 7).

Since this mutant has been shown to be still capable of activating acetate to acetyl-coenzyme A [31,19], the failure of acetate to stimulate the rate of isocitrate lyase synthesis by *M 22–64* argues against acetate (or acetyl-coenzyme A) as a direct inducer of this enzyme. These observations are, however, those expected if the differential rate of isocitrate lyase formation is governed by the intracellular levels of some repressor substance(s) metabolically close to oxaloacetate: in the wild-type organism, acetate would serve to lower these levels by the formation of citrate but, in the mutant, would be unable to act in this manner.

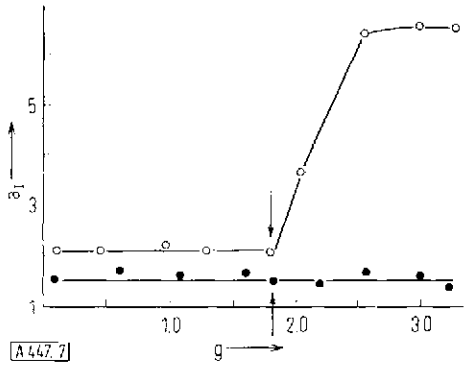

Fig. 7. Effect of 20 mM acetate on isocitrate lyase formation by *E. coli W* (o) and its mutant *M 22–64* (●) during growth on proline. Acetate was added at the points indicated by arrows.
Ordinate: Specific activity of isocitrate lyase.
Abscissa: Number of bacterial generations.

Further evidence for this view was provided from the effect of acetate on *M 22–64* growing on 20 mM glycolate plus 2 mM glutamate. In the absence of acetate, isocitrate lyase was produced at a specific activity of 2,2, which remained constant over nearly 2 generations. The addition of 50 mM acetate after this time not only failed to induce isocitrate lyase formation but caused a sharp decrease in the specific activity of the enzyme without causing any decrease in the growth rate. Similarly, when the glycolate/glutamate-grown mutant was inoculated into a medium containing these carbon sources plus 50 mM acetate, the growth of the organisms was accompanied by an initial decrease in the content of isocitrate lyase to a new level, which was less than 60% of that present in cells growing in the absence of acetate and which was maintained constant during the subsequent growth (Fig. 8).

Since it is known [19] that acetate can enter the metabolic pathways of this mutant during growth on glycolate, by combining with glyoxylate to form malate (cf. Fig. 3),

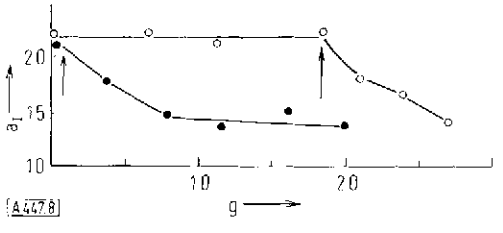

Fig. 8. Effect of acetate on isocitrate lyase formation by *M 22–64* growing on 20 mM glycolate plus 2 mM glutamate (o) or on this medium plus 50 mM acetate (●). The experiments were begun with cells grown on glycolate plus glutamate; acetate was added at the points indicated by arrows.
Ordinate: Specific activity of isocitrate lyase.
Abscissa: Number of generations.

[35] *H. L. Kornberg*, Biochim. biophysica Acta *73*, 517 (1963).
[36] *R. F. Rosenberger*, Biochim. biophysica Acta *64*, 168 (1962).

these observations are consistent with the formation from malate of repressor(s) of isocitrate lyase.

c) Possible Identity of the Metabolite Responsible for Isocitrate Lyase Repression

It was observed that, during growth on glycolate plus acetate, the specific activity of isocitrate lyase in the mutant *M 191–6* (which could not oxidize pyruvate) was less than 30% of that present in *M 22–64* (Fig. 8) and less than 15% of that in the parent wild-type *E. coli* (Fig. 5) under similar growth conditions. This suggested that, if a particular metabolite acted as a specific repressor of isocitrate lyase synthesis, that metabolite is likely to be a C_3-compound rather than an intermediate of the tricarboxylic acid cycle. There are several other lines of evidence in favor of this hypothesis:

(1) The acetate-requiring mutant *M 191-6* was grown on a mixture of 20 mM glycolate plus 10 mM acetate. After an increase in cell density of approximately 0.1 mg dry weight/ml, samples of the cultures were taken for enzyme assay and the volumes of liquid removed were replaced by fresh growth medium. Under these conditions, in which the organism grew at constant rate and remained at relatively constant cell density, they produced isocitrate lyase at constant though unusually low specific activity (0.3 μmoles/mg protein/hour). However, when the liquid removed in the course of sampling was replaced by equivalent volumes of 20 mM glycolate medium from which acetate had been omitted, the exhaustion of the acetate in the growth medium led to a progressive decrease in growth rate and ultimate cessation of growth.

As expected from the known metabolic lesion of this mutant, the decrease in growth rate was also accompanied by the accumulation of pyruvate (identified as the 2,4-dinitrophenylhydrazone) in the medium. The specific activity of isocitrate lyase in successive samples taken from this culture fell sharply to very low levels, which suggested that the overproduction of catabolic products from glycolate raised the concentration of metabolites inside the cells to a level at which isocitrate lyase synthesis was virtually abolished. Since the mutant was unable to oxidize pyruvate to acetate and hence was unable to form malate from glyoxylate in the absence of added acetate, this unusually strong repression of isocitrate lyase synthesis occurred under conditions characterized by an over-production of C_3-compounds without the prior formation of malate.

(2) The addition of pyruvate to a culture of *M 22-64* growing on proline as sole carbon source did not decrease the rate of growth but markedly lowered the rate of isocitrate lyase formation (Fig. 9). In this mutant, the addition of pyruvate could presumably have raised the intracellular levels of C_4-dicarboxylic acids as well as those of C_3-compounds, but could not have raised those of other intermediates of the tricarboxylic acid cycle.

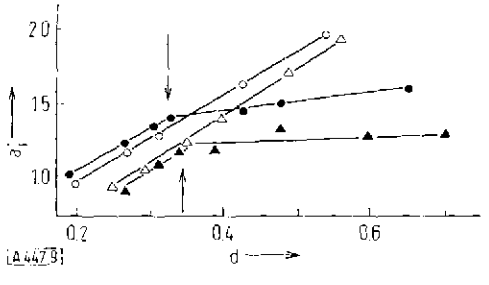

Fig. 9. Effect of pyruvate on isocitrate lyase formation by *M 22–64* (Δ, ▲) and by *Bm* (o, ●) at 30 °C during growth on proline. Pyruvate to 5 mM was added to the cultures marked with closed symbols at the points indicated by arrows.

Ordinate: Specific isocitrate layse activity × cell density.
Abscissa: Cell density [mg dry weight/ml].

(3) The addition of pyruvate to a culture of the mutant *Bm* growing on proline as sole carbon and nitrogen source did not decrease the rate of growth but markedly lowered the rate of isocitrate lyase synthesis (Fig. 9). In this mutant, pyruvate could be oxidized but could not give rise to the net formation of C_4-dicarboxylic acids.

(4) The addition of pyruvate to a culture of *Bm* growing on 50 mM acetate plus 5 mM glutamate, added as sole nitrogen source, did not decrease the rate of growth of the organism but led to a decrease of over 85 % in the high rate of isocitrate lyase synthesis; this effect persisted until the added pyruvate had been used up (Fig. 10). Since glutamate had been added as sole nitrogen source, and since no α-oxo acids were detected in the medium, the amino acid must have been utilized for growth but without causing the intracellular accumulation of repressor substances; such substances were, however, formed from pyruvate, although no net formation of C_4-dicarboxylic acids from pyruvate could occur in this mutant.

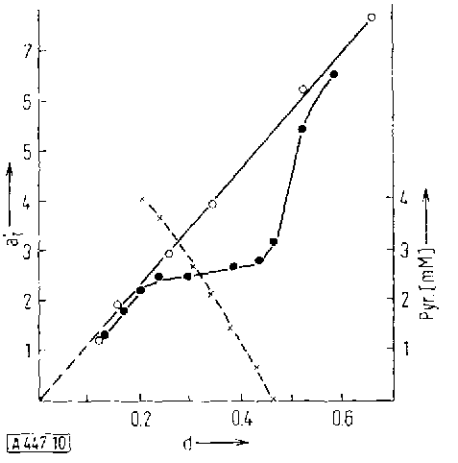

Fig. 10. Effect of pyruvate on isocitrate lyase formation by *Bm* during growth on 50 mM acetate plus 5 mM glutamate, in the absence of other nitrogen sources. Pyruvate to 5 mM was added to the culture marked (●); the decrease in the pyruvate content of the medium is indicated by (×). The culture marked (o) received no pyruvate.

Ordinates: left: Specific activity of isocitrate lyase × cell density.
right: Pyruvate concentration [mM].

Abscissa: Cell density [mg dry weight/ml].

(5) The addition of pyruvate to a culture of *Bm* growing on 50 mM acetate plus 5 mM aspartate, added as sole nitrogen source, did not decrease the rate of growth but caused a sharp decrease in the high rate of isocitrate lyase synthesis (Fig. 11). Again, the amino acid must have been utilized for growth and must therefore have provided oxaloacetate to the organism, but at a rate insufficient to lower significantly the high rate of isocitrate lyase formation: again, the enzyme was repressed by the addition of pyruvate although, in this mutant, this C_3-compound could not give rise to the net formation of C_4-compounds.

These findings suggest that, if any single metabolite may be regarded as a specific repressor of isocitrate lyase, that metabolite cannot be a C_4-dicarboxylic acid (results with *Bm*), cannot be another intermediate of the tricarboxylic acid cycle (results with *M 22–64*), and cannot be an oxidation product of pyruvate (results with *M 191–6*): the metabolite must be either pyruvate itself or some product metabolically close to both pyruvate and oxaloacetate.

If it can be assumed that the factors which regulate isocitrate lyase synthesis in *E. coli* are similar to those which regulate it in other micro-organisms (and data obtained

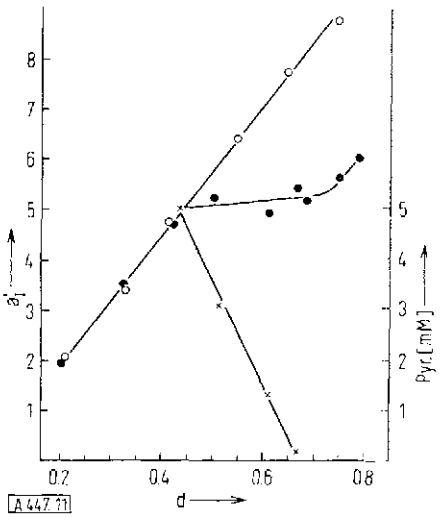

Fig. 11. Effect of pyruvate on isocitrate lyase formation by *Bm* during growth on 50 mM acetate plus 5 mM aspartate, in the absence of other nitrogen sources. Pyruvate to 5 mM was added to the culture marked (●); the decrease in the pyruvate content of the medium is indicated by (×). The culture marked (○) received no pyruvate.

with bacteria [10], fungi [37,38], algae [39,40], and protozoa [41] suggest that this assumption is justified), then pyruvate itself is not likely to act as a repressor metabolite. Evidence for this belief stems from results obtained with *Achromobacter d–15*. This organism is unusual in that cell-free extracts contain isocitrate lyase of high specific activity (6–8 μmoles/mg protein/hour) after growth on pyruvate, lactate, or alanine as sole carbon sources, though, as observed with other organisms, the enzyme is synthesized to only a small extent during growth on intermediates of the tricarboxylic acid cycle. A second unusual feature of *Achromobacter d–15* is that it is unable to grow on glucose, glycerol, or glycolate; this disability may be ascribed [42] to the absence of pyruvate kinase (Reaction m) activity, with

$$CH_3{-}CO{-}CO_2H + ATP \rightleftharpoons CH_2{=}C(CO_2H)O{-}PO_3H_2 + ADP \quad (m)$$

consequent inability to gain entry into the tricarboxylic acid cycle for catabolites which must traverse this essential step of the Embden-Meyerhof sequence to do so. It is thus probable that the high levels of isocitrate lyase found in extracts of pyruvate-grown *Achromobacter d–15* are similarly symptomatic of the inability of this organism directly to form phosphoenolpyruvate from pyruvate[*]; since this substance can still be formed from oxaloacetate (*via* Reaction d), and since growth on intermediates of the tricarboxylic acid cycle yields only low levels of isocitrate lyase, it is tempting to conclude that one of the repressor metabolites responsible for regulating the synthesis of isocitrate lyase is phosphoenolpyruvate.

It is probable that more than one metabolite exerts a regulatory function over isocitrate lyase. Evidence for this view stems from studies with a mutant, *BmR*, which, though derived from *Bm*, differs from it in being able to grow on glycerol, glucose, or pyruvate. This growth pattern is, however, not due to a reversion, with consequent restoration of phosphoenolpyruvate carboxylase activity, but (as has also been reported [43] for a similar mutant of *E. coli K 12*) is the result of a second mutational change affecting a regulator gene for isocitrate lyase synthesis (Table 2).

Table 2. Effect of growth substrates on isocitrate lyase levels in wild-type *E. coli* and the mutant *BmR* at 30 °C.

Growth substrate	Specific activity [μmoles/mg protein/hour] of isocitrate lyase in	
	Wild-type *E. coli*	Mutant *BmR*
Glucose	0.3	10
Lactate	0.5	20
Malate	0.8	27
Succinate	1.0	34
Acetate	15	50

Thus, even during growth on glucose, the differential rate of isocitrate lyase synthesis is over thirtyfold that observed in wild-type *E. coli*, and the necessary net formation of C_4-acids can, in *BmR*, be effected *via* the glyoxylate cycle despite the presence of substrates which strongly repress this enzyme in wild-type organisms and in *Bm*. It is, however, remarkable that extracts of *BmR* obtained from cells, grown on a variety of substrates, exhibit a pattern of variation of isocitrate lyase activity with the mean doubling time on that substrate which is qualitatively similar to that observed with wild-type cells (*cf.* Fig. 6): to adapt the famous slogan of *George Orwell*'s "Animal Farm", it is clear that, although isocitrate lyase production in *BmR* is constitutive, it is under some circumstances more constitutive than under others. These observations suggest that *BmR* has escaped from the repression exerted by one metabolite but remains subject to repression by another [44].

7. "Fine Control" of the Glyoxylate Cycle

Although the variations in the differential rate of synthesis of isocitrate lyase described represent one type of control of the glyoxylate cycle, such a regulatory process must be relatively "coarse". Studies with *E. coli*, strain *B*, and its mutant *Bm* suggest that, in addition, a "fine" control of the cycle may be exerted by variations in the intracellular levels of phosphoenolpyruvate, which has been found to be a powerful non-competitive inhibitor of isocitrate lyase [9].

[41] *J. F. Hogg* and *H. L. Kornberg*, Biochem. J. *86*, 461 (1963).

[42] *H. L. Kornberg, J. Dennis*, and *E. M. Wilson*, Biochem. J. *92*, 55P (1964).

[*] Note added in proof: It is unlikely that phosphoenolpyruvate can be formed from pyruvate by Reaction (m) since *E. coli* contains a PEP-synthase system for this purpose distinct from pyruvate kinase. – Cf. *R. Cooper* and *H. L. Kornberg*, Biochim. biophysica Acta *104*, 618 (1965).

[43] *E. Vanderwinkel, P. Liard, F. Ramos*, and *J. M. Wiame*, Biochem. biophysic. Res. Commun. *12*, 157 (1963).

[44] These observations are analogous to the finding that mutants lacking the *i* gene for β-galactosidase are still subject to catabolite repression: see *J. Mandelstam*, Biochem. J. *82*, 489 (1962); *W. F. Loomis* and *B. Magasanik*, J. molecular Biol. *8*, 417 (1964).

Although the addition of pyruvate to cultures of *E. coli B* growing on acetate, or of *Bm* growing on acetate in the presence of glutamate or aspartate, did not decrease the rate of growth, the addition of this C_3-compound to a culture of the mutant growing on acetate in the absence of these amino acids speedily arrested its growth, which was resumed when the added pyruvate had been utilized (Fig. 12).

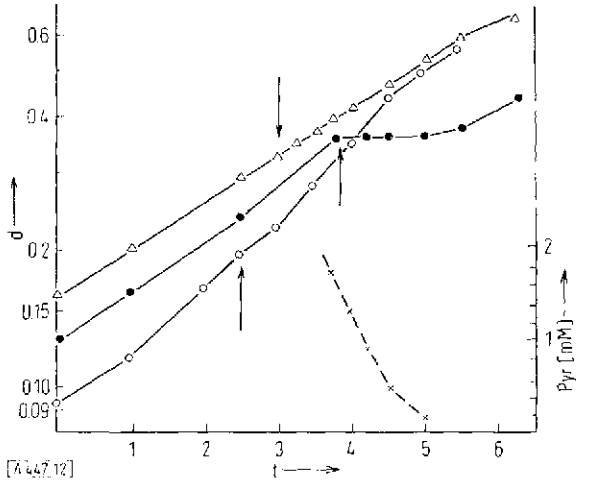

Fig. 12. Effect of pyruvate at 30 °C on the growth of *E. coli B*, (Δ) on 50 mM acetate, and on the growth of its mutant *Bm* in media containing 50 mM acetate (●), or 50 mM acetate plus 5 mM glutamate (○). Sodium pyruvate was added where indicated by arrows. The inset (×) records the decrease in the pyruvate concentration (mM) after its addition to *Bm* growing on acetate (●).

Ordinates: left: Cell density [mg dry weight/ml].
right: Pyruvate concentration [mM].
Abscissa: Time [hours].

This observation indicated that pyruvate, or a product of pyruvate metabolism, inhibited the net formation of C_4-compounds from acetate: as an alternative mode of formation of such compounds, *e. g.* by carboxylation of phosphoenolpyruvate, was not possible in this mutant, its growth ceased. (The failure of pyruvate to inhibit the growth of *Bm* on acetate plus aspartate or glutamate is thus further indication that these amino acids were indeed utilized as sources of intracellular C_4-dicarboxylic acids: cf. Figs. 10 and 11). Since pyruvate was utilized by *Bm* though its growth had ceased, and since washed suspensions of the acetate-grown mutant readily oxidized pyruvate, it was evident that pyruvate did not inhibit a component reaction of the tricarboxylic acid cycle but probably acted on a key enzyme of the glyoxylate cycle.

An indication of the mechanism of this effect was provided by the finding that, whereas neither 0.1 mM nor 1 mM pyruvate inhibited significantly the activity of isocitrate lyase in cell-free extracts of acetate-grown *Bm*, phosphoenolpyruvate was a powerful inhibitor of this enzyme. At a concentration of 1×10^{-4} M, phosphoenolpyruvate reduced the quantity of glyoxylate formed from the cleavage of 2 mM isocitrate to 58%, and at 1×10^{-3} M to 11% of that observed in its absence. Quantitative spectrophotometric assay [45] showed that neither malate synthase nor citrate synthase was inhibited by 0.1 mM phosphoenolpyruvate, but that isocitrate lyase was inhibited non-competitively, with K_i 1.3×10^{-4} M. Other intermediates of the Embden-Meyerhof pathway (such as 2-phosphoglycerate, 3-phosphoglycerate and hexose mono- and di-phosphates) exerted no inhibitory action at 1 mM concentration. Similar results have been obtained with the isocitrate lyase in extracts of *E. coli W*, *Chlorella vulgaris*, Brannon No. 1 strain, and *Achromobacter d–15*.

[45] *G. H. Dixon* and *H. L. Kornberg*, Biochem. J. 72, 3P (1959).

Concluding Remarks

It has been the main purpose of this communication to summarize the evidence for the belief that, for a proper description of the flow of nutrients associated with the release of energy and its utilization for biosyntheses, a special type of metabolic pathway must operate inside the cell which may be regarded as serving solely to maintain the functioning of the tricarboxylic acid cycle and other amphibolic routes. It has been proposed to generically designate this type of ancillary pathway as an anaplerotic sequence. Key enzymes of anaplerotic sequences may be recognized as distinct biological entities, even when other enzymes exist in the cell which catalyse a closely similar or the same chemical reaction; their action is necessary for growth on C_3- and C_2-compounds to occur (Table 3).

Table 3. Catabolic and anaplerotic sequences in *E. coli*.

Carbon source	Catabolic route	Anaplerotic sequence
Glucose, glycerol or C_3-compounds	Tricarboxylic acid cycle	Phosphoenolpyruvate carboxylase
Acetate	Tricarboxylic acid cycle	Glyoxylate cycle
Glycolate	Dicarboxylic acid cycle	Glycerate pathway

Although little is known in detail of the factors which regulate the operation of the various anaplerotic sequences, studies on the glyoxylate cycle suggest that they act at least at two levels: *via* a "fine control" mechanism, achieved through inhibition of the activity of a pacemaker enzyme, and a "coarse control" mechanism, achieved through inhibition of the synthesis of that enzyme. The data obtained further suggest that both modes of control may be exerted, at least in part, through variations in the intracellular levels of the same metabolite – phosphoenolpyruvate. Since phosphoenolpyruvate can be regarded both as the precursor of many cell components (such as aromatic amino acids, the pentose moieties of nucleic acids, and other carbohydrates) in their formation from acetate and as the major product of the glyoxylate cycle, these types of control are further examples of feedback mechanisms [29], which enable micro-organisms sensitively and efficiently to adjust to changes in their environment.

Chemiluminescence in Organic Compounds

BY PROF. DR. K.-D. GUNDERMANN

ORGANISCH-CHEMISCHES INSTITUT DER BERGAKADEMIE CLAUSTHAL, TECHNISCHE HOCHSCHULE, CLAUSTHAL-ZELLERFELD (GERMANY)

Dedicated to Professor Fritz Micheel on the occasion of his 65th birthday

As a result of the development of very sensitive equipment, it is now possible to show that the chemiluminescence of organic compounds in solution is quite a common phenomenon. Notable advances have been made during recent years in the investigation of the chemiluminescence of substituted phthalic acid hydrazides and related compounds. A new and probably generally applicable method of producing chemiluminescence has recently been discovered in the reaction of aromatic free-radical anions with appropriate free-radical cations.

1. Introduction

Chemiluminescence reactions are processes in which a molecule capable of fluorescing is raised to an excited electronic state by chemical energy [1]. If the reaction is to be accompanied by the emission of visible light, it must supply an energy of at least 40–70 kcal/mole. This is the case, for example, in free-radical chain oxidations. There should consequently be a large number of chemiluminescence reactions, and many examples are in fact to be found in the literature (reviews: [2–7]). Only a few reactions are known, however, in which a really brilliant light is emitted. Owing to advances in the construction of equipment, it is now possible to measure accurately light intensities of some 10^3 photons cm^{-3} sec^{-1} [8,9], so that even weak chemiluminescence in organic reactions can be detected (cf. also the earlie workby *Audubert* [10]).

The relationships between the constitution of organic compounds and their ability to exhibit chemiluminescence are roughly parallel to the relationships between constitution and ability to fluoresce [11–15]. However, just as the fluorescence of organic compounds in solution is affected by many parameters relating to the medium, such as concentration, pH, solvent, quenching action of foreign substances present (cf. [15]), chemiluminescence is further complicated by the fact that the processes yielding the radiant energy may be accompanied by other chemical reactions (cf. Section 8).

Bioluminescence reactions are enzyme-catalyzed chemiluminescence processes in which oxygen acts as an electron acceptor. According to *McElroy* and *Seliger* [17], these oxidation processes are controlled by the enzyme so efficiently that the quantum yields are about unity [16], in contrast to organic chemiluminescence reactions in solution, which give quantum yields of at most 0.05.

2. Chemiluminescence in the Slow Autoxidation of Hydrocarbons, Aldehydes, Ketones, and Unsaturated Acids and their Esters

The very weak chemiluminescence in the autoxidation of hydrocarbons such as ethylbenzene, cumene, diphenylethane, cyclohexane, or tetralin can be measured with the aid of very sensitive photoelectric measuring devices[8,9,18,18a]. In the cases of cumene, cyclohexane, and tetralin, the emitted light has a maximum in the blue-green region of the spectrum, corresponding to a reaction enthalpy of approximately 55 kcal/mole [9].

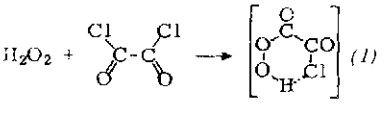
End products containing oxygen (alcohols, aldehydes, and ketones) are particularly capable of emitting visible light [18]. Kinetic studies show that the intensity of the light is in most cases proportional to the oxygen consumption [19]. The lifetime of the excited state in the oxidation of ethylbenzene (10^{-7} to 10^{-6} sec) agrees well [18] with that of the triplet state of acetophenone [18b]. The chemiluminescence accompanying the autoxidation of hydrocarbons is intensified by free-radical formers such as azobisisobutyronitrile [18] or by X-rays [9], and weakened by free-radical scavengers such as 2,6-di-butyl-*p*-cresol [9,20]. This fact offers a possible method of determining the efficiencies of antioxidants [21] and oxidation initiators [22] with the aid of chemiluminescence reactions.

The extremely weak light emission (quantum yields $\approx 10^{-8}$ to 10^{-10}) accompanying these autoxidations becomes stronger if the reaction medium contains fluorescent molecules, such as anthracene, oxazole, or pyrazole derivatives (sensitized or "activated" chemiluminescence). Thus the chemiluminescence in the oxidation of cyclohexane is intensified by a factor of almost 50 by 9,10-dibromoanthracene. The spectrum of the "activated" chemiluminescence corresponds to the fluorescence spectrum of the activator [18].

Other examples of autoxidative chain reactions exhibiting very weak chemiluminescence are the oxidation of acetaldehyde [23], oleic or linoleic acid [9], methyl oleate [18], and n-butyl oleate [9].

3. Chemiluminescence in the Reactions of Oxalyl Chloride or Nitriles with Hydrogen Peroxide

Chandross [24] observed a weak bluish-white chemiluminescence during the reaction of oxalyl chloride with hydrogen peroxide. He postulated the intermediate



(1)

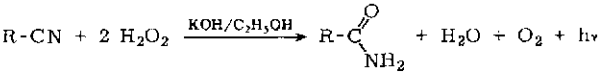
$\longrightarrow$ HCl + 2 CO + O_2 + hν

formation of monoperoxyoxalic acid monochloride *(1)*, which was then assumed to decompose into oxygen, carbon monoxide, and hydrogen chloride, with simultaneous liberation of the excitation energy required for the chemiluminescence. The luminescent species has not yet been established. The energy levels of HCl, CO, or CO_2 are too high, and the energy of an excited oxygen singlet (38 kcal/mole) is too low to cause the observed chemiluminescence.

It is interesting that the vapors escaping during the reaction of oxalyl chloride with hydrogen peroxide can excite fluorescence. One possible explanation according to *Chandross* is that the excitation energy is first absorbed by oxalyl chloride to give molecules in the triplet state; these are then carried out of the liquid phase with the reaction gases and pass on their excitation energy to a fluorescent molecule.

Acetyl chloride exhibits no luminescence under identical conditions. *Rauhut* et al. found that other derivatives of monoperoxyoxalic acid also decompose in the presence of sensitizers with light emission [24a], *e.g.* t-BuOOCO · CO · Cl [24b]. The simultaneous cleavage of all bonds involved ("concerted multiple bond cleavage") is decisive for the occurrence of chemiluminescence. Extremely weak chemiluminescence (quantum yields of 10^{-13} to 10^{-15}) has been observed in the reaction of adipyl chloride or benzoyl chloride with hexamethylenediamine or aniline [8,25].

A blue luminescence, which persists for a relatively long time and which is visible in the dark with the naked eye, occurs during the reaction of certain nitriles such as benzyl cyanide, acrylonitrile, or benzonitrile with hydrogen peroxide in alkaline solution [26]. The chemiluminescence observed with benzonitrile, however, is very



R = $C_6H_5CH_2$-; H_2C=CH-; C_6H_5-.

weak. Since the reactions proceed by a heterolytic mechanism [26], molecular oxygen can initially be formed only in an excited singlet state (cf. the investigations by *Bowen* et al. [27,28] on the chemiluminescence of dissolved oxygen; see also the next section).

4. Grignard Compounds and Polyphenols

The chemiluminescence accompanying the autoxidation of Grignard compounds was studied in detail as early as 1925 [29], together with the relationships between structure and chemiluminescence. It has been shown by a preparative method that the reaction proceeds *via* the

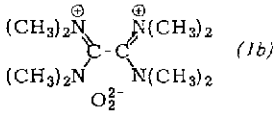
intermediate R–O–O– MgBr [30]. Kinetic studies on the autoxidation of phenylmagnesium bromide confirmed the relationship between chemiluminescence and the free-radical chain mechanism [31].

The intense red chemiluminescence observed during the reaction of pyrogallol with formaldehyde, hydrogen peroxide, and alkali has an emission band at 630 mμ due to excited oxygen molecules [27]. *Stauff* et al. [31a] found that the chemiluminescence spectra of the oxidation of formaldehyde with H_2O_2, and of other organic and inorganic oxidation reactions, correspond to the absorption bands of $(O_2)_2$ molecules, which should therefore be considered as the emitting species. The chemiluminescence that accompanies the oxidation of pyrocatechol, resorcinol, and other polyfunctional phenols with ozone can be sensitized by fluorescent dyes such as rhodamine B. Quantitative investigations have recently been carried out of the dependence of this sensitized chemiluminescence on the structure of the polyphenol [32].

5. Tetrakis(dimethylamino)ethylene

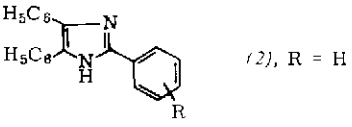
The autoxidation of the powerful electron donor tetrakis-(dimethylamino)ethylene, $[(CH_3)_2N]_2C{-}C[N(CH_3)_2]_2$ *(1a)*, and its reaction with bromine, occur with emission of green light [32a, b], the spectrum of which agrees with the fluorescence spectrum of *(1a)* [32c]. The products include tetramethylurea, tetramethyloxamide, and bis-(dimethylamino)methane [32b, d], which are formed, as shown by NMR-spectroscopy [32d], from the primary product *(1b)*, which can be isolated under suitable conditions. According to kinetic studies by *Paris* [32e], the carbene $[(CH_3)_2N]_2C{:}$ is an important intermediate.



(1b)

6. 2,4,5-Triphenylimidazole ("Lophine") and Related Compounds

The blue-green chemiluminescence accompanying the oxidation of lophine *(2)* with oxygen in alkaline solution [3] is one of the strongest known prior to the discovery of the chemiluminescence of "lucigenin" *(6)* and "luminol" *(11)*, which will be discussed in the next section.



(2), R = H

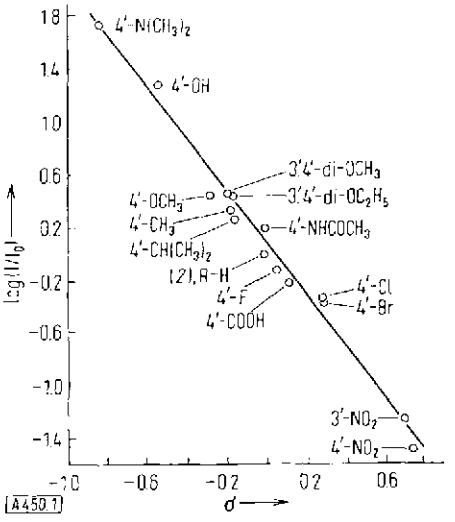


Fig. 1. Relative intensities of the chemiluminescence of substituted lophines *(2)* [35].
I_0: maximum intensity of lophine *(2)*.
I: maximum intensity of the substituted lophine.
Abscissa: σ constants according to *J. Hine* [33a].

The chemiluminescence intensities of a number of lophine derivatives containing substituents in positions 3' or 4' of the 2-phenyl group [33] have recently been compared. It can be seen from Fig. 1 that the substituent effects follow the Hammett equation. All the substituted lophines were found to have a chemiluminescence emission maximum at 530 mμ, irrespective of whether the oxidation is carried out with oxygen or with hydrogen peroxide. Recent investigations [34] indicate that the oxidation of *(2)* in alkaline media leads *via* the anion to the diimidazolyl derivative *(3)*, which exists in equilibrium with the radical *(4)*. This radical can react with

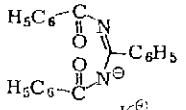
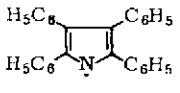
oxygen to form the peroxide *(4a)* [35a], which decomposes into benzoic acid, ammonia, and other products, with simultaneous emission of light. *(4a)* is relatively stable; it can be isolated, and it chemiluminesces in warm oxygen-free alkaline solutions or when heated to 110 °C [35a].

Since the chemiluminescence spectra of *(2)* and its derivatives are identical with the fluorescence spectra of diaroylarylamidine salts of the type *(4b)*, these salts are regarded as the emitting species [35b]. A similar reaction sequence is also postulated for the weakly chemiluminescent oxidation of 2,3,4,5-tetraphenylpyrrole [35], *i.e.* the radical *(5)* is an important intermediate in this case.



(4b)



(5)

7. 9,9′-Diacridinium Salts ("Lucigenin" and Related Compounds)

The intense green chemiluminescence observed during the oxidation of "lucigenin" *(6)* with H_2O_2 in alkaline solution was first described by *Gleu* and *Petsch* [36] (cf. [7]). The observation [37] that the color of the chemiluminescence changes from green to blue when the *N*-alkyl groups in compounds of the type *(6)* are replaced by phenyl groups to form *(7)*, was confirmed for the *N,N′*-di-*p*-tolyl compound *(8)* [38]. Recent spectroscopic and kinetic studies [39–46] corroborate the finding [47] that the radiating species in the "lucigenin" chemiluminescence is *N*-methylacridone *(10)*; this is probably formed in a free-radical chain reaction involving the hydroperoxide *(9)* [43,47a]. The peroxyacid derivative *(10a)* shows strong chemiluminescence with water.

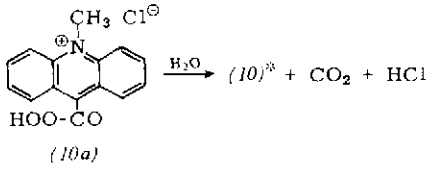
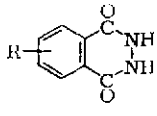
(10)



(10a)

8. 3-Aminophthalhydrazide ("Luminol") and Other Hydrazides

Since the first publication [48] describing the intense blue chemiluminescence accompanying the alkaline oxidation of 3-aminophthalhydrazide (5-amino-1,2,3,4-tetrahydrophthalazine-1,4-dione) *(11)*, these and similar chemiluminescence reactions have been studied in great detail [2–6,46,48]. The reader is referred in particular to *Anderson's* review [7], which presents an excellent analysis of the position regarding the luminol problem at the beginning of the second phase of these investigations (after 1945).



(11), R = 3-NH_2
(12), R = 4-NH_2

a) Constitution and Luminescence in Carbohydrazides

Albrecht [48] had referred as early as 1928 to the chemilumescence of *N,N′*-diacylhydrazines on oxidation in alkaline media; his investigations, however, were mainly confined to substituted phthalhydrazides, since these give by far the most intense effects. The chemiluminescence of acyclic diacylhydrazines was confirmed by *Kautsky* and *Kaiser* [49], who postulated that acyclic hydrazides are in principle capable of chemiluminescing, provided they are fluorescent (see also [50]). *Ojima* investigated *inter alia* the emission of light by monoacyl-

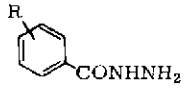
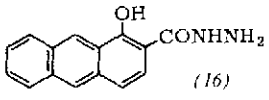
hydrazines on uncatalysed oxidation with hydrogen peroxide in alkaline solution. He found that the luminescence of anthranilhydrazide *(13)* is 5 orders of magnitude weaker than that of luminol; chemiluminescence is also observed with *m*-aminobenzhydrazide *(14)*, but not with the *p*-isomer *(15)* [2,51]. As explained in Section 8b, the deciding factor is whether the carboxylic acid on which the hydrazide is based, or its anion, is capable of fluorescing, as is the case with *(13)* and *(14)*,



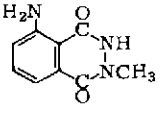
(13), R = o-NH_2
(14), R = m-NH_2
(15), R = p-NH_2

but not with *(15)*. Similar behavior is found with the isomeric hydroxybenzhydrazides [51], although the luminescence in this case is about ten times weaker. If, however, the hydrazinocarbonyl group is attached to a strongly fluorescent aromatic hydrocarbon residue, as in *(16)*, the quantum yield of the chemiluminescence is about 1/3 of that of Luminol [2].

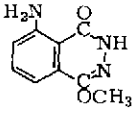


(16)

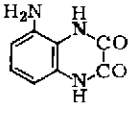
An extremely important point with regard to chemiluminescence is that the hydrazide group remains unaltered; thus *(17)*, *(18)*, and *(19)* do not chemiluminesce [52,53]. It is evidently essential that the molecule contains a bond system from which elementary nitrogen can be readily split off.



(17)



(18)



(19)

Drew et al. [54] have studied how substituents in the benzene ring affect the chemiluminescence of the phthalhydrazide, and have listed the intensities of the chemiluminescence of a number of substituted phthalhydrazides [55], which have been largely confirmed by subsequent measurements [56–58]. These investigations led to the formulation of two main rules:

1. The chemiluminescence is strengthened by electron-releasing substituents in the benzene nucleus of the phthalhydrazide system, and weakened by electron-attracting substituents, analogously to the substituted lophines (Section 6).

2. The effects of substituents in position 3 of the phthalhydrazide system are more pronounced than those of substituents in position 4; this is particularly obvious on comparing luminol *(11)* with the isomeric 4-aminophthalhydrazide *(12)*, the luminescence of which is an order of magnitude weaker than that of *(11)*.

α) Steric Hindrance of Resonance

Deviations from Rule 1 are observed in the cases of 3-methylamino- and 3-dimethylaminophthalhydrazide; the emission of the former is only about 60%, and that of the latter only 2%, of that of luminol, although the alkylamino and dialkylamino groups are stronger electron donors than the amino group [58]. This anomaly is due to steric hindrance of resonance. Thus the dimethylamino group in position 3 cannot lie in the same plane as the aromatic system, owing to the adjacent carboxyl group. The compound therefore behaves essentially as the parent phthalhydrazide system, which is only very faintly chemiluminescent. In 3-methylaminophthalhydrazide, on the other hand, the methylamino group can lie in the same plane as the benzene nucleus, but only in the configuration in which the *N*-methyl group is turned away from the carbonyl group. However, the steric hindrance of resonance in the phthalhydrazides is probably less important than in the corresponding phthalate dianions (which are the radiating particles; cf. Section 8b).

The chemiluminescence of 3-methylphthalhydrazide [52] is weaker than that of phthalhydrazide, although the methyl group acts as an electron donor; this is probably again due to steric hindrance.

β) 4-Dialkylaminophthalhydrazides

Dialkylamino groups in position 4 of the phthalhydrazide or of the phthalate dianion are not sterically hindered, and the luminescence in this case is an order of magnitude stronger than that of 4-aminophthalhydrazide. The maximum chemiluminescence intensity of 4-diethylaminophthalhydrazide (in the hemin-catalysed oxidation) is equal to that of luminol, and the total emission exceeds that of luminol by 20–30% [58]; this was the first hydrazide found to have a greater chemiluminescent power than luminol. Other 4-dialkylaminophthalhydrazides exhibit chemiluminescence as strong as that of luminol [58,59] (Table 1).

Table 1. Relative emissions of 4-dialkylaminophthalhydrazides [58,59] (luminol = 100).

	Chemiluminescence (relative emission)
(20), R = $-N(CH_3)_2$	87
(21), R = $-N(C_2H_5)_2$	120
(22), R = 1-Pyrrolidinyl	105
(23), R = 1-Piperidinyl	80

[56] *A. Spruit van der Burg*, Recueil Trav. chim. Pays-Bas *69*, 1525 (1950).

[57] *A. A. Ponomarenko*, *N. A. Murkar'yan*, and *A. I. Komlev*, Dokl. Akad. Nauk SSSR *89*, 1061 (1953); cited by [3].

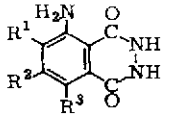
[58] *K.-D. Gundermann* and *M. Drawert*, Chem. Ber. *95*, 2018 (1962).

[59] *K.-D. Gundermann*, *W. Horstmann*, and *G. Bergmann*, Liebigs Ann. Chem. *684*, 127 (1965); Angew. Chem. *76*, 686 (1964); Angew. Chem. internat. Edit. *3*, 637 (1964).

The chemiluminescence of the hydrazides *(20)*–*(23)* is much less sensitive to alkali than that of luminol. In the system aqueous alkali/hydrogen peroxide/hemin, the emission of luminol reaches its optimum value at an alkali concentration of 0.03 N, and falls off as the pH is raised further; the emission of the 4-dialkylaminophthalhydrazides, on the other hand, reaches its optimum value at an alkali concentration of 0.1 N, and shows no appreciable decrease between this concentration and 1.0 N (cf. [60–62]).

γ) Polysubstituted Phthalhydrazides

According to Rule 1 above, strong chemiluminescence should be observed above all with phthalhydrazides having several electron-releasing substituents in the benzene nucleus. Although such compounds often exhibit very strong fluorescence, however, their ability to chemiluminesce is by no means always equally pronounced. It is obvious, therefore, that strong fluorescent power is not necessarily synonymous with strong chemiluminescent power, and that chemical stability in oxidizing media is also an important factor. Thus 3,6-diaminophthalhydrazide exhibits extremely weak chemiluminescence [55] because, being a *p*-phenylenediamine derivative, it is very rapidly oxidized to a red quinone dye. The chemiluminescence of 3,5-diaminophthalhydrazide *(24)*, however, which cannot be oxidized directly to a quinone, is also very weak [58].



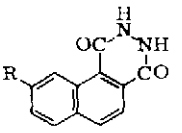
(24), R^1 = H, R^2 = NH_2, R^3 = H
(25), R^1 = R^2 = H, R^3 = OCH_3
(26), R^1 = H, R^2 = R^3 = OCH_3
(27), R^1 = R^2 = R^3 = OCH_3

The compound *(25)* fluoresces strongly in neutral solution and gives an initially intense chemiluminescence on hemin-catalyzed oxidation in aqueous solution; however, the intensity of the chemiluminescence falls off very rapidly. On the other hand, the quantum yields of the chemiluminescence of *(26)* and *(27)* in the system dimethyl sulfoxide/tert-butoxide/oxygen exceed the quantum yield of luminol by 13 and 30% respectively [2].

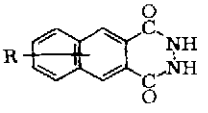
For a discussion of the partly sterically hindered 3,4-dimethoxyphthalhydrazide and of 3,4-methylenedioxyphthalhydrazide, both of which exhibit only weak chemiluminescence, see [61].

δ) Naphthalenedicarbohydrazides

As would be expected from the larger π-electron system, the isomeric naphthalenedicarbohydrazides *(28)* and *(29)* exhibit stronger chemiluminescence than phthalhydrazide [52, 54]. Nevertheless, the aminonaphthalenedicarbohydrazides *(30)* and *(31)* fall far short of luminol in intensity [52, 54].



(28), R = H
(32), R = $N(CH_3)_2$
(33), R = $N(C_2H_5)_2$
(34), R = $N(n\text{-}C_3H_7)_2$
(35), R = 1-Pyrrolidinyl



(29), R = H
(30), R = 1-NH_2
(31), R = 8-NH_2

The intense green chemiluminescence of 7-dialkylaminonaphthalene-1,2-dicarbohydrazides of the type *(32)*, however, is two to three times as strong as that of luminol (Table 2) [59] These hydrazides may be regarded as vinylogues of the 3-dialkylaminonaphthalhydrazides, in which the dialkylamino groups, as we have seen, cannot exert their chemiluminescence-promoting effect, owing to steric hindrance of resonance. The effect of the alkali concentration on the chemiluminescence of 7-substituted naphthalene-1,2-dicarbohydrazides is very similar to that observed in the case of the 4-dialkylaminophthalbydrazides. Since compounds *(32)*–*(35)* are yellow, autoabsorption of the chemiluminescence becomes noticeable at lower hydrazide concentrations than in the case of the colorless luminol.

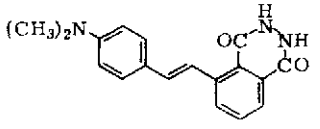
Table 2. Chemiluminescence, fluorescence, and relative emission of naphthalene-1,2-dicarbohydrazides (luminol = 100) [59].

	Chemiluminescence		Fluorescence [*] λ_{max} [mμ]	
	λ_{max} [mμ]	Relative emission	A	B
(32)	514	2.28	529	514
(33)	514–518	2.54	529	516
(34)	515	3.00	529	515
(35)	515	2.07	529	515

[*] Chemiluminescence under optimum conditions [59].
A: fluorescence of the hydrazide in 0.2 N NaOH.
B: fluorescence after chemiluminescence has ceased.

ε) 4′-Dialkylaminostilbene-2,3-dicarbohydrazides [63,63a]

The *trans*-isomers of compounds of the type *(36)* are also sterically unhindered vinylogues or phenylogues of 3-dialkylaminophthalhydrazides. In this case, however,



(36)

the transmission of the electron-donating effect of the dialkylamino group requires even greater "de-aromatization" than in the 7-dialkylaminonaphthalene-1,2-dicarbohydrazides [64]; consequently, the chemiluminescence emissions of these stilbene derivatives are lower than those of the naphthalene derivatives. Thus the

[60] *K. Weber, A. Režek*, and *V. Vouk*, Ber. dtsch. chem. Ges. *75*, 1141 (1942).

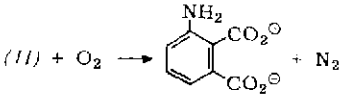
chemiluminescence of *(36)*, although considerably stronger than that of the sterically hindered 3-dimethylaminophthalhydrazide, is only about 2/3 as strong under optimum conditions as that of luminol. The optimum chemiluminescence is obtained by the addition of about 40 vol-% of dimethyl sulfoxide to the aqueous alkaline oxidation solution (H_2O_2/hemin). This promoting effect of dimethyl sulfoxide (which is also shown to a lesser extent by dimethylformamide and by *N*-methylpyrrolidone) on the chemiluminescence of hemin-catalysed oxidations has so far been observed only with stilbene derivatives of the type *(36)*. The chemiluminescence accompanying the oxidation of luminol in aqueous alkali with H_2O_2/hemin is greatly reduced by even small quantities of dimethyl sulfoxide (cf. the entirely different relationships observed in the chemiluminescence of luminol in the system dimethyl sulfoxide/tert-butoxide/oxygen [46]).

b) The Mechanism of the Chemiluminescence Reaction of Luminol

Albrecht [48] had assumed as early as 1928 that the oxidation of luminol led to 3-aminophthalic acid and nitrogen. Since, however, he could isolate only unchanged luminol from the reaction mixture after the chemiluminescence had ceased, he thought that luminol itself was the emitting species. This view was also shared by other authors (for a review see [52]).



(11) *(37)*

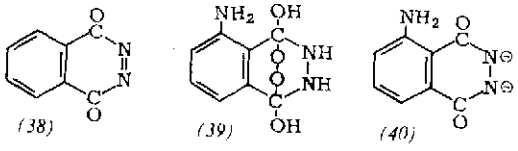
All earlier investigations on the course of the chemiluminescence reaction of luminol were impeded by the fact that the initial products of the reaction in aqueous alkaline media very rapidly undergo further oxidation and secondary reactions; for a long time, therefore, no definite breakdown product of luminol could be isolated. It was only by the use of polar organic solvents such as dimethyl sulfoxide, with oxygen as the oxidizing agent and tert-butoxide as the base [46], that it became possible to isolate 3-aminophthalic acid as a product; the yield (as the dimethyl ester) was such as to show, on comparison with the quantum yield of the chemiluminescence, that the dianion *(37)* is the product and the emitting particle of the luminol reaction, and does not result from a "dark reaction" that accompanies the chemiluminescence reaction. The consumption of alkali and oxygen and the quantity of nitrogen produced lead to the overall equation:

(11) + 2 NaOH + O_2 → N_2 + 2 H_2O + *(37)* (as the di-Na salt).

Comparison of the chemiluminescence spectrum of the luminol reaction with the fluorescence spectra of luminol and of *(37)* also shows that the radiating species is not luminol, but *(37)* [2].

The emitting particles in the chemiluminescence of the 7-dialkylaminonaphthalene-1,2-dicarbohydrazides (Section 8a) are again probably not the hydrazides themselves, but the substituted naphthalene-1,2-dicarboxylate dianions (cf. Table 2). The same applies to the stilbene derivatives *(36)* [64a].

The intermediate steps involved in the chemiluminescence reactions of hydrazides of the luminol type are still not known with certainty. The intermediate formation of an azodiacyl compound of the type *(38)* [48,49] is unlikely, since *e.g.* dihydrophthalazinedione *(38)* prepared by another route [65, 66] does not chemiluminesce under conditions in which distinct chemiluminescence is observed with the phthalhydrazide [2,46]. The endoperoxide *(39)* described by *Drew* and *Garwood* [67] is apparently a luminol salt containing H_2O_2 of crystallization [2] [*].



(38) *(39)* *(40)*

The mesomeric dianion *(40)* could be an intermediate in the chemiluminescence reaction of luminol with oxygen. If the oxygen used is enriched in ^{18}O, more than 85% of the latter is found in the 3-aminophthalic acid after the reaction [68].

No free-radical intermediates could be detected in the luminol reaction by electron spin resonance measurements [68]. A free-radical chain mechanism may nevertheless be assumed, at least in other oxidizing systems, for the chemiluminescence reaction of luminol also [69–71]. Thus chemiluminescence has been brought about in aqueous solutions of luminol by the action of X-rays, and this effect can be blocked by the introduction of cysteine, which acts as a free-radical interceptor [72].

Further evidence in favor of a free-radical mechanism is to be found in the recent extensive literature on the influence of catalysts on the chemiluminescence reaction of luminol (cf. the reviews [73,74]; also [74a]).

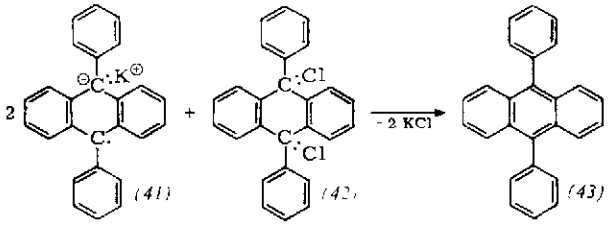
9. Chemiluminescence of Aromatic Free-Radical Ion Pairs

When anthracene, chrysene, pyrene, and other highly condensed aromatic hydrocarbons are electrolysed in dimethylformamide or acetonitrile with tetraethylammonium salts as electrolytes, chemiluminescence occurs in the neighborhood of the cathode, provided that atmospheric oxygen (which has a quenching effect in this case) is excluded. This chemiluminescence is due to an excited singlet state of the hydrocarbon [75]; this presumably results from the formation at the electrodes of hydrocarbon radical ions. $\cdot Ar^{\oplus}$ and $\cdot Ar^{\ominus}$, which then react with each other in solution by a one-electron transfer.

This new type of chemiluminescence reaction can also be brought about by purely chemical means. Thus the compound *(41)* obtained by the reaction of potassium metal with 9,10-diphenylanthracene *(43)* reacts with 9,10-dichloro - 9,10-diphenyl - 9,10 - dihydroanthracene *(42)*, emitting a bright chemiluminescence that has been identified as the fluorescence of 9,10-diphenylanthracene [76]. Basically this reaction again involves the



transfer of an electron from the free-radical anion of the potassium compound *(41)* to the acceptor *(42)*, which is a potential 9,10-diphenylanthracenium dication; *(43)* is then formed, partly in the excited singlet state (recombination luminescence; cf. [76]).

The investigations carried out so far have indicated that this type of chemiluminescence reaction is of general importance; thus the free-radical anion *(41)* may be replaced by another donor, such as the sodium compound of naphthalene or of *N*-methylacridone. Other electron acceptors that can be used are diacylperoxides or even aluminum chloride. The only essential point seems to be that the free-radical anion must be derived from a molecule that fluoresces in the visible region of the spectrum, and that the acceptor molecule has no quenching action.

According to *Chandross*, one-electron transfers of this type are probably much faster than chemical reactions in which covalent bonds are formed or broken. The faster the release of chemical energy in the smallest possible volume of the reaction solution, the smaller should be the losses due to radiationless energy transformations (into heat, *etc.*), and the greater the proportion of the chemical energy transformed into excited electronic states. It is likely, therefore, that this new type of chemiluminescence reaction comes closer than most other types to the ideal conditions of bioluminescence reactions.

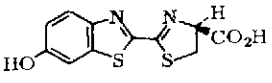
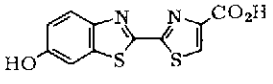
10. Firefly Luciferin

The bioluminescence of the American firefly *(Photinus pyralis)* is probably the most widely studied of the biological luminescence reactions (for a review, see [17]). The structure elucidation and synthesis of the substrate of this reaction, *i.e.* firefly luciferin *(44)* is due to *White* et al. [77]. *In vivo*, *(44)* is converted to the dehydro compound *(45)*, with simultaneous emission of light, by the action of the enzyme luciferase together with adenosine triphosphate [*], Mg^{2+} ions, and oxygen. It has been possible to study these processes *in vitro*, since both the luciferin and the luciferase have been isolated in the crystalline state [17].



(44)



(45)

The light emitted on dehydrogenation of firefly luciferin has a maximum at 562 mμ (cf. also [78]), corresponding to an energy of at least 57 kcal/mole. *(44)* can also be made to luminesce (although only very weakly) in the absence of the enzyme by the use of powerful oxidizing agents [79].

11. Closing Remarks

Notable progress has been made during recent years in the investigation of the chemiluminescence of organic compounds. Nevertheless, many questions, such as that of the quantitative relationship between chemiluminescence and structure, have not yet been answered. The mechanisms of many chemiluminescence reactions also require further clarification. A possible additional advantage of knowing these mechanisms is that they may suggest methods of obtaining higher quantum yields than are possible at present.

I am grateful to Dr. Bergmann for many helpful discussions and for his collaboration in the experimental work.

The Structure of Sugar Phenylosazones

BY PROF. DR. L. MESTER

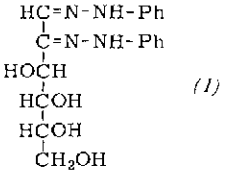
CENTRE NATIONAL DE LA RECHERCHE SCIENTIFIQUE, PARIS;
INSTITUT DE CHIMIE DES SUBSTANCES NATURELLES, GIF-SUR-YVETTE (FRANCE)

Dedicated to Professor Fritz Micheel on the occasion of his 65th birthday

The open-chain chelate structure of sugar osazones, first proposed by Fieser and Fieser, has now been confirmed by chemical methods, X-ray analysis, and NMR spectroscopy. These investigations showed that the properties of sugar osazones are best described by a formula containing a quasi-aromatic chelate ring.

Introduction

Although the first sugar phenylosazones were prepared 80 years ago, the problem of the structure of this group of compounds has continued to intrigue many carbohydrate chemists up to the present day. When *Emil Fischer* [1,2] first prepared the sugar phenylosazones,



(1)

he represented them as open-chain compounds *(1)*. But as our knowledge of the nature and reactions of sugar osazones has increased, it has become evident that this structure does not fulfil all the requirements necessary. *Fischer*'s open-chain structure does not explain:

1. Why osazone formation stops at the second carbon atom, instead of continuing to the third and further carbon atoms.

2. Why the two phenylhydrazone groups in the sugar osazones behave differently in most of their reactions. These differences are manifested:

a) on methylation [3–6], when only one of the two imino groups is methylated;

b) on transosazonization [7]: the phenylhydrazine attached to C–1 is always more easily substituted by another molecule of phenylhydrazine than that on C–2;

c) by formation of osone-hydrazones [8]: the phenylhydrazone group on C–2 is always hydrolysed first, while that on C–1 displays increased stability;

d) by formation of osotriazoles [7,9]: it is the phenylhydrazone group on C–1 which furnishes most of the aniline liberated in the course of the reaction;

e) by the different behaviour of the two phenylhydrazone groups on reduction [10–13]: the phenylhydrazone group on C–1 is reduced to the amine, while that on C–2 is eliminated (except under extreme conditions [14]).

3. Why there is a distinct difference between the phenylosazones and the 1-(methylphenyl)-2-phenylosazones, on the one hand, and the bis(methylphenyl)osazones, on the other. The difference is shown:

a) in the ultraviolet spectra [15–20];

b) in the formation of anhydro-osazones [21,22] which are readily obtained from the first group of compounds and not at all from the second;

c) in the formation of dehydro-osazones [23]: the second group of compounds does not give these derivatives;

d) in the mutarotation [24,25]: this phenomenon is peculiar to the phenylosazones and to mixed osazones;

the bis-(methylphenyl)-osazones do not change their rotation except as a result of a change in temperature [26].

4. Why the behavior of sugar osazones is entirely different from that of non-sugar osazones. Here, the differences are shown:

a) in the spectra of the two groups of products [15–20];

b) in the formation of osotriazoles [7,9]: with sugar osazones, the aniline is liberated mainly from the phenylhydrazone group on C–1, while in the case of non-sugar phenylhydrazones the aniline comes equally from the phenylhydrazone groups on C–1 and C–2;

c) on reaction with diazotized aniline [27,28]: sugar osazones yield osazone formazans, while non-sugar osazones react with substitution of the phenyl ring of the aniline on C–1 or do not react at all.

5. Why it is impossible to tritylate the primary hydroxy group of sugar osazones [23,29] under the usual conditions.

Early Attempts to Define the Structure of Sugar Osazones

Many investigators have tried to find the answers to these questions, which explains the surprising abundance of work in this field. Several tautomeric structures have been proposed, some cyclic, some non-cyclic, but none of these formulae explains all the properties of osazones.

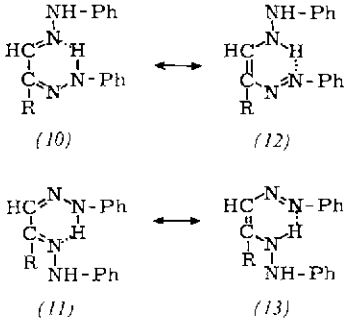
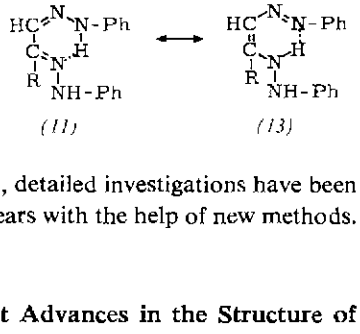
In 1907, *Baly* et. al. [15] put forward the open-chain structures *(2)* and *(3)*, in which the two phenylhydrazines are differently bound: one as a phenylhydrazone and the other in the azo form. *Zerner* and *Waltuck* [30] proposed the open-chain phenylhydrazino-phenylazo structures *(4)* and *(5)* with a double bond between C–1 and C–2, while *Haworth* [31] and *Percival* and *Percival* [5] preferred cyclic structures *(6)* or *(7)* and *(8)* or *(9)*.

As an explanation of the properties of osazones, *Baly* and his collaborators [15] already advanced the idea that in the osazones the two hydrazone groups could form a "condensed system" containing an intramolecular linkage.

Fieser and *Fieser* [32] revived and developed this idea in proposing, on purely theoretical grounds, two alternate chelate structures *(10)* and *(11)* for sugar osazones, these being stabilized by resonance with the forms *(12)* and *(13)*. They considered that the formation of a chelate ring between C–1 and C–2 prevented further electron displacement necessary to osazone formation, and thus explained why the reaction stops at C–2. In 1948, in the absence of experimental proof, *Percival* [33], in his detailed study on the sugar osazones, did not accept this hypothesis and in 1952 *Hardegger* and *Schreier* [34] also considered any attempt to define the structure of osazones as being premature.



(10) (12)



(11) (13)

To solve this problem, detailed investigations have been made in the last ten years with the help of new methods.

Recent Advances in the Structure of Sugar Osazones

1. The Formazan Reaction

Mester [27] in 1955 studied the structure of sugar osazones by means of the formazan reaction. By the action of diazotized aniline on D-glucosazone *(14)* in alkaline ethanolic solution, the osazone formazan *(15)* of D-glucose is obtained as dark violet needles. Mild acetylation produces a black tetra-*O*-acetate.

[30] *E. Zerner* and *R. Waltuch*, Mh. Chem. *35*, 1025 (1914).

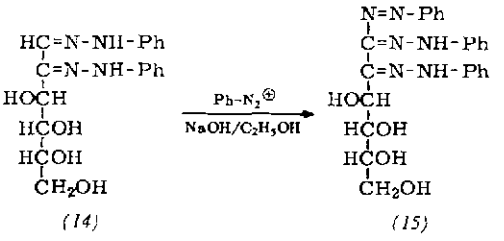
[31] *W. N. Haworth*: The Constitution of Sugars. Edward Arnold & Co., London 1929, p. 7.

[32] *L. F. Fieser* and *Mary Fieser*: Organic Chemistry. Heath and Co., Boston, Mass. 1944, p. 351.

[33] *E. G. V. Percival*, Adv. Carbohydrate Chem. *3*, 23 (1948).

[34] *E. Hardegger* and *E. Schreier*, Helv. chim. Acta *35*, 232 (1952).

This reaction confirmed, first of all, that the osazones have an open-chain structure, since a cyclization involving C–1 [formulae *(6)* and *(7)*], as proposed by



(14) *(15)*

Haworth [31], excludes the possibility of formazan formation. Cyclization involving C 2 [formulae *(8)* and *(9)*], suggested by *Percival* and *Percival* [5], is also excluded since study of the ultraviolet spectra of the osazone formazan obtained in the course of the reaction shows, in addition to the formazan group, the presence of a further chromophore. Moreover, the ultraviolet spectra of the osazone formazans of D-glucose and pyruvaldehyde are very similar (Fig. 1), and in the latter compound such a cyclization is quite impossible.

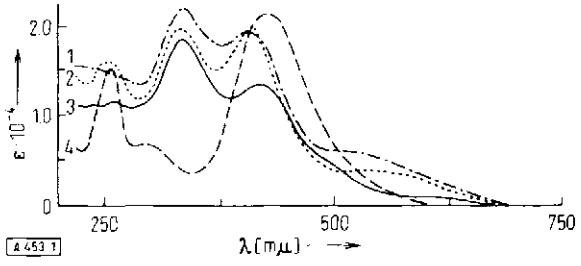


Fig. 1. Ultraviolet spectra in ethanol.
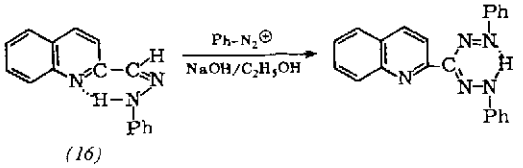
Curve 1: D-Glucose phenylosazone formazan.
Curve 2: Tetra-*O*-acetyl-D-glucose phenylosazone formazan.
Curve 3: Pyruvaldehyde phenylosazone formazan.
Curve 4: D-Glucose diphenylformazan.

On the other hand, the fact that formazan formation from sugar osazones requires a medium more basic than pyridine, indicates the occurrence of chelation, since this prevents the formation of formazans in pyridine [35]. Mention may be made of quinoline-2-carboxaldehyde phenylhydrazone *(16)* as a model compound. Here, too



(16)

chelation prevents the formazan reaction in pyridine, whereas the formazan is produced in an alkaline alcoholic solution.

Thus the formazan reaction constituted the first experimental proof in favour of the formulae proposed by *Fieser* and *Fieser* for the sugar osazones: chelated, open-chain structures.

[35] *G. Zemplén, L. Mester, A. Messmer*, and *A. Major*, Acta chim. Acad. Sci. hung. *7*, 455 (1955).

[36] *B. Jambor* and *L. Mester*, Acta chim. Acad. Sci. hung. *9*, 485 (1956).

2. Polarographic Behavior of Sugar Osazones

The chelate structure of sugar osazones and mixed osazones has been confirmed by *Jambor* and *Mester* [36] with the aid of polarography. D-Glucosazone, 1-(methylphenyl)-2-phenyl-D-glucosazone, and bis(methylphenyl)-D-glucosazone exhibit a four-electron reduction wave, which for the third compound is 200 mV more positive than for the first two.

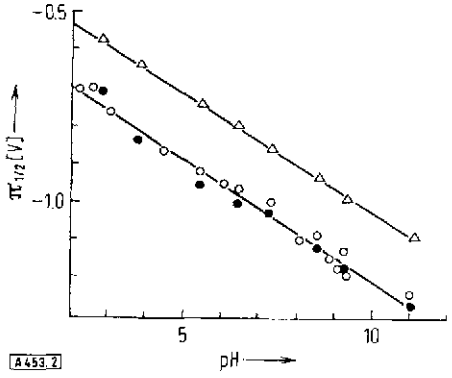


Fig. 2. Polarographic reduction potentials of sugar osazones.
o –o D-Glucose phenylosazone.
●—● D-Glucose-1-methylphenyl-2-phenylosazone.
Δ—Δ D-Glucose bis(methylphenyl)osazone.
Ordinate: Half-wave potential [V].

This difference between D-glucosazone and 1-(methylphenyl)-2-phenyl-D-glucosazone, on the one hand, and bis(methylphenyl)-D-glucosazone, on the other, is a further manifestation of the structural difference which characterizes these two groups of compounds. The fact that the first two are less readily reduced (their reduction potential is more negative) is explained by the increased stability conferred by their chelate structures, in contrast with the bis(methylphenyl)hydrazone structure which cannot be stabilized by chelation.

3. Ultraviolet Spectra of Osazones

Figure 3 shows the spectra of D-glucose phenylosazone, 1-(methylphenyl)-2-phenyl-D-glucosazone, bis(methylphenyl)-D-glucosazone, and benzil phenylosazone. It will be seen that the spectra of the first two compounds are

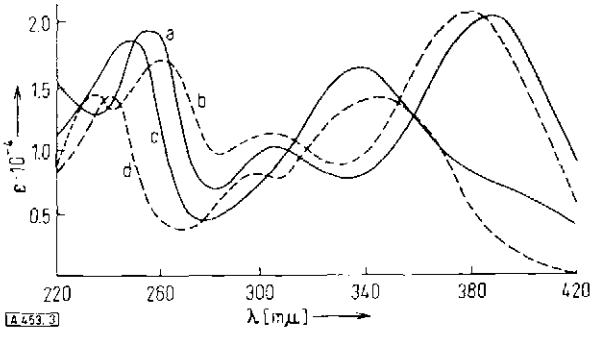

Fig. 3. Ultraviolet spectra in ethanol of (a) D-glucose phenylosazone, (b) D-glucose 1-(methylphenyl)-2-phenylosazone, (c) D-glucose bis-(methylphenyl)osazone and (d) benzil phenylosazone.

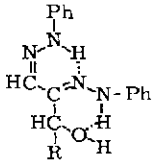
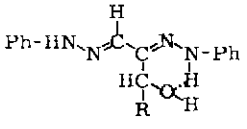
very similar and differ from the spectra of the bis(methylphenyl)-D-glucosazone and of the non-sugar osazone. By comparison with the spectra of diphenylpolyenes and diphenylpolyenazines, *Henseke* et al. [19] concluded that osazones form a mesomeric bond system conjugated with the two benzene rings, in which the two NH-groups correspond in absorption to a double bond. Taking into account the often evoked role played by the hydroxy group on C–3 in these molecules [16,24,37], they proposed the formulae *(17)* and *(18)* for sugar osazones.



(17)



(18)

The existence of a hydrogen bond of the type N–H···O in the osazones is considered to be supported by the fact that it is more stable (2 kcal/mole) than a bond of the type N–H···N– (1.3 kcal/mole). In formula *(18)* the N–H···N– type of chelation, proposed by *Fieser* and *Fieser*, is abandoned because 1-(methylphenyl)-2-phenyl-osazones exhibit the same behavior as unsubstituted osazones.

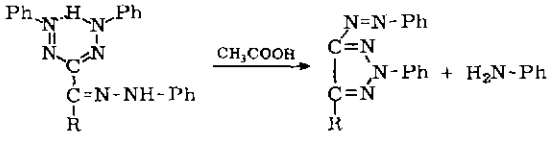
4. Infrared Spectra of Osazones

Ottig [38] was the first to publish infrared spectra of a number of sugar osazones and to compare them with the spectrum of glyoxal phenylosazone. The bands characteristic of osazones are situated between 1550 and 1600 cm^{-1}, especially at 1495–1500, 1530, 1570, and 1600 cm^{-1} for sugar osazones. For glyoxal phenylosazone the same bands were found, except for the weakest osazone band at 1530 cm^{-1} which was replaced by a strong band at 1510 cm^{-1}.

Although the infrared spectra can be used to identify osazones, they do not shed further light on the structure of osazones.

5. Formation of Osotriazoles from Osazone Formazans

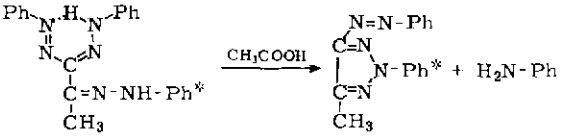
If a solution of an osazone formazan *(19)* is refluxed in acetic acid for a few minutes, a 1-phenylazoosotriazole derivative *(19a)* is formed with the elimination of aniline [39].



(19) *(19a)*

Applying this reaction to osazone formazans labelled with ^{14}C, *Mester* and *Weygand* [40] provided additional confirmation of the chelated structure of the sugar osazones.

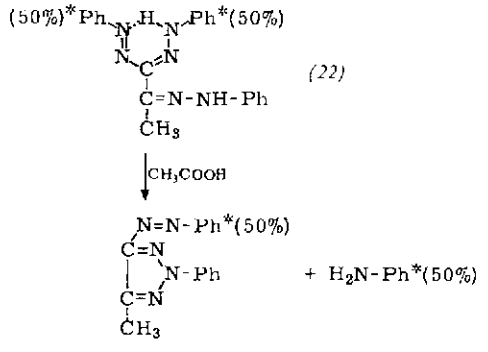
They synthesized the osazone formazan *(20)* of methylglyoxal labelled in the phenylhydrazone group on C–2 by the reaction of [^{14}C]-phenylhydrazine with pyruvaldehyde formazan. The osotriazole *(21)* formed from it contained the same radioactivity, which means that the



(20) *(21)*

aniline liberated arises exclusively from the substituent on C–1 of the osazone formazan. The same result is obtained with a D-glucosazone formazan labelled in the phenylhydrazone group on C–2.

If the radioactivity is introduced into the substituent on C–1 of the methylglyoxal osazone formazan *(22)* by coupling pyruvaldehyde phenylhydrazone with diazotized [^{14}C]-aniline, followed by condensation with non-radioactive phenylhydrazine, then exactly half the radioactivity is lost with the aniline in the osotriazole reaction.



(22)

In contrast, if D-glucosazone is coupled with diazotized [^{14}C]-aniline and the D-glucosazone formazan *(23)* obtained submitted to the osotriazole reaction, 58% of the total radioactivity is found in the osotriazole and only 42% in the liberated aniline. This difference is a direct proof of the presence of chelation in D-glucosazone, which disturbs the usual equilibration of the radioactivity between the substituents on C–1 in the osazone formazan.

6. Sugar Dehydro-Osazones

The structure of dehydro-D-glucosazone was studied by *Mester* and *Moczar* [41,42]. This compound, very similar in appearance to the initial osazone, was obtained first by *Diels* et al. [23] in 1938 by oxidation of D-glucosazone in alkaline solution with air. The loss of two hydrogen atoms stabilizes the osazone structure which can therefore be conveniently investigated using dehydro-osazones.

The ultraviolet spectra of dehydro-osazones are similar to those of the osazones, with maxima at 255, 315, and 386 mμ. The only difference is that the maximum at 315 mμ is more accentuated in the spectra of dehydro-osazones (Fig. 4).

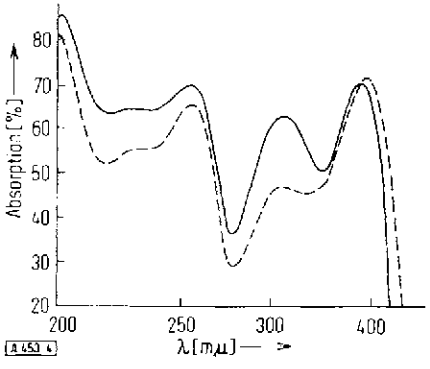

Fig. 4. Ultraviolet spectra in ethanol of (— ·) dehydro-D-glucose phenylosazone and (- - -) D-glucose phenylosazone.
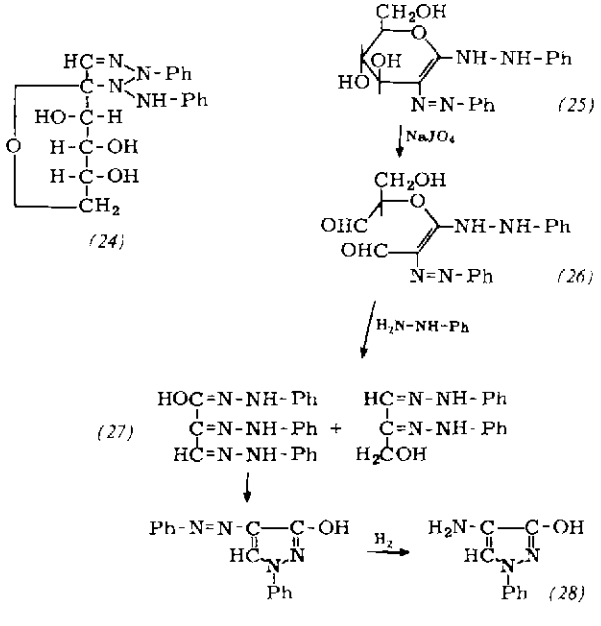
Ordinate: Absorption [%].

Diels et al. have proposed the structure *(24)* for dehydro-D-glucosazone. Results of investigations carried out by *Mester* and *Moczar* [41] did not confirm this structure. On oxidation of the compound with periodic acid, only one mole of reagent is consumed instead of two moles, and there is no formation of formic acid, as would be expected on the basis of structure *(24)*. Moreover, no formazan is formed, even in alkaline solution. These observations together with the infrared spectrum of the compound suggest the structure *(25)*, which has been confirmed by the phenylhydrazinolysis [41] of the product *(26)* of periodate oxidation.



Degradation of the oxidation product *(26)* by refluxing it with phenylhydrazine in ethanol, water, and acetic acid gave D-glyceraldehyde phenylosazone and the phenylhydrazide *(27)* of formylglyoxalic acid phenylosazone. The latter compound was transformed by acid hydrolysis with elimination of phenylhydrazine into 3-hydroxy-1-phenyl-4-phenylazopyrazole, which on catalytic hydrogenation gave 4-amino-3-hydroxy-1-phenylpyrazole *(28)*.

To confirm the proposed structure, the NMR spectrum of tri-*O*-acetyldehydro-D-glucosazone was determined at 60 Mc in deuterated chloroform [42] (Fig. 5).

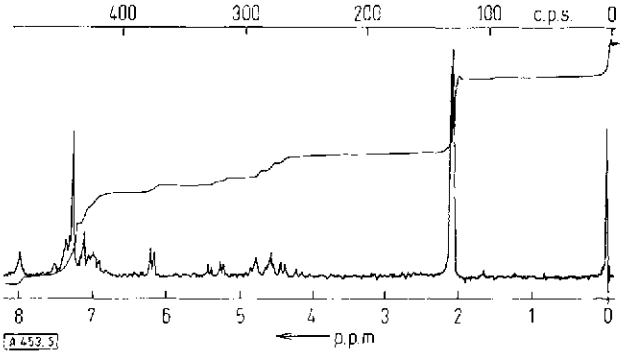


Fig. 5. NMR spectrum of tri-*O*-acetyldehydro-D-glucose phenylosazone at 60 Mc in $CDCl_3$ (internal standard: tetramethylsilane).

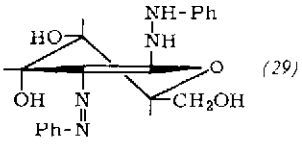
The integrated curve shows the presence of three *O*-acetyl groups, five hydrogens attached to the sugar carbon chain, two hydrogens on nitrogen, and two phenyl groups. The sharp doublet at 6.2 p.p.m., well separated from other signals, requires the presence of a hydrogen atom coupled with only one neighboring hydrogen atom. The spacing for this signal (3 c.p.s.) recurs in the quartet of intensity one centered at 5.3 p.p.m. The position of the latter signal is characteristic of hydrogen atoms on secondary carbon atoms in carbohydrate structures which at the same time carry an acetoxy group each. This signal can therefore be assigned to the hydrogen atom on C -4 and the broad spacing of the quartet (10 c.p.s.) requires the hydrogen to be axially oriented and coupled with two hydrogen atoms, one of which is axial in orientation and must be the hydrogen at C–5. The other hydrogen atom must be quasi-equatorially oriented in view of the weak coupling; it must give rise to the doublet at 6.2 p.p.m. and must be located at C–3 because of the chemical shift. That this shift is 0.9 p.p.m. less than normal can be ascribed to the decreased diamagnetic shielding of equatorial over axial hydrogens together with paramagnetic deshielding arising from the neighboring double bond.

The multiplet from 4.60 to 5.32 p.p.m. corresponds to three hydrogen atoms. It can be assigned to the hydrogen atoms on C–5 and C–6. Similar splitting in this region was observed in the spectra of acetylated sugar osazones; it is characteristic of a *C*-methylene group which carries an acetate function. Signals at this position are not

[41] *L. Mester* and *E. Moczar*, Chem. and Ind. *1962*, 554.
[42] *L. Mester* and *E. Moczar*, J. org. Chemistry *29*, 247 (1964).

present in the spectrum of di-*O*-acetyldehydro-L-rhamnosazone, hut instead a doublet centered around 1.44 p.p.m. occurs, which is typical for a methyl group.

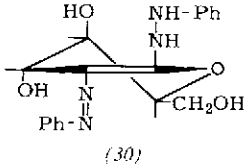
The group of lines centered around 2.10 p.p.m. can be assigned to the three acetate methyl groups. Finally, there are two peaks at 7.97 and 12.50 p.p.m. which seem to correspond to the two N–H bonds. Therefore, the structure *(29)* is assigned to dehydro-D-glucose phenylosazone (without regard to chelation).



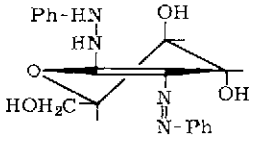
(29)

This is the same structure which was found for dehydro-D-glucosazone on the basis of chemical investigations *(25)* [41], except that the hydroxy group on C–3 is not equatorially oriented as in the original D-glucose configuration, but has the axial position (D-allose configuration). This transposition is certainly due to steric hidrance of this hydroxy group in the equatorial position by the vicinal azo group, and occurs during dehydrogenation in an alkaline medium.

The structure *(29)* was supported by further chemical evidences. In the D-scries of hexoses, four dehydro-osazones (derived from D-glucose, D-galactose, D-allose, and D-gulose) may be expected if no transposition of the OH-group on C–3 occurs. If, however, the 3-hydroxy group does undergo a transposition to the axial position, then D-glucose should give the same dehydro-osazone as D-allose, and D-galactose should give the same as D-gulose. Furthermore dehydro-D-glucosazone and dehydro-L-allosazone, on the one hand, and dehydro-D-galactosazone *(30)* and dehydro-L-gulosazone *(31)*, on the other, must be optical antipodes (enantiomers).



(30)



(31)

The experimental data are in accord with these expectations. It was found that dehydro-D-glucosazone (m.p. 202–203 °C, $[\alpha]_D^{24}$ + 346 °, c = 0.5 in pyridine/ethanol 1:1) is identical with dehydro-D-allosazone (m.p. 203 °C, no depression with dehydro-D-glucosazone, identical infrared spectrum and optical rotatory power), while dehydro-D-galactosazone (m.p. 212 °C, $[\alpha]_D^{24}$ + 300 °, c = 1 in pyridine/ethanol 1:1) and dehydro-L-gulosazone (m.p. 212–213 °C, identical infrared spectrum, but $[\alpha]_D^{24}$ −298 °) are enantiomers.

The establishment of the steric structure of dehydro-D-glucosazone permitted a more exact delineation of the chelated structure of sugar osazones by NMR spectroscopy (see Section 8).

7. X-Ray Analysis

A very important contribution to the problem of the structure of sugar osazones has been the X-ray analysis made by *Furberg* et al. [43]. The *p*-bromophenylosazones of D-glucose, D-xylose, and D-ribose all have the same crystal structure (Fig. 6).

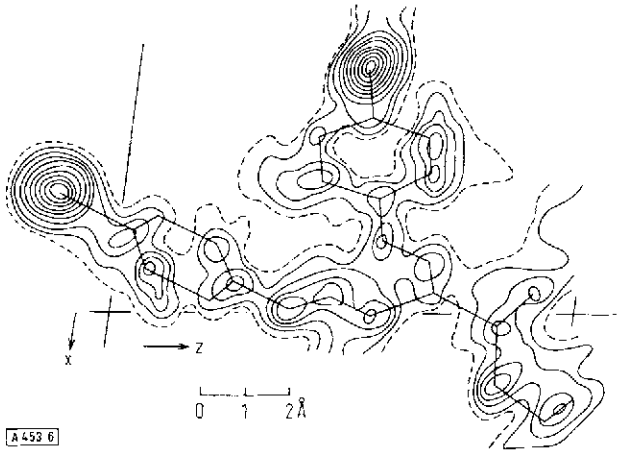


Fig. 6. Electron-density projection in the direction of the b axis of xylose *p*-bromophenylosazone. The distances between lines of equal density are arbitrary.

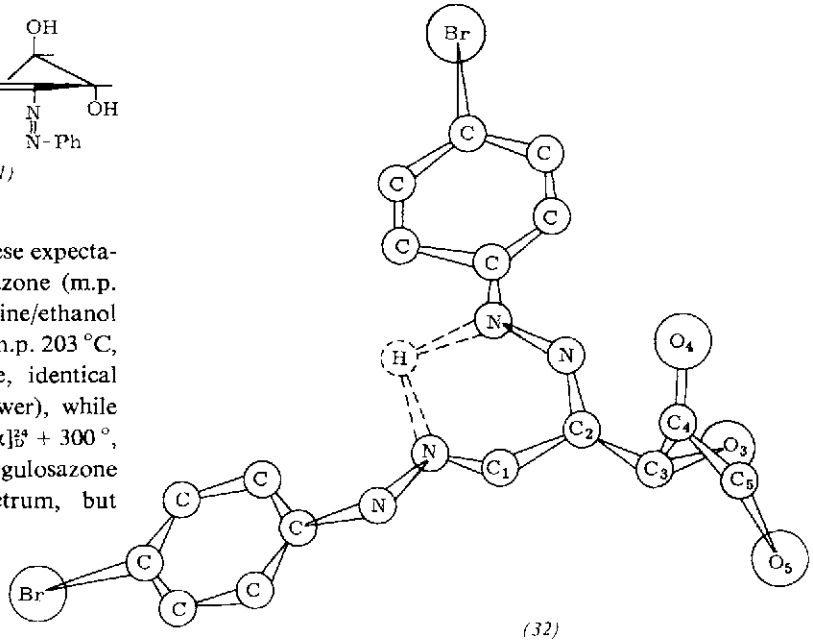
The electron-density projection in the direction of the b axis of these crystals has confirmed the open-chain structure of the sugar osazones and has also revealed the presence of chelation between the two phenylhydrazone groups. The two benzene rings and the chelate ring are almost coplanar. Hydrogen bonding between the hydroxy group on C–3 and the phenylhydrazone group on C–2, as suggested by *Henseke* [19], is unlikely because of the distance separating both groups.



(32)

[43] *K. Bjamer, S. Dahm, S. Furberg*, and *C. S. Petersen*, Acta chem. scand. *17*, 559 (1963).

From the electron-density projection, formula *(32)* can be derived for *p*-bromophenyl-D-xylosazone which agrees exactly with the formula proposed by *Mester* for sugar osazones on the basis of chemical studies.

8. NMR Spectra of Osazones

Final confirmation of the structure of sugar osazones has been obtained by the examination of their NMR spectra. On the basis of NMR studies, *Wolfrom* et al. [44] put forward the chelate structure *(11)*, while *Mester*, *Moczar*, and *Parello* [45–47] have confirmed structure *(10)*.

The chemical shifts of the signals corresponding to the protons on C–1 and on the nitrogen atoms in sugar osazones, dehydroosazones, and a number of related compounds are given in Table 1. In the spectra of compounds *(33)*–*(37)* a signal corresponding to a chelated N–H proton is present between 12 and 13 p.p.m. It is absent in the spectrum of compound *(38)*, whose aldehydophenylhydrazone structure has been proved. It is also absent from the spectrum of the symmetrical bisphenylhydrazone *(39)*.

Table 1. NMR signals of the protons on C-1 and on the nitrogen atoms of sugar osazones, dehydro-osazones, and related compounds. The data are chemical shifts [p.p.m.] relative to the signal of tetramethylsilane (internal standard).

(39)	Glyoxal bisphenylhydrazone	–	10.33	7.69	–	11.10	8.12

[*] Signal included in the benzene peaks.

The signal of the non-chelated imino proton in *(38)* at 11 p.p.m. in deuteriopyridine (at 10.12 p.p.m. in dimethyl sulfoxide) is also present in the spectra of compounds *(33)*–*(37)*. A strong signal in the same region corresponding to two protons was found in the spectrum of *(39)*. Furthermore a signal between 7 and 8 p.p.m., corresponding to the C–1 proton, occurs in the spectra of the compounds *(35)*–*(37)*, but is absent in the spectra of the cyclic compounds *(33)* and *(34)*. The identity of the signals corresponding to the NH protons in the spectra of dehydro-D-glucosazone and of the sugar osazones suggests a great similarity of the chelate structures of both types of compounds.

Since the hydroxy group on C–3 is axially oriented in dehydro-D-glucosazone [42], it cannot form a chelate ring with the phenylhydrazine residue on C–2, as was proposed by *Henseke* [19] for the sugar osazones. Moreover, such a chelation in sugar osazones was excluded also by X-ray analysis (see Section 7) [48]. Thus the chelate ring must be formed by the two phenylhydrazine residues in the dehydroosazones as well as in the sugar osazones according to the structure proposed by *Fieser* and *Fieser*.

A more exact delineation of these chelate structures has been made possible by exchange of the hydrogens bonded to nitrogen with deuterium oxide: In deuteriochloroform the NMR signal of the free imino proton is located between 7 and 8 p.p.m. (Table 2). It disappears instantaneously on shaking of the compound with deuterium oxide. The signal at 12–13 p.p.m., corresponding to the proton involved in the chelation, disappears somewhat less rapidly; here shaking and heating are needed. The signal of the C–1 proton is located at 7.56 p.p.m. in compounds *(36)* and *(41)*, while in the spectra of compounds *(37)* and *(40)* it is overlapped by the signals of the protons of the aromatic rings. In compound *(34)* there is no C–1 proton.

The fact that replacement of the α-imino hydrogen in the phenylhydrazine residue on C–1 by a methyl group [compound *(40)*] has practically no influence on the position of the signal of the chelated NH group, while the signal of the non-chelated NH group disappears, proves that the position of the non-chelated proton in the sugar osazones is the same as the position of the methyl group in the 1-methylphenyl-2-phenylosazones. This position is chemically well defined [22, 27]. Thus the sugar osazones must have the structures *(10)* and *(12)* rather than *(11)* and *(13)*.

Table 2. NMR signals of the protons on C-1 and on the nitrogen atoms of some osazones in deuteriochloroform. The data are chemical shifts [p.p.m.] relative to the signal of tetramethylsilane (internal standard).

Recent work of *Chapman* et al. [49] and of *El Khadem* et al. [50], based on NMR spectral data, also favors the chelate structure *(10)*.

Moreover, a long-range spin-spin coupling between the C–1 proton and the non-chelated NH proton (Fig. 7) [45–47] supports the structures *(10)* and *(12)*. The weak splitting (J ≈ 1 c.p.s.) of the signal of the C–1 proton at 7.56 p.p.m. in the spectra of compounds *(36)* and *(41)*

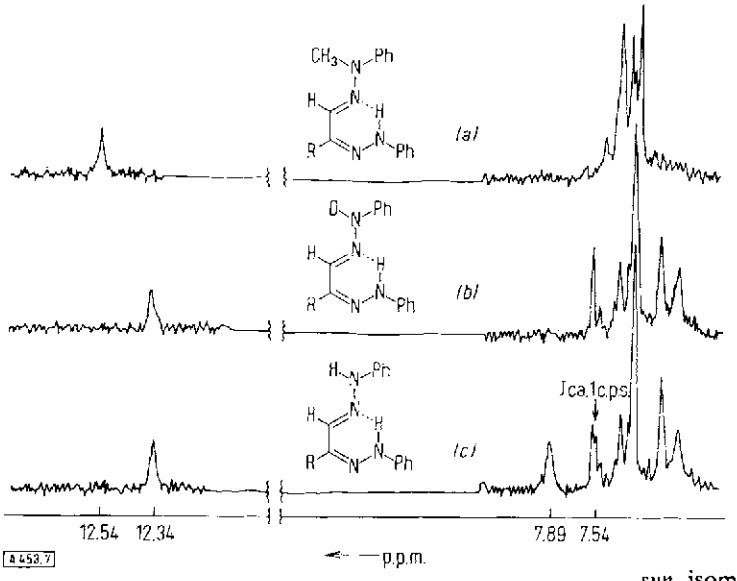

Fig. 7. NMR spectra of (a) tetra-*O*-acetyl-D-glucose 1-methylphenyl-2-phenylosazone *(40)*, (b) tetra-*O*-acetyl-D-galactose phenylosazone after partial deuteration, and of (c) non-deuterated tetra-*O*-acetyl-D-galactose phenylosazone *(36)*. The spectra were recorded at 60 Mc in $CDCl_3$ (internal standard: tetramethylsilane).

disappears during exchange of the non-chelated NH proton for deuterium, giving place to a singular but more accentuated peak (Fig. 7b).

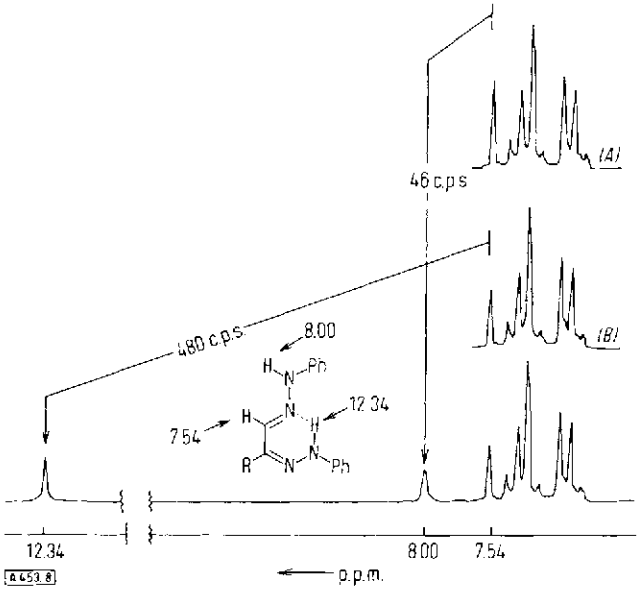

Fig. 8. High-resolution NMR spectrum (100 Mc) of tetra-*O*-acetyl-D-galactose phenylosazone in deuteriochloroform. Decoupling of the C-1 proton (7.54 p.p.m.): *(A)* Decoupling by irradiation of the non-chelated NH proton (8.00 p.p.m.). *(B)* Decoupling showing no coupling with the chelated NH proton (12.34 p.p.m.). — Internal standard: tetramethylsilane.

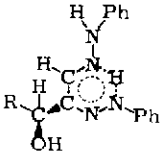
High-resolution NMR spectroscopy (100 Mc) using the double-resonance method (Fig. 8) also confirmed that the C–1 proton is coupled with the non-chelated NH proton (signal at 8.0 p.p.m.) and not with the chelated NH proton whose signal is at 12.34 p.p.m.

A similar long-range spin-spin coupling between the C–1 proton and the α-imino proton was reported for the *syn* isomers of aldehyde 2,4-dinitrophenylhydrazones [51]. The positions of both protons in these compounds and in the sugar osazones *(10)* and *(12)* are very similar. A comparable coupling between the C–1 proton and the distant free NH proton in structures *(11)* and *(13)*of the sugar osazones is highly improbable.

Considering the behavior of the sugar osazones and their ultraviolet, infrared, and NMR spectra, it seems probable that the structures *(10)* and *(12)* are limiting forms of a quasi-aromatic structure *(42)*. This would be



(42)

supported by the results of X-ray analysis [43,48] which show (cf. Section 7) that the six-membered chelate ring is approximately planar, and that its bond angles are about 120°. Moreover, polarographic analysis [36] indicates that the chelated sugar phenylosazones are more stable by about 10 kcal/mole, than the non-chelated sugar 2-methylphenyl-1-phenylosazones. This difference in stability is much larger than the normal chelation energy.

Conclusions

The quasi-aromatic structure *(42)* is proposed for the sugar osazones. It allows a satisfactory interpretation of most of their properties:

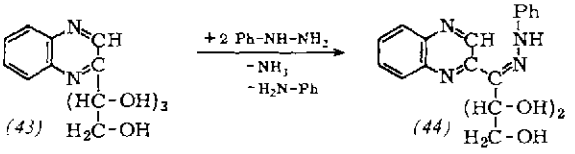
[49] *O. L. Chapman, R. W. King, W. J. Welstead*, Jr., and *T. J. Murphy*, J. Amer. chem. Soc. *86*, 4968 (1964).

[50] *H. El Khadem, M. L. Wolfrom*, and *D. Horton*, J. org. Chemistry *30*, 858 (1965).

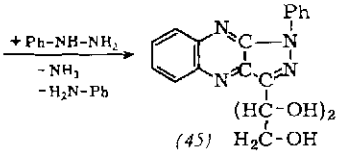
[51] *G. J. Karabatsos, B. L. Shapiro, F. M. Vane, J. S. Fleming*, and *J. S. Ratka*, J. Amer. chem. Soc. *85*, 2784 (1963).

1. Osazone formation must stop at the second carbon atom, since the phenylhydrazone attached to C–2 is engaged in the formation of the quasiaromatic chelate ring and thus cannot initiate further osazone formation.

If, however, the first two carbon atoms of a sugar are part of a quinoxaline system *(43)* having a double



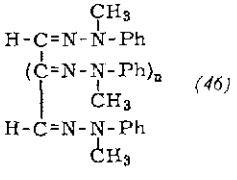
(43) *(44)*



(45)

Schiff-base structure, then the hydroxy group on C–3 undergoes a reaction analogous to osazone formation [52]: it is first oxidized by phenylhydrazine to a keto group which then condenses with a second molecule of phenylhydrazine *(44)*. In this particular case, the reaction goes further, yielding the tricyclic derivative *(45)* by oxidation with a third molecule of phenylhydrazine.

The hypothesis that the chelate ring stops the osazone reaction after C–2 has been reached was recently confirmed by *Champan* et al. [53]. They succeeded in oxidizing sugars completely by means of 1-(methylphenyl)hydrazine, thus synthesizing a new type of sugar derivative, the alkazones *(46)*, which are nothing else than sugars completely converted into osazones. Taking



(46)

into account that the methylphenylosazones cannot form chelate rings, it is readily understood that in this case osazone formation can proceed right through the entire carbohydrate chain.

2. The difference between phenylosazones and mixed osazones, on the one hand, and the bis(methylphenyl)-osazones, on the other, can also be explained by structure *(42)*: compounds of the latter group cannot give rise to chelate rings.

3. Formula *(42)* shows the difference between the two phenylhydrazone groups in the sugar osazones and thus explains their different behavior on methylation, reduction, transosazonization, osonehydrazone formation, and osotriazole formation.

The abnormal behavior of the primary hydroxy group of sugar osazones on tritylation has not yet been satisfactorily interpreted. The special character of this group is also shown in the NMR spectra [42,44] and in the fact that a benzoyl group attached to it is readily hydrolysed [54,55]. *Wolfrom* et al. [44] attribute the irregularities observed in the NMR spectra to the non-equivalence of the two protons on C-6 which is caused by the asymmetry of C-5. Possibly, however, this phenomenon is due rather to steric hindrance between the hydroxy group on C-6 and the rest of the molecule, in particular the hydroxy groups on C-3.

4. The presence of a hydroxy group (free or substituted) on C–3 favors the stabilization of the chelate ring in the quasi-aromatic structure *(42)*. At the same time the electron-attracting effect of the quasi-aromatic system influences the behavior of this hydroxy group in many of its reactions [16,37,42].

The absence of a hydroxy group on C–3 in the case of non-sugar osazones makes the formation of a chelate structure similar to *(42)* more difficult. This is the reason why both groups of osazones behave so differently. However, in some cases, the size of a substituent on C–2 in non-sugar osazones may favor the formation of a chelate ring [49], which then differs in nature from that present in sugar osazones [28,56].

New Methods in Preparative Organic Chemistry IV [*]

New Reactions of Alkylidenephosphoranes and their Preparative Uses

Part I: The Acid-Base Character of Phosphonium Salts and Alkylidenephosphoranes [**]

BY PROF. DR. H. J. BESTMANN

INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT ERLANGEN-NÜRNBERG (GERMANY)

Phosphonium salts may be regarded as Bronsted acids, and alkylidenephosphoranes as the conjugate bases. Compounds of the two classes exist in equilibrium with each other. Phosphonium salts and alkylidenephosphoranes can be obtained by this "transylidation". Other methods are also given for the preparation of members of both classes.

A. Introduction

The discovery by *Wittig* and co-workers [1] that alkylidenetriphenylphosphoranes react with aldehydes and ketones to form olefins and triphenylphosphine oxide has supplied the incentive to a large number of investigations. The Wittig reaction has already been discussed by *Schöllkopf* [2] and by *Trippett* [3], as well as by *Bergelson* and *Schemjakin* [4].

[*] The contributions in the previous three series have been published collectively in three volumes by Verlag Chemie, Weinheim/Bergstr.; English edition: Academic Press, New York-London.

[**] Parts II and III will appear shortly in this journal.

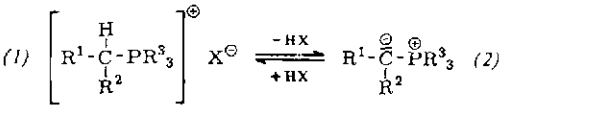
[3] *S. Trippett* in: Advances in Organic Chemistry. Vol. 1, Interscience, New York 1960; Quart. Rev. *17*, 406 (1963).

The aim of the present series of articles is to show that the recently discovered reactions of alkylidenephosphoranes with polar compounds are also of interest in preparative chemistry.

B. Phosphonium Salts and Alkylidenephosphoranes as Conjugate Acid-Base Pairs

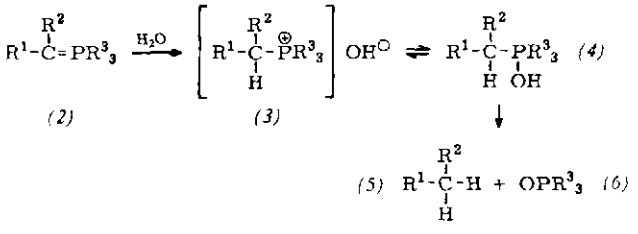
Strong bases eliminate HX from phosphonium salts *(1)* to form alkylidenephosphoranes *(2)*. *Staudinger* [5] found that the latter in turn can add HX, with re-formation of the phosphonium salts *(1)*.

Thus phosphonium salts can be regarded as Bronsted acids, and alkylidenephosphoranes as the conjugate bases.



(1) *(2)*

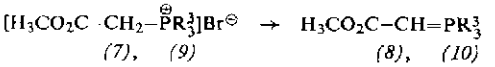
The basicity of the ylides *(2)* is also apparent in their reaction with water [1b, 1c, 2, 6, 7], in which addition of a proton to the free electron pair of the open C–P double bond leads to formation of the phosphonium hydroxide *(3)*.



(2) *(3)* *(4)* *(5)* *(6)*

The hydroxides *(3)* decompose *via* the compounds *(4)* of pentavalent phosphorus into a hydrocarbon *(5)* and a phosphine oxide *(6)* [8, 9]. The ligand eliminated from the phosphorus atom of *(3)* as a hydrocarbon is always the most strongly electronegative or the most highly resonance stabilized of the four [9, 10].

The acid-base strength of the phosphonium salts *(1)* and the alkylidenephosphoranes *(2)* depends mainly on R^1 and R^2. Electron-attracting groups increase the acidity of the phosphonium salt *(1)* and lower the basicity of the corresponding ylide *(2)*. Thus dilute sodium carbonate solution is sufficient to precipitate the ylide *(8)* from an aqueous solution of triphenylmethoxycarbonylmethylphosphonium bromide *(7)*, which is a very strong acid owing to the presence of the ester group [11, 12]. Compound *(8)* is stable towards cold water, since the ester group lowers the basicity and so hinders the attack of a proton on the lone electron pair of the open C–P double bond. The alkylidenephosphorane *(8)* decomposes with water into methyl acetate and triphenylphosphine oxide only on boiling.



(7), *(9)* *(8)*, *(10)*

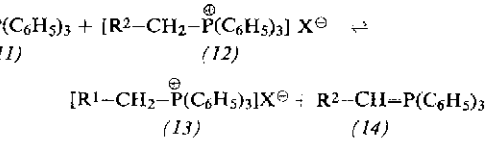
(7), *(8)*: $R^3 = C_6H_5$; *(9)*, *(10)*: R_3 = Cyclohexyl

The acid and base strengths of *(1)* and *(2)* are also determined by R^3. The electron-attracting inductive effect of the three phenyl groups in *(7)* loosens the H atoms of the CH_2 group. If the triphenylphosphine residue in *(7)* is replaced by a tricyclohexylphosphine residue, the (–I) effect of the three cyclohexyl residues in the phosphonium bromide *(9)* strengthens the CH bonds of the methylene group. The deprotonation of *(9)* can no longer be effected with sodium carbonate solution, but requires the use of dilute sodium hydroxide solution [12].

Methoxycarbonylmethylidenetricyclohexylphosphorane *(10)* is more strongly basic than the triphenyl compound *(8)*. In contrast to *(8)*, *(10)* decomposes simply on standing for a short time in cold water.

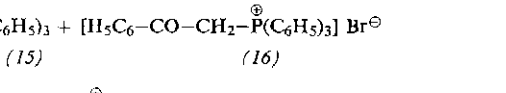
C. Transylidation

Since phosphonium salts and alkylidenephosphoranes are related as an acid-base pair, and since the strength of these acids and bases is governed by R^1 and R^2, an acid-base equilibrium is set up between alkylidenetriphenylphosphoranes *(11)* and triphenylphosphonium salts *(12)* [13].



(11) *(12)* *(13)* *(14)*

The position of the equilibrium is governed by the residues R^1 and R^2. If the basicities of *(11)* and *(14)* or the acid strengths of *(12)* and *(13)* are very different, the equilibrium always favors the formation of the more weakly basic alkylidenephosphorane and the more weakly acidic phosphonium salt. Thus the reaction of methylidenetriphenylphosphorane *(15)* with triphenylphenacylphosphonium bromide *(16)* yields triphenylmethylphosphonium bromide *(17)* and benzoylmethylidenetriphenylphosphorane *(18)* in almost 90% yield. This is an example of a reaction which we shall refer to as transylidation.



(15) *(16)* *(17)* *(18)*

Transylidation provides a method of comparing the strengths of the mesomeric or inductive effects of the substituents on the acidity of the methylene group α to

the P atom in the phosphonium salt or on the basicity of the alkylidenephosphorane. Such a comparison gives the sequence:

$C_6H_5{-}CO > CO_2CH_3 > C_6H_5 >$ alkyl

The reaction of phosphonium salts

$[R^1{-}CH_2{-}P^{\oplus}(C_6H_5)_3]X^{\ominus}$

with alkylidenephosphoranes $R^2{-}CH{=}P(C_6H_5)_3$ in which R^2 lies to the right of R^1 in the above series leads to transylidation.

Experiments with phosphonium salts labelled with tritium have shown that transylidation also takes place if R^1 and R^2 in *(11)* and *(12)* are identical, or if the inductive or mesomeric effects of R^1 and R^2 differ only slightly [13].

Procedure:

Preparation of Benzoylmethylidenetriphenylphosphorane by Transylidation [13]

Finely powdered triphenylphenacylphosphonium bromide *(16)* (9.24 g), which has been dried in vacuum over P_2O_5, is added to a salt-free solution (see Section D2 for preparation) of 0.02 mole of methylidenetriphenylphosphorane *(15)* in 100 ml of anhydrous toluene [14], and the mixture is refluxed for 24 h in the absence of moisture and oxygen. The benzoylmethylidenetriphenylphosphorane *(18)* is filtered off, the precipitate is washed with toluene, and the solution is evaporated in vacuum. The crystalline residue is mixed with 15 to 20 ml of ethyl acetate and filtered. A small second fraction is obtained by slow evaporation of the filtrate. Total yield 6.65 g (87.5 %); m.p. and mixed m.p. with benzoylmethylidenetriphenylphosphorane 180 °C.

The salt filtered off from the solution in ethyl acetate weighs 7.8 g. It is dissolved in 60 ml of water by warming, and the pH of the solution is adjusted to 13–14 with dilute sodium hydroxide solution, whereupon 0.65 g of *(18)*, formed from unchanged triphenylphenacylphosphonium bromide *(16)*, precipitates. This is filtered off, and the aqueous solution is acidified with acetic acid, heated to boiling, and a solution of 3 g of NaI in 10 ml of water is added. Triphenylmethylphosphonium iodide crystallizes on cooling; yield 4.9 g (60.8 %), m.p. and mixed m.p. 182 °C (from isopropanol).

D. Preparation of Phosphonium Salts and Alkylidenephosphoranes

1. Phosphonium Salts

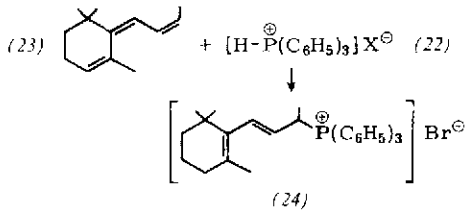
Phosphonium salts *(21)* are generally prepared from alkyl halides *(19)* and triphenylphosphine *(20)* [2].

$$\underset{(19)}{R{-}X} + \underset{(20)}{P(C_6H_5)_3} \rightarrow \underset{(21)}{[R{-}\overset{\oplus}{P}(C_6H_5)_3]\,X^{\ominus}}$$

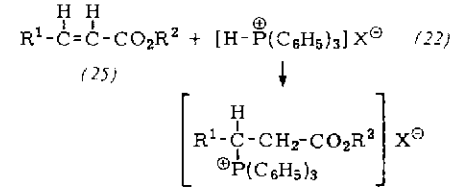
The following method is of great preparative interest [15, 16]:

$$R{-}OH + \underset{(22)}{[H{-}\overset{\oplus}{P}(C_6H_5)_3]X^{\ominus}} \rightarrow \underset{(21)}{[R{-}\overset{\oplus}{P}(C_6H_5)_3]X^{\ominus}} + H_2O$$

A phosphonium salt *(21)* is obtained from an alcohol by reaction with triphenylphosphonium halides *(22)* (preferably the bromide). Triphenylphosphonium bromide *(22)*, X = Br, adds onto the ends of many polyene chains by ω,ω'-addition. Thus 1,6-addition of the bromide *(22)*, X = Br, to the triene *(23)* leads to the phosphonium salt *(24)* [16].



Phosphonium salts can also be obtained from compounds containing polarized C–C double bonds (*e.g.* α,β-unsaturated nitriles, esters of carboxylic acids *(25)*, and nitro compounds) by reaction with the bromide *(22)*, X = Br [17].



The reaction of quaternary ammonium salts of Mannich bases *(26)* with triphenylphosphine also allows the preparation of phosphonium salts *(27)* which are difficult or impossible to obtain by other methods [18].

$$\underset{(26)}{[R{-}CH_2{-}\overset{\oplus}{N}(CH_3)_3]X^{\ominus}} + P(C_6H_5)_3 \rightarrow \underset{(27)}{[R{-}CH_2{-}\overset{\oplus}{P}(C_6H_5)_3]X^{\ominus}} + N(CH_3)_3$$

New possibilities in the preparative field are opened up by additions to vinylphosphonium salts *(28)* [19] and to phenylethynylphosphonium salts *(29)* [20].

$$3\,\underset{(28)}{[(C_4H_9)_3\overset{\oplus}{P}{-}CH{=}CH_2]\,Br^{\ominus}} + H_3C{-}CO{-}C_6H_5 \rightarrow \{[(C_4H_9)_3\overset{\oplus}{P}{-}CH_2{-}CH_2]_3C{-}CO{-}C_6H_5\}\,3\,Br^{\ominus}$$

$$\underset{(29)}{[(C_6H_5)_3\overset{\oplus}{P}{-}C{\equiv}C{-}C_6H_5]\,Br^{\ominus}} + H_2N{-}C_6H_5 \rightarrow [(C_6H_5)_3\overset{\oplus}{P}{-}CH_2{-}\overset{N{-}C_6H_5}{\overset{\|}{C}}{-}C_6H_5]\,Br^{\ominus}$$

The possibility of synthesizing phosphonium salts from alkylidenephosphoranes and halogen compounds is discussed in Part II.

Procedures:

β-Methoxyethyltriphenylphosphonium Bromide [15]

A mixture of 34 g of triphenylphosphonium bromide *(22)*, X = Br, and 8 g of glycol monomethyl ether is refluxed for 7 h with 50 g of anhydrous tetrahydrofuran. When the reaction mixture is cooled, 17 g of β-methoxyethyltriphenylphosphonium bromide *(21)*, R = $H_3C-O-CH_2CH_2$, m.p. 216 °C, separates out. A further 7 g is obtained by concentration of the mother liquor.

Phosphonium Salts from Compounds Containing Activated Double Bonds and Triphenylphosphonium Bromide [17]

Method a: 2.62 g (10 mmole) of triphenylphosphine *(20)* and 10 mmole of the component containing an activated double bond are heated with stirring at 100 °C with 5 ml of 48 % aqueous HBr for 5–15 min. The mixture is then diluted with about 10 ml of water, extracted with ether to remove any unchanged starting material, and the phosphonium salt is allowed to crystallize or is extracted with chloroform, depending on its solubility. Iodides can be precipitated by addition of excess NaI.

Method b: 3.4 g (10 mmole) of triphenylphosphonium bromide *(22)*, X = Br, and 10 mmole of the component containing an activated double bond are heated in 5 ml of acetonitrile for 5–15 min on a boiling water bath. The phosphonium salt is then precipitated with ethyl acetate or ether, and purified as described under a.

Skatyltriphenylphosphonium Methylsulfate [18]

Three grams of gramine methylsulfate is boiled with 15 mmole of triphenylphosphine *(20)* in 30 ml of methanol for 90 min under nitrogen (trimethylamine is liberated). The precipitate formed on cooling is washed with methanol, and can be recrystallized from water to give a pale pink salt, m.p. = 185–186 °C.

2. Alkylidenephosphoranes

The best method of preparing alkylidenephosphoranes is the action of bases on phosphonium salts *[(1)→(2)]* (see Section B). The strength of the base necessary for deprotonation depends on the acidity of the phosphonium salt. A base recently found to be particularly useful is the methylsulfinyl carbanion obtained from dimethyl sulfoxide and sodium hydride and used in dimethyl sulfoxide as solvent [21a].

In many of the reactions described below, it is important that the ylide solutions used should be free from lithium salts, since these react with the ylide to form complexes which strongly interfere with the reaction. The most suitable method for the preparation of such solutions is the sodamide method [21b] described below.

Schöllkopf [2] has made reference to elimination reactions which can hinder ylide formation. The action of bases on phosphonium salts containing activated hydrogen β to the phosphorus atom can lead to decomposition of the initially formed ylide into an olefin and triphenylphosphine by intermolecular proton migration [22] (cf. also Part II, Section C 1, on the Hofmann degradation of quaternary phosphonium salts). In such cases, sodium alkoxides should not be used as bases, since these compounds strongly favor the Hofmann degradation [22].

Ylides are also formed from triphenylphosphine and carbenes *(30)*. Alkylidenephosphoranes with halogen atoms on the C-atom α to the C–P double bond have become available by this method [23,24].

$$(C_6H_5)_3P + :C\begin{matrix}X\\Y\end{matrix} \longrightarrow (C_6H_5)_3P{=}C\begin{matrix}X\\Y\end{matrix}$$

(30)

Aliphatic diazo compounds can also be used as sources of carbenes for the preparation of ylides. However, they must be decomposed in the presence of copper salts [25], since the reaction of diazo compounds with triphenylphosphine generally leads to phosphazines *(31)* [26].

$$(C_6H_5)_3P + |N{\equiv}\overset{\oplus}{N}\text{–}\overset{\ominus}{C}R_2 \xrightarrow{Cu^{2+}} (C_6H_5)_3P{=}CR_2 + N_2$$

$$\rightarrow (C_6H_5)_3P{=}N{-}N{=}CR_2$$

(31)

The dihalogenomethylidenephosphoranes *(32)* are also readily obtainable by the reaction of triphenylphosphine with carbon tetrachloride or carbon tetrabromide [27].

$$2\ P(C_6H_5)_3 + CX_4 \rightarrow (C_6H_5)_3P{=}CX_2 + (C_6H_5)_3PX_2$$

X = Cl, Br *(32)*

The reaction of acrylic acid derivatives *(33)* with triphenylphosphine leads to ylides *(34)* which can be intercepted with carbonyl compounds by a Wittig reaction [28], and which are difficult to obtain by other methods owing to the ease with which the Hofmann degradation takes place.

$$(C_6H_5)_3P + H_2C{=}CHR \rightarrow (C_6H_5)_3P{=}CH{-}CH_2R$$

(33) *(34)*

R = $-CO_2R^1$; $-CONH_2$; $-C{\equiv}N$

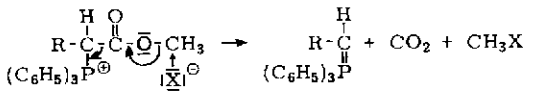
Alkylidenephosphoranes are also formed on thermal decomposition of triphenyl-α-methoxycarbonylalkylphosphonium salts *(35)* [29].



(35)

The ylides formed can be isolated if they are stable. They can also be intercepted by various reagents, or undergo intramolecular reactions.

Procedures:

Salt-free Alkylidenephosphorane Solutions

All operations are carried out under nitrogen or argon. Ammonia is condensed in a trap cooled with liquid air and containing sodium. The resulting dry ammonia is distilled into a second tube (75–100 ml), and the required quantity of finely chopped sodium (up to 25 % excess) and a few grains of ferric nitrate are added. When the blue sodium solution has turned grey, the absolutely dry and finely powdered phosphonium salt is added, stirred for a short time with a glass rod, and the ammonia is then evaporated off through a mercury valve. The evaporation is accelerated by heating the tube with hot air. To the residue is added 100 ml of an inert, anhydrous solvent, *e.g.* benzene, toluene, ether, or tetrahydrofuran, and the solution is boiled for about 10 min to remove residual gas, the reflux condenser being sealed with mercury. The solid residue is then filtered off using a G-3 frit. The filtration can be dispensed with if the subsequent reactions are not affected by excess sodamide and undissolved sodium halide.

Preparation of Ylide Solutions by the Dimethylsulfinate Method

The preparation must be carried out under nitrogen and in the strict absence of moisture. The stoichiometric quantity of sodium hydride (as a 50 % suspension in mineral oil) is freed from mineral oil by repeated washing on a sintered glass filter with anhydrous petroleum ether, and placed in the reaction vessel. Dimethyl sulfoxide (dried over calcium hydride) is added (50 ml of dimethyl sulfoxide per 100 mmole of NaH), a reflux condenser with a mercury valve is fitted to the vessel, and the mixture is slowly heated to 70–80 °C, with stirring (magnetic stirrer). The evolution of hydrogen stops after about 45 min. The resulting solution of the dimethyl sulfoxide anion is cooled in ice and the solution or suspension of the phosphonium salt in dimethyl sulfoxide (50 mmole of salt in about 100 ml of dimethyl sulfoxide) is added. The mixture is stirred for a further 10–20 min at room temperature before being used for further reactions.

Chloromethylidenetriphenylphosphorane Solution [24b]

A solution of 40 mmole of butyl-lithium in about 25 ml of anhydrous ether is added dropwise, over a period of 40 min, to a well-stirred solution of 35 mmole of triphenylphosphine in 45 ml of absolute methylene chloride at −60 °C. The resulting solution of the chloromethylidenetriphenylphosphorane is then used for further reactions.

Melting and Crystal Structure – Some Current Problems

BY PROF. DR. A. R. UBBELOHDE

DEPARTMENT OF CHEMICAL ENGINEERING AND CHEMICAL TECHNOLOGY, IMPERIAL COLLEGE, LONDON (ENGLAND)

The "classical" definition of liquid and solid phases acording to mechanical criteria is unsatisfactory. It is now known that "premelting" effects occur in crystals, and in many liquids the formation of clusters is observed near the melting point, with structures which can correspond to the short-range order of the crystals from which the melt is derived. – In particular, the implications of the theories of Lennard-Jones and Devonshire and of Mizushima and Ookawa are discussed.

As is now well known, many melts have structures which resemble the crystals from which they are formed more or less closely. This is shown, for example, by the similarity of density. X-ray diffraction shows, too, that the interatomic or intermolecular distance in many melts is quite close to that in the crystals. However, the conventional radial distribution function of melts gives data which are far too condensed to be really informative. Methods are required which give a three-dimensional representation of regions or domains in the liquid, as a counterpart to the elaborate three-dimensional information usually available about the crystals.

This gap in our direct structural knowledge about the molecular arrangements in melts is a serious obstacle to systematic development of theories of the liquid state. It has tended to direct mathematical theories to the discussion of liquids whose units of structure are extremely simple, such as atoms or diatomic molecules [1]. Actually, such melts form only a minute fraction of the range of known liquids; their

[1] *K. Furukawa*, Rep. Progr. Physics *25*, 396 (1950).

behaviour is not necessarily representative of melting in general. Alternatively, statistical theories of liquids may be developed on a quasi-gaseous analogy [2]. Whilst this approach is rather more broadly based, it is applicable most generally near the critical temperature of the liquids, and does not yield particularly refined structural information about the solid-liquid transformation at the melting point. This consideration makes it convenient to refer to liquids at temperatures around their freezing point as *melts*, to distinguish them in broad terms from quasi-gaseous fluids near the critical temperature.

The primary distinction between solid and liquid, regarded as condensed states of matter, is mechanical. But at the present time, for these as for other states of matter, the most general approach to theories of transitions between them has to be based on thermodynamic and statistical considerations. With reference to the role of structural features in melting, some of the concepts from which new lines of experimentation may originate will be briefly reviewed here.

Two principal thermodynamic parameters of general interest in discussing structural aspects of melting are the entropy of fusion S_f and the fractional change in molar volume $\Delta V_f/V_s$, where V_s is the molar volume of the crystal at the melting point T_f. These are related by the Clausius-Clapeyron equation

$$dP/dT = S_f/\Delta V_f.$$

Subsidiary thermodynamic properties, of great interest for particular structures, are derived parameters such as the compressibility, the thermal expansion coefficient and the heat capacities. It can be very informative to known what is the change in these quantities at the melting point, but very often the data are not available. Also of great importance are any premonitory changes in these subsidiary parameters, in premelting or prefreezing effects. The entropy of fusion is particularly useful in its correlation with the melting of different kinds of crystal structures by virtue of the Boltzmann relationship

$$S_f/R = \ln (W_L/W_S)$$

where W_L and W_S are the number of independent ways of contriving the liquid and solid states respectively.

For all known cases of melting, S_f is positive, *i.e.* the fluid condensed state has a higher entropy than any state with rigidity. In general the higher entropy of the melt can be attributed to its greater disorder. More specifically, various types of crystal structure can be disordered in different ways. Each distinguishable mode of disordering constitutes a mechanism of melting. Some crystal structures exhibit a single mechanism of melting, whereas others combine more than one mechanism of disordering on passing from the crystal to the melt.

A representative but not exhaustive discussion of mechanisms of disordering may be conveniently given, with emphasis on directions in which research is currently particularly active, or where problems seem ripe for attack.

I. Positional Melting

As is apparent for example from X-ray diffraction studies, all crystals undergo loss of long-range order on melting. What is not quite as well established is the extent of the disordering of local packing. Current diffraction methods [1] establish a smooth average, but for some theories of the structures of melts, particularly in the temperature range around T_f, it is important to know to what extent cooperative fluctuations about the smoothed average lead to clusters of any kind. Some types of cluster can act as crystal nuclei; other types of assembly may have an enthalpy lower than the average, but lack 3-dimensional lattice ordering and thus are non-crystallizable. This kind of information about domains or cooperative fluctuations in the melt is only beginning to receive attention by the use of diffraction methods [3]. Other aspects will be referred to later in connection with prefreezing phenomena.

Numerical values of the entropy of positional disordering may be given a kind of norm from data for crystals of the rare gases. Where quantum effects, *i.e.* contributions from zero-point energy, can be neglected, the entropy of positional disordering on melting of these crystals is about 3.3 e.u. [4]. This value can be built into a particularly straightforward statistical thermodynamic model of positional melting, first discussed in mathematical details by *Lennard-Jones* and *Devonshire* in 1939 [5]. In their model, positional disordering is restricted to the insertion of atoms in interstitial sites, in the so-called Frenkel positional defects. According to this theory, equilibrium can be established at T_f between a slightly defective crystal (the solid) and a highly defective crystal (the liquid). Changes of vibrational entropy are neglected, and the cooperative influence of crystal defects upon neighboring crystal sites is allowed for in terms of the expansion on melting by a Bragg-Williams type of volume-dependent interaction. Despite its obvious oversimplifications, this well-known model helps to clarify the main features of positional melting. It is one of the simplest ways of describing the structure of a quasi-crystalline liquid.

Amongst current developments of this simple version of positional melting, the following may he noted:

1. Dislocation Melting

Any crystal defect whose energy of creation is lowered by virtue of defects on neighboring lattice sites may be termed cooperative to distinguish it from an isolated or point defect. As an alternative or an addition to Frenkel defects the intervention of cooperative defects in mechanisms of melting has been proposed on qualitative

[3] *V. K. Prokhorenko* and *J. Z. Fisher*, Zh. Fiz. Khim. *33*, 1852 (1959).

[4] *A. R. Ubbelohde*, Quart. Rev. (Chem. Soc., London) *4*, 356 (1950).

[5] *J. E. Lennard-Jones* and *A. F. Devonshire*, Proc. Roy. Soc. (London) A *169*, 317 (1939); ibid. *170*, 464 (1939).

grounds [6], but a quantitative theory has proved difficult to elaborate. Recently, an attempt has been followed through to describe the positional melting of metals on a dislocation theory [7,8].

In its present form, this theory still involves some harsh simplifications. However, this development of a cooperative defect model appears to be significant for at least two aspects of the behavior of melts.

a) It points to the kinds of positional disordering in a quasi-crystalline liquid on a more realistic basis than the interstitial defect model of *Lennard-Jones* and *Devonshire*. A dislocation type of approach can be of importance for describing thermodynamic behaviour, and may also be more readily applicable when dealing with any transport processes that show some chain-mechanism character in the melt. Thus the Lennard-Jones model harmonises most readily with the theory that transport processes in liquids all occur by the activated hopping discussed by *Eyring* [9], according to which momentum transfer is the outcome of mass transfer. Dislocation models suggest that in addition to any hopping of units, momentum transfer may occur by dislocation movement, in a kind of zip fastener action.

b) In calculating the total entropy of fusion, a particular dislocation model gives [7]:

$$S_f = \Delta S_{vib.}\ (0.69\ \text{e.u.}) + \Delta S_{pos.}\ (1.08\ \text{e.u.})$$

This contribution of a change of vibrational entropy $\Delta S_{vib.}$ to the total entropy of fusion S_f marks a difference from the Lennard-Jones theory in which $\Delta S_{vib.}$ is assumed zero.

2. Melting of Metals

Types of molecules are known which have quasispherical (globular) repulsion envelopes, when close packed in the crystals. For these too, $S_f \sim 3$ e.u., showing that a simple model for positional melting has quite wide generality. However, a large class of crystals is known, mostly metallic in properties, in which the units of structure are atoms, but for which $S_f < 3$ e.u. The reason why many metals have a lower S_f and thus a lower overall disorder in the melt than rare gases has not yet been fully elucidated.

The repulsion force fields may be lower, since $\Delta V_f/V_s$ for metals is markedly lower than for inert gases. Reasons for lower repulsion force fields are however not at all apparent: even alkali metals have S_f and $\Delta V_f/V_s$ much lower than the rare gases whose electronic core is nevertheless similar. Another possible explanation of the low values of melting parameters of metals is that factors contribute to S_f that do not greatly increase the enthalpy of fusion H_f, resulting in a lower T_f according to the expression $T_f = H_f/S_f$, where H_f is the molar enthalpy of fusion. Indications of this possibility may be found from the abnormally long liquid range of metals as seen from the high value of $T_{crit.}/T_f$ or $T_b/T_f \approx 3$, compared with T_b/T_f of about 1.03 for rare gases and $T_b/T_f \approx 1.6$ for the structurally related halides with rare-gas configurations [10] (T_b is the boiling point at 1 atm).

3. Melting of Ionic Crystals of Simple Structure

For halides of inert-gas structure with low polarizability, for example salts of lithium, S_f and $\Delta V_f/V_s$ are close to values for the inert gases, suggesting that positional disordering is similar in both types of crystals. However, for the more polarizable ions of higher atomic number in similar salts, both these parameters fall below the inert gas values. Again, a review of all the evidence suggests that the liquid state is abnormally favored relative to the crystalline state for the more polarizable ions. This polarizability might favor cluster formation in ways to be discussed later.

4. Premelting Effects in Crystals

The Lennard-Jones and Devonshire model for positional melting indicates considerable premelting in the crystals. It does not allow for any quasi-crystalline or microcrystalline domains in the melt, since the Bragg-Williams treatment of cooperative interactions between defects excludes such considerations. For solid argon, the fraction of atoms in defect sites at the melting point T_f, where there is a discontinuous jump to the melt, is about 0.05 in the model originally proposed by these authors.

In this theory, the extent to which positional thermal defects are present in the crystals at T_f is unfortunately too sensitive to the precise assumptions made about intermolecular force fields to permit significant correlation with experiment. It is claimed that precise experiments on Ar, CO, N_2O, HCl, and HBr do not indicate any appreciable excess specific heat [11], such as premelting defect formation might require in crystals to which the model is expected to apply.

5. Orientational Disorder of Molecular Axes in Crystals

For molecules whose repulsion envelope is not wholly spherical, a model can be readily contrived which may be combined with positional disordering in a Lennard-Jones type of statistical theory of melting. This analysis confirms the experimental finding that in some crystals, two mechanisms of fusion, for which $S_f = \Delta S_{pos.} + \Delta S_{orient.}$, occur simultaneously at T_f. For others, orientational randomization occurs at a transition temperature T_c in the solid well below T_f [12,13]. For some molecules, orientational randomization may not be complete even above T_f; this may be the case when molecular repulsion envelopes do not permit free

rotation about the three principal axes in the space available in the melt [14–16].

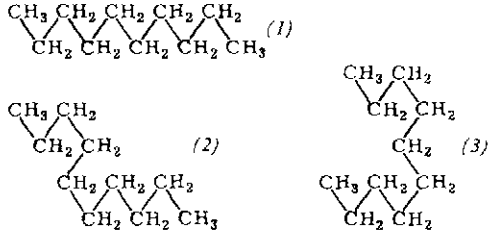
As a guide to mechanisms of melting, a great merit of any reasonably workable theory of positional disorder is that it permits more precise discussions of various departures from the norm. Many of those referred to above can still be discussed within the framework of a quasi-crystalline model for the melt. A quasi-crystalline model signifies an assembly which can be arrived at by positional (and orientational) disordering of units of structure definable with respect to the crystal lattice. The molecular arrangement of a quasi-crystalline melt defined in this way is arrived at by increasing the entropy of position (including vibrations) and orientation, *i.e.*:

$$S_f = \Delta S_{vib.} + \Delta S_{pos.} + \Delta S_{orient.}$$

II. Melts that are Not Quasi-Crystalline

Considerable attention is being paid at present to melts whose structure is not quasi-crystalline in the sense described, but is more complex.

One important group of crystals whose melts cannot be described on any quasi-crystalline model is formed by flexible molecules, such as n-alkane hydrocarbons and their derivatives, or *meta*-polyphenyls, or in general whenever the molecules can assume a variety of different configurations in free space. In the case of n-decane, for example, some of these may be represented by *(1)–(3)*.



(1)

(2)

(3)

When the different configurations in free space have free energies differing by not more than one or two units of kT, a mixture of configurations will be formed in the vapour, and somewhat less freely in the melt. On the other hand, the crystal normally selects only one configuration (usually the fully stretched one) for economical packing into a crystal lattice. For such crystals, the overall entropy of fusion includes an additional contribution due to configurational disorder *i.e.*:

$$S_f = \Delta S_{vib.} + \Delta S_{pos.} + \Delta S_{orient.} + \Delta S_{config.}$$

It has long been known that this additional mechanism leads to convergence melting points in homologous series of molecules whose skeleton is flexible. Currently, increasing attention is being paid to the fact that these melts cannot be represented by a quasi-crystalline model, for example in theories of transport processes, since they constitute a mixture of different molecular configurations. Similar remarks apply to molecular tautomerism in which the free energies of the tautomers are comparable and rates of change are sufficiently high. Anomalies have been reported in some of the transport properties, *e.g.* in *o*-terphenyl, as T_f is approached [17]. These may indicate the onset of prefreezing phenomena, which are best discussed in general terms of cluster formation on approaching the melting temperature.

III. Cluster Formation and Prefreezing Phenomena in Melts

Fluctuation theories of phase transformations, such as the theory of *Frenkel* [18], indicate a kind of symmetry in the concentration of micro-regions or domains of any phase, in the bulk of the other phase, near a transition temperature T_c or melting point T_f. In discussing possible structure anomalies of a melt as its freezing point T_f is approached or traversed, conventional forms of co-operative fluctuation theory as discussed by *Frenkel* [18], *Lukasik* [19], and *Turnbull* and *Fisher* [20] indicate the presence of minute concentrations of micro-domains of crystalline structure, swimming in the more disordered melt. Below a critical nucleation temperature T_N, crystalline micro-domains can act as crystal nuclei inducing spontaneous crystallization of the melt. For a variety of crystal types, it has been established that normally $T_N \approx 0.8\ T_f$ [21]. However, certain melts fail to nucleate spontaneously in this way [22,23]. Brief comment may be made about the origin of this difference in behaviour.

One view attempts to focus any anomaly in the prefreezing region in terms of the "free volume" in a melt. This parameter, which has analogies with the Bragg-Williams treatment of cooperative effects in solids, represents the difference between the occupation volume of a melt (the specific volume) and the volume of repulsion envelopes of all the molecules. If the "free volume" falls below critical limits before T_N is reached, spontaneous nucleation may be inhibited, and a melt may pass smoothly and progressively into a glass as its temperature falls. This approach does not predict any particular anomaly of properties as T_f is approached, and traversed, on cooling the melt. However, it appears to be grossly oversimplified. An alternative view draws attention to the fact that many molecules can be close-packed or clustered together with their repulsion envelopes in contact, in domains with various configurations. When the number of units in a cluster is small, space can usually be filled more economically by this

denser packing than is given by the mean density of the melt or vapour. A reduction in enthalpy of the order H_f/N per unit may be expected to accompany clustering, where N is Avogadro's number. A melt near T_f may contain such clusters, regarded as cooperative fluctuations from more open packing, in appreciable concentrations. However, as more and more units attempt to aggregate onto any particular cluster, an important discrimination must be made. If all the molecules in a cluster are arranged on a crystalline lattice so that they form regular repeat sequences in space, the cluster can act as a crystal nucleus. It can grow indefinitely by aggregation, without change of packing. This leads to spontaneous crystallisation below T_f. By contrast, if a cluster is close-packed in a non-crystallizable way, attempts to aggregate more and more units inevitably lead to the formation of fronds or inclusions of voids and clefts, with consequent lowering of its mean density. Quite soon, a non-crystallizable cluster ceases to grow by aggregation because the reduction in enthalpy resulting from closer packing ceases to operate if the number of units it comprises is too large. This second model emphasises local, more condensed regions. If it fails to crystallize on a regular crystal nucleus, such a melt eventually congeals, through contact between non-crystalline clusters.

Cooperative fluctuations of packing in melts, as they are progressively cooled, may be expected to involve more or less marked anomalies with respect to quasi-crystalline behaviour regarded as the norm. The extent to which departures from a quasi-crystalline model are found will depend on intermolecular forces. For example, different non-crystallizable types of aggregation have been proposed in hydrogen-bonded melts, such as water [24]. Clustering is also suspected in various molten metals, as well as in certain ionic melts [25].

Methods of studying the micro-structure of melts experimentally are still too scanty to investigate theories of cooperative fluctuations directly. Indirect methods include the studies of spontaneous crystallization or failure to crystallize spontaneously already mentioned. Another line of approach is to measure various transport processes in the melt as this is progressively cooled to and below T_f. When cooperative fluctuations lead to significant aggregation into clusters, the relaxation time for their dispersal may be compared with the normal relaxation time characteristic for the property under examination. For example, in viscous flow, the characteristic normal relaxation time in a quasi-crystalline melt seems to be of the order indicated by the Eyring theory [9] of hopping frequency of viscosity and of mass transport. If clusters are formed whose duration is long compared with this time, these can only be moved as a whole in the melt, *i.e.* they behave like colloidal particles suspended in it. On this basis, an increase of viscosity should be observed of the order

$$\frac{\eta_{actual}}{\eta_{ideal}} = 1 + 2.5\,\Phi + 7\,\Phi^2 + \ldots$$

where Φ is the volume fraction occupied at any instant by the clusters regarded as spherical. A decrease of mass diffusion constant should likewise be observed, due to the volume blocking of clusters [26].

In order to avoid complications from possible modifications in attractive forces due to changes of local configurations in hydrogen bonding or intermetallic bonding, a series of studies on prefreezing anomalies have been carried out on melts of polyphenyls [27]. In these, opportunities for molecular close-packing in the melt are determined predominantly by the shapes of the repulsion envelopes. Determinations of room to rotate in the melt show that for the majority of such molecules, nearest neighbors must in any case be roughly aligned, since as already stated, the free space is much too small to permit random orientation of molecular axes of neighbors. Transport properties do not necessarily show marked prefreezing anomalies; in many cases an Arrhenius type of equation is obeyed over considerable ranges of temperature, with fair accuracy, down to T_f. However, when the repulsion envelopes have marked re-entrant cavities, as for *o*-terphenyl or for 1,3,5-tri-α-naphtbylbenzene, marked excess viscosities are found as T_f is approached and traversed. It is quite difficult to cause such melts to crystallize. Normally, they pass smoothly into glasses on sufficient cooling [16, 27].

As a working hypothesis, excess viscosities defined by the Arrhenius equation as norm (with the melt at high temperatures regarded as a free fluid and treated as reference), and other excess properties above those of a normal fluid whose behaviour can be studied, may be interpreted on the hypothesis that transient cluster formation blocks easy configurational rearrangements that involve hopping in the melts.

What is urgently needed is a greater diversity of physical means for examining the structures and local density fluctuations of melts. When the latter are not quasi-crystalline, this can have a close bearing on their freezing and melting behaviour.

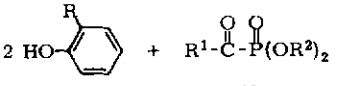
Bis-(*p*-hydroxyphenyl)alkylphosphonic Acid Esters and Derived Polycarbonates

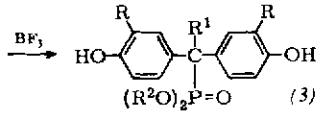
By Dr. M. I. Iliopulos [1] and Dipl.-Chem. H. Wieder

Institut für Organische Chemie
der Technischen Hochschule Stuttgart (Germany)

Dialkyl 1-bis-(*p*-hydroxyphenyl)alkylphosphonates *(3)* are made by condensation of the adduct obtained from the phenol *(1)* and BF_3 with dialkyl acylphosphonates *(2)* in a molar ratio of 3:1 to 6:1, cooling being applied to maintain the reaction temperature at 30–40 °C. The same products are also obtained under similar conditions by passing BF_3 into a mixture of *(1)* and *(2)*. When the condensation is complete, the reaction mixture is diluted with acetic acid and poured into water. The crude product crystallizes out and can be recrystallized from methanol/water.



(1) *(2)*

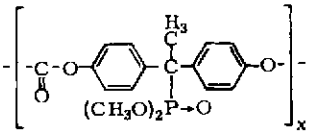


(3)

	R	R^1	R^2	Mp. [°C]	Yield [%]
(3a)	H	CH_3	CH_3	217	70
(3b)	Cl	CH_3	CH_3	213	49
(3c)	Cl	CH_3	C_2H_5	143.5	64
(3d)	H	C_6H_5	CH_3	270	89
(3e)	Cl	C_6H_5	CH_3	259–260	70

If sulfuric or hydrochloric acid is used instead of BF_3, the dialkylacylphosphonate *(2)* is split into the corresponding carboxylic acid and dialkyl phosphite. No condensation takes place with polyphosphoric acid.

Dimethyl 1-bis-(*p*-hydroxyphenyl)ethylphosphonate *(3a)* undergoes a two-phase condensation with phosgene to yield a polycarbonate *(4)*. The compound *(3a)* is dissolved in 0.75 N sodium hydroxide, and triphenylbenzylphosphonium chloride is added as catalyst and dichloromethane as solvent for the polycondensation product to be formed. The mixture is stirred vigorously and a slight excess [based on *(3a)*] of phosgene is passed in. The pH is maintained above 10 throughout the reaction. The resultant polycarbonate *(4)* has an intrinsic viscosity of 0.038 l/g and a molecular weight of 16000; its phosphorus content is 8.9 %.



(4)

Sheets of *(4)* 0.085–0.090 mm thick ignite when held in a Bunsen burner pilot flame 5–6 cm long but cease to burn immediately upon removal from the flame. Films made from the polycarbonate produced from phosgene and 2,2-bis-(*p*-hydroxyphenyl)propane burn out completely under the same conditions.

The phosphorus content of the polycarbonates can be reduced by copolycondensation of *(3)* and 2,2-bis-(*p*-hydroxyphenyl)-propane, but the fire-resistance of the products is reduced correspondingly.

Synthesis of *N,N'*-Bis(chlorodimethylsilyl)-tetramethylcyclodisilazane [1]

By Dr. P. Geymayer and Prof. Dr. E. G. Rochow

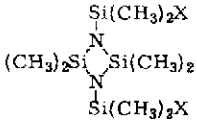
Department of Chemistry,
Harvard University, Cambridge, Mass. (U.S.A.)

1,3-Dichlorotetramethyldisilazane *(2)* [2,3] was hitherto obtainable only in unsatisfactory yields but can now be conveniently prepared in yields of 80 % by refluxing octamethylcyclotetrasilazane *(1)* with an excess of dimethyldichlorosilane (molar ratio 1:5) for 24 h. The product is isolated by subsequent distillation.

$$[-Si(CH_3)_2-NH-]_4 + 4\,(CH_3)_2SiCl \rightarrow 4\,[Cl(CH_3)_2Si]-NH-[Si(CH_3)_2Cl]$$

(1) *(2)*

Compound *(2)* reacts with sodium bistrimethylsilylamide [4] with substitution of one or both chlorine atoms. The products formed are not stable but decompose even at room temperature to hexamethyldisilazane and *N,N'*-bis(chlorodimethylsilyl)tetramethylcyclodisilazane *(3)* or *N,N'*-bis(trimethylsilyl)tetramethylcyclodisilazane *(4)* [5], respectively.



(3), X = Cl
(4), X = CH_3

When a solution of sodium bistrimethylsilylamide in ether is added dropwise to a vigorously stirred solution of *(1)* in petroleum ether at room temperature (molar ratio of the components = 1:1), *(3)* can be secured in yields of up to 70 %. Compound *(3)* forms beautiful colorless crystals, m.p. 70 °C, which can be purified by recrystallization from petroleum ether and sublimation at 55 °C/0.03 mm. The NMR spectrum of a 20 % solution of *(3)* in CCl_4 has only a single sharp proton signal (δ = 0.33 ppm). In benzene, on the other hand, two signals are observed. It appears that the two types of protons present in *(3)* happen to have the same chemical shifts in CCl_4. The structure of *(3)* was proved by elemental analysis, ebullioscopic molecular-weight determinations and by its infrared and mass spectra.

We consider *(3)* to be a potential starting material for the synthesis of polymers containing cyclodisilazane structures.

1,6-Anhydroidose Derivatives with Rings Containing Nitrogen [1]

By Priv.-Doz. Dr. H. Paulsen and Dipl.-Chem. K. Todt

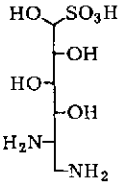
Chemisches Staatsinstitut, Institut für Organische Chemie,
Universität Hamburg (Germany)

In acidic solution, the piperidinoses obtained from 5-amino sugars are always spontaneously dehydrated to form 3-hydroxypyridine derivatives [2]. We have found that free piperidinoses – in contrast to all other monosaccharides –

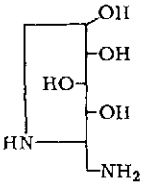
are stable only in alkaline solution and can be prepared only in such media. For instance, the piperidinose *(2)* is obtained from 5,6-diamino-5,6-dideoxy-L-idose-1-sulfonic acid *(1)* [3,4] by cleavage with barium hydroxide in aqueous solution, and is converted spontaneously and quantitatively into the idosan derivative *(3)* comprising two rings containing nitrogen. After deionization and concentration of the solution *(3)* is obtained either as the free base or as its monohydrochloride ($[\alpha]_D^{23} = +58°$, c = 2 in water) in crystalline form. The cyclization is made possible by the amino substituent on the secondary alcohol grouping at C-1 of the piperidinose *(2)*, which facilitates displacement of the hydroxyl group by the more strongly nucleophilic amino group on C-6 of *(2)*. Ring closure is also promoted by the transition to the 1-C conformation, in which all of the hydroxyl groups in *(3)* are in equatorial positions.

The tendency of piperidinoses to react as Mannich bases and to form the 1,6-anhydro ring is also illustrated by the alkaline cleavage of 5-amino-5-deoxy-L-idose-1-sulfonic acid [3]. Conditions analogous to those used for the preparation of *(3)* lead here to the anhydro compound *(4)*, $[\alpha]_D^{23} = +114°$, c = 2 in water. Even 6-amino-6-deoxy-L-idose, whose hydrochloride has long been known [5], can be cyclized with surprising ease to the indosan derivative *(5)* containing nitrogen in the five-membered ring ($[\alpha]_D^{23} = +39°$, c = 2 in water), by mere concentration of the aqueous solution of the free base.

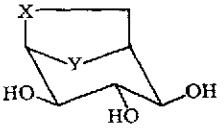
Compounds *(3)* and *(4)* are the first crystalline carbohydrate derivatives containing a free amino group in the glycosidic ring.



(1)



(2)



(3), X = Y = NH
(4), X = O; Y = NH
(5), X = NH; Y = O

Acetylation of *(3)–(5)* with acetic anhydride/pyridine affords the peracetylated derivatives, which can be partially saponified with catalytic amounts of sodium methoxide in methanol to the *N*-acetyl compounds. Free rotation in the latter compounds is hindered by amide mesomerism [6]. The NMR-spectra of the amides of *(4)* and *(5)* indicate that both isomeric forms are present. The coalescence temperature for the signal of the amide with the five-membered ring is 95 °C; that for the signal of the amide with the six-membered ring is 10 °C. The *N,N'*-diacetate of *(3)* contains two amide groups whose free rotations are hindered. Accordingly, four isomers can be detected from the NMR spectrum: the acetylamino signal consists of four peaks which converge to a single line at 95 °C.

The structures of all the compounds made were confirmed by infrared, NMR, and mass spectroscopy.

Preparation of Triphenylphosphine from Triphenylphosphine Oxide by Reduction with Boranes

By Dr. R. Köster and Yoshiharu Morita

Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr (Germany)

Triphenylphosphine oxide can be reduced by boranes, *e.g.* trialkylboranes, alkyldiboranes, or trialkylamineboranes, to give high yields of triphenylphosphine. The reaction with compounds containing BH groups begins a little above 100 °C, but trialkylboranes, *e.g.* triethylborane or tripropylborane, react only above 220 °C.

Equimolar amounts of triphenylphosphine oxide and tetrapropyldiborane rapidly release about 0.5 mole of hydrogen at ca. 120 °C; further 0.5 mole hydrogen is released afterwards, but only slowly. The total amount of gas liberated corresponds to the following transformation of the phosphorus compound.

$$(C_6H_5)_3PO + (R_2BH)_2 \rightarrow (C_6H_5)_3P + R_2BOBR_2 + H_2$$

Dialkylboric acids R_2BOH are formed as intermediates and react immediately with R_2BH to form hydrogen and tetraalkyldiboron oxides

$$(C_6H_5)_3PO + R_2BH \rightarrow (C_6H_5)_3P + R_2BOH$$
$$R_2BOH + R_2BH \rightarrow R_2BOBR_2 + H_2$$

and then undergo ligand exchange to yield in addition alkylboroxines and trialkylboranes.

$$3\ R_2BOBR_2 \xrightarrow{+\ BH} 3\ BR_3 + (RBO)_3$$

Since boron hydrides form various stable adducts with triphenylphosphine, *e.g.* $(C_6H_5)_3P{-}BH_2(C_2H_5)$, m.p. 115 °C, or $(C_6H_5)_3P{-}BH_3$, m.p. 182 °C, complete utilization of the BH entities available for the reduction of the triphenylphosphine oxide occurs only above 180 °C.

$$(C_6H_5)_3P{-}BH_2R + (C_6H_5)_3PO \rightarrow 2\ (C_6H_5)_3P + 1/3(RBO)_3 + H_2$$

If triphenylphosphine oxide and diethylborane are therefore allowed to react in a molar ratio of 1:5 at 120 °C, a quantitative yield of triphenylphosphinylborane is obtained.

$$(C_6H_5)_3PO + 5\ R_2BH \rightarrow (C_6H_5)_3P{-}BH_3 + R_2BOBR_2 + 2\ BR_3 + H_2$$

Trialkylamineboranes $H_3B{-}NR_3$ are also suitable as reducing agents.

$$3(C_6H_5)_3PO + 2\ H_3B{-}NR_3 \rightarrow 3(C_6H_5)_3P + 3\ H_2 + B_2O_3 + 2NR_3$$

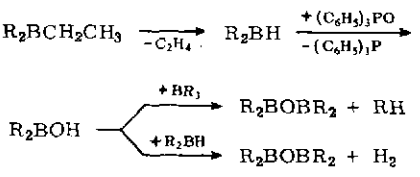
Here the reaction proceeds in steps as indicated by the following equations.

$$3\ (C_6H_5)_3PO + 5\ H_3B{-}NR_3 \xrightarrow{>120°C} 3\ (C_6H_5)_3P{-}BH_3 + 3\ H_2 + B_2O_3 + 5NR_3$$

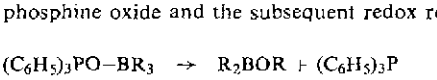
$$3\ (C_6H_5)_3PO + 2\ (C_6H_5)_3P{-}BH_3 \xrightarrow{>180°C} 5\ (C_6H_5)_3P + 3\ H_2 + B_2O_3$$

Triphenylphosphine oxide reacts with trialkylboranes BR_3 only above about 250 °C. However, since the phosphines do not form stable adducts with trialkylboranes the latter are particularly suitable for preparing pure triphenylphosphine from its oxide. This reaction proceeds mainly *via* compounds containing BH groups as intermediates. The rate-determining

step is a dehydroboration (formation of alkene) which is followed by a protonolysis which results in the formation of the alkane alongside a little hydrogen; for example:



The addition of the trialkylboranes onto the triphenylphosphine oxide and the subsequent redox reaction



are insignificant compared with the reactions proceeding *via* the BH compounds.

Preparation of Triphenylphosphine: A mixture of 24.8 g (89.3 mmoles) of triphenylphosphine oxide and 37.5 g (268 mmoles) of tripropylborane is heated for 5 h at about 250 °C in an autoclave of 200 ml capacity; the pressure rises to 38 atm at 250 °C. When the autoclave is cooled (ca. 10 atm at 20 °C) and vented [3.41 l (S.T.P.) exhaust gas (152 mmoles) consisting of 48.8 % propylene, 49.6 % propane, and 1.6 % hydrogen] and the organoboranes are distilled off (ca. 27.5 g, b.p. 30–85 °C/12 mm), 22.5 g or 96.2 % of pure triphenylphosphine, m.p. 81 °C, b.p. 123–125 °C/10^{-3} mm, is obtained.

The reaction of triphenylphosphine oxide with trialkylaluminum compounds R_3Al or dialkylaluminum compounds R_2AlH is not so straightforward since organoaluminum derivatives form adducts with organophosphorus compounds [1]. Despite the redox reactions that occur, the isolation of pure triphenylphosphine is only possible after complete hydrolysis of the organoaluminum components of the reaction mixture.

Preparation of Peptides with 3-Pyridyl Esters

By Prof. Dr. E. Taschner and Dr. B. Rzeszotarska
in collaboration with L. Lubiewska

Laboratorium für Peptidchemie
der Technischen Hochschule Gdansk (Poland)

During peptide syntheses using the *p*-nitrophenyl ester method [1] the reaction mixture finally contains not only the *N*-protected peptide ester desired but also some unchanged *p*-nitrophenyl carbobenzoxyamino ester and the *p*-nitrophenol which has been released during the synthesis. Both are very difficult to separate from the main product.

Following an observation made by *Y. Ueno* et al. [2], we used esters of hydroxypyridines, which are soluble in dilute acids, instead of *p*-nitrophenyl esters. 3-Pyridyl esters are obtained in high yields from the carbobenzoxyamino acids or Cbo-peptides and 3-hydroxypyridine with dicyclohexylcarbodiimide [3] in the form of colorless or yellow oils or waxes.

In order to prepare peptides, 1.1 mmole of the crude 3-pyridyl ester in 2 ml of ethyl acetate is mixed with 1 mmole of another amino ester hydrochloride and 1 mmole of triethylamine and left standing for 16–18 h at 20 °C. The solution is then washed with 5 % $NaHCO_3$, 1 N HCl, or 5 % citric acid in order to remove the excess pyridyl ester and then three to four times with water in order to remove the 3-hydroxypyridine released; the ethyl acetate layer is then dried with $MgSO_4$. After evaporation of the solvent, the required carbobenzoxypeptide ester is obtained in high purity and in good yields.

3-Pyridyl ester	Peptide ester	M.p. [°C] Crude product	Lit. value
Cbo-Ala-3-OPy (94 %) [a]	Cbo-Ala-Gly-OEt (88 %)	94.5–96	97.5–98
Cbo-Gly-3-OPy (81 %)	Cbo-Gly-DL-Phe-OEt (92 %)	85–88	92
Cbo-Phe-3-OPy (95 %)	Cbo-Phe-Phe-OEt (92 %)	130	140
Cbo-Phe-3-OPy (95 %)	Cbo-Phe-Gly-OEt (90 %)	98–107	110–111
Cbo-Gly-Phe-3-OPy (94 %)	Cbo-Gly-DL-Phe-Gly-OEt (50 %)	127–129	132–134
Cbo-Leu-Gly-3-OPy (75 %)	Cbo-DL-Leu-Gly-Gly-O-Et (72 %)	90–92	102

Tri(isopropylidene)cyclopropane [1]

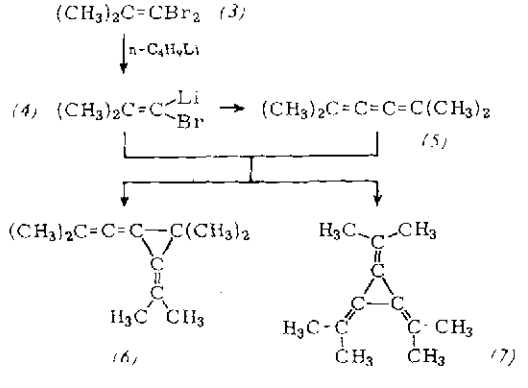
By Doz. Dr. G. Köbrich and cand. chem. H. Heinemann

Organisch-Chemisches Institut
der Universität Heidelberg (Germany)

The ring system of trismethylenecyclopropane *(1)*, the lowest member of the class of radialenes *(2)*, is still unknown. A free-valence index of 0.90 was calculated for the parent compound *(1)* using a simple molecular-orbital method; this value indicates a high tendency for *(1)* to polymerize in the condensed state [2].

(1) *(2)*

We have prepared the hexamethyl derivative *(7)* as the first – remarkably stable – representative of the class of compounds *(1)* as follows. Thermal decomposition of α-halogeno-β,β-dialkylvinyl-lithium compounds in tetrahydrofuran gives rise to tetraalkylbutatrienes [3,4], *e.g.* tetramethylbutatriene *(5)* from *(4)* [4]. When, however, carbenoid compounds of type *(4)* are created under conditions where they are unable to dimerize on account of their short lifetime, *e.g.* at elevated temperatures or in diethyl ether [5–7], they can react with



(6) *(7)*

olefins. When both processes are combined by producing some *(4)* from 1 mole of the dibromide *(3)* and 0.63 mole of n-butyl-lithium in tetrahydrofuran at −110 °C [4,8], converting it into the butatriene *(5)* by allowing the solution to warm up to −60 °C, and transforming the residual dibromide *(3)* into the carbenoid *(4)* at the same temperature by adding a further 0.37 mole of n-butyl-lithium, processing of the reaction mixture with exclusion of oxygen affords a 2 % yield of a colorless solid, which crystallizes in needles from ethanol and which forms compact crystals on vacuum sublimation; the latter melt almost without decomposition in an evacuated capillary at 131–132 °C.

Evidence for the structure *(7)* for this compound was derived from its sum formula $C_{12}H_{18}$ (elemental analysis, mass spectrum) and the equivalence of all eighteen protons in its NMR spectrum, which contains only a single sharp peak at −2.01 p.p.m. (tetramethylsilane as internal standard). Hydrogenation of *(7)* over Raney nickel in ethanol at 25 °C led to an uptake of 2.94 moles of hydrogen. The absorption bands in the double-bond region of the infrared spectrum of *(7)* are at relatively low frequencies for a methylenecyclopropane structure [1610 (vs), 1690 (m), and 1710 cm^{-1} (m) in carbon tetrachloride] and its ultraviolet absorption maximum is at a rather long wavelength [λ_{max} = 309.5 mμ; log ε = 4.26 in hexane]; both phenomena are probably due to the conjugation of the three double bonds.

Another reaction product is compound *(6)*, which was identified by comparison of its spectra with those of another sample recently prepared by *Bleiholder* and *Shechter* [7] by a different route.

This first example of a reaction between a butatriene derivative and a carbenoid has prompted us to examine now whether the reaction has general applicability.

The diffraction pattern obtained from the hexagonal crystals of *(7)* in a preliminary X-ray structural analysis carried out by *J. D. Dunitz* and *A. Mugnoli*, Zürich (Switzerland), is compatible with an arrangement of planar or almost planar molecules in layers 3.6 Å apart.

A calculation by *E. Heilbronner*, Zürich, revealed that the long-wavelength maximum in the ultraviolet spectrum of *(7)* is due to a transition that is allowed in *(1)* but forbidden in all radialenes *(2)* with $n \gg 3$.

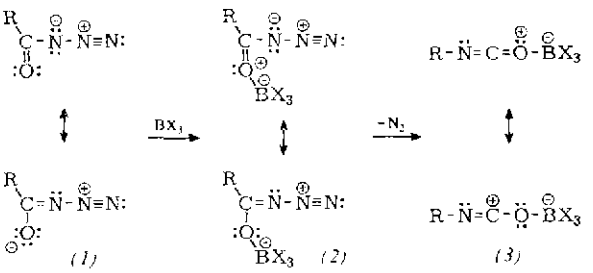
Curtius Reaction with Boron Halides

By Priv.-Doz. Dr. E. Fahr and Dipl.-Chem. L. Neumann [1]

Chemisches Institut der Universität Würzburg (Germany)

The acyl azides *(1a)–(1f)* react with boron trifluoride or trichloride in toluene at ca. −60 °C to give the adducts *(2a)–(2f)*. The infrared spectra of the adducts in dichloromethane indicate that the BX_3 molecules add onto the carbonyl group, for the azide bands remain unchanged whereas the carbonyl bands are shifted to longer wavelengths (1645–1667 cm^{-1}) [2].



(1) *(2)* *(3)*

(a), R = C_6H_5– *(d)*, R = p-O_2N–C_6H_4–
(b), R = p-H_3CO–C_6H_4– *(e)*, R = m-O_2N–C_6H_4–
(c), R = o-H_3C–C_6H_4– *(f)*, R = p-Cl-m-O_2N–C_6H_3–

When analytically pure, the adducts obtained from *(2a)*, *(2b)*, *(2d)*, and *(2f)* with BF_3 and from *(2a)* and *(2b)* with BCl_3 are colorless to pale yellow crystalline substances. They decompose between −20 and 0 °C by releasing nitrogen and undergoing the Curtius rearrangement to yield the corresponding isocyanate-BX_3 adducts *(3)* [3].

Dichloromethane is used as solvent for the Curtius reaction and the adducts are not isolated. The solution of acyl azide is cooled with solid carbon dioxide/acetone and saturated with BF_3 or BCl_3; it is then warmed up to room temperature, and a little alcohol and twice the volume of the reaction mixture of water are added. The urethane formed can be isolated from the organic phase.

Acyl azide	Yield [%] of urethane [a] from the reaction with BF_3		BCl_3	
	[b]	[c]	[b]	[c]
(1a)	70	66	–	46
(1b)	67	56	–	71
(1c)	94	67	92	68
(1d)	91	81	68	60
(1e)	92	69	77	66
(1f)	100	78	100	76

[a] Based on acyl azide.

[b] Determined by infrared spectroscopy.

[c] Determined by isolation.

If the adduct obtained from benzazide and BF_3 is decomposed in toluene, the C_6H_5–NH–CO– residue formed by the rearrangement substitutes in the benzene ring of the toluene; we therefore obtained *p*-toluylanilide in 29 % yield. On the other hand, decomposition of the adduct made from benzazide and BCl_3 in toluene afforded 89 % *N,N'*-diphenylallophanyl chloride.

German version: Angew. Chem. 77, 591 (1965)

[1] Part of Doctorate Thesis, *L. Neumann*, Universität Würzburg.

[2] An analogous shift was observed by *R. Kreher* and *G. Jäger*, Z. Naturforsch. *20b*, 276 (1965), for the $AlCl_3$ adduct of methyl azidoformate.

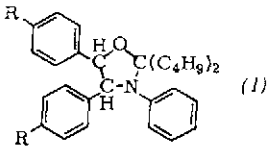
[3] Analogously, the temperature of decomposition of diazoketones is also reduced by formation of their BX_3 adducts; cf. *E. Fahr* and *W. D. Hörmann*, Liebigs Ann. Chem. *682*, 48 (1965). – *M. S. Newman* and *H. L. Gildenhorn*, J. Amer. chem. Soc. *70*, 317 (1948), mentioned that acids catalyse the decomposition of acyl azides. They assumed that a proton attacks the nitrogen atom adjacent to the carbonyl group. – The kinetics of the decomposition of acyl azides in the presence of Lewis acids (Fe, Sb, Ti, Te, Sn, Ga, and Al halides) were measured by *R. A. Coleman, M. S. Newman*, and *A. B. Garrett*, J. Amer. chem. Soc. *76*, 4534 (1954) without isolating the adducts.

Preparation of 1,3-Oxazolidines from Isonitriles and Aldehydes by a Multicomponent Reaction

By Prof. Dr. G. Hesse, Dr. H. Witte, and cand. chem. W. Gulden [1]

Institut für Organische Chemie
der Universität Erlangen-Nürnberg (Germany)

If a mixture of 1 mole of phenyl isonitrile and 2 moles of an aromatic aldehyde in diethyl ether or tetrahydrofuran is added dropwise to 1 mole of tri-n-butylborane, oxazolidine derivatives *(1)* are obtained.



(1)

	Aldehyde	M.p. [°C]	Yield [%]
(1a)	Benzaldehyde	101	72
(1b)	*p*-Chlorobenzaldehyde	136	72
(1c)	*p*-Nitrobenzaldehyde	164	66

The products crystallize after evaporation of the solvent and addition of methanol and are recrystallized from methanol.

Hydrolysis of *(1a)* with 6 N hydrochloric acid in dioxane yielded 58 % di-n-butyl ketone and 82 % *threo*-1,2-diphenyl-2-(*N*-phenylamino)ethanol, m.p. 112 °C; these products clarified the structures of the oxazolidines *(1)*. The NMR spectrum of *(1a)* with tetramethylsilane as internal standard contains an unresolved multiplet at 0.8–2.5 p.p.m. due to the 18 protons of the butyl groups and a signal for 15 aromatic protons at 6.5–7.3 p.p.m. The aliphatic protons on the ring appear as an AB system at 4.75 p.p.m. with $J \approx 8$ c.p.s. The structures of *(1b)* and *(1c)* follow from their elemental compositions, molecular weights, and infrared spectra.

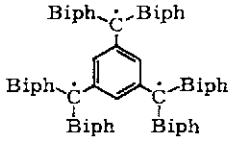
1,3,5-Tris(di-p-biphenylylmethyl)benzene, a New Triradical

By cand. chem. G. Schmauss, Dr. H. Baumgärtel, and Prof. Dr. H. Zimmermann

Institut für Organische Chemie
der Universität München (Germany)

R. Kuhn et al. [1] recently prepared the triradical 1,3,5-tris-(1,5-diphenyl-3-verdazylyl)benzene. We have been working independently on the preparation of carbon triradicals and have synthesized the triple free radical 1,3,5-tris(di-*p*-biphenylylmethyl)benzene *(1)*.



(1), Biph = Biphenyl-4-yl

Treatment of triethyl trimesate with *p*-biphenylyl-lithium in diethyl ether yields 1,3,5-tris(di-*p*-biphenylhydroxymethyl)benzene *(2)* as colorless crystals, m.p. 280–281 °C. When *(2)* is refluxed with acetyl chloride, 1,3,5-tris-[(di-*p*-biphenylyl)chloromethyl]benzene *(3)* is obtained as colorless crystals, m.p. 210–211 °C. Removal of three atoms of chlorine from *(3)* with zinc powder in benzene yields the triradical *(1)* as red-violet crystals, m.p. 205–210 °C (decomp.). Molecular-weight determinations indicated that in benzene, associated molecules are present alongside monomeric triradical molecules.

The triradical *(1)* is extremely sensitive towards oxygen and reacts with chlorine to re-form *(3)*.

The free-radical nature of *(1)* was ascertained by ESR measurements. Spectra taken with the solid and its solutions did not exhibit hyperfine structure on account of interactions among the unpaired electrons. The same situation was encountered with 1,3,5-tris-(1,5-diphenyl-3-verdazylyl)benzene [1].

We also made renewed attempts to prepare the triradical 1,3,5-trisdiphenylmethylbenzene *(4)* [2]. Trisdiphenylchloromethylbenzene *(5)* [2] was treated with sodium in liquid ammonia to give 1,3,5-tris(diphenylsodiomethyl)benzene; the resultant Bordeaux red solution was treated with an equivalent amount of *(5)* in toluene. Sodium chloride was eliminated, giving rise to a yellow product which was isolated from the toluene phase. This product is amorphous to X-rays and has no definite melting point; the results of elemental analyses, molecular-weight determinations, and infrared and ESR-spectra indicate it to be polymeric with composition *(4)* containing varying amounts of toluene. In contrast to the ESR-spectrum of *(1)*, the polymeric product in benzene does exhibit hyperfine structure.

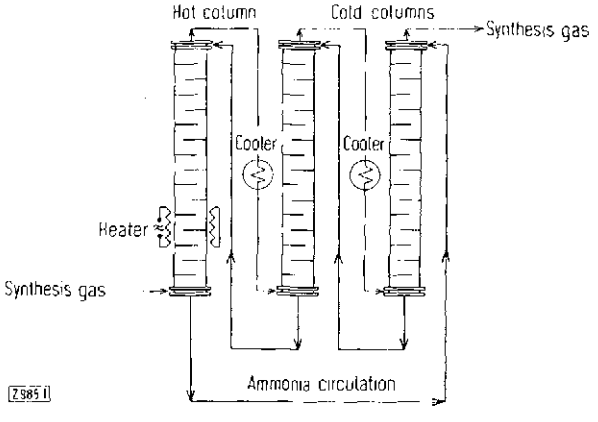
Enrichment of Deuterium by Countercurrent Isotope Exchange between Hydrogen and Ammonia in a Hot-and-Cold Plant

By Dr. S. Walter,
Friedrich Uhde GmbH., Dortmund (Germany)

and Doz. Dr. U. Schindewolf
Institut für Kernverfahrenstechnik der Technischen Hochschule und des Kernforschungszentrums Karlsruhe (Germany)

Heavy water is produced mainly by the hydrogen sulfide process [1] which is based upon the temperature dependence of the isotope exchange equilibrium between hydrogen sulfide and water. Replacement of the system hydrogen sulfide/water by ammonia/water with dissolved potassium amide as catalyst has been frequently proposed [2, 3], since here the isotope exchange is much larger and is more dependent upon the temperature [*] and since here there is the thermodynamically favorable possibility [2] of using hydrogen as starting material. However, no enrichment attempts have been published to date.

Our plant consists of two cold columns in series with a total length of 28 m and a hot column with a total length of 17.5 m (see Figure). The cold columns are cooled by two deep freezers, and the hot column is heated by an electrical heating



element. Each column has an internal diameter 120 mm and contains about 200 sieve plates. The upper and lower plates of the hot column act as direct heat exchangers. Ammonia containing dissolved potassium amide is circulated in the system. Synthesis gas (hydrogen-nitrogen mixture for ammonia synthesis) which is taken directly from the producer plant, is passed through the deuterium enricher, and then on to the consumer. At a pressure of 200 atm and a temperature of 60 °C in the hot column and −20 °C in the cold column, with a potassium amide concentration of 50 g per kg of ammonia, and with a throughput of 450 m³ (S.T.P.) of synthesis gas and 50–100 kg of ammonia per hour, a six- to sevenfold enrichment of the deuterium was achieved in the hydrogen at the top of the hot column and an over twentyfold enrichment in the ammonia, based on the original deuterium content of the hydrogen introduced at the foot of the hot column. The enrichment is expressed by the ratio of the relative deuterium contents in the enriched hydrogen or ammonia and in the original hydrogen, *i.e.* $(n_D/n_H)_{product}$: $(n_D/n_H)_{starting\ hydrogen}$, where n_D and n_H are the mole fractions of HD and H_2, or NH_2D and NH_3, respectively [4].

The degrees of enrichment achieved are in agreement – within the limits of error – with values calculated from laboratory experiments with single sieve plates.

The Quaternary Structure of Catalase from Beef Liver

By Dr. K. Weber and Doz. Dr. H. Sund

Chemisches Laboratorium
der Universität Freiburg/Breisgau (Germany)

Denaturing agents cause catalase (molecular weight *ca.* 250000 [1]) to dissociate into subunits. Depending on the experimental conditions, fractions are obtained with molecular weights which have been found to be one-sixth, one-third, one-half, or two-thirds of that of native catalase [2]. However, in accordance with the iron and heme content of catalase, dissociation into 4 or 4n subunits should be expected.

We succinylated catalase with succinic anhydride according to [3] and obtained a dissociation product which was found to be monodisperse in the analytical ultracentrifuge and still contains bonded heme. Extrapolation to infinite dilution gives a value of 4.4×10^{-7} cm²/sec for the diffusion coefficient $D^{\circ}_{20,w}$ and 3.2×10^{-13} sec^{-1} for the sedimentation coefficient $s^{\circ}_{20,w}$ (measured in 0.067 M potassium sodium phosphate buffer at pH 7.6 and 20 °C). Taking a partial specific volume of 0.73 ml/g [1], the molecular weight of this dissociation product was calculated by the Svedberg formula to be 65000. Succinylation therefore causes dissociation of the catalase molecule into four subunits which according to sedimentation and diffusion measurements are of equal size. This finding is in agreement with the results of electron-microscopic investigations [4]. The action of dodecyl sulfate leads to a dissociation product with the same sedimentation constant.

If it is assumed that each of the four heme groups in the enzyme is located at an active site, then there must be an active site in each of the catalase subunits. The question whether the subunit of molecular weight 65000 is already the polypeptide chain or whether it contains several –

probably different – polypeptide chains cannot yet be answered. Investigations of the amino acid sequence [5] also permit no definite conclusions so far.

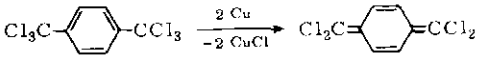
Synthesis and Reactions of α,α,α′,α′-Tetrachloro-p-xylylene

By Dr. H. Gilch [1]

Union Carbide Plastics Division, Research and Development, Bound Brook, N.J. (U.S.A.)

If *p*-bis(trichloromethyl)benzene *(1)* is passed at a pressure of 0.1–1.0 mm over a copper gauze (42 cm² surface area per gram of copper) at 300–600 °C, α,α,α′,α′-tetrachloro-*p*-xylylene *(2)* is formed.



(1) *(2)*

Pressure [mm]	Temp. [°C]	Yield [%] of *(2)*
0.1	300	1
0.1	400	19
0.1	500	92
0.1	600	87
0.3	300	12
0.3	400	22
0.3	500	91
0.3	600	83
1.0	400	35

The cuprous chloride formed can be separated off by cooling the mixture to 250 °C, and the product *(2)* is then passed into toluene which is stirred rapidly at −78 °C. The yellow suspension of *(2)* in toluene obtained is filtered at −78 °C, and the solid residue is crystallized from tetrahydrofuran between 0 and −60 °C. All manipulations must be carried out under nitrogen.

The yellow needles of *(2)* secured in this way can be stored under nitrogen at −78 °C for at least a month. At room temperature they become white and form poly-(α,α,α′,α′-tetrachloro-*p*-xylylene). A 0.0244 M solution of *(2)* in tetrahydrofuran is 50 % polymerized after abont 30 min at 20 °C.

The ultraviolet spectrum of *(2)* in cyclohexane has maxima at 349 mμ (ε = 45000), 331 (26000), 316 (9200), and 247 mμ (6300).

Solvents that are electron donors stabilize *(2)*. A solution of *p*-bis(dimethylamino)benzene in toluene reacts with a solution of *(2)* to form dark blue crystals with a specific resistivity of 4×10^{-8} ohm cm [2], a value of the same order of magnitude as that of the electron donor-acceptor complex obtained from chloranil and *p*-bis(dimethylamino)benzene [3]. Bromine adds onto *(2)* to yield *p*-bis(bromodichloromethyl)benzene, m.p. 130–131 °C.

Nitrogen dioxide and *(2)* react to form *p*-bis(dichloronitromethyl)benzene, m.p. 95 °C. This melting point rises from 95 °C to 105 °C when the compounds is kept for a few weeks at room temperature or heated for a short time at 105 °C, but no change in the infrared spectrum is observed.

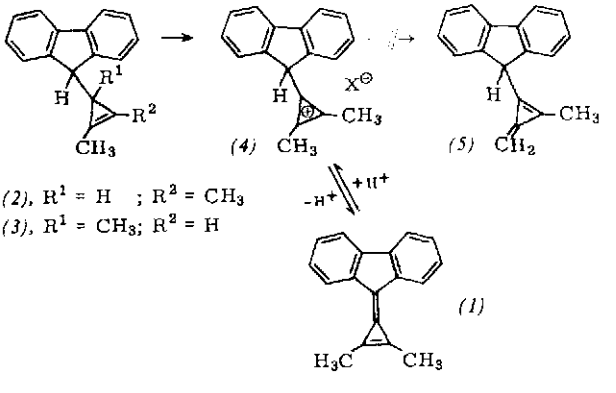
Synthesis and Properties of 5,6-Dimethyldibenzo[*a*,*c*]calicene

By Doz. Dr. H. Prinzbach and Dipl.-Chem. U. Fischer

Chemisches Laboratorium der Universität Freiburg/Breisgau (Germany)

We recently reported the synthesis of 5,6-dimethylbenzo[*a*]-calicene [1], a compound which exists only in dilute solutions. We have now made a crystalline, fairly stable derivative of calicene, namely 5,6-dimethyldibenzo[*a*,*c*]calicene *(1)*, which is suitable for dipole moment measurements and X-ray structural analysis.

The reaction of fluorenyl-lithium (20.0 mmoles) with dimethylcyclopropenium fluoroborate (20.0 mmoles) in ether at −30 °C leads to a 4:1 mixture of the isomers *(2)* and *(3)*. After evaporation of the ether, *(2)* can be obtained in 50–70 % yield in pure form by recrystallization from ethanol (m.p. 121–122.5 °C); its structure is established *inter alia* by its infrared spectrum in KI (low-intensity C=C absorption at 1852 cm⁻¹) and its NMR spectrum in chloroform [multiplet at 2.2–2.9 τ, doublet at 6.46 τ (J = 5.5 cps), singlet at 8.0 τ, doublet at 8.46 τ (J = 5.5 cps) in ratios 8:1:6:1]. Abstraction of a hydride ion from *(2)* to give *(4)* can be achieved quantitatively with trityl fluoroborate [1]. The salt *(4)*, X = BF_4^-, forms light green crystals, m.p. 180–187 °C, with λ_{max} = 261 mμ (ε = 14900) in 70 % $HClO_4$; its NMR spectrum in CF_3COOH has a multiplet at 2.0–2.6 τ, a broad singlet at 4.26 τ, and a singlet at 7.09 τ in ratios of 8:1:6. The proton on C–9′ is exchanged for D within a few minutes in CF_3COOD, but the intensity of the methyl proton resonance signal decreases noticeably only after several days.



In accordance with this observation, mainly (75–80 %) the calicene derivative *(1)* is produced from *(4)* by reaction with water or triethylamine; no *(5)* can be detected.

Compound *(1)* crystallizes from pyridine or dimethyl sulfoxide as pale yellow platelets, m.p. 205–207 °C. Its infrared spectrum contains the strong absorption for the endocyclic cyclopropene C=C bond at 1859 cm⁻¹ plus two other C=C absorptions, *viz.* at 1605 and 1553 cm⁻¹, the latter band being the most intense absorption in the whole spectrum [3]. The NMR spectrum consists of a broad multiplet at 1.90–2.80 τ due to the 8 fluorene protons and a singlet at 7.35 τ for the

two methyl groups. This position of the methyl proton signal is in good agreement with the value calculated for the chemical shift of the methyl protons in a polar 1,1-dicyanodimethyltriafulvene [4]. Differences in the polarity of the solvents used for taking the electronic spectrum of *(1)* influence mainly the long-wavelength region, the fine structure undergoing significant but the positions of the maxima only slight changes: λ_{max} in ethanol = 356 mμ (shoulder, ε = 14000), 325 (22000), 295 (16650), 271 (shoulder, 14000), 262.5 (20600), 247 (28100), 237 (shoulder, 44000), and 233 (46000); λ_{max} in cyclohexane = 353 mμ (ε = 17200), 336 (18600), 325 (18600), 295 (17400), 283.5 (shoulder, 12200), 265 (12100), 258.5 (13600), 254 (shoulder, 15000), 248 (shoulder, 25800), 241 (46500), and 235 (49000).

The solvatochromism observed with the phenyl-substituted analogues of *(1)* [2a] is obviously caused by the phenyl substituents. As expected, even in media of low proton activity, *(1)* is protonated to give *(4)*. It combines with tetracyanoethylene to give a π-complex which crystallizes in blue-black needles from CH_2Cl_2; the complex has λ_{max} at 780 mμ in tetrahydrofuran and at 795 mμ in dichloromethane.

Dimethyldihydrocalicene is obtained in 40% yield by condensation of cyclopentadienylsodium and dimethylcyclopropenium fluoroborate in tetrahydrofuran; attempts to dehydrogenate this compound with benzoquinone derivatives by analogy to the production of sesquifulvalene [5] have so far not led to satisfactory results.

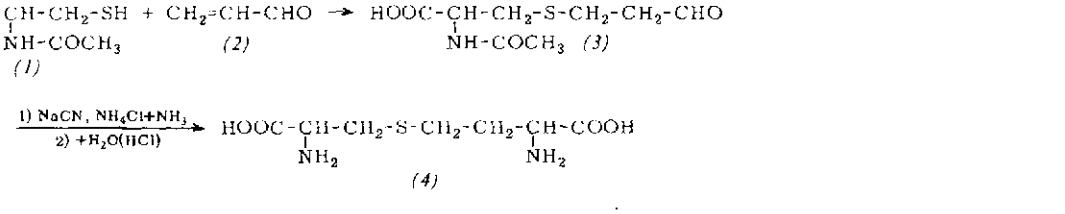
A New Synthesis of Cystathionine and Allocystathionine [*]

By Prof. Dr. A. Schöberl and Dipl.-Chem. J. Borchers

Chemisches Institut
der Tierärztlichen Hochschule Hannover (Germany)

Reaction of 1 mole of acrolein *(2)* and 1.25 mole of L-(+)-*N*-acetylcysteine *(1)* [1] in a mixture of pyridine and water at pH 5.5 for 3 h at 55 °C leads to a quantitative yield of the thioether *(3)*. This compound can be subjected without further purification to a Strecker synthesis to produce a mixture of L-cystathionine *(4)* and L-allocystathionine in 43% yield [based on *(1)*].



It is even better to condense *(1)* with acrolein cyanohydrin (1-cyano-1-hydroxyprop-2-ene) [2] at 75 °C. Here, instead of *(3)*, the corresponding cyanohydrin is obtained, which then undergoes the Strecker synthesis to give a 70% yield [based on *(1)*] of a disulfide-free mixture of the cystathionine isomers. This mixture contains equal amounts of L-(+)-cystathionine *(4)* and L-(−)-allocystathionine, which can be purified and separated [3] *via* their dibenzoyl derivatives [m.p. 233 (decomp.) and 186 °C, respectively].

Reinvestigation of the Assumed Homopolar Dissociation of the Sn—Sn Bond

By Prof. Dr. W. P. Neumann,
cand. rer. nat. E. Petersen, and Dr. R. Sommer

Institut für Organische Chemie
der Universität Gießen (Germany)

Free stannyl radicals exist as reactive intermediates [1], can be generated by photolysis of organotin hydrides, and are stable at low temperatures [2].

Cryoscopic determinations of the molecular weights of aliphatic and aromatic distannanes resulted in values lower than the formula weights [3]; it was therefore assumed that homopolar dissociation of the Sn–Sn bond occurred giving rise to free stannyl radicals.

$$R_3Sn\text{-}SnR_3 \rightleftharpoons 2\ R_3Sn\bullet \qquad (a)$$

However, when we measured the molecular weights of hexacyclohexyldistannane and hexaphenyldistannane in a thermistor vapor-pressure osmometer [4], we always obtained the calculated values, even at concentrations as low as 10^{-3} molar in benzene. Hence there cannot be any significant dissociation in the sense of Equation (a). Nevertheless, we confirmed the anomalous cryoscopic results using highly purified distannanes. On the other hand, no dissociation could be detected with the magnetic balance [5], and ESR measurements on our solutions did not indicate any free radicals [6]. These results do not exclude the possibility that dissociation occurs to a slight extent. If this were so, an unsymmetrical distannane should disproportionate slowly, at higher temperatures at least. We therefore prepared pure triethyltrimethyldistannane with careful exclusion of air [7].

$$(CH_3)_3Sn\text{–}N(C_2H_5)_2 + H\text{–}Sn(C_2H_5)_3 \rightarrow (CH_3)_3Sn\text{–}Sn(C_2H_5)_3 + HN(C_2H_5)_2$$

This compound distils without decomposing at 106.5–107 °C/11 mm and is completely homogeneous in gas chromatograms (2 m of PH 300 silicone oil at 190 °C). It is completely unaltered after heating for several hours at 170 °C. Since control experiments revealed that hexaethyldistannane and hexamethyldistannane appear as clearly separated peaks in the gas chromatogram, no disproportionation and hence no dissociation according to Equation (a) can take place.

Above 190 °C, traces of the two symmetrical distannanes begin to appear, but so do tetraethyltin and tetramethyltin. In addition, some elemental tin is deposited, hence the reaction at 190 °C is not a well defined disproportionation but a drastic decomposition.

Analogously, the two symmetrical distannanes can be mixed and heated without formation of unsymmetrical distannane in more than trace amounts.

Reaction of Organolithium Compounds with Silicon Dioxide

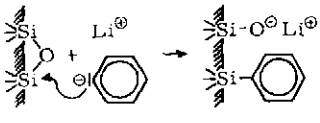
By Doz. Dr. H. P. Boehm, Dr. M. Schneider, and Dipl.-Chem. H. Wistuba

Anorganisch-Chemisches Institut
der Universität Heidelberg (Germany)

Treatment of finely divided silicon dioxide (Aerosil or silica gel) with solutions of lithium alkyls or aryls in ether produces organosilicon compounds. The reaction mixture is refluxed for about 8 h, filtered, and washed with 2 N HCl and water; the ether is then driven off on a steam bath, and the residual oil is dissolved in a little benzene and fractionated by precipitation with acetone.

The following compounds obtained in this way from phenyllithium were identified in the reaction products: tetraphenylsilane (melting point and mixed melting point 235 °C; infrared spectrum [1]), triphenylsilanol, diphenylsilandiol, and polymeric phenylsilicones (by infrared spectroscopy). The infrared spectra of the products obtained with butyllithium indicated the presence of hexa-n-butylcyclotrisiloxane, probably octa-n-butylcyclotetrasiloxane, and long-chain polymers.

The reaction can be interpreted as a nucleophilic attack of the siloxane bonds lying on the surface of the SiO_2 lattice analogous to the cleavage of Si–O–Si bonds by alkali hydroxides. The reaction proceeds mainly to SiR_4, even



though $Si(OH)_2R_2$ compounds should be favored statistically. This appears to be due to the influence of the first substituents introduced upon the electron density on the silicon atoms. An effect of this kind has already been observed by *Gilman* et al. [2] during the nucleophilic cleavage of hexaaryldisiloxanes.

In contrast to the findings of *Kautsky* and *Bartocha* [3], no reaction occurred with Grignard reagents.

The yield of organosilicon compounds is normally low (corresponding to about 30–40 mg of SiO_2 per g of Aerosil). The reaction stops as soon as the surface of the SiO_2 particles is covered with organic substituents and $\rangle Si-O^{\ominus}Li^{\oplus}$ groups. The amount of silicon solubilized corresponds approximately to the number of surface silicon atoms. Aerosil is attacked most strongly by butyl-lithium, but only very minute amounts of organosilicon compounds are formed by methyl-lithium. After thorough washing following the reaction, the residual Aerosil contains 40–100 meq. of phenyl or n-butyl groups on its surface per 100 g of SiO_2, depending on its specific surface area. Phenylated Aerosil is hydrophobic and exhibits an infrared absorption band at 1435 cm^{-1} [4].

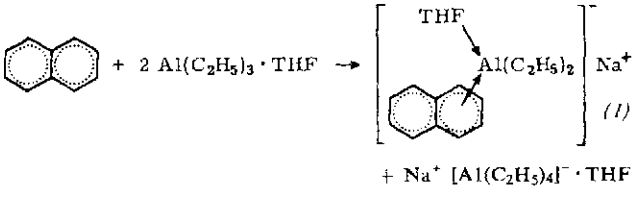
Aluminum-Arene Complexes

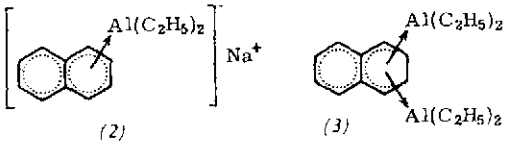
By Dr. H. Lehmkuhl [1]

Max-Planck-Institut für Kohlenforschung,
Mülheim/Ruhr (Germany)

Treatment of 2 moles of triethylaluminum with 2 moles of sodium in tetrahydrofuran (THF) at 20–30 °C in the presence of 1 mole of naphthalene results in deep yellow-brown solutions from which diethylaluminonaphthalenesodium *(1)* precipitates as its tetrahydrofuran adduct in the form of bright yellow crystals in about 75 % yield.



Sodium tetraethylaluminate is formed as by-product; no metallic aluminum is deposited. Corresponding complexes are also obtained with Li or K. When heated at 60–80 °C/ 10^{-3} mm, *(1)* releases THF and is converted into deep yellow *(2)*.



Compounds *(1)* and *(2)* give no ESR signal. Alcoholysis of *(1)* and *(2)* produces ethane in the theoretical amount together with 1,2-dihydronaphthalene and a little 1,4-dihydronaphthalene. Oxidation with dry oxygen yields only naphthalene from the aromatic part of the molecule.

The reaction of *(2)* with diethylaluminum chloride affords bisdiethylaluminumnaphthalene *(3)*, which decomposes already at 20 °C with separation of aluminum.

In THF, the stable bistetrahydrofuran adduct of *(3)* is formed; it is a deep yellow liquid which on alcoholysis yields 1,2-dihydronaphthalene plus a little 1,4-dihydronaphthalene. Oxidation of this liquid with oxygen gives naphthalene; this suggests that *(3)* and its bis-THF adduct are ion-pair com-

pounds of the naphthalene dianion and two $[AlEt_2]^{\oplus}$ or two $[THF{\rightarrow}AlEt_2]^{\oplus}$ cations and not derivatives of dihydronaphthalene. They can be only slightly dissociated, however, for the specific conductance of a 0.5 M solution of the THF adduct of *(3)* in THF is 1.3×10^{-5} ohm^{-1}/cm at 20 °C, whereas that of a 0.5 M solution of *(1)* is 1.1×10^{-3} ohm^{-1}/cm.

Compounds corresponding to the THF adduct of *(3)* can be obtained by dehalogenation of Et_2AlCl or $EtAlCl_2$ with solutions of alkali metal arenes (*e.g.* anthracenesodium or naphthalenelithium) in ethers (*e.g.* THF or dimethyl ether). The THF adduct of bisdiethylaluminobiphenyl obtained from sodium biphenyl and $Et_2AlCl{\leftarrow}THF$ decomposes at 20 °C/15 mm with release of biphenyl. A free $Et_2Al{\leftarrow}THF$ radical, which becomes stabilized by disproportionation to form aluminum, THF, and $Et_3Al{\leftarrow}THF$, is formed as an intermediate in this reaction.

Synthesis of 2,4-Dinitrophenyl α- and β-*O*-Glycosides

By Dipl.-Chem. W. Hengstenberg and Prof. Dr. K. Wallenfels

Chemisches Laboratorium
der Universität Freiburg/Breisgau (Germany)

2,4-Dinitrophenyl glycosides were previously known only in the form of acetylated derivatives [1] since the very labile 2,4-dinitrophenyl-*O*-glycosidic bond cannot withstand acidic or basic deacetylation.

We have prepared free 2,4-dinitrophenyl glycosides in the following manner. Ethyl thioglycosides are protected according to *Bently* et al. [2] with a trimethylsilyl group, which is easy to remove by hydrolysis. The ethylthio residue is then replaced by a bromo substituent by treatment of the protected glycosides with bromine in carbon tetrachloride [3]. The sirupy trimethylsilylated bromohexose obtained is converted into the glycoside of 2,4-dinitrophenol with silver oxide according to *Koenigs* and *Knorr* [4]. The trimethylsily groups can then be removed with a mixture of methanol water, and glacial acetic acid (20:20:1 v/v) at room temperature. The excess 2,4-dinitrophenol is separated by chromatography on silica gel with benzene as eluant. The 2,4-dinitrophenyl glycoside is then eluted with ethyl acetate.

The anomers of the 2,4-dinitrophenyl glycosides can be separated by thin-layer chromatography with benzene/methanol (2:1 v/v) as solvent or by column chromatography on silica gel with ethyl acetate as eluant.

2,4-Dinitrophenyl glycoside	M.p. [°C] (decomp.)	Yield [%] [a]	$[\alpha]_D^{22}$
α-D-Galactoside	158	22	+322°, c = 0.66 [c]
β-D-Galactoside	150–151	22	−105°, c = 1.0 [c]
β-D-Glucoside [b]	100–101	10	−92.8°, c = 1.06 [c]
α-D-Mannoside	149	28	+161°, c = 1.0 [c]
α-L-Arabinoside	167	32	−103°, c = 1.05 [d]
β-L-Arabinoside	158	32	+367°, c = 0.96 [d]

[a] Based on the amount of ethyl thioglycoside taken.
[b] Crystals contain 1 mole of acetone.
[c] In methanol.
[d] In dimethylformamide.

2,4-Dintitrophenyl β-D-galactoside and 2,4-dinitrophenyl α-L-arabinoside are both split rapidly by the β-galactosidase from *Escherichia coli*. 2,4-Dinitrophenyl β-D-glucoside is also a substrate – albeit a very poor one – for this crystalline β-galactosidase. 2,4-Dinitrophenyl α-D-galactoside is a substrate only of the α-galactosidase from coffee beans. Dilute alkali hydrolyses all the glycosides listed in the table.

CONFERENCE REPORTS

International Symposium on Thermal Analysis

On April 13th and 14th, 1965, the Chemistry Department of the Northern Polytechnic in London (England) arranged a Symposium on Thermal Analysis.

From the lectures:

Differential Thermal Analysis of Polymer Dissolution

D. A. Blackadder and *H. M. Schleinitz*, Camhridge (England)

Polyethylene precipitated from a dilute solution crystallizes in thin diamond-shaped lamellae whose thickness increases regularly with temperature of crystallisation. Annealing crystals in a solvent at a temperature between the crystallization and melting temperatures causes partial dissolution starting at the crystal edges and subsequent reprecipitation on the same sites at a thickness characteristic of the annealing temperature. The melting or dissolution temperature is dependent upon the thickness and consequently upon the thermal history of the crystals.

Differential thermal analysis at low heating rates was applied to suspensions of polyethylene single crystals in various solvents. The melting point of the crystals increases monotonically with the temperature of crystallization. It was found that crystals prepared at lower temperatures anneal to a greater extent and at a greater rate than those prepared at higher temperatures. Samples annealed for short times showed a multiplicity of peaks characteristic of both the original crystallization temperature and the annealing temperature. The implication is that under annealing conditions the crystals do not thicken regularly. Either some crystals thicken as expected and others not at all, or else only parts of each crystal thicken. Electron microscopy revealed that the latter interpretation is correct.

Simultaneous Thermogravimetric and Differential Thermal Analysis of the Decomposition of Chromates and Dichromates

E. L. Charlsley and *J. P. Redfern*, London (England)

Thermal decompositions can be studied by thermogravimetric analysis (TGA), but the results often must be supplemented with other data, notably from differential thermal analysis

(DTA). Correlation of the two sets of data often is difficult, since the instruments used normally do not employ the same experimental conditions. A Stanton HT–D thermobalance was therefore modified to enable simultaneous DTA and TGA measurements to be made.

With this instrument, the thermal decompositions of numerous chromates and dichromates were investigated, where the following reactions occur (among others):

$$M_xCrO_4 \cdot n\ H_2O\ (s) \rightarrow M_xCrO_4\ (s) + n\ H_2O\ (g) \quad (1)$$

[x = 1 or 2]

This reaction may be multi-stage.

$$M_xCrO_4\ (s) \rightarrow M_xCrO_4\ (l) \quad (2a)$$

$$2\ M_xCrO_4\ (s) \rightarrow 2\ M_xO \cdot Cr_2O_3\ (s) + 3/2\ O_2\ (g) \quad (2b)$$

$$2\ M_xO \cdot Cr_2O_3\ (s) \rightarrow M_xO \cdot Cr_2O_3\ (s) + M_xO\ (s) \quad (3a)$$

$$2\ M_xO \cdot Cr_2O_3\ (s) \rightarrow 2\ M_xO\ (s) + Cr_2O_3\ (s) \quad (3b)$$

These reactions may be simultaneous to or even precede reaction 2(b)

$$M^{II}OCr_2O_3\ (s) + MO\ (s) \rightarrow M_2^{I}Cr_2O_4\ (s) + {}^1/_2\ O_2\ (g) \quad (4)$$

Thermal Analysis of Inorganic Azides

H. Rosenwasser and *O. F. Kezer*, Fort Belvoir, Virginia (U.S.A.)

The reaction of rare earth sesquioxides with hydrazoic acid yields basic azides. These compounds containing the elements from lanthanum through dysprosium in the lanthanide series have a metal to nitrogen ratio of 1:6 and may be formulated as $Ln(OH)(N_3)_2 \cdot 1{,}5\ H_2O$, whereas the heavier lanthanide elements (and yttrium) form compounds with lower azide contents, which fit the formula $Ln_2(OH)_5N_3 \cdot H_2O$. Infrared spectra, however, indicate that the compounds have an oxo-structure.

These compounds were studied by means of differential thermal analysis. In general, the thermograms show the endothermic peaks caused by loss of water, and exothermic peaks due to the conversion of azide groups to nitrogen molecules. Both processes sometimes occur simultaneously. From thermogravimetric analyses, an oxyazide and an oxyhydroxide are postulated as intermediates in the decompositions.

Although the thermal decomposition of the basic azides of lanthanum and praseodymium proceeds smoothly in air, the reactions taking place in vacuum often lead to explosions. Studies with a DuPont micro-DTA unit show the effect of heating rate as a factor in determining whether or not the samples will explode. Information recorded on the thermograms includes crystalline phase transitions, melting points, and decomposition of the azide ions. In the case of thallium azide, a crystal structure change has been indicated for the first time.

Thermal Analysis of Poly-(m-Aminostyrene) and Related Polymers

R. H. Still and *C. J. Keattch*, Hatfield and Boreham Wood (England)

m-Aminostyrene was homopolymerized using two different concentrations of α,α'-azobisisobutyronitrile to yield two homopolymers *(1)* and *(2)* of differing molecular weight. Copolymerization with styrene yielded a 2:1 copolymer *(3)* (2 moles styrene : 1 mole *m*-aminostyrene). Acetylation of these polymers yielded poly-(*m*-acetamidostyrene) *(4)* and *(5)*, and the corresponding 2:1 copolymer *(6)*. These substances were studied by TGA in static air. The homopolymers *(1)* and *(2)*, owing to the presence of amino groups, are thermally more stable than polystyrene, but the copolymer *(3)* showed no enhanced thermal stability.

An acetamido group in the *meta* position of styrene increases the thermal stability of the resultant homopolymers *(4)* and *(5)* to a lesser degree than an amino group does, whereas the acetylated copolymer *(6)* has a thermal stability similar to that of the acetylated homopolymers *(4)* and *(5)* but shows enhanced thermal stability over the amino copolymer *(3)*. The molecular weight apparently has no effect upon the thermal stability. On pyrolysis in nitrogen, practically no difference was found for the polymers *(1)*, *(5)*, and *(6)* from the pyrolysis in air.

Thermogravimetric Analysis of Oxides

H. Uwents, Drogenlos (Belgium)

The reduction of simple oxides in a hydrogen atmosphere or hydrogen stream using a thermobalance allows their stoichiometry to be determined.

This method was extended to mixtures of a non-volatile (A_mO_x) and a volatile (B_nO_y) oxide. After preparation under conditions (calcination at high temperature) where partial evaporation of the volatile compound could be expected, the composition of the final product was determined by the following procedure: The weight loss on reduction gave the total amount of oxygen bound in the mixture. From the weight of the residue the total quantity of metal (A+B) became known. In a separate run the volatile oxide B_nO_y was evaporated at high temperature under vacuum. The subsequent reduction of the residue gave the amount of the metal A. The quantity of the metal B was calculated by difference.

When the oxides form a solid compound ($A_pB_qO_z$), an excess of the volatile oxide can be removed at high temperature and atmospheric pressure. Subsequent reduction of the residue gives the amount of the combined metallic components (A_pB_q). The oxygen content of the combination $A_pB_qO_z$ is obtained by the weight loss during reduction. Finally the amount of component A is determined as decribed above.

Microanalytical Redox Titrations

J. Zýka, Prague (Czechoslovakia)

Suitable solutions for redox microtitrations include lead(IV) acetate in glacial acetic as an oxidizing agent and hydrazine sulfate or hydroquinone as reducing agents. The redox potentials of other solutions can be shifted by combining the oxidized or reduced form of the reagent in a complex or sparingly soluble product. Examples of this are titrations with iron(II) sulfate in triethanolamine [1]. Under alkaline conditions and in the presence of triethanolamine, iron(II) sulfate is a strong reducing agent. Compounds of trivalent manganese, copper(II) and bismuth(III) salts, as well as dichromates and tellurates can be titrated directly. The titration of dichromate by this method is more sensitive than in acid solution. It is suitable for the microdetermination of dichromate in the presence of vanadate(V) which is not reduced under these conditions. Tellurates can be determined in the presence of tellurites and compounds of four- and six-valent selenium. The method can also be used for the potentiometric microdetermination of aromatic nitro groups (reduction to NH_2 groups) and of nitroso and azo compounds.

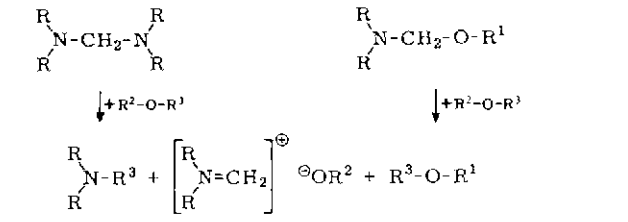
New Cleavage Reactions of Methylenediamine Derivatives and α-Dialkylamino Ethers

H. Böhme, Marburg/Lahn (Germany)

α-Halogenated amines are formed by cleavage of aminals with acid halides. Analogously, *N,N,N',N'*-tetraalkylmethylenediamines react with sulfonic anhydrides to yield dialkylmethyleneimonium sulfonates and dialkylsulfonamides. Tetraethyl pyrophosphate reacts with aminals or α-dialkylamino ethers to produce carbimonium salts of diethylphosphoric acid and phosphoric ester amide or triester. The carbimonium salts of diethylphosphorous acid, formed from tetraethyl pyrophosphite, undergo a Michaelis-Arbusow rearrangement, whereby dialkylaminomethylphosphonic esters can be isolated.

If mixed anhydrides are used for the cleavage reaction, the imonium salt of the stronger acid present in the anhydride is formed, together with the amide or ester of the weaker acid.



R, R^1 = Alkyl

R^2, R^3 = R-CO-, R-SO_2-, R-SO-, $(RO)_2PO$-, $(RO)_2P$-

On the other hand, the reactions of acetyl nitrate with aminals yield dialkylnitramines and acetoxymethyldialkylamines which are also obtainable by cleavage of aminals with carboxylic anhydrides. When the reaction is carried out using the mixed anhydride of acetic and formic acids, the primary product α-formyloxymethyldialkylamine is decarboxylated even at −20 °C and methyldialkylamine is formed.

Carbimonium halides which are usually considered to be α-halogenated amines, on heating or on recrystallization from aprotic polar solvents, yield dimers and trimers which are also formed in the reaction of methylenediamine derivatives with methylene halides. Contrary to the monomers, the dimers and trimers do not possess the band of the C=N double bond in the infrared spectrum at 5.95 μ.

The Bond Character in Aromatic Phosphorus Compounds – a Contribution to the Problem of the Existence and Properties of $p_\pi-d_\pi$ Bonds

G. P. Schiemenz, Kiel (Germany)

The participation of vacant d-orbitals of the valence electron shell of hetero-atoms of the fifth main group in aromatic π-bonding systems ($p_\pi-d_\pi$ bond) can be expected, according to theory, to be most pronounced for phosphorus. This is the case particularly if the phosphorus carries a positive charge. Three models were discussed for phosphonium salts containing one to four *p*-dimethylaminophenyl groups, and for phosphine oxides, phosphine sulfides, and phosphines with one to three *p*-dimethylaminophenyl groups:

1. No participation of phosphorus d-orbitals.

2. Participation of a phosphorus d-orbital, with conjugation across the phosphorus atom.

3. Participation of a phosphorus d-orbital, the phosphorus atom inhibiting conjugation.

The ultraviolet absorption of all compounds investigated could not be explained on the basis of models 1 and 2 or of a model which had previously been suggested by other authors [1]. On the other hand, all predictions based on the third model were found to be verified in the ultraviolet and infrared spectra. An acceptor effect of phosphorus was found experimentally which is greater than that of a CN group in the salts, and which is nearly equal to CN in the phosphines, oxides and sulfides. Increase of the electron density at the phosphorus atom (replacement of C_6H_5 by CH_3; solvation of the phosphonium group; comparison of the phosphines, oxides, and sulfides with onium salts) lessens the acceptor effect. As borne out by the infrared spectra of the oxides and sulfides, the same holds for the $p_\pi-d_\pi$ character of the P=O and P=S bonds: the frequency and intensity of the PO- and PS-valence vibrations decrease (as would be expected according to model 3) with an increase of the donor effect acting on the phosphorus.

The acceptor effect is not unambiguously discernible in compounds with unsubstituted phenyl groups; however, the small participation of the phosphorus 3p-orbital in the aromatic π-bond systems of triphenylphosphine may be caused by a counteraction of 3p- and 3d-orbital participation. As strong electron donors demonstrated the participation of 3d-orbitals, it seemed possible that 3p-orbital participation would be detected after introduction of strong acceptor substituents. This was in fact the case, as indicated hy the properties of the phosphines $(C_6H_5)_2P-C_6H_4-A(p)$, where A = NO_2, CN, CHO, $COOCH_3$, COOH, $CON(CH_3)_2$, or $CONH_2$.

[GDCh-Ortsverband Kiel (Germany), February 25th, 1965] [VB 917/216 IE]

German version: Angew. Chem. 77, 593 (1965)

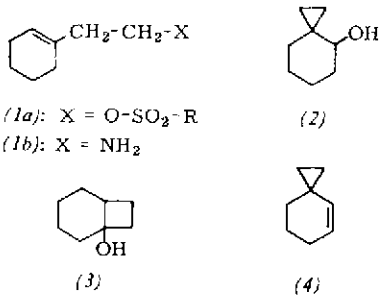
Cyclopropane and Cyclobutane Derivatives by Rearrangement of Unsaturated Compounds

M. Hanack, Tübingen (Germany)

Open-chain homoallyl compounds are isomerized smoothly to cyclopropylmethyl compounds, hut yields are lower in the case of cyclic homoallyl compounds. Here, the primarily formed homoallyl cations are partly stabilized by hydride shift. Thus, cyclohexen-4-yl tosylate is isomerized to an extent of only 10 % during acetolysis to yield the stereoisomeric bicyclo[3.1.0]hex-2-yl acetates. On hydrolysis, cyclopenten-4-yl sulfonates yield 40 % cyclopenten-4-ol and 60 % cyclopenten-3-ol. Similarly, the reaction of 4-bromocyclopentene with Ag_2O in water, proceeding by an S_N1-mechanism, does not result in a bicyclic compound. The reduction of cyclopenten-4-yl sulfonate with $LiAlH_4$, on the other hand, yields 4 % bicyclopentane, together with other hydrocarbons.

On hydrolysis, 2-(cyclohexen-1-yl)ethyl sulfonates *(1a)* isomerize, as does 2-(cyclohexen-1-yl)ethylamine *(1b)* during deamination with nitrous acid, to form spiro[2.5]octan-4-ol *(2)* and bicyclo[4.2.0]octan-1-ol *(3)*; both alcohols can thus he obtained in high yield.

[1] *H. Goetz*, Angew. Chem. *75*, 675 (1963); Angew. Chem. internat. Edit. *2*, 552, (1963).



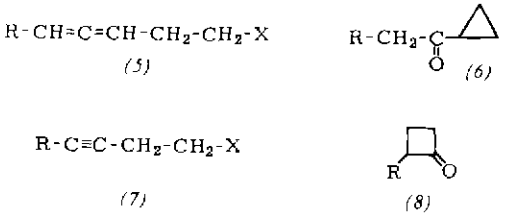
(1a): X = O-SO_2-R
(1b): X = NH_2

(2)

(3)

(4)

On the other hand, 2-(cyclopenten-1-yl)ethylamine and cyclopenten-1-yl tosylate, on deamination or hydrolysis respectively, afford predominantly bicyclo[3.2.0]heptan-1-ol. Derivatives of bicyclo[4,2,0]octan-1-ols *(3)* behave anomalously: the *p*-nitrobenzoate yields, both on pyrolysis and by elimination reactions with strong bases, mainly spiro[2,5]oct-4-ene *(4)*.



(5)

(6)

(7)

(8)

Allenes (such as *(5)*, X=OSO_2R or NH_2) also rearrange readily during solvolysis reactions to give cyclopropane derivatives in good yields. These reactions may be compared to homoallyl rearrangements and afford alkyl cyclopropyl ketones *(6)*. In strongly ionizing solvents, acetylenes such as *(7)* can be cyclized with formation of cyclobutanones *(8)*.

Interactions of Plasticizers with Poly(vinyl chloride)

H. Luther, Clausthal (Germany)

The interactions of plasticizers with poly(vinyl chloride) (PVC) were studied by infrared spectroscopy [1], NMR and dielectric measurements [2] on the pure substances and their solutions, microscopic observation of the swelling of PVC in individual plasticizers and mixtures of plasticizers [3]; viscometric measurements of the solubility of PVC in plasticizers using a rotation viscometer and the plastograph [4], infrared spectroscopical observation of plasticizer separation [5] and diffusion [6].

Plasticizers do not form associates of definite stoichiometric composition with PVC but simply dissolve in the polymer. Chloroform/plasticizer mixtures can serve as model systems of low molecular weight; their heats of mixing are determined from the shifts in the infrared bands of the plasticizers on alteration of the concentration.

The solubility of PVC in esters of plasticizers with aliphatic alcohols is greatest when the alcohols contain 3–4 carbon atoms. NMR spectra reveal that the good solubility is due to dissociation of intramolecular associates of the esters as the chain length of the alcohol component increases, for the PVC can then undergo intermolecular association with the ester. However, as the chain length increases, the intermolecular association is again suppressed.

When mixtures of plasticizers are used, the interactions among them determine their solvent powers. The Flory-Huggins interaction parameters do not reflect this situation satisfactorily. The measured (apparent) diffusion coefficients of plasticizers in PVC exhibit a large discontinuity in the glass transition range but are only slightly dependent upon the concentration beyond this range, being proportional to the vapor pressure of the plasticizer at the temperature of the experiment. This proportionality can be explained by the fact that the limiting conditions assumed for measurements of the diffusion of plasticizers out of plasticized PVC plates are seldom fulfilled. The diffusion of the plasticizer is generally overlapped by processes that occur during the drying of a porous system and which depend on the vapor pressure of the volatile components.

A theory developed by *G. Kanig* [7] for the glass temperature of plasticized polymers can account satisfactorily for some of the values so far found by experiment and thus forms a good starting point for further research.

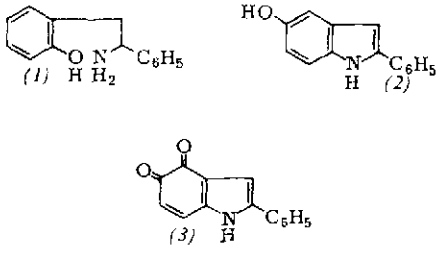
New Reactions in the Quinone and Heterocycle Series

H.-J. Teuber, Frankfurt/Main (Germany)

o-Hydroxyphenethylamine derivatives are oxidized by potassium nitrosodisulfonate to 5-hydroxyindoles, which on further oxidation yield *o*-quinones. For instance, compound *(1)* affords red-violet 2-phenylindole-4,5-quinone *(3)* in an overall yield of 80 % *via* the isolable intermediate *(2)* [1].

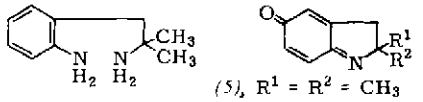


(1)

(2)

(3)

If a tertiary phenethylamine such as *(4)* is used, the product is a yellow cyclic quinone imine such as *(5)* or *(6)*.



(4)

(5), $R^1 = R^2 = CH_3$
(6), $R^1 + R^2 = -(CH_2)_5-$ or $-(CH_2)_4-$

2,2,4-Trimethyl-1,2-dihydroquinoline *(7)* [2] also yields a yellow *p*-quinone imine, *viz.* *(8)*; however, when the *p*-position is substituted, the product is a red *o*-quinone imine, *e.g.* *(9)*.

[1] Experimental work in collaboration with *O. Glosauer*.

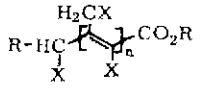
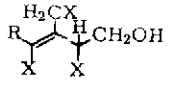
Synthesis and Reactions of Organic Fluoro Compounds

H. Machleidt, Biberach/Riss (Germany)

Carbonyl olefinations of ketones or fluoroketones with ethyl diethoxyphosphinoacetate or ethyl diethoxyphosphinofluoroacetate or their vinylogues lead to fluoro-substituted α,β-unsaturated esters of type *(1)*.

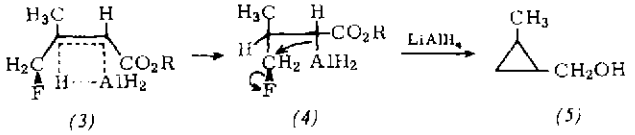


(1), X = H or F



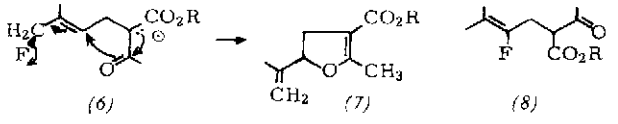
(2), X = H or F

$LiAlH_4$ reduces compounds of type *(1)*, X = F, n = 1, at −78 °C to fluoroisoprenols. At higher temperature, a reductive elimination of the γ-fluoro substituent occurs with partial isomerization of the double bond to isoprenols of type *(2)*. At the same time, an intramolecular nucleophilic substitution of the fluorine occurs which is largely independent of the temperature and proceeds *via (3)* → *(4)*. Further reduction leads to the cyclopropane derivative *(5)*.



(3) *(4)* *(5)*

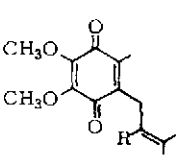
A similar substitution of fluorine is observed with β-keto esters *(6)*, leading to dihydrofuran derivatives *(7)*. Fluoro-β-keto esters of type *(8)* are stable.



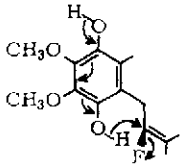
(6) *(7)* *(8)*

[3] *H.-J. Teuber, D. Cornelius*, and *E. Worbs*, Tetrahedron Letters *1964*, 331; *H.-G. Teuber* and *D. Cornelius*, Chem. Ber., in press.

Fluoroisoprenols are used to synthesize fluoro-coenzyme Q, *e.g.* FQ_1 *(9)*.



(9), R = F
(11), R = H



(10)

The dihydro derivative of enzyme FQ_1 *(10)* is unstable and undergoes an intramolecular redox reaction by an addition-elimination mechanism to yield coenzyme Q_1 *(11)* and HF.

Fluoroisoprenols were converted into their pyrophosphates, some of which are inhibitors of steroid biosynthesis.

[GDCh-Ortsverband Nordbayern, May 7th, 1965 in Erlangen (Germany)] [VB 927/232 IE]

Inorganic Ring Systems with Silicon and Nitrogen Atoms as Ring Members

U. Wannagat [1], Graz (Austria)

1,3-Dihalogenodisilazanes $X-SiR_2-NR'-SiR_2-X$ *(1)* are excellent starting materials for the synthesis of inorganic rings with Si–N units. They can be prepared by the following methods:

a) By cleavage of cyclotrisilazanes, cyclotetrasilazanes, or polysilazanes with hydrogen halides in yields of 40–70 % (X = F, Cl, or Br):

$$-SiR_2-NH-SiR_2-NH- + 3\,HX \rightarrow X-SiR_2-NH-SiR_2-X + NH_4X$$

b) By intermolecular condensation of dialkylchloroaminosilanes in yields of 40 % (based on the amount of chloroaminosilane charged):

$$4\,R_2Si(NHR')Cl \rightarrow Cl-SiR_2-NR'-SiR_2-Cl + Cl-SiR_2-NR'-SiR_2-NHR' + [R'NH_3]Cl$$

c) By equilibration of cyclotrisilazanes or cyclotetrasilazanes with dimethyldichlorosilane by boiling in yields of 70 %[2]:

$$(-R_2Si-NH-)_3 + 3\,R_2SiCl_2 \rightarrow 3\,Cl-SiR_2-NH-SiR_2-Cl$$

d) By the action of the adducts of silicon halides on cyclosilazanes:

$$-SiR_2-NH-SiR_2-NH- + SiF_4(NH_3)_2 \rightarrow F-SiR_2-NH-SiR_2-F + 2\,NH_3 + 1/x\,[SiF_2(NH)]_x$$

The 1,3-dihalogenodisilazanes are readily converted by alcohols, amines, and hydrazines in the presence of triethylamine into the corresponding derivatives *(1)*, X = RO, R_2N, and R_2NNH. Analogous reactions, some of which require prior metallation of NH groups, lead to numerous new ring systems. Compounds made include *(2)* from *(1)* plus water, *(3)* from *(1)* plus ammonia, *(4)* from *(1)* plus hydrazine, *(5)* from *(1)* plus ethylene diamine, and *(6)* from *(1)* plus bistrimethylsilylurea. The Si–N four-membered ring of *(7)* is formed in surprisingly high yields during attempts to produce dichlorotrisilazanes according to method (c) but with different ratios of reagents [3].

[1] In collaboration with *E. Bogusch* and *G. Schreiner*.

[2] *P. Geymayer* and *E. G. Rochow* independently carried out this reaction in a sealed tube (personal communication).

[3] *P. Geymayer* and *E. G. Rochow* also obtained this compound from *(1)*, X = Cl, and sodium bistrimethylsilylamide (personal communication).

Compound *(5)* with R = CH$_3$ and R' = H or CH$_3$ decomposes without melting when heated; it can be characterized by its infrared and NMR spectra.

[GDCh-Ortsverband München (Germany), May 11th, 1965] [VB 924/231 IE]

German version: Angew. Chem. *77*, 626 (1965)

SELECTED ABSTRACTS

The structures of Gastrins I and II, two closely related polypeptide hormones from pig stomach mucosa, which on subcutaneous injection strongly activate the excretion of acid into the stomach, were elucidated by *H. Gregory* and collaborators by amino-acid analysis, end-group analysis, and determination of the amino-acid sequence (by degradation with papain, subtilisin, chymotrypsin, and cyanogen bromide). Gastrin II is pyro-Glu-Gly-Pro-Try-Met-(Glu)$_5$-Ala-Tyr (SO$_3$H)-Gly-Try-Met-Asp-Phe-NH$_2$ *(1)*, and is converted by removal of the sulfato group from the tyrosine residue into gastrin I. Resynthesis of *(1)* can be effected by treating gastrin I with the pyridine-SO$_3$ complex in alkaline solution. Investigation of 12 synthetic peptides closely related to the gastrins revealed that only the *C*-terminal tetrapeptide sequence is required for complete physiological activity. / Nature (London) *204*, 931,933,935 (1964) / –Ma.

[Rd 211/420 IE]

The mutagenic activity of thalidomide (Contergan®) in bacteria was examined by *A. Tumulka* and *R. W. Kaplan* on three auxotrophic strains of *Serratia* CV, since it is known that 29 out of 36 substances which are mutagenic for humans are significantly mutagenic for these strains, too. With the strains gly 1 and arg 1, the mutagenic action of Contergan could be demonstrated; this proves its direct or indirect attack on the bacterial DNA. There is therefore a considerable probability that Contergan is also mutagenic for the genes (DNA) of human cells. Fetal malformations do not however result from changes in the DNA in the embryonic cells, but by modifications of the embryonic development. It is not yet known whether there is any connection between the teratogenic activity of Contergan – RNA is partly responsible for phenogenetic development – and the mutagenic action. / Naturwissenschaften *52*, 20 (1965) / –De. [Rd 230/438 IE]

The behavior of alkali metal chlorates on heating was studied by *M. M. Markowitz, D. A. Boryta,* and *H. Stewart* by differential thermoanalysis and thermogravimetry. Mainly two reactions occur: direct decomposition of chlorate to chloride and oxygen, and disproportionation to chloride and perchlorate, which is also converted into chloride and oxygen at higher temperatures. The direct decomposition is the preferred reaction with the chlorates of the lighter alkali metals, the disproportionation with the chlorates of the heavier ones. MnO_2 accelerates the direct decomposition. All the alkali metal chlorates melt without decomposing; the temperatures at which decomposition starts lie 100–200 °C above the melting points. Of the perchlorates, only $LiClO_4$ melts unchanged. / J. physic. Chem. *68*, 2282 (1964) / Hz.

[Rd 233/441 IE]

Fluorosulfuric acid was used as an acid-base system in studies by *J. Barr, R. J. Gillespie,* and *R. C. Thompson,* who found that anhydrous HSO_3F, m.p. –89.0 °C, b.p. 162.7 °C, undergoes autoprotolysis. In this system, bases are substances

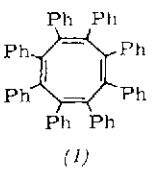
$$2\ HSO_3F \rightleftharpoons H_2SO_3F^{\oplus} + SO_3F^{\ominus}$$

which increase the $SO_3F^{\ominus}$ concentration, *e.g.* fluorosulfates of alkali and alkaline earth metals. Conversely, acids are substances which increase the concentration of $H_2SO_3F^{\oplus}$ ions. / Inorg. Chemistry *3*, 1149 (1964) / –La. [Rd 243/450 IE]

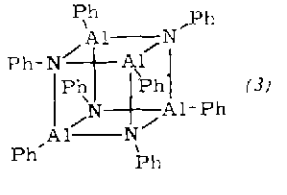
A one-step synthesis of 1,1-difluoroolefins from ketones is reported by *A. S. Fuqua, W. G. Duncan,* and *R. M. Silverstein.* A solution of sodium difluoroacetate in an anhydrous polar solvent such as *N*-methylpyrrolidone, tetramethylurea, dimethylformamide, dimethylacetamide, or dimethyl sulfoxide is added to a solution of the ketone and tributylphosphine in the same solvent under nitrogen at 160–180 °C. Fractional distillation after the reaction leads to 46 % difluoromethylenecyclohexane, b.p. 105–106 °C, from cyclohexane or 34.6 % 3,3-difluoro-α-methylstyrene, b.p. 58–59/21 mm, from acetophenone. / Tetrahedron Letters *1965*, 521 / –Ma.

[Rd 258/467 IE]

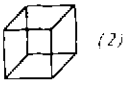
"Octaphenylcubane" is actually octaphenylcyclooctatetraene *(1)* according to the results of the three-dimensional Patterson analysis carried out by *H. P. Throndsen, P. J. Wheatley,* and *H. Zeiss.* This finding is surprising, since unsubstituted cubane *(2)* is known and since the Al–N compound *(3)*, which is isoelectronic with *(1)* – except for the extra L-shell of the



(1)



(3)



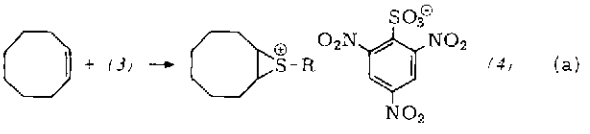
(2)

aluminum –, has the same space group ($I4_1/a$) as *(1)* and has very similar unit-cell dimensions. Hydrocarbon *(1)* forms tetragonal crystals (from diphenyl ether) with a = 19.388 Å, c = 10.606 Å, and Z = 4. / Proc. chem. Soc. (London) *1964*, 357 / –Kr. [Rd 232/440 IE]

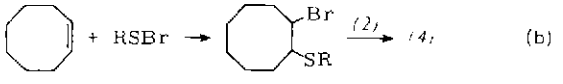
Stable episulfonium salts in the cyclooctane series have been isolated by *D. J. Pettitt* and *G. K. Helmkamp*. Alkanesulfenyl bromides *(1)* react in nitromethane with silver 2,4,6-trinitrobenzenesulfonate *(2)* in CH_2Cl_2 at −25 to 0 °C to form alkanesulfenyl 2,4,6-trinitrobenzenesulfonates *(3)*, which are unstable and are difficult to isolate. However, after removal of the AgBr formed by filtration, the salts *(3)* can be condensed in solution with cyclooctene to give 60–70 % cyclooctene-*S*-alkylepisulfonium salts *(4)*, which can be crystallized from hot nitromethane/ether or acetone/ether. The salts *(4)* are also obtained in pure form and in high yield by Route (b) and by direct alkylation of episulfides. Thus, for example, *(4a)* was produced from cyclooctene episulfide and trimethyloxonium 2,4,6-trinitrobenzenesulfonate *(5)* according to Equation (c) [1]. The salt *(5)*, m.p. 115–120 °C (decomp.),

(1) $RSBr + (NO_2)_3C_6H_2\text{-}SO_3^{\ominus}Ag^{\oplus}$ *(2)*

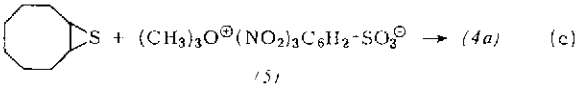
$\rightarrow AgBr + [(NO_2)_3C_6H_2\text{-}SO_3^{\ominus}RS^{\oplus}]$ *(3)*



(4) (a)



(4) (b)



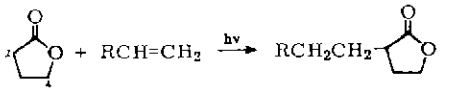
(4a) (c)

(5)

(4a): R = CH_3, m.p. 122–123 °C
(4b): R = C_2H_5, m.p. 123–124 °C
(4c): R = n-C_3H_7, m.p. 116–117 °C
(4d): R = n-C_4H_9, m.p. 104–105 °C

is readily obtainable by the reaction of 2,4,6-trinitrobenzenesulfonic acid and diazomethane in dimethyl ether at 35 °C [1]. The ring strain in the salts *(4)* is indicated *inter alia* by their reaction with NaI in acetonitrile: in contrast to the unstrained sulfonium salts, which can form stable iodides, here quantitative separation of iodine occurs, *(4)* being split into cyclooctene and the corresponding alkyl disulfide in a molar ratio of 2:1. / J. org. Chemistry *29*, 2702 (1964) / −Bi.
[Rd 224/448 IE]

Photoinduced addition of γ-butyrolactone *(1)* **onto terminal olefins** has been observed by *D. Elad* and *R. D. Youssefyeh*. The reaction proceeds at room temperature and affords mainly the corresponding 2-alkylbutyrolactone, together with some 4-alkyl derivative. A solution of the olefin in the lactone is irradiated. Photochemical induction with acetone leads to higher yields. For example, 1-heptene gives a 52 % yield (based on the olefin charged) of 2-heptylbutyrolactone,



(1)

m.p. 9–10 °C, on irradiation with a Hanau Q81 mercury vapor lamp or a 63 % yield on irradiation with sunlight. Similarly, 1-octene gives 42 or 66 % 2-octylbutyrolactone, m.p. 19–20 °C, and 1-decene gives 48 or 58 % 2-decylbutyrolactone, m.p. 32–33 °C, respectively. / Chem. Commun. *1965*, 7 / −Ma.
[Rd 282/491 IE]

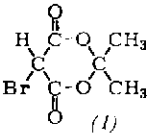
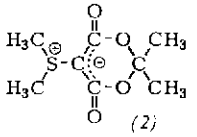
The biological activity of bradykinine was found to disappear on alteration of the configuration of the terminal arginine group by *E. D. Nicolaides*, *D. A. McCarthy*, and *D. E. Potter*. This vasodilator hormone is a peptide consisting of 9 L-amino acids in the sequence Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg. [1-D-Arginine]bradykinine was prepared by condensation of the heptapeptide with carbobenzoxynitro-D-arginylproline, and [9-D-arginine]bradykinine and [1,9-bis-D-arginine]bradykinine by conventional total synthesis. All three synthetic peptides had practically no biological activity (activity only $2 \cdot 30 \times 10^{-5}$ that of bradykinine). Their *in vivo* half-lives did not differ from that of bradykinine (about 30 sec). Since the [D-arginine]bradykinines are not attacked by carboxy- or aminopeptidases, and since the biological half-lives are the same as that of bradykinine itself, it can be concluded that exopeptidases are not involved in its degradation. / Biochemistry *4*, 190 (1965) / −Hö.
[Rd 303/512 IE]

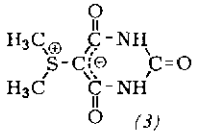
New stable sulfonium ylides have been described by *A. Hochrainer* and *F. Wessely*. When the bromo derivative of Meldrum's acid *(1)* is allowed to stand in dimethyl sulfoxide for several hours, the hydrobromide of *(2)* is formed spontaneously; when the latter is dissolved in methanol and reprecipitated with ether, the free dimethylsulfonium ylide *(2)* of Meldrum's acid is obtained in 30–40 % yield. It melts



(1)



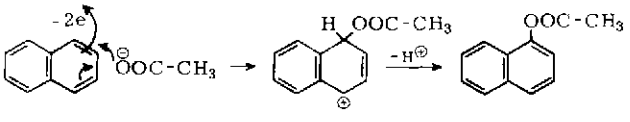
(2)



(3)

at 197 °C after purification by sublimation. The structure of *(2)* was proved by infrared, ultraviolet, NMR, and mass spectroscopy. Bromobarbituric acid gives a good yield of the analogous ylide *(3)*. / Tetrahedron Letters *1965*, 721 / −Ma.
[Rd 284/493 IE]

The anodic acetoxylation of aromatic compounds was found by *L. Eberson* and *K. Nyberg* not to proceed by the Kolbe mechanism. The acetate ions are not oxidized to acetoxyl radicals, which would then attack the aromatic compound; instead, two electrons are abstracted from the aromatic compound at the anode, and combination with acetate anions then occurs. In 0.5 M sodium acetate in acetic acid, the oxidation

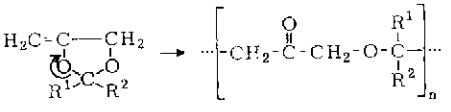


half-wave potential on a platinum electrode is 1.72 v for naphthalene and 1.67 v for anisole relative to the saturated calomel electrode. Here the acetoxylation cannot proceed *via* acetoxyl radicals, for the acetate ion is not discharged until 2.0 v. Moreover, the formation of specifically 1-acetoxynaphthalene and *o*- plus *p*-anisole is in contradiction to a free radical mechanism. Since the potentials measured at the anode for several electrolytic syntheses correlate well with the molecular-orbital coefficients for the highest occupied orbital, it is likely that numerous oxidations begin with oxidation of the substrates and not with that of the anionic species present. This assumption does not only apply to electrochemical oxidations. / Acta chem. scand. *18*, 1568 (1964) / −Eb.
[Rd 238/446 IE]

One peptide chain is formed at every protein-synthesizing ribosome. *J. R. Warner* and *A. Rich* estimated this using the protein-synthesizing system from rabbit reticulocytes, which produces only hemoglobin. The active ribosomes form poly-

somes with the messenger RNA and can therefore be separated from the inactive ribosomes in a sucrose concentration gradient. Tetrameric to hexameric polysomes were used for the experiments. On the average, six leucine and 2.7 phenylalanine residues become attached to each ribosome. Rabbit hemoglobin contains 16 leucine and 8 phenylalanine residues. It is assumed that in the steady state, the growing peptide chain has on the average half the length of the complete protein molecule. Various correction factors, particularly the known distribution of leucine and phenylalanine in the hemoglobin molecule, bring the values (twice 6 and 16 Leu and twice 2.7 and 8 Phe) into good agreement. Thus, the number of peptide chains synthesized simultaneously at a single molecule of messenger RNA, *i.e.* a polysome is equivalent to the number of ribosomes it contains, probably 4–6. / J. molecular Biol. *10*, 202 (1964) / –Hö. [Rd 217/426 IE]

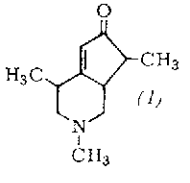
A vinyl polymerization coupled with polymerization by acetal ring opening has been observed by *M. Goodman* and *A. Abe* with the 4-methylene-1,3-dioxolane derivatives *(2)* and *(3)* in the presence of cationic catalysts at 178 °C (BF_3 etherate) or at room temperature ($AlCl_3$). For example, 4.7 g of monomeric *(3)* is polymerized with 0.2 ml of 48% BF_3 etherate in ether within 36 h at –78 °C to give a 64% yield of a polymer with a softening point of 85–90 °C and $[\eta]$ = 0.16 dl/g in CCl_4 at 26.8 °C. A strong carbonyl absorption is observed in the infrared spectrum of the product at 1725 cm^{-1}. This can be explained only by the assumption that the opening of the C=C double bond during molecular growth is coupled with a simultaneous opening of the acetal ring to form the



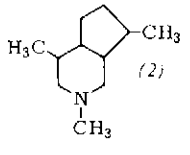
(1): $R^1 = R^2 = H$
(2): $R^1 = CH_3$, $R^2 = H$
(3): $R^1 = R^2 = CH_3$

keto-ether sequence shown. The parent compound 4-methylene-1,3-dioxolane *(1)*, on the other hand, polymerizes preferentially by opening of the vinylic double bond. / J. Polymer Sci. *A 2*, 3471 (1964) / –Hl. [Rd 227/435 IE]

Tecomine and tecostanine are two antidiabetic alkaloids which have been isolated from the leaves of *Tecoma stans* (Juss.) and tested clinically on animals by *Y. Hammouda, Abdel-Kader Rashid*, and *M. S. Amer*. Tecomine *(1)* and tecostanine *(2)* were injected intravenously into rabbits in doses of 20 mg/kg body weight and induced respectively 47 and 49% reduction of the blood sugar concentration; they are therefore much better than the antidiabetic tolbutamine (250 mg/kg *per os*).



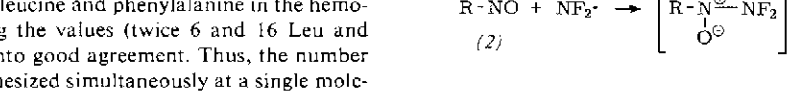
(1)



(2)

The hypoglycemic action was respectively 179 and 186% of that of tolbutamine. Hypoglycemics having this skeleton were hitherto unknown. / J. Pharmacy Pharmacol. *16*, 833 (1964) / –De. [Rd 228/436 IE]

Syntheses and properties of N'-fluorodiimide N-oxides R–N(O)=NF *(1)* are described by *T. E. Stevens* and *J. P. Freeman*. Monomeric *C*-nitroso compounds *(2)* in inert solvents, *e.g.* chlorobenzene, CCl_4, or CH_2Cl_2, absorb tetrafluorohydrazine N_2F_4 at reduced pressure and 0–20 °C, sometimes at 60–80 °C, to form *(1)*. The reaction of *(2)* in pyridine/CH_2Cl_2 with gaseous difluoroamine (HNF_2) diluted with nitrogen also leads to *(1)* in 23–90% yield. Trifluoronitrosomethane (CF_3NO) and N_2F_4 also undergo a thermal or light-induced reaction to yield *(1)* with R = CF_3 [1].



(2) *(1)*

The reaction probably proceeds *via* a radical mechanism; SiF_4 and fluorosilicates are formed as by-products. However, an ionic ($NF_2^{\ominus}$) or nitrene mechanism (:NF_2) cannot be excluded with certainty. Derivatives prepared include *(1)*, R = C_6H_5, b.p. 78 °C/4 mm, 53% yield; *(1)*, R = t-butyl, b.p. 56 °C/64 mm, 33%; *(1)*, R = benzyl, b.p. 70 °C/0.1 mm, 60%; and *(1)*, R = cyclohexyl, b.p. 70/0.1 mm, 90%. Aromatic derivatives are stable toward boiling acetic acid, diethylamine, concentrated HCl, sodium methoxide in methanol, cold concentrated H_2SO_4, and BF_3 etherate; decomposition into NO, N_2O, N_2, and SiF_4 occurs in concentrated H_2SO_4 at 70 °C. Aliphatic derivatives are less stable. Catalytic hydrogenation over Pt converts the aromatic derivatives, *e.g.* *(1)*, R = C_6H_5, into anilines; reduction with Sn/

(3)

HCl affords aryl hydrazines. Azoxy compounds *(3)* are produced from *(1)* and Grignard reagents at 0 °C in ether or tetrahydrofuran, but more readily from organonitrosohydroxylamine tosylates R–N(O) = N–OTos and RMgX [2]. / J. org. Chemistry *29*, 2279 (1964) / –Bi. [Rd 218/427 IE]

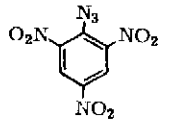
The existence of two isomeric cyclohexyl thiols was detected by *Y. Takeoka* by infrared spectroscopy. The isomerism is caused by the possibility of either an axial or an equatorial position for the substituent on the chair form of the cyclohexane ring. In the liquid form and between the melting point (–18 °C) and transition temperature (–87 °C), the two forms coexist; below –87 °C, only the more stable equatorial form is present. The difference in energy between the two forms is 0.78 kcal/mole in dilute solution in carbon disulfide, 0.80 kcal/mole in the pure liquid, and 0.58 kcal/mole in the solid between –87 and –18 °C. / J. molecular Spectroscopy *15*, 29 (1965) / –Hz. [Rd 280/489 IE]

The standard potentials of the gold/chloroaurate system in the forms $Au/AuCl_2^{\ominus}$, $Au/AuCl_4^{\ominus}$, and $AuCl_2^{\ominus}/AuCl_4^{\ominus}$ were determined by *J. Pouradier, M. C. Gadet*, and *H. Chateau*. In disagreement with earlier observations, it was found that the potential of a gold electrode immersed in a chloroaurate(III) solution is not determined by the concentration of chloroaurate (III) but by that of the chloroaurate (I) which is always present in lower concentration. On the basis of this discovery, the following standard potentials were then found with gold and platinum indicator electrodes: $Au/AuCl_2^{\ominus}$ = 1.148 V; $Au/AuCl_4^{\ominus}$ = 0.995 V; $AuCl_2^{\ominus}/AuCl_4^{\ominus}$ = 0.921 V. Diffusion potentials and activity coefficients were taken into account as far as possible. In the presence of metallic gold, the activities of chloroaurate(I) and chloroaurate(III) are related by $\log_{10}[a(AuCl_4^{\ominus}) \cdot a\text{-}(Cl^{\ominus})/a^3(AuCl_2^{\ominus})] = 7.68$. / J. Chim. physique *62*, 203 (1965) / –Hz. [Rd 281/490 IE]

Aziridines and Schiff bases were obtained from picryl azide *(1)* and olefins by *A. S. Bailey, J. J. Merer*, and *J. E. White*. Mild hydrolysis of the Schiff bases with acids gives picramide

[1] *J. W. Frazer* et al., J. inorg. nucl. Chem. *24*, 45 (1962).
[2] *T. E. Stevens*, J. org. Chemistry *29*, 311 (1964).

and a ketone. Chloroform is suitable as a solvent for preparative work. The duration of the addition reaction varies from a few minutes for norbornylene and dihydropyran to 4 days



(1)

for cyclohexene. Norbornylene, dicyclopentadiene, and α-pinene afford photolabile aziridines; simple olefins such as cyclopentene yield Schiff bases. The azide can be prepared by nitration of either *o*- or *p*-nitrophenyl azide. / Chem. Commun. *1965*, 4 / –Ma. [Rd 283/492 IE]

Surface area estimations according to *Brunauer*, *Emmett*, and *Teller* with krypton or xenon as adsorbate on nickel films deposited by evaporation sometimes lead to erroneous results. After chemisorption of oxygen or ethylene, for example, different values are obtained. *K. C. Cambell* and *D. T. Duthie* consider it probable that this effect is not caused by sintering of the metal due to the energy released on chemisorption; instead, they conclude from the variation in the apparent relative change of surface area after chemisorption of various gases that the polarization of the rare gas atoms is augmented by the metal surface if it is already partially occupied by other adsorbates. This polarization leads to a change in the effective cross-section of the Kr or Xe atoms. It follows that the BET assay of the surface areas of solids using heavy rare gases is not reliable in such cases. / Trans. Faraday Soc. *61*, 558 (1965) / –Hz. [Rd 278/487 IE]

The C-N bond between the benzene ring and the nitroso group of *p*-nitroso-*N*,*N*-dimethylaniline has some double bond character and is therefore restricted in its rotation. *D. D. MacNicol*, *R. Wallace*, and *J. C. D. Brand* found the heat and entropy of activation for the rotation to be $\Delta H^* = 11.2 \pm 1.1$ kcal/mole and $\Delta S^* = -3.0 \pm 5$ cal·deg^{-1}·mole^{-1}. The temperature dependence of the NMR spectrum of the aromatic protons in the compound was used to determine these figures. The rotation around the C–N bond between the benzene ring and the dimethylamino group has no influence on the spectrum. The activation enthalpies determined in this fashion are in good agreement with the position of the corresponding torsional vibration in the far infrared (166 cm^{-1}). / Trans. Faraday Soc. *61*, 1 (1965) / –Hz. [Rd 279/488 IE]

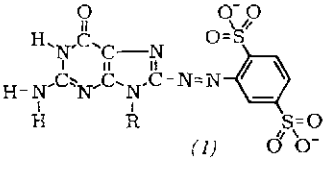
Enzymatic ω-oxidation of long-chain fatty acids containing 6, 8, 10, 12, 14, 16, or 18 carbon atoms was investigated by *M. Kusunose*, *E. Kusunose*, and *M. J. Coon*. They found that the enzyme concerned belongs to the group of the mixed-function oxidases, which generally catalyse oxidations by introducing an oxygen atom into the substrate molecule (one oxygen atom per substrate molecule). The second atom of the O_2 molecule is reduced to water by oxidation of a molecule of reduced diphosphopyridine nucleotide (DPNH). The

$$\text{Fatty acid} + O_2 + \text{DPNH} + H^{\oplus} \rightarrow \omega\text{-Hydroxy fatty acid} + \text{DPN}^{\oplus} + H_2O$$

oxidase isolated from a strain of *Pseudomonas* grown on hexane as sole source of carbon consists of two components, whose functions are not yet quite clear. The enzyme requires $Fe^{2\oplus}$ as cofactor besides DPNH and oxygen. – Lauric acid (C_{12}) is oxidized fastest, myristic (C_{14}), caprylic (C_8), and capric acids (C_{10}) almost as fast, and palmitic (C_{16}) and stearic acids (C_{18}) somewhat slower. Caproic acid (C_6) is not attacked. The Michaelis constants for the first four substrates are 3.3×10^{-5}, 3.9×10^{-5}, 1.2×10^{-3}, and 1.8×10^{-3} mole/l respectively. The pH optimum is near 7. The ω-hydroxy fatty acids are oxidized further by the same system with $\text{DPN}^{\oplus}$ as electron acceptor. / J. biol. Chemistry *239*, 1374, 2135 (1964) / –Hö. [Rd 262/471 IE]

Symmetrically substituted azobenzenes were produced from substituted aromatic amines by *C. H. Wheeler* and *D. Gonzales*. The amine (0.01 mole) is refluxed with 0.06 mole of dry activated MnO_2 in 50 ml of benzene for 6 h with a water trap. The hot solution of the product is then filtered. The yields of azobenzenes obtained from aniline and its *o*- or *p*-fluoro, *m*- or *p*-chloro, *p*-bromo, *o*- or *p*-iodo, *o*-ethyl, 3,5-dichloro, and 2,6-dimethoxy derivatives, and from *p*-anisidine, *p*-biphenylamine, and 2-aminopyridine were all over 90%. The oxidation is a bimolecular reaction at active sites on the MnO_2 surface; a mixture of two differently substituted anilines yields only the simple azo compounds and no mixed product. Nitranilines and aminobenzoic acids are not attacked by MnO_2, because here the nitro or carboxyl group is more strongly adsorbed on the MnO_2 surface. When these groups are sterically hindered, small yields of azo compounds are in fact obtained, *e.g.* 10% 4,4′dinitro-3,3′,5,5′-tetrachloroazobenzene from 3,5-dichloro-4-nitraniline. Polycyclic aromatic amines, *e.g.* 1-aminoanthracene, also fail to react, but polymerize instead, probably after oxidation to quinones. / Tetrahedron *20*, 189 (1964) / –Bi. [Rd 223/432 IE]

Selective labelling of guanine in polynucleotides has been achieved by *E. M. Moudrianakis* and *M. Beer*; this improves the chances of base sequence analysis by electron microscopy. Diazotized 2-aminobenzene-1,4-disulfonic acid reacts with guanine at pH 9 sixty times faster than with cytosine, adenine, thymine, or uracil, yielding the diazo compound *(1)*.



(1)

The reaction can be followed by spectrophotometry since *(1)* has λ_{max} at 382 mμ with $\varepsilon_{max} \approx 11000$. The 2-aminobenzene-1,4-disulfonic acid tag fulfils three demands placed upon chromophoric group for use in electron-microscopic investigations: it has sufficiently high specificity, the molecule is small enough not to disturb the native arrangement of the bases, and it introduces a substituent on the nucleic acid chain which causes a large local increase in electron density owing to its two sulfur atoms together with the nearby chain phosphorus atom. / Biochim. biophysica Acta *95*, 23 (1965) / –Hö. [Rd 263/472 IE]

The isoenzyme pattern of maize catalase has been determined genetically. *L. Beckman*, *J. G. Scandalios*, and *J. L. Brewbaker* investigated the endosperm catalase of two pure strains of maize and found that they differed in their rates of migration on electrophoresis (F = fast, S = slow). When they crossed the two species and the male parent plant had the S-property, they obtained a catalase isoenzyme pattern with an F-hand and three bands lying between F and S (FH bands). If the female parent was of the S type, the S-band and three bands lying between S and F (SH type) were observed. Crossing of the FH and SH species led to the S and F types again, together with FH and SH species in a ratio of 1:1. It is assumed that the enzyme is a tetramer, for this explains the occurrence of five isoenzymes: these have the compositions SSSS, SSSF, SSFF, SFFF, and FFFF. In a diploid organism, they ought to appear in the F_1 generation after crossing of F × S (male) types in numerical ratios of 16/81 FFFF, 32/81 FFFS, 24/81 FFSS, 8/81 FSSS, and 1/81 SSSS. The intensities of the bands correspond to these figures, and the appearance of only four bands can be explained by the fact that the concentration of SSSS was too low for detection. This work provides not only a feasible explanation of the phenomenon of isoenzymes, but also opens up a completely novel approach to the study of the structures of enzymes. / Science (Washington) *146*, 1174 (1964) / –Hö. [Rd 264/473 IE]

Base-catalysed addition of dimethylsulfoxide onto olefins and the pyrolysis of the resultant sulfoxides to give olefins with homologous carbon chains have been studied by *C. Walling* and *L. Bollyky*. The anion *(1)* formed from dimethylsulfoxide with, for example, potassium t-butoxide or NaH according to Equation (a) adds on rapidly and quantitatively to arylated olefins, *e.g.* 1,1-diphenylethylene *(2)*, to form new sulfoxides according to Equation (b), *e.g.* here *(3)*, m.p. 70 to 71 °C. The latter decompose at 150–200 °C under reduced pressure to a new olefin, here 3,3-diphenylpropene *(4)* in 96% overall yield, and probably methanesulfenic acid, which apparently decomposes further [Equation (c)]. – Thus, 1 mole of NaH is dissolved in 400 ml of dimethylsulfoxide and 1 mole of olefin is added. After dilution with water, the product is extracted with ether, the extract is concentrated, and the crude residue is subjected to pyrolytic distillation.

$$t\text{-}C_4H_9O^{\ominus} + CH_3SOCH_3 \rightleftharpoons t\text{-}C_4H_9OH + CH_3SOCH_2^{\ominus} \quad (1) \quad (a)$$

$$\underset{(1)}{CH_3SOCH_2^{\ominus}} + \underset{(2)}{(C_6H_5)_2C{=}CH_2} \rightleftharpoons \underset{(5)}{CH_3SOCH_2CH_2\overset{\ominus}{C}(C_6H_5)_2} \quad (b)$$

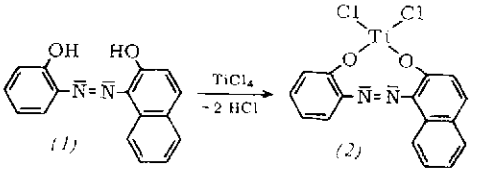
$$\underset{(5)}{CH_3SOCH_2CH_2\overset{\ominus}{C}(C_6H_5)_2} + CH_3SOCH_3 \rightleftharpoons \underset{(5)}{CH_3SOCH_2CH_2CH(C_6H_5)_2} + \underset{(3)}{CH_3SOCH_2^{\ominus}}$$

$$\underset{(3)}{CH_3SOCH_2CH_2CH(C_6H_5)_2} \xrightarrow{\Delta} \underset{(4)}{CH_2{=}CH{-}CH(C_6H_5)_2} + CH_3SOH\ (?) \quad (c)$$

Analogously, styrene yields 88% allylbenzene at 25 °C, while allylbenzene gives 92% 2-methyl-3-phenylpropene because of its isomerization to 1-phenylpropene in alkaline medium. The addition reaction [Equation (b)] does not take place with simple aliphatic olefins, *e.g.* cyclohexene, but any olefins that are capable of yielding resonance-stabilized carbanions such as *(5)* do react to give 3-arylpropylsulfoxides and hence 3-arylpropenes. / J. org. Chemistry *29*, 2699 (1964) / –Bi.

[Rd 222/431 IE]

Novel chelated catalyst systems for polymerizing ethylene at 60 °C and low pressures have been discovered by *K. J. Taylor*. When, for example, *o*-hydroxyphenylazo-β-naphthol *(1)* is treated with $TiCl_4$ in dry toluene at 20 °C, a dark opaque solution of the chelate *(2)* is obtained. If diethylaluminum chloride is then added, it combines with the free HCl to form



(1) *(2)*

ethylaluminum dichloride, which acts as cocatalyst during the

$$(C_2H_5)_2AlCl + HCl \rightarrow C_2H_5AlCl_2 + C_2H_6$$

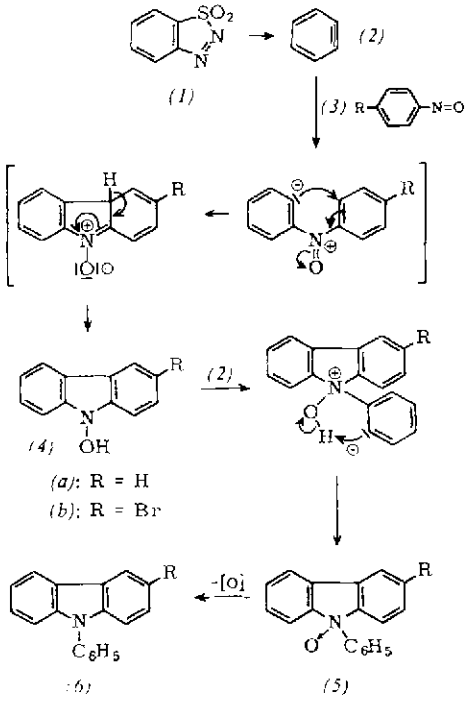
polymerization. The fact that it is the chelate *(2)* which participates in catalysing the reaction and not a Ziegler catalyst, which could be formed from dimethylaluminum chloride and $TiCl_4$ produced according to the equation

$$2\ TiCl_2R \rightleftharpoons TiCl_4 + TiR_2;\ R = -O-C_6H_4-N_2-C_{10}H_6-O-$$

is proved by the complete solubility of the catalyst system and the alterations in catalytic activity with changes in R. Further examples of R are *o,o'*-bis-*o*-hydroxyphenylazomethine and 3-chloro-6-hydroxy-2-methylphenylazo-β-naphthol. / Polymer *5*, 207 (1964) / –Hl. [Rd 225/433 IE]

The degradation of linear macromolecules during freeze-drying was studied by *F. Patat* and *W. Högner*. The concept developed by *W. Kuhn* [1] that the network fibers of high molecular-weight gels are ruptured by the growth of solvent crystals on freezing at –195 °C also applies to linear macromolecules, *e.g.* polystyrene PS 98 with $\bar{M} = 6.0 \times 10^5$ [2]. As the molecular weight rises, the probability of rupture increases for chain sections of equal length. In poor solvents, the macromolecules are coiled and have therefore less tendency to break than the straight macromolecules which occur in good solvents. Oxygen accelerates the degradation of polystyrene, for example: macroradicals produced by the homolytic cleavage of a bond have a great tendency to recombine owing to their close proximity; oxygen reduces this tendency by the formation of more stable peroxyl radicals. The degradation is also strongly influenced by the rate of freezing. At fast rates of freezing, the macromolecule behaves like a rigid body and is incapable of withdrawing before the advancing front of the growing solvent crystals and is therefore degraded more severely than at slower rates of freezing. / Macromolekulare Chem. *75*, 85 (1964) / –Hl. [Rd 226/434 IE]

Dehydrobenzene condenses with nitrobenzenes to form the carbazole ring system according to studies by *G. W. Steinhoff* and *M. C. Henry*. If dehydrobenzene (benzyne) *(2)* is prepared in the presence of nitrobenzene *(3a)* by thermolysis of 1,2,3-benzothiadiazole 1,1-dioxide *(1)* [3] in tetrahydrofuran by allowing the reaction mixture to warm up from –5 °C to room temperature, a 45.5% yield of *N*-phenylcarbazole *(6a)* is formed. Similarly, *(6b)* is obtained in 40% yield from *(3b)*. The reaction probably proceeds *via* the hydroxylamine derivative *(4)* and the unstable *N*-oxide *(5)*. If a one-step reaction occured instead, *(1b)* would be converted into *N*-(*p*-bromophenyl)carbazole, but the latter is not encountered. Support for the occurrence of the intermediates *(4)* and *(5)* is derived



from the observation that diphenylhydroxylamine can be converted into triphenylamine in 40% yield by dehydrobenzene under the same reaction conditions. / J. org. Chemistry *29*, 2808 (1964) / –Bi. [Rd 221/430 IE]

[1] *W. Kuhn*, Helv. chim. Acta *39*, 1071 (1956).

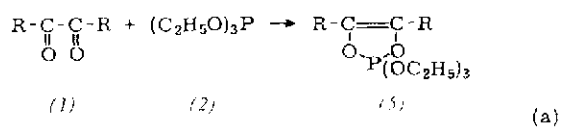
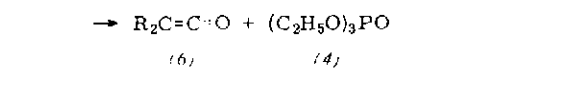
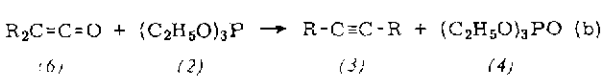
Diarylacetylenes and 1-alkyl-2-arylacetylenes can be prepared by deoxidation of 1,2-diketones with triethyl phosphite, as was discovered by *T. Mukaiyama, H. Nambu*, and *T. Kumamoto*. When 1 mole of benzil *(1)*, R = C_6H_5, was heated with 2 moles of triethyl phosphite *(2)* for 2.5 h at 215 °C without solvent under nitrogen, 60% diphenylacetylene and 88% triethyl phosphate *(4)* were formed, together with 24% dimeric diphenylketene as by-product. The yield of acetylenic products could be markedly increased both here and in the following examples by heating the adducts *(5)* formed exothermally from equimolar amounts of *(1)* and *(2)* in the presence of excess triethyl phosphite [5 moles per 1 mole of *(5)*] for



(a)





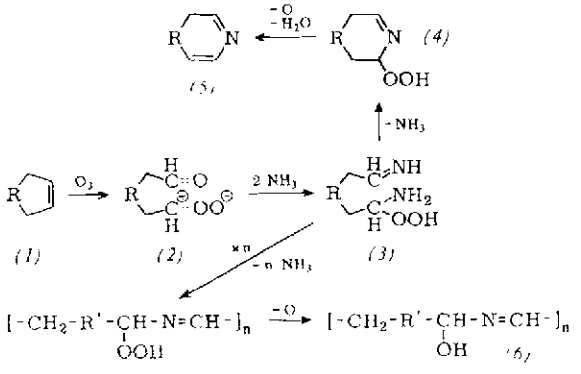
(b)

4–7 h in a sealed tube at 215 °C under nitrogen. Acetylenes prepared include diphenylacetylene *(3)*, b.p. 113–115 °C/2 mm, 81% yield; *(3)*, R = *p*-ClC_6H_4, m.p. 176 °C, 59%; *(3)*, R = *p*-$H_3COC_6H_4$, m.p. 146 °C, 58%; and propynylbenzene, b.p. 74 °C/15 mm, from 1,2-dioxopropylbenzene, 54%. Diphenylketene *(6)*, R = C_6H_5, also reacts directly with *(2)* to yield 65% diphenylacetylene according to Equation (b) [1]. / J. org. Chemistry *29*, 2243 (1964) / –Bi. [Rd 219/428 IE]

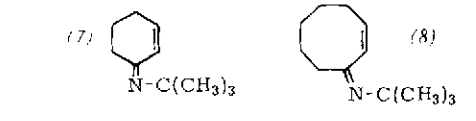
The ozonolysis of cyclo-olefins in ammonia was studied by *M. I. Fremery* and *E. K. Fields*. They treated olefins, *e.g. (1)*, as 5% emulsions in liquid ammonia or 50% aqueous ammonia containing a wetting agent (*e.g.* 0.5% Pronon 523) with one molar equivalent of ozone at −35 to −60 °C and obtained compounds such as *(2)*, which were either extracted from the reaction medium following evaporation of the ammonia or removed by steam distillation. The ammonia is relatively stable towards ozone in the presence of a more reactive olefin,

[1] *T. Mukaiyama* et al., J. org. Chemistry *27*, 3651 (1962).

but it reacts with *(2)* to form *(3)*. The further course of the reaction is largely determined by steric factors or by the ring size if the cyclo-olefins are unbranched. Cyclo-olefins with a five-membered ring, such as *(1)*, undergo a further intramolecular condensation leading to cyclic imines *(4)*, whose hydroperoxide group is reduced by NH_3 or by the K_2SO_3 added after the ozonization, the resultant alcohol then being dehydrated to form the six-membered N-heterocycle *(5)*, provided the latter is stable. If the cyclo-olefin ring is larger, the reaction proceeds by intermolecular polycondensation of *(3)* to yield hydroperoxy- and hence hydroxy-polyimines *(6)*, which produce dialdehydes on hydrolysis.



Thus, for example, cyclopentadiene yields 18% pyridine plus polymers, indene gives 62% isoquinoline, 3-methylindene gives 48% 4-methylisoquinoline, and indole gives 9% quinazoline. The poly(hydroxy imines) of type *(6)* produced from cyclohexene and cyclooctene can be hydrolysed to adipaldehyde, which condenses intramolecularly to cyclopentene-1-carboxaldehyde (18%), and suberic dialdehyde (26%), respectively. In contrast, when cyclohexene and cyclooctene are ozonolysed in t-butylamine, the imines *(7)*, b.p. 150 °C



(41%), and *(8)*, b.p. 75 °C/18 mm (49%), can be isolated; these probably arise from the 3-hydroperoxy derivatives formed in the O_2/O_3 current *via* the 3-ketones. / J. org. Chemistry *29*, 2240 (1964) / –Bi. [Rd 220/429 IE]

BOOK REVIEWS

Lexicon Alchemiae sive Dictionarium Alchemisticum (Lexicon of Alchemy and Alchemical Dictionary). By *Martin Ruland*. Photomechanical reprint of the 1612 Frankfurt/Main Edition. Georg Olms Verlagsbuchhandlung, Hildesheim 1964. VII + 487 pp., linen DM 68.– (about $ 17.00).

Soon after their appearance, the writings of *Paracelsus* initiated widespread controversy, for they contained many new names and concepts invented by their author or gave new shades of meaning to then known expressions. Consequently some disciples and admirers of *Paracelsus* compiled dictionaries designed to explain the meanings of his terms. These volumes included, for example, "Onomastica" by *Michael Toxites* (Strassbourg, 1574), the "Dictionarium Theophrasti Paracelsi" by *Gerhard Dorn* (Frankfurt/Main, 1583/84), and the "Onomasticum" by *Leonhard Thurneysser* (Berlin 1583). The "Lexicon Alchemiae" by *Martin Ruland*, was published in Frankfurt/Main in 1612 with a special imprimatur from the Kaiser for the period of ten years. It also contained, as the subtitle states, "Theophrast-Paracelsicarum Phrasium Planam Explicationem" (Distinct Explanations of Theophrastus Paracelsus' Phrases).

There is some uncertainty as to the person of the author, for *Jöcher* and *Ferguson* consider him to be *Martin Ruland the Elder* (1532–1602), who was physician-inordinary to *Philipp Ludwig*, the Duke of the Palatinate, and who introduced many chemicals, including antimony compounds, as medicines. *Thorndike*, on the other hand, considers the writer to be the son, *Martin Ruland the Younger* (1569–1611), who died in Prague as physician-inordinary to Kaiser Rudolph II. Since the dedication of the book bears the date 1611 and since the Kaiser's imprimatur – which was intended to suppress illicit copying of the book by another publisher under pain of retribution – is dated September 1607, it seems that *Thorndike's* opinion is more likely.

As usual, the "explicationes" (explanations) given here of *Paracelsus'* expressions are not unequivocal. For instance, it is written (p. 43) that "Annus philosophicus est mensis vulgaris" (the philosophical year is simply a month) but again (p. 330) that "mensis philosophicus est tempus putrefactionis... qui in aliquibus est triginta, in aliquibus quadraginta dierum" (the philosophical month is the time of putrefaction... which is sometimes thirty, sometimes forty days). The concept of

Alchemy is interpreted by *Paracelsus* to mean the preparation of pure substances for medicinal purposes: "Alchemia est impuri separatio a substantia puriori" (alchemy is the separation of impure from pure substance) on p. 26 or "est itaque ars chymica, ars physica separandi purum ab impuro ad conficiendum medicamenta tam corporibus humanis persanandis, quam metallicis ad summam perfectionem perducendis, accomodata" (the chemical art is a physical art adapted to separating the pure from the impure for making medicines, for curing human bodies, and for converting metals to the height of perfection) on p. 149.

A thorough knowledge of Latin is essential in order to understand the "Lexicon" even though explanations in German are frequently interspersed. However, anyone wanting to peruse original texts dating from the Middle Ages will have the necessary command of Latin and will be able to use this reprint with profit, for it often contains references to other classical authors of its day and age. *W. Ruske* [NB 322/180 IE]

Einführung in das anorganisch-chemische Praktikum (einschließlich der quantitativen Analyse) [Introduction to Practical Inorganic Chemistry, Including Quantitative Analysis]. By *J. H. Jander* and *E. Blasius*. S. Hirzel Verlag, Stuttgart 1964. 6th completely revised edit., XX + 483 pp., 97 figs., 4 tables, plastic covers DM 19.80 (about $ 5.–).

With this new edition of their book, the authors have succeeded in compiling a modern textbook which, like the previous editions, will certainly find resonance among students.

The theoretical chapters have been brought up to date, but it would have been pleasing if the concept of orbitals had been introduced and if the covalent bond had been dealt with more thoroughly in the section on "Ionic Theory and Bonding Types".

The preparative and analytical sections of the book are based on reliable practical procedures and characterization tests. The separation schemes for qualitative analysis are flawless and accurate, as the reviewer can confirm from his own experience. However, it is questionable whether the numerous organic reagents mentioned, *e.g.* magneson, sodium rhodizonate, morin, *etc.*, will be of much help to the student with chemistry as a minor subject, for the proper use of these substances generally demands some experience.

The quantitative section gives an excellent survey of the usual methods, including very modern methods, which are well illustrated by detailed descriptions of individual determinations. On the whole, the book can be highly recommended to both students and tutors alike.

O. Glemser [NB 353/211 IE]

Die Mutterkorn-Alkaloide (Ergot Alkaloids). By *A. Hofmann*. Sammlung chemischer und chemisch-technischer Beiträge. Edited by *R. Pummerer*, *L. Birkofer*, and *J. Goubeau*. New Series, No. 60. Ferdinand Enke Verlag, Stuttgart 1964. 1st Edit., VII + 218 pp., 27 illustrations, 50 tables, linen, DM 64.– (about $ 16.00).

The ergot alkaloids have undergone a dramatic history, first as the cause of devastating mass intoxications, then as valuable medicines, and finally as the subject of intense chemical investigations. Important advances within recent years, such as the total synthesis of the main ergot alkaloids by the author and his school and the succesful study of the biogenesis of lysergic acid, make the present volume particularly interesting.

The book has four sections, that dealing with the chemistry of the ergot alkaloids being the longest (159pp.). Descriptions are given of the properties and isolation of all the alkaloids of the lysergic acid and clavine types, including the identifications of their structures, their syntheses, analyses, biogeneses, and conversion into derivatives with different biological activities. The treatment given to the stereochemistry of lysergic acid and its derivatives is comprehensive and supplemented with explicatory formulae and therefore deserves special praise. In this connection, it is almost regrettable to think that these outstanding configurational studies were brought to a successful conclusion before there was a chance to apply the methods of NMR and mass spectrometry. Another notable feature of the book is the presentation given to the syntheses in the ergotamine group.

The other three chapters are much shorter and deal respectively with the botany (7 pp.) and history (6 pp.) of ergot and with the pharmacology and therapeutic applications of ergot alkaloids (22 pp.). The description of the psychotropic activity of lysergic acid derivatives and its discovery by the author in self-experiments will be read with excitement even by the non-pharmacologist.

The literature has been sifted up to the beginning of 1963. In addition, the book contains many more recent research results from the author's own laboratory. Regrettably, the book has no subject index, and a price of 7 cents per page. However, the condensed and lucid style and the complete coverage make it an extremely stimulating summary of this interesting field of natural products for chemists, botanists, and pharmacologists alike. *B. Franck* [NB 331/189 IE]

Taschenbuch für Chemiker und Physiker (D'Ans-Lax), Vol. II: Organische Verbindungen (Handbook for Chemists and Physicists, Vol. II: Organic Compounds). Edited by *Ellen Lax* in collaboration with *Claudia Synowietz*, Springer-Verlag, Berlin-Göttingen-Heidelberg 1964. 3rd completely revised edition, VIII + 1177 pp., linen DM 48.– (about $ 12.00).

"D'Ans-Lax" is due to appear in a new, completely revised edition. The reorganization of the book is noticeable already from its external appearance, for it has been divided up into three volumes. Volume II, "Organic Compounds", has just been published.

A feature that will be extremely valuable to many users of the book is the poignant introduction to the nomenclature of organic compounds written by *K. Dimroth*. Here the most important IUPAC rules for naming organic compounds are recorded in a version that is easy to read and to grasp; however, these are often mixed with older nomenclature habits, so that the list of methods for naming materials sometimes lacks in perspicuity. A table of the most important ring systems and their numbering is also included.

This introductory section is followed by a list almost 900 pages long – designated as Table 12 – of about 7000 organic compounds; for each substance; the name and a literature reference, the formula, molecular weight, melting or boiling point, and characteristic properties such as the state of aggregation, solubilities, odor, color, *etc.* are given. This table has always formed the core of the "D'Ans-Lax" for many chemists.

It is therefore regrettable that the nomenclature in this table is not uniform throughout. For example, the compound $CH_3–CO–CH_2OH$ is recorded under "Acetol" but $C_6H_5–CO–CH_2OH$ under "Benzolcarbinol". 4-Methyl-2-phenylpyrimidon-(6) is described as such, but its isomer 4-methyl-6-phenylpyrimidon-(2) is to be found – without any indication of the systematic name – under "Benzoylacetonharnstoff"! In the reviewer's opinion, the depiction of the formulae with dots instead of hyphens for bonds is unfortunate, because this notation is not as easy and rapid to scan.

The long list of compounds is followed by supplementary tables in which the compounds are arranged according to increasing melting and boiling points and according to their composition. A section with thermochemical data is also included.

It is hardly necessary to give "D'Ans-Lax" a good recommendation. This handbook is a standard work and the second volume of the new edition corresponds to this classification. The contents of the other volumes can be looked forward to. *H. Grünewald* [NB 315/173 IE]

Physical Methods in Heterocyclic Chemistry. Edited by *A. R. Katritzky*. Vol. I: Nonspectroscopic Methods. Vol. II: Spectroscopic Methods. Academic Press Inc., New York 1963. 1st edit., Vol. I: XI + 346 pp., numerous tables, linen $ 12.–. Vol. II: XI + 398 pp., numerous figs. and tables, linen $ 14.–.

It is the aim of this two-volume work to single out the application of the most important physical methods to the chemistry of heterocyclics and to summarize the literature on this subject. The following topics are discussed: in Vol. I: ionization constants (*A. Albert*), heteroaromatic reactivity, with a section on molecular-orbital calculations (*J. Ridd*), X-ray diffraction by heterocyeles (*W. Cochran*), solubilities of heterocyclic compounds (*W. Pfeiderer*), dipole moments in heterocyclic systems (*S. Walker*), and electrochemical properties in solutions (*J. Volke*); in Vol. II: electronic absorption spectra (*S. F. Mason*), nuclear quadrupole resonance (*E. A. C. Lucken*), nuclear magnetic resonance spectra (*R. F. M. White*), and infrared spectra (*A. R. Katritzky* and *A. P. Ambler*). As the titles of the chapters indicate, the selection of topics is somewhat random and by no means comprehensive. Some cnapters are somewhat beyond the general topic of the book.

Each chapter begins with a short, usually clear review of the principle of the specific method in question. This is followed by more or less detailed indications of its use in heterocyclic chemistry. The style of the individual chapters varies from author to author. Sometimes the treatment is superficial, but other chapters are very extensive and attack the subject matter with great thoroughness. On the whole, the hooks represent more a series of essays than a well rounded-off work, but the variety of their suhject matter and their numerous references (literature up to the start of 1962) provide many an incentive not only to the specialist in the field of heterocyclics.

K. Dimroth [NB 352/210 IE]

Fluorine Chemistry. Vol. III: Biological Effects of Organic Fluorides. By *H. C. Hodge, F. A. Smith*, and *P. S. Chen*. Edited by *J. H. Simons*. Academic Press, New York-London 1963. 1st edit., XI + 240 pp., 7 figs., 34 tables, linen $ 10.–.

The chemistry of organic fluorine compounds has developed rapidly since 1945. Fluorinated organic compounds are being used more and more as solvents, plastics, dyestuffs, and pharmaceuticals. Since the discovery of the high toxicity of fluoroacetate, the biological properties of organofluorine compounds have become part of the realm of toxicologists and biochemists. It is therefore a laudable enterprise that the authors have undertaken here in critically reviewing about 1600 publications which have appeared until 1961. The biological properties of fluoroacetate, fluorophosphoric acid derivatives, aliphatic fluoro compounds which may be used as solvents or working gases, and fluorinated pharmaceutical preparations are described on 54 pages. The metabolism of fluoroacetate is discussed critically and with reserve. The influence of organofluorine compounds on enzyme systems, microorganisms, viruses, and insects also receives mention. Next follow 130 pages of tables. The large number of articles to be evaluated makes any attempt at comprehensive treatment too difficult. It is therefore not surprising that the reviewer remarked the omission of some articles on enzyme inhibition with fluorine-substituted organic enzyme substrates. The authors have placed the main accent on toxicological aspects.

H. Machleidt [NB 349/207 IE]

Fluorine Chemistry. Vol. V. Edited by *J. H. Simons*. Academic Press, New York-London 1964. 1st Edit., XV + 505 pp., 89 figures, 80 tables, linen, § 16.50.

So far, Volumes I, II, III, and V of the series on "Fluorine Chemistry" started in 1950 are now available; Volume IV is still in preparation.

The first chapter of Volume V, which appeared in 1964, deals with the compounds of fluorine with other elements, including the actinides, but does not describe the inert gas fluorides, which have apparently become known only too recently. With this review, the corresponding twelve sections of Volumes I and II have been repeated in a highly condensed form and supplemented, particularly by preparative results obtained within the past two decades. In the second chapter, the physicochemical properties – mainly thermodynamic data – of carbon/fluorine compounds are collected and compared among themselves and with those of analogous hydrocarbons and chlorocarbons. This chapter supplements the discussion of preparative results in earlier volumes. The third section is devoted to the nuelear chemistry of fluorine, the production of radioactive fluorine isotopes, and their use as tracers in chemistry and biology. Also the radiation chemistry of fluorine compounds, particularly the influence of short-wave radiation on polymeric fluorocarbons, is dealt with.

In the final chapter, for the first time in the series, the applications of fluorine and its compounds in industry and technology are discussed. It is apparently assumed that the technology and use of inorganic fluorine compounds are familiar to the reader; the technical applications of hydrogen fluoride, boron trifluoride, and sulfur hexafluoride are only touched upon briefly, and it is only the application of fluorine and of some fluorine compounds as rocket fuels that receives extensive treatment. The main accent of this chapter lies on the multifarious uses of organic fluorine compounds, *e. g.* as refrigerants, fire-extinguishers, lubricant and aerosol solvents, dielectrics, plastics, and elastomers, and as surfactants in galvanizing and in the leather and paper industries for making products hydrophobic and oleophobic. Their increasing use as foaming agents for making foam rubber and plastics is not mentioned.

Thus, Volume V gives a comprehensive review of the present status of fluorine chemistry and at the same time recapitulates briefly the contents of the previous volumes.

H. Jonas [NB 342/199 IE]

Progress in Organic Chemistry. Vol. 6. Edited by *J. W. Cook* and *W. Carruthers*. Butterworths Scientific Publications, London 1964. 1st edit., VII + 256 pp., several figs. and tables, linen £2.17.6 (about $ 8.–).

As usual, the latest volume of this series brings progress reports from the pens of competent authorities. In the first chapter, *E. Haslam* and *R. D. Haworth* review the current status of research in the field of "Vegetable Tannins". In the second chapter, *M. F. Grundon* describes the interesting class of compounds of the "Bisbenzylisoquinoline Alkaloids". Structural elucidations, syntheses, stereochemistry, and biosynthesis are given particular attention. "Polyacetylenes and Related Compounds in Nature" and the biogenetic relationships between these compounds are discussed by *J. D. Bu'Lock*. *W. Schäfer* reviews the present situation of the "Chemistry of Phenoxazones" in the fourth chapter. Interest in this ring system has been augmented by the isolation and elucidation of the structures of the ommochromes, actinomycin, and the orceine dyestuffs. The next chapter on "Carbenes" by *W. Kirmse* gives an excellent review of the turbulent developments in this field of organic chemistry. In the final chapter, *S. F. Mason* demonstrates with examples the application of the molecular orbital theory to reaction equilibria and rate constants.

Progress reports by acknowledged experts, such as appear in so attractive a mixture in the present volume, are becoming more and more important in view of the ever increasing gush of articles flooding the chemical literature. Like its predecessors, the new volume of this series therefore represents a veritable embellishment of the chemical literature. However, it would have been useful for the reader if some indication were given of the date up to which the literature was reviewed for the individual topics.

H. Stetter [NB 355/213 IE]

Colloidal Surfactants. Some Physicochemical Properties. By *K. Shinoda, T. Nakagawa, B. Tamamushi*, and *T. Isemura*. Physical Chemistry. A Series of Monographs, Vol. 12. Edited by *E. Hutchinson* and *P. van Rysselberghe*. Academic Press, New York-London 1963. 1st Edit., 310 pp., numerous figures and tables, linen, $11.50.

This book is divided into four sections dealing with 1. the formation of micelles, 2. physicochemical studies in aqueous solutions of nonionic surfactants, 3. adsorption phenomena, and 4. monomolecular layers.

In parts 1 and 2, an extensive discussion is given of micelle formation, the critical micelle concentration (CMC), and the various factors effecting this concentration (*e.g.* the structure of the surfactant, additives, or mixtures of surfactants). This text is based on a particularly broad review of the literature. In part 3, the fundamentals for calculating adsorption and the influences on adsorption at air/solution, solution/oil, and solution/solid interfaces are dealt with. Also some special aspects of adsorption are described, *viz.* the adsorption at a solution/mercury interface and the interaction between surfactants and hydrophobic or hydrophilic colloids. In part 4, the behavior of films of surface-active compounds and polymers, particularly synthetic polymers, is discussed.

K. Shinoda and his colleagues have successfully evaluated recent literature in order to give a review mainly of micelle formation and adsorption phenomena from the standpoint of the physicochemical properties of surfactants, paying particular attention to Japanese publications. Many important research communications in this field were written in Japanese and were thus difficultly accessible to scientists in other countries.

P. Kurzendörfer [NB 340/198 IE]

Basic Principles of Organic Chemistry. By *J. D. Roberts* and *M. C. Caserio*. W. A. Benjamin, Inc., New York-Amsterdam 1964. 1st, edit., XXV + 1315 pp., numerous figs. and tables, clothbound $ 15.30.

This book is a successor to the 1935 edition of "Organic Chemistry" by *H. J. Lucas*, and is no less original than its predecessor. Despite the conventional subdivision according to substance classes, the authors manage to place the fundamental principles of synthesis, structure and stereochemistry, bonding phenomena, and reaction mechanisms in the forefront of their discussion. They also succeed in cleverly applying the latest developments in the subject in a didactic fashion without either becoming unintelligible for the beginner or giving only superficial treatments. In all discourses on reaction mechanisms, they carefully stress the pertinent experimental background.

The introduction to spectroscopic methods in Chapter 2 is particularly striking. Structure and bonding relationships are given a solid theoretical foundation on the basis of spectroscopic, thermochemical, and thermodynamic results. Atomic and molecular orbitals are introduced critically alongside the theory of resonance. The modern character of the book is emphasized by its chapters on the biogenesis of terpenes and steroids, color photography, organic photochemistry, polymers, and organosilicon, organophosphorus, and organoboron chemistry, *etc.* No important facet of organic chemistry has been overlooked.

The authors have successfully introduced a subdivision according to reaction types subordinate to their main division according to compound classes. For the compound classes, the modes of preparation are given only in tables, and a detailed discussion of their scope, the reaction conditions, and synthetic importance is then to be found under the reaction type. Thus, for example, "Aliphatic Substitution and Elimination" are to be found in the chapter on alkyl halides, and "Addition Reactions" under alkenes. Reaction mechanisms are always given if they are required to contribute to an understanding of the reaction. A separate index of methods of preparation of all classes of compounds shows how much importance the authors justifiably attach to adequate training in methods of synthesis.

The length of the book is not caused by an excess of material, but by the thorough discussion of essential principles that is given. There are several hundred – occasionally very difficult – questions and exercises interspersed in the text, which can only be answered by proper application and combination of these principles, not by unconnected knowledge of facts. These "Problems" often go beyond the material dealt with in the book. This raises a problem only when the answers to such questions are essential for an understanding of the subsequent text or when important reactions appear only in the exercises (*e.g.* sugar extension or sugar degradation reactions or peptide syntheses with carbodiimides).

There is very little fault to be found with the excellently illustrated text: the bridged bromonium radicals rejected on p. 189 have been positively detected in the meantime by *Skell*; the preference of a two-step mechanism for the Diels-Alder reaction is not necessarily correct (p. 268); the intermediates of the Bucherer reaction (p. 909) are tetralonesulfonic acids and not hisulfite adducts of the keto form of naphtholes (*A. Rieche* 1960); *Goldschmidt*'s 9-chlorophenanthroxyl (p. 916) does not give an electron spin resonance signal and is probably a dimeric quinol ether (*E. Müller* 1959).

This didactically outstanding textbook can be heartily recommended to every student of chemistry and to chemists who wish to refresh or renew their knowledge. It should be especially worthwhile for beginners to work through the not altogether easy text alongside their organic chemistry courses.

O. Rüchardt [NB 379/237 IE]

Advances in Organic Chemistry: Methods and Results. Edited by *R. A. Raphael, E. C. Taylor*, and *H. Wynberg*. Vol. 3. Interscience Publishers, a Division of John Wiley & Sons, New York-London 1963. 1st edit., 333 pp., several illustrs. and tables, linen £5.5.0 (about $ 14.50).

The valuable series on "Advances in Organic Chemistry" continues with this third volume, which contains four review articles. The first contribution by *R. I. Reed* on "Mass Spectrometry as a Structural Tool" discusses the most important applications of mass spectrometry to structure elucidations (74 pages). The literature is reviewed effectively only until 1959; since then, good monographs on this subject have appeared, which also take the latest rapid developments into account. However, the reviewer does not claim to be an expert judge in this field.

The next essay by *D. M. Brown* on "Phosphorylation" gives a surprisingly comprehensive survey in 83 pages. Such a complete review of this subject was hitherto not available. The report is critical and comprehensive, easy to read and well organized. The fact that it will nonetheless not always be easy for the newcomer to this field to find the most suitable phosphorylation methods for his purposes by mere perusal of this article, is probably due to the complicated nature of the phenomenon of phosphorylation.

The following articles by *R. A. Boissonnas* on amine protecting groups for peptide syntheses (31 pp.) and by *J. F. W. McOmie* on "Protective Groups" (103 pp.) fully discuss these topics without any significant overlapping. The review by *McOmie* is especially interesting and contains a wealth of information: it was an excellent idea of the editing committee to include articles containing a review of all protective groups. The series, particularly Vol. 3, belongs in every chemical library.

F. Cramer [NB 356/214 IE]

Physical Organic Chemistry. By *K. B. Wiberg*. John Wiley & Sons, Inc., New York-London-Sydney 1964. 1st Edit., VIII + 591 pp., numerous illustrations and tables, linen, £ 4.0.0 (about $ 11.00).

In the foreword to this book, *K. B. Wiberg* says that he has made an attempt to write a useful textbook which concentrates on the physical- chemical aspects of "Physical Organic Chemistry". By this he means the theoretical background of physical measurements on organic compounds, the mathematical treatment of experimental data, and the physical interpretation of empirical relations. This also includes the quantum-mechanical theory of the chemical bond, which is dis-

cussed together with electronic spectra and the theory of vibrational and nuclear magnetic resonance spectra in the first section on "Bonding and Spectra". The second section, "Equilibria", deals with chemical equilibria and includes chapters on the partition function, heats of formation, solvent and isotope effects, linear free energy relationships, and acidity functions, *etc.* The third section, entitled "Kinetics", first describes methods of determining the rate constants and rate laws from kinetic data and then discusses the absolute rate theory, kinetic isotope effects, the influences of solvents, linear free energy relationships, and acid catalysis. The book closes with a long appendix containing tables, a discussion of the mathematical treatment of NMR spectra and kinetic data, and an introduction to programming for electronic computers, together with a collection of Fortran programs for the problems dealt with in the book. "Physical Organic Chemistry" is expressly written as a textbook and therefore does not attempt an exhaustive compilation of the publications that have appeared on individual fields; instead, the methodology is explained by means of carefully selected examples, which are given a detailed treatment. Each chapter is rounded off with problems and reading lists.

This brief description of the contents suffices to show that precisely those borderline fields are dealt with which are essential for understanding many publications but which still receive only little attention in textbooks and lecture courses. From this point of view the attempt to write a useful textbook has been highly successful. The value of the book is not impaired by the relatively large number of misprints and by an occasionally subjective selection of material (*e. g.* the somewhat one-sided presentation of the arguments of *Dewar* and *Schmeising* on the delocalization of π-electrons). Unfortunately, however, the book is rather unbalanced and at times didactically inadequate, as the following examples indicate, which could easily be multiplied.

In the chapter on vibrational spectra, the terms normal modes, degenerate vibrations, and parallel and perpendicular type bands are applied without being explained. Methods are given for calculating the spectrum of an A_2X_2 spin system, but the definition of an A_2X_2 system is sought for in vain. Frequently (*e. g.* on pp. 5, 215, and 453), at the vital point in a detailed mathematical derivation, the next step is introduced merely by "it can be shown that...". On p. 16, the same symbol is used within a single formula with two different meanings. On p. 28, the text and the figure and on p. 420 the text and the table do not agree. The equations are not numbered, and thus the text is sometimes hard to understand and cross-references become difficult. Factual errors occur, for example, on p. 116, where it is stated that the integral (11/12) disappears when using orthonormal orbitals, but this is only true when applying the Mulliken approximation, which is not mentioned. On p. 453, it is stated: "The properties of determinants deduced previously (*e. g.* by multiplication of a row or a column with a factor, the determinant is multiplied by this factor) also apply to matrices".

Most of the inaccuracies and broken trains of thought could be remedied, and the missing definitions could be included without increasing the size of the book if the figures on pp. 29–35, *etc.* were reduced to reasonable dimensions and if the appendix were shortened: Especially since it is assumed that the reader makes use of electronic computers, 24 pages with tables of the thermodynamic functions of a harmonic oscillator and 13 pages of overlapping integrals are superfluous, when other sections are kept so brief (*e. g.* the treatment of symmetry by the group theory is restricted to 3 pages!) that they must necessarily remain incomprehensible without reverting to further literature.

One would like to see as many students as possible acquainted with the material presented here. The book should therefore be strongly recommended. Unfortunately, however, the reader must be willing to take the trouble that the author should have invested in order to develop this book into a really useful text. It can only be hoped that a completely revised edition will soon appear. *M. Klessinger* [NB 341/204 IE]

Radiolysis of Hydrocarbons. Edited by *A. V. Topchiev*. English edition edited by *R. A. Holroyd*. Elsevier Publishing Co., Amsterdam-London-New York 1964. 1st Edit., XII + 232 pp., 69 figures, 35 tables, linen, DM 36.– (about $9.00).

In the radiation chemistry of hydrocarbons, there are some reactions, *e. g.* cracking, that are of preparative and technological interest. Kinetic studies are of particular importance since they furnish information on the reactions of radicals, on energy-transfer mechanisms, and on the influence of catalysts on radiolytic reactions. *Topchiev*'s book goes into all of these matters insofar as they have been investigated in the Institute for Petroleum Research in the U.S.S.R. between 1957 and 1961. The book contains a lot of experimental results and theories on the radiation chemistry of hydrocarbons, and thus gives an excellent survey of advances in the radiolysis of hydrocarbons in the U.S.S.R. up till 1961.

Radiation chemistry flourishes and fades with the rapid changes in theoretical concepts, which in turn depend upon the advances in molecular and radiation physics and in experimental methods. *Topchiev*'s book conveys the impression of being dedicated especially to energy transfer. The phenomenon of energy transfer is demonstrated convincingly by electron spin resonance measurements on irradiated solid hydrocarbons containing minute amounts of an inhibitor which, although immobile, reduces the radical yield. The author presents a theory according to which inhibition occurs by radiationless transfer before the energy of electronic excitation is converted into vibrational energy. The assumption that this theory – which is developed in clear and precise mathematical terms – is generally applicable to inhibition effects, even in liquid systems, appears to be hardly justified, because of the complexity of radiochemical reactions.

Energy transfer from oxide catalysts to adsorbed hydrocarbon molecules is also described in detail and formulated mathematically. Attention is drawn to the difference between energy dissipation by fast charged particles in gases and in condensed materials. For example, the principle of "collective" excitation which is occupying the theoreticians in radiation chemistry so much at present, is anticipated by the discussion on p. 113.

In concluding it can be said that although some of the material presented is probably already superseded by newer results because of the rapid development in this field of research, *Topchiev*'s book contains many ideas on the theory of radiation chemistry with which the expert in this discipline ought to be familiar. *A. Henglein* [NB 343/200 IE]

Experimental Spectroscopy. By *R. A. Sawyer*. Dover Publications Inc., New York 1963. 3rd Edit., X + 358 pp., 110 figures, paperback, $2.00.

Sawyer restricts his discussion to spectroscopy in the range from the ultraviolet to the infrared available with prism or diffraction grating spectrographs: other ranges and interference methods are intentionally excluded. A simple, easily understandable discourse on the experimental aspects of spectroscopy is developed in 13 chapters, starting from fundamentals and going on to instrumentation, then to photographic processes, the determination of wavelengths and intensities, and finally discussing ultraviolet and infrared spectroscopy and spectrochemical analysis. However, some essential points are overlooked; for example, the light intensity of a spectrograph is characterized by its relative aperture, without making it clear to the inexperienced reader that the length of the basis of the refracting element is the most important factor for the energy density per wavelength region in the plane of the image.

The chapter on photographic processes contains so many elementary mistakes that it is hard to imagine how the author's attention has not been called to this by users of the previous editions. The photographic process is described in details that are unnecessary for practical spectroscopy and

which swell up the book with redundant and erroneous information. This section has apparently not been revised since the appearance of the first edition in 1944. – The subject index is unsatisfactory: it should be more extensive and built up on a better system of classification.

Despite these shortcomings, the book may be recommended as a cheap but authoritative introduction to spectroscopy.

W. F. Berg [NB 332/190 IE]

Infrared Spectroscopy and Molecular Structure. An Outline of the Principles. Edited by *M. Davies*. Elsevier Publishing Co., Amsterdam-London-New York 1963. 1st Edit., XIII + 468 pp., 171 figs., 70 tables, linen ca. DM 42.– (about $ 10.50).

This book is intended for all who use infrared spectroscopy not merely as an empirical fingerprint method but as a theoretically founded process for the investigation of the structures and properties of molecules. Here the theoretical and methodical principles as well as the scope and limitations of the various applications of infrared spectroscopy are presented by 13 authorities in clear and understandable terms. The most important concepts and facts, from both the chemical and physical points of view, are unraveled so lucidly even when the material dealt with is complicated that also those who are less experinced find a good introduction to this discipline. The fact that the authors have concentrated on important examples contributes significantly to this effect.

The introductory section written by the editor is followed by chapters on instrumentation and experimental techniques *(A. E. Martin)*, on long-wave infrared spectroscopy in the region from 1 to 200 cm^{-1} which has only recently become utilizable *(G. R. Wilkinson)*, on the infrared spectra of simple molecules *(W. J. Jones)*, on the calculation of force constants *(J. M. Mills)*, and on Raman spectra *(J. C. Evans)*. The chapter by *D. Hadzi* on the origin of characteristic group frequencies deserves special mention. Further sections deal with the infrared spectra of crystals and high polymers *(S. Krimm)* and of inorganic compounds *(E. A. V. Ebsworth)*. The technique of infrared intensity measurements, which becomes more and more important, and its application for the determination of polarity are discussed by *J. Overend*. The methods of dispersion measurements, including the practically important technique of attenuated total reflection, are described by *J. Fahrenfort*. The book then closes with chapters on hydrogen bonding and solvent effects *(H. E. Hallam)* and on infrared emission spectra *(W. C. Price)*. The text is supplemented by some 800 references.

The editor has succeeded well in coordinating the contributions from the individual authors into a largely homogeneous book with an up-to-date selection of themes. On account of its admirable didactic qualities, it is recommended in general as a textbook of spectroscopy for the advanced specialist and for those striving to attain this status, for it teaches the reader to think in spectroscopic terms. The outlay and print of the book are exemplary in their clarity.

W. Lüttke [NB 326/184 IE]

Infrared Spectra of Inorganic and Coordination Compounds. By *K. Nakamoto*. John Wiley & Sons, Inc., New York-London 1963. 1st Edit., XII + 324 pp., numerous illustrs. and tables, linen £ 2.12.0 (about $ 7.25).

There has long been a lack for a book reviewing the greatly increased literature on vibrational spectra of inorganic compounds and giving a critical appraisal of publications in this field with regard to both the practice of spectroscopy (*e. g.* for structural analysis) and the theory of molecular physics as related to force constants. The author attempts to satisfy this need, to assign the published data to normal vibrations, and to interprete their significance for the structures of molecules and ions. The first of the three sections of the book (63 pp.) gives a brief but lucid discourse on the theory of spectra. In the second part (69 pp.), the spectra of simple organic compounds are discussed, again very briefly. In the large third section, which forms the mainpart of the book, data for inorganic complex compounds are described. Five appendices (45 pp.) include *inter alia* tables of point groups, F and G matrix elements of model compounds, and, by way of an example, the complete normal coordinate analysis of an acetylacetonate. The text is supplemented by numerous tables, illustrations, and literature references.

On account of the expansiveness and ready surveyability of the material and its intelligible presentation, the book could be warmly recommended to inorganic chemists interested in spectroscopy and especially to complex chemists, if the author had only discussed the material (particularly in Part II) with greater criticism. For example, in contrast to the data given on p. 71, hydrogen halides (except for HF) do not associate in the condensed phase; this follows from the fact that the $\nu X-H$ frequencies of liquid hydrogen halides are lower by 2–3% than those of the gaseous compounds. It does not follow from the appropriate spectra that there are "essentially covalent bonds" in AgCN and AuCN (p. 73); the high CN frequencies indicate only the presence of Ag···CN···Ag···CN··· bridges (or Au). A free $UO_2^{\oplus}$ ion (p. 77) cannot be observed, according to more recent publications; ligands are always coordinated in the plane vertical to the UO_2 axis. Results dating from 1938 are given for H_2Se and D_2Se (p. 83), although more recent measurements *(Palik, 1959)* with some remarkably great differences in frequencies are available. NT_3, PT_3, and AsT_3 (p. 84) have never been measured, but were only calculated. The C_{2v} structure given for N_2F_2 on p. 102 has been shown to be incorrect; the compound is subject to geometric isomerism. The numerical values given for CH_4 and CD_4 (p. 104) are not up-to-date. The data for NH_4Cl (p. 104) are not characteristic of the $NH_4^{\oplus}$ ion, because ν_4 (1400 cm^{-1}) here is strongly split by Fermi resonance. Insufficiencies of this kind are easy to eradicate in a new edition, and it would also be desirable for the author to go deeper into the relations between spectra and molecular structures (*e. g.* how to derive information about the bond order from the force constants). Sufficient space can be made quite easily by omission or reduction of some figures (*e. g.* on pp. 74, 94, 147, 170, 174, and 200). All in all, the book is usefull for the critical, well-informed reader; the outward appearance and the print are good.

W. Lüttke [NB 327/185 IE]

Inorganic Thermogravimetric Analysis. By *C. Duval*. Translated from the French by *R. E. Oesper*. Elsevier Publishing Co., Amsterdam-London-New York 1963. 2nd Edit., XV + 722 pp., 77 figs., linen ca. DM 67.– (about $ 17.00).

The principle of thermogravimetry is the continuous registration of alterations in weight of a solid sample during a heating program. Thanks to the development of modern automatically recording thermobalances, this process is easy and rapid to execute and is a versatile aid in the investigation of inorganic compounds: determination of moisture contents and water of crystallization, controlled drying to constant weight, testing of analytical precipitates for their suitability for gravimetric estimations, detection of the limits of stable phases, quantitative analysis based on the loss of weight during decomposition reactions (even of two components of a mixture), investigations of reactions between solids and gases, *etc.*

Duval has compiled the first extensive monograph on this field, in the development of which he has himself taken a significant part. In the first section of the second edition (164 pp.), following a historical introduction, the apparatus and experimental methods of thermogravimetry are dealt with. This part has been extended by about 100 pp. in comparison with the 1953 edition, owing mainly to the description of the automatically recording thermobalances which have been developed in the meantime and which are now commercially available. The main section of the book (519 pp.) contains the results of thermogravimetric investigations of analytical precipitates from 78 elements, arranged according to increasing atomic weight. In all, the behavior of about 1200

precipitates during thermolysis is described; here the author has relied mainly upon the results of his own school. In contrast to the first edition, the reproduction of thermolysis curves for individual compounds has been omitted, because the detailed appearance of the curves depends too much upon the experimental conditions. The author restricts his description to the principal parts of the curves, the horizontal sections and the stability regions, and to the suitability of individual compounds for purposes of gravimetric analysis. *Duval*'s book is thus a comprehensive reference work on thermogravimetry.

Despite the widespread application of thermogravimetry, it appears to the reviewer that the relationships of this method to the thermodynamics of heterogeneous equilibria have not yet been sufficiently pointed out, even though a profitable field is offered here. The processes that occur during thermogravimetry are in fact often highly complex and depend upon the experimental conditions, since the ideal conditions of isobaric decomposition under equilibrium conditions are normally far from being attained. For this reason, the form of the thermolysis curves depends upon the particle size and pretreatment of the sample, upon the rate of flow and composition of the gaseous phase, and upon the rate of heating. Therefore, the decomposition points found in this way need not be identical with the temperatures at which the equilibrium pressure of a gaseous decomposition product, such as water vapor, reaches the value of 1 atmosphere.

These comments are not intended to depreciate the value of *Duval*'s book, but rather to serve as an incentive for its readers to occupy themselves with the still unused potentialities of thermogravimetry.

The lay-out and appearance of the book are excellent, in keeping with the high standards of the Elsevier publishing house. This volume should not be missing in any chemical library or inorganic chemistry laboratory.

Friedrich Becker [NB 325/183 IE]

Analytical Chemistry of Uranium $_{92}U^{238.03}$. Published by the Academy of Sciences of the U.S.S.R. and edited by *D. I. Ryabchikov* and *M. M. Senyarin*. Translated from the Russian by *N. Kaner*. Series: Analytical Chemistry of Elements. Israel Program for Scientific Translations, Jerusalem 1963. 1st Edit., VII + 374 pp., 70 figs., 51 tables, linen $14.00.

Because of the widespread use of uranium in nuclear technology, there are numerous methods for determining and detecting uranium in ores, uranium compounds, and alloys scattered in the literature, but so far no comprehensive monograph on the analytical chemistry of uranium has appeared (with the exception, perhaps, of a few difficultly accessible compilations [1–4]). The present volume is a critical review of material from over a thousand publications. Following a general introduction to the chemistry of uranium (Chapter 1), in which the most important properties of the element, its isotopes, and some of the most common uranium minerals are described, a short review is given in Chapter 2 on the special inorganic chemistry of uranium, with particular stress upon analytical aspects. Valuable tables of solubilities and complexing constants in various solvents are given.

In Chapter 3, on the qualitative detection of uranium, it is mainly color and fluorescence tests that are dealt with. Besides the well known fluorescence reaction in the NaF bead, reactions with inorganic and organic color reagents are described in detail and compiled in a long table. Although the interferences caused by other elements are described, no reference is made to the behavior of neptunium and plutonium. There is also no mention here of the classical precipitation reaction as sodium uranylacetate crystals, which also works with $NpO_2^{2\oplus}$, $PuO_2^{2\oplus}$, and $AmO_2^{2\oplus}$. This is found somewhat out of place on p. 236.

Chapter 4 contains 174 pages devoted to methods for estimating uranium and thus makes up over a third of the book. It is subdivided into three sections: A) chemical methods of analysis, B) physico-chemical methods of analysis, and C) physical methods of analysis. The subsection on colorimetric and spectrophotometric methods of analysis without and with the use of organic color reagents is worth mentioning. Here, too, the reader finds welcome extensive tabulations with data on extinction coefficients (pp. 89 and 114).

Methods for separating uranium from other elements are given in Chapter 5, and methods for determining uranium in minerals and industrial wastes in Chapter 6. Although, for example, the analysis of uranium/zirconium alloys is described briefly (p. 301), no attention is called to the danger of explosions on dissolution of such alloys in nitric acid. The book closes with Chapter 7 on the testing of the purity and estimation of impurities in uranium, and with a comprehensive bibliography (1093 references). Here the translator has made some errors in his retranscription of names from Kyrillic into Latin script, for it should be *Götte* and not *Gotte* in reference 554, and *Ladenbauer* and not *Ladenbayer* in reference 981. The numerous practical procedures given would have profited from tests of their experimental usefulness. The print is clean and tidy, but the lay-out could have been better arranged.

Despite these minor shortcomings, the book is recommended to all higher institutions of chemical learning, to uranium processing industries, and to analytical laboratories, for it covers practically the whole of the more important literature on the analytical chemistry of uranium in a single volume and helps one to find rapid recourse to original publications via its bibliography.

F. Weigl [NB 324/182 IE]

Nobel Lectures. Physiology or Medicine 1942 – 1962. Published by the Nobel Foundation. Presentation Speeches and Laureates' Biographies. Elsevier Publishing Co., Amsterdam-London-New York 1964. 1st edit., XIV + 839 pp., numerous illustrs., a few tables, price for complete 3-volume work in half-linen Hfl. 240.–.

The Nobel Prize in Physiology or Medicine was awarded twenty times between 1942 and 1962, including thirteen awards for work in biochemical research. For this reason, the present volumes can be recommended to the chemist. Many, especially biochemists, will find material in the contents which touches directly their own work. However, this does not represent the prime purpose of the book; its aims go much further. All the Nobel lectures held between 1942 and 1962 in the fields of physiology or medicine are reproduced here in English in chronological order, together with the laudations and biographies of the prize-winners. The result is an extremely vivid and fascinating picture of the development of medicine, physiology, and physiological chemistry over these two decades. When one reads at the end of the Nobel lecture by *Sir Alexander Fleming* (1945) "the time may come when penicillin can be bought by anyone in the shops..." and then considers how soon afterwards not only penicillin but also a great number of its derivatives became available in sufficient amounts, then one appreciates even as an outside observer just how much has been achiev-

ed. The book will be indispensable to the historian, for it offers first-hand insight into scientific history, when, for example, *Hans Adolf Krebs* reports on the "evolution" of the tricarboxylic acid cycle or when *E. C. Kendall* relates the exciting developments which, though beset with disappointments, finally led to the synthesis and therapeutic application of cortisone.

The publishing house can be congratulated to this undertaking of making all the Nobel lectures available in collective volumes, and it is to be hoped that these reproductions of testimonies of great human achievements will arouse the interest they deserve.

Organic Dyes as Photoelectric Semiconductors

BY DR. HANS MEIER

STAATLICHES FORSCHUNGSINSTITUT FÜR GEOCHEMIE, BAMBERG (GERMANY)

Photoconduction in organic dyes is caused by the formation and migration of electronic charge carriers, and is not due to impurities or photochemical decomposition. The phenomena of dark and light-induced conduction in dyes can therefore be interpreted in the same way as in inorganic semiconductors.

A. Introduction

In spite of *Zcodro's* discovery in 1919 [1] that organic dyes undergo slight changes in conductivity on illumination, and the observation of similar phenomena in anthracene several years earlier [2, 3], systematic investigation of this effect did not commence until thirty years later. This delay might well have been due to the predominant application of inorganic semiconductors, brought about by the rapidly developing science of semiconductor physics after 1920 and initiated by the work of *Gudden* and *Pohl* [4–8]. The slow response, irreversibility, dependence on the surrounding gas, and small magnitude of the then known photoelectric effects of organic substances [1–3, 9, 10] suggested that changes in the resistivity on illumination were due to bleaching rather than to internal photoelectric effects analogous to those occurring in inorganic photoconductors.

Growing interest in the elucidation of the spectral sensitization of photographic materials and in photochemical aspects of biology led to a systematic investigation of the photoelectric behavior of dyes. *Vartanyan* [11] in Russia, *Nelson* [12] in the United States, and *Noddack et al.* [13–16] in Germany began independent studies in the early 1950's. *Vartanyan* and *Nelson* obtained evidence of photoconduction in basic dyes only, but *Noddack's* group demonstrated that acidic and nonionic dyes also exhibit this effect. From the very beginning, the laws established from a study of more than 50 dyes of various types indicated an electronic mechanism in accord with the phenomena observed in inorganic photoconduction effects [14–16]. Thermoelectric power measurements and the Hall effect have since established clearly that electronic charge carriers formed in the solid dyes, rather than impurities or decomposition products, are responsible for photoconduction.

B. Fundamentals

The agreement between photoconduction phenomena of organic and inorganic photoconductors leads to an approach to the fundamental semiconductor properties of organic dyes according to the theory of photoconductors in general [7, 17–20].

I. Thermal and Optical Excitation Energy

Photoconduction is based on the formation of negative and positive electronic charge carriers by optical means, whereas dark conduction depends on the thermal excitation of electrons and positive holes (dissociation or auto-excitation).

$$\sigma_D = \sigma_{D0} \exp(-\Delta E_{therm}/2kT) \quad (1)$$

The thermal activation energy, ΔE_{therm}, is obtained from the temperature coefficient of the dark conductivity σ_D and is in substantial agreement with the energy of the light quanta, ΔE_{opt}, which must be absorbed to produce photoconduction. ΔE_{opt} can be determined from the limiting wavelength λ_g corresponding to the absorption edge or from the long wavelength limit λ_g^* of the photoconduction. The required relationship is

$$\Delta E_{opt} = hc/\lambda_g;\ \Delta E_{opt} = hc/\lambda_g^* \quad (2)$$

The agreement of the excitation energies ΔE_{therm} and ΔE_{opt} of intrinsic semiconductors indicates that dark and light-induced conduction are distinguished merely by the nature of the excitation of the charge carriers. Propagation of the carrier through the solid is subject to the same laws in both the dark and illuminated state.

This rule is not vitiated by occasional deviations such as the displacement of the threshold wavelength of the internal photoelectric effect to longer wavelengths than the absorption edge, or the difference between excitation energies measured by thermal and optical means respectively. These deviations are simply due to the presence of impurity levels formed by added foreign atoms (*e.g.* in defined form in extrinsic semiconductors), lattice imperfections, and dislocations, which can also excite charge carriers.

II. n- and p-Type Conductivity

Thermal and optical excitation produces an equal number of electrons and positive holes (defect electrons) in the semiconductor. Both migrate through the solid under the influence of an electric field to produce the observed conductivity [21]. If dislocations are present in the solid, charge carriers can be excited also from these sites. In the case of donor centers, the conductivity is due predominantly to electrons (n-type conductivity); acceptor centers accept electrons to form displaceable positive holes which are the major charge carriers (p-type conductivity).

III. Characterization of Conductivity

To characterize the conductivity of a solid, data concerning the lifetime τ, the mobility μ, the mean free path w and, in the special case of photoconduction, the quantum yield G, are significant in addition to the nature of the charge-carrier. The relationships between these quantities can best be illustrated by a discussion of the photoconductivity of solids (semiconductor cross-section $B \times D$ [cm^2], electrode spacing L [cm], semiconductor volume v [cm^3].

1. *Lifetime, Mobility, Mean Free Path, Transit Time*

Free mobility of the optically (or thermally) formed charge carriers is limited to their mean lifetime τ which is terminated by recombination with ionized dislocations, capture centers, oppositely charged carriers, and so on. During this period, a charge carrier moving with a velocity u traverses a distance w, the mean free path:

$$w = \tau u \quad (3)$$

or

$$w = \tau \mu \mathfrak{E} \quad (4)$$

since

$$u = \mu \mathfrak{E} \quad (5)$$

In Equations (4) and (5), μ [cm^2 volt^{-1} sec^{-1}] is the mobility of the charge carriers and $\mathfrak{E}$ is the field strength. Assuming that g charge carriers are formed per cubic centimeter per second, *i.e.* gLBD or gv in the system considered, each of which travel an average distance w, the photocurrent flowing in the outer circuit is given by

$$I_{phot} = gve\tau\mu\mathfrak{E}/L \quad (6)$$

When the transit time T which a carrier requires to travel from one electrode to the other [given by Equation (7)] is substituted in Equation (6):

$$T = L/\mu\mathfrak{E} \quad (7)$$

it follows, since $u = L/T$ and $u = \mu\mathfrak{E}$ that:

$$I_{phot} = gLBDe\tau/T \quad (8)$$

At equilibrium the number of charge carriers formed per unit time is equal to the number of charge carriers which disappear by recombination, so that the carrier concentration Δn is given by

$$\Delta n = g\tau \quad (9)$$

and

$$I_{phot} = \Delta n ve\mu\mathfrak{E}/L \quad (10)$$

For a semiconductor in which L, B, and D are each 1 cm, the photocurrent density j is given by

$$j_{phot} = \Delta ne\mu\mathfrak{E} \quad (11)$$

Hence if Ohm's law ($j = \sigma\mathfrak{E}$) is valid, the photoconductivity is given by

$$\sigma_{phot} = \Delta ne\mu \quad (12)$$

For photoconduction by electrons and positive holes with equilibrium concentrations Δn_n and Δn_p and mobilities and μ_n and μ_p respectively, we have

$$\sigma_{phot} = e(\Delta n_n\mu_n + \Delta n_p\mu_p) \quad (13)$$

$$j_{phot} = e(\Delta n_n\mu_n + \Delta n_p\mu_p)\mathfrak{E} \quad (14)$$

Equation (14) presupposes that both the mobilities and the field strength $\mathfrak{E}$ inside the semiconductor do not change on illumination. This condition is practically fulfilled for the mobilities, but formation of space charges inside the semiconductor changes $\mathfrak{E}$, so that Ohm's law is no longer obeyed.

[21] *E. Spenke*: Elektronische Halbleiter. Springer, Berlin 1956.

2. *Quantum Yield*

The quantum yield G may be expressed as the ratio of the number of charge carriers flowing through the outer circuit (I_{Phot}/e) to the number of light quanta (gv) absorbed in the same time. From Equation (6) we therefore obtain:

$$\frac{I_{phot}/e}{gLBD} \equiv G = (\mu\tau)\mathfrak{E}/L \qquad (15)$$

Substitution of the transit time T from Equation (7) leads to:

$$G = \tau/T \qquad (16)$$

G is also known as the "gain factor" [22] (Section F).

IV. Effect of the Contacts on the Photocurrent

The photoconductivity of inorganic semiconductors often shows complex behavior due to the effect of the electrodes and possible space charges. The question thus arises whether charge carriers can enter the photoconductor from the electrodes.

1. *Blocking Contacts*

a) Electrons and Positive Holes are Mobile

If the charge carriers formed by illumination have the same mobilities, an increase in the field strength increases the rate at which carriers reach the electrodes, but no charge carriers are supplied from them if contact barriers are present. As soon as all optically formed charge carriers are being removed at a given field strength, saturation of the photocurrent occurs and the quantum yield reaches its maximum value of unity. Movement of the two types of charge carrier in opposite directions can give rise to a space charge which is superposed on the applied field in the semiconductor and leads to a deviation from the linear relationship between current and illumination intensity, especially at low fields.

Occurrence of saturation currents does not indicate the presence of contact barriers in every case. Saturation can take place at high fields also with electrodes which release charge carriers, because of the formation of space charges. This is the case, for example, when the transit time T ($=L/\mu\mathfrak{E}$) is less than the period $\tau_R = \varepsilon\varepsilon_0/\sigma$ required to compensate the space charge (ε = dielectric constant; $\varepsilon_0 = 8.86 \times 10^{-14}$ sec ohm^{-1} cm^{-1}; σ = conductivity), so that the elimination of the space charge by the injected charge carriers is no longer operative.

b) One Charge Carrier Only is Mobile

When only one type of charge carrier migrates towards the oppositely charged electrode, while the other remains effectively stationary, a high space charge is formed in the vicinity of one of the electrodes. Since the space charge neutralizes the field in the photoconductor, only the charge carriers formed in the vicinity of this electrode can contribute to form a very small photocurrent.

2. *Replenishment Electrodes*

When the thermal work function of one electrode is small compared to that of the semiconductor, the eliminated charge carriers can be replaced by the electrode. Strictly speaking, this is equivalent to an extension of the lifetime, so that quantum yields $G > 1$ are possible when $\tau > T$ as is clear from Equation (16). Since these replenished charge carriers can lead to the disappearance of space charges, the electric field inside the semiconductor remains substantially homogeneous.

Ohm's law is therefore obeyed at high fields, becoming invalid only when space-charge-limited currents are involved. Saturation currents are observed for the case $T < \tau_R$ (see Section B. II. 1. a)), since the injected charge carriers can no longer effectively compensate the space charges [17]. It is also possible for the current to be limited by space charges generated by the moving carriers as soon as the concentration of the injected carriers exceeds the concentration n_i of the excited carriers. From this limiting potential $V_R = n_i eL^2/2\varepsilon$ upwards, the current grows at a faster rate than indicated by Ohm's law (cf. Section D. II.).

It is noteworthy that space charges can be used to force a replenishment of charge carriers from electrodes having a higher thermal work function than the semiconductor (cf. Section F. II.).

A distinction was formerly made between a primary photocurrent ($G < 1$) and a secondary current ($G > 1$) [4, 5]. Since the replenishing process at the electrode – which is ultimately responsible for $G > 1$ – does not strictly represent a secondary process, this distinction is not necessary.

V. The Effect of Capture Centers

Lattice defects, impurities *etc.* produce so-called trapping centers in semiconductors. These can accept charge carriers, and consequently have a particularly strong effect on the response times, *i.e.* on the rate of change of current when the illumination is altered [22, 23].

As explained in Section D. VII., centers of this nature are probably responsible for a number of temperature effects in photoconduction.

VI. Energy Relationships in a Solid

1. *The Band Model*

The band model is a schematic representation of the energy states of the charge carriers in a solid. In this representation, the electron energies are plotted along the vertical coordinate, and the horizontal coordinate indicates the spatial distribution. This model shows a large number of energy levels, most of which can be unified to form groups or bands (Fig. 1).

[22] *A. Rose*, RCA Review *12*, 362 (1951).

[23] *H. Meier*, Z. physik. Chem. *208*, 340 (1958).

In principle, each band originates from a discrete energy level of an atom (or molecule) capable of being occupied by electrons. The electron interaction (exchange degeneracy) causes an originally discrete atomic or molecular level to be split into many components on transfer into the solid. Since these exchange degeneracy effects increase with decreasing spacing of the atoms and molecules in the lattice as a result of greater overlap of the wave functions, a reduction in the spacing will lead to a greater band width, *i.e.* to a greater energy difference among the partial levels. Energy bands can be formed from particles up to 10 Å apart [24].

Electrons which pass into the level of an empty or partially filled band by thermal excitation can be regarded as freely mobile when they take up energy from an applied field. When the predominant migration is in the conduction band E_L, n-type conductivity occurs. In a filled ground-state band E_V, any holes behave as positive charge-carriers (defect electrons), as is confirmed by Hall-effect measurements and other evidence. Hence, p-type conductivity is obtained when these carriers predominate.

2. *Definition of Important Energy Levels in Solids*

A knowledge of the following energy magnitudes (see Fig. 2) is important for a discussion of the photovoltaic effects or the effect of contact materials:

a) Fermi Levels

The Fermi energy E_F is the limit of the energy levels of a solid up to which a filling with electrons occurs at the absolute zero of temperature, and is identical with the electrochemical potential of the electrons. Since the probability f(E) of filling a level having energy E is given by the Fermi-Dirac relationship

$$f(E) = \frac{1}{1 + \exp[(E - E_F)/kT]} \qquad (17)$$

it is clear that only at higher temperatures is there a significant probability for the energy levels $E > E_F$ to be occupied.

Whereas E_F for metals lies in the middle of the conductivity band, it falls inside the forbidden energy zone in the case of non-conductors and intrinsic semiconductors. For n-conductors the Fermi level is displaced towards the conduction band because of the electron-filled (donor) energy level lying in the forbidden zone; in p-conductors it is displaced towards the ground-state band (see Fig. 1).

Illumination produces an increase in the number of electrons in the conduction band, and their concentration n_L and that of the vacant sites in the conduction band (effective density of state) N_c obey the general relationship

$$n_L/N_c = \exp[-(E_L - E_F)/kT] \qquad (18)$$

when $n_L \ll N_c$. Hence, E_F on illumination must be higher than the Fermi level in the dark [$(E_L - E_F)$ decreases]. The new position of the Fermi level is called the quasi-Fermi level. For illuminated p-conductors the quasi-Fermi level lies below the dark value E_F (see Section C. I. 3.).

The significance of the Fermi level in solids – in addition to providing data concerning the filling of the levels – is above all that E_F provides exact information about systems in contact (*e.g.* metal/semiconductor). An interchange of electrons must constantly take place on the contact surface, so that in the equilibrium state E_F has the same value in the linked systems, *i.e.* the Fermi edge E_F runs horizontally.

Since transfer of electrons from one solid to the other must take place to balance the different Fermi levels, an electrical double layer is formed on each contact surface producing a space charge in semiconductors and dyes (see Section G). Among other phenomena, this space charge produces the photovoltaic effects. Applied to the band model, it causes the bands to curve to an extent which is identical for all terms (see Fig. 2).

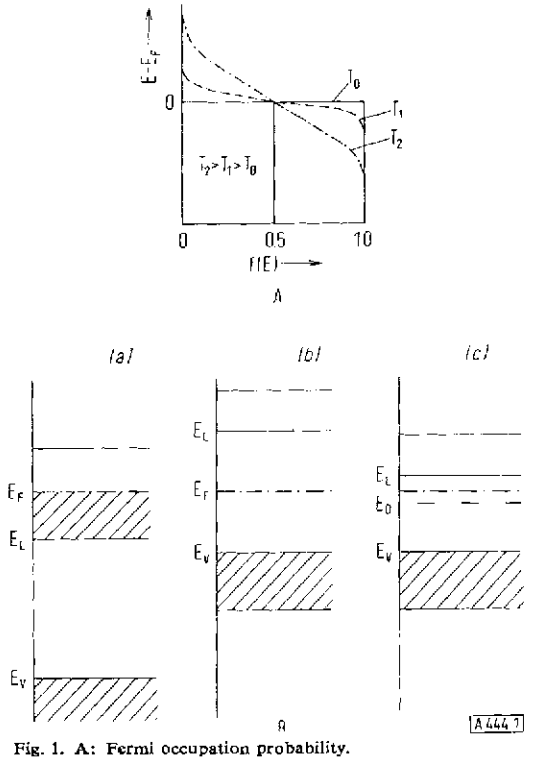

Fig. 1. A: Fermi occupation probability.
B: Position of the Fermi levels in metals (a), intrinsic semiconductors (b), and semiconductors (n-type) (c).

b) Thermal Work Function

The thermal work function ψ is the thermal energy required to remove an electron from a solid. ψ is the difference in energy between the electrostatic surface potential, possibly influenced by a double layer potential jump, and the Fermi level.

The magnitude of the work function can be determined from the contact potential (ex Volta potential) K [see Equation (19)] of two substances in vacuum if the work function of one of the solids is known.

$$K = \psi_1 - \psi_2 \qquad (19)$$

The contact potential is determined by two methods: (1) the Thomson vibration method [21], in which the Volta potential generated on a vibrating condenser is balanced by a counter-EMF; (2) by plotting a current-

[24] *A. F. Joffe:* Physik der Halbleiter. Akademie-Verlag, Berlin 1958.

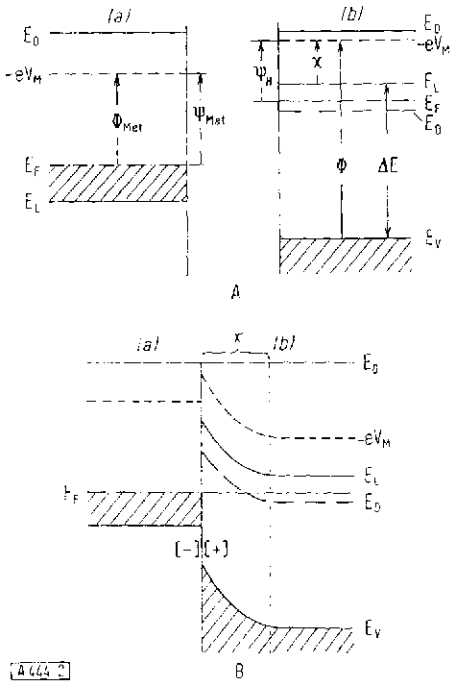

Fig. 2. Energy levels in a metal (a) and an n-type semiconductor (b). A separately; B in contact (x denotes the space charge zone). The crystal energy or the chemical bond energy of the electrons (E_L, E_D, *etc.*) is measured relative to the electrostatic energy $-eV_M$ (V_M = macroscopic electrostatic potential, possibly due to macroscopic space charges).

potential curve for the photoelectric or thermal emission of electrons (for measurements on dyes, cf. [26–28]). It should be noted that when interference by adsorbed gases is eliminated, ψ is equal to the Fermi energy E_F.

c) Photoelectric Activation Energy

The photoelectric activation energy Φ is the energy required for the photoelectric emission of an electron, and can be determined from the long-wavelength limit of the external photoelectric effect. For metals, Φ and ψ are identical, but for semiconductors this is not the case, since here photoelectric emission emanates from impurity levels or from fully occupied valence bands and not from Fermi levels [*]. For photoemission from the valence band, Φ is identical with the ionization potential, and hence can be used to determine the position of this band.

d) Energy Band Spacing

The distance between the valence band and the conduction band $\Delta E = (E_L - E_V)$ (see Section B. 1.) can be determined from the absorption spectrum by measurement of the limiting wavelength λ_g or from the threshold wavelength λ_g^* for photoconductivity, provided no excitation by lattice defects takes place.

e) Electron Affinity and the Position of the Conduction Band

The electron affinity χ is defined as the negative work necessary to transform an electron from outside the solid into the conducting state, and is equal to the energy E_L of the lower edge of the conduction band of a semiconductor. For dyes, χ was calculated from measurements of Φ and ΔE [29], using the relationship

$$\chi = \Phi - \Delta E \qquad (20)$$

Other possible methods of determining χ are the measurement of the redox potential or of the polarographic half-wave potential [30, 31].

In this connection, it should be stated that Scheibe's rule [32] indicates that the first excited state of many organic molecules lies about 3.4 eV below the zero level E_0. The conduction band in dyes therefore lies about 3.4 eV below the macropotential. It is worth noting that measurements of χ from photoelectric activation energies Φ and the bandwidth ΔE in thin photoconducting layers of dyes, using Equation (20), lead to values [26] of the same order of magnitude as that indicated by Scheibe's rule (cf. Section D.X). This result demonstrates that the rule, which was intended for single molecules, holds also for dye layers, and that the characteristic energy functions of the semiconductors and the methods worked out for their determination can be applied to organic solids [33].

C. Measurement of Photoconduction in Dyes

I. Methods of Measurement

In principle, the photoelectric behavior of a dye can be studied similarly to that of an inorganic system. However, the high resistance of the solid dyes, their high extinction coefficients, the difficult preparation of single crystals, and the possibility of interference by photochemical reactions often make it necessary to modify the procedure used for inorganic materials.

1. *Photoresistance*

The decrease in resistance on illumination is determined by the change in the current at a given external EMF. The current increase recorded by a galvanometer or electrometer can be converted to the increase in conductivity using the dimensions of the layers of dye between the electrodes (see Section B. III. 1.).

[33] *L. E. Lyons* and *J. C. Mackie*, Proc. chem. Soc. (London) *1962*, 71.

Sandwich and surface-type cells are used for the measurement (see Fig. 3). In surface cells the dye layers are deposited uniformly between two electrodes applied onto glass or quartz in the form of a screen (Fig. 3 A) (suitable distance apart <0.1 mm); in sandwich cells the layer is packed between a lower metal electrode and an upper semitransparent electrode evaporated on the dye [15, 25, 34–36].

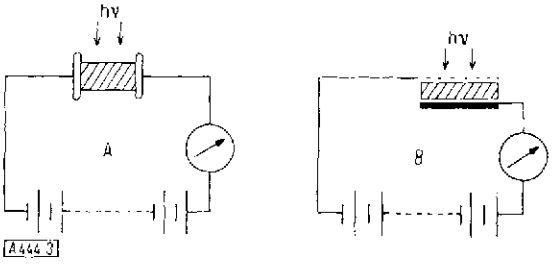

Fig. 3. Scheme of the Surface (A) and Sandwich (B) arrangement.

2. *The Condenser Method (Dember Effect)*

This method was initially developed by *Bergmann* [37] for the testing of powdered inorganic semiconductors. The dye is placed between two partly transmitting, insulated plates of a condenser charged by the charge carriers liberated by the changing illumination (photoelectric EMF about 0.01–0.1 mV/mW light energy [38–42]). Since the charge carriers follow the concentration gradient produced by the absorption of light, the sign of the EMF produced indicates the type of majority carrier [40, 43–47]. This procedure does not permit the determination of the photoelectric sensitivity when the illumination generates positive and negative charge carriers in approximately equal concentrations. Because of the insulation between dye and condenser, only the induced charge is determined and no current flows.

3. *Photocontact Potential*

Terenin et al. [40, 44, 48, 49] have used the change occurring on illumination in the contact potential between palladium and the dye for the study of the photoelectric sensitivity of various compounds. The change in potential was measured by the Thomson vibration method. The sign of the change (which is of the order of ±0.5 mV) provides information about the nature of the majority carriers formed. The differential displacement of the Fermi level on illumination of n- or p-type conductors, however, is likely to play a bigger part than the diffusion of the majority carriers into the semiconductor [44] (cf. Section B. VI. 2. a)).

4. *Short-Term Photoconductivity*

In addition to photoconductivity induced by prolonged illumination, flash-induced photocurrents are also of interest. The current produced provides information about the response times, and hence about possible photochemical reactions, and allows the measurement of μ and T.

a) Measurement of the Response Time

Response times of the order of milliseconds can be conveniently measured, for example by *Hauffe's* method [50], by a comparison of the oscilloscope trace of the burning of a flash bulb and the variation of the generated photocurrent with time. Using intermittent illumination (50–500 c.p.s.) it is likewise possible to measure photocurrent relaxation times of 5×10^{-6} to 1×10^{-2} sec on dyes [51–53].

b) Pulse Technique

In the pulse measurement technique proposed by *Kepler* and *Le Blanc* [54, 55], the migration of the charge carrier produced by a flash of 1–2 μsec duration is recorded oscillographically. The current pulse is a direct measure of the transit time T. A knowledge of this value permits the calculation of the mobility μ, when the EMF V and the electrode spacing L are known, using Equation (7) as follows:

$$\mu = L^2/VT \qquad (21)$$

5. *Photovoltaic Effects*

Photovoltaic effects, which are characterized by the appearance of photoelectric potentials and currents in the absence of applied potentials, are measured analogously to those in inorganic photoelectric elements. Both the open-circuit EMF V_∞ and the short-circuit current I_0 (current in a very low external resistance) are measured. Fig. 4 shows the arrangement used for the measurement of the photovoltaic effect of both inorganic and organic systems.

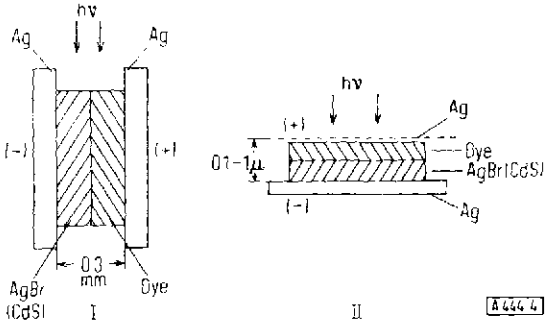

Fig. 4. Arrangement for determining the photovoltaic effects in inorganic/organic systems. Illuminated area 1 cm².

6. *Electrophotographic Methods of Measurement*

In this method the photoconductor properties are determined by measurements of the light-induced decay of the corona discharge-generated electrostatic charge on an organic layer. Although this process, taken from electrophotographic practice, has so far been employed predominantly for the study of organic high polymers [56], it seems fundamentally suitable for the study of photoconducting dye layers. The difficulties associated with the deposition of electrodes could well be avoided in this way.

7. *The Becquerel Method*

In the Becquerel arrangement the change in the potential of an illuminated dye electrode immersed in an electrolyte is measured [13, 59]. Although this effect can be used in some cases for the measurement of the photoelectric sensitivity [13, 59], its principal application lies in the investigation of the mechanism of photochemical bleaching processes in dyes. A positive or negative charge on the electrode will, for example, provide information as to whether the bleaching is due to photochemical reduction or oxidation of the dye [25, 60–62].

II. Preparation of the Photoconducting Dye Cells

1. *General*

Dyes are generally studied in thin layers obtained either by rapid precipitation from a volatile solvent or by sublimation in high vacuum, *e.g.* for merocyanines. Use of the correct technique for the preparation of the samples (control of crystal structure) improves the photoconducting properties of the product [63–64, 67–70]. The different modifications of the phthalocyanines do in fact possess different electrical and thermoelectric properties [65, 66]. It is noteworthy that the results obtained on single crystals of dyes, including tests of the directional dependence of conductivity [71 to 73], are quite unambiguous (for the case of phthalocyanines see [71, 74–79]).

2. *Purification*

Purification of the dyes by chromatography [64] or sublimation in high vacuum [80] does not reduce the photoconductivity, and may even increase it. This fact once again denies the frequent suggestion that impurities are responsible for the photoconduction. For example, the specific conductivity of Nacrosol Black B [*] increases from 10^{-11} to 10^{-7} ohm^{-1} cm^{-1} on purification [81]. Similarly, purification by zone melting does not eliminate the conductivity of heterocyclic compounds [82].

D. Properties of the Dye Photoconductors

I. Dark Conductivity

The dark conductivity of dyes is of the order of 10^{-10}–10^{-14} ohm^{-1} cm^{-1} and, in analogy with inorganic semiconductors, it increases with temperature in ac-

cordance with Equation (1) [50, 71, 83–89]. It is interesting to note that the thermal activation energy ΔE_{therm} determined from the slope of the linear plot of log σ_D against 1/T from Equation (1), is closely related to the structure of the organic solid. For example, ΔE_{therm} for linearly condensed hydrocarbons can be expressed as a function of the number of rings n by the relationship [90]:

$$\Delta E_{therm} = (17-n)^2/100 \quad (22)$$

In addition, it is found that ΔE_{therm} generally decreases with increasing number of electrons N, in accordance with the relationship given by the electron gas theory [89, 91]. If the relationship between ΔE and N for the open [Equation (23)] and cyclic [Equation (24)] π-electron systems is represented graphically, then the

$$\Delta E = 19.2(N+1)N^2 \quad [eV] \quad (23)$$

$$\Delta E = 38/N \quad [eV] \quad (24)$$

ΔE_{therm} value obtained from conductivity measurements on many organic compounds – including dyes [86] – lies between the two curves [89]. Deviations generally point to a perturbed conduction process [92]. The value of ΔE_{therm} = 1.7 eV [71, 93] measured for single crystals of phthalocyanine leads to the conclusion that the 18 π-electron system is responsible for light absorption and for conduction. The agreement of the ΔE_{therm} values with the ΔE_{opt} values obtainable from the upper wavelength limit of the photoconductivity is also worth noting (cf. Section B. I. and Table 1) [49].

Table 1. ΔE_{therm} and ΔE_{opt} of some dyes, calculated by means of Equations (1) and (2).

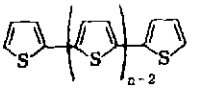
	Phenosafranine	Pinacyanol	Cu-phthalocyanine
ΔE_{therm} (eV)	2.08	1.8	1.7
ΔE_{opt} (eV)	2.07	1.77	1.63

II. Spectral Dependence of Photoconductivity

The results of numerous investigations [39, 41, 50, 77, 79, 94–98] have confirmed that the action spectra [*] of the photoconductivity measured on thin layers of dyes, including those of associated dye molecules, are in substantial agreement with the absorption spectra [42]. This proves that the energy absorbed by the molecule – and not absorption by lattice imperfections – is the cause of photoelectric conduction.

Deviations observed for thick layers [94, 96], which occur in surface-type cells (photocurrent minimum near the absorption maximum) are probably due to only a fraction of the charge carriers formed at the surface reaching the electrical field between the electrodes. With illumination through the gap between the electrodes, these deviations are eliminated [96]. With a sandwich-type cell of, *e.g.* phthalocyanine single crystals [77], the action and absorption spectra correspond. This behavior of single crystals of aromatic compounds can be used to determine the absorption spectrum [99].

Kuhn et al. [98] have found that in the case of polythienyl *(1)* built into a sandwich-type cell with barium stearate, the action spectrum of the photoconduction differs from the absorption



(1)
n=6

spectrum of the oriented dye in the layer but agrees with the spectrum in solution. It is assumed that the photoconduction is due to a small fraction of the molecules, which cannot be detected in the absorption spectrum, having the unperturbed planar structure, as in the solution.

III. Dependence on the Potential

In organic and inorganic conductors alike, Ohm's law is generally found to be valid up to field strengths of 10^3 V/cm [75, 88, 100], the maximum being 10^5 V/cm [101, 102] (cf. Fig. 5). At higher fields the current increases at a faster rate than the potential [25, 75, 90, 103] – the Wien-Poole effect – or saturation of the photocurrent occurs [15, 104]. It is not known to what extent the conditions mentioned in Section B. IV. 1. (blocking contacts, *etc.*) occur in the formation of saturation currents or to what extent currents limited by space charges must be assumed in the case of ohmic contacts ($T < \tau_R$) (cf. Section B. IV. 2. and [105, 106]). Significantly, if ohmic contacts which replenish charge carriers are present, Ohm's law ($I \propto V$) is replaced by

Childs' law ($I \propto V^2$) for space-charge-limited currents [102] above a limiting potential. Measurements on phthalocyanine [75] show this transition point.

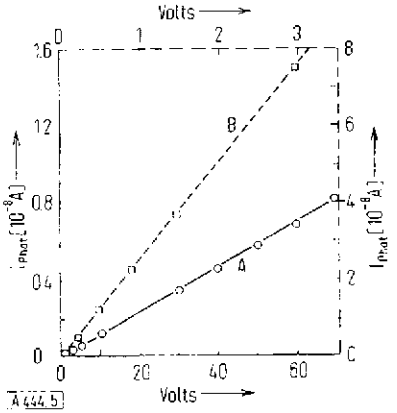

Fig. 5. Dependence of the photocurrent on the applied potential for A (lower abscissa, left-hand ordinate): Cu phthalocyanine (surface-type cell), and B: merocyanine A-10 (sandwich-type cell).
Illumination conditions: A. Unfiltered white light; 1.8 mW/cm².
B. λ = 6220 Å; 370×10^{13} quanta/(cm² sec).
Cell dimensions: Electrode spacing $\leqslant$0.01 cm (A) and 10^{-4} cm (B); illuminated area 1 cm².

To clarify numerous problems concerning the current-potential relation, it would be desirable to study metal/dye systems systematically, with special reference to the work function, the type of the majority carrier, the type of contact, and possible space-charge-limited currents [107, 108].

IV. The Intensity Dependence

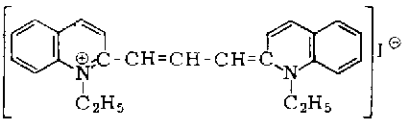
Numerous dyes exhibit a linear growth of the photocurrent in sandwich-type cells with increasing intensity of light B [36, 80, 109]. Measurements on phthalocyanine surface cells [96] show a proportionality between the photocurrent and $B^{1/2}$. Similar relationships between I_{phot} and B are known for many inorganic and organic photoconductors [110] and can be derived kinetically [17].

V. Quantum Yield

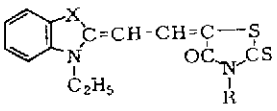
The quantum yield G (cf. Section B. III. 2.) is of the order of unity in several undoped dyes [25, 80, 104], *e.g.* in malachite green (G = 0.2), pinacyanol *(2)* (G = 0.37) and merocyanine A-10 *(3)* (G = 0.6).

These values conflict with the view that photoconduction is a result of a photochemical bleaching process, since the quantum yield for an oxidative bleaching process is of the order of 10^{-3} [25]. The quantum yield depends on the following factors:

1. G increases with decreasing layer thickness; *e.g.* for crystal violet it increases from 0.06 for a layer 1×10^{-5}cm



(2)



(3): X = S; R = C_2H_5
(4): X = O; R = CH_3

thick to 0.33 for a 3×10^{-6} cm layer. This rule was established by means of Becquerel cells [59] with a surface-type arrangement [104] and by means of the external photoelectric effect [111].

2. In agreement with Equation (15), the quantum yield increases with decreasing distance between the electrodes at constant field strength and layer thickness (cf. Table 2 [104]).

Table 2. Relation between the quantum yield and electrode spacing for crystal violet (λ = 5870 Å; $\mathfrak{E}$ = 7000 volts/cm; layer thickness 3×10^{-6} cm)

L [cm]	0.08	0.042	0.02	0.01	0.003
G	0.0009	0.0012	0.0026	0.0052	0.014

These figures prove that the general relationships of Section B. III. hold also for dye photosemiconductors.

3. According to measurements carried out to date, G varies with the dye structure as follows [25]:

In triphenylmethane dyes the photoconductivity is proportional to the degree of methylation of the amino groups [12, 64]; replacement of a methyl group by ethyl or by hydrogen has a sensitivity-reducing effect, *i.e.* $CH_3 \gg C_2H_5$, H, C_6H_5. The photoconductivity increases with the number of methine groups, *i.e.* with a growth in the conjugated chain length, as is demonstrated from studies of cyanines and merocyanines.

VI. The Rise and Decay Process

The photocurrent of dye semiconductors is established within 10^{-5} to 10^{-6} sec, as shown by measurements on metal-free and copper phthalocyanines [52, 96]. It is possible that the onset of current, detection of which is governed by instrumental limitations, occurs even more rapidly. At the end of illumination the current decays with time constants ranging between 10^{-3} sec and several seconds or more. It has been demonstrated that the current decay generally follows a second-order law in accordance with Equation (25) [11, 50, 96, 112, 113], *i.e.* it can be traced to a bimolecular charge-carrier recombination.

$$1/I(t) = Kt + \text{const.} \qquad (25)$$

With large photocurrents – corresponding to high charge-carrier concentrations – decay is slower than

[107] *W. Helfrich* and *P. Mark*, Z. Physik *166*, 370 (1962).
[108] *J. Adolph*, *E. Baldinger*, and *I. Grānacher*, Physics Letters *8*, 224 (1964).

[110] *S. C. Ganguly* and *N. K. Chandhury*, Rev. mod. Physics *31*, 1013 (1959).
[111] *F. Hlucka*, Z. Physik *81*, 66, 516 (1933).
[112] *R. C. Nelson*, J. chem. Physics *22*, 885 (1954).

expected from Equation (25). *Tollin* [96] attempted to explain this anomaly by a concentration dependence of the charge-carrier mobility, possibly analogous to that found in ionic solutions [114]. Decay periods of several minutes are explained by a strongly diffusion-dependent bimolecular recombination [115].

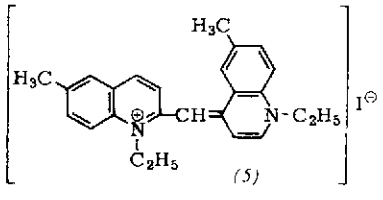
The analogy between inorganic and organic photoresistors points to the influence of trapping centers on the response times. As an example of this theory, dye cells, like inorganic systems [7], can be subdivided into slow and fast cells [25, 49, 116]. In addition, the response time can be markedly reduced by high field strengths and by the use of cells with small electrode spacings (sandwich-type cells) [25]. Moreover, the charge carriers present at the end of the illumination period can be thermally ejected by heating the photoconductor [113, 117], just like those in inorganic crystal phosphors containing numerous trapping centers (conductivity glow curves). The use of organic photoconductors for storing electrical energy (photoelectrets) is quite feasible [118].

VII. Dependence on Temperature

The photocurrent increases with temperature in accordance with Equation (26):

$$I_{phot} = A\exp(-\Delta E_H/kT) \qquad (26)$$

The plot of log I_{phot} against 1/T gives a straight line from the slope of which the thermal activation energy ΔE_H of the photoconduction can be calculated (0.4 to 0.6 eV) [49, 50, 109, 112, 113, 119]. ΔE_H ist not identical with ΔE_{therm} (*e.g.* for Orthochrome T *(5)*, $\Delta E_{H\,therm}$ = 1.5 eV; ΔE_H = 0.44 eV [86, 113]).



(5)

In analogy with inorganic crystalline phosphors [120–122], the temperature dependence of the photocurrent can probably be ascribed to trapping centers [108, 123–128] which are filled by a fraction of the charge-carriers formed during illumination. As the temperature increases, these centers become vacant, which produces an increase in the current. Experiments [*] carried out to determine the depth of the traps ΔE_H gave consistent results.

VIII. n- and p-Type Conduction in Dyes

Dyes can be divided into n- and p-type conductors according to the effect of oxygen [34, 129]. In some dyes, (triphenylmethane derivatives, rhodamines) the conductivity decreases when oxygen is adsorbed (n-type conduction); others (merocyanines, phthalocyanines) exhibit increased conductivity (p-type conduction) under these conditions. Hydrogen behaves in the reverse manner [130] (cf. Fig. 6).

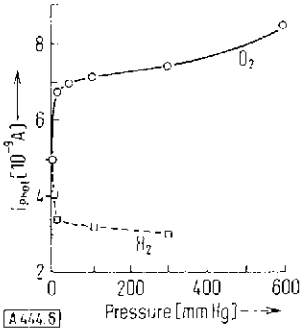


Fig. 6. Pressure-dependence of the photocurrent of a merocyanine A-10 surface cell in an oxygen and in a hydrogen atmosphere. In vacuum (5×10^{-6} mm Hg), the photocurrent is 5×10^{-9} A (applied potential 80 V; λ = 6000 Å, 12×10^{15} quanta/(cm² sec); illuminated area 1 cm², electrode separation 0.01 cm.

This classification of dyes presupposes:

1. an electron interaction between the gas and the solid dye analogous to that in inorganic semiconductors and metals [131–136], and

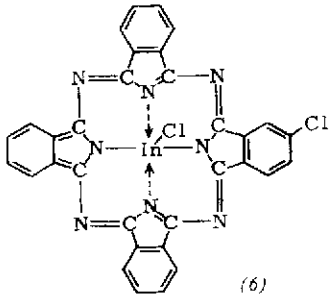
2. the validity of *Heckelsberg's* method [137] for determining the type of majority charge carriers in organic systems.

Both assumptions are supported by overwhelming evidence. Gases such as NO, BF_3, and SO_2 produce the same changes in conductivity in organic and inorganic systems [*] [124, 138–143] and the n- and p-type conduction mechanisms are confirmed by Hall-effect measurements [74, 144, 145], thermoelectric power measurements [65, 71, 146–149], measurement of the sign of the diffusion EMF in a static condenser [40, 43, 44], and by studies of the changes in the contact potential using the vibration method [49]. In every case, dye single crystals exhibited the same type of conduction as layers. Further, dyes belonging to the same class exhibit the same conduction type; *e.g.* more than 40 merocyanine dyes showed p-type behavior.

The cause of the two types of conduction in the various dyes is not yet known [25]. Studies of systems in which the type of conduction changes, *e.g.* transition from p-type to n-type conduction of chloroindium chlorophthalocyanine *(6)* [65] or the behavior of mixtures [34], may possibly help to elucidate the problem.



(6)

[137] *L. F. Heckelsberg, G. Bailey,* and *H. Clark,* J. Amer. chem. Soc. *77,* 1373 (1955).

[*] Chemiesorption of gases having electron-donating properties (*e.g.* H_2O, NH_3, *etc.*) on thin metal films leads to an increase in conductivity, whereas electron acceptors (O_2, NO, BF_3, *etc.*) give rise to the reverse effect since they withdraw electrons from the substrate. In semiconductors the effect of chemisorption depends on the mechanism of conduction: thus electron donors increase the conductivity of electronic semiconduction (n-type) and decrease that of electron-defect semiconductors (p-type), and *vice versa* for electron acceptors. Since chemisorption affects the surface layers of the semiconductor, this effect ist most pronounced for thin films, in which the surface conductivity exceeds the bulk conductivity.

Both types of charge carriers are of course present in both p- and n-type conduction, but in different proportions [21, 54].

IX. Lifetime and Mobility

No precise information regarding the lifetime τ during which the charge carriers are freely mobile inside the solid dyes is as yet available. The decay curves, varying from 10^{-2} sec to several minutes, are probably subject to interference by the temporary residence of charge carriers in trapping centers. For example, crystal phosphors containing numerous trapping centers have a long decay time of the photocurrent; yet the lifetime characteristic for the free movement of charge carriers without capture on trapping centers is only about 5×10^{-8} sec [123].

The possibility that triplet states are the primary participants in the conductivity process and that a lifetime of 10^{-4} sec and longer [96] can therefore be expected, is excluded by short-duration measurements on phthalocyanines which permit the detection of charge carriers within 10^{-6} sec or less [150]. Since the life of the excited singlet states of the phthalocyanines is approximately 10^{-9} sec [151], lifetime values lying between 10^{-6} and 10^{-9} are quite feasible [152].

On the basis of Hall-effect measurements, *Delacote* and *Schott* [145] found a mobility of 100 $cm^2\ V^{-1}\ sec^{-1}$ for the charge carriers in phthalocyanines. This result raises the question as to what corrections must be applied to the mobilities determined from electron spin resonance [153], from the mean free path [25, 36], and from other measurements [25, 94, 154–156]. A comparison with germanium ($\mu_{\oplus}$ = 1700 $cm^2\ V^{-1}\ sec^{-1}$) is interesting, and seems to show that the mobilities in inorganic semiconductors and organic dyes are not very different.

X. Energy Levels

Data concerning the magnitude of the energy levels is available for only a few dyes [26, 27, 29, 44, 157–165]; see Table 3.

(governed by the thermal work function) of the different dyes differ markedly, so that further measurements are necessary to establish the value of E_F precisely.

E. The Mechanism of Conduction in Dyes

The agreement between the electrical behavior of organic and inorganic semiconductors may be regarded as proof that photoconduction in solid organic dyes is not due to a photochemical decomposition reaction or an ionic mechanism but to the formation and migration of electronic charge carriers. This leads to the question of how the charges are transported through the solid dye. Whereas in inorganic crystals the lattice spacings are approximately 1.4 Å, molecular latticcs in organic molecules are relatively widely spaced (about 3.5 Å) [25, 166, 167].

I. The Tunnel Effect Mechanism

A possible explanation is the postulate that an excited electron (*e.g.* in the singlet state) reaches a vacant term of the neighboring molecules by tunneling through the potential barrier [50]. Since the probability for this transition $Dz \approx 10^{14}$ (where D is the transmission coefficient and z [sec^{-1}] is the number of impacts against the potential barrier) is greater than the probability $1/\tau \approx 10^9$ of return to the ground state, the transport of charges by the tunnel effect (hopping mechanism) from molecule to molecule seems feasible [90, 168], since $Dz/(1/\tau) \approx 10^{14}/10^9$.

Any increase in this ratio [126] leads to the participation of the longer-lived triplet state in photoconduction [90, 169, 170] and increases the likelihood of this mechanism.

II. Band Model Hypothesis

One objection to the tunnel effect mechanism, in which the charge carriers are localized at the lattice points for a certain time, is that the triplet states are not primary participants in the conduction [171]. Since, moreover, the boundary between the hopping mechanism and the quasi-free transport postulated by the band hypothesis

is a mobility of about 1 $cm^2/V^{-1}\,sec^{-1}$, and values of up to 100 $cm^2/V^{-1}\,sec^{-1}$ have been found for phthalocyanines [145], the energy band hypothesis is more probably correct. Additional evidence for the free movement of the electrons and positive holes in energy bands, which was already stated for dye photoconductors in 1954 [172], is provided by the observed decrease in the mobility with increasing temperature in organic single crystals [54, 55]. The tunnel effect mechnism requires the opposite to happen, because higher temperatures lead to an increase in z.

The relatively narrow energy bands in organic solids may well be due to the discrete energy levels of the molecules caused by electronic interaction (exchange degeneracy), as has been discussed in greater detail in Section B. VI. 1. Since ultimately the degree of overlap of the electron clouds is responsible for the bands, and hence for the mobility of the charge carriers, the relative orientation of the molecules, the distance between them, and their structure are very significant.

The directional character of the conduction is in accord with the band hypothesis [71, 173, 174]. Optical studies show that during crystallization the phthalocyanines show a transition from the sharp energy levels of the free molecules of the vapor state to wide, quasi-continuous bands [77].

III. The Exciton Hypothesis

Several authors [94, 175–178] have postulated the primary formation of excitons to explain the mechanism of photoconduction in organic compounds (cf. [25]). These diffuse to the surface, decompose, and contribute to the formation of electrons and positive holes. The migration of these secondary charge carriers is likewise interpreted by means of the band model. Naturally, the exciton theory offers no explanation for conduction in the dark. Dyes with good photoconductivity ($G \gg 1$) do not require the existence of additional excitons, which only partly decompose into charge carriers.

F. Doping

The addition of small quantities of organic compounds, *e.g.* *o*-chloranil, can increase both the dark and light conductivity of organic semiconductors by several orders of magnitude [179–188]. The following laws govern the doping effect in dyes:

1. The photoconductivity of p-type phthalocyanines [189, 190] and merocyanines [191] is increased by a factor of 5 to 10^4 by the addition of electron acceptors (iodine, *o*-chloranil, tetracyanoethylene) (cf. Fig. 7).

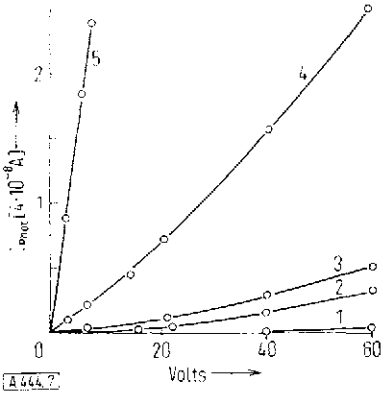

Fig. 7. Potential- and doping-dependence of a merocyanine FX-30 surface cell illuminated with white light at 1.8 mW/cm²; cell dimensions as in Fig. 6.
Curve 1: Undoped merocyanine FX-30. Curves 2, 3, 4, and 5: doped with dibromosuccinic acid (10^{-7} mole/cm² [*]), tetraiodophthalic anhydride (10^{-7} mole/cm²), *o*-chloranil (10^{-7} mole/cm²), and iodine (10^{-8} mole/cm²).

Specific dark conductivities up to $10^{-2}\,ohm^{-1}\,cm^{-1}$, *i.e.* values similar to those found in inorganic semiconductors, are possible.

2. No change occurs in the type of conduction.

3. Doping is effective at quantities of less than 10^{-7} mole on a photoconductive layer 1 cm² in area (Fig. 8).

4. The quantum yield G is increased by several orders of magnitude and may exceed unity (for merocyanine A-10, G = 2.3).

The doping effect is probably due to a transfer of electrons from the donor dye to the acceptor molecule by a light-induced charge transfer process in the sense expressed by *Mulliken* [192] and the acceptor action of the impurities, similar to the effects observed in inorganic semiconductors [193].

Fig. 9 shows that the transfer causes acceptors to become negatively charged and increases the positive hole concentration in the ground-state band of the dye, and hence the p-type conductivity. This is confirmed by,

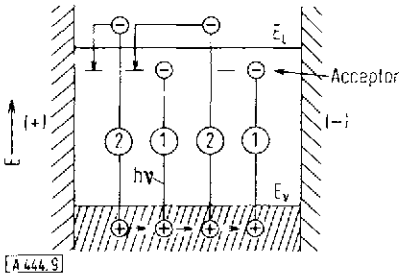

Fig. 9. Explanation of the doping effect.
1. Charge-transfer complex between the dye and the acceptor.
2. Trapping effect of the acceptor.

for example, electron spin resonance measurements [190], which show an increase in the conductivity with increasing number of electrons taken up by the acceptor molecules when the concentration of the doping agent is increased [194]. The reverse doping of n-type conductors (acceptors) with electron donors [56] is likewise in accord with this hypothesis.

A quantum yield G > 1 (see Section B. IV. 2.) may be explained in analogous manner to that in inorganic semiconductors, *e.g.* in CdS [195]. It means that the substantially immobile electrons shown in Fig. 9, which are taken up by the acceptors, build up a negative space charge on illumination. Positive holes are thereby injected from the anode just as in anthracene [196–198]. Owing to this replenishing effect, a positive hole exists even after its entry into the cathode. Since this is formally equivalent to an extension of the lifetime of the charge carrier, G (= τ/T) can exceed unity for $\tau > T$.

G. Photovoltaic Effects in Dyes

According to Section B. VI. 2. a), space charges are formed in the interface between two semiconductors in contact to give rise to photovoltaic effects. The observation of such effects in dyes confirms that the relationships which hold for "inorganic" boundary faces (*e.g.* postulation of the Fermi level) are also feasible for dye systems.

I. Dye/Metal Systems

Photocurrents (up to 10^{-8} A) and photopotentials (up to 10 mV) arise in dye/metal systems just as in Cu_2O and selenium photoelements [14–16, 199]. The slight rectifying action of the unilluminated arrangement indicates the probable presence of a barrier layer photoeffect (but cf. [200, 201]). Similar effects are also observed in metals (Pt, Au, Ag) in contact with polynuclear aromatic compounds (perylene, coronene) [202].

II. n-Type Dye/p-Type Dye Systems

Photocurrents of the order of 10^{-8} to 10^{-9} A and maximum photopotentials of 100 mV are found when n-type and p-type dyes are combined, *e.g.* rhodamine B (n)/merocyanine (p) [25, 36, 158, 203]. The currents rise in less than 10^{-2} sec (cf. *e.g.* Fig. 10) and grow with increasing illumination, indicating an electron transfer from the p-conductor to the n-conductor in the interior of the

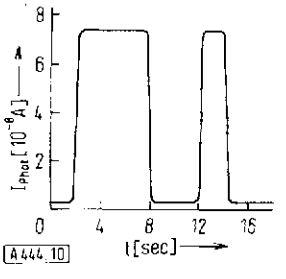

Fig. 10. Oscillogram of the photovoltaic sandwich cell of malachite green (n) and merocyanine A-10 (p). λ = 6220 Å, 3.7×10^{15} quanta/cm² sec); cell as in Fig. 4, II.

cell independent of the direction of illumination, similar to the case of inorganic systems. Analogous photovoltaic effects are obtained on coupling p-type aromatic amines with n-type dyes (crystal violet) [204] and in systems of magnesium phthalocyanine and air-oxidized *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (maximum photopotential 200 mV [205]).

[205] *D. Kearns* and *M. Calvin*, J. chem. Physics *29*, 950 (1959)].

Photocurrents up to 10^{-8} A and photopotentials up to 300 mV arise [195, 207] in mixed organic/inorganic systems, where the components are arranged side by side [164, 206] or superposed in thin layers (cf. Fig. 4). This high value for the photopotential as compared to those found in dye/metal systems demonstrates that the interface between the inorganic semiconductor and the dye and not the metal/semiconductor contact is responsible for the photovoltaic effect.

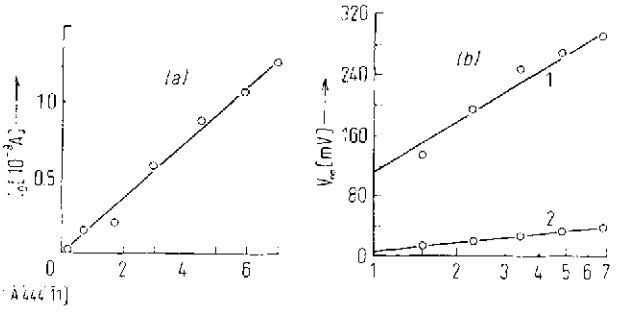

Fig. 11 *(a)*: Dependence of the short-circuit current on illumination (λ = 5580 Å; CdS/merocyanine A-10; Cell as in Fig. 4, I). *(b)*: Dependence of the open-circuit photopotential on the illumination [λ = 6000 Å; curve 1: AgI/Rhodamine B (arrangement I in Fig. 4). Curve 2: AgBr/Rhodamine B (arrangement II in Fig. 4).
Abscissae: Illumination (Hefner units).
Note: 1 Hefner unit = 94.7 μW/cm².

The arrangements behave substantially in the same way as purely inorganic pn-photovoltaic systems, as is shown by the dependence of the photocurrent on the light intensity (see Fig. 11), and by the facts that the current rises in less than $^1/_{50}$ sec, and the action and absorption spectra agree. The dependence of the photocurrent and the photopotential on the type of conduction of the combination (p or n) is significant, and agrees with the direction of travel of the electrons predicted by the p–n junction theory [19] (cf. Table 4).

Comparison of the energy levels (see Section D. X.) shows that, *e.g.* electron transfer is possible in the dark from an n-type dye to AgBr, since E_F (AgBr) lies below E_F (dye), to produce an internal electric field. The dye in the boundary layer becomes positive and the silver halide negative. The resulting field separates the electron-positive hole couples formed on illumination in the sense given by the p–n junction theory.

The photovoltaic effect of the inorganic/organic combinations can be increased by doping the p-type dye component; an example is shown in Fig. 12.

H. Significance and Applications of Dye Photosemiconductors

I. Photochemical and Biological Problems

The extent of the participation of electronic charge carriers in the primary process of photosynthesis is an interesting problem [25, 210–213]. Electronic charge carriers are indeed formed [13, 36, 41, 43, 164, 214–216], since chlorophyll and its analogues (chlorophyll a, b; methylchlorophyllide a + b; chlorophyll pigments with β-carotene, xanthophyll, neoxanthine, and violaxanthine) exhibit photoconductivity. Measurements of the dependence on oxygen pressure and of the crystal photoeffect have shown that positive holes are the majority carriers in these processes. It is feasible that these add to water molecules which then split into molecular oxygen and hydrogen, while the electrons are taken up by an acceptor (*e.g.* coenzyme Q) and participate in the CO_2 reduction process [25, 210, 211].

The similarity between the photocurrents of electroretinograms measured in the eye and dye photocurrents indicates that the primary reaction of the process of vision is electronic and not photochemical in nature [199, 217].

In agreement with the electroretinograms, certain dye photoelements [16, 172] alter the direction of the photocurrent when the wavelength of the incident monochromatic light changes [218–220], (Fig. 13).

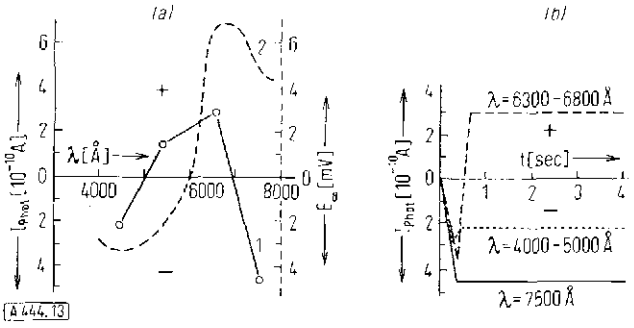

Fig. 13. *(a)*: Wavelength-dependence of the direction of the photovoltaic effect (photocurrent and photopotential). Curve 1: Orthochrome T, 1 mW/cm² [16, 172]; curve 2: β-carotene [221], 3.9×10^{15} quanta/(cm² sec).

(b): Variation of the photocurrent with time for Orthochrome T for different wavelengths [16, 172].

Similar behavior is shown by the receptors which are charged in dependence on the wavelength and transmit the stimuli [25, 217]. According to a recent study [221], the direction of the photocurrent in β-carotene, which is closely related to visual purple, is likewise wavelength-dependent. It may be noted that the photocurrents in β-carotene (which is p-conducting [25, 222]) depend on potential, intensity of illumination, gas atmosphere, *etc.* in the same way as those in other p-conducting dyes such as merocyanines and phthalocyanines [223—226]. The 15,15′-*cis* isomer of β-carotene which is formed in the eye exhibits a photoelectric sensitivity which is 1000 times greater than that of the (absent) all-*trans* isomer [227]. This fact also speaks in favor of an electronic mechanism of the process of vision.

II. Spectral Sensitization

An electron transfer mechanism for the spectral sensitization of the photographic process and the photoconductivity of semiconductors [13, 25, 158, 228—233] presupposes the formation and migration of electronic charge carriers in the sensitizing agent. As the photoelectric sensitivity of the various sensitizer dyes shows (pinacyanol *(2)*, infrared sensitizer S 916 [*], this is indeed the case [16, 80, 100, 229, 234].

Knowledge of the type of conduction of the sensitizing dyes and the positions of their energy levels, as well as the photovoltaic effects on sensitized system models (e.g. CdS/dye) leads to the interpretation of the sensitization as a type of p-n photoeffect [158, 207, 235]. Supersensitization [**] of photoconductivity is possibly related to the doping effect (see Sections F and G III) and can be explained in a similar manner [193, 207, 236, 237].

III. Dyes as Organic Photoconductor Models

The simple method of construction of photoconducting dye cells in comparison to other organic photoconductors (high polymers, aromatic compounds), giving relatively high, reproducible photocurrents in the visible spectral region makes dyes, and particularly the phthalocyanines [238—241], the preferred organic semiconductors for further study. Many results and hypotheses obtained with these substances can be applied to other types of organic semiconductors (cf. [8, 25, 54, 55, 102, 149, 242—246]).

IV. Technical Applications

The rectifying effect of metal/dye systems can reach substantial magnitudes in phthalocyanines placed between two different metals [247—250]. At 10 Kc/s, rectification in the ratio of 1000:1 is possible.

The electronic interaction mechanism between organic semiconductors and adsorbed gases, which is analogous to that in inorganic catalysts, leads to expected catalytic properties of the organic semiconductors. For example, the para → ortho conversion of hydrogen is catalysed by α,α′-diphenyl-β-picrylhydrazyl [138] and by polymeric and monomeric copper

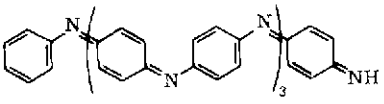
phthalocyanine [250a]. Conjugated polymers such as polybenzimidazole catalyse the decomposition of N_2O as well as the liberation of H_2 from alcohols and formic acid [251]. Dyes such as Aniline Black *(10)* and Paramine Brown [*] can also behave as catalysts [252]. In some instances, organic catalysts have proved to be more efficient than inorganic ones [253, 254].



(10)

The possible technical use of organic dyes as photoresistors or photoelements cannot yet be evaluated. It is not the magnitude of the attainable photocurrent (up to 10^{-4} A at an applied EMF of 100 volts) and photopotentials (up to 0.4 V) but rather the stability of the photoelectric cells which is likely to be decisive. Organic semiconductors possibly can be used as photosensitive electrets, electrode materials, *e.g.* for fuel cells [149, 249], semiconductor radioactivity detectors [255, 256], or as superconductors [257] (see Fig. 14).

The Chemistry of Nitrous Acid and of its Derivatives in Liquid Hydrogen Fluoride

BY PROF. DR. F. SEEL

INSTITUT FÜR ANORGANISCHE CHEMIE DER UNIVERSITÄT DES SAARLANDES, SAARBRÜCKEN (GERMANY)

The reaction of liquid hydrogen fluoride with nitrous acid, dinitrogen trioxide, dinitrogen tetroxide, and nitrosyl compounds leads to unexpectedly high-boiling liquids which contain nitrosyl fluoride in the form of remarkably stable, electrolytically dissociated hydrogen fluoride solvates. Nitrosyl fluoride solvated by pure hydrogen fluoride is a new reagent, valuable in fluorine chemistry since it reacts with many elements and compounds to form fluorine derivatives of preparative importance.

1. Introduction

Hydrogen fluoride is a liquid between −85 and +19.6 °C and can dissolve many inorganic and organic substances. Like water it can combine with saturated compounds, thus giving rise to solvates. In striking contrast to its aqueous solution, anhydrous *liquid* hydrogen fluoride is a very strong acid with respect to water; it forms salts even with very weakly basic nitrogen and oxygen compounds, and decomposes derivatives of weaker acids by solvolysis. These properties determine the chemistry of liquid hydrogen fluoride.

This interesting field of chemistry, full of experimental difficulties, was pioneered by *K. Fredenhagen* and his

school (1929–39) [1, 2], who investigated the behavior of numerous compounds in liquid hydrogen fluoride, but not that of nitrous acid and its derivatives. Owing to this surprising omission, the intriguing chapter of nitrous acid chemistry in liquid hydrogen fluoride could be opened up only recently.

2. The Reaction between Nitrous Acid and Hydrogen Fluoride

Fredenhagen reported that potassium nitrite dissolves in hydrogen fluoride with the evolution of nitrogen oxides [2]. The reaction was not further investigated, possibly because it was assumed that merely solutions of potassium fluoride were formed. However, when nitrite is cautiously added to hydrogen fluoride at a low temperature, practically no nitrogen oxides are evolved and the "trivalent nitrogen" content of the solution remains unchanged for a long time in vessels resistant to hydrogen fluoride. Obviously nitrous acid is stabilized under these conditions, as it is by the reaction with concentrated perchloric acid or sulfuric acid yielding nitrosyl perchlorate or nitrosylsulfuric acid (or their monohydrates). Ultraviolet spectroscopy reveals that the reactions of nitrous acid with strong oxyacids and with hydrogen fluoride are in fact of the same type. When nitrites are dissolved in perchloric acid [3] or sulfuric acid [4] of decreasing water content, the longest-wavelength band of nitrous acid is seen to transform progressively into the charge-transfer band of the hydrated nitrosyl cation $NO^+ \cdot OH_2$ [4]. The same phenomenon is observed in mixtures of hydrogen fluoride and water, containing 45 to 60 % by weight of HF [5] (cf. Fig. 1).

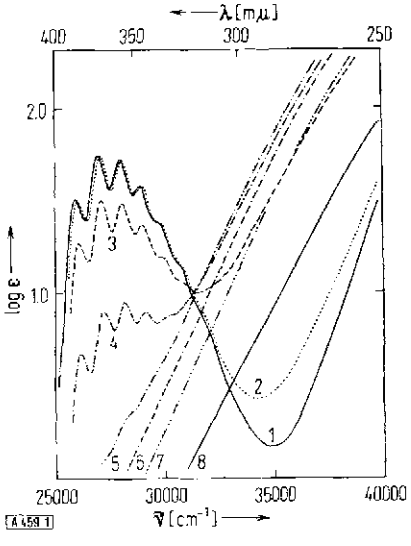

Fig. 1. Absorption of light by solutions of sodium nitrite in 30.8 to 70.5 % aqueous hydrofluoric acid.

Curve	1	2	3	4	5	6	7	8
HF [%]	30.8	45.2	50.2	52.5	54.6	57.0	59.8	70.5

Similarly to solutions of nitrous acid in aqueous perchloric acid or sulfuric acid, solutions in hydrogen fluoride do not show a sharp isosbestic point owing to the absorption shift caused by the solvent. The concentration of unchanged nitrous acid can however be determined from the height of the characteristic band maxima in the extinction diagram. If the logarithm of the ratio of the concentrations of $NO^+ \cdot OH_2$ and NO·OH is plotted against the acidity function H_0 [6] of the HF/H_2O mixture, a straight line is obtained, which is parallel to the corresponding straight lines for nitrous acid in aqueous $HClO_4$ and H_2SO_4. Since the slope of the straight lines in Fig. 2 is about 2, there cannot be a significant connection between H_0 and the position of the protolytic equilibrium. This is due to the fact that nitrous acid is not a proton-acceptor base, but a hydroxyl-donor base.

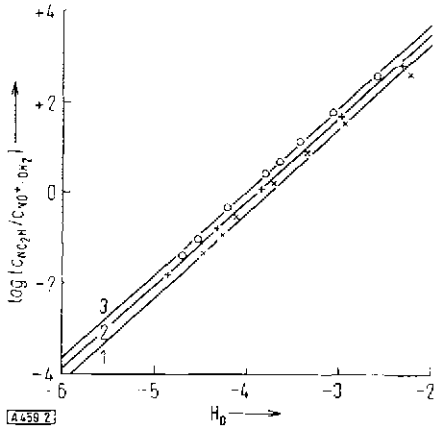

Fig. 2. Stability of nitrous acid and the hydrated nitric oxide cation as a function of H_0 in various strong acids [curve 1 (×): $HClO_4/H_2O$; curve 2 (+): HF/H_2O; curve 3(o): H_2SO_4/H_2O].

The solvent chemistry of hydrogen fluoride is seen here, as on other occasions, to be remarkably similar to that of perchloric acid and sulfuric acid. In all these strong acids, nitrous acid behaves as a base.

$$NO{\cdot}OH + HClO_4 \rightarrow NO^+ \cdot OH_2 + ClO_4^-$$
$$NO{\cdot}OH + H_2SO_4 \rightarrow NO^+ \cdot OH_2 + HSO_4^-$$
$$NO{\cdot}OH + HF \rightarrow NO^+ \cdot OH_2 + F^-$$

In anhydrous hydrogen fluoride, the molar conductivity of nitrous acid is twice as high as that of a 1:1 electrolyte (*i.e.* the molar conductivity of potassium nitrite is three times the value expected for a single electrolytic dissociation) [7]. Clearly a further protonation of the nitrous acid must take place, which has also been detected in solutions of nitrous acid in anhydrous sulfuric acid [8], and which consists of the complete separation of the hydroxyl group to form the oxonium ion:

$$NO^+ \cdot OH_2 + H_2SO_4 \rightarrow NO^+ + OH_3^+ + HSO_4^-$$
$$NO^+ \cdot OH_2 + HF \rightarrow NO^+ + OH_3^+ + F^-$$

Up to a molar ratio of 1:11, solutions of sodium nitrite in liquid hydrogen fluoride are colorless and no more nitrite can be dissolved without nitrous acid decomposing into nitrogen oxides. The solution of nitrous acid in hydrogen fluoride, which is colorless up to a molar ratio of 1:9, is decomposed by the addition of soluble fluorides. Evidently a solution of nitrous acid is stable only in the presence of sufficient hydrogen fluoride as a solvating agent.

Like solutions of nitrosylsulfuric acid in sulfuric acid, solutions of nitrous acid in hydrogen fluoride develop a deep indigo color when treated with nitric oxide or subjected to partial reduction with sulfur dioxide or methanol. On cooling these blue solutions exhibit the thermochromism which is characteristic of the nitrosyl-nitric oxide ion [9]:

$$NO^+ + NO \rightarrow N_2O_2^+$$

(*It was on addition of sodium nitrite to a solution of* sulfur dioxide in hydrogen fluoride that the "purple hydrogen fluoride" was discovered [10], and this stimulated the investigations described here.)

3. Reactions of Dinitrogen Trioxide with Hydrogen Fluoride

Solutions of dinitrogen trioxide in liquid hydrogen fluoride can be prepared by passing an equimolecular mixture of nitric oxide and nitrogen dioxide into the solvent, or by liquefying a gaseous mixture of NO, NO_2, and HF. Colorless solutions are again obtained if the amount of HF present is sufficient for a complete reaction. The colorless solution of composition $N_2O_3 \cdot 12.8$ HF or $NOF \cdot 5.4$ HF $\cdot 0.5$ H_2O can be distilled at 68 °C under atmospheric pressure without change in composition, and can also be separated by distillation from solutions of different composition. It can be shown by infrared spectroscopy that hydrogen fluoride, dinitrogen trioxide, and its decomposition products nitric oxide and nitrogen dioxide are present in the vapor of the "68 °C product". This indicates that distillation leads to reversible decomposition of the liquid. (Surprisingly the liquid turns only faintly brown, even when heated to its boiling point.)

The liquid boiling at 68 °C can also be distilled from solutions of metal nitrites ($NaNO_2$, KNO_2, $AgNO_2$) in hydrogen fluoride [11]. The ease of formation of the "68 °C product" is clearly due to the decomposition of nitrous acid into N_2O_3 (or NO + NO_2) and water, which is retained by the hydrogen fluoride. Solutions of nitrous acid obtained by passing N_2O_3 (or NO + NO_2) into aqueous hydrogen fluoride can be separated by fractional distillation into the "68 °C product" and the azeotropic mixture (b.p. 112 °C) of hydrogen fluoride and water [12].

The "68 °C product" can also be obtained by treating a mixture of nitric acid and hydrogen fluoride with nitric oxide, or by treating hydrogen fluoride alone with nitric oxide under pressure. In the presence of excess nitric oxide, the deeply colored "purple hydrogen fluoride" is formed first. These methods for preparing solutions of dinitrogen trioxide in HF are based on the well known reaction of nitric acid with nitric oxide to give nitrous acid and dinitrogen trioxide, and on the disproportionation of nitric oxide into dinitrogen trioxide and nitrous oxide.

On cooling to below −12 °C, the liquid of composition $N_2O_3 \cdot 12.8$ HF first becomes viscous and then solidifies into a glass melting between −17 and −23 °C [13]. It is extremely unlikely that we are dealing here with an azeotropic mixture of dinitrogen trioxide and hydrogen fluoride [14], or of HF and an N_2O_3-HF compound. If dinitrogen trioxide behaves towards HF as it does towards H_2SO_4 or $HClO_4$, then hydrogen fluoride first solvolyses dinitrogen trioxide into nitrosyl fluoride and nitrous acid:

$$N_2O_3 + HF \rightarrow NOF + HNO_2$$

and the nitrous acid subsequently reacts with HF to give $NO^+ \cdot OH_2$ or NO^+ and F^-.

That the solution contains an electrolyte is indicated by the electrical conductivity of the "68 °C product," which resembles that of a fused electrolyte (*e.g.* fused zinc chloride). The molar conductivity of a much more dilute (about 0.1 M) solution of N_2O_3 in liquid hydrogen fluoride is about three times as high as that of a potassium fluoride solution of the same concentration. This indicates the following overall reaction, neglecting solvation of the ions:

$$N_2O_3 + 3\ HF \rightarrow 2\ NO^+ + OH_3^+ + 3\ F^-$$

The infrared spectrum of the liquid "68 °C product" shows a band at 2350 cm^{-1}, which is characteristic of the nitrosyl cation [15] (cf. Fig. 3).

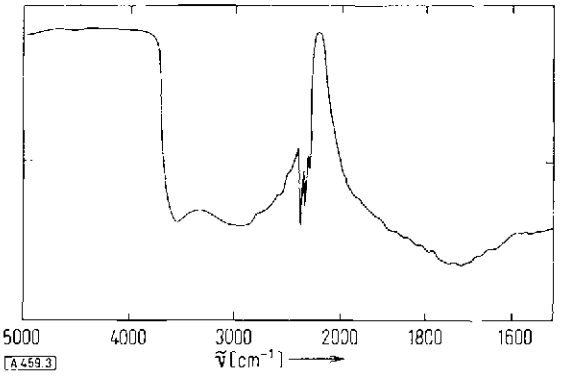

Fig. 3. The infrared spectrum of $N_2O_3 \cdot 12.8$ HF.

When a solution of dinitrogen trioxide in hydrogen fluoride is subjected to partial freezing, the solid phase is seen to contain not only HF and N_2O_3, but also NOF, while the liquid phase contains H_2O in addition to HF

and N_2O_3, corresponding to an enrichment of nitrosyl-hydrogen fluoride in the solid phase and of oxonium-hydrogen fluoride in the liquid phase. These observations further indicate that the solution of dinitrogen trioxide in liquid hydrogen fluoride contains no undecomposed, HF-solvated N_2O_3 molecules.

Water can be removed from the "68 °C product" by treating the latter with sulfur tetrafluoride:

$$SF_4 + H_2O \rightarrow SOF_2 + 2\ HF$$

After the removal of thionyl fluoride, a pure solution of nitrosyl fluoride in hydrogen fluoride is obtained. Fractional distillation of this solution yields a product (b.p. 94 °C) of the composition NOF + 3 HF, which will be described in Section 5. The low volatility of the HF-solvated nitrosyl fluoride explains why NOF cannot be isolated by distilling a solution of solvolysed dinitrogen trioxide in hydrogen fluoride.

If sodium fluoride or potassium fluoride is added to $N_2O_3 \cdot 12.8$ HF, hydrogen fluoride is removed from the solution by the formation of metal hydrogen fluorides, and nitric oxide and nitrous oxide are liberated.

4. Reactions of Dinitrogen Tetroxide with Hydrogen Fluoride

Very little was previously known of the behavior of dinitrogen tetroxide towards hydrogen fluoride. The fact that colorless mixtures containing a maximum of 25 mole-% nitrogen dioxide can be prepared proves that NO_2 and HF do in fact react with each other. On the basis of the behavior of nitrogen dioxide towards concentrated perchloric and sulfuric acids, it seems reasonable to propose the solvolysis of the nitrosyl nitrate form of dinitrogen tetroxide:

$$(O_2N \cdot NO_2 \rightleftharpoons 2\ NO_2 \rightleftharpoons ON \cdot ONO_2) + HF \rightarrow NOF + HNO_3$$

Admittedly, an unfavorable value is obtained for the free energy of this reaction on substituting in the following equation the values for the energies of formation of the four gaseous participants [16]:

$$\Delta F°_{298} = -[\Delta F°(N_2O_4) + \Delta F°(HF)] + [\Delta F°(NOF) + \Delta F°(HNO_3)]$$
$$= -(24.8-64.7) + (-12.5-19.0) = +8.4\ \text{kcal/mole}$$

Possibly, however, the energy deficit is compensated by solvation in the condensed phase. This is indicated by the fact that the fractional distillation of a colorless mixture of nitrogen dioxide with excess hydrogen fluoride enables the separation into NOF·3 HF (b.p. 94 °C), mentioned above, and a constant-boiling liquid (b.p. 52 °C) of composition [17]

$$N_2O_4 + 7.0\ HF + 0.87\ HNO_3 = NOF + 6.0\ HF + 1.87\ HNO_3$$

The "52 °C product" is colorless at room temperature, but becomes golden yellow on boiling, which shows that on distillation it decomposes into N_2O_4 and HF. Evidently nitric acid, being more volatile than NOF·3 HF and less basic than nitrous acid, distils out of the solution of N_2O_4 in hydrogen fluoride during the evolution of NO_2 and HF. The constant-boiling products obtained by treating hydrogen fluoride with N_2O_3 and N_2O_4 are listed in Table 1.

Table 1. Constant-boiling products.

B.p. [°C]	Composition
52	N_2O_4 + 7.0 HF + 0.87 HNO_3 or NOF + 6.0 HF + 1.87 HNO_3
68	N_2O_3 + 12.8 HF or NOF + 5.4 HF + 0.5 H_2O
94	NOF + 3 HF

5. Hydrogen Fluoride Solvates of Nitrosyl Fluoride

a) Preparation and Properties

Whereas the reaction of nitrogen dioxide with hydrogen fluoride leads to the unexpectedly high-boiling liquid (b.p. 94 °C) of composition NOF·3 HF in a yield of only about 20 %, the distillation of a solution of nitrosyl fluoride in anhydrous hydrogen fluoride results in the "94 °C product" in quantitative yield (based on the nitrogen compound). It is worth noting that the NOF–HF solvate can also be prepared from nitrosyl chloride and hydrogen fluoride in the liquid or gaseous phase [18–25] (in the second case at somewhat higher temperatures [21]). The reaction

$$NOCl + HF \rightarrow NOF + HCl$$

is thermodynamically unexpected, since an unfavorable free energy is calculated from the energies of formation of the gaseous participants [16] (as in the case of N_2O_4 and HF):

$$\Delta F°_{298} = [\Delta F°(NOCl) + \Delta F°(HF)] + [\Delta F°(NOF) + \Delta F°(HCl)]$$
$$= (15.9-64.7) + (-12.5-22.8) = +13.5\ \text{kcal/mole}$$

It is obvious that the formation of a solvate between nitrosyl fluoride and hydrogen fluoride facilitates the reaction.

[16] Sources: *W. M. Latimer*: Oxidation Potentials. 2nd edit., Prentice-Hall, New York 1952. The value of $\Delta F°(NOF)$ was calculated from the heat of the reaction 2 NO + F_2 → 2 NOF, assuming that the entropy of formation is the same for NOF as for NOCl [*H. S. Johnston* and *H. J. Bertin*, J. Amer. chem. Soc. *81*, 6402 (1959)].

Pure NOF·3 HF is a colorless, hygroscopic liquid. Its weakly yellowish color points to partial hydrolytic decomposition. The specific gravity of the substance is unexpectedly high (1.50) indicating that nitrosyl fluoride occupies only a very small space in the HF solution. The liquid is immiscible with hydrocarbons and with partially and fully chlorinated or fluorinated hydrocarbons. It can be stored in containers made of paraffin, Hostafion C (Kel F), Teflon, or pure nickel. In carbon tetrachloride, the solvate forms large floating drops which can be frozen out by cooling with ice. On the skin, NOF·3 HF produces painful wounds, but not as fast as liquid hydrogen fluoride.

In the vapor of the "94 °C product" free nitrosyl fluoride, hydrogen fluoride, and nitric oxide (originating from hydrolysis) can be detected [13]. The vapor density indicates that NOF and HF are associated in the gaseous phase as well.

Like $N_2O_3 \cdot 12.8$ HF, the solvate NOF·3 HF exhibits the electrical conductivity of a fused salt. Dilute (about 0.25 M) solutions of NOF in HF show the same molar conductivity as solutions of a 1:1 electrolyte [7]. Obviously nitrosyl fluoride in hydrogen fluoride dissociates into nitrosyl cations and fluoride anions.

When hydrogen fluoride is pumped off from the 94 °C product at room temperature, a liquid of composition NOF·2.67 HF is left behind, which melts sharply at 4.7 °C, whereas NOF·3 HF melts between 1 and 5.5 °C. Nitrosyl fluoride is given off on heating the melt of NOF·2.67 HF, and finally NOF·3 HF is obtained again by distillation at 94 °C. It appears therefore that several addition compounds of nitrosyl fluoride and hydrogen fluoride can coexist in equilibrium in the liquid and gaseous phase.

It emerges from the ^1H- and ^{19}F-NMR spectra [27] that the hydrogen and the fluorine atoms of the nitrosyl fluoride-hydrogen fluoride, and also of $N_2O_3 \cdot 12.8$ HF, participate in rapid exchange reactions between 0 and 5 °C. The liquids give only one signal (cf. Table 2) [27]. The positions of the fluorine signals show that the exchange of the fluorine atoms takes place not between undissociated molecules of nitrosyl fluoride and hydrogen fluoride but *via* an intermediate containing hydrogen

Table 2. Nuclear magnetic resonance spectra.

fluoride and fluoride ions. This is further proof of the fact that salt-like hydrogen fluoride addition compounds are formed from nitrosyl fluoride and HF.

Solutions or compounds of nitrosyl fluoride and hydrogen fluoride can also be decomposed chemically in such a way that either one or the other component is set free.

Hydrogen fluoride is split off by alkali metal fluorides [20–22]. Nitrosyl fluoride is best prepared by passing the vapors from NOF/HF solutions obtained from nitrosyl chloride and hydrogen fluoride into a KF melt [22]. Nitrosyl fluoride can be separated with metal fluorides and non-metal fluorides, which form stable nitrosyl salts of complex fluoro acids.

$$NOF(HF)_m + BF_3 \rightarrow NOBF_4 + m\ HF$$
$$NOF(HF)_m + As(Sb)F_5 \rightarrow NO[As(Sb)F_6] + m\ HF$$

Conversely, less stable nitrosyl salts, *e.g.* $(NO)_2SiF_6$, are decomposed by hydrogen fluoride into the nitrosyl fluoride-hydrogen fluoride addition compound:

$$(NO)_2SiF_6 + 2m\ HF \rightarrow 2\ NOF(HF)_m + SiF_4$$

b) The Reaction with Water

Whereas NOF-rich NOF/HF solutions are immediately hydrolysed by water with the evolution of nitrogen oxides, solutions rich in HF can take up water without liberating nitrogen oxides, which is undoubtedly due to the fact that nitrous acid is stabilized by a sufficient quantity of hydrogen fluoride. It is understandable that the 68 °C product of composition

$$N_2O_3 + 12.8\ HF = 2\ NOF + 10.8\ HF + H_2O$$

can also be obtained from NOF·3 HF, hydrogen fluoride, and water, and that the addition of 0.5 mole of water per mole of nitrosyl fluoride to NOF·3 HF, followed by distillation, leads to nitrous fumes in addition to the 68 °C product. Hydrogen fluoride solutions containing nitrosyl fluoride and dinitrogen trioxide, or more than 2 moles of nitrosyl fluoride per mole of water, can be separated by distillation into pure solutions of NOF and of N_2O_3. (Such solutions are formed in the reaction of aqueous hydrogen fluoride or nitrosyl chloride containing nitric oxide.) This separation appears to be a distillation of two immiscible liquids (cf. Fig. 4). This is undoubtedly due to the fact that volatilization

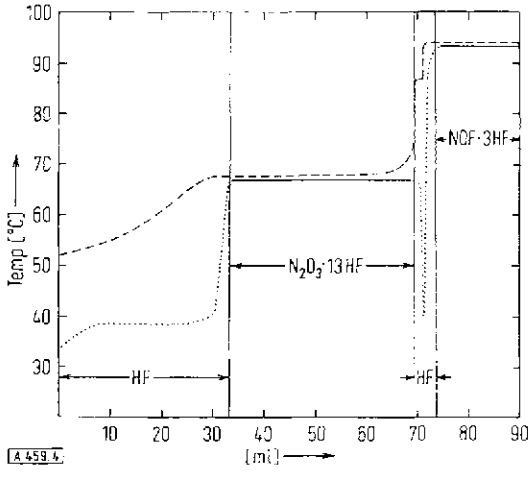

Fig. 4. Temperature changes observed in the distillation of a solution of dinitrogen trioxide and nitrosyl fluoride (or nitrous acid and excess nitrosyl fluoride) in liquid hydrogen fluoride.

– Condensate in the vapor zone; .... vapor; ---- boiling liquid

[26] U.S. Patent 3160623 (Dec. 23rd, 1960); Brit. Pat. 963823 (Dec. 4th, 1961); French Pat. 1310192 (Dec. 22nd, 1961), Allied Chem. Corp., inventors: *L. G. Anello* and *C. Woolf*.

[27] For these investigations, the author wishes to thank Dr. *W. Brügel*, Badische Anilin- & Soda-Fabrik, Ludwigshafen (Germany).

and condensation of the product to distil first are based on chemical reactions:

$$2\ NO^+ + OH_3^+ + 3\ F^- \rightleftharpoons NO + NO_2 + 3\ HF$$

The 68 °C product obtained by the distillation of aqueous hydrogen fluoride with nitrosyl chloride or of anhydrous hydrogen fluoride with nitrosyl chloride containing dinitrogen trioxide was first regarded as pure nitrosyl fluoride-hydrogen fluoride [20, 21]. The compound corresponding to NOF·6 HF, claimed in addition to NOF·3 HF in many patents [20–24], certainly does not exist as a pure substance, although it may be present as a component in a mixture of liquid HF-solvates of nitrosyl fluoride. The correct composition of the 68 °C product was first determined independently by *B. Fox, R. Siegel, S. L. Speirs*, and *R. H. Wiswall jr.* [14] and by *G. Fuchs* [11].

c) Reactions with Alcohols and Amines

The reaction of nitrosyl fluoride-hydrogen fluoride with alcohols was investigated with amyl and benzyl alcohol. Similarly to amyl and benzyl nitrite, the alcohols are dehydrogenated to the aldehydes, so that the following two-step reaction appears probable:

$$R{-}CH_2OH + NOF \rightarrow R{-}CH_2O{-}NO + HF$$
$$R{-}CH_2O{-}NO + NOF \rightarrow R{-}CHO + 2\ NO + HF$$

(The solvation of the nitrosyl fluoride is neglected here and in the following equations.) Both anhydrous and water-containing solutions of nitrosyl fluoride in hydrogen fluoride are capable of diazotizing aromatic amines [21, 26]:

$$C_6H_5NH_2 + NOF \rightarrow H_2O + C_6H_5N_2F \rightarrow C_6H_5F + N_2$$

The resulting diazonium fluorides decompose with evolution of nitrogen, even at low temperatures, yielding the fluorinated compound corresponding to the amine used. Diazotizations with solutions of nitrosyl chloride and sodium nitrite in liquid hydrogen fluoride have been described earlier [28, 29].

d) Chlorine-Fluorine Exchange

Numerous chlorine-fluorine exchange reactions can be carried out with solutions of nitrosyl fluoride in hydrogen fluoride, as with pure hydrogen fluoride [21, 23]. One of the advantages of the new process is that open vessels can be used, at higher temperatures and lower vapor pressures. When hydrogen chloride is passed into boiling NOF·3 HF, nitrosyl chloride and hydrogen fluoride are obtained. These exchange reactions proceed very fast when the chlorine compound is of the nature of an acid chloride. In the reactions of the trichlorides of phosphorus, arsenic, and antimony, the valence of these elements is increased, and the well known nitrosyl fluoride addition compounds of the pentafluorides are obtained:

$$6\ NOF + P(As,Sb)Cl_3 \rightarrow NOP(As,Sb)F_6 + 5\ NO + 1.5\ Cl_2$$

[28] U.S. Pat. 2563796 (May 26th, 1948), Harshaw Chem. Comp., inventors: *W. I. Shenk* and *G. R. Pellon*.

[29] German Patent 600706 (March 23rd, 1933), I.-G. Farbenindustrie, inventors: *Ph. Osswald* and *O. Scherer*.

The preparation of thionyl fluoride from sulfur dichloride and a mixture of the 68 °C product and the 94 °C product, ascribed to the action of nitrosyl fluoride-hydrogen fluoride [24], may be attributed to a reaction with the 68 °C product only:

$$SCl_2 + N_2O_3 \rightarrow SOCl_2 + 2\ NO$$
$$SOCl_2 + 2\ HF \rightarrow SOF_2 + 2\ HCl$$

When iodine trichloride is treated with nitrosyl fluoride-hydrogen fluoride, iodine trifluoride seems to be formed first. It disproportionates into iodine and iodine pentafluoride, and the latter finally adds onto nitrosyl fluoride to form $NOIF_6$ [30].

Chloro compounds, such as carbon tetrachloride or chloroform, remain unreactive until the temperature of NOF·3 HF exceeds its boiling point. For this reason, reactions of this type offer no advantage over fluorinations with pure hydrogen fluoride [23].

e) Reactions with Oxides and Oxyacids

Oxides also react with the nitrosyl fluoride-hydrogen fluoride solvate, giving rise chiefly to fluorides (and oxide fluorides). These reactions are of particular interest to the analyst. Difficultly soluble silicates, in fact even quartz, are dissolved by the 94 °C product within a few minutes. The solubilization of natural beryl may be of industrial importance; the reaction gives gaseous silicon fluoride, HF-soluble nitrosyl fluoroberyllate, and insoluble aluminum fluoride.

The preparation of sulfuryl fluoride from sulfur dioxide is based on the reaction of the latter with nitrosyl fluoride [25]:

$$2\ NOF + SO_2 \rightarrow SO_2F_2 + 2\ NO$$

Perchloric acid and fluorosulfonic acid precipitate nitrosyl perchlorate and nitrosyl fluorosulfate. When 3 moles of nitrosyl fluoride-hydrogen fluoride are distilled with 1 mole of anhydrous sulfuric acid, the 68 °C product distills off, leaving behind a residue of nitrosyl fluorosulfate. The 94 °C product is converted into the 68 °C product also by distillation with conc. sulfuric acid and, surprisingly, with fuming sulfuric acid. Since nitrosylsulfuric acid reacts with NOF·3 HF to give nitrosyl fluorosulfate, the reaction of $NOF(HF)_m$ with sulfuric acid can probably be explained by the following series of reactions:

$$NOF(HF)_m + SO_4H_2 \rightarrow NOSO_4H + (m+1)\ HF$$
$$NOF(HF)_m + NOSO_4H \rightarrow NOSO_3F + NO{\cdot}OH + m\ HF$$
$$NOF(HF)_m + NO{\cdot}OH \rightarrow N_2O_3 + (m+1)\ HF$$

f) Reactions with Elements

The reactions of nitrosyl fluoride-hydrogen fluoride with the elements themselves are of even greater importance in preparative chemistry than are the chlorine-fluorine exchange reactions [21] (cf. Table 3). In this respect, the nitrosyl fluoride-hydrogen fluoride solvate surpasses pure hydrogen fluoride, since nitrosyl fluoride splits more easily into nitric oxide and fluorine than does hydrogen fluoride into hydrogen and fluorine. Thus even red phosphorus is attacked. In principle, both the nitrosyl fluoride and the hydrogen fluoride moiety can react.

[30] Experiments carried out by *A. B. Ray*.

The nitrosyl fluoride adducts of pentafluorides (or the nitrosyl salts of the hexafluoro acids) are formed by elements whose maximum valence is five. If nitrosyl fluoride-hydrogen fluoride contains some nitrogen dioxide (formed by hydrolysis), nitrosyl salts of oxyfluoro acids, such as $NOTeOF_5$ and $NOMoOF_5$, can also be formed. Many interesting compounds are to be found among the reaction products with various elements, for example: $CrF_3 \cdot 3\,NOF \cdot 3\,HF$, which decomposes stepwise into $(NO)_2CrF_5$ and CrF_3 [11], or nitrosyl hexafluorouranate(V) $NOUF_6$, prepared by treating metallic uranium, as well as UF_4, UO_2F_2, and UO_3 with the 94 °C, 68 °C, or 52 °C products [9]. Nitrosyl hexafluorouranate(V) can be converted into UF_6 or UF_7NO with fluorine or chlorine trifluoride, respectively. Mercury(II) fluoride, which is a particularly effective reagent in chlorine-fluorine exchange reactions, is now readily available through its preparation from $NOF \cdot 3\,HF$ and mercury(I) fluoride, which can be precipitated from aqueous solutions. A purely chemical route leads from hydrogen fluoride to fluorine *via* nitrosyl fluoride-hydrogen fluoride, mercury(II) fluoride, and potassium fluoroplatinate(IV), which can be decomposed pyrolytically above 500 °C [31]:

$$HF + NOCl \rightarrow NOF + HCl$$
$$2\,NOF + Hg_2F_2 \rightarrow 2\,HgF_2 + 2\,NO$$
$$3\,HgF_2 + K_2PtCl_6 \rightarrow 3HgCl_2 + K_2PtF_6$$
$$K_2PtF_6 \rightarrow 2\,KF + Pt + 2\,F_2$$

Fluorosulfuric Acid as a Reaction Medium and Fluorinating Agent in Inorganic Chemistry

BY PROF. DR. A. ENGELBRECHT

INSTITUT FÜR ANORGANISCHE UND ANALYTISCHE CHEMIE
DER UNIVERSITÄT INNSBRUCK (AUSTRIA)

Fluorosulfuric acid is known both in aqueous solution and as the anhydrous compound. The anhydrous acid exhibits electrical conductivity which indicates its autodissociation. Even strong acids such as H_2SO_4 or $HClO_4$ behave as proton acceptors, i.e. as bases, in fluorosulfuric acid. Volatile inorganic acid fluorides can be readily prepared using fluorosulfuric acid as fluorinating agent.

1. Fluorosulfuric Acid in Aqueous Solution

Fluorosulfuric acid was first prepared in 1892 by *Thorpe* and *Kirman* [1] from sulfur trioxide and anhydrous hydrogen fluoride:

$$SO_3 + HF \rightleftharpoons HSO_3F$$

[1] *T. E. Thorpe* and *W. Kirman*, J. chem. Soc. (London) *1892*, 921.

Since it reacts very vigorously with water, the compound was at first assumed to be hydrolysed instantaneously and completely in this medium:

$$HSO_3F + H_2O \rightleftharpoons H_2SO_4 + HF$$

Many years elapsed before *Traube* [2] found salts of fluorosulfuric acid to be fairly stable in aqueous solution and the acid to be incompletely hydrolysed on slow addition to water accompanied by cooling.

[2] *W. Traube*, Ber. dtsch. chem. Ges. *46*, 2513 (1913).

Woolf [3] subsequently prepared pure aqueous solutions of fluorosulfuric acid from its salts with the aid of a strongly acidic ion exchanger. *Hayek* and *Czaloun* [4] succeeded in preparing pure dilute aqueous solutions of the acid from its anhydride, pyrosulfuryl fluoride $S_2O_5F_2$.

The stability of the aqueous acid is comparable to that of aqueous tetrafluoroboric acid, but is greater than that of the complex fluoro acids of Group Va elements [3]. Conductivity measurements in very dilute solutions indicate the dissociation

$$HSO_3F + H_2O \rightleftharpoons SO_3F^- + H_3O^+$$

When only limited amounts of water are present, it is found that fluorosulfuric acid and water are in equilibrium with sulfuric acid and hydrogen fluoride.

The similarities between perchlorates and fluorosulfates in respect to solubility and crystallographic properties suggest that the ionic radii of the anions are comparable and that solvation is analogous in both cases. This is supported by a comparison of their ionic mobilities which can be derived from the equivalent conductivities. The latter are 69 $cm^2 \cdot ohm^{-1}$ for ClO_4^- and 71 $cm^2 \cdot ohm^{-1}$ for SO_3F^-, both at 25 °C.

The conductometric titration curve [3] of aqueous fluorosulfuric acid is practically identical with the neutralization curve for sulfuric acid, *i.e.* the two acids have approximately the same strength in water.

2. Anhydrous Fluorosulfuric Acid

The special properties of anhydrous fluorosulfuric acid are best shown by a comparison with sulfuric acid. The relatively low viscosity and low freezing point of anhydrous HSO_3F are particularly conspicuous. These properties are undoubtedly due to the presence of a smaller number of hydrogen bonds.

Table 1. Comparison of fluorosulfuric and sulfuric acids.

	HSO_3F	H_2SO_4
Boiling point [°C]	162.7	290—317
Freezing point [°C]	−89.0	10.37
Density at 25 °C [g/ml³]	1.7264	1.8267
Viscosity at 25 °C [cp]	1.56	24.54
Dielectric constant at 25 °C	*ca.* 120	100
Heat of formation (liq.), [kcal/mole]	184	194
Specific conductivity at 25 °C [ohm^{-1} cm^{-1}]	1.085×10^{-4}	1.03×10^{-2}

Auto-dissociation of the fluorosulfuric acid must be assumed to explain its conductivity which cannot be further decreased by repeated purification [5, 8]:

$$2\ HSO_3F \rightleftharpoons H_2SO_3F^+ + SO_3F^- \quad (a)$$

Woolf [3] has also considered the following dissociations:

$$HSO_3F \rightleftharpoons HSO_3^+ + F^- \quad (b)$$

$$2\ HSO_3F \rightleftharpoons H_2F^+ + S_2O_6F^- \quad (c)$$

but, on the evidence of electrolysis experiments, concludes that they are at most of minor importance.

Hydrogen is the only gas evolved at the cathode during electrolysis of fluorosulfuric acid, and the amount given off is in agreement with that expected from Equation (a) or (c). The observed fluorine migration towards the anode can be reconciled only with Equation (a) or (b), since for dissociation (c), the relative ionic mobilities would lead to a movement of fluorine towards the cathode. In addition, the electrolyte acts as an oxidizing agent at the anode, in virtue, presumably, of the formation of peroxodifluorosulfate ions:

$$2\ SO_3F^- - e^- \rightarrow S_2O_6F_2^-$$

This postulate has recently been confirmed by *Dudley* [6], who succeeded in preparing peroxopyrosulfuryl difluoride by electrolysis of solutions of alkali metal fluorosulfates in fluorosulfuric acid:

$$2\ SO_3F^- - 2\ e^- \rightarrow S_2O_6F_2$$

In order to avoid reduction of the peroxopyrosulfuryl difluoride by the cathodic gases, the experiment was carried out in vacuum diaphragm cells. This reaction can be regarded as analogous to the formation of peroxodisulfates during the anodic oxidation of sulfuric acid.

The equivalent conductivities of alkali metal and alkaline earth metal fluorosulfates [5] are very similar. This observation shows that the current is carried mainly by the fluorosulfate ions. The values indicate that solvation increases in the sequence:

$$NH_4^+ < Rb^+ = K^+ < Na^+ = Li^+ < Ba^{2+} < Sr^{2+}$$

This series is more or less the one expected from the size and charge of the cations and agrees with their solvation in sulfuric acid [7].

The abnormally high mobility of the SO_3F^- ion is probably due to a proton transfer mechanism of the Grotthus type, as postulated for water and sulfuric acid. The $H_2SO_3F^+$ ion likewise seems to obey this mechanism [5].

3. Acid-Base Reactions in Fluorosulfuric Acid

According to Equation (a), acids and bases in the fluorosulfuric acid system can be defined as substances which increase the relative concentration of the fluorosulfate acidium ion $H_2SO_3F^+$ or of the fluorosulfate ion, respectively.

The relative concentration of the fluorosulfate ion can be increased by adding either a dissociating alkali metal fluorosulfate or substances which act as proton acceptors and therefore decrease the concentration of the fluorosulfate acidium ion.

Since even substances which are strong acids in water, *e.g.* H_2SO_4 or $HClO_4$, act as proton acceptors in fluorosulfuric acid, it must be assumed that true acids do not

[3] *A. A. Woolf*, J. chem. Soc. (London) *1954*, 2840.

[4] *E. Hayek* and *A. Czaloun*, Mh. Chem. *87*, 790 (1956).

[5] *J. Barr*, *R. J. Gillespie*, and *R. C. Thompson*, Inorg. Chem. *3*, 1149 (1964).

[6] *F. B. Dudley*, J. chem. Soc. (London) *1963*, 3407.

exist in this medium. Acid behavior is to be expected only from substances such as SbF_5 which combine with the SO_3F^- anion and therefore increase the relative concentration of the fluorosulfate acidium ion (see Table 2).

Table 2. Acids and bases in fluorosulfuric acid.

Bases	Acids
Alkali and alkaline earth fluorosulfates	SbF_5
AsF_3	AuF_3
SbF_3	BF_3
IF_5	TaF_5
$HClO_4$	PtF_4
H_2SO_4	SO_3
HF	

Conductometric titrations with potassium fluorosulfate or antimony pentafluoride make it possible to determine whether a compound acts as an acid or as a base in fluorosulfuric acid. Potassium fluorosulfate (in HSO_3F) is added to a solution of the compound to be investigated (in HSO_3F) and the change in conductivity is recorded. If the substance acts as an acid, the latter is neutralized by the fluorosulfate and the conductivity falls to a minimum. Neutralization, naturally, represents the reverse of autoprotolysis:

$$H_2SO_3F^+ + SO_3F^- \rightleftharpoons 2\ HSO_3F$$

The behavior of H_2SO_4, HF, $HClO_4$, and their salts in fluorosulfuric acid gives an indication of the strength of the latter. On dissolution of potassium sulfate in fluorosulfuric acid, the conductivity observed is almost exactly twice that of an equimolar solution of potassium fluorosulfate [5]. It follows that potassium sulfate is completely solvolysed in this medium:

$$K_2SO_4 + 2\ HSO_3F \rightleftharpoons 2\ K^+ + 2\ SO_3F^- + H_2SO_4$$

Conductometric investigations point to a weakly basic behavior of sulfuric acid in fluorosulfuric acid, characterized by a base constant $K_b = 10^{-4}$, *i.e.* the following equilibrium can be postulated:

$$H_2SO_4 + HSO_3F \rightleftharpoons H_3SO_4^+ + SO_3F^-$$

During electrolysis of a solution of hydrogen fluoride in fluorosulfuric acid, *Woolf* [8] observed a migration of fluorine towards the cathode. This result and quantitative conductivity measurements are best explained by the formation of H_2F^+ ions, even if only to a very small extent, according to the following basic dissociation:

$$HF + HSO_3F \rightleftharpoons H_2F^+ + SO_3F^-$$

The interpretation of the behavior of perchloric acid or potassium perchlorate in fluorosulfuric acid involves some difficulty. *Woolf* [8] titrated a solution of perchloric acid in HSO_3F with antimony pentafluoride and with potassium fluorosulfate, and obtained a minimum in the first but not in the second case. Nevertheless, he assumed equilibrium (d), corresponding to the well-known reaction of $KClO_4$ with HSO_3F which leads to perchloryl fluoride [9].

$$2\ HSO_3F + HClO_4 \rightleftharpoons ClO_3^+ + H_3O^+ + 2\ SO_3F^- \qquad (d)$$

On the other hand, *Barr et al.* [5] concluded from measurements of the conductivity of potassium perchlorate in fluorosulfuric acid that perchloric acid must be a very weak basic electrolyte in accordance with Equation (e):

$$HClO_4 + HSO_3F \rightleftharpoons H_2ClO_4^+ + SO_3F^- \qquad (e)$$

while the conductivity expected from Equation (d) would be substantially higher than the observed value.

On dissolution of AsF_3 in fluorosulfuric acid, the conductivity increases gradually to reach a constant value in about four days [5]. Titration of such solutions with SbF_5 in HSO_3F has shown that AsF_3 dissolves as a weak base in accordance with equilibrium (f) proposed by *Barr et al.* The increase in conductivity can then be explained by the secondary reactions (g) and (h) leading to a fluorosulfate capable of dissociating.

$$AsF_3 + HSO_3F \rightleftharpoons HAsF_3^+ + SO_3F^- \qquad (f)$$

$$AsF_3 + HSO_3F \rightleftharpoons AsF_2(SO_3F) + HF \qquad (g)$$

$$AsF_2(SO_3F) \rightleftharpoons AsF_2^+ + SO_3F^- \qquad (h)$$

Solutions of antimony trifluoride in HSO_3F have considerably higher conductivities and are even less stable than solutions of AsF_3 [5]. Antimony trifluoride also behaves as a base, but forms secondary products relatively quickly even at room temperature. These secondary products then dissociate, probably in the same way as postulated for AsF_3.

4. Fluorosulfuric Acid as a Fluorinating Agent

Fluorosulfuric acid is an excellent fluorinating agent for the preparation of volatile inorganic acid fluorides and fluorosulfates. Some acid fluorides prepared in this manner are listed in Table 3.

Table 3. Preparation of acid fluorides with HSO_3F.

Starting material	Fluoride	B.p. [°C]	Ref.
$KMnO_4$	$FMnO_3$	60	[10]
K_2CrO_4 (CrO_3, $K_2Cr_2O_7$)	F_2CrO_2	30	[11]
P_4O_{10}	F_3PO	−39	[12]
$BaSeO_4$	F_2SeO_2	− 8	[13]
As_2O_5 ($BaHAsO_4$)	AsF_5, ($OAsF_3$)	−53 (+24)	[12]
As_2O_3	AsF_3	63	[14]
$BaTeO_4$	F_5TeOH	60	[15]
$KClO_4$	$FClO_3$	−46	[9]

When an alkali metal or alkaline earth metal salt of the acid, or the acid anhydride, is introduced into fluorosulfuric acid, the fluoride is formed either instantaneously in the cold or gradually on heating or boiling. For example, no perchloryl fluoride can be detected by NMR spectroscopy in a cold solution of potassium perchlorate in fluorosulfuric acid [16]. However, between 50 and 85 °C the product distils over in very good yield [9].

$$KClO_4 + 2\ HSO_3F \rightarrow ClO_3F + H_2SO_4 + KSO_3F$$

[15] *A. Engelbrecht* and *F. Sladky,* a) Angew. Chem. *76,* 379, (1964); Angew. Chem. internat. Edit. *3,* 383 (1964); b) Mh. Chem. *96,* 159 (1965).

[16] *J. Bacon, R. J. Gillespie,* and *J. W. Quail,* Canad. J. Chem. *41,* 3063 (1963).

Woolf [8] has postulated the following reactions:

$$3\ HSO_3F + KClO_4 \rightleftharpoons ClO_3^+ + 3\ SO_3F^- + H_3O + K^+$$
$$ClO_3^+ + SO_3F^- \rightleftharpoons ClO_3F + SO_3$$

according to which perchloryl fluoride is formed by the thermal decomposition of the ion pair $ClO_3^+\ SO_3F^-$.

The analogous reactions which lead to MnO_3F and CrO_2F_2 [10,11] are instantaneous, and formation of the oxide fluorides is accompanied by the evolution of a considerable amount of heat.

It is worth noting that all the compounds prepared in this manner are highly volatile, and complete conversion is generally obtained only by removal of the acid fluorides already formed. This indicates equilibria which may be intrinsically unfavorable for the formation of acid fluorides, but which can be displaced by the volatility and the relatively low solubility of the reaction products in fluorosulfuric acid.

The preparation of SeO_2F_2 from barium selenate and fluorosulfuric acid involves complete solvolysis (i) as the primary stage, followed by the protolysis (k) of the selenic acid, which probably behaves as a base towards to fluorosulfuric acid:

$$BaSeO_4 + 2\ HSO_3F \rightleftharpoons H_2SeO_4 + Ba^{2+} + 2\ SO_3F^- \quad (i)$$
$$H_2SeO_4 + HSO_3F \rightleftharpoons H_3SeO_4^+ + SO_3F^- \quad (k)$$

Elimination of water from the selenate acidium ion may represent the rate-determining reaction which is strongly temperature-dependent.

$$H_3SeO_4^+ \rightleftharpoons H_2O + HSeO_3^+ \quad (l)$$

The last step is then probably the decomposition of the resulting ion pair $HSeO_3^+\ SO_3F^-$, leading to formation of SO_3, which combines with the water formed in Eq. (l) to give sulfuric acid:

$$HSeO_3^+\ SO_3F^- \rightleftharpoons HSeO_3F + SO_3$$

An analogous repetition of this reaction sequence then leads to the formation of selenium dioxide difluoride:

$$HSeO_3F + HSO_3F \rightleftharpoons H_2SeO_3F^+ + SO_3F^-$$
$$H_2SeO_3F^+ \rightleftharpoons H_2O + SeO_2F^+$$
$$SeO_2F^+\ SO_3F^- \rightleftharpoons SeO_2F_2 + SO_3$$

All reactions listed in Table 3 formally represent the replacement of a hydroxy group by fluorine. A thermally unstable fluorosulfate is indeed formed as an intermediate in addition to the acidium ion:

$$O_nX{-}OH + HSO_3F \rightleftharpoons O_{n-1}X(OH)^{2+} + SO_3F^- \quad (m)$$
$$O_{n-1}X(OH)_2^+ \rightleftharpoons H_2O + O_nX^+ \quad (n)$$
$$O_nX^+ + SO_3F^- \rightleftharpoons O_nXOSO_2F \quad (o)$$

Its thermal decomposition then leads to formation of the acid fluoride. Evidently the elimination of water from the acidium ion in accordance with Eq. (n) determines the rate of formation of the acid fluoride, since MnO_3F and CrO_2F_2 are formed by very fast reactions. It is well known that the acids H_2CrO_4 and $HMnO_4$ likewise form anhydrides relatively easily.

In some cases, the fluorosulfate itself is volatile and thermally sufficiently stable to distil without decomposition. One example is the reaction of As_2O_5 with fluorosulfuric acid, which leads not only to varying amounts of AsF_5 and probably $AsOF_3$, but also to a mixture of $AsF_2(SO_3F)_3$ and $AsF_3(SO_3F)_2$ [12]. The reaction of H_4BaTeO_6 with HSO_3F shows that the fluorosulfates of metals in high oxidation states can be relatively stable: the compound F_5TeOSO_2F is obtained in very good yield [15b].

5. Salts of Fluorosulfuric Acid

Alkali, alkaline earth, and ammonium fluorosulfates have been known for a long time [2]. A much used general method of preparation is the reaction between metal fluorides and sulfur trioxide [3,17–20]:

$$MF + SO_3 \rightleftharpoons MOSO_2F$$

An alternative procedure is based on the reaction of fluorides [21] or chlorides [19,22,23] with fluorosulfuric acid, and is accompanied by liberation of HF or HCl. However, chloride-, fluoride- and oxide fluorosulfates are sometimes formed during these reactions [19,23].

$$MCl_x + yHSO_3F \rightarrow MCl_{x-y}(SO_3F)_y + (x{-}y)HCl$$
$$M = Ti^{4+},\ Sn^{4+},\ Ta^{5+},\ Sb^{5+}$$

$$M(SO_3F)x \rightarrow MO(SO_3F)_{x-2} + S_2O_5F_2$$
$$M = Al^{3+},\ Sb^{3+},\ Nb^{5+},\ W^{6+}$$

$$MCl_x + xHSO_3F \rightarrow MF_{x-y}(SO_3F)y + (x{-}y)HCl + yHSO_3Cl$$
$$M = Th^{4+},\ Zr^{4+}$$

6. Thermal Decomposition of Fluorosulfates

Unlike the thermally stable fluorosulfuric acid, many fluorosulfates decompose at relatively low temperatures, *via* the following types of reactions [12,19,20,24–26]:

$$OMSO_2F \rightleftharpoons MF + SO_3$$
$$M(OSO_2F)_2 \rightleftharpoons MSO_4 + SO_2F_2$$
$$M(OSO_2F)_2 \rightleftharpoons M{-}O + S_2O_5F_2$$
$$M(OSO_2F)_3 \rightleftharpoons {-}M(F)O{-} + S_3O_8F_2$$

Pyrosulfuryl fluoride $S_2O_5F_2$ [27], the anhydride of fluorosulfuric acid, is formed at low temperatures. Sulfuryl fluoride is obtained by decomposition of $S_2O_5F_2$ above 350 °C:

$$S_2O_5F_2 \rightleftharpoons SO_3 + SO_2F_2$$

Decomposition of fluorosulfates into SO_3 and metal fluorides occurs when fluoride formation is favored by a particularly stable crystal lattice.

New Methods in Preparative Organic Chemistry IV [*]

New Reactions of Alkylidenephosphoranes and their Preparative Uses

Part II. Alkylidenephosphoranes and Halogen Compounds [**]

BY PROF. DR. H. J. BESTMANN

INSTITUT FÜR ORGANISCHE CHEMIE DER UNIVERSITÄT ERLANGEN-NÜRNBERG (GERMANY)

The reactions of alkylidenephosphoranes with compounds containing halogens can be used to prepare ylides, which can be converted into useful products, e.g. by hydrolysis, by thermal decomposition, or by other reactions. Examples of such products are ketones (including cyclic, unsaturated, and branched-chain ketones), carboxylic esters (including those of unsaturated, branched-chain, polyenecarboxylic, acetylenecarboxylic, and allenecarboxylic acids), and aldehydes.

A. Introduction

The basic nature of alkylidenephosphoranes is shown not only by the reactions discussed in Part I, but also by the ability of these compounds to react with methyl iodide [1, 2]. The first step in this reaction [1] is methylation of the ylide *(1)* to the phosphonium salt *(2)*, R = CH_3.

$$(C_6H_5)_3P{=}CH_2 + R\text{-}I \rightarrow [(C_6H_5)_3\overset{\oplus}{P}\text{-}CH_2\text{-}R]\,I^{\ominus}$$
(1) *(3)* *(2)*

$$[(C_6H_5)_3\overset{\oplus}{P}\text{-}CH_2\text{-}R]\,I^{\ominus} \xrightarrow{H_2C=P(C_6H_5)_3\ (1)} (C_6H_5)_3P{=}CH\text{-}R + [H_3C\text{-}\overset{\oplus}{P}(C_6H_5)_3]\,I^{\ominus}$$
(4) *(5)*

After the recognition of the principle of transylidation, however, it was necessary to assume that halogen compounds *(3)* containing an electron-attracting group R give a salt *(2)* which is a strong acid, and which immediately enters into a transylidation reaction with a second molecule of the ylide *(1)*. The products in this case should be an alkylated ylide *(4)* and the phosphonium salt *(5)*.

Other reactions have also been observed besides the formation of the salt *(2)* or the immediate transylidation to form *(4)*. Thus whilst *(4)* results from attack by a second ylide molecule in the α position relative to the phosphorus atom of the salt *(2)*, the reaction with the second ylide can lead to a Hofmann degradation if the β position of *(2)* is activated. γ-Eliminations (with respect to the P atom) have also been observed. All these reactions open up new preparative methods, which will be discussed below.

B. Reactions Involving Transylidation

1. C-Acylation of Alkylidenephosphoranes

a) Reaction with Acyl Chlorides

Alkylidenephosphoranes *(6)* react with acyl chlorides *(7)* in accordance with Scheme 1 [3a, 3b].

The H atom on the α carbon of the initially formed phosphonium chloride *(8)* is strongly acidic, owing to the influence of the adjacent carbonyl group. Compound *(8)* therefore immediately enters into a transylidation reaction with a second molecule of the ylide *(6)*, to

$$(C_6H_5)_3P{=}\overset{H}{\underset{}{C}}\text{-}R^1 + R^2\text{-}CO\text{-}Cl \rightarrow \left[(C_6H_5)_3\overset{\oplus}{P}\text{-}\overset{H}{\underset{O=C\text{-}R^2}{C}}\text{-}R^1\right] Cl^{\ominus}$$
(6) *(7)* *(8)*

$$\xrightarrow{(6)} (C_6H_5)_3P{=}\underset{O=C\text{-}R^2}{\overset{}{C}}\text{-}R^1 + [(C_6H_5)_3\overset{\oplus}{P}\text{-}CH_2\text{-}R^1]\,Cl^{\ominus}$$
(9) *(10)*

Scheme 1

form an acylated alkylidenephosphorane *(9)* and the phosphonium salt *(10)* [4]. The stoichiometry of the reaction can be represented as 2 *(6)* + *(7)* → *(9)* + *(10)*.

The reaction with the acyl chlorides is carried out in a boiling benzene solution of the ylide containing no lithium salts. The salt *(10)* precipitates and can be used to prepare fresh *(6)*; the acylated alkylidenephosphoranes *(9)* remain in solution. It is essential to avoid an excess of acyl chloride, since these compounds can also attack *(9)*. Acylalkylidenetriphenylphosphoranes prepared by this method are listed in Table 1.

Table 1. Acylalkylidenetriphenylphosphoranes $R^2\text{—}CO\text{—}CR^1{=}P(C_6H_5)_3$ *(9)*.

	R^1	R^2	M.p. [°C]	Yield [%] with acyl chloride	Yield [%] with thioester

(22)	C_3H_7	$C_6H_5\text{—}CH_2\text{—}CH_2$	147—149 [e]	36	63
(23)	C_6H_5	CH_3	166—168 [a]	73	68
(24)	C_6H_5	C_6H_5	192—194 [a]	64	58
(25)	CO_2CH_3	C_6H_5	133—135 [a,f]	83	—

[a] Colorless or pale yellow crystals from ethyl acetate.

[b] Yellow needles, which rearrange on melting (159—161 °C) to form a red modification with m.p. 176—178 °C.

[c] Yellow crystals from a large volume of ethyl acetate; darkens on melting.

[d] Yellow crystals from ethyl acetate.

[e] Colorless to pale yellow crystals from ethyl acetate/petroleum ether.

[f] Obtained in ethyl acetate without protection by nitrogen.

The lowest yields are obtained from the reactions of strongly basic alkylidenephosphoranes with acyl chlorides having an activated H atom close to the carbonyl group. In these cases (*e.g.* with phenylacetyl chloride), the reaction yields dark resinous products from which triphenylphosphine oxide can be isolated.

[*] The contributions in the previous three series have been published collectively in three volumes by Verlag Chemie, Weinheim/Bergstr. (Germany). English edition: Academic Press, New York-London.

[**] For Part I see Angew. Chem. *77*, 609 (1965), Angew. Chem. internat. Edit. *4*, 583 (1965). Part III will appear shortly in this journal.

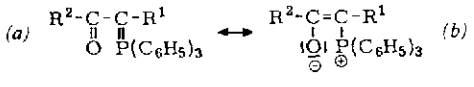
[3b] *H. J. Bestmann* and *B. Arnason*, Tetrahedron Letters *1961*, 455; Chem. Ber. *95*, 1513 (1962).

[4] *S. Trippett* and *D. M. Walker*, J. chem. Soc. (London) *1961*, 1266, have also reported reactions of alkylidenephosphoranes with acid chlorides. They used ylide solutions containing lithium salts. These authors did not, however, recognize the principle of C-acylation with simultaneous transylidation, and state that the reaction stops at the stage of the salt *(8)*; cf. [3b]. *P. L. Pauson* and *W. E. Watts*, J. chem. Soc. (London) *1963*, 2990 isolated a salt of the structure *(8)* after reaction of benzoyl chloride with an ylide of the ferrocene series, prepared with an organolithium compound.

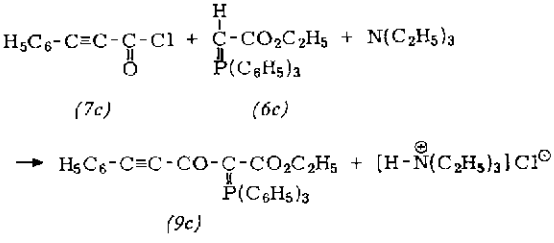
These disadvantages are avoided if thiol esters are used instead of acyl chlorides (cf. Section B 1b).

All the compounds listed in Table 1, with the exception of α-caproylethylidenetriphenylphosphorane *(19)*, are crystalline. They can be recrystallized from ethyl acetate or ethyl acetate/petroleum ether, and retain the solvent extremely tenaciously. However, drying need not be as thorough before further reactions as for melting-point determinations. The compounds are not attacked by atmospheric oxygen and cold water.

The CO band in the infrared spectra of all acylalkylidenetriphenylphosphoranes is displaced to 6.5–6.7 μ, as was observed earlier by *Wittig* [5] and *Ramirez* [6] for compounds *(23)* and *(24)*. *Ramirez* attributed the shifts to resonance between forms *(a)* and *(b)*.



This explanation agrees with the fact that the O atom is attacked in the reactions of acylalkylidenetriphenylphosphoranes *(9c)* with halogen compounds [6]. *Gough* and *Trippett* [7] have shown that when the alkylidenephosphorane *(6c)* used contains a strongly electron-attracting group R, so that the phosphonium salt intermediate *(8c)* (see Scheme 1) is a strong acid, the second molecule of ylide can be replaced by triethylamine.



Reactions of this type proceed only when the amine is a stronger base than the ylide [8].

Procedure:

Acylation of Alkylidenetriphenylphosphoranes with Acyl Chlorides [3]

A salt-free solution of 0.022 mole of an alkylidenetriphenylphosphorane in 100 ml of anhydrous benzene is heated to boiling under nitrogen in a Schlenk tube with a Claisen head fitted with a mercury-sealed reflux condenser and a dropping funnel. A solution of 0.01 mole of the acyl chloride in 50 ml of benzene is added dropwise to the boiling, red solution. The phosphonium chloride precipitates. The addition of acyl chloride is stopped when the ylide has been exhausted, as shown by decoloration of the solution. (An excess of acyl chloride must be avoided, since this compound also attacks the acylated ylide). When the reaction is complete, the inert atmosphere can be dispensed with. The phosphonium chloride is filtered off and washed with benzene, and the solution is concentrated in vacuum. The residue is mixed with 20 ml of ethyl acetate, cooled for a short time in ice/salt, and filtered.

A second fraction can be obtained by concentration of the mother liquor. Evaporation of the solvent frequently leaves behind an oily residue, but this generally dissolves in ethyl acetate and crystallizes after 24 h in a refrigerator.

Most acylalkylidenetriphenylphosphoranes can be recrystallized from ethyl acetate. The solubility of the compounds in this solvent increases with the number of methylene groups they contain. The crystallization is frequently slow, and can be accelerated by a few ml of ether. Many acylalkylidenetriphenylphosphoranes tenaciously retain the solvent.

It is not absolutely necessary to isolate the acyl compound in preparation for further reactions; it can be hydrolysed or made to react with aldehydes directly after concentration of the benzene solution. If benzene is to be used as the solvent for the reaction with aldehydes, the acylation solution can be used directly after the phosphonium salt has been filtered off.

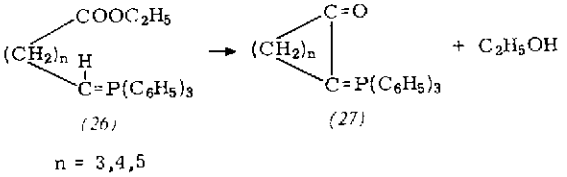
The phosphonium chlorides are formed in yields of 80 to 100%, and can be used to prepare fresh ylide after a single reprecipitation from chloroform with ether, followed by careful drying. The chlorides are occasionally obtained in the form of oils, but these can be crystallized by friction.

b) Reaction with Esters, Thiol Esters, and Acylimidazoles

Acylalkylidenetriphenylphosphoranes can be used for the synthesis of ketones, as will be shown in Section B 1c. Since the preparation of acyl ylides starting from α-bromoketones proceeds smoothly in only a few cases [9], the C-alkylation of alkylidenephosphoranes is of considerable practical importance.

Acylation with acyl chlorides has the disadvantage that one mole of the ylide used is lost as the triphenylalkylphosphonium chloride *(10)*, although the compound *(6)* can be recovered from this salt. A method of acylation which avoids this disadvantage is the reaction of alkylidenephosphoranes with esters.

Ylide solutions generally do not react with ethyl or methyl esters in the absence of salts [3, 10]. However, the ω-ethoxycarbonylalkylidenetriphenylphosphoranes *(26)* have been observed to undergo an intramolecular C-alkylation to form cyclic ylides *(27)* [11a, 11b]. This reaction presents new possibilities for the synthesis of cyclic carbonyl compounds.



n = 3,4,5

Surprisingly, however, the alkyl esters react with alkylidenephosphoranes in the presence of lithium salts [4, 5]. These reactions also proceed by transylidation [3]. The products obtained are the acylalkylidenetriphenylphosphoranes *(9)* and

[10] *H. Behringer* and *K. Fulkenberg*, Chem. Ber. *96*, 1428 (1963), report the reaction of a vinylogous ester with ethoxycarbonylmethylidenetriphenylphosphorane.

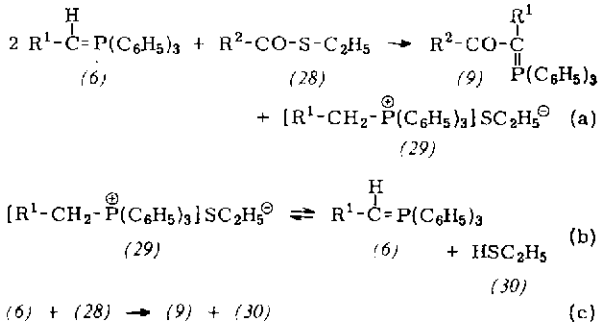
[11a] *H. O. House* and *H. Babad*, J. org. Chemistry *28*, 90 (1963).

[11b] *L. D. Bergelson*, *V. A. Vaver*, *L. I. Barsukov*, and *M. M. Schemyakin*, Izv. Akad. Nauk SSSR, Otd. Khim. Nauk *1963*, 1134; Chem. Abstr. *59*, 8607d (1963).

the triphenylalkylphosphonium bromides [*(10)*, with $Br^{\ominus}$ in place of $Cl^{\ominus}$], the latter resulting from reaction of the initially formed alkoxides [*(10)*, with $OC_2H_5^{\ominus}$ in place of $Cl^{\ominus}$] with the LiBr present in the solution. Thus the starting materials react in a molar ratio of 2:1; however, the yields of acylated ylide *(9)* are poor.

Better results are obtained in the reaction of salt-free solutions of alkylidenephosphoranes with activated esters, such as phenyl esters and thiophenyl esters [3], or with acylimidazoles [12]. These reactions again proceed by transylidation, and present important methods of formylation [8, 13].

A particularly useful group of acylating agents is formed by the *S*-ethyl esters of thiocarboxylic acids *(28)* [3].



The first step in this reaction is the formation of the acylalkylidenephosphorane *(9)* and the phosphonium ethylthiolate *(29)*, which precipitates out [Equation (a)]. Like the phosphonium alkoxides [14], *(29)* loses ethyl mercaptan on heating to form the ylide *(6)* [Equation (b)]. This can then react with further thiol ester *(28)*, and is removed in this way from the equilibrium, as is shown by the slow dissolution of the precipitated salt *(29)*, which is frequently in the form of an oil. The overall reaction is represented by Equation (c). This method requires one mole of ylide less than the acyl chloride method. The yields are noted in Table 1.

Procedures:

Acylation of Alkylidenetriphenylphosphoranes with S-Ethyl Esters of Thiocarboxylic Acids [3]

The reaction should be carried out in a Schlenk tube, and it is advisable to close the top of the reflux condenser with a mercury valve. 0.02 mole of the S-ethyl thiocarboxylate is added to a boiling solution of 0.022 mole of an alkylidenephosphorane (salt-free) in absolute toluene (the solution need not be filtered). The mixture is boiled for 18 hours, during which time the oily phosphonium thiolate which initially precipitates is slowly redissolved. If an unfiltered ylide solution is used, it is now necessary to remove the sodium halide by hot filtration (a protective nitrogen atmosphere is not required). Evaporation of the solution leaves the acylalkylidene triphenylphosphorane, which can be crystallized by friction. The yields and the solvents used for recrystallization are given in Table 1. The excess of phosphonium salt required increases with the length of the residue R in the triphenylalkylphosphonium salts $[R-CH_2-P^{\oplus}(C_6H_5)_3]X^{\ominus}$ (*e.g.* triphenylbutylphosphonium bromide: 35% excess).

[12] *H. J. Bestmann, N. Sommer*, and *H. A. Staab*, Angew. Chem. *74*, 293 (1962); Angew. Chem. internat. Edit. *1*, 270 (1962).

[13] *H. A. Staab* and *N. Sommer*, Angew. Chem. *74*, 294 (1962); Angew. Chem. internat. Edit. *1*, 270 (1962).

[14] *G. Wittig* and *W. Haag*, Chem. Ber. *88*, 1654 (1955).

The S-ethyl esters of thiocarboxylic acids are generally prepared from the acyl chlorides and $NaSC_2H_5$ [15].

α-Oxocyclohexylidenetriphenylphosphorane [11a]

Triphenyl-ω-ethoxycarbonylamylphosphonium iodide *(42g)* is added to a solution of 3.4 g of potassium in 300 ml of t-butanol. The mixture is refluxed for 12 hours and concentrated in vacuum, and the residue is shaken with chloroform/water. The chloroform solution is dried and the ylide *(27)*, n = 4, is precipitated with ethyl acetate; yield 22.1 g (79%); m.p. 243–245 °C.

c) Preparation of Ketones by Cleavage of Acylalkylidene Triphenylphosphoranes

Acylalkylidenetriphenylphosphoranes *(9)* are weak bases, and are therefore stable towards cold water. On boiling with water, however, they break down to form ketones *(31)* and triphenylphosphine oxide [6, 3].

Some examples are given in Table 2.

Table 2. Ketones $R^1-CO-CH_2-R^2$, *(31)*, obtained by hydrolysis of acylalkylidenetriphenylphosphoranes *(9)*.

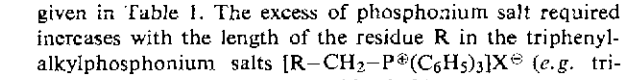
R^1	R^2	Yield [%]
CH_3	H	83 [a]
C_6H_5	H	93 [a]
$C_6H_5-CH_2-CH_2$	H	78
C_6H_5	CH_3	84 [a]
$C_6H_5-CH=CH$	CH_3	74
C_5H_{11}	CH_3	95

[a] Yield determined *via* the 2,4-dinitrophenylhydrazone.

The hydrolysis is carried out in aqueous alcohol. The reaction is accelerated by the addition of a little alkali metal hydroxide. The acylbenzylidenetriphenylphosphoranes *(23)* and *(24)*, *p*-nitrobenzoylmethylidenetriphenylphosphorane *(14)*, and benzoylmethoxycarbonylmethylidenetriphenylphosphorane *(25)* cannot be hydrolysed, probably owing to the proximity of resonance-stabilizing groups which interact with the C–P double bond. This interaction reduces the basicity of the carbon atom to such an extent that the phosphonium hydroxide can no longer be formed.

The cyclic ylides *(27)* are hydrolysed only on heating in *o*-dichlorobenzene/water/ethanol (1:3:5) in a pressure tube at 150 °C; the products are cyclic ketones and triphenylphosphine oxide [11a].

Ketones are also obtained by reductive cleavage of acylalkylidenetriphenylphosphoranes *(9)* with zinc in glacial acetic acid [4].

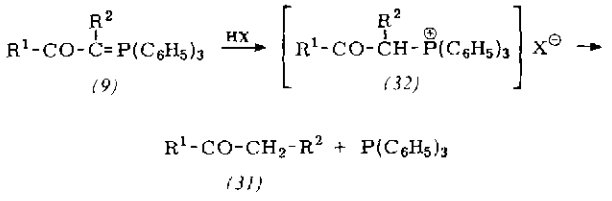


This reaction proceeds particularly well when the residue R^1 is aromatic (yields > 90%). With aliphatic residues R^1, the yields of ketone are much poorer than

[15] Cf. *H. J. Bestmann* and *H. Schulz*, Chem. Ber. *92*, 530 (1959).

those obtained by hydrolysis, and in some cases this method fails completely.

Another preparatively important reaction is the electrolytic cleavage of quaternary phosphonium salts [16]. The acylalkylidenetriphenylphosphorane is dissolved in the stoichiometric quantity of mineral acid, and the resulting solution of the salt *(32)* is electrolysed in a closed vessel fitted with a reflux condenser, using a lead cathode which is bent around the diaphragm of the carbon anode, a short distance away. The ketone *(31)* and triphenylphosphine are obtained in yields of 60–80 % [3b].



$$R^1\text{-}CO\text{-}\underset{\textit{(9)}}{\overset{R^2}{\overset{|}{C}}}\text{=}P(C_6H_5)_3 \xrightarrow{HX} \left[R^1\text{-}CO\text{-}\underset{\textit{(32)}}{\overset{R^2}{\overset{|}{C}}}\text{-}\overset{\oplus}{P}(C_6H_5)_3\right] X^{\ominus} \rightarrow$$

$$R^1\text{-}CO\text{-}CH_2\text{-}R^2 + P(C_6H_5)_3$$

(31)

This method fails with aromatic residues R^1, since in this case the ylides *(9)* are regenerated. The same is true when R^1 is C_6H_5–CH=CH–. On the other hand, the method is recommended for aliphatic residues R^1. Thus the electrolytic method supplements the method of reductive cleavage with zinc and glacial acetic acid, and *vice versa*. The advantage of these methods is the regeneration of the triphenylphosphine.

Procedures:

Preparation of Ketones by Hydrolysis [3]

The acylalkylidenetriphenylphosphorane (the unpurified product of the acylation can be used) is dissolved in 50–80 ml of 80% aqueous methanol, 1–2 ml of 2N NaOH is added, and the mixture is refluxed for 12 h. After addition of 3 ml of glacial acetic acid, the ketone formed is steam-distilled. The distillate is extracted with ether, the ether solution dried, and the ketone is distilled or recrystallized after the solvent has been driven off.

All the ketones listed in Table 2 can be isolated. If the product is not steam-volatile, the solution must be concentrated after addition of the glacial acetic acid, and the ketone is then separated from the triphenylphosphine oxide by treatment of the residue with petroleum ether. This separation can also be conveniently carried out by the zinc chloride method [17]. The yields are noted in Table 2.

Preparation of Ketones by Reductive Cleavage [3]

The acylalkylidenetriphenylphosphorane (0.005 mole) is dissolved in 25 ml of chloroform. Zinc powder is added (12 g), and 50 ml of glacial acetic acid is added to the boiling mixture over a period of 1 h. After boiling for a further hour, the reaction solution is steam-distilled, and the ketone is extracted from the distillate with ether. The residue from the steam-distillation is extracted with ether, and the ether phase is washed with 2N NaOH and dried over magnesium sulfate. The solvent is distilled off in vacuum, leaving behind triphenylphosphine, which can be recrystallized from methanol (m.p. and mixed m.p. 81 °C).

[16] *L. Horner* and *A. Mentrup*, Liebigs Ann. Chem. *646*, 65 (1961).

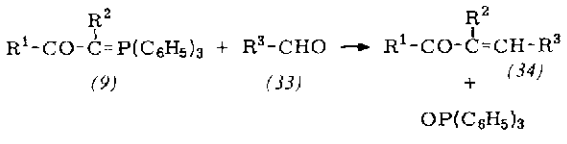
[17] *H. J. Bestmann, H. Buckschewski*, and *H. Leube*, Chem. Ber. *92*, 1345 (1959).

Preparation of Ketones by Electrolysis

The electrolysis is carried out in a three-neck flask (≈ 250 ml) with a wide middle neck, through which the diaphragm is introduced and fixed with a rubber collar. The lead cathode is bent around the diaphragm at a distance of 2–3 cm. A wire fused into a stopper which is fitted in one of the necks is connected to the cathode through a terminal. The third neck should be fitted with a reflux condenser, since the electrolysis is accompanied by a large increase in temperature. The acylalkylidenetriphenylphosphorane (0.01 mole) is dissolved in the stoichiometric quantity of HCl. The solution is diluted to 50–100 ml, and electrolysed at 24–30 volts. The current increases to 2–3 amp within 15 min, and slowly falls off again towards the end of the reaction. Many ketones can be steam-distilled directly from the reaction solution. The residue is triphenylphosphine. If the ketone is not steam-volatile, the electrolysed solution is extracted with ether and the solution is dried. After the ether has been driven off, the residue is distilled in a rotating bulb tube, or methanol is poured over it (0 °C) to remove triphenylphosphine. (For the experimental arrangement, see [16]).

d) Synthesis of α-Branched α,β-Unsaturated Ketones

Acylalkylidenetriphenylphosphoranes *(9)* can react with aldehydes *(33)* in a Wittig reaction to form α,β-unsaturated ketones, particularly with chain branching in the α position *(34)* [3, 6].



$$R^1\text{-}CO\text{-}\underset{\textit{(9)}}{\overset{R^2}{\overset{|}{C}}}\text{=}P(C_6H_5)_3 + \underset{\textit{(33)}}{R^3\text{-}CHO} \rightarrow R^1\text{-}CO\text{-}\underset{\textit{(34)}}{\overset{R^2}{\overset{|}{C}}}\text{=}CH\text{-}R^3 + OP(C_6H_5)_3$$

A number of compounds obtained by reaction with benzaldehyde are shown in Table 3.

Table 3. α-Branched α,β-unsaturated ketones C_6H_5–CH=CR^2–CO–R^1 obtained from acylalkylidenetriphenylphosphoranes $(C_6H_5)_3P$=CR^2–CO–R^1 and benzaldehyde.

Compound	R^1	R^2	Time [days]	Yield [%]
(35)	CH_3	H	3	76 [a]
(36)	C_6H_5	H	3	70 [a]
(37)	C_6H_5–CH_2–CH_2	CH_3	3	64
(38)	C_6H_5–CH=CH	CH_3	4	81
(39)	C_5H_{11}	CH_3	1	40
(40)	C_6H_5–CH_2–CH_2	C_3H_7	3	60 [a]

[a] Yield determined *via* the 2,4-dinitrophenylhydazone.

The reactions take much longer than the normal Wittig reaction. In order to obtain good yields, it is necessary in most cases to boil for 3 to 4 days in anhydrous benzene. Ketones do not react in this way [18]. The acylalkylidenetriphenylphosphoranes which are resistant to hydrolysis are also unable to undergo Wittig reactions with aldehydes.

Since triphenylalkylphosphonium salts can be prepared from alkyl halides or alcohols, the C-acylation of alkylidenephosphoranes provides a new method of synthesizing ketones from alkyl halides or alcohols and derivatives of carboxylic acids.

[18] Cf. the acid-catalysed reactions of the stable alkoxycarbonylethylidenetriphenylphosphoranes: *Ch. Rüchardt, S. Eichler*, and *P. Panse*, Angew. Chem. *75*, 858 (1963); Angew. Chem. internat. Edit. *2*, 619 (1963); *S. Fliszar, R. F. Hudson*, and *G. Salvadori*, Helv. chim. Acta *47*, 159 (1964).

Procedure:

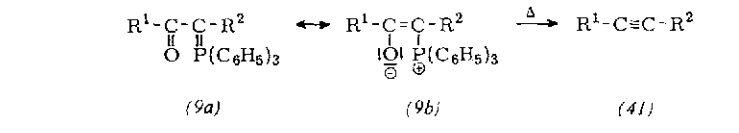
2-Methyl-1,5-diphenyl-1,4-pentadien-3-one (38)

Cinnamoylethylidenetriphenylphosphorane (8.4 g) *(17)* and 2.12 g of benzaldehyde are refluxed for 4 days in anhydrous toluene, in the absence of oxygen and moisture. The solvent is evaporated in vacuum, and the residue is mixed with 10–20 ml of ether at −40 °C and filtered (insoluble component: 4.5 g of triphenylphosphine oxide; m.p. and mixed m.p. 153 °C; yield 80 %). The filtrate is evaporated to dryness. The residue crystallizes on trituration with a little petroleum ether, and can be recrystallized from isopropanol at −40 to −60 °C; m.p. 62 °C, yield 4.0 g (81 %).

e) Synthesis of Acetylene Derivatives

Acylalkylidenetriphenylphosphoranes *(9)* can be represented by two resonance structures (cf. Section B 1a). The reactions with alkyl halides and acyl chlorides are formulated as passing through *(9b)*, since the attack takes place on the O atom [3, 6, 19].

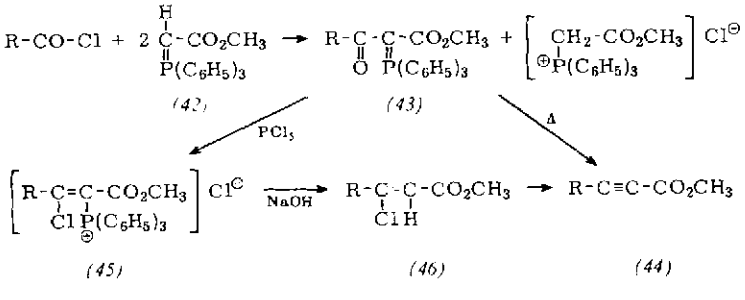
The thermal decomposition of the acylated ylides to form acetylenic compounds *(41)* probably also proceeds *via (9b)* [19, 20].



(9a) *(9b)* *(41)*

This reaction occurs only if R^1 or R^2 is an aromatic group, and if neither R^1 nor R^2 is hydrogen. The yields are around 50 %. If R^1 = C_6H_5 and R^2 = alkyl, the products include allenes as well as acetylenes [21].

The C-acylation of methoxycarbonylmethylidenetriphenylphosphorane *(42)* with acyl chlorides, which proceeds by transylidation, provides an easy route to the α-acyl-α-methoxycarbonylmethylidenetriphenylphosphoranes *(43)*. The thermal decomposition of these compounds leads to very high yields of esters of acetylenecarboxylic acids *(44)* (see Table 4), as was shown by *Märkl* [22] and independently by *Gough* and *Trippett* [19].



(42) *(43)* *(45)* *(46)* *(44)*

It is also possible in this way to obtain esters of bis-acetylenecarboxylic acids [7]. The place of the ester group may also be taken by a cyano group [20].

o-Cl–C_6H_4	66	130–131
	75	107–110 (decomp.)

[a] Amide.

The reaction of the ylides *(43)* with PCl_5 or Vilsmeier reagents leads to phosphonium salts *(45)*, which react with NaOH, without first being isolated, to form the esters of acetylenecarboxylic acids *(44)* *via* the compound *(46)* [23].

Procedure:

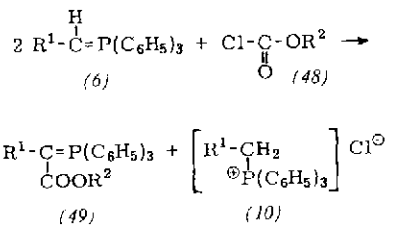
Acetylenecarboxylic Acids [22]

One gram of the ylide *(43)* [22] is placed in a sausage flask or a flask with a descending air-condenser running to a suction tube which acts as both an adaptor and a flask. Depending on the boiling point of the ester expected, the pressure is reduced to between 12 and 0.05 mm Hg, and the ylide is heated slowly to 220–260 °C. The greater part of the triphenylphosphine oxide as well as the ester distils over within about 15 min at 0.05 mm Hg. The distillate is taken up in methanol, and 3 ml of concentrated sodium hydroxide solution is added. The mixture is allowed to stand for 24 h at room temperature, the methanol is evaporated in vacuum, and 30 ml of water is added. Triphenylphosphine separates as an oil at first, but rapidly crystallizes in the cold. The crystals are filtered off, and the filtrate is acidified with a little concentrated hydrochloric acid. The acid which precipitates is subsequently recrystallized from a suitable solvent, depending on its properties.

2. Reaction of Alkylidenephosphoranes with Esters of Chloroformic Acid. Synthesis of Carboxylic Acids

a) Alkoxycarbonylation of Alkylidenephosphoranes

Alkylidenephosphoranes *(6)* react with esters of chloroformic acid *(48)* by transylidation. The reaction allows the alkoxycarbonylation of ylides *(6)* to the esters *(49)* (cf. Table 5).



(6) *(48)* *(49)* *(10)*

The ester carbonyl band in the infrared spectrum of the alkoxycarbonylalkylidenetriphenylphosphoranes

	R^1	M.p. [°C]	[%]
(50)	H	164 [a]	80
(51)	CH_3	145 [a]	95
(52)	C_2H_5	125 [b]	88
(53)	C_3H_7	105 [c]	96
(54)	C_6H_5	155 [a]	80
(55)	Cyclohexyl	oil	75

[a] From ethyl acetate.
[b] From ethyl acetate/petroleum ether.
[c] From benzene/petroleum ether.

(49) is displaced to 6.15 μ [24,25], indicating the strongly "open" character of the carbonyl C–O bond.

Procedure:

Methoxycarbonylation of Alkylidenetriphenylphosphoranes [24]

Methyl chloroformate (0.1 mole) in 50 ml of benzene is added dropwise, in an atmosphere of nitrogen, to a boiling salt-free solution of 0.22 mole of an alkylidenetriphenylphosphorane in anhydrous benzene. The phosphonium chloride *(10)* precipitates. The dropwise addition is stopped immediately the ylide has been consumed, as shown by decoloration of the red solution. An excess of methyl chloroformate must be avoided, since this also attacks the alkoxycarbonylated ylide *(49)*. The nitrogen atmosphere is unnecessary when the reaction is complete. The phosphonium chloride is filtered off and washed with benzene, and the solution is concentrated in vacuum. The residue can be recrystallized from ethyl acetate or from mixtures of ethyl acetate or benzene with petroleum ether. The yields are shown in Table 5. It is not essential to isolate the alkoxycarbonylated ylide prior to further reactions. The benzene solution can be treated with aldehydes directly after removal of the phosphonium chloride, or the crude product can be hydrolysed after the benzene has been driven off.

The phosphonium chlorides are obtained in 80 to 100% yields. They can be used for regeneration of the ylide after a single reprecipitation from chloroform with ether, followed by careful drying. Chlorides which are initially oily can be crystallized by friction.

b) Carboxylic Acids from Methoxycarbonylalkylidenetriphenylphosphoranes

The alkoxycarbonylalkylidenetriphenylphosphoranes *(49)*, which are easily obtained by the above method, can be used for the synthesis of carboxylic acids [24,26]. Hydrolysis of the ylides *(49a)* results in the formation of esters of carboxylic acids *(56)*.

$$R\text{-}\underset{\underset{P(C_6H_5)_3}{\|}}{C}\text{-}CO_2CH_3 + H_2O \rightarrow R\text{-}CH_2\text{-}CO_2CH_3 + OP(C_6H_5)_3$$

(49a) *(56)*

Thus compound *(54)* yields phenylacetic acid (97% yield on boiling in alkaline solution; *(55)* gives cyclohexylacetic acid (75%).

Wittig reaction of compounds *(49a)* with aldehydes *(57)* leads to esters of α-branched α,β-unsaturated carboxylic acids *(58)* [24,26–28].

$$R^1\text{-}\underset{\underset{P(C_6H_5)_3}{\|}}{C}\text{-}CO_2CH_3 + R^2\text{-}CHO \rightarrow R^1\text{-}\overset{OP(C_6H_5)_3}{\overset{+}{\underset{\underset{R^2\text{-}CH}{\|}}{C}}}\text{-}CO_2CH_3$$

(49a) *(57)* *(58)*

Thus α-*trans*-alkylcinnamic acids were obtained by reaction of *(52)* and *(53)* with benzaldehyde [29], and 4-phenyl-1-n-propyl-1,3-butadienecarboxylic acid has been prepared from *(53)* by reaction with cinnamaldehyde.

Ketones generally do not react with the ylides *(49)*. *Fodor* and *Tömösközi* [30], however, were able to carry out reactions of this type in a pressure tube at 100 to 170 °C. Similar reactions can be effected in solution by acid catalysis [18].

Procedures:

Preparation of Carboxylic Acids by Hydrolysis of Methoxycarbonylalkylidenetriphenylphosphoranes (49a)

The ylide *(49a)* is refluxed for 1 h with a 10% solution of potassium hydroxide in aqueous methanol ($H_2O:CH_3OH \approx 1:1$). After cooling, the contents of the flask are mixed with ten times their volume of water, whereupon precipitation of the greater part of the triphenylphosphine oxide occurs. The mixture is filtered, and the filtrate is concentrated to 50–100 ml, cooled, and brought to pH 1 to 3 by addition of sulfuric acid. The subsequent working up is carried out in accordance with the properties of the carboxylic acid formed.

Preparation of α-Branched α,β-Unsaturated Carboxylic Acids by the Wittig Reaction

A solution containing the alkylmethoxycarbonylmethylidenetriphenylphosphorane *(49a)* and the aldehyde *(57)* in benzene is heated for several hours in a Schlenk tube which is fitted with a reflux condenser closed by a mercury valve. The solvent is evaporated in vacuum, and the residue extracted with petroleum ether or with a little ether. Some of the triphenylphosphine oxide remains undissolved. After filtration, the petroleum ether or ether is driven off, and the residue is hydrolysed as described above. Dilution of the reaction mixture with water results in the precipitation of the remaining triphenylphosphine oxide, and the subsequent working up depends on the properties of the carboxylic acid.

3. Reaction with Organic Halides and Carbonium Salts

a) Synthesis of Carboxylic Acids from Organic Halides and Methoxycarbonylmethylidenetriphenylphosphoranes [26]

The reaction of methoxycarbonylmethylidenetriphenylphosphoranes *(42)* with halides *(59)* leads first to the phosphonium salts *(60)*. If the residue R is a ligand with

[24] *H. J. Bestmann* and *H. Schulz*, Angew. Chem. *73*, 27 (1961); Liebigs Ann. Chem. *674*, 11 (1964).

[25] Cf. also *G. Aksnes*, Acta chem. scand. *15*, 692 (1961).

[26] *H. J. Bestmann* and *H. Schulz*, Chem. Ber. *95*, 2921 (1962).

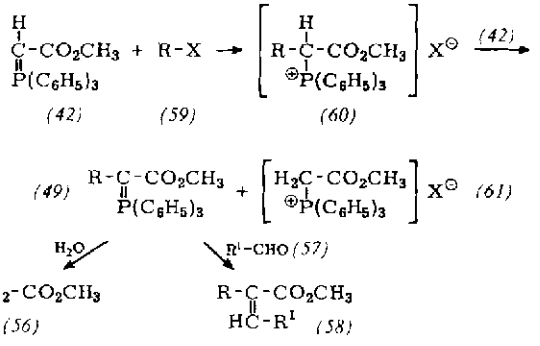
[27] *O. Isler, H. Gutmann, M. Montavon, R. Rüegg, G. Ryser*, and *P. Zeller*, Helv. chim. Acta *40*, 1242 (1957).

[28] *H. O. House* and *G. Rasmusson*, J. org. Chemistry *26*, 4278 (1961).

[29] The *cis*-compounds were not found; cf. [28].

[30] *G. Fodor* and *I. Tömösközi*, Tetrahedron Letters *1961*, 579.

a (−I)-effect, *(60)* will be a strong acid, and will immediately react with a second molecule of ylide *(42)* by transylidation. The resulting products are a substituted methoxycarbonylmethylidenetriphenylphosphorane and the phosphonium salt *(61)*, from which the starting ylide *(42)* can be easily recovered by treatment with a base.



When *(42)* is treated with alkyl iodides, the reaction in anhydrous ethyl acetate stops at the stage of the alkylated phosphonium salt *(60)*, since *(60)* is a weaker acid than the salt *(61)* which would result from transylidation, owing to the (+I)-effect of the aliphatic residue R. However, the yield of the salt *(60)* decreases rapidly with increasing length of the aliphatic group R, owing to the lower polarity of the C-halogen bond. Since the acid-base equilibrium (see Part I) gives rise to partial transylidation between alkylidenephosphoranes and phosphonium salts with equal acid and base strengths, unwanted by-products can be formed [26].

There is no doubt, however, about the course of reactions in which the inductive effect of the substituent R leads to complete transylidation (Table 6).

Table 6. Alkylmethoxycarbonylmethylidenetriphenylphosphoranes $(C_6H_5)_3P{=}CR{-}CO_2CH_3$ *(49a)* obtained from organic bromides *(59)* and methoxycarbonylmethylidenetriphenylphosphorane *(42)*.

R	Yield [%]	M.p. [°C]
$CH_2{-}CH{=}CH_2$	93	oil
$CH_2{-}CO_2CH_3$	98	157–158
$CH_2{-}CN$	89	138–139
$C_6H_5{-}CH_2$	75	186–187
$C_6H_5{-}CH{=}CH{-}CH_2$	81	oil

Anhydrous ethyl acetate is generally used as solvent. The triphenylmethoxycarbonylmethylphosphonium halide *(61)* precipitates (80 to 95% yield). The alkylmethoxycarbonylmethylidenetriphenylphosphoranes *(49a)* are obtained by concentration of the reaction solution. The compounds *(49a)* can be used to prepare the most diverse carboxylic acids *(56)*, *(58)* [26].

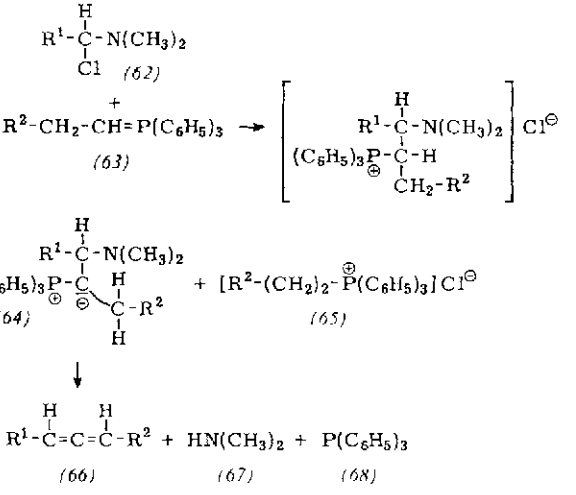
Procedure:

Alkylation of Methoxycarbonylmethylidenetriphenylphosphorane [26]

The alkyl halide *(59)* (0.2 mole) is added to a boiling solution of 0.4 mole of methoxycarbonylmethylidenetriphenylphosphorane *(42)* in anhydrous ethyl acetate, and the mixture is refluxed for 2 hours. The methoxycarbonylmethyltriphenylphosphonium halide *(61)* which precipitates is filtered off (yield 80–95%), and the filtrate is concentrated. The residue consists of the alkylated ylide *(49a)*, which is often obtained as an oil, but which can generally be crystallized by friction and recrystallized from ethyl acetate. The yields are noted in Table 6.

b) Allenes from Alkylidenephosphoranes and 1-Chloro-1-dimethylamino Compounds

The reaction of the readily obtainable dimethylaminochloro compounds *(62)* [31] with alkylidenephosphoranes *(63)* surprisingly yields allenes *(66)* [32].



Scheme 2

Investigations on the mechanism and stoichiometry of the reaction are still in progress [33]. It may be assumed that the reaction proceeds as shown in Scheme 2. From the compound *(62)* and the alkylidenephosphorane *(63)* a salt is formed at first, which undergoes transylidation with a second molecule of *(63)* to give the phosphonium salt *(65)* and the nitrogen-containing alkylidenephosphorane *(64)*. The latter decomposes by an intramolecular β-elimination into the allene *(66)*, dimethylamine *(67)*, and triphenylphosphine *(68)*. This decomposition may be regarded as an intramolecular Hofmann degradation. The amine *(67)* liberated can react with unchanged *(62)* to form *(69)*. The hydrochloric acid formed is bound by the ylide *(63)*.

$$HN(CH_3)_2 + R^1{-}CHCl{-}N(CH_3)_2 \rightarrow R^1{-}CH[N(CH_3)_2]_2 + HCl$$
(67) *(62)* *(69)*

Procedure:

Phenylallene [33]

α-Chlorodimethylbenzylamine (40 mmole) (prepared from benzylidenebisdimethylamine [31]) is added to a salt-free solution of 60 mmole of ethylidenetriphenylphosphorane [*(63)*, $R^2 = H$] in anhydrous tetrahydrofuran under N_2; the light yellow solution is stirred until it is decolorized. The triphenylethylphosphonium chloride which precipitates is filtered off.

[31] *H. Böhme, E. Mundlos*, and *O. E. Herboth*, Chem. Ber. *90*, 2003 (1957); *H. Böhme* and *K. Hartke*, Chem.Ber. *93*, 1305 (1960).

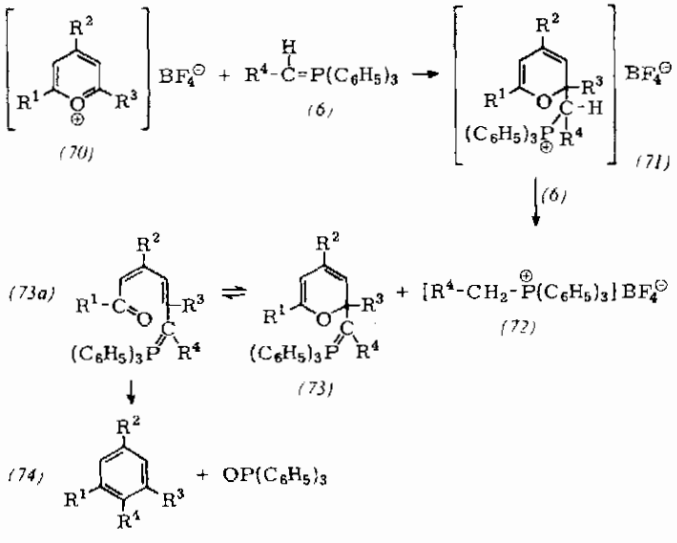
[32] *H. J. Bestmann, F. Seng* and *J. Berthold*, unpublished work; cf. also *H. J. Bestmann* and *F. Seng*, Angew. Chem. *75*, 1117 (1963); Angew. Chem. internat. Edit. *3*, 140 (1964).

[33] *H. J. Bestmann, F. Seng*, and *J. Popp*, unpublished work.

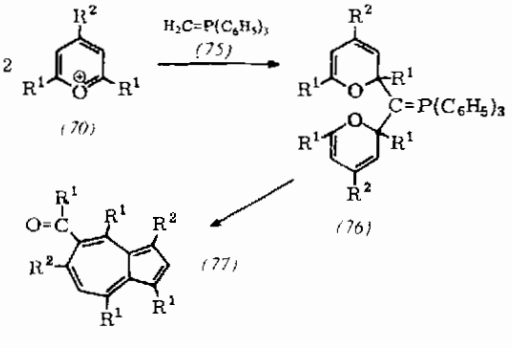
The filtrate is mixed with 20 g of methyl iodide and refluxed for 3 h to precipitate the triphenylphosphine and the compound *(69)*, $R^1 = C_6H_5$, formed in the secondary reaction. After removal of the precipitate, the solvent is distilled off over a small column and the residue is fractionated in vacuum. Phenylallene is obtained in 60% yield; b.p. 70 °C/20 mm Hg.

c) Aromatic Compounds and Azulenes from Alkylidenephosphoranes and Pyrylium Salts

The discovery of transylidation [34], and of the reaction of alkylidenephosphoranes and halogen compounds with simultaneous transylidation [3, 24, 26], has opened the way to new syntheses. Thus the salts *(71)*, which are the initial products of the reaction of pyrylium salts *(70)* and alkylidenephosphoranes *(6)*, react (by transylidation) with a second molecule of ylide *(6)* to form the phosphonium salt *(72)* and a new ylide *(73)*. This ylide undergoes an intramolecular Wittig reaction in its tautomeric form *(73a)* to form the aromatic compound *(74)* [35].



The reaction of pyrylium salts *(70)* with excess methylidenetriphenylphosphorane *(75)* leads to the formation of azulenes *(77)* [36]. It may be assumed that the ylide [*(73)*, R^4 = H] again undergoes transylidation with another molecule of pyrylium salt *(70)* to form the compound *(76)*, from which the azulene *(77)* is formed. The mechanism of the last reaction is not yet known.



[34] *H. J. Bestmann*, Chem. Ber. *95*, 58 (1962).

[35] *G. Märkl*, Angew. Chem. *74*, 696 (1962); Angew. Chem. internat. Edit. *1*, 511 (1962).

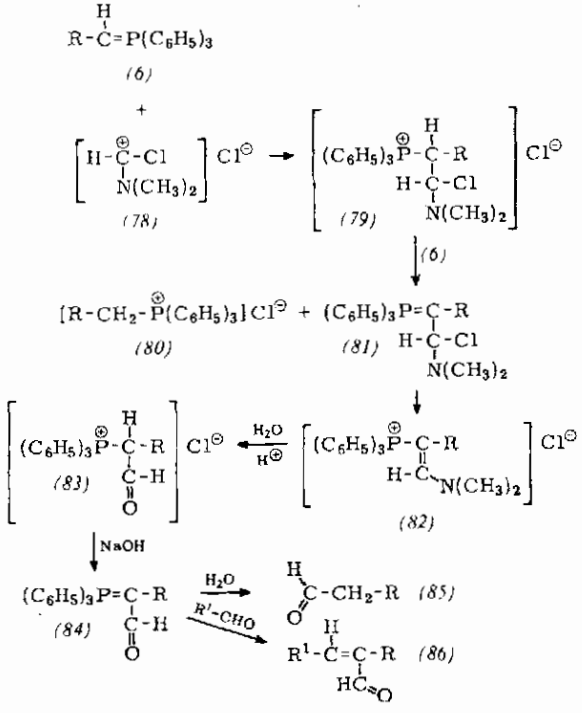
Procedure:

1,3,5-Triphenylbenzene [35]

Ten millimoles of 1,3,5-triphenylpyrylium tetrafluoroborate in a little acetonitrile is added over a period of 1 h to 20 mmole of methylidenetriphenylphosphorane *(75)* in 100 ml of boiling toluene. The violet color produced at the point of addition disappears instantaneously. When the addition is complete, the brown solution is boiled for a further 30 min and concentrated to 30 ml; precipitation is completed by addition of 100 ml of ether. The filtrate is evaporated to dryness, the residue is mixed with a little methanol, and the 1,3,5-triphenylbenzene is filtered off after some time; m.p. 170–172 °C, yield 59%.

d) Reaction of Alkylidenephosphoranes with Dimethylformamide Chloride. Synthesis of Aldehydes

The reaction of the ylide [*(6)*, R = C_6H_5 or CO_2CH_3] and the formamide chloride *(78)* yields the salt *(79)*, which undergoes transylidation with *(6)* to form the phosphonium chloride *(80)* and the alkylidenephosphorane *(81)* [37]. The compound isomerizes to the



phosphonium salt *(82)*, which reacts as an enamien with dilute hydrochloric acid to form the salt *(83)*. The action of sodium hydroxide on this salt gives the ylide *(84)*, which decomposes on hydrolysis into triphenylphosphine oxide and an aldehyde *(85)* [4, 13], and can undergo a Wittig reaction to form α-branched α,β-unsaturated aldehydes *(86)*.

The thermal decomposition of the 1-formyl-1-methoxycarbonylmethylidenetriphenylphosphorane [*(84)*, R = CO_2CH_3] yields methyl propiolate. Reactions of strongly basic ylides with formamide chlorides have not yet been studied.

[37] *G. Märkl*, Tetrahedron Letters *1962*, 1027.

Procedure:

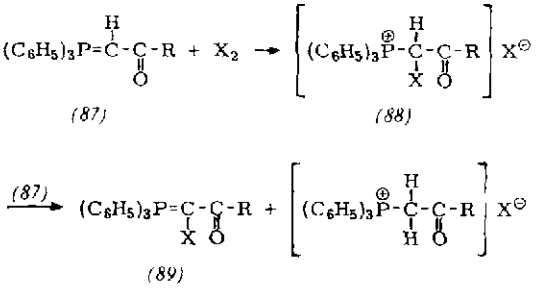
Triphenyl-1-formylbenzylphosphonium Chloride and 1-Formylbenzylidenetriphenylphosphorane

Benzylidenetriphenylphosphorane [*(86)*, R=C_6H_5] (30 mmole) in 150 ml of toluene is added at −5 °C to 20 mmole of dimethylformamide chloride in a little chloroform, acetonitrile, or dimethylformamide. The red solution is immediately decolorized, and the precipitate *(80)* is filtered off after a few hours. After the solvent has been driven off, the enaminephosphonium salt *(82)* is dissolved in a little water. The phosphonium chloride [*(83)*, R = C_6H_5] crystallizes on addition of a little concentrated hydrochloric acid (m.p. = 223 °C, yield 72%); the ylide *(84)*, R = C_6H_5, m.p. 124 to 126 °C (monohydrate), is obtained directly with dilute sodium hydroxide solution (yield 80%).

4. Reaction of Alkylidenephosphoranes with Halogens

a) Halogenation of Alkylidenephosphoranes

Stable alkylidenephosphoranes *(87)* react with free halogens at room temperature by transylidation [38a, 38b].



The second molecule of ylide can be saved by carrying out the halogenation in the presence of triethylamine [38b, 39], since the latter is a stronger base than the ylide *(87)*. At −70 °C, the reaction stops at the stage of the salt *(88)*. The ylide *(89)* can then be obtained from *(88)* with bases [39, 40]. Phenyl iodide chloride, $C_6H_5ICl_2$, is a particularly suitable chlorinating agent [38a, 38b]. Iodinations are best carried out in methanol, and brominations in glacial acetic acid [38b]. The reaction of strongly basic alkylidenetriphenylphosphoranes with halogens is accompanied by side reactions [41].

Procedures:

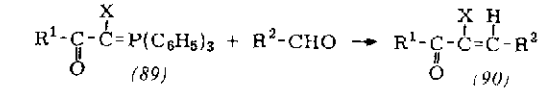
Bromoacylmethylidenetriphenylphosphoranes [(89), X = Br]

α) *In glacial acetic acid:* 10 mmole of *(87)* and 12.5 mmole of anhydrous sodium acetate are dissolved in 25 ml of glacial acetic acid, and 10 mmole of bromine in 10 ml of glacial acetic acid are added with stirring. After addition of 5 ml of concentrated hydrochloric acid, the solvent is evaporated in vacuum (thin layer evaporator); the residue is dissolved in water or water/methanol, and the ylide *(89)* is precipitated with dilute sodium hydroxide solution and recrystallized from ethyl acetate/petroleum ether or methanol/water.

β) *In chloroform:* 10 mmole of bromine in 10 ml of chloroform is added dropwise at 10 °C to a solution of 10 mmole of ylide *(87)* and 11 mmole of freshly distilled triethylamine in 25 ml of chloroform. The reaction mixture is washed twice with water to eliminate the triethylammonium chloride. After drying, the solvent is distilled off and the residue [the ylide *(89)*] is recrystallized as in α.

b) Preparation of α-Halogenated α,β-Unsaturated Carboxylic Acid Esters and Ketones

The halogenoylides *(89)* react with aldehydes.



The halogenated alkoxycarbonylmethylidenetriphenylphosphoranes [*(89)*, $R^1 = OR^2$] react much more readily than the acyl compounds [*(89)*, R^1 = alkyl or aryl]. The reaction leads to α-halogenated α,β-unsaturated ketones and carboxylic acid esters *(90)*, which are very difficult or impossible to obtain by other methods. Since compounds *(90)* react with bases to form acetylenes, this provides a possible synthesis of acetylenic ketones and esters of acetylenecarboxylic acids [38a].

C. Reactions Involving β-Elimination

1. The Mechanism of the Hofmann Degradation of Quaternary Phosphonium Salts

Ammonium salts of the type $[R^1-CH_2-CH_2N^{\oplus}R^2_3]X^{\ominus}$ are preferentially broken down by the action of bases into olefins and amines (Hofmann degradation) [42–44]. The analogous phosphonium salts, on the other hand, are decomposed by $OH^{\ominus}$ ions into a phosphine oxide and a hydrocarbon, whilst reaction with other bases, such as sodamides, organolithium compounds, and sodium alkoxides, leads to the formation of the alkylidenephosphoranes. Decomposition of phosphonium salts into an olefin and a phosphine occur in only a few cases, where the hydrogens in the β position with respect to the P atom are strongly activated [45–47].

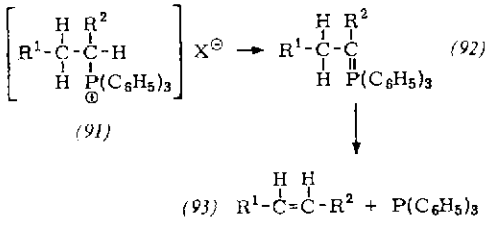
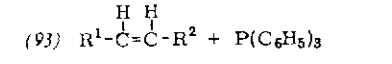
The Hofmann degradation of quaternary ammonium salts proceeds either by β-elimination or by α',β-elimination [44, 48]. Primary α-elimination following in intramolecular or intermolecular proton shift from the β position to the α position of the same ligand of the N atom has not been observed [49]. However, since α protons in phosphonium salts are split off 10^5 times more rapidly than in ammonium salts [50], the primary α-elimination should be preferred in the decomposition of triphenylphosphonium salts.

It has been shown, using compounds labeled with tritium, that when organolithium compounds or sodamide are used for the Hofmann degradation of phosphonium salts *(91)* in which the residue R^1 is strongly electron-attracting, the primary reaction is α-elimination to form the ylide *(92)* [51].



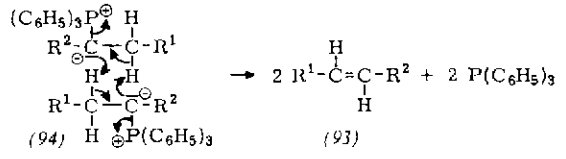
(91) *(92)*



(93)

Reactions with completely deuterated compounds have shown that the alkylidenephosphorane *(92)* then decomposes by intermolecular hydrogen shift to an olefin *(93)* and triphenylphosphine [51].

It is assumed that two molecules of the ylide come together to form a transition state *(94)*, which under-



(94) *(93)*

goes a reciprocal β-elimination, with simultaneous loss of triphenylphosphine. This means that the Hofmann degradation of phosphonium salts, which begins with an α-elimination from the same ligand, is induced by an intermolecular β-elimination. The ylide formation can therefore be regarded as an "interfering reaction" in the Hofmann degradation.

The rate of the intermolecular hydrogen shift (reciprocal β-elimination) is determined by the residues R^1 and R^2 in the ylide *(92)*. Electronegative residues R^1 increase the rate by increasing the mobility of the β protons, whilst electronegative residues R^2 retard the reaction by decreasing the basicity of the ylides (as proton acceptors). Some examples are given in Table 7 [51]. The decomposition temperature is taken as a measure of the rate of the intermolecular proton shift.

Table 7. Temperatures at which alkylidenetriphenylphosphoranes $R^1-CH_2-CR^2=P(C_6H_5)_3$ *(92)* decompose into olefins and triphenylphosphine.

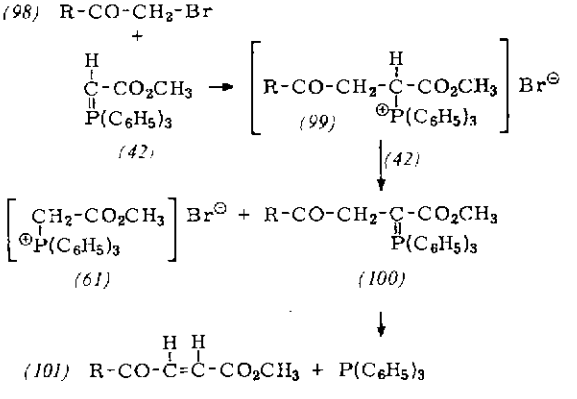
Ylide	R^1	R^2	Temperature of decomposition [°C]	Olefin
(95)	C_6H_5	CO_2CH_3	Stable to 200 °C	—
(96)	CH_3O_2C	CO_2CH_3	170	Dimethyl fumarate
(97)	CH_3O_2C	C_6H_5	50	Methyl cinnamate

Compound *(95)* is more stable than *(96)*, since the (−I)-effect of the residue R^1 is greater for the methoxycarbonyl group than for the phenyl group. For the same reason, *(97)* decomposes more readily than *(96)*.

The Hofmann degradation of quaternary phosphonium salts is of interest for reactions taking place by transylidation. If a phosphonium salt *(91)* with activated hydrogen atoms β to the phosphorus atom is formed by the reaction of a halogen compound with an alkylidenephosphorane, the ylide *(92)* formed primarily by transylidation is expected to decompose into an olefin and triphenylphosphine, as described above. This sequence of reactions can also be employed in syntheses, as will be shown below.

2. Synthesis of Esters of β-Acylacrylic Acids [47]

α-Bromoketones *(98)* react with methoxycarbonylmethylidenetriphenylphosphorane *(42)* to form a phosphonium salt *(99)*, which gives the ylide *(100)* and the salt *(61)* by transylidation with a second molecule of *(42)* [51].



(98) *(42)* *(99)* *(61)* *(100)*

(101)

In the ylide *(100)*, the H atoms β to the P atom are activated by the adjacent carbonyl group. The ylide *(100)* therefore decomposes to form an ester of a β-

Table 8. Methyl β-acylacrylates, R—CO—CH=CH—CO_2CH_3 *(101)* obtained from methoxycarbonylmethylidenetriphenylphosphorane *(42)* and α-bromoketones R—CO—CH_2—Br *(98)*.

	R	M.p. [°C]	Yield [%]

acylacrylic acid *(101)* and triphenylphosphine [47]. A number of examples is given in Table 8.

The new method for the preparation of β-acylacrylates is inferior in a number of cases to the reaction of maleic anhydride with aromatic compounds [52]; however, the esters of β-acylacrylic acid with aliphatic and cycloaliphatic residues R, which had previously been difficult to prepare, can now be readily obtained in high yields by a "single pot process".

Esters of α-branched β-acylacrylic acids can be obtained from alkoxycarbonylalkylidenetriphenylphosphoranes *(49)* and α-bromoketones [24] (cf. Sections B 2b and B 3a).

Since α-bromoketones can be easily prepared from carboxylic acids *via* the diazoketones *(102)* [53], we now have a new method of synthesizing the ester *(101)* of an acid containing three more C atoms in its chain than the original carboxylic acid.

$$R\text{-}CO_2H \rightarrow \underset{(102)}{R\text{-}CO\text{-}CHN_2} \rightarrow \underset{(101)}{R\text{-}CO\text{-}CH{=}CH\text{-}CO_2CH_3}$$

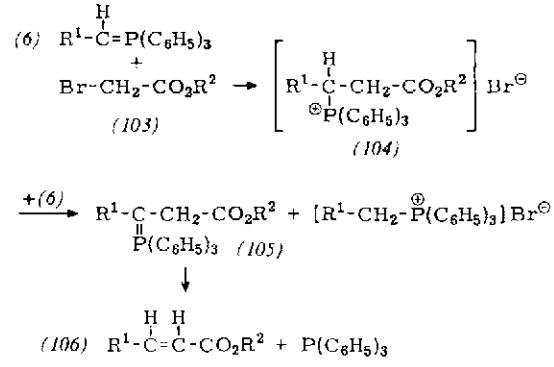
Procedure:

Methyl β-Acylacrylates

To a boiling solution of 20 mmole of methoxycarbonylmethylidenetriphenylphosphorane *(42)* in 100 ml of anhydrous benzene, 10 mmole of the bromoketone *(98)* is added, and the mixture is refluxed for 2 h. The triphenylmethoxycarbonylmethylphosphonium bromide *(61)* which precipitates is filtered off (yield 90–100%), and the solution is mixed with 10 mmole of methyl bromoacetate (possibly in slight excess) and boiled for a further 2 h. The phosphonium salt *(61)* formed from triphenylphosphine and methyl bromoacetate precipitates and is filtered off (yield 70–80%). The benzene is evaporated from the filtrate under reduced pressure. The residue is recrystallized from methanol, cooling to between −60 and −40 °C being preferable in many cases. If the acrylate cannot be recrystallized from methanol, the residue left when the benzene has evaporated is distilled in a rotating bulb tube at about 0.1–1 mm Hg. The yields of the methyl β-acylacrylates are given in Table 8.

3. Synthesis of Esters of α,β-Unsaturated Carboxylic Acids

Alkylidenetriphenylphosphoranes *(6)* react readily with esters of bromoacetic acid *(103)*. Transylidation of the initially formed salt *(104)* with *(6)* leads to the ylide *(105)* and a phosphonium salt. The H atoms β to the P atom in *(105)* are activated by the ester group. The compounds therefore decompose more or less readily, depending on the inductive effect of R^1, into esters of α,β-unsaturated acids *(106)* and triphenylphospbine [54].



This process is particularly suitable for reactions with ylides *(6)* in which the basicity is weakened as a result of a (−I)-effect of R^1 (*e.g.* aromatic compounds and CO_2R). As the basicity of *(6)* increases, side reactions become pronounced; these are being investigated [54].

Procedure:

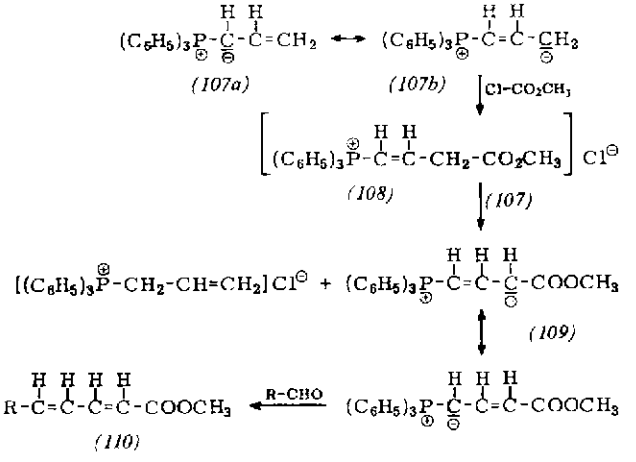
Cinnamic Acid

A salt-free ylide solution is prepared (see Part I, Section D 2) from 16 g of triphenylbenzylphosphonium chloride. Methyl bromoacetate *(103)* (3.05 g) is added to this solution, and the mixture is refluxed for 1 h. The phosphonium salt formed is filtered off, and the solvent distilled off over a small column. The residue is hydrolysed by refluxing for 2 h with 2.4 g of KOH in 100 ml of aqueous methanol. The methanol is distilled off, and the remaining solution is diluted with 200 ml of water. The triphenylphosphine oxide is filtered off, the filtrate is acidified, and the cinnamic acid is extracted with ether, which is then removed; m.p. 135 °C, yield 2.2 g (75%).

D. Reactions Involving γ-Elimination

1. Reaction of Allylidenetriphenylphosphoranes with Esters of Chloroformic Acid. Preparation of Esters of Polyenecarboxylic Acids

The reactions described so far show that transylidation can occur during the reaction of phosphonium salts with alkylidenephosphoranes by α-elimination. If the β position with respect to the P atom is activated, the α-elimination is often followed by a reciprocal β-elimination with simultaneous loss of triphenylphosphine.



[52] *H. G. Oddy*, J. Amer. chem. Soc. *45*, 2156 (1923).

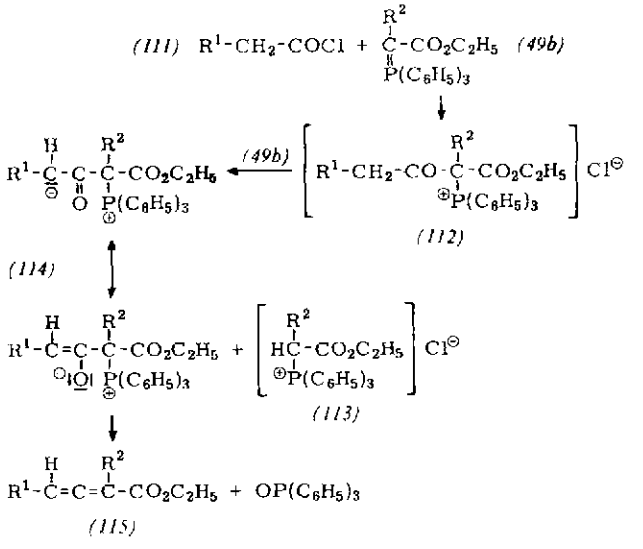
[53] Cf. *B. Eistert* in *W. Foerst*: Neuere Methoden der präparativen Organischen Chemie. Verlag Chemie, Weinheim/Bergstr. 1944, Vol. I, p. 359; *F. Weygand* and *H. J. Bestmann*, Angew. Chem. *72*, 535 (1960).

[54] *H. J. Bestmann* and *K. Rostock*, unpublished work.

We have now also observed γ-eliminations. Allylidenetriphenylphosphorane *(107)* reacts from the resonance form *(107b)* with methyl chloroformate to form the salt *(108)* [24], from which another molecule of the ylide *(107)*, acting as a base, extracts a proton from the γ position with respect to the P atom. The result is the ylide *(109)*, which has previously been prepared by another method [55], and which undergoes Wittig reactions to yield esters of polyenecarboxylic acids *(110)*.

2. Synthesis of Esters of Allenecarboxylic Acid

Another reaction which proceeds by γ-elimination is the formation of esters of allenecarboxylic acid [56].



Acyl chlorides *(111)* and 1-ethoxycarbonylalkylidenetriphenylphosphoranes *(49b)* react to form phosphonium salts *(112)*. A second molecule of ylide *(49b)* removes a proton from the γ position with respect to the P atom in *(112)*, with formation of a phosphonium salt *(113)* and a betaine *(114)*. The latter spontaneously loses triphenylphosphine oxide, providing a simple route to the esters of allenecarboxylic acids *(115)*, which were formerly very difficult to prepare, and which can be smoothly hydrolysed to form the crystalline allenecarboxylic acids. Some examples of the esters *(115)* are given in Table 9.

Table 9. Esters of allenecarboxylic acids $R^1HC=C=C(CH_3)CO_2C_2H_5$ *(115)* obtained from acyl chlorides R^1-CH_2-COCl *(111)* and 1-ethoxycarbonylethylidenetriphenylphosphorane $(C_6H_5)_3P=C(CH_3)-CO_2C_2H_5$.

	R^1	B.p. [°C/mm Hg]	Yield [%]
(115a)	H	52/11	59
(115b)	C_2H_5	70/11	55
(115c)	C_4H_9	97/11	66
(115d)	C_5H_{11}	109/11	80
(115e)	$C_6H_5-CH_2$	114/1	51

The infrared spectra of the esters *(115a)–(115e)* show a pronounced allene band at 1950 cm^{-1}.

The reaction is best carried out in tetrahydrofuran. The phosphonium salt *(113)* precipitates in this solvent, and can be used for regeneration of the ylide *(49b)*. The solution retains the ester of the allenecarboxylic acid, which can be distilled off from the triphenylphosphine oxide after removal of the solvent. The ylides *(49b)* can be synthesized from alkylidenephosphoranes and esters of chloroformic acid (cf. Section B 2).

Procedure:

Esters of Allenecarboxylic Acids (115)

1-Alkylethoxycarbonylmethylidenetriphenylphosphorane (60 mmole) is dissolved in 70 ml of anhydrous tetrahydrofuran by heating in the absence of moisture. This solution is cooled to about 40 °C, and 30 mmole of the acyl chloride, dissolved in 5–10 ml of tetrahydrofuran, is added. After a short time, the phosphonium salt precipitates. The mixture is refluxed for 3–4 h, and the phosphonium salt is filtered off and washed with 20 ml of ether. The solvent is distilled from the filtrate over a small column. The residue is mixed with 30–40 ml of petroleum ether, whereupon the greater part of the triphenylphosphine oxide crystallizes. The solution is filtered, the petroleum ether evaporated off, and the allenecarboxylate is distilled in vacuum.

E. Reactions of Alkylidenephosphoranes with Halogen Compounds at a Molar Ratio of 1:1

1. Synthesis of Esters of α-Branched β-Oxocarboxylic Acids

In the above reactions of alkylidene phosphoranes with halogen compounds, the initially formed phosphonium salt reacts with a second molecule of ylide. This step can be suppressed in some cases, *e.g.* by the use of low temperatures, and the salts so obtained can be used for further reactions. In this way, compounds *(118)* difficult to obtain by other methods can be synthesized.

Acyl chlorides *(116)* react with methoxycarbonylmethylidenetriphenylphosphoranes *(49)* at 0–20 °C to

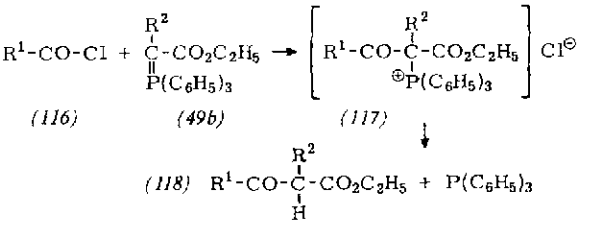


Table 10. Esters of α-branched β-oxocarboxylic acids $R^1-CO-CHR^2-CO_2C_2H_5$ *(118)* obtained from acyl chlorides R^1-COCl and ylides $(C_6H_5)_3P=CR^2-CO_2C_2H_5$ by electrolysis of the phosphonium salt *(117)*.

Ester	R^1	R^2	B.p. [°C/mm Hg]	Yield [%]
(118a)	CH_3	CH_3	70–71/13	77
(118b)	C_3H_7	CH_3	93/10	64
(118c)	C_5H_{11}	CH_3	115/10	78
(118d)	$(CH_2)_2-CO_2CH_3$	CH_3	95/2	68
(118e)	C_6H_5	CH_3	100/0.4	70
(118f)	$C_6H_5-CH=CH-$	CH_3	117/0.3	73
(118g)	$C_6H_5-CH_2-CH_2$	CH_3	115/0.2	73
(118h)	C_5H_{11}	C_3H_7	75/0.3	50
(118i)	C_6H_5	C_3H_7	95/0.3	45

[55] *E. Buchta* and *F. Andree*, Chem. Ber. *92*, 3111 (1959).

[56] *H. J. Bestmann* and *H. Hartung*, Angew. Chem. *75*, 297 (1963); Angew. Chem. internat. Edit. *2*, 214 (1963).

[57] *H. J. Bestmann, G. Graf*, and *H. Hartung*, unpublished work.

form the acylated salts *(117)*. Electrolysis of these compounds at a mercury cathode yields triphenylphosphine, together with esters of α-branched β-oxocarboxylic acids *(118)* [57]. Some examples are shown in Table 10.

Procedure:

Esters of α-Branched β-Oxocarboxylic Acids

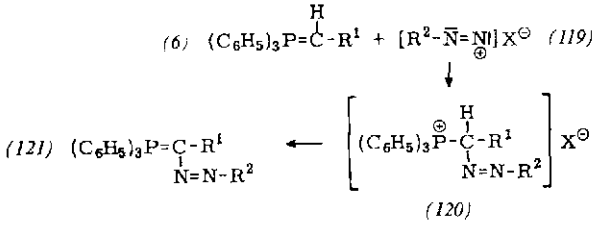
Acyl chloride (0.11 mole) is added to a solution of 0.1 mole of the α-alkyl- or α-arylalkoxycarbonylmethylidenetriphenylphosphorane in anhydrous benzene (0–20 °C). The mixture is allowed to stand for 24 h in a refrigerator, and the benzene is then decanted from the oily phosphonium salt. The latter is freed from solvent in vacuum at 30 °C and dissolved in a little water. The solution is extracted with ether, and the aqueous phase electrolysed.

The electrolysis is carried out in a three-necked flask with a cooling jacket. The middle neck carries a diaphragm with a carbon anode. A pool of mercury on the bottom of the flask is used as the cathode, to which connection is made by a fused-in molybdenum wire. The electrolysis is carried out at a temperature of under 35 °C with a current of 1–2 amp at 24 volts.

During the electrolysis, the triphenylphosphine and the keto-ester separate at the surface as an oil. As soon as the current ceases to flow, the mixture is extracted with ether. The ether phase is dried over anhydrous $MgSO_4$, and the solvent is evaporated. The residue is distilled at 15 mm Hg, using a rotating bulb tube. The ester distils, leaving the triphenylphosphine behind. The latter is recrystallized from methanol; the ester is purified by vacuum distillation.

2. Reactions with Diazonium, Nitrilium, and Oxonium Salts

Alkylidenephosphoranes *(6)* react with diazonium salts *(119)* to form diazotized phosphonium salts *(120)* which can be isolated, and which react with bases to yield the azoylides *(121)* [58].

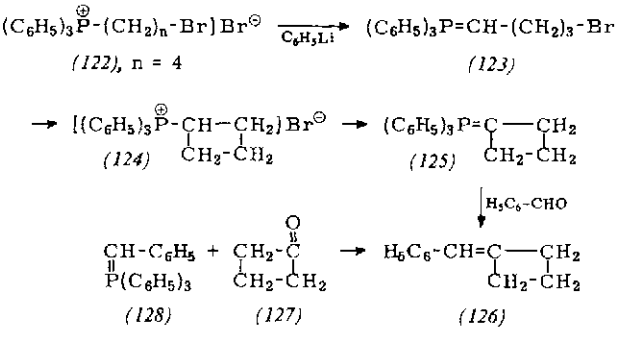


The salt *(120)* can evidently be isolated only when weakly basic ylides *(6)* (*e.g.* $R^1 = C_6H_5$, CO_2R^3) are used. In reactions involving more strongly basic alkylidenephosphoranes, a transylidation again appears to take place [58]. Similar reactions occur with nitrilium salts and trialkyloxonium fluoroborates [37].

F. Intramolecular Ring Closure

1. Monocyclic Compounds

Intramolecular reactions between alkylidenephosphoranes and halogen compounds are also possible, and offer new methods for the synthesis of cyclic compounds. *Mondon* [59] presumed that, in the reaction of the salt *(122)* with phenyl-lithium, the initially formed ylide *(123)* cyclizes to give the salt *(124)*. This assumption was subsequently confirmed by conversion of *(124)* into cyclobutylidenetriphenylphosphorane *(125)* and the reaction of the latter with benzaldehyde to form benzylidenecyclobutane *(126)* [60], which was synthesized from cyclobutanone *(127)* and benzylidenetriphenylphosphorane *(128)*.



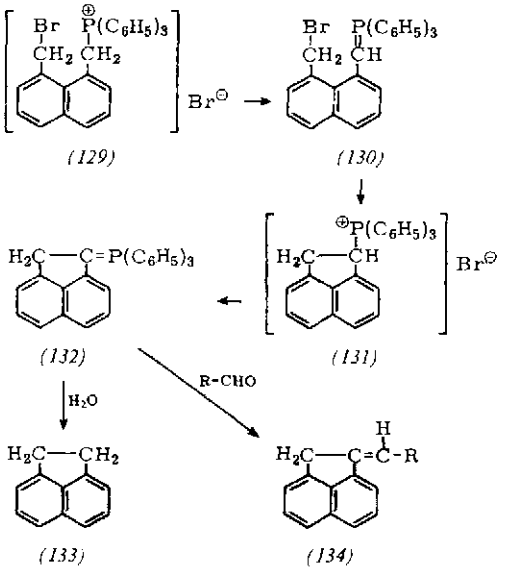
These reactions are generally given by phosphonium salts such as *(122)* containing more than 3 methylene groups [60, 61].

The reaction of ω,ω'-bishalogen compounds with 1 mole of triphenylphosphine [62] for the preparation of the phosphonium salts *(122)* is almost useless at $n \geq 5$, since as the chain length is increased, the reaction yields mixtures of the mono- and bis-phosphonium salts, or the latter alone [60].

2. Polycyclic Compounds

a) Acenaphthene and Indene Derivatives

Ring closure by intramolecular C-alkylation of alkylidenephosphoranes provides a particularly suitable method for the synthesis of polycyclic compounds



[58] *G. Märkl*, Tetrahedron Letters *1961*, 807.

[59] *A. Mondon*, Liebigs Ann. Chem. *603*, 115 (1957).

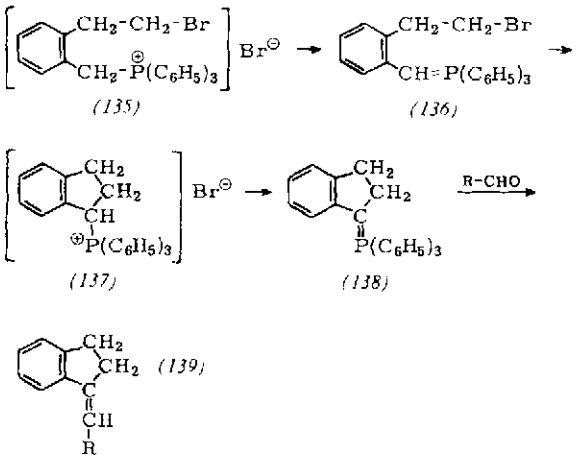
[60] *H. J. Bestmann* and *H. Häberlein*, unpublished work.

[61] *H. J. Bestmann* and *H. Häberlein*, Z. Naturforsch. *17b*, 787 (1962).

[62] *K. Friedrich* and *H. G. Henning*, Chem. Ber. *92*, 2756 (1959).

[60, 61]. The phosphonium salt *(129)* reacts with one mole of sodium alkoxide to form the ylide, which very readily undergoes ring closure with formation of the salt *(131)*. Compound *(131)* reacts with a second mole of alkoxide to form the cyclic alkylidenephosphorane *(132)*, which yields acenaphthene on hydrolysis, and which undergoes a Wittig reaction with aldehydes to give olefins *(134)* [61].

Similarly, the reaction of the phosphonium salt *(135)* with 2 moles of sodium alkoxide leads *via* compounds *(136)* and *(137)* to the ylide *(138)*, which reacts with aldehydes to form the hydrindene derivatives *(139)* [60].



Procedure:

1-(8-Bromomethyl-1-methylnaphthalene)-triphenylphosphonium Bromide (129)

A solution of 20 mmole of 1,8-bis(bromomethyl)naphthalene and 20 mmole of triphenylphosphine in 30 ml of benzene is heated for 15 to 20 h on an oil bath at 120 °C. The mono-quaternary phosphonium salt *(129)* which crystallizes out is extracted twice with boiling benzene and dried in a high vacuum at 100 °C over P_2O_5; m.p. 203 °C, yield 10.5 g (91 %).

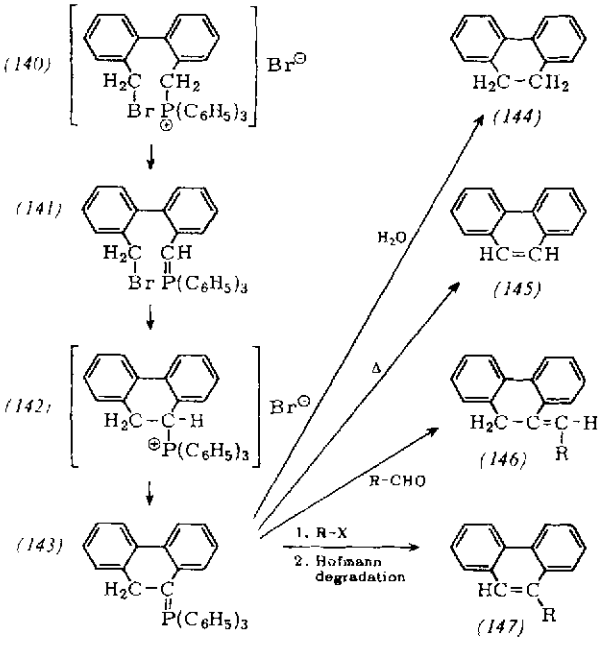
Acenaphthene

The phosphonium salt *(129)* (5 mmole) is dissolved in 30 ml of ethanol. 10 mmole of sodium ethoxide in ethanol is added dropwise to the colorless solution, with stirring, in an atmosphere of nitrogen. The solution turns red-orange and is boiled with 20 ml of water until no further lightening of the color occurs. The N_2 atmosphere can now be dispensed with. Acenaphthene *(133)* crystallizes on cooling (if no crystallization occurs, more water may be added). The crystals are filtered off, washed with dilute alcohol, and allowed to dry in air. A further crop of hydrocarbon can be obtained by steam distillation of the strongly concentrated filtrate. The melting point of the unrecrystallized product agrees with the value given in the literature (96 °C); yield 62 %.

b) Synthesis of Phenanthrene Derivatives [60, 61]

The great variety of syntheses made possible by intramolecular C-alkylation is illustrated by a new synthesis of phenanthrene derivatives.

On reaction with sodium alkoxide, the phosphonium salt *(140)* loses a proton to form the ylide *(141)*, which immediately undergoes ring closure to yield the salt *(142)*. Compound *(142)* reacts with a second mole of sodium alkoxide or with sodamide to form the deep red ylide *(143)*. The reaction of *(143)* with water yields 8,9-dihydrophenanthrene *(144)*, whilst heating, preferably in alcohol, results in Hofmann degradation to phenanthrene *(145)*. The formerly unknown compounds of the type *(146)* can now be obtained by reaction of *(143)* with aldehydes. The ylide *(143)* reacts with



halogen compounds in a molar ratio of 2:1 with simultaneous Hofmann degradation to the compounds *(147)*. It is possible in this way to introduce alkyl groups and ester groups into the 9,10 position of phenanthrene. 4,5-Dimethylphenanthrene and 2,7-dinitrophenanthrene have also been synthesized by this method [60]. The same sequence of reactions can also be used for the specific labeling of phenanthrene with tritium in the 9,10 position [51].

Procedures:

2'-Bromomethylbiphenyl-2-ylmethyl-triphenylphosphonium Bromide (140)

A solution of 100 mmole of 2,2'-bis(bromomethyl)biphenyl and 100 mmole of triphenylphosphine in 100 ml of benzene is refluxed for 5 hours. The crystals which separate are extracted twice with boiling benzene and dried in a high vacuum at 120 °C over P_2O_5; yield 57.2 g (95 %), m.p. 239–240 °C.

9,10-Dihydrophenanthryl-9-triphenylphosphonium Bromide (142)

The phosphonium salt *(140)* (20 mmole) is dissolved in 50 ml of anhydrous methanol under nitrogen, and 20 mmole of sodium methoxide in 50 ml of anhydrous methanol is added dropwise, the solution being agitated with a magnetic stirrer. The mixture turns yellow, and simultaneously the cyclic phosphonium salt *(142)* crystallizes out. The stirring is continued

for some time at room temperature, the N_2 atmosphere is removed and the salt is filtered off. It is extracted with boiling benzene until the extract gives no reaction for triphenylphosphine [24], and is finally dried in a high vacuum at 100 °C over P_2O_5. The phosphonium salt *(142)* obtained is very sparingly soluble in water, alcohol, or chloroform; m.p. 223–224 °C, yield 87%.

9,10-Dihydrophenanthrene (144)

Five millimoles of the phosphonium salt *(140)* is dissolved in 1000 ml of hot water, 50 mmole of NaOH is added, and the mixture is heated to boiling. Two substances separate out, one being crystalline, and the other an oil which solidifies on cooling. The solids are filtered off and washed with water, and the crystals are dried in air. The hydrocarbon *(144)* is sublimed from the crystal mixture on the water bath at 90–100 °C/1 mm Hg, and recrystallized from methanol, yield 89%. The sublimation residue is pure triphenylphosphine oxide (m.p. 153 °C).

9-Benzylidene-9,10-dihydrophenanthrene

The phosphonium salt *(140)* (10 mmole) is converted under nitrogen by the sodamide method (see Part I, Section D 2) to a suspension of the ylide in anhydrous benzene. The ylide is only sparingly soluble; for this reason, the sodium bromide formed is not filtered off. To the red suspension of the ylide 10 mmole of freshly distilled benzaldehyde is added, and the reaction mixture is stirred magnetically at room temperature until it becomes colorless (about 10 h). The N_2 atmosphere can now be dispensed with. The sodium bromide is filtered off, and the filtrate is evaporated to dryness. The residue is extracted twice with 25 ml portions of boiling methanol to remove the triphenylphosphine oxide. The benzylidene compound, which is practically insoluble in methanol, has m.p. 152 to 156 °C in the crude form, and can be purified by recrystallization from n-hexane (m.p. 158 °C, yield 72%).

Modern Theoretical Views on the Chemical Bond

BY PRIV.-DOZ. DR. H. PREUSS

MAX-PLANCK-INSTITUT FÜR PHYSIK UND ASTROPHYSIK, MÜNCHEN (GERMANY)

Starting from classical concepts, semi-empirical approaches to an understanding of the chemical bond are critically discussed, particularly with respect to their limitations. Rules such as the additivity of the bond constants and the octet rule are reviewed in relation to new chemical compounds. It is shown that these rules are not sufficient to explain chemical bonding; this is also true of the simple concept of hybridization, the basis of which is discussed. Some generally valid statements regarding the chemical bond can be propounded on the basis of wave-mechanical considerations. It is shown that the hybridization concept and a number of other rules are too primitive to provide generally valid information or a basis for predictions about the chemical bond, and even that they are partly based on false premises. A better foundation for an understanding of the chemical bond can only be laid with the aid of wave mechanics.

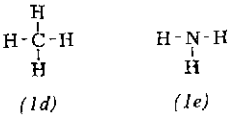
1. Introduction

When chemists speak about the chemical bond, they differentiate between the ionic bond, the covalent bond, or the semipolar bond. The first two are often termed polar and non-polar (homopolar) bonds.

In ionic bonding, it is assumed that electrons are transferred from one of the bonded atoms to the other, so that oppositely charged ions result which attract one another. This picture was first proposed by *Kossel* (1917). It explained certain properties of a limited number of ionic compounds, but was found to be inadequate in many cases, since the formation of ionic molecules does not necessarily proceed by initial ionization of the atoms being linked, and since many ionic compounds do not dissociate to form ions. In this picture, the number of bonds drawn in a structural formula is identified with the number of electrons transferred to the other atom. For example, if we assume that CaO, HF, and CO contain the ions Ca^{2+}, O^{2-}, F^-, C^{2+}, and the proton, we obtain

Ca=O *(1a)*, F–H *(1b)*, or C=O *(1c)*.

It could even be assumed that CH_4 and NH_3 contained the ions C^{4-} and N^{3-}. This would lead to the formulae *(1d)* and *(1e)*, which are generally drawn in two dimensions, although experience has shown that they are



(1d) *(1e)*

tetrahedral and pyramidal, respectively (see Fig. 1).

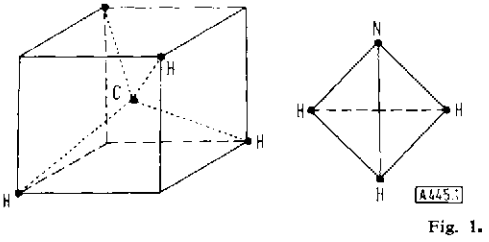


Fig. 1.

According to this view, all the atoms of a compound have the "rare gas configuration", which was formerly

thought to be particularly stable, and hence chemically inert. In the above examples, we have the following correspondences:

$Ca^{2+} \triangleq Ar$, $C^{2+} \triangleq Be$,
$O^{2-} \triangleq Ne$, $C^{4-} \triangleq Ne$,
$F^{-} \triangleq Ne$, $N^{3-} \triangleq Ne$.

This concept has been extended somewhat in putting C^{2+} in correspondence to Be. Although the electronic configuration of Be does not correspond to that of any of the rare gases (He, Ne, Ar, Kr, Xe, Rn), it can be regarded as being similar to that of the rare gases.

Almost simultaneously with the rise of the electrostatic theory, *Lewis* developed his "octet rule". It was essentially intended to apply to molecules consisting of atoms from the first and second periods. According to this rule, the atoms do not become ionized; instead, the bonding electrons are shared by the atoms in such a way that each atom "fills up" its electron shell to "rare gas configuration" [two or ten (8+2) electrons]. It is usual to represent the electrons by dots, so obtaining, for example, Figures 2 and 3.

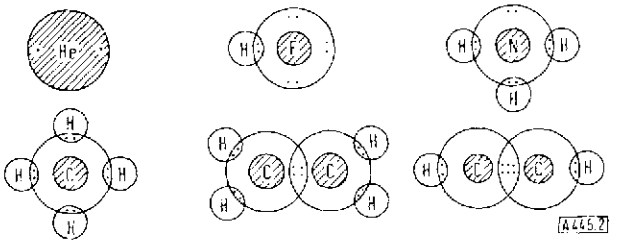

Fig. 2.

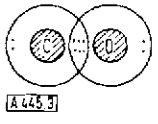

Fig. 3.

In these illustrations, the shaded circle represents the configuration of a closed shell containing two electrons, as found in helium. The Lewis model is also applicable to bonds between similar atoms (see *e.g.* Fig. 4). In Cl_2,

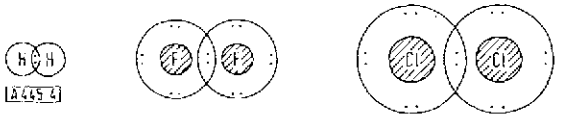

Fig. 4.

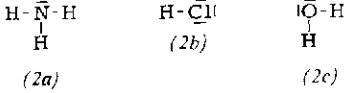
the inner circles represent the shells containing two (He) and eight electrons (Ne).

The Lewis rule presupposes some knowledge of the electronic configurations of the atoms involved, and can be extended to elements with nuclear charges of up to $Z = 36$ by assuming the formation of a krypton shell. The remaining elements can be included in a similar manner. In every case, the configurations assumed to be stable have "magic" numbers of electrons, *e.g.* 2 or 10, which are correlated with the inert gas configurations. Every pair of electrons between atoms corresponds to a bond, and is represented by a line; all bonds are thus two-electron bonds.

Thus the valence bond has different meanings in the Kossel picture and in the Lewis picture, although both concepts often give the same valence-bond diagram, as is shown by *(1b)*, *(1d)*, *(1e)* and Figures 2 and 4. Even when the valence-bond representations are identical, however, they are generally not chemically equivalent (cf. the C–C bond in CH_3–CHO and CCl_3–CHO).

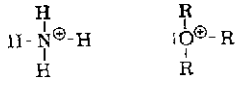
From the valence-bond representation it would be assumed that the same bond in different molecules has the same properties. The chemical nature of a molecule would then be determined by the sum of the properties of the bonds in the molecule. Such additivity actually does exist to a close approximation in many classes of compounds. There are other compounds, however, in which the molecular properties cannot be even roughly described in this way. There is always some interaction between bonds, often leading to completely new properties in a molecule. Thus the valence-bond representation gives only a rough indication. It shows the atoms between which the most important interaction, leading to chemical bonding, exists.

In pursuance of *Lewis'* ideas, the outer-shell electron pairs in an atom which are not involved in a bond are referred to as "lone" pairs of electrons, which appear to be outwardly saturated, so to speak, by an "internal bond". In such a case, a line is often drawn beside the atom in question, as shown in *(2a)* and *(2b)*. This



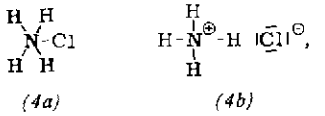
(2a) *(2b)* *(2c)*

concept also leads to the structures *(3a)* and *(3b)*, since the octet rule can be applied to ions, too. By the same



(3a) *(3b)*

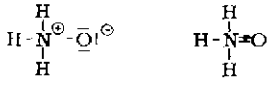
token, we have not *(4a)*, but *(4b)*, a representation which agrees with experience. Thus there is an ionic



(4a) *(4b)*

bond between the $[NH_4]^{\oplus}$ and the chloride ion, whereas the four $N^{\oplus}$–H bonds are covalent.

In the Kossel scheme, the bond between $[NH_4]^{\oplus}$ and $Cl^{\ominus}$ would also be denoted by a line. However, it has become common practice to use the line for a two-electron bond only, and to indicate an ionic bond by the signs of the charges, as shown in *(4b)*. Thus amine oxide should be written as *(5a)*. This compound contains a "semipolar"



(5a) *(5b)*

bond and is therefore frequently represented by *(5b)*, the arrow indicating that negative charge has been transferred from the nitrogen to the oxygen.

These methods of bringing order to the maze of chemical experience have not lost their value. In many cases, chemical bonds are formed by sharing electrons, but an increasing number of new chemical compounds fit into this scheme only with great difficulty, or not at all. This group includes the simplest molecule $H_2^{\oplus}$, or *e.g.* the molecule NO, which is stabilized by an odd number of electrons. New structural representations must be found for free radicals, in order to take into account the unsaturated electron. The van der Waals molecules or molecules containing ion-dipole bonds also fail to fit into this scheme. The group further includes the boron hydrides and their derivatives, as well as the "sandwich" complexes. Compounds of the inert gases should be incapable of existence, since it is the inert gas configuration which is considered to be the most stable one.

Although schemes of this type bring a certain order into experimental observations, this order is formal, and offers no possibility of quantitative calculation. This is also true for most symmetry considerations, unless they exclude certain atomic constellations.

Using the general valence-bond representation (including atomic charges and lone pairs of electrons), it is possible to write several "structures" for many compounds. This ambiguity, which arises from the definition of the valence-bond structure, has often been erroneously correlated with energy principles, by assuming that the stability of a compound increases with the number of valence-bond structures which can be used to represent it. In reality, this is an incorrect application of a wave-mechanical approximation method, as we shall show (Section 4, Eq. 44).

2. Semi-empirical Approaches

The ability of atoms to form molecules can be explained by the electronic structure of the atoms. Two important properties of the electron systems are the first ionization energy I_Z and the electron affinity A_Z of the atom Z. If energy supplied to a system is regarded as positive, the energy which must be expended to transfer an electron from the atom Z to the atom Y is

$$I_Z - A_Y \qquad (a)$$

Similarly, if the electron is transferred from Y to Z, the energy is

$$I_Y - A_Z \qquad (b)$$

If the two atoms approach each other, the behavior of the electrons will depend on which of these two energies is greater, unless they are equal, as is the case when $Z = Y$.

$$I_Z - A_Y \gtrless I_Y - A_Z \qquad (c)$$

Rearrangement of (c) gives

$$I_Z + A_Z \gtrless I_Y + A_Y \qquad (d)$$

The atomic parameter

$$\chi = I + A \ \text{[kcal/mole]} \qquad (e)$$

is known as the electronegativity, and has been used by *Pauling* and by *Mulliken* in the discussion of chemical bonds. Using this parameter, *Pauling* introduced some order into the diversity of bonds. The important quantity here is the difference in the electronegativities of the two atoms A and B:

$$X = \chi_A - \chi_B \qquad (f)$$

It was found that the dissociation energies D(A–B) of single bonds approximately satisfy the relationship

$$D(A-B) \approx \alpha + \beta X^2 \qquad (g)$$

where α and β are constants. When $X = 0$, Equation (g) becomes

$$D(A-B) \approx \alpha \qquad (h)$$

Since α is independent of X, it represents the dissociation energy of a bond between two identical atoms when $A \equiv B$. Therefore, Equations (i) and (k) can be written, both of which satisfy Equation (g) reasonably well.

$$\alpha = \frac{1}{2}\left\{D(A-A) + D(B-B)\right\} \qquad (i)$$

$$\alpha = \sqrt{D(A-A)D(B-B)} \qquad (k)$$

This ambiguity shows that Equation (g) is a somewhat arbitrary formulation using the quantity X; if (g) is expressed in the form (l) it is seen that in some cases the

$$D(A-B) - \frac{1}{2}\left\{D(A-A) + D(B-B)\right\} = \beta X^2 \qquad (l)$$

left-hand side of Equation (l) becomes negative, which is meaningless, since β is always positive. The question therefore arises of to what extent bond relationships can be described by the simple parameters χ. The expression (c) can have meaning only for single bonds. Second ionization energies (and second electron affinities) are not considered at all.

Thus we have a greatly simplified picture of the bond, although originally this represented a considerable advance. The main value of expression (c) is that, in contrast to the octet rule and the valence-bond scheme, it points to a continous transition between ionic and covalent bonding. The line representing a bond is correlated with the ionization energy and electron affinity, both of which can be calculated only with the aid of wave mechanics.

According to the octet rule, the xenon atom (like all inert gas atoms) has a full shell of electrons (octet), *i.e.* it cannot be expected to combine with another atom in order to share further electrons. With the concept of electronegativity, however, we must ask whether the transfer of an electron to another atom might not be energetically favored. Thus the inert gases are distin-

guished by their first ionization energies. A possible bonding partner must have an electron affinity which is comparable with these ionization energies, since only then can an electron be transferred from the inert gas atom. However, it cannot be decided on the basis of these semi-empirical rules whether this process in fact takes place, since it remains unknown whether or not the four pairs of electrons in an octet are equivalent. Moreover, the behavior of the inner electrons (and other effects) are not taken into account. The semi-empirical rules must therefore be regarded as a primitive stage of theory. In fact, examples show that Equation (g) is only of limited applicability. Thus, with $\beta = 0.00137$, expression (m)

$$\left[\frac{1}{\beta}\left\{D(A-B)-\frac{1}{2}D(A-A)+D(B-B)\right\}\right]^{1/2} \qquad (m)$$

yields the following values for P–H, C–S, H–Br, and O–F, respectively:

36.4 66.3 96.2 80.6 kcal/mole. (n)

According to Equation (l), these values should be equal to $|X|$. Equations (e) and (f) give the values

85.4 2.0 30.8 126.5 kcal/mole. (o)

The electronegativity χ as given by Equation (e) is usually divided by 130 to facilitate comparison with *Pauling's* scale of electronegativities (cf. below). Thus

$$\chi' = (I + A)/130 \qquad (e')$$

This leads to the values (n') and (o'), since β in Equation (m) must now be replaced by the constant $\beta' = 23.11$.

0.28 0.51 0.74 0.62 (n')
0.66 0.02 0.23 1.02 (o')

There is no agreement between the sets of values (n') and (o'). It should be remembered, however, that α in Equation (g) is large in comparison with the "correction" βX^2, which for the above examples is

1.8 6.7 12.5 9.1 kcal/mole.

These values are small in comparison with D(A–B), so that the expression (g) does not appear to be unjustified. It is obvious that corrections must be applied to the electronegativity values introduced in Equation (e). *Pauling* therefore calculated another scale of χ'' values, using Equation (p).

$$D(A-B)-\frac{1}{2}\left\{D(A-A)+D(B-B)\right\}=\beta' X''^2 \qquad (p)$$

$$X'' = \chi''_A - \chi''_B \qquad (q)$$

From this and with an arbitrary reference value, *e.g.* $\chi''_F = 4.0$, we obtain:

$\chi''_H = 2.1$ $\chi''_C = 2.5$ $\chi''_O = 3.5$
$\chi''_F = 4.0$ $\chi''_P = 2.1$ $\chi''_S = 2.5$ $\chi''_{Br} = 2.8$ (r)

These values of χ'' were calculated by averaging the values of X'' obtained for the same bond in various compounds. The value of β' was also found in this way, so that the χ'' values can be compared with the electronegativities χ' [see Equation (e')] introduced by *Mulliken*:

$\chi'_H = 2.53$ $\chi'_C = 2.23$ $\chi'_O = 3.08$
$\chi'_F = 4.06$ $\chi'_P = 1.87$ $\chi'_S = 2.21$ $\chi'_{Br} = 2.76$ (s)

It is thus possible to construct different electronegativity scales, one based on Equation (e) or (e') and the other on Equation (p). Comparison of the two sets of values, (r) and (s), shows that the results correspond to within certain limits. A similar agreement is found in other examples:

$\chi''_{Cl} = 3.0$ $\chi''_I = 2.5$ $\chi''_{Li} = 1.0$ $\chi''_{Rb} = 0.8$ (r')
$\chi'_{Cl} = 3.01$ $\chi'_I = 2.43$ $\chi'_{Li} = 0.95$ $\chi'_{Rb} = 0.74$ (s')

It should be noted that the accuracy of the approximation (g) is greatly affected by the differences between χ'' and χ'. We shall prefer the definition of electronegativity given by Equation (c) or (e'), which is unambiguous and consistent. Equation (g) might be improved by taking χ'^4 into account, as in Equation (g'),

$$D(A-B) = \alpha + \beta X^2 + \gamma X^4 \qquad (g')$$

and fixing the coefficients α, β, and γ. The choice of α in Equation (g), using Equation (i), gives negative values for the left-hand side of Equation (l) for some bonds. Thus the values found for As–H, C–I, and Se–H are −12.0, −1.8, and −7.5 kcal/mole, respectively.

Clearly, the electronegativity is of some importance, but it has not yet been possible to find completely satisfactory relationships between electronegativity and other measurable quantities. Thus X is an important, but insufficient quantity for the description of the bonding processes, so that all semi-empirical relationships involving X must be incomplete to some extent.

This is particularly true of the ionic character λ_{AB} of a bond, which is defined in terms of X [see Equation (u)]. This property is applicable only in the case of the hydrogen halides, for which it was first derived. The assumption that Δ in Eq. (t) should be a measure of the polarity of a bond,

$$\Delta = D(A-B)-\frac{1}{2}\left\{D(A-A)+D(B-B)\right\} \qquad (t)$$

because $\Delta = 0$ when $X = 0$, appears to have little justification if, for example, the expression Δ' is compared with Δ (see Table 1). As expected, there is no relation between Δ and Δ'.

$$\Delta' = D(A-B)-\left\{D(A-A)D(B-B)\right\}^{1/2} \qquad (t')$$

Table 1. Dissociation energies and energy values Δ and Δ' for a number of hydrogen compounds AH.

AH	HF	HCl	HBr	HI	LiH	NaH
D(A–H)	147.5	102.7	87.3	71.4	57.7	52.3
Δ	64.0	22.1	12.5	1.6	−7.6	8.7
Δ	66.5	25.4	18.3	10.2	4.7	8.7

For this reason, equations such as (u), which relate X to the ionic character [1] should be viewed with suspicion. It can

$$\lambda_{AB} = 0.16\,|X| + 0.035\,|X|^2 \qquad (u)$$

[1] *L. Pauling*: The Nature of the Chemical Bond. 3rd Edit., Cornell University Press, Ithaca (N.Y.) 1960.

be shown with the aid of wave mechanics that the polarity of a bond need not be directly related to the dipole moment. Consequently the so-called effective charges introduced in this connection suffer greatly from their arbitrary nature. The definition

$$\mu_{AB}/eR^{\circ}_{AB} = \lambda_{AB} \qquad (v)$$

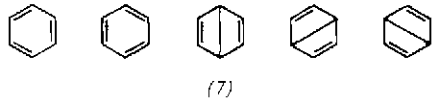
in which μ_{AB} is the dipole moment of the single bond and R°_{AB} is the bond length (e = electronic charge), is therefore applicable only in the case of a pure single bond, *i.e.* where bonding is effected by one pair of electrons, so that each of the atomic residues carries a positive charge; this condition is adequately fulfilled in only a few cases. It is desirable not to identify λ_{AB} in Equation (v) with that in Equation (u), since $|X|$ can only be a measure of the approximate charge separation in a bond, if no other effects are involved. Polarization effects are also disregarded.

Let us repeat, then, that although a large $|X|$ may indicate the existence of charge displacement in the single bond, *e.g.* as in H(+)Cl(−) or Li(+)H(−), any quantitative data derived from the semi-empirical rules should be regarded with caution, and the value of such data is at best orientative.

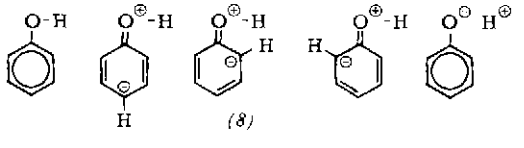
However, the symbols (+) and (−) go further than + and − or $^{\oplus}$ and $^{\ominus}$, since partial charge transfers can now be included. Thus ionic bonding and covalent bonding (as well as semipolar bonding) become limiting cases of the same bonding mechanism. This view, which is very close to the wave-mechanical picture, has unfortunately been over-simplified in the semi-empirical representation. Here a superposition of ionic and non-polar structures, *e.g. (6a)*, *(6b)* and *(6)*, is assumed. The same is true of

$A^{\ominus}B^{\ominus}$ *(6a)* $A^{\ominus}B^{\oplus}$ *(6b)* A–B *(6)*

the resonance picture, which is based on the fact that one molecule can be represented by several structural formulae. The best-known example is that of benzene *(7)*. If ionic structures are also admitted, the number of formulae can be greatly increased as, for example, in the case of phenol *(8)*. Here it is assumed that the bonding



(7)



(8)

behavior of the atom ions is essentially the same as that of neutral atoms containing the same number of electrons, *i.e.*

$C^{+} \triangleq B(III)$, $C^{-} \triangleq O^{+} \triangleq N(III)$,
$B^{-} \triangleq N^{+} \triangleq C(IV)$, $N^{-} \triangleq O(II)$, $O^{-} \triangleq F(I)$.

In this picture, the valence is a purely empirical quantity, and the properties of the atoms are characterized only by the number of electrons. With the introduction of the concept of electronegativity it becomes possible to distinguish, at least in one property, the most weakly bound electron and the eletron which can be taken up. In some cases lone pairs of electrons occur.

It is widely believed that the structures which make the greatest contributions to a molecule are those in which the most electronegative atoms are negative with respect to their neighbors; however, the situation is not always quite so simple. The stability of a compound cannot be determined by the number of possible structures, since on the basis of the electronegativity concept, certain statistical weights must be assigned to the various structures, although these weights cannot be given quantitatively, particularly to excited states. In other words, the resonance treatment cannot lead to a quantitative theory, since it is incapable of yielding information regarding the actual contribution of a given structure. It is therefore very misleading to suppose that certain structures are responsible for given aspects of the behavior of the molecule. For this reason, an interpretation of this type is generally given *after* a reaction has been found to occur.

An important point which is almost always overlooked in the resonance picture is the interatomic distance. Taking this into account, it is even less plausible to attribute resonance energy to a structure whose significance must remain unknown.

In writing structures, care is taken to ensure that all the valences are saturated, *i.e.* the only structures written are those in which the number of bonds leaving an atom corresponds to its valence; this is also borne in mind in the case of ionic structures. Structures in which valences remain unsaturated represent free radicals.

It might be asked, however, whether free-radical structures should also be considered for molecules in which each atom is using all its valences. It is generally believed that such structures have only small statistical weights, the doubtful (and sometimes false) argument being that these "molecular states" are energetically "unfavorable". This question will be examined in connection with the wave-mechanical arguments.

Thus structural formulae are made to satisfy the octet rule as far as possible. The principle of saturation of valence is taken to mean that the most stable compound is obtained when all valences are saturated, and when no further atoms will be bound, *i.e.* when the approach of other atoms does not lead to a further decrease in the energy of the system.

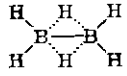
According to this principle, the H_2 molecule cannot bind a further H atom, and the sum of the energies of He and H is smaller the energy of HeH. The energy of $NH_3 + H$ should also be smaller than the energy of NH_4, and the approach of a hydrogen atom to an HF molecule should lead to repulsion. Recent wave-mechanical calculations have shown, however, that the energy of NH_4 is lower by about 5 kcal/mole than that of $NH_3 + H$, and that the four H atoms are situated about 1.0 Å from the nitrogen, and form the corners of a regular tetrahedron [2]. This is an infringement of the octet rule, although NH_4 probably cannot exist as a stable molecule, and almost certainly decomposes rapidly [Reaction (w)].

$$NH_4 + NH_4 \rightarrow 2\,NH_3 + H_2 \qquad (w)$$

[2] *D. M. Biskop*, J. chem. Physics *40*, 432 (1964).

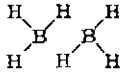
Who can guarantee that there are no stable molecules which should, according to the octet rule, be unstable or metastable. How is the NH_4 radical stabilized, *i.e.* why does NH_4 contain less energy than $NH_3 + H$?

One may adopt the view that the octet rule is only applicable to molecules, and not to molecular complexes. How then are we to explain *e.g.* the simplest of the boron hydrides, namely diborane *(9)*, or the sandwich compounds derived from cyclopentadiene (*e.g.* ferrocene)?

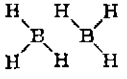


(9)

In order to satisfy the "valence rule", B_2H_6 must be assumed to contain the structures *(9a)* and *(9b)*; these representations seem very artificial, since what are we to

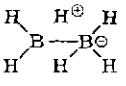


(9a)

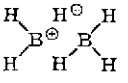


(9b)

understand by σ-bonds which oscillate back and forth? The difficulty is not resolved by assuming that the structures *(9a)* and *(9b)* are present in diborane, since there are in fact two BH_3 units simultaneously exchanging two H atoms. Since the electronegativities of B and H are essentially the same, ionic structures such as *(9c)* and *(9d)* can be ruled out.

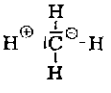


(9c)

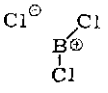


(9d)

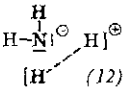
On the other hand, formulae such as *(10)* and *(11)* are often written. So why should we not represent NH_4 by



(10)

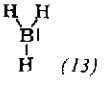


(11)



(12)

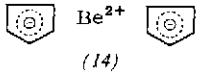
formula *(12)* (there are six possible structures)? Thus an H_2^+ unit would be indicated in NH_4 as BH_3 is in diborane by formula *(9a)*. It can be seen that the octet rule is satisfied in formula *(12)*. In *(9a)* or *(9b)* it would be necessary to include "inner" electrons in order to obtain formula *(13)*. In *(11)*, on the other hand, only Cl^-



(13)

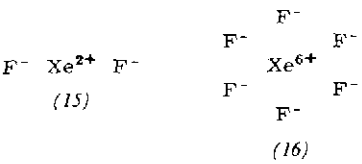
has a closed shell, whereas two electrons of B^+ participate in bonding, and the K shell forms the atomic residue.

If it is still impossible to satisfy the octet rule using considerations of this kind, it is usual to turn to completely ionic formulae, as in the case of $Be(C_5H_5)_2$ *(14)*, or



(14)

XeF_2 *(15)*. Is it then permissible to write the structure *(16)*? Here things become doubtful, particularly since Be in $Be(C_5H_5)_2$ is not centrally positioned between the rings as is postulated in structure *(14)* [3].



(15) *(16)*

We can see from all this that such an "interpretation" of bonding relationships is unsatisfactory. On the one hand, more and more knowledge of the electronic structures of the atoms involved is required, and on the other, we encounter ambiguities, so that it is no longer possible to speak of a true understanding. Here it is felt that the relative importance of the individual structures of the real molecule is not known. What does it mean to say a certain structure of a molecule is more important than the others? Can this conclusion be drawn with certainty from the physical and chemical properties of the compound? Should it not be possible to predict, and possibly understand, the behavior of the molecule from theoretical considerations?

Clearly, many compounds can be decribed by the octet rule and the usual structural formulae. Although these descriptions are not accurate, they can at least be used by the chemist as a temporary measure, without which all practical experience would remain unrelated. However, many of the compounds discovered in recent years can be reconciled with these rules only with difficulty, or fall entirely outside the scope of previous chemical views. It is clear, moreover, that false information may be obtained for these new compounds if the old scheme is used indiscriminately.

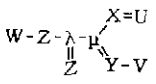
Normally a rule is applicable only to certain classes of compounds. For example, the additivity of the mean dissociation energies is valid only in the case of localized bonds, *i.e.* for molecules which can be essentially described by a single valence structure. The bond constants remain additive as long as the interactions between the various bonds are of the same type. However, it is difficult to determine the range of validity, particularly since the significance of the individual valence structures can only be discussed on the basis of wave mechanics. All molecules for which the mean dissociation energies are approximately additive are compounds for which the octet rule is approximately valid.

The rule of the additivity of dissociation energies gives only a rough representation of the situation; this can be seen in the case of the ideal disosciation energies $\tilde{D}_T$ introduced by *Szabo* [4], for which there is no additivity rule. Assuming, however, that the perturbations on a given bond are due only to the adjacent atoms and bonds, it is possible to determine the true dissociation energies D_T such that a useful rule is obtained. The di-

[3] *A. Almenningen, O. Bastiansen,* and *A. Haaland,* J. chem. Physics *40*, 3434 (1964).

[4] *Z. G. Szabo,* Z. Elektrochem., Ber. Bunsenges. physik. Chem. *61*, 1183 (1957). – $\tilde{D}_T$ refers to a bond which is unperturbed by neighboring atoms and bonds.

sturbances due to the neighbors are given by a quantitivity d, which should be constant for a given atom and a given bond, irrespective of the nature of the molecule. Thus in



(17)

the case of a compound of the type *(17)*, the expression for the bond λ–μ is:

$$D_T(\lambda-\mu) \approx \widetilde{D}_T(\lambda-\mu) + d(-X) + d(=Y) + d(-Z) + d(=Z) \qquad (x)$$

This rule can be extended to cover unsaturated and aromatic systems and is important for the estimation of activation energies. The form of this rule comes close to the theoretical views of the valence bond and group function methods. It fails when there is a change in the bonding relationships.

3. Hybridization

No concept is so frequently used in valence theory and none is so controversial as that of hybridization.

The problem of directed valence, *i.e.* the spatial structure of a molecule, was essentially explained by *Slater* and *Pauling* [5] in 1931. However, the usual elementary picture involves more theory than is supposed, and has therefore not been free from serious objections [6].

The logical application of the hybridization concept requires the use of wave-mechanical concepts such as that of the atomic state (O) and the atomic functions (φ_s, φ_p), as well as the introduction of electron spin (↑, ↓). This is generally illustrated graphically, *e.g.* for the atoms Be, C, N, and O, as shown in Figure 5. In this illustration, C* denotes an excited state.

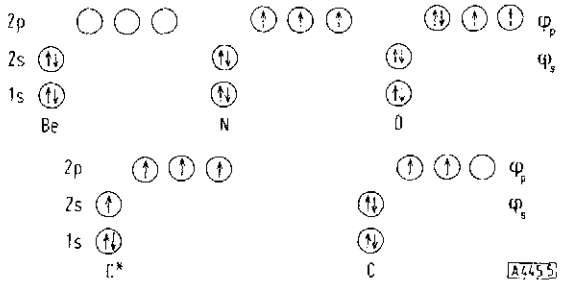


Fig. 5.

According to this concept, the directed valence is determined by the electronic structure of the central atom; this assumption is by no means satisfactorily fulfilled in every case, as we shall see.

The elementary picture of hybridization is based on two postulates:

(1) the wave functions ψ_1, ψ_2 ... ψ_M of the valence electrons of the central atom are mutually orthogonal, and

(2) the surrounding atoms arrange in those directions in which the wave functions ψ_1, ψ_2 ... have their maxima.

The ψ_j functions are linear combinations of the atomic functions φ_s and φ_p, as shown in Equation (y), where λ

$$\psi_j = \frac{\varphi_s + \lambda\varphi_{p_j}}{\sqrt{1+\lambda^2}} \qquad (j = 1, 2, 3 \ldots M) \qquad (y)$$

is the hybridization parameter. The form of Equation (y) is so chosen that ψ_j is normalized:

$$\int \psi_j^* \psi_j \, d\tau = 1 \qquad (y')$$

The p functions in Equation (y) at first lie in any direction in space; the number of ψ_j functions involved depends on the number of valence electrons, which are defined here as the electrons of the singly occupied energy levels of the free atoms. The direction of the p_j functions and the value of λ are given by assumptions 1 and 2. When d and f functions are involved, Equation (y) expands to give (z). However, the most important points can be studied with the aid of Equation (y). According to Figure 5, four ψ_j functions must be formed in the excited state C* of carbon. According to assumption 1, Equation (a*) must be satisfied. This together

$$\psi_j = \frac{\varphi_s + \lambda\varphi_{p_j} + \mu\varphi_{d_j} + \nu\varphi_{f_j}}{\sqrt{1+\lambda^2+\mu^2+\nu^2}} \qquad (z)$$

$$\int \psi_i^* \psi_j \, d\tau = 0; \; (i \neq j) \qquad (a^*)$$

with Equation (y) leads to Equation (b*), where Θ_{ij} is

$$\cos\Theta_{ij} = -1/\lambda^2; \; (i, j = 1 \cdots M; \; i \neq j) \qquad (b^*)$$

the angle between the two functions φ_{pi} and φ_{pj}. In order to satisfy postulate (2) we introduce the bond strength, as defined in Equation (c*), which represents the angular dependence of a ψ_j function in the direction of maximum

$$B(\lambda) = \frac{1+\lambda\sqrt{3}}{\sqrt{1+\lambda^2}} \qquad (c^*)$$

$$\frac{dB}{d\lambda} = 0 \qquad (d^*)$$

extension [*]. Thus, with (d*), Equation (c*) leads to (e*):

$$\lambda = \sqrt{3} \qquad (e^*)$$

This value of λ leads to Equation (f*), which shows that the four bonds of C* are directed towards the corners of

$$\cos\Theta_{ij} = -1/3, \; i.e. \; \Theta_{ij} = 109.5^\circ \qquad (f^*)$$

a tetrahedron, according to postulate (2). It should be remembered here that the four atoms bound by a carbon atom are assumed to combine with the carbon in

[5] *J. C. Slater*, Physic. Rev. *37*, 481 (1930); *38*, 1109 (1930); *L. Pauling*, J. Amer. chem. Soc. *53*, 1367 (1930); Physic. Rev. *37*, 1185 (1930); The Nature of the Chemical Bond [1].

[*] The factor $\sqrt{3}$ in Eq. (c*) is contributed by the p-function.

these directions, in which the ψ_j functions have maximum values. This assumption is not, as often asserted, self-evident since there are systems in which carbon has five neighbors. This brings us back to the NH_4 radical or compounds in which phosphorus could be assumed to be tetravalent. According to Figure 5, N (like P) has three valence electrons in p states, and no s functions. Thus λ in Equation (y) must be infinitely large, and there is no hybridization [$\Theta = 90°$ according to Equation (b*)]. Pentavalent phosphorus might be thought to contain states such as those shown in Figure 6. However, which

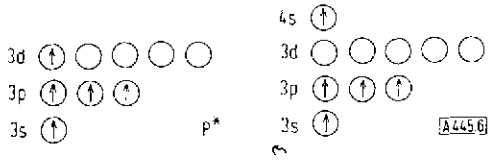

Fig. 6.

valence state is closest to the true situation evidently depends on energetic factors and on the number of different states (*e.g.* five in the case of d states), which must be found from wave-mechanical considerations. Can nitrogen also exist in a pentavalent state, as has sometimes been assumed, *e.g.* for the azide ion *(18)*? Would it not also be possible to write *(18a)*?

(18) *(18a)*

Whereas *(18)* should involve hybridization with 3d or 3s functions, the electron shell of the central nitrogen atom-ion in *(18a)* is the same as that of carbon, so that we can again use Equation (y). This does not enable us to decide whether *(18)* or *(18a)* is closer to reality, since the energy required for the participation of d states in *(18)* is offset by the need to form charges in *(18a)*.

If we consider the molecules BeX_2 and BX_3 (Figure 7), the result obtained using Equations (d*) and (b*),

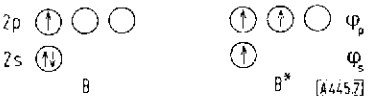

Fig. 7.

which led to $\lambda = \sqrt{3}$, is in conflict with observation, since BeX_2 is linear, whereas BX_3 is planar, with bond angles of 120°. It is usual in these cases to assume $\lambda = 1$ and $\lambda = \sqrt{2}$, respectively; Equation (b*) then gives $\Theta = 180°$ and $\Theta = 120°$. This is contrary to postulate (2), which gave such good agreement with experiment in the case of carbon. These examples (and many others) show that postulates 1 and 2 are not sufficient to lead to directed valence. It is the empirical assumption that $\lambda = 1$ and $\lambda = \sqrt{2}$ which ensures that the desired result will be obtained. *Artmann* [6] was probably the first to point out this discrepancy; he gave a better interpretation which did not make use of hybrization, and which we shall discuss in Section 4.

The lower values of λ are often explained by assuming that the production of the sp (or sp^2) configuration from the ground state of the central atom requires an excitation energy ($\varepsilon_p - \varepsilon_s$), with the result that the p-component in Equation (y) is smaller than predicted by Equation (d*); the transitition to the sp^3 state also requires an excitation energy. This gives rise to an energy principle which opposes postulate (2). At the same time, some uncertainty is introduced into the determination of the valence angle, since it is necessary to know the relationship between λ and the excitation energy. Estimates made in theoretical studies show [7] that this relationship can be represented by Equation (g*), where ε_D is

$$\lambda \approx (\varepsilon_p - \varepsilon_s)/\varepsilon_D \qquad (g^*)$$

the energy of dissociation of a bond partner from the central atom. Equation (g*) is obviously not connected with Equation (b*). The criterion of maximum overlap, which is involved in Equation (d*), is therefore not sufficient for a calculation of valence angles, as has already been pointed out by *Van Vleck* [8]. In agreement with the above considerations, it was found that both postulates (1) and (2) cannot be satisfied simultaneously even for CH_4, when small deviations of the H atoms from their equilibrium positions are considered.

The above discussion shows that, in addition to its ambiguity, the usual elementary form of the hybridization concept cannot be satisfactorily substantiated, and leads to contradictions. The value of this concept in chemical bonding is therefore doubtful. It is generally called upon only as an aid to the interpretation of experimental findings.

4. Wave-Mechanical Aspects

The determining factor here is the wave function Ψ, which depends on all the electronic coordinates (including the two possible electron spin directions, which are described by spin co-ordinates), and the square of which, $\Psi^*\Psi$, is proportional to the probability W of finding the electrons at the positions given by the chosen values of the electronic coordinates:

$$W \propto \Psi^*\Psi \qquad (h^*)$$

Each electron distribution ${\Psi_k}^*\Psi_k$ is associated with a certain energy ε_k ($k = 0, 1, \ldots$) of the system as a whole, which is a function of the positions of the atoms in space. In fact

$$\varepsilon_k = E_k + \Lambda, \qquad (k = 0, 1, 2\ldots) \qquad (k^*)$$

where E_k is the electronic energy and Λ is the repulsive energy of the positive atomic nuclei (charge $Z_\lambda e$;

$$\Lambda = \sum_{\lambda=1}^{N-1} \sum_{\mu=\lambda+1}^{N} \frac{e^2 Z_\lambda Z_\mu}{R_{\lambda\mu}} \qquad (l^*)$$

$\lambda = 1 \ldots N$), which is of the form (l*) for N atoms, where $R_{\lambda\mu}$ is the distance between the nuclei of atoms λ and μ. Ψ_k and the associated energy ε_k (or E_k) can in principle be determined as accurately as desired from the Schrödinger equation. Generally, however, it is sufficient to know the approximate values $\tilde{\Psi}_k$ and $\tilde{\varepsilon}_k$ for

[7] *K. Artmann*, Z. Physik *138*, 640 (1954).

[8] *J. H. van Vleck*, J. chem. Physics *1*, 209 (1933).

a discussion of bonding. Every conceivable fact about an atom or molecule can theoretically be found from Ψ^* and ε.

According to Equation (k*), a molecule generally has an infinite number of energy states ε_k, which should be regarded as a function of the bond length R (see Figure 8a). The electron energies E_k (Figure 8b) are described

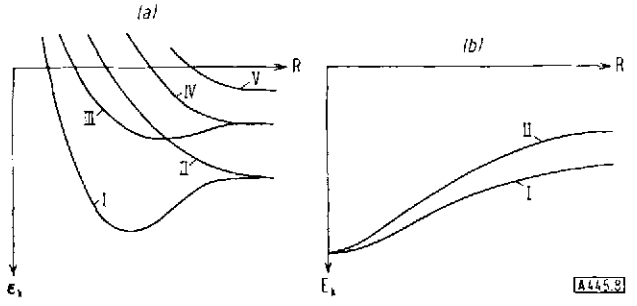

Fig. 8. Total energy ε_k and electronic energy E_k of a diatomic molecule, as functions of the interatomic distance R. Curves I, II, III, IV and V correspond to different values of k.

for $R \rightarrow 0$ as the energy $E_{UA}^{(k)}$ of a united atom, and for $R \rightarrow \infty$ as the energy $E_{SA}^{(k)}$ of the separated atoms. For example, as far as the electronic energy is concerned, the united atom of the H_2 molecule is the He atom. CH_4 corresponds to Ne when all the C–H distances tend to zero; if only one C–H distance tends to zero, the result corresponds to the NH_3 system.

It can be seen from Figure 8 that the repulsion of two atoms at short interatomic distances is not due to interpenetration of the "electron clouds" and the resulting mutual repulsion of the electrons. The repulsion is due only to the Λ term in Equation (k*), since E_{UA} is always smaller than E_{SA}.

The kinetic energy K of the electrons is found [9] with the aid of the virial theorem to be

$$K = -\varepsilon - R\frac{d\varepsilon}{dR'} \qquad (m^*)$$

Since in the case of bond formation there is an equilibrium distance $R = R_0$ such that, for $0 < R < \infty$,

$$\varepsilon(R_0) \leqslant \varepsilon(R) \qquad (n^*)$$

and

$$(d\varepsilon/dR)_{R=R_0} = 0, \qquad (o^*)$$

(cf. Figure 8, Curve I), we find from (m*):

$$K(R_0) = -\varepsilon(R_0) \qquad (p^*)$$

When $R \rightarrow \infty$, on the other hand, the second term in (m*) disappears to give:

$$K_{R\rightarrow\infty} = -\varepsilon_{R\rightarrow\infty} = -E_{SA} \qquad (q^*)$$

Because of the relationship (n*), a comparison of Equations (p*) and (q*) gives

$$K(R_0) > K_{R\rightarrow\infty} \qquad (r^*)$$

[9] *E.g. P. O. Löwdin*, Molecular Spectroscopy *3*, 46 (1959).

which is valid for all bonds, and which states that the kinetic energy of the electrons is higher in a bond. The total energy ε is equal to the sum of the kinetic energy K and the potential energy P of the total system, as expressed in Equation (s*). In general, therefore, the

$$\varepsilon = K + P \qquad (s^*)$$

potential energy of the entire system is so greatly reduced in any bond, that it more than compensates for the increase in the kinetic energy of the electrons.

An important factor in chemical bonding is the change in the energies ε as a function of the internuclear distances. Energy curves such as those shown in Figure 8a can intersect. It can now be shown that the overlapping of certain energy states is forbidden [10]. In this case, we may obtain Figure 9a, where the energy ε_1 corresponds to an excited state, since when $R \rightarrow \infty$, ε_1 is greater

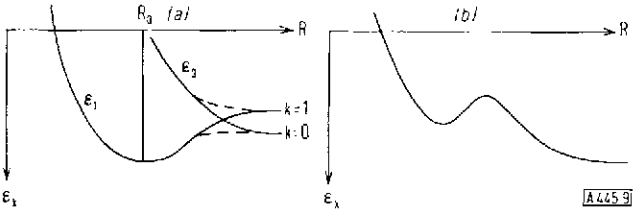

Fig. 9. (a): Change in the total energy for a bonding and a non-bonding state; overlapping forbidden.
(b): Energy curve for metastable systems (*e.g.* XeF).

than the energy of the ground state ε_0. At the "intersection", the curves follow the broken lines. Thus if we were to examine only the ground state, disregarding ε_1, there would be no bonding, since $\varepsilon_0 = f(R)$ does not have a minimum.

A similar situation is found *e.g.* in CH_4, when R is the C–H distance (all the C–H distances being regarded as equal). When $R \rightarrow \infty$, ε_1 corresponds to the energy of the system $C^* + 4\,H$, whereas ε_0 is the energy of the system $C + 4\,H$. Similar bonding relationships probably also prevail in the xenon fluorides: ε_1 corresponds to $Xe^{\oplus}$–$F^{\ominus}$, and ε_0 to Xe–F. If the ε_1 curve is higher, while still intersecting ε_0, metastable states can be formed, giving a lowest energy curve as shown in Figure 9b. This is the case in $He_2^{\oplus}$ or in the metastable systems formed by the rare gases Ne and Ar with fluorine or oxygen.

Knowing the potential energy curves (or the potential energy surfaces when more than two atoms are under consideration), we can calculate the vibrational and rotational states of the systems with the aid of wave mechanics. Reactions can also be examined, since these can be regarded as movements of a system on the energy surfaces. Thus the theories of reaction kinetics and spectroscopy are based on a knowledge of ε as a function of the distances between the atomic nuclei. The difference between a stable and a transient molecule can also be seen from the energy curves.

[10] *E.g. H. Hellmann*: Einführung in die Quantenchemie. Deuticke, Wien 1937, pp. 285–290.

For the molecule $M(C_5H_5)_2$, it would be feasible as an approximation to express the energy as the sum of the curves of the potential energy between the metal and each ring.

$$\varepsilon(H_5C_5\text{-}M\text{-}C_5H_5) \approx \varepsilon(H_5C_5\text{-}M) + \varepsilon(M\text{-}C_5H_5) \qquad (t^*)$$

The ε values on the right-hand side of Equation (t*) change as shown in Figure 8a, whereas the left-hand side is of the form shown in Figure 10 if the

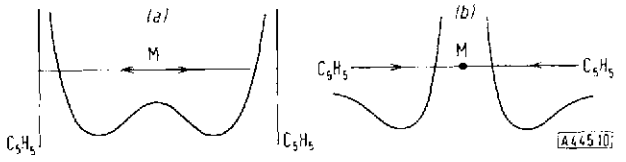

Fig. 10. Change in the course of the energy curve for a dicyclopentadienylmetal $M(C_5H_5)_2$, according to the masses of the partners.
(a) $m_M < m_{C_5H_5}$ (b) $m_M > m_{C_5H_5}$.

metal can move. We find that, under certain circumstances, the asymmetric position of the metal becomes understandable if the "potential peak" in the middle (Figure 10a) is sufficiently high and the vibrations of the molecule consist preferentially in the vibration of the metal. This can be the case only if the mass of the metal is small in comparison with that of the five-membered rings [*e.g.* in *(14)*]. If the metal atom is heavy, on the other hand, the vibrations will be essentially those of the rings, thus leading to the potential curve of Figure 10b; in this case the molecule should not be asymmetric, even if the two rings are identical in structure.

The chemical significance of potential energy surfaces has gained increasing recognition in recent years. Liquefaction and solidification are also connected with molecular interaction energies, the temperatures at which these processes occur being determined by the position and depth of the minima. The slight minimum in the potential energy curve of He...He, for example, causes the formation of condensation nuclei at very low temperatures.

There is no place for the hybridization concept in considerations involving the use of energy surfaces, unless several energy curves corresponding to different states of the central atom are being studied. More can be said about hybridization if we introduce the Ψ functions. In theoretical work, the approximation $\tilde{\Psi}$ is generally used instead of Ψ, constructed by a linear combination [Equation (u*)] of the Φ_j functions; the sum can repre-

$$\tilde{\Psi} = \sum_{j=i}^{M} C_j \Phi_j \qquad (u^*)$$

sent the accurate Ψ function when the number of Φ_j functions becomes very large ($M \to \infty$). The coefficients C_j are given by the requirement that $\tilde{\Psi}$ (for a fixed M) should be as close as possible to Ψ. (This requirement can be used, although Ψ itself is unknown). In this case, $\tilde{\varepsilon}$ is also an approximation to ε.

The functions Φ_j are generally expressed as determinants, which depend on one-electron functions χ_i

$$\Phi = \left| \chi_1(1)\begin{Bmatrix}\alpha\\\beta\end{Bmatrix}, \chi_2(2)\begin{Bmatrix}\alpha\\\beta\end{Bmatrix}, \ldots, \chi_n(n)\begin{Bmatrix}\alpha\\\beta\end{Bmatrix} \right| \qquad (v^*)$$

($i = 1, 2 \ldots$). It has been assumed in the expression (v*) that the system in question contains n electrons. α and β represent the spin functions for the two possible spin directions, which we shall indicate by $\uparrow$ (α) and $\downarrow$ (β). Equation (v*) satisfies one requirement imposed on Ψ, *i.e.* that only the sings of the wave functions should change when the coordinates of two electrons are interchanged (Pauli's principle).

It is demanded of the chosen χ functions that they should represent a complete system of functions, and that the integrals formed from them be defined.

Let us again consider BeX_2 as an example. This molecule may be regarded as a four-electron system, since for each bond there are two electrons situated inside the field of the remaining electrons. According to Figure 5, the two valence electrons of the Be occupy a 2s and a 2p state (φ_s, φ_p), so that two functions ψ_1 and ψ_2 must be formed according to Equation (y). The electrons of the two atoms X should occupy the orbitals φ_x and $\varphi_{x'}$. As an approximation to the wave function of BeX_2, we find:

$$\tilde{\Psi} = |\psi_1\alpha, \psi_2\alpha, \varphi_x\beta, \varphi_{x'}\beta| + |\psi_1\beta, \psi_2\beta, \varphi_x\alpha, \varphi_{x'}\alpha| - |\psi_1\beta, \psi_2\alpha, \varphi_x\alpha, \varphi_{x'}\beta| - |\psi_1\alpha, \psi_2\beta, \varphi_x\beta, \varphi_{x'}\alpha| \qquad (w^*)$$

(the derivation cannot be discussed in the present paper). According to Equation (y), λ has not yet been fixed, and is determined so that $\tilde{\Psi}$ is the best possible approximation to Ψ. Similarly the directions of φ_{p1} and φ_{p2} are still undecided, but the molecule is assumed in the first place to be linear, in order to simplify the calculations. One obtains $\lambda = 0.61$, and it is found, in accordance with Equation (x*), that ψ_1 and ψ_2 are not mutually orthogonal, as assumed in the hybridization theory [postulate (1) and Equation (a*)].

$$\int \psi_1^* \psi_2 d\tau = 0.40 \qquad (x^*)$$

Equation (x*) means that postulates (1) and (2) cannot be imposed if all the bonding electrons are taken into consideration. The same has been found for BX_3 and CH_4. More generally, we can say that the orthogonality requirement (1) is almost always a violation of the wave-mechanical treatment of the molecule. There are therefore no reasons for imposing condition (a*) on the functions (y). A wave-mechanical discussion of the valence angle shows that, *e.g.* in the case of BeX_2, an angular molecule is obtained if we admit only the λ values which agree with Equation (a*) [6, 7].

If, as a simplification, we assume the interatomic distances to be increased, so that to a close approximation only the central atom need be considered in relation to the valence angle, this atom is only slightly influenced by the outer atoms (separated atom model). For example, if we consider the C* atom of Figure 5, we can write

$$\tilde{\Psi} = |\varphi_s\alpha, \varphi_{p_x}\alpha, \varphi_{p_y}\alpha, \varphi_{p_z}\alpha| \qquad (y^*)$$

where p_x, p_y, and p_z denote the p functions in the x, y, and z directions.

If we now examine the probability W [cf. Equation (h*)] of finding electrons on a spherical surface surrounding the C atom, we obtain the remarkable result that the maximum probabilities for the four electrons occur at the corners of a tetrahedron, so that the outer atoms can best be accommodated in these directions [6, 7].

This result follows from the simple assumption that the four valence electrons are present in the sp^3 configuration, and is not restricted to the C atom. This procedure also gives the correct angles for the sp^2 and sp configurations. The maximum probabilities for the four electrons in the case of the sp^2d configuration occur at the corners of a square; this agrees with experimental results, *e.g.* for $[PdCl_4]^{2-}$.

It must be emphasized that the notation of Equation (y*) follows purely from Pauli's principle, and that no electrostatic effects among the electrons are involved; moreover, the concept of hybridization has not been used. The wave-mechanical procedure is therefore already superior to the elementary hybridization theory, particularly since it permits an unambiguous determination of the bond directions. If there are several configurations to be discussed, the potential energy curve for each configuration should be derived from these calculations, paying attention to forbidden overlapping. One reason why the usual concept of hybridization is unsatisfactory is that partial wave functions are used.

The procedure indicated in Equation (v*) may be carried further, in order to obtain a better approximation to Ψ. For example, the Ψ function of He is known with very great accuracy. The most probable distribution of the electrons on the surface of a sphere surrounding the helium atom, as shown in Figure 11, is that of case (a).

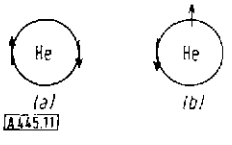

Fig. 11.

In the case of the Xe atom, the most probable distribution is that of Figure 12, if we consider the p^6 configuration of the ground state. On the approach of another atom whose electron affinity is comparable with the ionization energy of Xe (*e.g.* F or O), this new atom can

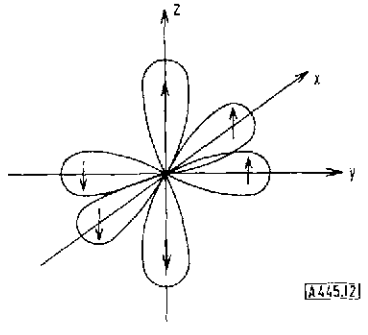

Fig. 12. Most probable distribution of electrons in the xenon atom (p^6 state).

attract a p-electron to itself, so that a bond is formed. The bonding in XeF_2, XeF_4, and XeF_6, which are reported to have linear, square, and octahedral structures respectively, could be of this type.

These greatly simplified considerations on the xenon fluorides show that the electronegativity as defined in Equation (e) can be used for a rough treatment. However, the detailed situation can only be correctly represented by the wave-mechanical calculations involving Ψ and ε. A number of wave-mechanical points have already been taken into account in Figures 11 and 12.

As was pointed out above, we must seek a $\tilde{\Psi}$ which closely approaches Ψ. When M is small the expressions corresponding to Equation (u*) are somewhat arbitrary as regards the choice of the Φ_j functions. In the valence-bond method, the Φ_j functions are sometimes identified with particular structures. Such a procedure is dubious, however, since we do not always know the part played by the structures which have been omitted. It is only when a large number of Φ_j functions (all, if possible) are considered, that we can assign a certain significance to the C_j values obtained. It must be remembered that the Φ_j functions do not occur in the molecule, since they do not describe a stationary state of the system. In this interpretation, therefore, the Φ_j functions have an imaginary character; consequently, the resonance energies which are often calculated in this connection are also without absolute significance, since these depend on the Φ_j functions chosen. Since the only important point is $\tilde{\Psi}$, it is possible to use entirely different Φ_j systems, provided that they represent the exact Ψ functions when $M \to \infty$. In other words, a picture of chemical bonding is only admissible if it is based on adequate wave-mechanical foundations. An example of what we mean is the remark which is sometimes made, that antiparallel electron spins in different atoms lead to bonding. This is not, however, the reason for chemical bonding, but the fact that the spins are antiparallel is a characteristic of a special type of bond.

Finally, from $\tilde{\Psi}$ and the integral

$$\int \Psi^* \begin{Bmatrix} x_1 + x_2 + \cdots x_n \\ y_1 + y_2 + \cdots y_n \\ z_1 + z_2 + \cdots z_n \end{Bmatrix} \Psi d\tau \qquad (z^*)$$

for a system containing n electrons, the coordinates of the center of negative charge can be determined, which can provide information on dipole moments. It should be noted, however, that this center of charge must be correlated with that of the positive nuclear charges. Thus, the relationship between the dipole moment and Ψ is not mathematically simple. There is no relationship between the dipole moment and the difference in the electronegativities of the bonded atoms. An example is carbon monoxide, for which there is a strong tendency to attach considerable importance to the structure $C^{\ominus} \equiv O^{\oplus}$, particularly since CO is very similar to N_2; however, the dipole moment of CO is very small.

Progress in the Chemistry and Molecular Biology of Flavins and Flavocoenzymes [1]

BY PRIV.-DOZ. DR. P. HEMMERICH, INSTITUT FÜR ANORGANISCHE CHEMIE UNIVERSITÄT BASEL (SWITZERLAND)

PROF. C. VEEGER, BIOCHEMISCHES LABORATORIUM DER LANDWIRTSCHAFTSHOCHSCHULE, WAGENINGEN (THE NETHERLANDS)

AND

DR. H. C. S. WOOD, DEPARTMENT OF CHEMISTRY, UNIVERSITY OF STRATHCLYDE, GLASGOW (GREAT BRITAIN)

An attempt is made to create a basis for the understanding of flavin- (Vitamin B_2-) dependent oxidations in terms of molecular structure. The main points of this survey can be summarized as follows: a) The flavins must be differentiated according to their redox states (quinone state, radical state, hydroquinone state), since configuration, energy content of the tautomeric forms, metal affinity etc., alter drastically during reduction. – b) The methyl group on C–8 of the flavoquinone is reactive. – c) The electron transfer properties of the flavin system frequently depend on the coupling of secondary redox systems to the apoprotein. This interaction thermodynamically stabilizes the half-reduced state of the flavin. – d) Numerous novel flavin types, among them stabilized free radicals, have become available through syntheses at the dihydro stage. – e) Reaction of the flavin radical with O_2 is slow as long as no disproportionation occurs, i.e. the fast flavin autoxidation proceeds via the dihydro state. – f) The flavin nucleus gains affinity for heavy metal ions only by the acceptance of one, and only one, electron. – g) Redox activity and contact with the flavin coenzyme have been confirmed for Fe and Mo, which occur in flavoproteins. The properties of the metal coordination sphere are determined primarily by sulfur-containing groups of the apoprotein.

I. Introduction

1. Definition and Nomenclature of the Flavins

Flavin is the trivial name of the chromophoric, redox-active prosthetic group of a class of respiratory enzymes occurring widely in animals and plants, *i.e.* the flavoproteins. The flavin group forms part of the flavocoenzyme, a non-protein, low molecular-weight sub-unit, which is linked with the apoprotein (cf. Section VI,1). The two known flavocoenzymes are called flavin nucleotides (FMN = flavin mononucleotide, FAD = flavin adenine dinucleotide, Scheme 1), although this term is inapt, since the flavin is not held by a glycosidic linkage in the flavocoenzymes.

Acid hydrolysis therefore leaves the polyhydroxy substituent on the flavin nucleus intact, and leads to riboflavin. This compound is the oldest known flavin derivative (*Warburg* and *Christian* 1932) [3] and was initially termed lactoflavin (vitamin B_2).

Unlike FAD, riboflavin and FMN are light-sensitive in dilute solution (cf. Section II,2). Flavin is a redox system which on absorption of light dehydrogenates its own hydroxylic side chain. This irreversible process ("photolysis") can be prevented by addition of exogenic electron donors, *e.g.* tertiary amines, which are more easily attacked (dehydrogenated) by the light-activated flavin (triplet state) so that merely a "photoreduction" (reversible with O_2) takes place.

Photolysis under acidic or neutral conditions is a special case of the N–10 dealkylation which is characteristic of all flavins (cf. Section II,2). The product of this reaction, lumichrome *(1)*, has no flavin properties. Under alkaline conditions photolysis does not lead to dealkylation; rather the side chain is degraded until only a methyl group is left. The simplest flavin compound, lumiflavin *(2)*, obtained in this way resembles the native coenzyme in its spectral, acid-base, and redox properties. Lumiflavin was the first flavin to be synthesized (*Kuhn* and *Weygand*, 1934) [4].

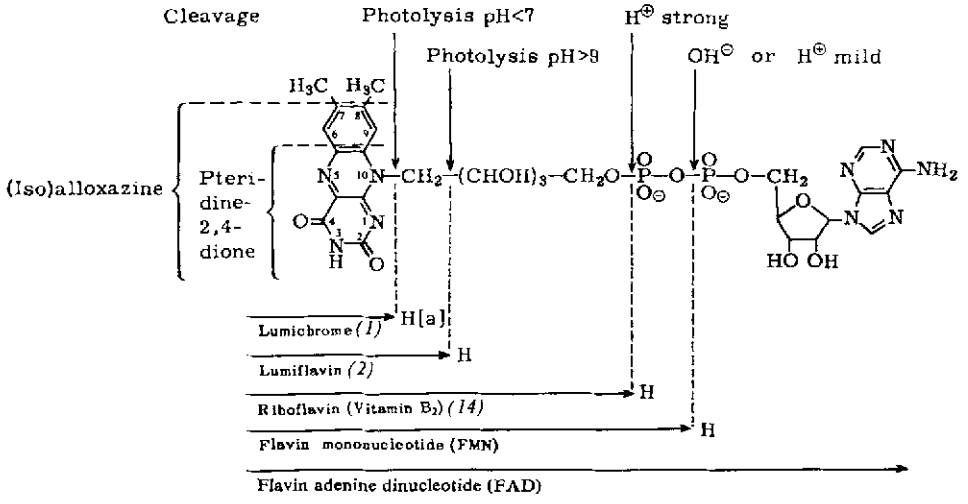


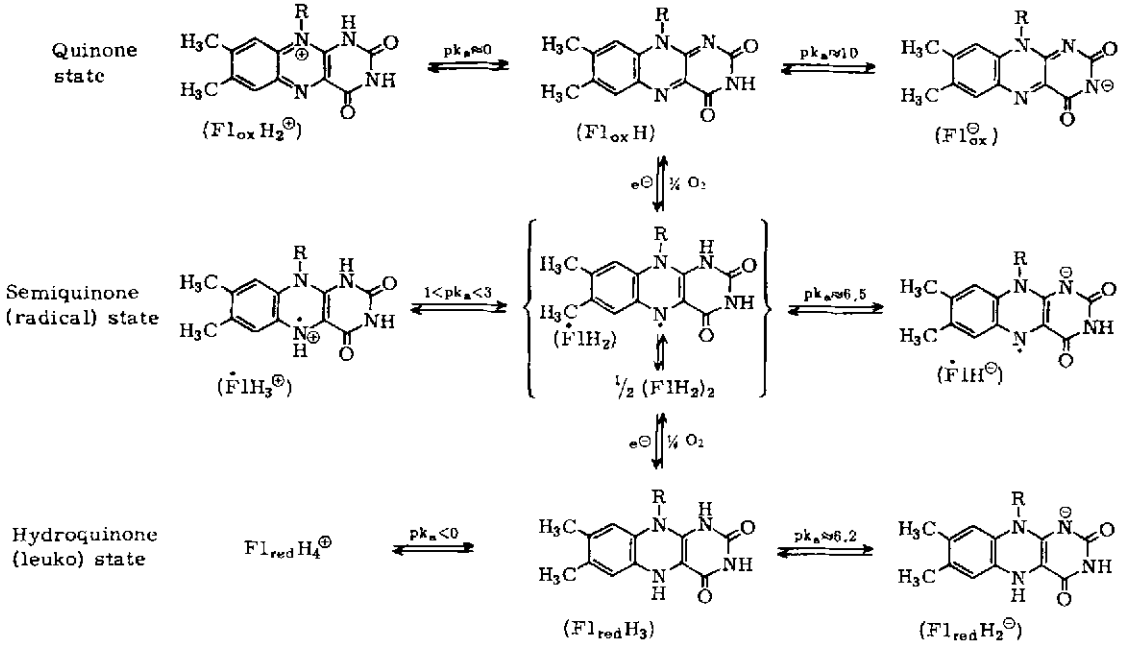
Scheme 1. Flavin nomenclature. — [a] The hydrogen is on N-1.

This synthesis started from alloxane and therefore the name "isoalloxazines" was assigned to the flavins [5]. We prefer the name benzopteridines. This nomenclature is justified by the biosynthesis of these compounds (cf. Section III,2) which proceeds *via* pteridine; at the same time it shows the relationship among flavins, folic acid, and the purines. In the following, the designation "flavins" is taken to mean 10-alkylated 2,4-diones with a benzopteridine skeleton, *e.g.* lumiflavin *(2)*.

Lumichrome *(1)*, the product of the N–10 dealkylation of flavin, is the prototype of a separate class of compounds, *i.e.* the alloxazines. The reverse reaction, *i.e.* the formation of flavins from lumichrome by alkylation, is not feasible. The 10-alkylation of alloxazines found by *Stern* and *Holiday* [6] can be conducted only at temperatures at which the opposite reaction ensues. Methylation therefore proceeds to an equilibrium in which a few percent of lumiflavin is present in addition to lumichrome.

The oxidoreduction of the flavins is thermodynamically reversible, irrespective of whether one or two electrons per flavin molecule are being transferred. Thus flavin fulfils the criteria of a "quinoid" redox system. The chemical properties of the flavin species which is stable under aerobic conditions are frequently taken to be representative of the entire system. However, the chemistry of the reduced, autoxidizable flavin species is entirely different. For this reason, a differentiation of the flavin oxidation states is required (Scheme 2 and Table 1).

In addition, each of the three redox states of flavin is amphoteric, although the "isoelectric intervals" extend over wide pH ranges. A total of at least nine monomolecular flavin species can be distinguished, *i.e.* one cation, one neutral species, and one anion in each redox state. We shall use the abbreviations shown in Scheme 2, *i.e.* in particular "flavoquinone" for the air-stable form, "flavosemiquinone" for the radical form, and "flavo-



Scheme 2. The flavin redox system. Occurrence of the flavin species as a function of pH and redox state.

[5] *R. Kuhn* and *H. Cook*, Ber. dtsch. chem. Ges. *70*, 761 (1937), were the first to criticize the isoalloxazine nomenclature. Although "flavin" may be confused with "flavone" or "flavan", the compounds named by these terms are so different that serious misunderstandings are unlikely.

hydroquinone" for the completely reduced form. The synonym "leucoflavin" is intentionally avoided, since flavohydroquinone is colorless only in very dilute solution; under certain conditions it may be even more intensely colored than flavoquinone (cf. Section IV,5). In concentrated aqueous solutions flavin molecular complexes occur (cf. Section IV,8); here "flavoquinhydrone" $(FlH_2)_2$ is the prototype. "Intermediate valences" can occur in these complexes but there is no evidence that such "sandwich" structures are biochemically important.

2. Function of Flavin in Flavoproteins

Two main groups of flavoproteins can be distinguished. One contains iron (and sometimes also molybdenum) as an essential cofactor, while the other is independent of metals.

The "teleological" question as to the function of the iron cannot yet be answered with certainty. In no instance has it been possible to separate the metal (or the flavin) from iron flavoproteins without irreversible deactivation. Further, it is certain that flavin and iron belong to the same active center and are in direct contact with one another (cf. Section VI,5). For this reason the problem of the flavin-metal interaction is of fundamental importance.

Flavoproteins of both groups [7], like the free coenzymes [7a], are able to react with their substrates in a two-electron process, which is evidently independent of the metal. Since this reaction is not always accompanied by proton exchange with the medium, one may talk formally of a "hydride transfer". The electrons accepted by the flavin can then be transferred further, either simultaneously, as a "hydride equivalent", or successively, in the form of two radical electrons and a proton.

[7] *Ph. Strittmatter*, J. biol. Chemistry *237*, 3250 (1962); *O. Gawron, A. J. Glaid, J. Francisco*, and *T. P. Fondy*, Nature (London) *197*, 1270 (1963): Hydrogen transferred to flavoprotein is inactive. This is surprising in view of the fact that it must be bound to N–5 of the flavin. Model compounds are being prepared in order to determine whether the inactivity of the hydrogen atom at N–5 is caused by the enzyme protein or can be found in the free coenzyme as well.

[7a] *C. H. Suelter* and *D. E. Metzler*, Biochem. biophysica Acta *44*, 23 (1960).

The latter reaction requires stabilization of the half-reduced state of the flavin, for example by complex formation with a heavy metal (cf. Section V,2), by coupling with a secondary redox system of suitable potential (*e.g.* 2 RSH $\rightleftharpoons$ $(RS)_2$; cf. Section IV,4), or by coupling with a second flavin molecule.

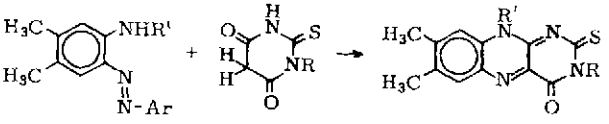
A survey of the substrates [dihydropyridine nucleotides, succinate, dihydrolipoamide, acyl-CoA, aldehyde (glucose), azomethines (purines), and amino acids] reveals that in contrast to the pyridine nucleotide dependent enzymes, the flavoproteins can attack only activated X–H bonds. It is further significant that flavohydroquinone reacts extremely rapidly with O_2 to form H_2O_2. Very probably, this reaction does not involve a radical intermediate but proceeds directly to H_2O_2 in a two-electron step (cf. Section IV,6).

Flavoproteins thus occupy a key position in the metabolism of all respiratory organisms. The manifold nature of the phenomena in the biochemistry of flavoproteins has made it difficult to describe these reactions in terms of molecular mechanisms. It is the aim of this article to provide a bridge between the chemistry and biology of the flavin group.

II. Synthesis and Breakdown of the Flavin Nucleus

1. Advances in Flavin Synthesis

The classical flavin synthesis [4] from aromatic *o*-diamines and alloxane by *Kuhn* and *Weygand*'s method is of very limited applicability, since even the simplest functional derivatives of alloxane are hardly accessible. In addition, alloxane derivatives behave as oxidizing agents towards phenylenediamines, so that the yields are rarely satisfactory. The process of *Tishler et al.* [8], in which an azo group is split by a carbanion, is similarly limited; 2-thiobarbituric acid *(3)* is the only functional derivative of barbituric acid which can be used to give an acceptable yield [9]. The *S*-methyl derivative of *(3)* does not react.



(3) R = H, CH_3

For this reason, despite many experiments [10] no flavins with altered functions at C-2 or C-4 were known up to 1956, although it was established by that time that the natural purines are flavin precursors [11]. If natural flavin is regarded as a xanthine analogue, then syntheses and properties of "(iso)-guanine-analogous flavins" *[(4)*; X,Y = O, NH] and of flavins with strictly monovalent substituents at C-4 [*e.g. (4a)*] are of interest.

In the two flavin syntheses mentioned above, N–5 and N–10 of the flavin nucleus are introduced by the homoaromatic component. The reverse path, which is the

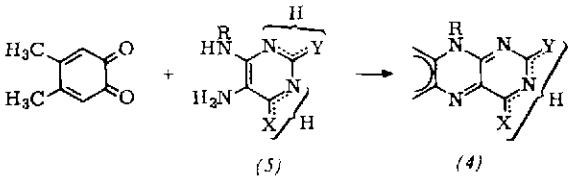
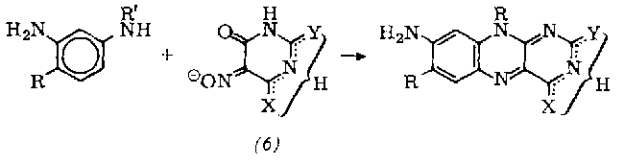
[11] *W. S. McNutt*, J. Amer. chem. Soc. *83*, 2303 (1961).

natural one (cf. Section III), was followed by *Creswell et al.* [12], who for the first time prepared 4-alkylamino-5-amino-pyrimidines *(5)* and treated them with *o*-xyloquinone.



(5) *(4)*

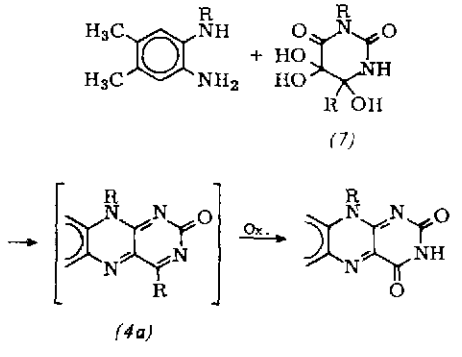
This synthesis suffers from the sensitivity of both starting components and their tendency to autocondensation, and from the equivalence of the carbonyl functions, which in the case of asymmetrically substituted quinones leads to the formation of isomer mixtures. These difficulties are avoided by the condensation of 5-nitrosopyrimidones *(6)* with aromatic *m*-diamines [13].



(6)

The second donor function in the benzene nucleus, which unfortunately is a prerequisite for the synthesis, must be subsequently removed. In the analogous reaction of 4-alkylamino-5-nitrosopyrimidines with phenols, a second donor function would not be absolutely necessary since the *o*-position of a phenoxide is sufficiently activated for attack by the nitroso group. To the best of our knowledge, no such reaction has so far been studied.

Replacement of alloxane in *Kuhn* and *Weygand*'s synthesis by "isodialuric acids" *(7)* should lead to "desoxo"-flavins *(4a)* with H or alkyl on C-4. However, only 2,4-dioxo products, *i.e.* "normal" flavins, could be obtained [14].



(7) *(4a)*

This was the first indication of the instability of strictly monovalent groups at C-2 and C-4 of the flavin nucleus. The *de novo* synthesis of such flavins was not followed further, since they had meanwhile become accessible by other routes (cf. Section IV).

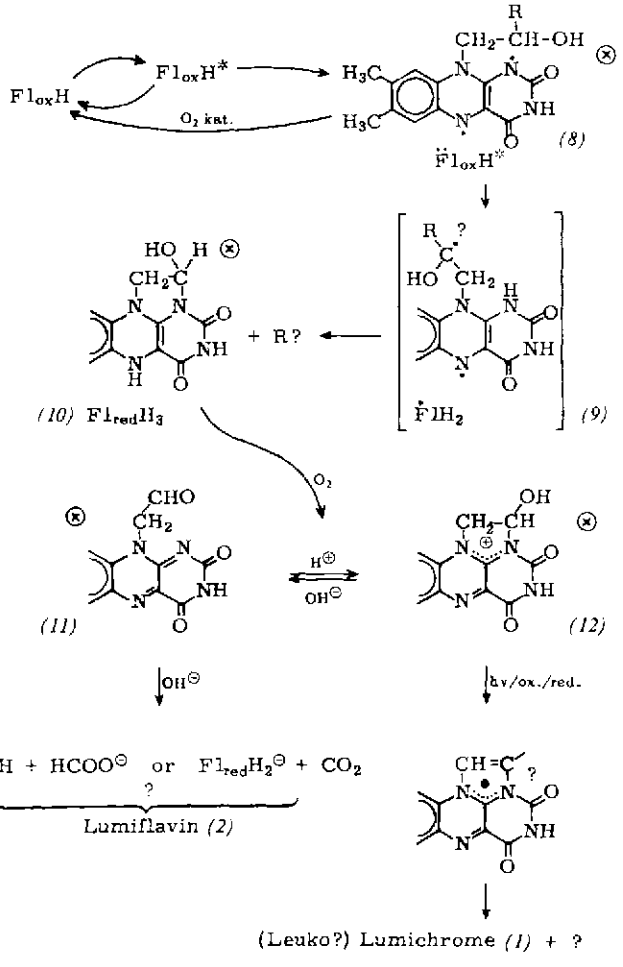
2. The Breakdown of Flavin

As already mentioned, it is appropriate to distinguish between flavin photolysis and flavin dealkylation. The course of riboflavin photolysis, unresolved for decades, has recently been essentially clarified [15–17] (Scheme 3).



Scheme 3. Flavin breakdown. The abbreviations denote the redox state of the flavin nucleus but not that of the side chain. The stages marked with ⊗ have been confirmed.

Photolysis occurs only in those flavins which contain a >CHOH group in the 2′-position. The C–H bond of this group is split by the flavoquinone triplet state *(8)* [17], with one electron passing to the flavin nucleus along with the proton (confirmed by the deuterium effect, cf. [15]). The resulting flavosemiquinone *(9)* has been identified (flash photolysis, cf. [18]). How the second unpaired electron is primarily stabilized in the side chain remains to be investigated. In the absence of O_2, the next product [*] is a flavohydroquinone *(10)* which is irreversibly [15] oxidized to formyl-lumiflavin *(11)* (identical with the product of periodate degradation of riboflavin, cf. [16]). The irreversibility of this oxidation is explained by the equilibrium *(11)* ⇌ *(12)*, which is displaced to the right in the reduced state. Similar 1-alkylflavins have been obtained as flavoquinonium perchlorates (cf. Section IV).

[16] *E. C. Smith* and *D. E. Metzler,* J. Amer. chem. Soc. *85*, 3285 (1963).

[17] Review: *B. Holmström,* Ark. Kemi *22*, 329 (1964).

[*] The second flavin occurring upon photolysis was termed "deuteroflavin". Use of this name should be avoided, however, because of its similarity to "deuterioflavin".

[18] *B. Holmström,* Bull. Soc. chim. belges *71*, 869 (1962).

With $OH^{\ominus}$, *(11)* reacts to form lumiflavin *(2)*. Whether this reaction is purely hydrolytic (haloform reaction), *i.e.* whether it proceeds with quantitative liberation of formate, is not yet known. Because of its aldehyde group, *(11)* is even more photolabile than riboflavin in neutral solution. The formylmethyl side chain is completely eliminated by air, and more rapidly by peracetic acid. Flavin-10-acetic acid could not be obtained as an intermediate [19]. The aldehyde *(11)* can also be dealkylated reductively, *e.g.* with zinc and acid, provided that sufficient O_2 is present to maintain the flavosemiquinone state [19]. In general, each substituent at N-10 of flavosemiquinone, $\dot{F}lH_2$, can be eliminated under weakly acidic or neutral conditions [20]. While photolysis represents a disproportionation of the flavoquinone triplet state *(8)* (the side chain is dehydrogenated, the nucleus reduced), dealkylation represents a (thermal) decomposition of the flavosemiquinone, which presumably proceeds according to a fragmentation mechanism [21]. The nature of the fragments formed from the substituent at N-10 will have to be elucidated using model compounds.

The photoreduction, *i.e.* the reversible photocatalysed "substrate" dehydrogenation by flavin is entirely independent of the nature of the side chain [17], but may be strongly influenced by agents which bring about a change in the energy content or life-time of the flavoquinone triplet state, *e.g.* by paramagnetic co-solutes (O_2, heavy metal ions) or by agents forming charge transfer complexes (cf. Section IV, 8).

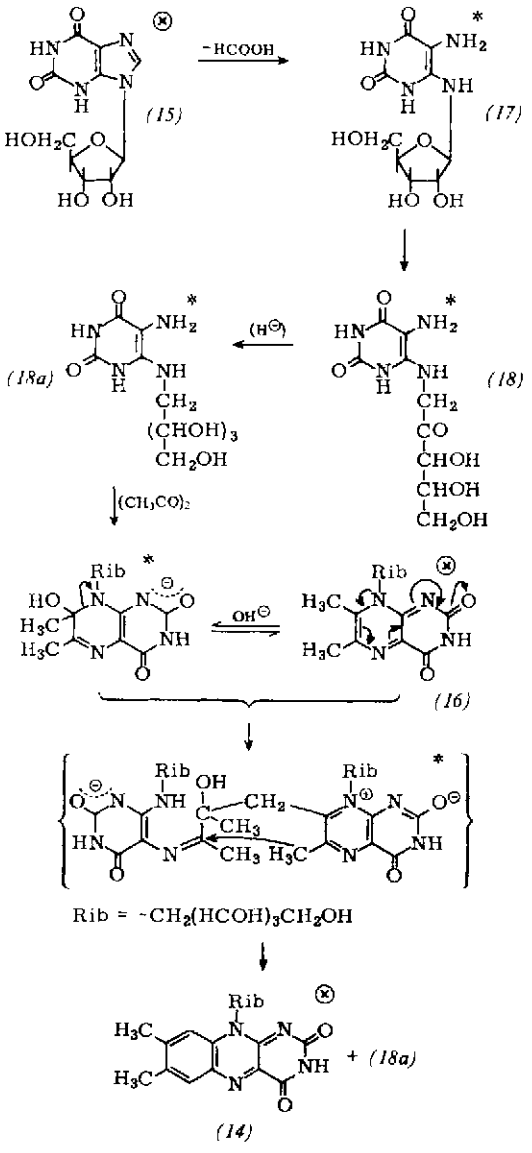
III. Flavin Biosynthesis

1. Synthesis of Riboflavin from Pteridine Precursors

The essential steps of flavin biosynthesis have been elucidated during the past few years, particularly by the studies of *McNutt* [11,22], *Masuda* [23], and *Plaut* [24]. In this article, the biosynthesis will be discussed only insofar as it contributes to the understanding of flavin chemistry (Scheme 4).

The nitrogen atoms of natural riboflavin *(14)* are derived from purine nucleotides *(15)* [25–27], while the dimethylbenzene part is built up from C_2-fragments (diacetyl or acetoin) originating from pyruvate. An important advance was the isolation from *Eremothecium ashbyii* [28,29] of an intermediate which proved to be 6,7-dimethyl-8-D-ribityllumazine *(16)*.

Surprisingly, the enzymatic transformation of this pteridine *(16)* into riboflavin requires no further carbon source. Hence compound *(16)* acts as both donor and acceptor of a C_4-fragment.



Scheme 4. Biosynthesis of riboflavin *(14)*. ⊗: confirmed stages; *: intermediates proposed from model reactions.

Experiments with model compounds [30] showed that "quinoid" 8-alkylpteridones [31], for example *(16)*, readily take up $OH^{\ominus}$ at C-7 under the influence of chelating metal ions even at neutral pH (cf. Section V, 1), so that the pyrazine ring closure is reversible in such pteridines. On the other hand, hyperconjugated CH_3 groups of strongly electron-deficient heteroaromatic compounds readily undergo aldol-like condensations, so that the route from *(16)* to riboflavin requires little additional activation. Thus, *Rowan* and *Wood* [32] obtained riboflavin *(14)* by non-enzymatic reaction of *(16)* in an aqueous phosphate buffer at pH 7.3, in 56 % yield.

2. Biosynthesis of the Precursor Pteridine *(16)*

Studies of the biosynthesis of pteridines indicate that the following reactions contribute to the transformation of the ribosyl group of the precursor purine into the ribityl group of flavin:

(a) Opening of the imidazole ring in adenosine *(15)*.

(b) Amadori rearrangement of the 5-amino-4-ribosylaminopyrimidine *(17)*.

(c) Reduction of the keto sugar *(18)*.

As regards (a), it is known that purines can be hydrolysed at C-8 by weak alkali after blocking the electron pair at N–7 by alkylation [33, 34] or (for enzymatic reactions) by coordination of metal ions or hydrogen bonding to N–7. With regard to (b), a mechanism like the one postulated by *Micheel* and *Dijong* [35] for the Amadori rearrangement of simple glycosylamines (intermediate formation of a 1,1-diamine) can be assumed. For (c), *Neilson* and *Wood* [36] were able to show that the reduction of a pyrimidylaminopentulose of type *(18)* proceeds stereospecifically even *in vitro*, which is ascribed to a specific conformation of the pyrimidyl residue and the side chain.

3. Substrate Specificity in the Biosynthesis of Flavocoenzymes

The search for flavin antimetabolites has so far met only with little succes. Biological effects achieved with riboflavin analogues were traced back to an inhibition of the flavocoenzyme synthesis but not of the flavocoenzyme function [38–40]. The correct ribityl side chain is required for both flavin synthetase [37], which catalyses the reaction *(16)* → *(14)*, and flavokinase [38], which transforms riboflavin into its 5'-phosphate by means of ATP. Surprisingly, even the slightest modification of the heteroaromatic nuclei abolishes the substrate function for flavin synthetase and even for flavokinase, although the kinase reaction seems not to concern the heteroaromatic system. This leads to the conclusion that, contrary to expectation, the flavin nucleus does participate in the kinase reaction. In any case, it follows that the inhibition of the flavin-dependent respiration by FMN analogues can only be tested if these have previously been phosphorylated. A flavin enzyme which can be reversibly split into FMN and apoprotein [39], *i.e.* the NADPH-cytochrome-c-oxidoreductase from yeast, has already been investigated.

The biosynthesis of FAD from FMN is not very substrate-specific [40], *i.e.* other flavin purine dinucleotides can also be prepared enzymatically. Further studies in this direction should help to elucidate the role of the adenosine moiety in FAD.

IV. Structural Chemistry of the Flavin Nucleus

1. Nucleophilic Substitution

Nucleophilic attack at a flavoquinone does not lead to substitution. Reactions at the carbonyl groups under solvolytic conditions lead to opening of the strongly electron-deficient pyrimidine ring. Solvolysis is always accompanied by a reaction at the C–8 methyl group (cf. Section IV,2). Under non-solvolytic conditions this last reaction is the predominant one. Therefore, reactions with phosphorus halides in tertiary amines are not possible with flavoquinone.

The introduction of sulfur with P_4S_{10} is an exception, but here a reduction initially takes place [41]. Flavoquinone is quite generally reduced by sulfides (thiolates), although only slowly [42]. The flavohydroquinone formed can then react with P_4S_{10}, the sulfur entering selectively at C–4 (cf. Scheme 5); a similar reaction occurs in the purine and pteridine series [43].

Nucleophilic substitutions are possible with flavoquinones in which the 2- (or 4-) positions has been activated. Two methods are available: (a) the (indirect) alkylation of the carbonyl oxygen with intermediate formation of the "active" flaviniminol esters (Section IV,3) and (b) nucleophilic replacement of the "active" sulfur in 2-thioflavins *(28)* (cf. Section II,1) and 4-thioflavins *(30)* [44] (see above). The thioflavins have a thioquinone rather than thioamide character, and hence react even at room temperature with carbonyl reagents to form oximes, hydrazones, or azines of flavoquinone [*(26)*, *(31)*, X = OH, NH_2, or N = CHAr]. These deep-violet to blue derivatives can generally be isolated only in the form of their orange-yellow to brownish-red salts. The free bases gradually disproportionate in solution, particularly under the influence of light, with dehydrogenation of =NOH or $=NNH_2$ and reduction of the flavin nucleus. In the presence of oxygen the reaction ultimately leads back to unsubstituted flavoquinone. The thioflavins *(28)* and *(30)* are similarly sensitive and are slowly desulfurized by autoxidation even at room temperature.

S-Methylation of the thioflavins *(28)* and *(30)* is possible under very mild conditions (cf. Section IV,3). The resulting "flaviminol thioesters" *(25)* and *(27)* react also with weakly nucleophilic reagents such as primary and secondary amines [cf. Scheme 5, *(19)*, *(24)*], but not easily with ammonia [*(33)*]. The NH_2 group can, however, be introduced *via* hydrazones [*(26)*, *(31)*; X= NH_2] and reduction with $SnCl_2$.

Monovalent substituents at C–2 or C–4 of flavoquinone, which cannot be oxidized, can be readily removed by hydrolysis, some even in neutral aqueous solution (cf. Section IV,3), *e.g.* in *(27)* and *(20)*.

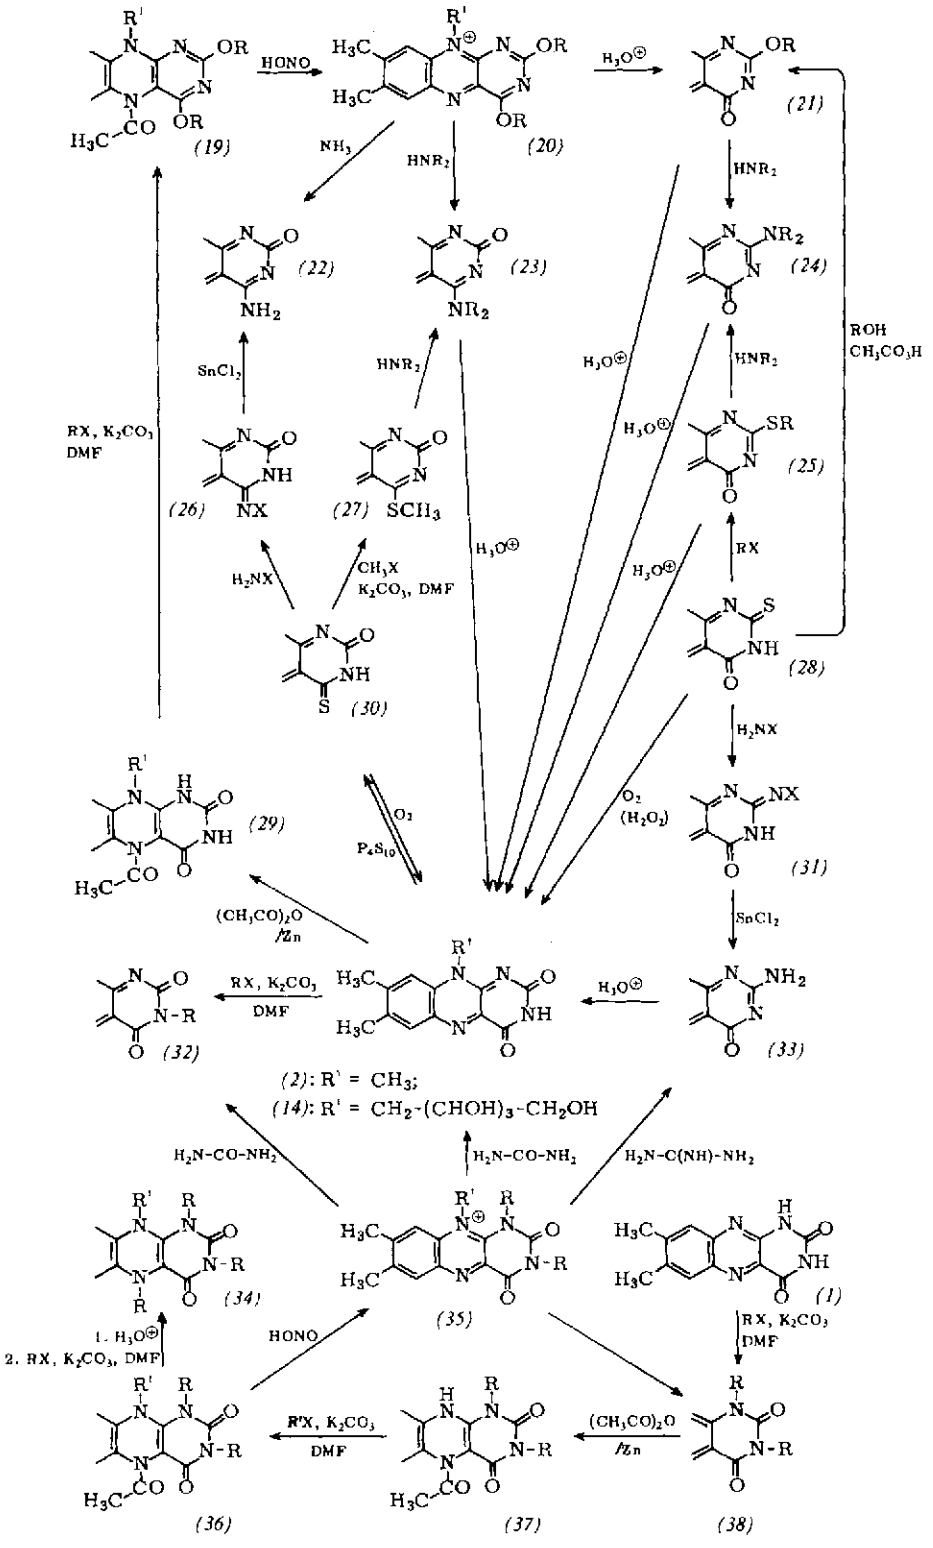

Scheme 5. Substitution reactions at the flavin nucleus.

2. Reactions of the C-8 Methyl Group

Similarly to vitamin K and ubiquinone [45], flavoquinone has a methyl group whose reactivity has received little recognition in the past. There are, however, flavoquinones, *i.e.* salts of type *(20)*, which irreversibly dimerize to form the diradicals *(40)* even at pH 7 and room temperature, even before the very sensitive iminol ester functions have had time to undergo hydrolysis [46]. An irreversible disproportionation is involved, in which the substituent is oxidized while the nucleus is reduced (as in photolysis).

The diradicals *(40)* react with excess flavoquinone or O_2 to form "diflavoquinones". The same reaction occurs in the case of unsubstituted flavoquinones, *e.g.* riboflavin, under strongly basic, non-solvolytic conditions [$HCON(CH_3)_2/(CH_3)_3COK$ or CH_3OH/BaO] or with weak bases (K_2CO_3) on heating [47]. Analogously, the C-8 methyl group of a flavoquinone can

[45] *E. Lederer*, Experientia *20*, 473 (1964).

[46] *K. Dudley*, *P. Hemmerich*, and *F. Müller*, unpublished work.

react with aldehydes to form Fl_{ox}–CH=CH–R [48], *e.g.* *(41)*. The C-8 methyl group appears to be at least as reactive as the methyl group in nitrotoluenes, and for this reason can be classified as a functional group of the flavoquinones.

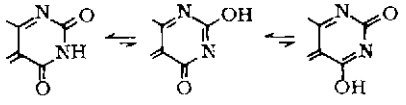
3. Electrophilic Substitution, Flaviniminol Esters

The base-catalysed alkylation of flavoquinone is possible only under non-solvolytic conditions and with bases that are weak enough to avoid irreversible dimerization (cf. Section IV,2), for example with potassium carbonate in dimethylformamide at room temperature [49]. Substitution occurs exclusively at N–3 *(32)*. With flavohydroquinone, N–5 of which has been protected by acetylation *(29)*, the same reaction does not lead to the expected *N*–1,*N*–3-dialkyl derivative *(36)*, but to an easily separable mixture of the *N*–3,*O*- and the *O*,*O*-dialkyl derivatives *(19)* [20]. Thus, N–1 is not alkylated, and this is probably due to hindrance by the alkyl group on N–10; on the other hand, sterically hindered *N*–1-alkylflavohydroquinones such as *(36)* are accessible *via* lumichrome *(1)* [20], which in the oxidized form is dialkylated at N–1 and N–3 to form *(38)*. The N–10-alkyl group can be subsequently introduced into the *N*–5-acetyldihydro derivative *(37)*. The lack of reactivity at N–1 of the flavohydroquinone *(29)* is thus reinforced by the higher electron density in the 2,4-dioxo groups. In confirmation, the flaviniminol esters in the hydroquinone state *(19)* are difficult to hydrolyse; the acetyl group on N–5 can be selectively eliminated [50]. If an oxidizing radical scavenger, *e.g.* HONO, is added, then the dialkylflavoquinonium salts *(35)* and *(20)* are obtained directly from *(19)*, and partial hydrolysis of these leads to the formation of the flavoquinone-2-iminol esters *(21)* [46, 51]. These are still very reactive, as are the analogous thioesters *(25)* (cf. Section IV,1). For example, CH_3SH is quantitatively eliminated in 30 minutes from the thioester *(27)* at pH 2–3 and 20 °C. Such esters do not differ markedly in their spectra from normal flavoquinone, but differ in their basicity [51].

The formation and hydrolysis of the esters *(21)* indicate that the energy content of the iminol forms increases sharply during oxidation of flavohydroquinone to flavoquinone (cf. Section IV,4).

4. Carboximide-Iminol Tautomerism

The positions of the tautomer equilibria in the different flavin redox states have been investigated by comparison of the visible, ultraviolet, and infrared spectra, and also of the pK_a values of *O*- and *N*-alkylated derivatives [51]. In accord with the high energy content of the flavoquinoneiminol esters *(21)* (cf. Section IV,3), flavin is present almost entirely in the carboximide form *(39)* in the oxidized state.



(39)

The reduced flavin likewise exists predominantly in the carboximide form; however, the properties of the flavohydroquinoneiminol esters *(19)* indicate a marked participation of the iminol form in the equilibrium.

Thioflavins such as *(30)* and *(28)* likewise occur in the C(S)NH form; only the "flavimines" *(22)* and *(33)* do not have the mobile proton at N–3 and therefore must be designated as aminobenzopteridones. In the semiquinone state, *N*–1-alkylflavins exhibit a behavior strongly deviating from that of the *O*-alkyl isomers and the unsubstituted parent substances, in regard to both stability and spectrum [51–53]. While the visible and ESR spectra of the neutral flavosemiquinones O,O-$\dot{F}lR_2$ and O,N–3–$\dot{F}lR_2$ are in good agreement with those of N-3-$\dot{F}lHR$ and $\dot{F}lH_2$, no evidence of an N–1,N–3-$\dot{F}lR_2$ has yet been obtained, although the protonated forms, $\dot{F}lHR_2^{\oplus}$ (*Kuhn*'s "Rhodoflavins" [54]), behave normally in every case irrespective of the location of the alkyl group.

O,O- and O,N–3–$\dot{F}lR_2$ are obtained by alkylation of chloroform-soluble $Fl_{ox}H$ or N–3–$Fl_{ox}R$, *e.g.* tetraacetylriboflavin or 3-alkyl-lumiflavin (in chloroform/triethylamine plus supernatant aqueous $Na_2S_2O_4$), and partial reoxidation with I_2 [55]. They form deep green, strongly paramagnetic solutions, which on replacement of the chloroform by a mixture of methanol and water change color towards blue, and on addition of acid turn red. Deep red N–1,N–3–$\dot{F}lHR_2^{\oplus}$ [46] is formed on mild acid hydrolysis of *(36)*. The green chloroform solution obtained on neutralization does not show a magnetic susceptibility proportional to the optical extinction [51, 52]. In the aqueous phase the neutralization is accompanied by irreversible secondary reactions, which lead to *N*-10-dealkylated products, among others [46].

As a result, a mixture of the monoiminol forms *(21a)* and *(21b)* can be regarded as the most probable structure of the flavosemiquinone. Further studies are required to confirm this point.

(21a) ⇌ *(21b)*

Accordingly, the semiquinone would be more closely related to the hydroquinone than to the quinone, *i.e.* on abstraction of an electron from the radical a flavoquinoneiminol is the primary product, which is a very energy-rich form of the flavin (the term energy-rich here always refers to hydrolytic or prototropic processes). This may be of significance for the conservation of energy during biological oxidations.

It is frequently assumed that the distribution of the localized electrons in aromatic or heteroaromatic systems does not alter on addition or abstraction of delocalized electrons. Almost all quantum-chemical studies of the flavin system are based on this assumption. However, as shown above, the σ-bond system of the flavins is altered by the addition of an electron and a proton, because of a displacement, possibly even a reversal, of the energy content of the protopropic forms. So far only *Grabe* [56] has allowed for this phenomenon in MO calculations.

5. Stereochemistry

On the addition of a further electron, *i.e.* on transition from the semiquinone to the hydroquinone, the flavin molecule folds in the N–5,N–10 axis (Fig. 1). This

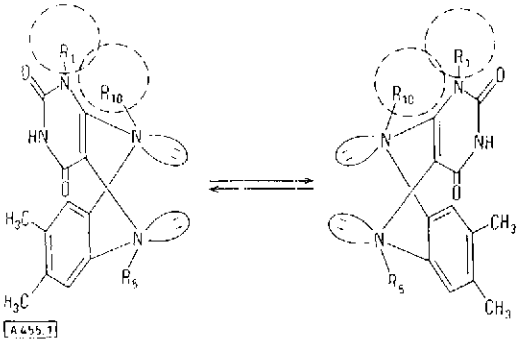

Fig. 1. Stereochemistry of flavohydroquinone; "Butterfly conformations".

means that the planar form can be described as an excited vibrational state. The change corresponds to the "buckling" of a planar CH_3 radical on transformation into a CH_3 carbanion. In the case of flavohydroquinone this buckling is indicated by the following observations [51]:

(1) The flavohydroquinone spectrum has a shoulder at 400 mμ, which disappears on protonation and deprotonation as well as on acylation (Fig. 2). Protonation and acylation occur at the most basic nitrogen atom, *i.e.* at N-5, which thereby assumes sp^3 configuration. The long-wavelength end absorption is therefore a measure of the delocalization (p-character) of the formally non-bonding electrons at N-5, which is highest in the planar state. The shoulder at 400 mμ has an extinction of ca. 2000 (mole·cm)$^{-1}$, which is too strong

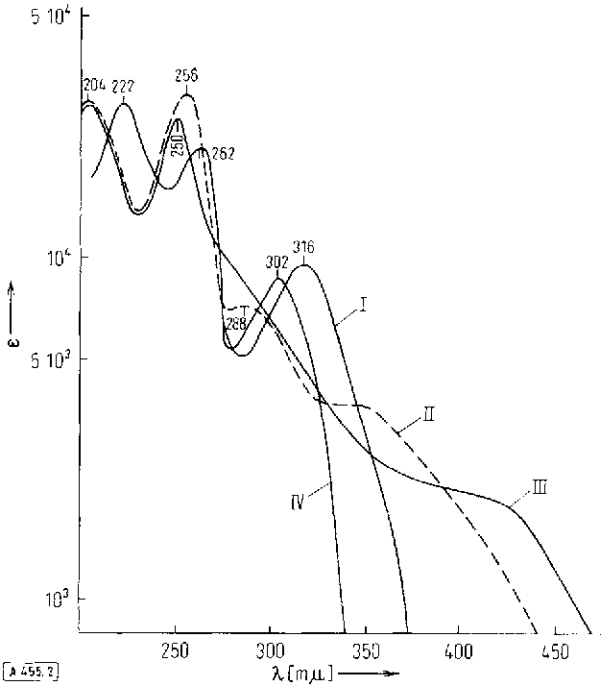

Fig. 2. Electronic spectra of the flavohydroquinone species (in H_2O unless otherwise stated), taken from [51].
I: $Fl_{red}\,H_4^{\oplus}$, pH < 0

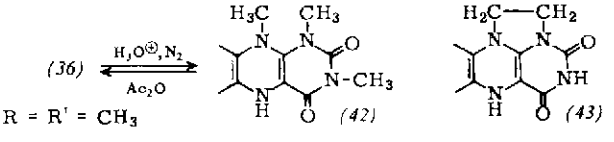
IV: *(29)*, R' = CH_3, in CH_3OH (cf. Scheme 2).

for an (n,π*)-transition but is relatively weak for a (π,π*)-transition, *i.e.* the orbital configuration on N-5 is neither strictly planar nor strictly tetrahedral.

(2) If alkyl substituents are introduced at N-1, as in *(42)*, a strongly hypsochromic shift occurs, although the direct electronic effect exerted by the conversion >NH → >N-alkyl in an N-heteroaromatic system should produce a bathochromic shift, if any.

Accordingly, alkyl substitution must have a steric effect which favors the buckled non-coplanar state. This corresponds to the steric hindrance which is to be expected of N–1 and N–10 substitution.

The effect disappears [51] if the two methyl groups at N–1 and N–10 in *(42)* are replaced by a $-CH_2-CH_2-$ bridge *(43)*.



A flattening of the flavohydroquinone system can also result from the formation of sandwich complexes (*e.g.* in $FADH_2$, cf. Section IV,8).

6. Acid-Base and Disproportionation Equilibria

Following the fundamental potentiometric studies of *Michaelis et al.* [57], *Beinert* [58] was the first to attack the problem of spectral classification of the individual

[56] *B. Grabe*, Doctorate Dissertation, University of Uppsala (Sweden) 1960.

[57] *L. Michaelis* and *G. Schwarzenbach*, J. biol. Chemistry *123*, 538 (1938).

flavin species. He assigned to the free monomeric radical $\dot{F}lH_2$ the band in the 600 mμ region and to the dimeric flavoquinhydrone $(\dot{F}lH_2)_2$ the diffuse absorption in the near infrared (Figs. 3a and 3b). This assignment was checked using model compounds [50] and extended (cf. Table 1). The problem is complicated by the unfavorable position of the disproportionation equilibrium

$$2\ \dot{F}lH_2 \rightleftharpoons Fl_{ox}H + Fl_{red}H_3,$$

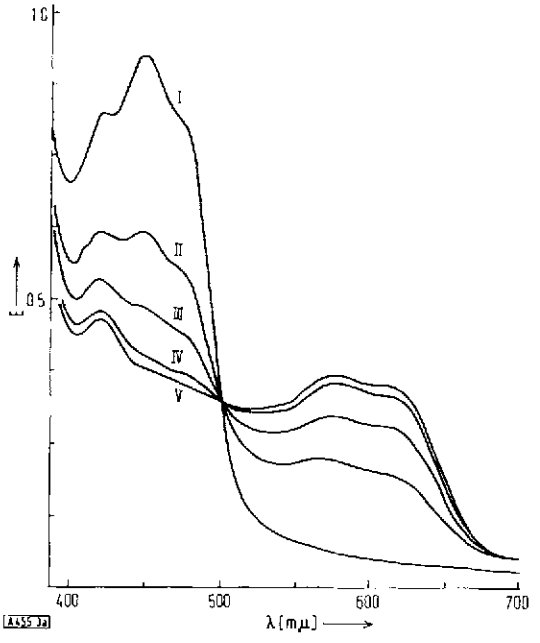

Fig. 3a. Change in absorption with time during reduction of metal-free flavoprotein [60] from *Azotobacter vinelandii* with $S_2O_4^{2-}$ at pH 7.0 in phosphate buffer. The kinetically stable blue semiquinone is not reduced further by excess $S_2O_4^{2-}$ under these conditions. About 30 minutes have elapsed between curve V (full reduction) and curve I. The ESR absorption likewise reaches a stable maximum during this period. Thanks are due to Prof. *H. Beinert*, Madison, for permission to publish these results.

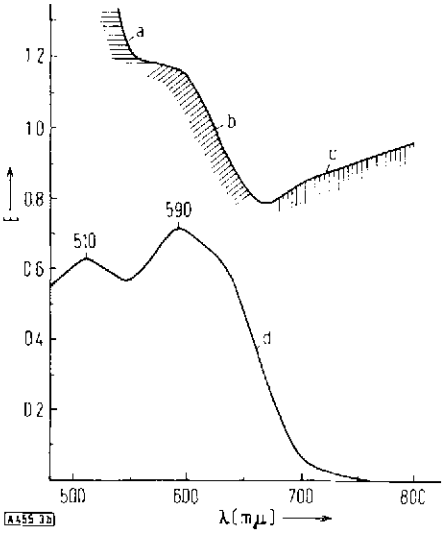

Fig. 3b. Spectrum of half-reduced FMN [Mixture of FMN, $(FMNH)_2$ and $\dot{F}MNH$] (upper curve) and a non-dimerizing model *(44)* of type $\dot{F}lR_2$ (lower curve) in aqueous solution, pH ≈ 5; taken from [51].

a = FMN- (flavoquinone-) part of the spectrum

b = $\dot{F}$MNH- (flavosemiquinone-) part of the spectrum

c = $(FMNH)_2$- (flavoquinhydrone-) part of the spectrum

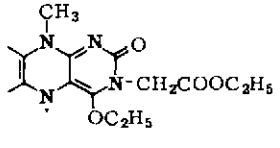
d = *(44)*.

which permits only very small radical concentrations in the protein-free half-reduced system. The pH-dependence of this equilibrium is extremely complex [49]. In strongly acidic solution the system is entirely comproportionated [49a] (*i.e.* the equilibrium is shifted to the left) and the radical cations $\dot{F}lH_3^{\oplus}$ (Scheme 2) can be readily observed. Since $\dot{F}lH_2$ is by far the most strongly basic of all uncharged flavin species, almost complete disproportionation occurs on neutralization, provided the dissociation $Fl_{ox}H_2^{\oplus} \rightarrow Fl_{ox}H$ is not blocked [*e.g.* by alkylation as in $Fl_{ox}R_2^{\oplus}$ *(20)*]. At physiological pH, five of the nine flavin species reproduced in Scheme 2 must be considered, *i.e.* $Fl_{ox}H$, $\dot{F}lH_2$, $\dot{F}lH^{\ominus}$, $Fl_{red}H_3$, and $Fl_{red}H_2^{\ominus}$, since the acid dissociation of both reduced states falls inside this pH range [57]. The pH-dependence of the disproportionation at physiological pH follows Equation (a) [49]

$$K(H) = \frac{[\dot{F}l_{total}]^2}{[Fl_{ox,\,total}]\,[Fl_{red,\,total}]} = Const. \cdot \frac{(1 + \dot{k}/[H])^2}{(1 + k_{red}/[H])} \qquad (a)$$

where H is the hydrogen-ion activity and $\dot{k}$ and k_{red} are the acid dissociation constants of $\dot{F}lH_2$ and $Fl_{red}H_3$, respectively. Since $Fl_{red}H_3$ is somewhat more acidic than $\dot{F}lH_2$, it follows that K(H) passes through a minimum (corresponding to a minimum in the radical concentration) precisely in the physiological pH range. Hence $\dot{F}lH_2$ is thermodynamically unstable and the same is true kinetically, since the disproportionation proceeds extremely fast as is common in the case of molecular charge transfer. The minimum of radical concentration was confirmed by *Ehrenberg* [59] from ESR measurements. The bonding of the flavin to the protein may be accompanied by an appreciable kinetic stabilization of the radical, provided the "active center" of the protein does not contain a second redox function in addition to that of the flavin, which is often the case (cf. Section VI).

A kinetically stabilized flavosemiquinone of this type has recently been found in a flavoprotein from *Azotobacter vinelandii* [60]. Figure 3a shows the spectral changes occurring when this flavoprotein is reduced with $S_2O_4^{2-}$. At pH 7 this reduction leads to a deep-blue radical. In Figure 3b the spectrum of this radical is compared with that of a likewise deep-blue model radical O,N-3-$\dot{F}lR_2$ *(44)* (cf. Section IV,3) [51].



(44)

Both radicals, *i.e.* the natural product and the model, exhibit proportionality between ESR intensity and optical extinction. Neither is able to dimerize to the quinhydrone, the natural product for kinetic reasons, the synthetic model for thermodynamic ones (cf. Section IV,8). This behavior confirms the spectral assignment

[59] *A. Ehrenberg*, Ark. Kemi *19*, 97 (1962).

[60] *Y. I. Shethna, H. Beinert*, and *P. Hemmerich*, unpublished work.

made by *Beinert* [58]. Both radicals react only slowly with O_2 and $S_2O_4^{2-}$, which shows that these reagents react faster by a two-electron transfer with the flavin species resulting from $\dot{F}lH_2$ by disproportionation. The autocatalysis of flavohydroquinone autoxidation [61] and the red intermediates observed during the reduction of certain flavoproteins [62] cannot, therefore, be ascribed to $\dot{F}lH_2$, nor to any other radical, *i.e.* paramagnetic species, unless there is proportionality between visible and ESR absorption.

As a rule, thermodynamic stabilization of a formally half-reduced flavin, *e.g.* by metal complex formation (cf. Section V,2), must also be considered.

7. Spin Density in Flavosemiquinones

Conclusions regarding the delocalization of the unpaired electron in the flavin radical species have been drawn from the ESR hyperfine structure. By the introduction of ^{15}N into positions 1, 3, and 5, and of deuterium at C–6, C–9, and C–10α, *Ehrenberg et al.* [52, 63] were able to show that in all radical species ($\dot{F}lH_3^{\oplus}$, $\dot{F}lH_2$, and $\dot{F}lH^{\ominus}$) the unpaired electron (or the electron hole) is predominantly found in the phenylenediamine part and not in the pyrimidone part of the tricyclic system. Thus, radical reactions in the flavin plane will occur only at positions 5, 8α, and 10α.

This is of significance for the understanding of flavin-catalysed one-electron transfer reactions (cf. Sections V,VI). In addition the question arises as to under what conditions electrons can be transferred vertically to the flavin plane (cf. Section IV,8).

8. Sandwich Complexes

Weber [64] has shown that flavin fluorescence occurs when the adenine frequency in FAD is excited. From this observation he deduced a sandwich arrangement of the two heteroaromatic components in FAD. Further studies by *Harbury* [65] and *Szent-Györgyi* [66] have shown a similar arrangement for the "charge-transfer interaction" between flavin and apoprotein. It is important that the stability of such a complex does not primarily depend on the energy which is gained by the charge transfer. Instead the formation of a stable complex in dilute solution is governed by a sterically favorable fixation of a donor-acceptor pair, and this is secured by the tertiary structure of the active center in the protein or by the covalent linkage between the flavin and adenine moieties in FAD. Alternatively, a stable complex arises only in concentrated solutions.

Charge-transfer effects are all the stronger if the donor and acceptor skeletons have a similar structure (self-charge-transfer in quinhydrones). The relatively most stable association is therefore that between neutral or dissimilarly charged flavin species at different redox states, as was shown by *Kuhn* and *Ströbele* [54] for solids and later by *Massey et al.* for concentrated solutions [67]. Such a complex can dissociate in two ways according to Equation (b) and thus could be interpreted as a radical

$$Fl_{ox} + Fl_{red}H_3 \rightleftharpoons \left\{ \begin{matrix} [FlH\text{-}FlH_3] \\ \Updownarrow ? \\ [FlH_2\text{-}FlH_2] \end{matrix} \right\} \rightleftharpoons 2\,\dot{F}lH_2 \qquad (b)$$

dimer or as a charge-transfer complex. Since the whole unit is diamagnetic, both forms must be tautomers. However, as has been discussed (Section IV,4), $\dot{F}lR_2$ forms no stable "dimer" $[FlR_2\text{–}FlR_2]$ so that $(FlH_2)_2 \equiv [FlH\text{–}FlH_3]$, *i.e.* a true charge-transfer complex is present. The comparison of $\dot{F}lH_2$ with $\dot{F}lR_2$ is permissible, since hydrogen bonds do not contribute to the stability of such complexes [67a].

V. The Metal Coordination Chemistry of the Flavin System

1. Metal Chelates of Flavoquinone (Charge-Transfer Chelates)

Considering the structural analogy between flavoquinone *(50)*, *(53)*, and 8-hydroxyquinoline ("oxine") *(45)*, one would expect that flavoquinone is a good chelating agent. Stabilities of flavoquinone chelates measured by *Albert* [68] and *Freiser et al.* [69] cannot, however, be assigned to oxinate-like structures *(52)* [70]. In contrast to pteridine-4-one *(46a)*, which forms chelates of structure *(46)* (cf. Scheme 6), the metal affinity of riboflavin is insufficient to suppress hydrolysis of metal ions. Also participation of the ribityl side-chain in complex formation cannot be excluded [70].

The absence of an interaction between flavoquinone and divalent d-metal ions in dilute solution has been confirmed by *Metzler* and *Baarda* [71] as well as by *Radda* and *Calvin* [72]. Similarly, the distribution of lumiflavin between water and chloroform is independent of the d-metal ion concentration at constant ionic strength [55].

[72] *G. K. Radda* and *M. Calvin*, Biochemistry *3*, 384 (1964).

In order to exclude any possible hindrance of metal coordination at N-5 by the CH group in position 6 of the flavin nucleus, comparison was made with the "pteroquinone" *(47)* whose structure is analogous to that of flavoquinone [73]. Upon addition of d-metal ions, this molecule, too, does not react like oxine, *i.e.* with liberation of $H^{\oplus}$, but accepts $OH^{\ominus}$ to form a "covalently hydrated" chelate *(48)*, R = H or CH_3, which cannot be dehydrated without decomposition.

In contrast, the affinity of Ag^+ toward flavoquinone is surprising [74]. Silver forms stable, oxinate-like chelates with flavoquinone. The spectra of these complexes AgFlR *(51)* and AgFl *(52)* correspond to that of the iso-π-electronic flavosemiquinone cation $\dot{F}lH_3^{\oplus}$. Copper(I) reacts similarly to silver [Equation (c) and Fig. 4].

$$CuFl \equiv [Fl_{ox}^{\ominus}Cu^{\oplus} \leftrightarrow \dot{F}l^{2\ominus}Cu^{2\oplus}] \qquad (c)$$

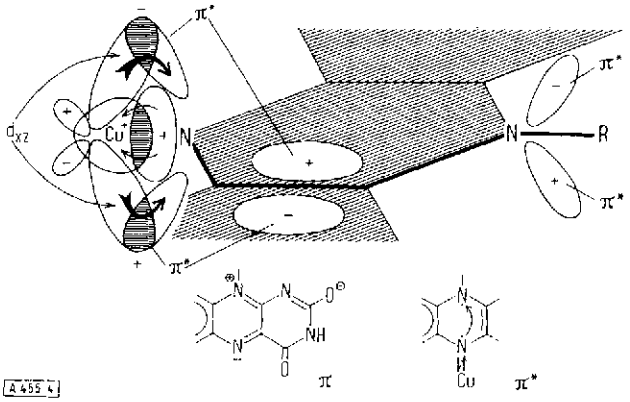

Fig. 4. Molecular orbital diagram of the metal-ligand charge transfer in flavoquinone-copper(I) chelate. Diagonal shading: plane of the flavin nucleus. Horizontal shading: overlap regions of metal and ligand orbitals on N-5 of the flavin; taken from [2].

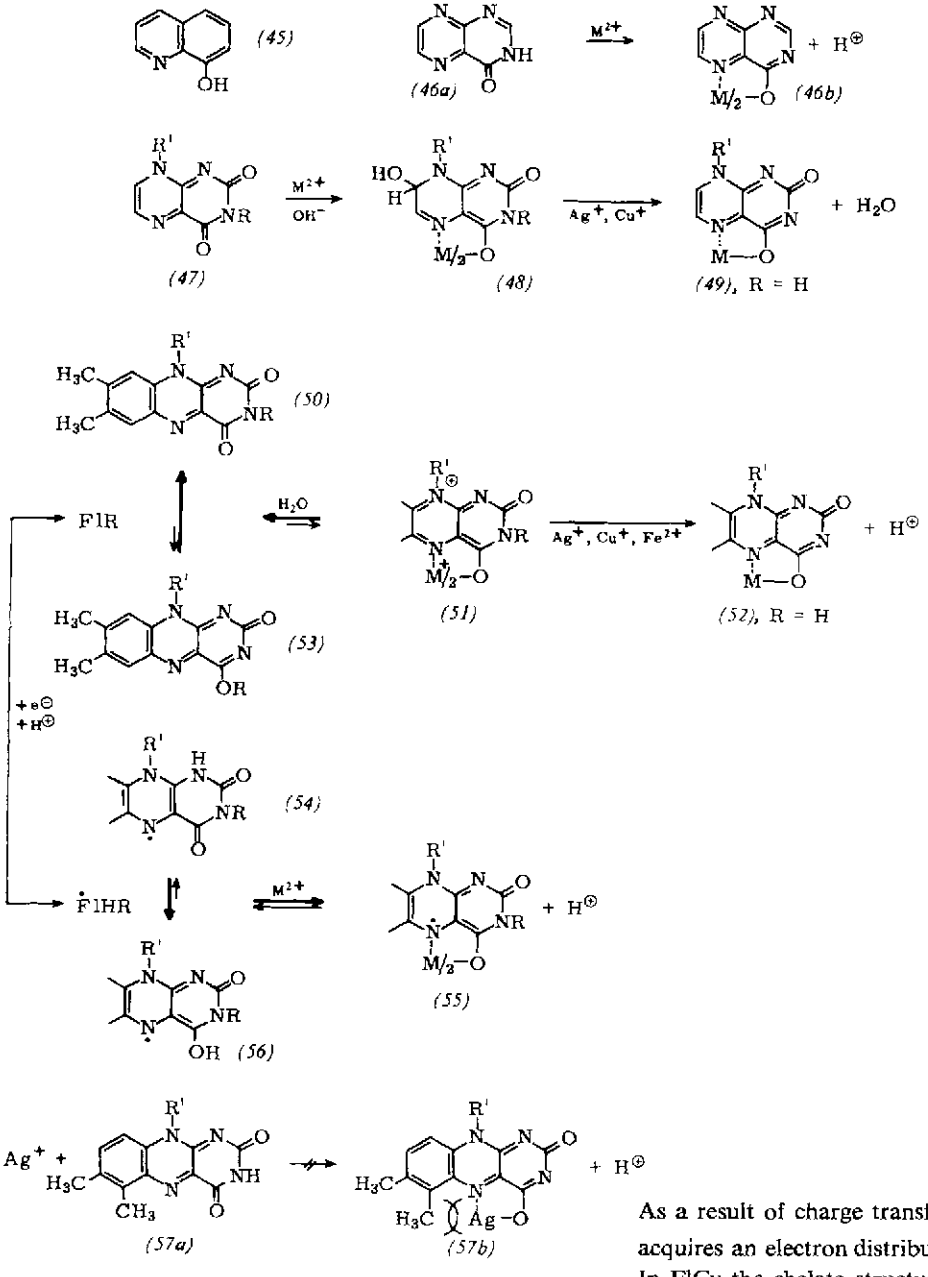


Scheme 6. Metal chelate formation of flavin and related systems.

As a result of charge transfer, the flavoquinone ligand acquires an electron distribution similar to that of $\dot{F}lH_3^{\oplus}$. In FlCu the chelate structure, *i.e.* the bidentate nature of the ligand, was confirmed by Reaction (d) [75]:

$$Cu(CH_3CN)_2^{\oplus} + Fl_{ox}H \rightleftharpoons FlCu + 2\ CH_3CN + H^{\oplus} \qquad (d)$$

[73] *P. Hemmerich* in *W. Pfleiderer* and *E. C. Taylor*: Pteridin-Chemistry. Pergamon Press, Oxford 1964, p. 143.

[74] *P. Bamberg* and *P. Hemmerich*, Helv. chim. Acta *44*, 1001 (1961).

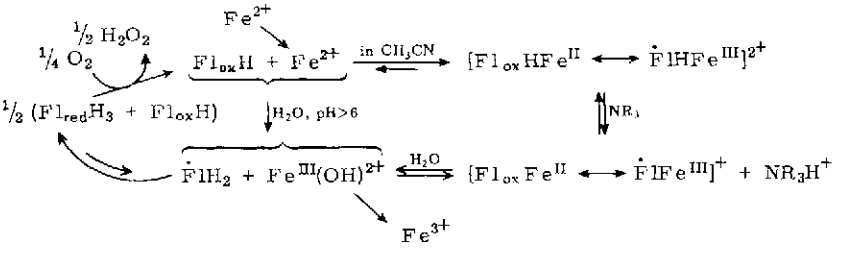
[75] *P. Hemmerich* and *C. Sigwart*, Experientia *19*, 488 (1963).

The observed dependence of FlCu-formation on the square of the CH_3CN concentration shows that FlH displaces two molecules of CH_3CN from the coordination sphere of Cu(I).

"Isoflavins" *(57a)* do not react with Ag^+ or Cu^+, because the coordination at N–5 is hindered by the CH_3 group at C–6 *(57b)* [74].

A more detailed study shows that all metal ions form chelates with flavoquinone under more drastic conditions, *i.e.* in anhydrous media. The extent of chelate formation depends on the ionization potential and on the hydration energy of the metal. Upon addition of a base, *e.g.* triethylamine, these chelates decompose. Thus, for example, the affinity of flavoquinone for Zn^{2+} is less than that of tertiary amines, *i.e.* $\log K^{Zn}_{FlZn} \approx 2.0$ [76, 77], whereas $\log K^{Ag}_{FlAg} = 8.0$ [74].

The interaction of Fe^{2+} and MoO^{3+} with flavoquinone is as strong as that of Ag^+ and Cu^+, *i.e.* on addition of triethylamine a proton is liberated from the complex $FlHM^{n\oplus}$ *[(51)* R = H]; however, in water the complex $[Fl_{ox}Fe]^{\oplus}$ from $Fl_{ox}H$ and Fe^{2+} dissociates into $\dot{F}lH^{\ominus}$ and $FeOH^{2+}$, whereas FlAg and FlCu are stable under similar conditions. In other words, flavoquinone is reduced by Fe^{2+} above pH 7. The $\dot{F}lH^{\ominus}$ liberated at once disproportionates to give $Fl_{ox}H + Fl_{red}H_2^{\ominus}$, and the latter is oxidized under aerobic conditions. The overall process represents a flavin-catalysed autoxidation of Fe^{2+} (Scheme 7).



Scheme 7. Flavin-catalysed autoxidation of Fe^{2+}.

2. Metal Chelates of Flavosemiquinone

As shown in Section V.1, flavin charge-transfer chelates can participate in two dissociation equilibria at different oxidation states. We assumed that the flavosemiquinone $\dot{F}lH_2$, unlike flavoquinone $Fl_{ox}H$, exhibits a general affinity for metal ions. As shown in Section IV.6, N–5 is more strongly basic in $\dot{F}lH_2$ than in $Fl_{ox}H$, and the C=O group in position 4 is more easily transformed into the hydroxy form required for chelate formation [cf. *(54)*, *(56)*]. During the pH titration of half-reduced flavin [49] it was found that the disproportionation maximum at pH 7–8, which is indicated by a color change from olive brown to light yellow, does not occur in the presence of arbitrary, non-oxidizing d-metal ions. Instead, the solution turns carmine red and an additional proton is liberated [Equation (e)].

$$Fl_{red}H_2^{\ominus} + Fl_{ox}H + 2\,M^{2\oplus} \rightleftharpoons 2\,[MFlH]^{\oplus} + H^{\oplus} \qquad (e)$$

(55), R=H

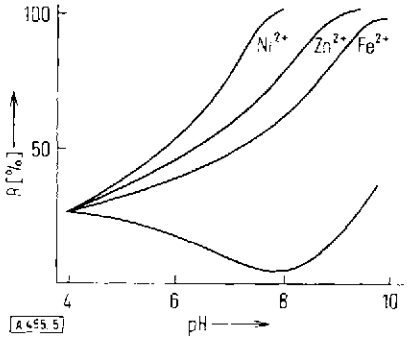


Fig. 5. pH-Dependence of flavosemiquinone disproportionation. R = radical. Bottom curve, disproportionation in the absence of metal ions. (Schematic representation).

Figure 5 shows the pH-dependence of the disproportionation in the presence and absence of d-metal ions. In Figure 6 the spectrum of a typical "radical chelate" *(57b)* with a diamagnetic central atom is compared with that of the iso-π-electronic radical cation $FlH_3^{\oplus}$ *(57a)*.
